* 3760 volunteer abstracts, 21 symposium/workshop abstracts.

CHRONOLOGICAL LIST OF SESSIONS

(See page v for Thematic List of Sessions.)

Continued in Part Two

THEMATIC LIST OF SESSIONS*

Theme A: Development and Plasticity

Session Number	Title	Type	Day	Time
83.	Axon Outgrowth, Growth Cones, and Guidance Mechanisms I	Poster	Tue	8:30 AM
266.	Axon Outgrowth, Growth Cones, and Guidance Mechanisms II	Slide	Fri	8:30 AM
70.	Cell Lineage and Differentiation I	Slide	Tue	8:30 AM
179.	Cell Lineage and Differentiation II	Poster	Wed	1:00 PM
9.	Development of Invertebrates I	Slide	Mon	8:30 AM
178.	Development of Invertebrates II	Poster	Wed	1:00 PM
122.	Development and Plasticity: Aging	Poster	Tue	1:00 PM
6.	Development and Plasticity: Autonomic Nervous System I	Slide	Mon	8:30 AM
52.	Development and Plasticity: Autonomic Nervous System II	Poster	Mon	1:00 PM
49.	Development and Plasticity: Biochemical and Pharmacological Correlates of Development	Poster	Mon	1:00 PM
168.	Development and Plasticity: Developmental Disorders	Poster	Wed	8:30 AM
89.	Development and Plasticity: Limbic System	Poster	Tue	8:30 AM
23.	Development and Plasticity: Neurotoxicology	Poster	Mon	8:30 AM
50.	Development and Plasticity: Nutritional and Prenatal Factors	Poster	Mon	1:00 PM
142.	Development and Plasticity: Retinotectal Connections	Slide	Wed	8:30 AM
216.	Development and Plasticity: Sensory Systems	Poster	Thu	8:30 AM
53.	Development and Plasticity: Trophic Agents I	Poster	Mon	1:00 PM
110.	Development and Plasticity: Trophic Agents II	Slide	Tue	1:00 PM
51.	Development and Plasticity: Trophic Interactions	Poster	Mon	1:00 PM
190.	Developmental Effects of Activity	Poster	Wed	1:00 PM
217.	Effects of Denervation	Poster	Thu	8:30 AM
54.	Endocrine Control of Development I	Poster	Mon	1:00 PM
249.	Endocrine Control of Development II	Poster	Thu	1:00 PM
180.	Morphogenesis and Pattern Formation I	Poster	Wed	1:00 PM
235.	Morphogenesis and Pattern Formation II	Slide	Thu	1:00 PM
277.	Motor System Development	Poster	Fri	8:30 AM
40.	Neural Plasticity in Adult Animals I	Slide	Mon	1:00 PM
215.	Neural Plasticity in Adult Animals II	Poster	Thu	8:30 AM
181.	Neuronal Death and Synapse Elimination	Poster	Wed	1:00 PM
262.	Regeneration in the Central Nervous System	Slide	Fri	8:30 AM
218.	Regeneration in the Central Nervous System: Forebrain Pathways	Poster	Thu	8:30 AM
248.	Regeneration in the Central Nervous System: Ventral Nerve Cord and Spinal Pathways	Poster	Thu	1:00 PM
12.	Regeneration in the Peripheral Nervous System I	Slide	Mon	8:30 AM
246.	Regeneration in the Peripheral Nervous System II	Poster	Thu	1:00 PM
233.	Retinogeniculate Development	Slide	Thu	1:00 PM
125.	Retinotectal Development and Organization	Poster	Tue	1:00 PM
205.	Role of Activity in Synaptic Sorting and Elimination	Slide	Thu	8:30 AM
121.	Specificity of Synaptic Connections	Poster	Tue	1:00 PM
84.	Sprouting and Sprouting Mechanisms	Poster	Tue	8:30 AM
247.	Synaptogenesis	Poster	Thu	1:00 PM
36.	Synaptogenesis: Molecular Approaches	Slide	Mon	1:00 PM
5.	Visual System: Geniculocortical Development I	Slide	Mon	8:30 AM
82.	Visual System: Geniculocortical Development II	Poster	Tue	8:30 AM
189.	Visual System: Geniculocortical Development III	Poster	Wed	1:00 PM

*Includes contributed paper sessions, symposia, and workshops only.

34.	The Assembly of Topographic Maps in the Central Nervous System: A Cartographer's Delight	Symp.	Mon	1:00 PM
137.	Genetic Correlates of Mental Disease	Symp.	Wed	8:30 AM
3.	Regulation of Acetylcholine Receptor and Channel Properties During Development	Symp.	Mon	8:30 AM
172.	Sex Hormones and Neural Development: Implications for the Genesis of Sexual Differentiation	Symp.	Wed	1:00 PM

Theme B: Cell Biology

Session Number	Title	Type	Day	Time
224.	Axonal Organelles, Transport, and Specific Staining	Poster	Thu	8:30 AM
237.	Axoplasmic Transport	Slide	Thu	1:00 PM
243.	Blood–Brain Barrier	Poster	Thu	1:00 PM
283.	Cell Biology: Metabolic Studies	Poster	Fri	8:30 AM
197.	Cell Surface Macromolecules, Receptors, and Membranes	Poster	Wed	1:00 PM
62.	Cell and Tissue Culture	Poster	Mon	1:00 PM
286.	Cellular Aspects of Disease	Poster	Fri	8:30 AM
63.	Glia: Morphology and Function	Poster	Mon	1:00 PM
196.	Identified Neurons	Poster	Wed	1:00 PM
207.	Identifying Neurons and Glial Cells	Slide	Thu	8:30 AM
116.	Membranes and Cell Surface Molecules	Slide	Tue	1:00 PM
203.	Neurogenetics and Gene Expression	Slide	Thu	8:30 AM
64.	Neuronal and Glial Macromolecules	Poster	Mon	1:00 PM
148.	Structure and Function of Neuroendocrine Cells	Slide	Wed	8:30 AM

Theme C: Excitable Membranes and Synaptic Transmission

Session Number	Title	Type	Day	Time
169.	Diseases of Synapses and Axons	Poster	Wed	8:30 AM
102.	Drug Effects on Receptors	Poster	Tue	8:30 AM
115.	Electrophysiological Behavior of Vertebrate Central Nervous System Neurons	Slide	Tue	1:00 PM
287.	Epilepsy	Poster	Fri	8:30 AM
194.	Invertebrate Neurobiology	Poster	Wed	1:00 PM
66.	Ionic Channel Mechanisms	Poster	Mon	1:00 PM
211.	Ionic Channels: Structure and Function	Slide	Thu	8:30 AM
33.	Ionic Mechanisms of Excitable Cells	Poster	Mon	8:30 AM
103.	Membrane Biophysics I	Poster	Tue	8:30 AM
271.	Membrane Biophysics II	Slide	Fri	8:30 AM
227.	Neurobiological Studies of Cells in Culture	Poster	Thu	8:30 AM
259.	Neurobiological Studies of Vertebrate Central Nervous System Neurons	Poster	Thu	1:00 PM
101.	Pharmacology of Synaptic Transmission: Central Nervous System	Poster	Tue	8:30 AM
226.	Postsynaptic Mechanisms: Central Nervous System	Poster	Thu	8:30 AM
135.	Postsynaptic Mechanisms: Peripheral Nervous System	Poster	Tue	1:00 PM
145.	Pre- and Postsynaptic Mechanisms I	Slide	Wed	8:30 AM
239.	Pre- and Postsynaptic Mechanisms II	Slide	Thu	1:00 PM
225.	Presynaptic Mechanisms: Central Nervous System	Poster	Thu	8:30 AM
134.	Presynaptic Mechanisms: Peripheral Nervous System	Poster	Tue	1:00 PM
258.	Sensory Transduction	Poster	Thu	1:00 PM
77.	Synaptic Structure and Function I	Slide	Tue	8:30 AM
133.	Synaptic Structure and Function II	Poster	Tue	1:00 PM
104.	Molecular and Genetic Studies of the Voltage-Dependent Sodium Channel	Symp.	Tue	1:00 PM
171.	Single Channel Recording	Symp.	Wed	1:00 PM

Theme D: Neurotransmitters, Modulators, and Receptors

Session Number	Title	Type	Day	Time
143.	Acetylcholine I	Slide	Wed	8:30 AM
221.	Acetylcholine II	Poster	Thu	8:30 AM
157.	Adenosine: Modulators	Poster	Wed	8:30 AM
146.	Adrenergic Receptors: Biochemistry I	Slide	Wed	8:30 AM
187.	Adrenergic Receptors: Biochemistry II	Poster	Wed	1:00 PM
185.	Alcohol II	Poster	Wed	1:00 PM
111.	Amino Acids	Slide	Tue	1:00 PM
27.	Behavioral Pharmacology I	Poster	Mon	8:30 AM
109.	Behavioral Pharmacology II	Slide	Tue	1:00 PM
28.	Behavioral Pharmacology: Sedatives and Anxiolytics	Poster	Mon	8:30 AM
158.	Benzodiazepines	Poster	Wed	8:30 AM
223.	Biogenic Amines: Phenethylamine, Tryptamine, Serotonin, and Histamine	Poster	Thu	8:30 AM
30.	Catecholamines: Anatomical Localization	Poster	Mon	8:30 AM
252.	Catecholamines: Biochemistry	Poster	Thu	1:00 PM
131.	Catecholamines: Physiological Effects I	Poster	Tue	1:00 PM
264.	Catecholamines: Physiological Effects II	Slide	Fri	8:30 AM
31.	Coexistence of Transmitters	Poster	Mon	8:30 AM
93.	Cyclic Nucleotides	Poster	Tue	8:30 AM
186.	Dopamine Receptors: Biochemistry I	Poster	Wed	1:00 PM
208.	Dopamine Receptors: Biochemistry II	Slide	Thu	8:30 AM
251.	Excitatory Amino Acids	Poster	Thu	1:00 PM
159.	GABA and Benzodiazepines	Poster	Wed	8:30 AM
29.	Hypothalamic Hormones: Anatomical Localization	Poster	Mon	8:30 AM
32.	Interaction Between Neurotransmitters	Poster	Mon	8:30 AM
92.	Muscarinic Receptors	Poster	Tue	8:30 AM
91.	Nicotinic Receptors	Poster	Tue	8:30 AM
26.	Opiates, Endorphins, and Enkephalins: Anatomical Localization	Poster	Mon	8:30 AM
130.	Opiates, Endorphins, and Enkephalins: Characterization, Biosynthesis, and Degradation	Poster	Tue	1:00 PM
61.	Opiates, Endorphins, and Enkephalins: Electrophysiological Effects	Poster	Mon	1:00 PM
60.	Opiates, Endorphins, and Enkephalins: Physiological Effects I	Poster	Mon	1:00 PM
222.	Opiates, Endorphins, and Enkephalins: Physiological Effects II	Poster	Thu	8:30 AM
59.	Opiates, Endorphins, and Enkephalins: Receptors I	Poster	Mon	1:00 PM
107.	Opiates, Endorphins, and Enkephalins: Receptors II	Slide	Tue	1:00 PM
160.	Peptide-Amine Interactions: Modulators	Poster	Wed	8:30 AM
161.	Peptides: Anatomical Localization I	Poster	Wed	8:30 AM
231.	Peptides: Anatomical Localization II	Slide	Thu	1:00 PM
8.	Peptides: Biochemical Characterization	Slide	Mon	8:30 AM
79.	Peptides: Physiological Effects I	Slide	Tue	8:30 AM
281.	Peptides: Physiological Effects II	Poster	Fri	8:30 AM
280.	Peptides: Receptors	Poster	Fri	8:30 AM
156.	Phosphorylation: Calmodulin and Calcium Channels	Poster	Wed	8:30 AM
10.	Receptor Localization and Characterization I	Slide	Mon	8:30 AM
183.	Receptor Localization and Characterization II	Poster	Wed	1:00 PM
234.	Regulation of Transmitter Metabolic Enzymes	Slide	Thu	1:00 PM
76.	Serotonin: Biochemistry and Physiology	Slide	Tue	8:30 AM
38.	Transmitter Cytochemistry and Immunohistochemistry I	Slide	Mon	1:00 PM
188.	Transmitter Cytochemistry and Immunohistochemistry II	Poster	Wed	1:00 PM
282.	Transmitters in Invertebrates	Poster	Fri	8:30 AM
44.	Transmitters and Receptors in Disease I	Slide	Mon	1:00 PM
155.	Transmitters and Receptors in Disease II	Poster	Wed	8:30 AM
132.	Uptake, Storage, and Secretion I	Poster	Tue	1:00 PM
144.	Uptake, Storage, and Secretion II	Slide	Wed	8:30 AM
184.	Uptake, Storage, and Secretion: Cholinergic Systems	Poster	Wed	1:00 PM
260.	Functions of Multiple Transmitters in Neurons	Symp.	Fri	8:30 AM
201.	Substance P as a Neurotransmitter	Symp.	Thu	8:30 AM
35.	Sympathetic Ganglia as Models for Synaptic Transmitter Action	Symp.	Mon	1:00 PM

Theme E: Endocrine and Autonomic Regulation

Session Number	Title	Type	Day	Time
88.	Brain Ventricular Systems	Poster	Tue	8:30 AM
73.	Cardiovascular Regulation: Central Transmitters I	Slide	Tue	8:30 AM
119.	Cardiovascular Regulation: Central Transmitters II	Poster	Tue	1:00 PM
21.	Cardiovascular Regulation: Functional Aspects I	Poster	Mon	8:30 AM
209.	Cardiovascular Regulation: Functional Aspects II	Slide	Thu	8:30 AM
120.	Cardiovascular Regulation: Hypertension and Stress	Poster	Tue	1:00 PM
39.	Endocrine and Autonomic Regulation: Central Pathways I	Slide	Mon	1:00 PM
118.	Endocrine and Autonomic Regulation: Central Pathways II	Poster	Tue	1:00 PM
19.	Hormonal Control of Behavior I	Poster	Mon	8:30 AM
267.	Hormonal Control of Behavior II	Slide	Fri	8:30 AM
20.	Neural Control of Immune System	Poster	Mon	8:30 AM
113.	Peripheral Autonomic Nervous System I	Slide	Tue	1:00 PM
153.	Peripheral Autonomic Nervous System II	Poster	Wed	8:30 AM
152.	Pineal Gland	Poster	Wed	8:30 AM
22.	Regulation of Autonomic Functions I	Poster	Mon	8:30 AM
74.	Regulation of Autonomic Functions II	Slide	Tue	8:30 AM
18.	Regulation of Pituitary Function	Poster	Mon	8:30 AM
154.	Respiratory Regulation	Poster	Wed	8:30 AM

Theme F: Sensory Systems

Session Number	Title	Type	Day	Time
288.	Auditory Cortex	Poster	Fri	8:30 AM
16.	Auditory and Vestibular Sensory Organs	Poster	Mon	8:30 AM
7.	Chemical Senses: Olfaction and Taste I	Slide	Mon	8:30 AM
55.	Chemical Senses: Olfaction and Taste II	Poster	Mon	1:00 PM
95.	Evoked Potentials I	Poster	Tue	8:30 AM
265.	Evoked Potentials II	Slide	Fri	8:30 AM
72.	Pain I	Slide	Tue	8:30 AM
220.	Pain: Modulation I	Poster	Thu	8:30 AM
230.	Pain: Modulation II	Slide	Thu	1:00 PM
17.	Retina: Intrinsic Organization I	Poster	Mon	8:30 AM
37.	Retina: Intrinsic Organization II	Slide	Mon	1:00 PM
244.	Sensory System: Somatosensory Cortex	Poster	Thu	1:00 PM
147.	Sensory Systems in Invertebrates I	Slide	Wed	8:30 AM
195.	Sensory Systems in Invertebrates II	Poster	Wed	1:00 PM
245.	Skin, Muscle, and Visceral Receptors	Poster	Thu	1:00 PM
15.	Somatosensory Cortex and Thalamus	Slide	Mon	8:30 AM
25.	Spinal Cord I	Poster	Mon	8:30 AM
43.	Subcortical Auditory Pathways I	Slide	Mon	1:00 PM
94.	Subcortical Auditory Pathways II	Poster	Tue	8:30 AM
289.	Subcortical Somatosensory Pathways	Poster	Fri	8:30 AM
56.	Subcortical Visual Pathways I	Poster	Mon	1:00 PM
71.	Subcortical Visual Pathways II	Slide	Tue	8:30 AM
112.	Subcortical Visual Pathways III	Slide	Tue	1:00 PM
129.	Transmitters in Sensory Systems	Poster	Tue	1:00 PM
191.	Visual Cortex: Cortical and Subcortical Relationships	Poster	Wed	1:00 PM
193.	Visual Cortex: Extrastriate Visual Areas I	Poster	Wed	1:00 PM
232.	Visual Cortex: Extrastriate Visual Areas II	Slide	Thu	1:00 PM
192.	Visual Cortex: Intrinsic Organization of Striate Cortex I	Poster	Wed	1:00 PM
204.	Visual Cortex: Intrinsic Organization of Striate Cortex II	Slide	Thu	8:30 AM
138.	Functions of Extrastriate Visual Cortex in Primates	Symp.	Wed	8:30 AM
69.	Physiological Insights Derived from Nerve Traffic Analysis in Conscious Man	Symp.	Tue	8:30 AM

Theme G: Motor Systems and Sensorimotor Integration

Session Number	Title	Type	Day	Time
140.	Basal Ganglia	Slide	Wed	8:30 AM
276.	Basal Ganglia: Functional Relationships	Poster	Fri	8:30 AM
48.	Basal Ganglia: Structural Relationships	Poster	Mon	1:00 PM
123.	Cerebellum I	Poster	Tue	1:00 PM
238.	Cerebellum II	Slide	Thu	1:00 PM
47.	Control of Posture and Movement I	Poster	Mon	1:00 PM
78.	Control of Posture and Movement II	Slide	Tue	8:30 AM
212.	Control of Posture and Movement III	Poster	Thu	8:30 AM
272.	Control of Posture and Movement IV	Poster	Fri	8:30 AM
274.	Disorders of the Motor System and Corrective Methods	Poster	Fri	8:30 AM
213.	Invertebrate Motor Function	Poster	Thu	8:30 AM
114.	Motor Systems: Cortex I	Slide	Tue	1:00 PM
150.	Motor Systems: Cortex II	Poster	Wed	8:30 AM
210.	Motor Systems: Spinal Cord and Brainstem I	Slide	Thu	8:30 AM
250.	Motor Systems: Spinal Cord and Brainstem II	Poster	Thu	1:00 PM
275.	Motor Systems: Spinal Cord and Brainstem III	Poster	Fri	8:30 AM
90.	Muscle	Poster	Tue	8:30 AM
124.	Muscle Afferents	Poster	Tue	1:00 PM
45.	Oculomotor I	Slide	Mon	1:00 PM
80.	Oculomotor II	Poster	Tue	8:30 AM
117.	Oculomotor III	Poster	Tue	1:00 PM
149.	Reflex Function	Poster	Wed	8:30 AM
273.	Sensorimotor Integration	Poster	Fri	8:30 AM
198.	Vestibular System	Poster	Wed	1:00 PM
269.	Vestibular System and Vestibulo-Ocular Reflex	Slide	Fri	8:30 AM
81.	Visuomotor Integration	Poster	Tue	8:30 AM
173.	Springing into Action: Mechanism and Function of Spring-Like Properties of Neuromuscular Systems	Wkshp.	Wed	1:00 PM
4.	Theoretical Approaches to Motor Control	Symp.	Mon	8:30 AM

Theme H: Structure and Function of the CNS

Session Number	Title	Type	Day	Time
285.	Brain Metabolism	Poster	Fri	8:30 AM
219.	Comparative Neuroanatomy	Poster	Thu	8:30 AM
57.	Cortex and Cortico-Subcortical Relationships I	Poster	Mon	1:00 PM
268.	Cortex and Cortico-Subcortical Relationships II	Slide	Fri	8:30 AM
13.	Diseases of the Central Nervous System I	Slide	Mon	8:30 AM
65.	Diseases of the Central Nervous System II	Poster	Mon	1:00 PM
24.	Epilepsy: Kindling	Poster	Mon	8:30 AM
126.	Epilepsy: Kindling and Pharmacology	Poster	Tue	1:00 PM
139.	Epilepsy: Pharmacology	Slide	Wed	8:30 AM
279.	Evoked Potentials and EEG	Poster	Fri	8:30 AM
240.	Limbic System and Hypothalamus I	Slide	Thu	1:00 PM
278.	Limbic System and Hypothalamus II	Poster	Fri	8:30 AM
58.	Limbic System and Hypothalamus: Structure	Poster	Mon	1:00 PM
284.	Spinal Cord II	Poster	Fri	8:30 AM
182.	Subcortical Organization	Poster	Wed	1:00 PM
202.	Application of Video Enhancement and Intensification Techniques to Neurobiology	Wkshp.	Thu	8:30 AM
229.	Functional Correlates of Brain Transplantation	Symp.	Thu	1:00 PM

Theme I: Neural Basis of Behavior

Session Number	Title	Type	Day	Time
241.	Aging	Poster	Thu	1:00 PM
163.	Alcohol I	Poster	Wed	8:30 AM
256.	Angiotensin and Drinking	Poster	Thu	1:00 PM
166.	Behavior and Learning in Invertebrate and Simple Vertebrate Preparations	Poster	Wed	8:30 AM
14.	Biological Rhythms I	Slide	Mon	8:30 AM
151.	Biological Rhythms II	Poster	Wed	8:30 AM
46.	Circuitry and Pattern Generation I	Slide	Mon	1:00 PM
214.	Circuitry and Pattern Generation II	Poster	Thu	8:30 AM
290.	Drugs of Abuse	Poster	Fri	8:30 AM
96.	Effects of Chronic Drug Administration and Neurotoxicology	Poster	Tue	8:30 AM
164.	Feeding and Drinking	Poster	Wed	8:30 AM
206.	Feeding and Drinking: Central Mechanisms and Neuropharmacology	Slide	Thu	8:30 AM
75.	Feeding and Drinking: Central and Peripheral Mechanisms	Slide	Tue	8:30 AM
255.	Feeding and Drinking: Cues for Need State	Poster	Thu	1:00 PM
257.	Feeding and Drinking: Metabolic Aspects	Poster	Thu	1:00 PM
165.	Feeding and Drinking: Neuropharmacology	Poster	Wed	8:30 AM
263.	Human Behavioral Neurobiology	Slide	Fri	8:30 AM
177.	Human Neuropsychology	Poster	Wed	1:00 PM
176.	Interhemispheric Relations	Poster	Wed	1:00 PM
106.	Invertebrate Learning and Behavior I	Slide	Tue	1:00 PM
236.	Invertebrate Learning and Behavior II	Slide	Thu	1:00 PM

2 SYMPOSIUM. FEDERAL SUPPORT FOR THE NEUROSCIENCES, CONCEPTION TO FUNDING: THE PROCESS AND PROGRAMS. S.H. Koslow, National Institute of Mental Health (NIMH)(Chairman); Donald Woodward*, Office of Naval Research; George W. Irving, III*, Air Force Office of Scientific Research/NL; Zaven Khachaturian, National Institute on Aging (NIA); Norman A. Krasnegor*, National Institute of Child Health and Human Development (NICHD); Constance W. Atwell*, National Eye Institute (NEI); Eugene Streicher*, National Institute of Neurological and Communicative Disorders and Stroke (NINCDS); James Brown, National Science Foundation (NSF).

This symposium will present an overview of the numerous factors which enter into the decision making processes of Governmental support for basic and applied Neuroscience research. Major support for this research is provided through the NSF, NINCDS, NIMH, NEI, NIA, NICHD, as well as from the different services of the Department of Defense. A description of each of these funding sources will be presented, along with specific identification of programs, as well as points of contact. An indepth description of each agency will follow outlining the "missions" of each, as well as presenting the overall areas of interest and responsibility. Major emphasis will be placed on the funding mechanisms utilized by investigators to apply for grant support. In addition, other support mechanisms will also be described, e.g., training grants, fellowships, small grants, cooperative agreements and contracts. For each of the funding agencies the process of applying for grants or contracts (including pre-submission contact with program directors), will be described. This will provide details of the processes of assignment to funding organization and review group, the process of review, constitution of review groups, second level of review, and decisions of funding by agency staff.

Following these presentations the full panel of Federal program directors will hold an open discussion session.

3 SYMPOSIUM. REGULATION OF ACETYLCHOLINE RECEPTOR AND CHANNEL PROPERTIES DURING DEVELOPMENT. Y. Kidokoro, The Salk Institute (Chairman); J. Patrick, The Salk Institute; Y. Nakajima, Purdue University; B. Sakmann , Max-Plank Institut; G.D. Fischbach, Washington University.

Multidisciplinary approaches are rapidly expanding our appreciation of the function and regulation of the acetylcholine (ACh) receptor. In this symposium we would like to bring together several different systems and techniques to present an overview of developmental changes in ACh receptors.

The genes that code for the ACh receptor from Torpedo have been cloned. cDNA clones have been isolated for two of the subunits (α and γ). These clones are being used to determine the structure and organization of the ACh receptor genes. They have been largely sequenced and the complete amino acid sequence of the ACh receptor is being deduced. These clones are also useful as probes to study the expression of the ACh receptor genes. The biosynthesis of ACh receptor will be discussed in relation to the finding that cDNA for the γ subunit codes for a precursor peptide containing a 'signal' sequence (Patrick, J.). Functional ACh receptors appear on the muscle surface membrane before synaptic transmission starts. One type of dispersed intramembrane particles seen in freeze-fracture electron micrographs correlate well with the appearance of functional ACh receptors assayed by ACh iontophoresis (Nakajima, Y.). During formation of the neuromuscular junction ACh receptors undergo various changes. Nerve induces high ACh receptor density along the contact soon after initial functional transmission. Properties of individual ACh receptor channels also change. The mean open time of ACh receptor channels shortens at the subjunctional membrane in the neonatal rat. The shortening is due to shift of ACh receptor channel population with a long mean open time to a short one. Since the turnover time for ACh receptors in the subsynaptic membrane is already long at this time, this shift of population is likely the result of modification of existing ACh receptor channels (Sakmann, B.). On the contrary the mean open time does not undergo developmental changes in the chick, although the density of ACh receptors increases at the subjunctional region. The clustering of receptors by itself, therefore, is not responsible for the open time shortening. During this period the rate of receptor degradation stays comparable to value obtained at extrajunctional sites on denervated adult muscles (Fischbach, G.). In Xenopus nerve-muscle cultures neurons from embryonic neural tube mediate changes in both the density and the functional properties of ACh receptors in the muscle cell. The neuronally mediated increase in the receptor density is restricted to the region closely associated to the nerve-muscle contact. In contrast to this regional effect of nerve, a nerve-dependent alteration in functional properties is observed for junctional and non-junctional receptor alike (Kidokoro, Y.).

4 WORKSHOP. THEORETICAL APPROACHES TO MOTOR CONTROL. E. Bizzi, M.I.T. (Chairman); R. Llinas, N. Y. Univ. Med. Ctr. (Chairman); L. M. Optican*, NEI, National Institutes of Health; A. Pellionisz, N. Y. Univ. Med. Ctr.; T. Poggio*, M.I.T.

There is little doubt that the problem of understanding the properties and the operations of the biological motor controller is an exceedingly difficult task. Experimentation in this area cannot proceed without theories which reflect and deal with the constraints imposed by physics and by the computational complexities related to the problems of coordinate transformation, kinematics and dynamics. Presently, in the field of motor control, there is a spectrum of theoretical approaches ranging from "System Theories" to Tensorial models of the brain, to control strategies based upon the mechanical properties of muscles. These ideas will be discussed and contrasted with computational theories derived from the field of Artificial Intelligence. The speakers participating in this symposium will describe these approaches, their relationship to experimental findings, and their possible impact on future experimentation.

The powerful electrophysiological techniques that are now used in many laboratories have certainly provided us with a great wealth of data on movement. We feel, however, that the predominant, almost extreme, empiricism which characterizes research in motor control might be in the long run disadvantageous for progress in this field. Our proposal is then directed at presenting and discussing those theories that might have a chance to guide experimentation in the areas of motor and sensory control.

Finally, an overview of current theoretical approaches to the problem of motor control may offer an interesting paradigm for other areas of neuroscience.

5.1 EFFECTS OF STRABISMUS ON RESPONSIVITY, SPATIAL RESOLUTION, AND CONTRAST SENSITIVITY OF CAT LATERAL GENICULATE NEURONS. Kim R. Jones, Ronald E. Kalil, and Peter D. Spear. Depts. of Psychology and Ophthalmology, Univ. of Wisconsin, Madison, WI 53706.

Previous studies have reported that rearing cats with esotropia causes two major physiological effects in the lateral geniculate nucleus (LGN): (1) a loss of responsive cells in the portion of lamina A1 that receives inputs from the peripheral (>10°) temporal retina of the deviated eye, and (2) a loss of spatial resolution among X-cells that have central (<5°) receptive fields. We extended these findings by quantifying the responsiveness of peripheral A1 cells, and by obtaining spatial contrast sensitivity functions for central X-cells.

Recordings were made from the portion of lamina A1 representing the peripheral retina in 3 normal and 3 esotropic cats. In normals, an average of 3.3 cells/penetration was encountered, and all but 1 of 43 cells were responsive. Mean peak response to an optimal stimulus was 177 spikes/sec. In esotropes, 2.7 cells/penetration were encountered, and all 30 cells studied were responsive. Mean peak response was 174 spikes/sec. The differences between normals and esotropes in these and other measures of responsiveness were not statistically significant. There also was no difference in percentage of X- or Y-cells between the two groups. Thus, esotropia had no effect on the responsivity of LGN cells with inputs from the peripheral temporal retina.

Spatial resolution was measured for X-cells with central receptive fields in 6 normal, 5 esotropic, and 4 exotropic cats. Stimuli were drifting (2 Hz) sine wave gratings of 30 cd/m^2 mean luminance and 64% contrast. In normals, mean spatial resolution for 43 X-cells was 3.1 c/°. Rearing with esotropia significantly reduced X-cell spatial resolution; the mean for 38 X-cells was 2.1 c/°. This reduction was seen consistently among individual cats. In 2 cats raised with one eye converged and the other lid-sutured, X-cell spatial resolution was intermediate between normal and esotropic cats. This suggests that the spatial resolution loss in esotropes is at least partly due to abnormal binocular interactions. In contrast to esotropia, rearing with exotropia had no significant effect on X-cell spatial resolution; the mean for 43 X-cells was 3.0 c/°. However, there was more variability among cats in this group than in the others.

Other measures of spatial contrast sensitivity were normal in esotropic cats. These included maximum sensitivity, peak spatial frequency, and amount of contrast sensitivity attenutation (roll-off) at low spatial frequencies. Thus, rearing with esotropia produces effects on LGN X-cells with central receptive fields that are limited to spatial resolution.

5.2 MONOCULAR DEPRIVATION CAUSES EXPANSION OF X-CELL AND REDUCTION OF Y-CELL RETINOGENICULATE TERMINATIONS IN CATS. M. Sur*, A.L. Humphrey and S.M. Sherman. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

We recently used the technique of intracellular HRP injection into single X- or Y-cell optic tract axons to demonstrate their termination patterns in the lateral geniculate nucleus (LGN) of normal cats. X-cell axons innervate lamina A or A1 in narrow zones (100-170μm wide) oriented perpendicular to the geniculate lamination. Some X-cell axons also sparsely innervate the medial interlaminar nucleus (MIN) of the LGN. Y-cell axons innervate laminae C and A (from the contralateral retina) or lamina A1 (from the ipsilateral retina) in broad zones (200-400μm wide), and the majority also densely innervate the MIN.

Early monocular lid suture alters these termination patterns. We have successfully injected and recovered 9 X- and 13 Y-cell axons from deprived retinas as well as 11 X- and 7 Y-cell axons from nondeprived retinas. Physiologically, deprived and nondeprived axons have normal response properties. Morphologically, nondeprived axons are indistinguishable from normal axons. However, 4 deprived X-cells have LGN terminations that are broader (180-220μm) than normal and two of these have dense terminations in the MIN. Deprived Y-cell terminations seem even more abnormal. Four deprived Y-cells from the contralateral retina innervate only the C-laminae and do not innervate lamina A. Four additional deprived Y-cell axons have terminal fields in lamina A or A1 that are narrower (160-190μm) and sparser than normal. In general, Y-cell terminations are most affected in the A-laminae, less so in the MIN, and seem normal in the C-laminae. However, 2 deprived Y-cell axons that innervate the monocular segment appear to have normal morphology.

We have retrogradely labelled the somata of several injected axons. To date, there appear to be no qualitative morphological differences between deprived and nondeprived retinal ganglion cells, even though there are large changes in the terminal fields of the former.

The "expanded" X-cell termination zones and "shrunken" or "absent" Y-cell termination zones constitute the most peripheral morphological effects of deprivation discovered so far, and suggest two complementary developmental mechanisms: (1) binocular competition, and (2) competition between X- and Y-cell pathways. Thus, X-cells which seem to innervate the LGN before Y-cells do may have exuberant terminations that are "pruned" as Y-cells develop functional connections. Perhaps visual deprivation severely reduces the ability of Y-cell axons to dislodge the already present X-cell terminations in the A-laminae.

5.3 CORTICAL AXON TERMINAL ARBORIZATION AND SOMA LOCATION OF SINGLE, FUNCTIONALLY IDENTIFIED LATERAL GENICULATE NUCLEUS NEURONS. A.L. Humphrey, M. Sur* and S.M. Sherman. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

We have used the technique of intracellular HRP injection to label the terminal fields of single axons from the lateral geniculate nucleus (LGN) in areas 17 and 18 of the normal, adult cat. In addition, we have labeled the parent somata of the afferents in the LGN by retrograde transport of HRP from the intra-axonal injections in cortex. This allowed us to examine relationships between a cell's soma size and location within the LGN and the location and extent of its axon terminal field in cortex. LGN axons were recorded in the optic radiations beneath areas 17 and 18 using micropipettes (90-120 Mohm) filled with 3% HRP. Each axon was identified extracellularly as X or Y using a battery of tests, including conduction latency to optic chiasm stimulation and linearity of spatial summation. The axon was then impaled and HRP iontophoresed into it. During subsequent histology, cortical sections were reacted with diaminobenzidine and cobalt chloride to allow complete reconstruction of the injected axons, and the LGN sections were reacted with O-dianisidine to visualize the parent cells. Each cell was matched to its axon by retinotopic position.

There is a marked heterogeneity of termination patterns both within and between each afferent cell class and between areas 17 and 18. Axons of X-cells project only to area 17, while Y-cells project to area 17, to area 18 or to both areas. Axons of Y-cells in area 17 terminate in layers IVab, lower III and VI, while X-cell axons end mainly in layers IVc and VI, in agreement with Ferster and LeVay (J.Comp.Neurol.,182:923,1978). However, a number of X-cell fields spill over into lower IVab, indicating a marked overlap of X- and Y-inputs there. Within area 18, Y-cells terminate mainly in layers IV and IIIb, but some also issue collaterals into upper layer I. At least some of these Y-axons that project to layers IV plus I arise from cells in lamina C of the LGN which do not project also to area 17.

Retrogradely-filled cell bodies of injected axons have been found throughout the LGN. In the A-laminae, somata of X-cells range from 110 to 500μm^2, with a bias toward larger cells (>200μm^2), while those of Y-cells are 280-660μm^2. These ranges of values agree well with the sizes of intracellularly stained X- and Y-cells reported by Friedlander et al. (J. Neurophysiol., 46:80,1981) from recordings in the LGN, and they indicate that our micropipettes can record and inject axons of representative LGN cells. A geniculate neuron's soma size appears to be correlated generally with the width of its axon terminal field in visual cortex.

5.4 THE EFFECTS OF MONOCULAR EYELID SUTURE ON THE TERMINAL ARBORIZATIONS OF PHYSIOLOGICALLY IDENTIFIED GENICULOCORTICAL AXONS. Michael J. Friedlander and Christiane Vahle-Hinz*. Dept. of Physiology and Biophysics, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

Early monocular eyelid suture in kittens results in a severe reduction in the number of neurons in visual cortex which can be activated through the deprived eye. This deficit has been attributed to at least 2 possible mechanisms: 1) a decrease in the number of geniculocortical synapses from axons of cells in the lateral geniculate nucleus (LGN) laminae innervated by the deprived eye. (Shatz, C. J., and M. P. Stryker, 1978, J. Physiol. (Lond.), 281:267-283), and 2) the active suppression of geniculocortical input from the deprived eye. (Kratz, K. E., P. D. Spear, and D. C. Smith, 1976, J. Neurophysiol., 39:501-511; and Burchfiel, J. L., and F. H. Duffy, 1981, Brain Res., 206:479-484).

We have begun studies to test the first hypothesis. We are using the intracellular horseradish peroxidase (HRP) technique to physiologically classify and stain individual geniculocortical axons in cats that have been reared with monocular eyelid suture. Kittens are monocularly sutured at 6-9 days of age. Experiments are done on animals from age 9-15 months. Micropipettes are filled with a 3% HRP solution and bevelled to final impedances of 130-180 MΩ at 200 Hz. Stimulating electrodes are placed in the optic chiasm and optic radiations for transsynaptic and orthodromic activation of geniculocortical cells' axons, respectively. Axons are classified as X- or Y- based on a battery of physiological tests (Friedlander, M. J., C.-S. Lin, L. R. Stanford, and S. M. Sherman, 1981, J. Neurophysiol., 46:80-129) including response latency to stimulation of optic chiasm and the linearity of spatial summation within the axon's receptive field. The axon is then impaled with the micropipette. After verifying the axon's receptive field properties with intracellular recording, the axon is filled iontophoretically with HRP. The size, shape, laminar distribution, and density of the axon's terminal arborization in visual cortex are compared for X- and Y- axons from the LGN laminae innervated by the normal and the sutured eye. Preliminary data indicate that the terminal arborizations of axons from cells in the non-deprived LGN laminae occupy a greater volume of visual cortex than those from cells of the deprived laminae. In addition, the total number and density of apparent presynaptic terminals from the axons of the non-deprived laminae also appear to be greater than those from cells of the deprived laminae.

5.5 GENICULATE Y-LIKE CELLS REMAIN AFTER MONOCULAR DEPRIVATION IN A PRIMATE. M. A. Sesma, T. Kuyk,* T. T. Norton, V. A. Casagrande, Depts. Anatomy and Psychology, Vanderbilt Univ., Nashville, TN; Dept. Physiol. Optics, School of Optometry, The Medical Center, Univ. of Alabama in Birmingham, Birmingham, AL.

Effects of early monocular lid closure in kittens and infant primates have been proposed by a number of investigators as a developmental model of human amblyopia. Deficits produced by this paradigm have been attributed to abnormal competitive interactions that, in cats, result in a reduction in recordable Y-cells (but not X-cells) in lateral geniculate nucleus (LGN) with correlated LGN cell size changes and form vision deficits (Sherman and Spear, '82). Similarly, in primates such as macaques and galagos, monocular suture produces profound changes in LGN cell size and associated visual deficits (Von Noorden et al., '76; Casagrande and Joseph, '80). However, in these primates the mean LGN cell size is altered in both the magno- and parvocellular laminae, suggesting that both Y- and X-like cells are affected by monocular lid closure.

We have examined this problem by recording from LGN neurons in 3 animals (Galago crassicaudatus), each deprived by monocular suture for more than 2 years. As before (Norton and Casagrande, '82), cell classification was determined using a battery of tests including linearity of spatial summation, latency to chiasm and cortical stimulation, receptive-field size, response to targets of appropriate standing contrast and phasic-tonic index.

In all 3 animals, deprived cells were easy to drive with visual stimuli and exhibited no gross abnormalities in receptive-field organization. Both linear and non-linear spatial summation were seen in the deprived Y-like cells of the magnocellular layer. Moreover, the encounter rate for deprived versus non-deprived neurons of all classes (W-, X- and Y-like) was the same for all layers regardless of whether retinal input was crossed or uncrossed.

These findings lead to two major questions. First, are the deprived LGN neurons of these primates really normal? We can so far only state that if physiological abnormalities exist in deprived Y-like cells or any other class in galagos, these effects seem quite subtle. Second, how can we reconcile the differences in deprivation effects on Y-cells in cats and galagos? The sensitivity of cat Y-cells to monocular deprivation may be a manifestation of the mixed retinal afferent input (both X and Y) to the same LGN laminae, a situation that would allow for direct competitive interaction within the LGN during development. This situation would be less likely to occur in primates where cell classes are segregated by layer, but still may compete at the cortical level. 5.6 EFFECTS OF VISUAL DEPRIVATION ON THE GENICULOCORTICAL W-CELL PATHWAY IN THE CAT: AREA 19 AND ITS AFFERENT INPUT. A.G. Leventhal and H.V.B. Hirsch. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132; Ctr. for Neurobiology, S.U.N.Y. at Albany, Albany, NY 12222.

We studied the receptive field properties of about 200 neurons in area 19 of normal cats and about 200 neurons in cats deprived of vision for 9-12 months by monocular lid suture. In these same animals we also studied the sizes of relay cells in the parvocellular C laminae of the dorsal lateral geniculate nucleus labeled by electrophoretic injections of horseradish peroxidase into area 19.

In area 19 of normal cats, the large majority of cells, regardless of laminar location and eccentricity, were binocular. Most responded equally well to the two eyes.

In area 19 of monocularly deprived (MD) cats, virtually all cells (97%), regardless of laminar location and eccentricity, responded only to stimulation of the normal eye. Thus, the effects of monocular deprivation upon area 19 are apparently more severe than those reported for area 17. In area 17 of MD cats, significant numbers of neurons in layer 4 can be activated by the deprived eye. Measurements of relay cells in the parvocellular C laminae labeled by injections into area 19 of deprived cats indicated that cell size in the deprived C laminae was unaffected by the deprivation even though cells in the deprived A laminae of these cats were severely shrunken.

These findings suggest that the types of cells found in the parvocellular C laminae (referred to collectively as W-cells) are not affected by visual deprivation in the same way as are the X- and Y-cells in the A laminae. Since laminar location is not related to binocularity in area 19 and the sizes of relay cells projecting to area 19 are not seriously affected by monocular deprivation, we suggest that binocular interactions in area 19 are mainly determined by intracortical connections.

5.7 NEUROGENESIS OF THE CAT'S PRIMARY VISUAL CORTEX. M.B. Luskin and C.J. Shatz. Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

The distribution of radioactively labeled cells in the primary visual cortex of cats that received injections of ^{3}H-thymidine at different embryonic ages was examined in order to study the relationship between the time of neuron origin and the elaboration of afferent and efferent connections. To do so, 15 fetuses between embryonic day 17 (E17) and E59 (gestation is 65 days) received intrauterine injections (Hickey and Cox, Neurosci. Abst., 5:788, 1979) of 0.3-1.0 mCi of ^{3}H-thymidine and survived until 2 months postnatally before autoradiographic processing.

The earliest labeled cortical cells resulted from injections between E24 and E30. These cells were embedded in the white matter immediately below layer 6. In one fetus injected at E27 and allowed to survive only until birth, labeled cells were also observed in layer 1. However, in another fetus which received an injection at E28, but allowed to survive until postnatal day 56, virtually no labeled cells were found in layer 1, indicating that a transient population of cortical neurons may be present in the development of the cat's visual cortex.

Cells destined for the cellular layers of the visual cortex are generated between E28 and E56. Labeled cells were first seen within deep layer 6 following thymidine injections at E28 and E30. An injection at E35 labeled cells extending throughout layers 5 and 6, with the majority of labeled cells concentrated in the upper half of layer 6. Labeling within layer 4, the primary zone of termination of geniculocortical afferents, was first observed following an injection at E39, and was greatest in layer 4b. Injections at E46 through E56 labeled cells situated in layers 2 and 3. There was no apparent gradient in the rostro-caudal dimension or along the central to peripheral visual field representation. Thus, the overall pattern of visual cortical neurogenesis in the cat resembles that in the monkey (Rakic, Phil. Trans. R. Soc., 278: 245, 1977). In both species there is an inside-out gradient of development such that the earliest generated cells come to occupy the deepest layers and cells generated progressively later migrate to more superficial positions.

To further examine the relationship between the developing geniculocortical pathway and its target cells in layers 4 and 6, ^{3}H-proline was injected intraocularly in 8 fetuses aged E29 to E59, which were then allowed to survive 6 days. At E35 and E39 transneuronally transported label was observed in the optic radiations. This finding suggests that the earliest generated cells belonging to the white matter and layer 6 could serve as the first targets for ingrowing geniculocortical afferents. (Supported by NIH grants NS07158 to M.B.L. and EY02585 to C.J.S.)

5.8 THE DEVELOPMENTAL TOPOGRAPHY OF OCULAR DOMINANCE COLUMNS IN THE CAT STRIATE CORTEX. Martin S. Silverman* (SPON: Brenda Martin). Dept. of Physiology, Univ. of California, San Francisco, CA.

Using the ^{14}C-2-deoxyglucose (2DG) autoradiographic technique, we studied the developmental topography of ocular dominance (OD) columns in the cat striate cortex. Kittens between 10 and 39 days of age and adult cats were unilaterally enucleated under ether anesthesia. 2DG was injected 1 hr postoperatively, after which the cats viewed the laboratory environment for 1 hr. Subsequent 2DG processing included flat mounting the cortex before freezing, a modification that allowed almost the entire cat striate to be viewed in single tissue sections, obviating the need for extensive montage reconstruction of autoradiographic images.

The results showed that OD columns first appear between 12 and 15 days of age adjacent to the cortical representation of the temporal monocular crescent for the inferior visual field (situated at the anteroventral region of cat striate) and to the cortical representation of the optic disk (situated in the posterior region of cat striate). From 18 to 22 days of age, the OD columnar system expands from these two regions, completely covering the striate by 35 days of age. Comparison across hemispheres in individual cats showed that OD columns develop first and are more apparent contralateral to the intact eye. In addition, contralateral OD columns form a more confluent mesh-like pattern whereas ipsilateral OD columns are more dot-like. In both hemispheres of the adult, OD columns take a reticulated strip-like form that is intermediate in continuity to those seen during development. The adult patterns are seen to stream from the monocular crescent anteriorly and the optic disk representation in the posterior striate.

The initial formation and the final adult configuration of the OD columns suggest that the monocular crescent and the optic disk representations in striate act as primary initiators and organizers for the development of the OD columnar system. The monocular crescent and the optic disk representations are uniquely monocular areas of striate. The monocular/binocular interface that these areas both make with the adjacent binocular striate may be important for the induction of the OD columnar system in cat striate. (Supported by EY0014-12 and BNS 78-06171 to Russell L. De Valois)

5.9 DEVELOPMENT OF OCULAR DOMINANCE COLUMNS IN CATS REARED WITH BINOCULAR DEPRIVATION OR STRABISMUS. R.E. Kalil, Department of Ophthalmology, University of Wisconsin, Madison, WI 53706

In the cat, geniculocortical afferents representing each eye terminate in layer IV of visual cortex in patches that are partially segregated. The development of these patches has been studied in the normal cat (LeVay et al., J.Comp.Neur., 179, 1978) as has the influence of monocular deprivation (Shatz and Stryker, J.Physiol., 281, 1978). However, relatively little attention has been paid to the effects of other forms of visual deprivation or abnormal visual experience.

In the present experiments, cats were raised with binocular deprivation or misalignment of the eyes. In two cats, complete binocular deprivation was achieved by dark rearing (DR) from birth through 36 weeks. In two other cats the lids of both eyes were sutured shut (BD) at the time of eye opening. These cats were reared for six months, receiving only diffuse light stimulation during this period. Ocular misalignment was produced in two cats by cutting the lateral rectus muscle at 10 days postnatal. Both of these animals were raised to adulthood with a pronounced convergent strabismus.

Transneuronal autoradiography was used to study geniculocortical projections in each animal. Fluctuations in silver grain density, corresponding to the distribution of geniculocortical afferents, were quantified by counting individual grains at 40X. All counts were made in horizontal sections through area 17 ipsilateral to the injected eye along a distance of about 3.5 mm. At least two sections were counted from each brain. The sections that were selected showed most clearly a pattern of silver grains presumed to represent ocular dominance columns. When present, periodic fluctuations in grain density could be described by computing a peak to trough ratio (PTR = ave. max. density ÷ ave. min. density for 3 cycles). For reference, autoradiographic material from normal cats was available.

In DR and BD cats evidence for ocular dominance columns was weak. In most sections labelling in layer IV was almost uniform with little or no fluctuation in grain density. The best PTR for DR cats and for BD cats was about 2.0. By contrast, ocular dominance columns in cats with convergent squint were sharply delineated, with a best PTR of 4.8. The PTR for two normal cats was 2.9.

In comparison with normal cats the present results show that when binocular visual experience during development is partially or completely eliminated, geniculocortical afferents fail to segregate normally in area 17. Rearing with the ocular misalignment, however, produces the opposite effect, namely that the segregation of afferents representing each eye is enhanced.

(Special thanks to Mary Kay Ellis for assistance)

5.10 THE EFFECTS OF MONOCULAR DEPRIVATION ON THE PHYSIOLOGY AND ANATOMY OF THE KITTEN'S VISUAL SYSTEM. J. Presson and B. Gordon. Psychology Dept., University of Oregon, Eugene, OR 97403-1227.

Among the changes that occur in the visual system of a kitten reared with monocular lid suture are: (1) loss of responsiveness of visual cortex cells to stimulation of the deprived eye, (2) shrinkage of cells in the deprived laminae of the LGN, (3) reduction in the area occupied by deprived LGN terminals in layer IV of the visual cortex. Some investigators have suggested that one of these changes is primary and causes the others (Cynader and Mitchell, 1980; Cragg et al., 1976). If so, the primary change should occur first and should be a prerequisite to the others. To determine the sequence of these changes, we have looked for each of them after relatively short term deprivation. Kittens were deprived for 10 days beginning at 3 weeks of age, for 10 days beginning at 5 weeks of age, or for 20 days beginning at 8 weeks of age. Loss of responses to the deprived eye was assessed by recording from single units in the visual cortex. Shrinkage of LGN cells was assessed by comparing the estimated cross sectional area of cells in the deprived and nondeprived layers in Nissl stained sections. Reduction in the area of layer IV occupied by deprived LGN terminals was assessed with transneuronal autoradiography following injection of tritiated proline into the deprived eye. After 10 days of deprivation begun at 3 weeks of age the deprived eye was virtually unable to drive cortical cells and the LGN cells had shrunk by 21%; however transneuronal autoradiography showed that layer IV was virtually continuously labelled. Ten days of deprivation begun at 5 weeks produced similar changes in ocular dominance and LGN cell size, but in these animals the geniculate terminals had segregated and the portion of layer IV occupied by terminals from the deprived eye was abnormally small. Twenty days of deprivation beginning at 8 weeks of age resulted in a loss of cortical responses to the deprived eye, but the effect was not as great as in the younger animals. These older animals showed minimal LGN cell shrinkage, about 9%. The reduction in the area of layer IV occupied by deprived LGN terminals was, however, similar to that in the animal deprived at 5 weeks. These results suggest that changes in the ocular dominance distribution do not require changes in the anatomic distribution of geniculate terminals, and that changes in terminal distribution can occur in the absence of marked LGN cell shrinkage. The possibility exists, however, that minute, but functionally significant, terminal retraction might not be visible in the light microscope; or that very small changes in LGN cell size might cause changes in terminal distribution. (This work was supported in part by the Medical Research Foundation of Oregon.)

5.11 VISUAL CORTICAL PLASTICITY: DEFICIT AFTER ACUTE, BUT NOT CHRONIC, NORADRENERGIC DENERVATION WITH 6-HYDROXYDOPAMINE. Mark F. Bear*, Michael A. Paradiso* and J. D. Daniels. Center for Neural Science, Brown University, Providence, RI 02912

Kasamatsu, Pettigrew, and coworkers have reported that depletion of cortical catecholamines by either intraventricular or intracortical administration of the neurotoxin, 6-hydroxydopamine (6-OHDA), renders visual cortex largely unresponsive to monocular deprivation. A convenient means to reliably deplete cortical norepinephrine (NE) is the systemic administration of 6-OHDA to neonates. We elected to try this approach in an attempt to test the idea that the normal noradrenergic innervation of cortex is required for developmental plasticity.

13 kittens received intraperitoneal injections of 6-OHDA (200 mg/kg) on postnatal days 1 and 2. Littermates served as vehicle-injected controls. At about one month of age, the kittens were monocularly deprived, and 10 days later, were prepared for extracellular recording from area 17. Following the recording session, visual cortical tissue was rapidly dissected, frozen and prepared for high pressure liquid chromatography (HPLC). The biochemistry confirmed the effectiveness of the drug treatment: injected animals had less than 11% of control NE. However, despite this marked depletion of NE, visual cortex responded normally to monocular lid closure with a fully-shifted ocular dominance histogram.

This result prompted us to try to repeat Kasamatsu and Pettigrew by following their exact 6-OHDA delivery procedure. 10 kittens, normally reared to 6-8 weeks of age, were monocularly deprived and fitted with osmotic minipumps and cannulae leading to visual cortex. 6-OHDA (1mg/ml) was delivered to area 17 of one hemisphere (1 ul/hr), vehicle solution to the other. Blind recordings 7 days later, revealed that the 6-OHDA perfused hemisphere was much less affected by monocular deprivation than the control. Again, biochemistry confirmed NE-depletion in the drugged cortex.

In summary, we observe that the chronic removal of cortical NE leaves visual cortical plasticity intact, while acute NE depletion causes a deficit in plasticity. We conclude: first, that some form of compensation for the lost NE occurs in kittens chronically depleted from birth; second, that a simple correlation of NE levels with plasticity is insufficient to account for all the developmental capabilities of kitten visual cortex.

5.12 THE ONTOGENETIC CHANGES IN METABOLISM OF cAMP IN THE VISUAL CORTEX OF CATS. C. Aoki* & P. Siekevitz. Dept. of Cell Biology, The Rockefeller University, New York, N.Y. 10021.

The evidence from many labs indicate that the neuronal plasticity of the postnatally developing visual cortex is dependent on visual experience.[1,2] Recently, Kasamatsu et.al. have reported evidence indicating that this form of plasticity is influenced by the local concentration of l-norepinephrine (NE) in the visual cortex[3,4,5,6] Further, Cynader's group has reported that the plastic period, which spans the first 3 to 4 months after birth, can be postponed at least a year, so long as the animal is completely deprived of visual experience during that time[7,8] Our goal was to study the molecular mechanism by which NE modulates visual cortical plasticity of this type. We have examined the ontogenetic changes in adenylate cyclase(ACase) specific activity which is stimulated by NE, as well as cAMP- and cGMP-phosphodiesterase(PDE). The ontogenetic changes in the enzymes' specific activities were then compared with those tissues obtained from kittens dark-reared for various lengths of time(donated to us by M Cynader's laboratory), so as to discriminate genetically determined developmental changes from changes dependent on visual experience. cAMP- and cGMP-PDE in area 17 of normally reared cats rise acutely in specific activity postnatally and plateau to adult level around the 2nd month. The levels of these enzymes were not affected by the dark-rearing condition. ACase specific activity of area 17 of normally reared cats is very low soon after birth, increases dramatically between 2nd and 4th week, and plateaus to adult level at the 3rd month. At all ages, a stimulation by NE and GTP was observed, and this stimulation by the hormone was greater during the critical period than at ages before or after the period. We are currently examining the ACase activity in dark-reared kittens.

5.13 RECOVERY OF BINOCULAR CONNECTIONS IN CAT VISUAL CORTEX.

Rafi Malach*, Robert Ebert* and Richard C. Van Sluyters. School of Optometry and Neurobiology Group, University of California, Berkeley, CA 94720.

We have examined recovery from the physiological effects of visual deprivation in kittens subjected to a total of 12 hr of monocular deprivation (MD) distributed over 2 days (three, 2-hr periods each day) at 4 wks of age, and then allowed various periods of binocular vision. Single units were recorded from the striate cortex of these kittens to assess the ocular dominance of cortical neurons at different stages of recovery. Recordings taken from 8 kittens immediately following the period of MD revealed that ocular dominance was shifted heavily in favor of the non-deprived eye and that the proportion of binocular units was reduced to about 25% of the visually responsive cells sampled. After allowing 3 wks of binocular vision, we recorded a second time from 6 of these kittens, and the pattern of ocular dominance had changed substantially. Now, the two eyes dominated roughly equal numbers of cells and the proportion of binocular neurons had increased to about 65%. Four of these kittens were given an additional 4 wks of binocular exposure, and a third recording session revealed an additional small increase in the relative number of binocularly driven neurons.

To examine somewhat further the speed with which the recovery process occurs, we recorded from another group of 6 kittens that were monocularly deprived for 12 hr and then allowed an identical period of binocular exposure. After 12 hr of binocular vision, the deprived eye had re-established functional connections with about half of the cells studied, but the proportion of binocular units was still substantially below that seen after 3 wks of recovery. Our results demonstrate that binocular visual experience can bring about a rapid and essentially complete recovery of functional cortical connections from the deprived eye in kittens subjected to a brief period of MD early in life. Possible mechanisms underlying this recovery process will be discussed.

6.1 DEVELOPMENT OF INNERVATION OF ARTERIES AND ARTERIOLES OF THE RAT MESENTRY. D.F. van Helden*, C.E. Hill* and G.D.S. Hirst* (SPON: B. Walmsley). Department of Pharmacology, John Curtin School of Medical Research, Australian National University, Canberra, ACT, 2601, Australia.

Here we report on the development of innervation of rat mesenteric arteries (diam. 200-300 μm) and arterioles (diam. 80-150 μm). Thirty two rats aged 1-21 days postnatally were used. In vitro intracellular recordings were made from the smooth muscle layer and responses to nerve stimulation examined. Perivascular nerve stimuli (pulse width .01-.1 ms, amplitude 10-100V) were applied using a suction electrode at the proximal end of the mesenteric artery.

Slow depolarizing potentials were often recorded from both arterioles and arteries even from the youngest animals examined. These were occasionally detected following a single stimulus but more often a train of stimuli was required. Excitatory junction potentials (EJPs) which could be summed by a train of stimuli to initiate an action potential, were first recorded in the arterioles of day 9 animals. However, EJPs could not be recorded from the more proximal arteries until at least day 12. EJPs recorded from these immature animals showed large variance in both amplitude and rise time with larger responses having faster rise times. This finding was consistent with the prediction from cable theory for a system with point current sources (synapses) distributed at low density over the cable (arteriole), with each source having a low probability of activation. Fluctuations of EJP amplitude and rise time diminished over the next 4 to 7 days and by about day 18 both arterioles and arteries had relatively uniform EJPs.

Using fluorescence microscopy, nerve fibres were detected running along the arteries and then branching sparsely on the arterioles as early as day 1. The density of this innervation increased with age, dense plexuses developing some 2 to 4 days earlier in the arterioles than in the arteries.

Taken together these data suggest that sympathetic nerves have discrete target zones within an artery/arteriolar tree.

6.2 EFFERENT SPLANCHNIC ACTIVITY IN NEONATAL SWINE. P.M. Gootman, H.L. Cohen, S.M. DiRusso*, A.P. Rudell and L.P. Eberle*. Dept. Physiol., Downstate Med. Ctr., SUNY, Brooklyn, N.Y. 11203.

Studies of postnatal neural control of the circulation (Gootman, et al., In Ciba Symposium #83 "Development of the Autonomic Nervous System", 1981, pp. 70-93, Fed. Proc., 1983, 42) have shown different rates of maturation for cardiovascular reflexes. Because the renal and superior mesenteric vascular beds are quite responsive in the neonate, we decided to examine the spontaneous efferent discharge of the major preganglionic sympathetic supply to these beds, the greater splanchnic nerve (SPL). Animals ranging in age from birth to 2 weeks of age were lightly anesthetized with halothane in O_2, immobilized with decamethonium Br and artificially ventilated to maintain normal arterial blood gases and pH. The SPL was located retroperitoneally and subdiaphragmatically, cut just proximal to the celiac ganglion and, in piglets 1 week or older, desheathed. Monophasic recordings were made with a bandpass of 0.1-1000 Hz and stored on magnetic tape along with simultaneous recordings of blood pressure, EKG and, in selected experiments, efferent phrenic nerve activity (monitor of the central respiratory oscillator). Off-line analyses involved computer averaging, correlation and power spectra techniques. At present, three types of periodicities have been observed: 1) 7-17/sec waves, 2) oscillations in phase with cardiac cycle, and 3) oscillations in phase with the central respiratory cycles (maximum activity during inspiration and minimum activity in early expiration). SPL activity in piglets less than 1 week of age, was found to be particularly sensitive to body temperature. A decrease in body temperature below 37°C, i.e., a change in 1°C, resulted in loss of SPL discharge. The results of these experiments indicate that tonic sympathetic discharge to the celiac ganglion and adrenal medulla is present in piglets at birth with periodicities similar to those seen in adult SPL (Cohen and Gootman, Am. J. Physiol., 1970, 218: 1092; Gootman and Cohen, Am. J. Physiol., 1970, 219: 897, J. Autonomic Nervous System, 1981, 3: 379; Gootman et al., Brain Res., 1975, 87: 395). The presence of SPL activity could account for the marked changes in renal and superior mesenteric blood flows observed during either afferent or central stimulation.
(Supported by USPHS Grant NIH #HL-20854).

6.3 NEURAL CREST-MICROENVIRONMENT INTERACTIONS IN THE FORMATION OF ENTERIC GANGLIA: AN ANALYSIS OF NORMAL AND LETHAL SPOTTED MUTANT MICE. T.P. Rothman, G. Nilaver and M.D. Gershon. Dept. Anatomy and Cell Biology and Dept. Neurology, Columbia Univ. P&S, NY, NY 10032.

The l^s/l^s (lethal spotted) mutant mouse develops megacolon proximal to a 2-3mm terminal segment of aganglionic bowel. The current experiments were done to determine whether this aganglionosis is due to a slowed transit down the gut of ganglion cell precursors from the rhombencephalic neural crest, an abnormal microenvironment in the aganglionic zone that is not conducive to the growth of intrinsic enteric neurons, or to a secondary degeneration of precursors that initially invade the terminal bowel. Segments of control (E9-E20) and l^s/l^s (E10-E20) gut were explanted and grown in organotypic tissue culture for 2 weeks. Neurons that contain acetylcholinesterase (AChE), substance P (SP), vasoactive intestinal polypeptide (VIP) or serotonin (5-HT) immunoreactivity were found in control explants, even from the terminal bowel, as early as days E9-E11. In situ, AChE and 5-HT-containing neurons appear first in the foregut on E12 and reach the terminal colon by day E14. SP- and VIP-containing neurons appear in the foregut in situ on day E14. Explants removed between E9 and E12 thus contain neuronal precursors that can give rise to at least 4 types of enteric neuron in vitro. These precursors, in control mice, reach the hindgut by day E9. Explants from l^s/l^s gut behave as control explants except for tissue removed from the terminal 2-3mm of bowel. Segments from this region at any age remain aneuronal in culture. The length of presumptive aganglionic bowel in fetal l^s/l^s mice is the same from E11 through birth and roughly corresponds to the length of the aganglionic segments of adults. In adults, the aganglionic region receives an innervation by axons containing SP, VIP, and AChE. These are probably extrinsic; however, the entirely intrinsic 5-HT-containing fibers are absent.

These studies indicate that the proximo-distal sequence of enteric neuronal phenotypic expression is not related to the rate of migration of precursors down the gut since the precursors reach the hindgut at the same time as they reach the foregut. No evidence was obtained to indicate that migration is slower than normal in l^s/l^s animals. Removal of presumptive aganglionic bowel to tissue culture fails to rescue enteric neurons. Results are consistent with the hypothesis that the microenvironment of the terminal 2-3mm of l^s/l^s bowel is abnormal and does not support its colonization by precursors of intrinsic enteric neurons or its innervation by intrinsic enteric axons. Supported by grants BNS79-11640, NS15547 and MOD 1-747.

6.4 EMBRYONIC DEVELOPMENT OF THE RAT SUPERIOR CERVICAL GANGLION. Eric Rubin* (SPON: C.J. Forehand), Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

Sympathetic ganglia are simple systems open to a variety of approaches for the study of neural development. I report here physiological and morphological findings which show the rapid development of several aspects of innervation in the rat superior cervical ganglion.

On embryonic day 11 (E11; conception = E0; birth = E22), no distinction can be made between the prospective superior cervical ganglion and its preganglionic nerve based on light microscopy (silver staining) or at the ultrastructural level; instead, a uniform cylinder of intermixed cells and axons extends through the cervical region, dorsal to the carotid artery. By E14, however, the ganglion has coalesced, and the pre- and postganglionic nerves are apparent.

On E15, the ganglion shows the following features. Restriction of preganglionic supply: Horseradish peroxidase (HRP) applied to the preganglionic nerve labels neurons in spinal segments T1-T5 (primarily T1-T3), the same segments as innervate the adult ganglion. Ganglionic synapse formation: Junctions with ultrastructural features typical of mature ganglionic synapses are present. Cholinergic transmission: Preganglionic stimulation evokes a two-component response in postganglionic nerves. The longer latency component of this response fatigues readily and is blocked by curare and by low Ca^{++}/high Mg^{++} Ringer. A similarly labile, but much smaller, response occurs on E14. Dendrites: Ganglion cells backfilled with HRP display several prominent dendrites. Axonal extension: The axons of some ganglion cells are in the vicinity of distant targets, since these neurons are labelled by HRP injected into the eye.

Thus, by E15 the superior cervical ganglion is already well organized. Such prompt maturation emphasizes that certain aspects of this system, such as the formation of specific synaptic connections, may originate during the earliest stages of ganglion development.

6.5 DEVELOPMENT OF INTRINSIC SYNAPSES IN THE RAT SUBMANDIBULAR GANGLION. K. Kawa* and S. D. Roper. Departments of Anatomy and Physiology, University of Colorado Health Sciences Center, Denver, CO 80262.

The submandibular ganglion in the rat is a good preparation for investigating neuron-target interactions. The organization of neurons and their synaptic connections is simple, and there are no interneurons in the ganglion. The target organs, the salivary glands, can readily be manipulated pharmacologically or surgically and the effects of such manipulations tested on the development and maintenance of neurons in the ganglion. Further, the submandibular ganglion is very thin and individual cells and their processes can be seen in the living isolated preparation.

In our ongoing investigations of the development and maintenance of synapses in the submandibular ganglion, we have discovered that there are excitatory synaptic connections between ganglion cells. These intrinsic ganglionic synapses occur both in newborn and adult animals.

To test for the presence of intrinsic synapses in the submandibular ganglion, rats were anesthetized, the chorda tympani nerve (which carries the preganglionic nerve supply) was severed at the middle ear, and the animals were allowed to recover for 3 days so that all extrinsic innervation to the ganglion degenerated. Submandibular ganglia were then removed and pinned out in a recording chamber, neurons impaled with glass micropipettes, and postganglionic axons stimulated with a suction electrode. Intrinsic synapses were readily distinguishable from antidromically-propagated action potentials. For example, intrinsic synaptic responses fluctuated in quantal steps when stimulated at frequencies above 1 Hz.

There was a regional distribution of intrinsic synapses in the adult rat. Neurons which innervated the submaxillary salivary gland tended to lie along the salivary ducts in large clusters and the incidence of intrinsic synapses was high in these clusters. Ganglion cells which innervated the sublingual salivary gland lay individually or in small clusters on the thin sheet of connective tissue which spans the gap between the preganglionic nerve supply and the salivary ducts. The incidence of intrinsic connectivity in these latter neurons was low.

We are currently investigating (a) whether the incidence of intrinsic synapses is determined more by the location of the ganglion cell or by the location of its target, and (b) how the incidence of intrinsic synapses changes as the rat matures from newborn to adult. These investigations were supported in part by NIH grant NS11505.

6.6 DEVELOPMENTAL CHANGES IN THE NEUROTRANSMITTER PROPERTIES OF CHOLINERGIC SYMPATHETIC NEURONS IN VIVO. R. E. Siegel*, M. Schwab* and S. Landis. Dept. of Neurobiology, Harvard Med. Sch., Boston, Mass. 02115 and Max Planck Institute for Psychiatry, Munich, Ger.

Neurons dissociated from sympathetic ganglia of newborn rats can be induced to undergo a transition from adrenergic to cholinergic function when grown in certain culture conditions. Examination of a cholinergic sympathetic system in vivo, the neurons innervating sweat glands (SGs) in rat footpads, has suggested that a similar transition in neurotransmitter expression takes place during normal development. While such markers of adrenergic function as catecholamine fluorescence and small granular vesicles are found in all fibers innervating SGs of 7 day postnatal rats, these markers are no longer detectable by 21 days.

We have used immunocytochemical techniques to obtain further evidence for transmitter plasticity in neurons innervating SGs. The properties of both the SG fibers and their cell bodies of origin have been characterized. At 7 days, nerve fibers possessing tyrosine hydroxylase (TH) and dopamine-B-hydroxylase (DBH) immunoreactivity are present around all SGs. Between 10 and 21 days, the intensity of the fiber staining decreases considerably but does not entirely disappear. In contrast, vasoactive intestinal peptide (VIP), a neuropeptide which has been localized in cholinergic but not adrenergic sympathetic neurons in the cat (Lundberg et al., 1982, PNAS 79:1303), and acetylcholinesterase (AChE) increase over the same time course. Histochemical staining for AChE appears around a few SGs at 7 days and VIP-like immunoreactivity is first detected 1 or 2 days later. By 21 days the plexus of SG fibers stains intensely for both markers.

The cell bodies of origin for the SG fibers of the front feet are thought to lie in the stellate ganglion. In the mature stellate, approximately 3% of the cells possess VIP-like immunoreactivity. If fluorescein-conjugated wheat germ agglutinin is injected into the front foot pads, a small proportion of these VIP immunoreactive cells are also retrogradely labeled. The target tissues of the remaining VIP positive cells are unknown. A majority of the VIP immunoreactive cells do not possess TH immunoreactivity, a finding consistent with the coexistence of acetylcholine and VIP in certain sympathetic neurons. However, almost all of the VIP positive cells do contain DBH immunoreactivity. These properties of the cell bodies, in conjunction with the changes observed in SG fibers during development, indicate that adrenergic neurons in vivo can become cholinergic while still retaining some adrenergic characteristics. Further studies are being performed to examine how the properties of individual neurons projecting to the SGs change during development. Supported by NINCDS and the American Heart Association.

6.7 EXPRESSION AND DEVELOPMENT OF THE ADRENERGIC PHENOTYPE IN RAT MEDULLA OBLONGATA. M.C. Bohn, M. Goldstein and I.B. Black. Division of Developmental Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021 and Dept. of Psychiatry, New York Univ. Medical Center, New York, N.Y. 10016.

We have previously reported that the epinephrine-forming enzyme, PNMT (phenylethanolamine-N-methyltransferase), a specific index of the adrenergic phenotype, initially appears in rat adrenal medulla and sympathetic ganglia on E17 (embryonic day 17). Moreover, the subsequent development of PNMT in these neural crest derivatives is regulated by glucocorticoids. We have now investigated the initial expression and development of PNMT in the medulla oblongata to determine whether adrenergic expression in brain and periphery are similarly regulated.

PNMT-containing cells were initially observed in the medulla by immunofluorescence at E14. By E15, the number of PNMT cells and the intensity of immunofluorescence had increased dramatically. Isolated cells with long beaded processes were located within the subventricular zone while clusters were observed ventrolaterally in the presumptive C1 region. Other cells appeared to be migrating from the ventricular zone to the C1 region, along a path rich in PNMT containing fibers. In the term embryo, PNMT cells were grouped in presumptive C1, C2 and C3 regions, as described in the adult rat (Howe et al, Neurosc. 5, 2229, 1980), although there still appeared to be PNMT cells in the process of migration.

PNMT catalytic activity was also assayed in the medulla to assess adrenergic development. PNMT activity was initially detectable on E14, and increased over 30-fold, reaching adult plateau values at 20 days. To evaluate the possible role of glucocorticoids in brain PNMT ontogeny, bilateral adrenalectomy was performed on the first day of life. Adrenalectomy did not alter the development of medullary PNMT. Moreover, treatment of pregnant rats with dexamethasone (1mg/Kg q.d.), from E14 to term did not alter enzyme activity in newborns. Finally, adrenalectomy in the adult did not alter medullary activity during the postoperative month.

Our observations suggest that there are marked differences between brain and periphery in expression and development of the adrenergic phenotype. PNMT is expressed in embryonic brain 3 days earlier than in the periphery, suggesting that adrenergic expression is not simultaneously triggered by a common signal in all regions of the embryo. Further, the ontogeny of PNMT in brain does not appear to be glucocorticoid dependent, whereas sympathoadrenal PNMT is critically dependent on the hormones. (Supported by NIH grants NS 00713, NS 18420, NINDS 06801, NS 10259, HD 12108 and by the Familial Dysautonomia Foundation).

6.8 THE EFFECT OF COPPER SUPPLEMENTATION ON THE CONCENTRATION OF COPPER AND THE ACTIVITY OF DOPAMINE-beta-HYDROXYLASE IN THE BRAIN OF THE BRINDLED MOUSE. G. L. Wenk and K. Suzuki. Department of Pathology/Neuropathology, Albert Einstein College of Medicine, The Bronx, NY 10461.

The brindled mutant mouse is a useful model to study Menkes Kinky Hair Syndrome. The metabolic dysfunctions in both humans and rodents are related to insufficient levels of bioavailable copper (Cu). The abnormal Cu distribution is thought to be due to the presence of significantly increased amounts of cysteine-rich 10,000 dalton Cu-binding protein (Labadie et al., Pediatr. Res. 15:257,1981). Recently Cu supplementation therapy has been able to both prevent the appearance of various neuropathological changes and prolong the life of these mutant mice (Nagara et al., J. Neuropath. Exp. Neurol., 40:428,1981). The optimum conditions for supplementation have been shown to be two intraperitoneal injections on post-natal days 7 and 10. This presentation reports on the brain Cu concentrations prior to, during, and after the same day 7 and 10 Cu therapy. The mice were sacrificed on various days and the brains were wet digested in nitric acid and the Cu concentrations were determined by atomic absorption spectrometry using a graphite furnace. The results show that post-natal days 7 and 10 correspond to two important epochs in Cu homeostasis. The supplementation therapy seems to provide sufficient bioavailable Cu to respond to the needs of the mice at these crucial times.

We also investigated the effect of the day 7 and 10 Cu therapy on the activity of the Cu-dependent enzyme dopamine-beta-hydroxylase (DBH). The DBH was assayed according to a method by Borchardt et al., (Anal. Chem., 51:1960,1979). The results follow the changes in DBH activity which occur when these mice are Cu-deprived, and then are given additional Cu. An improvement in DBH activity may be due to the increased availability of Cu to be used in the enzyme complex, or to the ability of Cu to inhibit various endogenous DBH inhibitors known to be present in the brain.

We have compared the in vitro activity with and without Cu added to the media, and the in vivo activity, by measuring endogenous norepinephrine and dopamine levels in separate aliquots of tissue homogenate.

6.9 EXPRESSION OF CATECHOLAMINERGIC CHARACERISTICS BY PERIPHERAL SENSORY GANGLION CELLS IN THE NORMAL ADULT RAT IN VIVO. D.M. Katz, K.A. Markey, M. Goldstein and I.B. Black. Div. of Developmental Neurology, Cornell Univ. Med. College, 515 E. 71st St., New York, New York 10021 & Dept. of Psychiatry, New York University Medical Center, New York, N.Y. 10016.

Recent work demonstrating the extreme lability of neurotransmitter phenotype in sympathetic neurons calls into question the identification of functional classes of neurons on the basis of individual phenotypic characteristics. In order to further examine relationships among neuronal phenotypic traits, we are studying the in vivo expression of catecholaminergic characteristics by sensory ganglion cells in the normal adult rat. Using a highly specific and well-characterized antibody against tyrosine hydroxylase (TOH) we have identified neurons in the nodose and petrosal ganglia that exhibit abundant TOH immunoreactivity. In addition, some ganglion cells exhibit faint formaldehyde-induced fluorescence, and this fluorescence is enhanced by pretreatment of animals with pargyline (50 mg/Kg, i.p.). Pargyline inhibits the enzyme, monoamine oxidase, that is responsible for the intraneuronal metabolism of catecholamines. The TOH-containing cells possess morphologic characteristics typical of primary sensory neurons, including an initial axon glomerulus and a single bifurcating neurite. These cells are readily distinguishable from TOH-containing SIF cells by their size, morphology, and staining characteristics. Furthermore, the TOH-containing neurons appear to be insensitive to neonatal treatment with 6-Hydroxydopamine, thereby distinguishing them from sympathetic neurons. Using a sensitive radiochemical assay we are able to measure TOH catalytic activity within the nodose and petrosal ganglia. Peripheral axotomy reduces specific TOH activity within the ganglia and depletes neuronal TOH immunoreactivity.

Our data indicate that some adult sensory ganglion cells normally express catecholaminergic phenotypic characteristics in vivo. Classically, the catecholaminergic phenotype has been associated, in the peripheral nervous system, with sympathetic neurons. The existence of sensory ganglion cells that exhibit catecholaminergic neurotransmitter traits and morphologic characteristics typical of sensory neurons suggests that the ability to express the catecholaminergic phenotype is not restricted to any particular functional class of peripheral neurons. (Supported by NIH post-doctoral fellowship NS06623-01 to D.M.K., and NIH Grants NS10259 and HD12108.)

7.1 DIFFERENT POPULATIONS OF GRANULE CELLS INNERVATE SUPERFICIAL AND DEEP SUBLAMINAE OF THE EXTERNAL PLEXIFORM LAYER OF THE RAT OLFACTORY BULB. Edward Orona and John W. Scott, Department of Anatomy, Emory University, Atlanta, Georgia 30322.

The basal dendrites of tufted cells of the main olfactory bulb ramify in the superficial half of the external plexiform layer (EPL), while those of most mitral cells are confined to the deep half of the EPL. The response properties of mitral and tufted cells are modulated by bulbar interneurons, including the granule cells. We report here that there may be different populations of granule cells with separate but overlapping projections.

Small, extracellular injections of horseradish peroxidase (HRP) were made iontophoretically (4% HRP) into the superficial and deep parts of the EPL and of the granule cell layer (GCL) in rats. Superficial EPL injections labeled principally superficial granule cell somata, whereas deep EPL injections additionally labeled deep granule cell somata. Injections deep in the GCL labeled granule cell dendritic processes extending only into the deep half of the EPL. In contrast, following superficial GCL injections, granule cell dendrites were observed extending across the entire EPL. These results were the same in material processed with the Hanker-Yates procedure where we could follow individual dendrites and in the more sensitive tetramethyl benzidine procedure.

It appears that tufted cells are innervated only by superficial granule cells. We cannot tell from this material whether the mitral cell dendrites of the deep EPL are contacted exclusively by deep granule cells or by the total population of granule cells. Since tufted cells differ from mitral cells in their responses to stimulation of the olfactory nerve (e.g. Schneider and Scott, Neurosci. Abstracts #217.5, 1981), these properties may be partly determined by the differences in granule cell innervation. Furthermore, centrifugal afferents terminate in distinct sublaminae of the GCL and could differentially affect these populations of granule cells (Davis et al. JCN, 204:475, 1981). Other recent reports also suggest that the granule cell layer has a laminar distribution of cell types (Davis et al. JCN, 204:377, 1982; Struble and Walters, Brain Res., 236:237, 1982). Our data are consistent with the hypothesis that mitral and tufted cells function differently in processing olfactory information and that their responses may be modulated by different populations of granule cells.

Supported by NSF grant BNS 81-02175.

7.2 ULTRASTRUCTURAL ORGANIZATION OF THE OLFACTORY BULB FOLLOWING LOSS OF MITRAL CELLS IN THE MUTANT MOUSE PCD. Charles A. Greer, Norbert Halasz* and Gordon M. Shepherd, Section of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

It has been found that a neurological mutant mouse, Purkinje Cell Degeneration (PCD), loses greater than 80% of its olfactory bulb (OB) mitral cells by 4 mon. postnatal and 96% by 8 mon. (Greer & Shepherd, Brain Res., 235: 145, 1982). This extraordinarily large and selective loss of a single cell type does not appear to affect the afferent input to the OB, as judged by mapping odor-induced activity with the 2-deoxyglucose method. Normally, the mitral cells, together with the tufted cells, are the main output neurons of the OB. Both cells are also intrinsic components of local circuits within the OB by means of dendrodendritic synaptic interactions with interneurons. We have therefore examined the ultrastructure of the PCD OB to assess the effect of mitral cell loss upon local circuit organization.

Affected, homozygous recessive, PCD mice and their normal, pcd/++, littermates were studied. The mice received an intracardiac perfusion of phosphate buffered 1% paraformaldehyde and 2.5% glutaraldehyde and their olfactory bulbs were processed for electronmicroscopy. The tissue was examined in both randomly chosen areas of approximately 130 um^2 and in montages of approximately 4000 um^2.

Examination of the electronmicrographs revealed in the homozygous recessive PCD mice a decrease in the frequency of large electron luscent dendritic profiles, characteristic of mitral cell dendrites, within the external plexiform layer. Smaller pale profiles, attributed to tufted cell dendrites were easily recognized as were the electron dense dendritic spines of granule cells. In addition, within the external plexiform layer, polarized synaptic contacts including Gray Type I (tufted to granule) and Gray Type II (granule to tufted) were observed both singly and in reciprocal dendrodendritic pairs.

Thus far the data suggest that the synaptic organization of tufted and granule cells is maintained following the loss of mitral cells although further quantitative analyses may reveal changes in the ratios of synaptic types. In addition to the difference between mitral and tufted cells in their control by the genome as suggested by these data, recent reports have indicated that the central projections of these two neurons differ (Scott et al., JCN, 194: 519, 1980). Therefore, PCD may also prove useful for studying aspects of plasticity and synaptic reorganization in the basal forebrain in parallel with those of the local circuits in the OB.

Supported by NS-07609, NS-10174 and NS-06159.

7.3 ANATOMICAL EVIDENCE FOR A CONVERGENCE OF OLFACTORY AND GUSTATORY-VISCERAL AFFERENT PATHWAYS IN MOUSE CEREBRAL CORTEX. Y. Geinisman, M.T. Shipley, and J.F. Disterhoft. Dept. Cell Biol. & Anat., Northwestern Univ. Med. Sch., Chicago, IL 60611

The perception of flavor depends on both olfactory and gustatory, and possibly visceral afferent (VA) sensations. The functional association among these distinct modalities must be mediated in the brain since the first order pathways for olfaction and gustatory-VA are widely separated. However, olfactory and gustatory-VA circuits have no known sites of convergence in the CNS. We report anatomical data which suggest that these modalities converge in the mouse cerebral cortex after traversing surprisingly few synaptic relays.

We have examined the connections of the mouse main olfactory bulb (MOB) using ortho- and retrograde transport of wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP). We confirmed (Neurosci. Abst., 1981, 7:731) afferent and efferent connections characteristic of the rodent MOB. In addition, we found strong orthograde labeling in the insular cortex (IC), dorsally adjacent to the piriform cortex (PC). To determine whether this labeling pattern represented a terminal projection, electron micrographs of PC were compared with ones of IC 3 days after a complete MOB transection. Degenerating presynaptic terminals in IC were indistinguishable from those in PC, in morphology and location.

The inputs and outputs of this MOB-recipient insular field were studied with small (8-10 nl) WGA-HRP injections. The results demonstrate that this IC sector has strong connections with every subcortical structure associated with the ascending gustatory-VA pathways. Massive inputs to IC were found from the gustatory-VA part of the ventrobasal thalamus (VB) and there were direct inputs from the second order gustatory relay, nucleus parabrachialis (NPB). Outputs of IC were traced to VB, NPB, the central nucleus of the amygdala and (heavily) to the first order gustatory-VA relay, the nucleus of the solitary tract. In addition there were reciprocal connections with the olfactory part of the medial dorsal thalamic nucleus.

These data suggest that the MOB has a direct terminal projection to the primary sensory cortex for the gustatory and VA systems. Thus, olfactory and gustatory-VA pathways appear to converge at a surprisingly early stage of synaptic processing. This inter-modal convergence area in IC may play a key integrative role in flavor perception, visceral feedback and learned tastes. The neurophysiology of this cortical area is currently under investigation.

7.4 DEVELOPMENT OF A FUNCTIONALLY AND MORPHOLOGICALLY SPECIALIZED REGION OF THE RAT OLFACTORY BULB: THE MODIFIED GLOMERULAR COMPLEX. William B. Stewart, Charles A. Greer, Patricia E. Pedersen and Gordon M. Shepherd. Sections of Neurosurgery, Neuroanatomy and Anatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

A modified glomerular complex (MGC), situated at the dorsomedial junction of the main and accessory olfactory bulbs, exhibits increased functional activity during odor-dependent suckling in 10 day old rat pups. On morphological and functional grounds, this complex appears to be a specialized region of the olfactory system in rats of this age. Therefore, we have examined the structural development and functional status of this region during the neonatal period.

Rat pups 0,3,6,9,12 and 15 days old injected I.P. with ^{14}C-2-deoxyglucose (2DG) (200uCi/kg) and placed with their anesthetized dam where they suckled for one hour. The pups were sacrificed at the end of this period and their brains processed for autoradiography. At all ages foci of increased 2DG uptake were centered over the MGC. Prior to day 6 focal 2DG uptake was present only in the MGC, although diffuse regions of uptake were found elsewhere in the glomerular sheet of the main olfactory bulb. Histological examination of the olfactory bulbs of Bouin's fixed littermates demonstrated that the MGC was morphologically distinct from birth, unlike glomeruli of the main and accessory olfactory bulbs. These findings suggest that the MGC matures more rapidly than other regions of the olfactory bulb.

To examine the afferents to the MGC, the nares of older rats were injected with a solution of 20% horseradish peroxidase. Following a 48 hour survival, the rats were sacrificed and their olfactory bulbs removed and processed using the tetramethylbenzidine method. Dense reaction product was evident throughout the entire glomerular sheet of the main olfactory bulb and in the MGC. Only a few glomeruli in the accessory bulb were labelled. These findings strongly suggest that the MGC receives input from the main olfactory receptor sheet.

Further support for this finding has come from 2DG experiments in which partial ablation of the olfactory epithelium was performed using the $ZnSO_4$ method. Those rats exhibiting foci of 2DG uptake in the MGC, but not in the main glomerular sheet, had a small region of intact olfactory epithelium in the dorsal recess of the nasal cavity.

The results demonstrate that the MGC: 1) is present in rat pups of all ages from birth; 2) is functionally active at birth; and 3) receives some portion of its input from the main olfactory receptor sheet.

7.5 IN UTERO LOCALIZATION OF 2-DEOXYGLUCOSE IN RAT MAIN AND ACCESSORY OLFACTORY BULBS. P.E. Pedersen, W.B. Stewart, C.A. Greer, and G.M. Shepherd. Secs. of Neuroanatomy, Neurosurgery, and Gross Anatomy, Yale University School of Medicine, New Haven, CT 06510.

The vomeronasal system and the main olfactory system process odors concerned with sexual/social behaviors in adult rodent species. While the main olfactory system has been clearly demonstrated to be important throughout development, little is known about the functional importance of the vomeronasal system in neonates. This is despite the morphological maturity of receptors at birth and the early embryonic development of the accessory olfactory bulb, the first relay of the vomeronasal system. Further, postnatal behavior of rat pups is influenced by their prenatal experience with amniotic fluid, which suggests that one or both of these chemosensory systems may be functional in utero. In light of these considerations, we used the ^{14}C-2-deoxyglucose (2DG) method to assess functional activity in main and accessory olfactory bulbs of near term fetal rats.

Sprague-Dawley pregnant rats were injected with 200 µCi/kg 14C2DG I.V. on Day 22 of gestation. One hour later, the dam was killed by decapitation. Each fetus was immediately delivered by Caesarean section, its brain was removed and was prepared for autoradiographic analysis.

Enhanced 2DG uptake appeared in the accessory bulb of 18 of 20 experimental animals from 4 different litters. Correlations of autoradiographs with histological sections indicated that maximal 2DG uptake occurred throughout the entire glomerular sheet of the accessory bulb. Foci of 2DG uptake were evident in the main bulb of only 4 animals. These were localized in the dorsocaudal portion of the main bulb. This region usually shows 2DG uptake under odor stimulus conditions in very young postnatal rat pups. 2DG uptake also appeared to be prominent in the anterior olfactory nucleus; further analysis will indicate whether other central structures are involved.

These findings demonstrate that the 2DG technique can be used to investigate cerebral glucose metabolism in utero. Moreover, the high 2DG uptake in the accessory bulb suggests fetuses may use the vomeronasal system to sample and to learn about their chemical milieu prenatally.

7.6 FLUORESCENT STUDIES OF THE PRIMARY OLFACTORY PATHWAY IN AMPHIBIA. Thomas V. Getchell. Department of Anatomy, Wayne State University School of Medicine, Detroit, MI 48201.

The cellular uptake and distribution of the fluorescent dye, Procion M-4RAN, has been studied in the olfactory mucosa of frogs and salamanders. The general techniques were modified from studies on fish olfactory epithelium (Holl, Stain Technology, 56:67, 1981) and monkey retina (Monasterio et al., Science, 213: 1278, 1981). The dye, 6% Procion/0.01M KCl, was delivered in three ways: a. intranasal irrigation, 0.5cc; b. submeningeal injection, 0.1cc and c. intravascular injection, 0.1cc. Following incubation for 40 min at 21°C and 1 hr at 4°C, the animals were perfused transcardially with fixative. The olfactory nasal sacs, nerves and bulbs were removed en bloc and prepared for fluorescent microscopy. As a result of intranasal irrigation, the dye was preferentially taken up by olfactory receptor neurons and to a much lesser extent by sustentacular cells, the cells of the ducts of Bowman's gland and cellular elements in the lamina propria. Typically, the entire receptor neuron was stained. The distribution of Procion-labeled neurons was not uniform throughout the sensory epithelium. But rather, assuming equal access of the dye to all "mature" receptor neurons, the dye was taken up by single neurons or small clusters of neurons. The reason for the apparent selectivity is not known, but may be related to the age of the receptor neuron, its metabolic state or functional activity at the time of exposure (Michael & Getchell, AChemS IV). As a result of submeningeal injection, small fascicles of fibers in the olfactory nerve layer of the olfactory bulb were preferentially labeled as well as large neurons deeper in the olfactory bulb. Retrograde labeling of receptor neurons in the olfactory epithelium was not seen. As a result of intracardial injection, the infranuclear region of sustentacular cells in the olfactory epithelium was labeled. Other studies (Rafols & Getchell) have shown that the basal expansion of this cell may terminate in close apposition to the capillary vasculature in the lamina propria. These initial results suggest that the use of Procion and other fluorescent dyes may be useful in labeling specific cells in the olfactory epithelium and in studying the cellular uptake and transport of molecules by the sustentacular cells from the blood vascular system.

7.7 ULTRASTRUCTURE OF SYNAPSES AND CILIA IN MOUSE VALLATE AND FOLIATE TASTE BUDS. J.C. Kinnamon, B. Taylor* and S. Roper. Anatomy Dept., Univ. of Colorado Med. Sch., Denver, CO 80262.

Using transmission electron microscopy (TEM) and high voltage electron microscopy (HVEM) of serial thin (<0.1 µm) and thick (0.5-1.0 µm) sections, we have characterized cell types and synapses found in mouse taste buds (TBs). With TEM and HVEM we have observed examples of Type I (dark), Type II (light), Type III and Type IV (basal) cells.

Cilia were found associated with Type I cells. These cilia contain microtubules which extend from an axial centriole. To date, however, we have not observed oblique centrioles, which are usually associated with cilia. The cilia do not appear to have a preferred orientation, and none have yet been found to extend into the taste pore. Hence we doubt that they play a primary role in gustation.

Synaptic contacts were found throughout vallate and foliate taste buds. In all instances observed to date the taste cell has been presynaptic and a neuronal process postsynaptic. We have tentatively classified these synapses based on their ultrastructural features and the density and quantity of synaptic vesicles. The type of synapse found with the highest incidence is characterized by a thickened presynaptic membrane containing periodic dense projections to which vesicles are closely apposed. A cleft of 16-30 nm separates the presynaptic region from the postsynaptic membrane. The postsynaptic densities are generally not as thick as the presynaptic thickenings. Vesicles in the presynaptic region are usually clear, but dense-cored vesicles may be present. These active zones are often characterized by gaps or breaks. Based on numerous observations of this phenomenon we speculate that these profiles may represent sections through an active zone, the shape of which is an annulus. We plan to analyze serial thin and thick sections to determine their exact shape. The second type of synapse has been observed much less frequently. It is characterized by a semicircular profile in which vesicles are clustered at the convex presynaptic density in higher numbers than are found in the first type of synapse. The presynaptic density is more uniform in the second type, but the periodic dense projections are less regular than those in the first type of synapse. In one instance we observed both types of synapses formed by a single taste cell onto what appeared to be separate neuronal processes.

The biological significance of our observation of two types of synapses is unknown, but we speculate that the differing synaptic structures may be indicative of functional differences. Future electrophysiological studies will be necessary to verify or disprove this hypothesis. This study was supported in part by NIH grant NS11505.

7.8 CAPSAICIN DESENSITIZATION OF TRIGEMINAL RECEPTORS TO ODORANTS. Wayne L. Silver[1,2] and Joel A. Maruniak[2]*. [1]Monell Chemical Senses Center; [2]Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Trigeminal receptors in the nasal cavity have long been known to respond to chemical stimuli. These free nerve endings make up part of the common chemical sense whose primary function is to elicit protective reflexes when stimulated with irritating compounds. However, the common chemical sense has also been shown to interact with olfaction to produce an overall odor sensation (Cain, 1974). An important question is whether these two functions are independent of each other, i.e., can stimuli which do not elicit painful or irritating sensations stimulate trigeminal receptors.

Repeated injections of capsaicin in rats desensitizes pain receptors to chemical stimuli (Jancso, 1960). We used this densensitization procedure and then recorded multiunit integrated responses from the ethmoid nerve to odor stimuli delivered via an air dilution olfactometer. No responses were obtained from capsaicin treated rats to amyl acetate or cyclohexanone, although tactile responses to touching the nose were just as vigorous as in controls. Propionic acid elicited responses at very high concentrations, > 987 ppm, in 3 of 6 experimental rats although the responses adapted more rapidly than in controls. The responses of the control rats produced by the three test stimuli were similar to those previously reported (Silver and Moulton, 1982). These results suggest that odorants which elicit responses from the common chemical sense do so by stimulating pain receptors and that chemical stimulation of nasal trigeminal receptors should produce painful or irritating sensations.

7.9 PARABRACHIAL GUSTATORY NEURONS ARE SENSITIVE TO STIMULUS TOXICITY. T.P.Collins*and T.R.Scott. Dep't. Psychology and Institute for Neuroscience, Univ. of Delaware, Newark, DE 19711.

Acceptance-rejection reflexes for gustatory stimuli are complete at or below the midbrain level in both rats and humans. Rejection is directly related to stimulus toxicity. This implies that there is a measure of stimulus toxicity in the brainstem afferent code for taste quality. We stimulated the tongue with an array of 16 chemicals having oral LD_{50}'s of 5 to 29,700 mg/kg in the rat, and recorded the responses of 41 single taste neurons in the parabrachial area (PBA) of the pons. We analyzed basic response characteristics (latencies, spike rates, time courses) for a 5-sec poststimulus period and determined the pattern of activity evoked by each stimulus across the neuronal sample. We calculated a correlation matrix showing the similarity between response patterns elicited by each possible stimulus pair. From these similarity coefficients we generated a 3-dimensional space, the axes of which should represent those stimulus characteristics to which the neurons were differentially sensitive. While two of the axes could not be identified with any obvious stimulus characteristics, the third correlated +0.71 ($p<.01$; N=16) with LD_{50}'s. This result demonstrates that stimulus toxicity, which activates rejection reflexes and which leads directly to the hedonic evaluation of a tastant, is a major determinant of a PBA neuron's response. At the least, this means that these neurons can activate acceptance-rejection reflexes and can transmit a toxicity measure to hypothalamus and amygdala, areas classically associated with hedonics and anatomically connected to PBA. It does not exclude the possibility that the hedonic appreciation of a chemical is determined by the activity of these brainstem cells, without the involvement of higher-order neurons.

Supported by NIH grant NS 10405 and a grant from the University of Delaware Research Foundation.

7.10 EFFECT OF CONCENTRATION ON THE TOPOGRAPHIC CODING OF ODORANT QUALITY. Alan Mackay-Sim and Paul Shaman*. Department of Psychology, Univ. of Wyoming, Laramie, WY 82071, and Department of Statistics, Univ. of Pennsylvania, Philadelphia, PA 19104.

When electro-olfactograms (EOGs) are recorded from many sites distributed over the surface of the olfactory epithelium of the salamander, the relative amplitudes of these EOGs can be used to draw a "topographic map" of responses across the epithelial surface. For a particular odorant such a response map shows a peak of highest responsivity, with EOG amplitudes decreasing in all directions away from this peak. Recently it was shown that odorants may elicit unique patterns of responses which may differ both in the location of the peak response and in the slope of the decrement in responses around the peak (Mackay-Sim, Shaman and Moulton, 1982). We proposed that the differing response maps were generated by the distribution of receptor cells with differing response spectra: cells with similar responses are located in similar regions of the epithelium. We concluded that the olfactory epithelium probably conveys a spatial code of odorant quality. If this is so, then not only must different odorants elicit different response patterns, but these patterns should not vary with the concentration of a given odorant. The aim of the present study was to test this proposal. At each of 12 sites on the ventral epithelium of the salamander we recorded at least 3 EOGs to each of 3 concentrations of an odorant. In this way maps of responses were generated for 3 odorants (pinene, amyl acetate, propanol) at 3 concentrations. Each odorant was tested in 4 animals. The odorants, delivered in 1S pulses from an air-dilution olfactometer, were presented through 3 stimulators, one for each concentration, attached to the electrode holder. This arrangement eliminates physical variables in odorant flow which can independently vary the EOG. The results show that the epithelial location of peak responsivity does not vary with concentration. For each odorant, an increase in concentration led to increases in EOG amplitudes over the whole epithelium. This resulted in a decrease in the rate of EOG decrement away from the peak of highest responsivity. We conclude that receptor cells of different response spectra are not mixed randomly throughout the olfactory epithelium. Cells of similar responsivity tend to be grouped together. Consequently, the location of greatest receptor responsivity could be a major factor in coding olfactory quality since different odorants elicit maximal responses from different epithelial locations which do not change with odorant concentration.

7.11 TASTE PREFERENCES AND NEURAL TASTE SENSITIVITY IN RABBIT. Robert J. Contreras, Edythe Bird*& Donald J. Weisz. Yale Univ., Dept. of Psychol., New Haven, CT 06520.

With few exceptions the rabbit is not ordinarily the preparation of choice for studies in taste. For example, we have found only two studies that have examined taste preferences (Carpenter, 1956; Ganchrow, 1979) and two older studies that have examined peripheral taste sensitivity in rabbit (Pfaffman, 1955; Beidler, Fishman & Hardiman, 1955). To provide more information on a potentially valuable animal preparation, we have further investigated the taste preferences (and aversions) and neural taste sensitivity of rabbit.

Five adult male rabbits were given a two-bottle preference test between water and various molar concentrations of sodium chloride (.003,.01,.03,.1,.3,.4,.5), potassium chloride (.01,.03, .1,.3), quinine hydrochloride (.00001,.0001,.001), hydrochloric acid (.0001,.001,.01), sucrose (.003,.01,.03,.1,.2,.3), and sodium saccharin (.003,.01,.03,.1). These rabbits showed normal increasing preferences for increasing concentrations of sucrose and increasing aversions to increasing concentrations of quinine hydrochloride and of hydrochloric acid as expected from similar data in rat and hamster. The rabbits exhibited, however, a weak preference for sodium chloride, being maximal at .03M with preference decreasing with both weaker and stronger concentrations. Sodium saccharin was rejected at all concentrations. The stimuli can be rank ordered in terms of decreasing preference as sucrose > potassium chloride > sodium chloride > hydrochloric acid > sodium saccharin > quinine hydrochloride.

In addition, we assessed neural taste sensitivity by recording the whole nerve response of the chorda tympani in several rabbits using the same stimuli of the preference study but with the addition of .1M and .3M lithium chloride. Notable in this data was the two-component response to sodium chloride which consisted of an immediate excitatory response followed by a tonic inhibitory response for the weaker concentrations (.003-.1M). In addition, low concentrations of sodium saccharin (.02,.1M) also elicited a tonic inhibitory response. Finally, potassium chloride elicited a stronger transient excitatory response than did sodium chloride from .03 to .3M concentrations.

7.12 EFFECT OF THE DIURETIC AMILORIDE ON THE SENSE OF TASTE. S. S. Schiffman and Elaine M. Lockhead*. Dept. of Psychiatry, Duke Medical Center, Durham, NC 27710.

The diuretic amiloride has recently been found to reduce the flux substantially across dog lingual epithelium (DeSimone et al., Science, 1981, 214, 1039). In order to determine whether specific ion channels are involved in taste reception, the effect of amiloride on taste intensity was examined for 6 stimuli: NaCl, KCl, sucrose, Na_2SO_4, $CaCl_2$, and K_2SO_4. Two pieces of filter paper cut in the shape of half-tongues were placed on the dorsal tongue surface for a total of 5 minutes. One filter paper was impregnated with 5×10^{-4} M amiloride. The other was soaked in deionized water. Circles of filter paper with a diameter of 1/2 inch impregnated with the stimuli were placed at symmetrical areas on the two sides of the tongue. The side of the tongue adapted to amiloride was presented with one stimulus of constant molarity, i.e. .2M NaCl, .3M KCl, .8M sucrose, .3M Na_2SO_4, .25M $CaCl_2$, and .45M K_2SO_4. The concentrations required to match the concentrations on the amiloride-side were determined. The results indicate that amiloride reduces the perceived intensity of NaCl, Na_2SO_4, and sucrose but has no effect on KCl, K_2SO_4, and $CaCl_2$.

8.1 SEQUESTERING OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN CHROMAFFIN GRANULES: A POSSIBLE HIGH MOLECULAR WEIGHT PRECURSOR Illana Gozes, Daniel T. O'Connor* and Floyd E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, and the San Diego Veterans Administration Medical Center, La Jolla, California.

Vasoactive intestinal polypeptide (VIP) has a wide variety of biological activities including vasodilation, regulation of energy metabolism and possible neurotransmitter function. The multiple actions of VIP are correlated with a widespread distribution in both endocrine and nerve cells. In search for mechanisms of regulation of VIP activity we investigated the modes of storage of the peptide in pheochromocytoma, a tumor known to contain copious amounts of the peptide.

Chromaffin granules, the norepinephrine storage granules of pheochromocytoma, were isolated from 5 human pheochromocytoma tumors. VIP immunoreactivity was detected in all of the granule preparations paralleling the synthetic VIP antibody binding curve over a range of serial dilutions. In addition, column chromatography revealed an immunoreactive peptide peak comigrating with VIP. However, a high molecular weight immunorective material was also detected on the column. This high molecular weight material was further characterized by $NaDodSO_4$ gel electrophoresis followed by electroblotting onto nitrocellulose paper and detection by anti-VIP antibodies and secondary antibody conjugated to horse radish peroxidase. A 70,000 M_r immunoreactive band was identified, in which reactivity with anti-VIP antibody was inhibited by VIP; this band did not cross react with non related antibodies.

In conclusion, VIP may be stored as a high molecular weight precursor, sequestered into chromaffin granules, cleaved and then the peptide may be released. Such a process offers multiple control points and may allow simultaneous or synchronic release of biologically active VIP and other neurotransmitters coexisting in the same storage vesicles.

The antibodies used in this study were kind gifts of Drs. R. Benoit and J. Fahrenkrug. The research was funded by Del E. Webb Foundation grants.

8.2 EVIDENCE FOR AN OPIOMELANOTROPIN ACETYLTRANSFERASE IN RAT PITUITARY NEUROINTERMEDIATE LOBE. M. C. Chappell*, Y. P. Loh and T. L. O'Donohue. (SPON: O. Floody). Lab. of Clin. Sci., NIMH, Lab. of Dev. Neurobiology, NICHHD and NIGMS, NIH, Bethesda, MD 20205.

In studies investigating the characteristics of the enzymatic acetylation of α-MSH, we found two distinct acetyltransferase enzymes in rat neurointermediate pituitary lobe. These acetyltransferases are distinguished by pH optima, subcellular distribution and sensitivity to magnesium and several solubilizing detergents. A general acetyltransferase, as characterized in the rat anterior pituitary lobe and rat lens, has a pH optima of 7.4 and is significantly inhibited by magnesium at 3mM concentrations. Subcellular fractionation of anterior and neurointermediate lobes revealed that this enzyme is primarily localized in the cytosol fraction. In contrast, the second enzyme has a pH optima of 6.0-6.6 and is severely inhibited by the detergents Triton X-100 (0.1%) and CHAPS (10mM). This enzyme is specifically localized in the secretory granules of the neurointermediate lobe. Comparative substrate studies reveal that this acetyltransferase is also capable of acetylating β-endorphin (1-31) and the characteristics of β-endorphin acetylation were quite similar to MSH acetylation in terms of pH optima, subcellular localization and detergent inhibition. Furthermore, acetylation of β-endorphin is dramatically inhibited by deacetylated α-MSH, suggesting that these peptides compete for the same acetyltransferase. These results indicate this single acetyltransferase is responsible for the acetylation of opioid and melanotropin peptides, and we have named this enzyme opiomelanotropin acetyltransferase (OMAT). Since the N-acetylated and deacetylated forms of α-MSH and β-endorphin express markedly different biological potencies, the enzymatic N-acetylation of these peptides may be an important regulatory process in modifying their biological activity.

8.3 IDENTIFICATION OF A BRAIN-PITUITARY PATHWAY FOR SECRETIN. C. G. Charlton*, T. L. O'Donohue, R. L. Miller*, G. E. Handelmann* and D. M. Jacobowitz (SPON: J. Haskins). Lab. of Clinical Science, NIMH, Bethesda, MD 20205 and Dept. of Pharmacology, Coll. of Med., Howard Univ., Washington, D.C. 20059.

Secretin, a 27 amino acid polypeptide, was previously thought to be located solely in the small intestine. Recently secretin-like immunoreactivity (SLI) has been identified and characterized in extracts of rat brain. The SLI showed retention characteristics similar to that of the rat duodenum and synthetic pig secretin on a high pressure liquid chromatographic reverse phase column. Highest concentrations of SLI were observed in the pituitary with moderate quantities in the hypothalamus, thalamus and the olfactory bulb.

Dissection of the pituitary gland revealed a 45 fold higher concentration of SLI in the neurointermediate lobe as compared with the anterior lobe. In pituitary stalk-transected rats the SLI of the neurointermediate lobe was significantly decreased, while the SLI of the anterior lobe remained unchanged. The source of the immunoreactive secretin is unknown, but highest secretin concentrations in the brain were measured in the paraventricular and supraoptic nuclei. These data suggest an anatomical similarity between secretin and vasopressin peptidergic systems. Also similar to vasopressin, the injection of synthetic pig secretin in anesthetized hydrated rats caused significant dose-related antidiuretic effects.

These data suggest anatomical and pharmacological similarities between secretin and vasopressin. Whether there is any functional physiological interaction between the two systems remains to be determined.

8.4 THE SEQUENCE OF TELEOST GONADOTROPIN RELEASING HORMONE (GnRH): MULTIPLE FORMS OF GnRH IN THE ANIMAL KINGDOM, N. M. Sherwood, L. Eiden*, M. J. Brownstein*, Unit on Neuroendocrinology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20205, J. Spiess*, J. Rivier* and W. Vale, Peptide Biology Laboratory, Salk Institute for Biological Studies, La Jolla, CA 92037.

GnRH-like material has been extracted from whole brains of salmon (Oncorhunchus keta). The immunoreactive GnRH was purified by molecular sieving on a Sephadex G-25 column and by reverse phase high pressure liquid chromatography (HPLC). The fish GnRH compared with mammalian GnRH is more hydrophobic as shown by HPLC analysis. In addition the two forms of GnRH are immunologically distinct in their reactivity with several antibodies. The fish GnRH may be widely distributed among different species; it is chromatographically and immunologically similar to the GnRH-like neurotransmitter found in the frog sympathetic ganglia. The amino acid composition and sequence of salmon GnRH shows that it differs from the mammalian decapeptide in two positions.

8.5 IN VIVO BIOSYNTHESIS AND TRANSPORT OF THE PEPTIDE NEUROTRANSMITTER CANDIDATE SUBSTANCE P IN THE STRIATONIGRAL TRACT OF INDIVIDUAL FREE-RUNNING RATS. J.E. Krause, J.P. Advis*and J.F. McKelvy. Dept. of Neurobiology and Behavior, State University of New York at Stony Brook, NY 11794.

The regulation of neuropeptide biosynthesis in the central nervous system (CNS) is an important aspect of the functioning of neuronal networks. We have approached this question by using as a model the striatonigral substance P (S) projection. Previous anatomical evidence suggested that SP neuronal perikarya in the basal ganglia (rostral corpus striatum) project ipsilaterally in a descending fashion to terminal fields within the substantia nigra. In the present studies, we have developed chemical methods for the purification of undecapeptide SP along the trajectory of this peptidergic system and have used them to assess in vivo biosynthesis and transport of striatonigral SP.

Rats were unilaterally cannulated (two 28 g cannulae) in the rostral corpus striatum (A: 1.5mm, L: 2.0 and 3.0mm, V: 5.0mm with respect to Bregma). The following day, either ^{35}S-methionine or an equimolar mix of ^{3}H-leucine and ^{3}H-proline was constantly infused into the striatum using an Alzet osmotic minipump delivery system at a rate of 1 ul/hr (750 uCi/rat/16 hrs). Under these in vivo labeling conditions, animals did not appear to be adversely affected since they exhibited normal motor and grooming behavior and/or slept during most of the infusion period. After decapitation, the ipsilateral corpus striatum (cell bodies), its striatonigral fasciculus (axons) and the ipsilateral substantia nigra (terminals) were separately microdissected from frozen coronal brain sections. Tissue samples were homogenized and ^{35}S- or ^{3}H-SP was acid extracted after carrier peptide addition. All individual samples were analyzed for total tissue ^{35}S or ^{3}H, 10% (w/v) trichloroacetic acid precipitable ^{35}S- or ^{3}H-protein and acid soluble ^{35}S or ^{3}H. ^{35}S- or ^{3}H- SP was purified from the latter fraction by adsorption to and elution from C-18 SEP-PAK cartridge, followed by sequential purification by High Performance Liquid Chromatography (HPLC). In all cases, the radiochemical purity of ^{35}S- or ^{3}H- SP was verified by specific derivative formation (Met^{11} sulfoxide-SP) and further HPLC.

In the corpus striatum, incorporation of ^{35}S or ^{3}H into tissue protein was greater than 70% of the total ^{35}S or ^{3}H taken up by the tissue. 35S- and ^{3}H-SP was positively identified in all three regions of this peptidergic pathway. Under these infusion conditions, radiolabeled SP was 20 to 80 fold more concentrated in the substantia nigra compared to the striatal and striatonigral fiber regions.

These results provide definitive biochemical evidence for the in vivo biosynthesis and transport of SP along this peptidergic striatonigral projection. (NSF BNS-7684506)

8.6 A PUTATIVE ENDOGENOUS PEPTIDE LIGAND FOR THE PHENCYCLIDINE RECEPTOR. C.B. Pert, T.L. O'Donohue, H. Everist, A. Pert and R. Quirion. Neuroscience Branch and Lab. of Clin. Sci., NIMH, Bethesda, MD 20205.

Specific [^{3}H]phencyclidine (PCP) binding sites on slices of rat brain can be displaced by a series of PCP analogs with the identical ($p < .001$) ligand selectivity pattern as that required to elicit discrimination of a PCP-like state in an awake behaving rat (Quirion et al., PNAS, 78:5881, 1981). The regional distribution of these specific PCP receptors has been visualized by computer-assisted densitometry (Quirion et al., ibid) and the relative receptor density is hippocampus > cerebellum > striatum > brainstem. The possibility that the brain contains an endogenous ligand for this receptor is supported by our finding that an efficient peptide extraction procedure (Bennett et al., Biochem. J., 175:1139, 1978) yields [^{3}H]PCP receptor inhibitory material with a regional distribution pattern similar to the receptors themselves (i.e., hippocampus: cerebullum: striatum: brainstem = 12: 3: 2: 1). Moreover, a high presssure liquid chromatographic (HPLC) fraction purified from porcine hippocampus selectively displaces [^{3}H]PCP binding in a dose-dependent manner. The same fraction in a concentration which displaces [^{3}H]PCP binding more than 70% fails to displace the binding of [^{3}H]dihydromorphine, [^{3}H]D-Ala^{2}, D-Leu^{5}enkephalin, [^{3}H]ethylketocyclazocine, [^{3}H]diazepam or [^{3}H]neurotensin. The ability of the fraction to inhibit [^{3}H]PCP binding is destroyed by preincubation with various enzymes including pronase, trypsin, leucine-aminopeptidase and carboxypeptidase A, suggesting that this endogenous inhibitor is a peptide. Finally, unilateral injection of this active material into rat substantia nigra induces PCP-like rotational behavior. Injection of an adjacent HPLC fraction with no PCP-inhibitory activity is without effect. These results spur us to determine the chemical structure of a putative endogenous peptide ligand for the phencyclidine receptor which we call "angeldustin."

8.7 EXTRAHYPOTHALAMIC VASOPRESSIN: IMMUNOLOGIC AND CHROMATOGRAPHIC BEHAVIOR, AND ITS REGULATION. D.M. Dorsa* and L.A. Bottemiller* (SPON: L. Halpern). GRECC, VA Medical Center, and Depts. of Pharmacology and Medicine, Univ. of Washington, Seattle, WA 98108.

Extrahypothalamic brain vasopressin (VP) may play an important role in CNS thermoregulatory, cardiovascular, and behavioral functions. In the present study, we examined the chemical nature of VP-immunoreactive (VP-IR) peptides inside and outside the hypothalamus and the effect of water restriction (WR) on VP content in selected brain nuclei.

For regulation studies, male Long-Evans rats were water deprived for 48 h (n=10) or given water ad lib (n=10) and were sacrificed by decapitation. Plasma was collected, and the brains and pituitaries were rapidly removed and frozen. Brain nuclei were sampled by a punch technique. Plasma VP was measured in an RIA after extraction using a Sep-Pak C_{18} procedure. Tissue VP was extracted by sonication in 0.1 N HCl, centrifugation, and lyophilization and was then reconstituted for VP RIA.

Ten other rat brains were removed, and the hypothalami were dissected out. 10% (w/v) homogenates of the hypothalami and remaining brain were prepared using 0.1 N HCl. Homogenates were centrifuged at low speed. Supernatant was lyophilized, reconstituted, and passed through a Sep-Pak C_{18} column and eluted in acid-ethanol. The concentrated samples were then fractionated using a phosphate buffer-acetonitile gradient HPLC system. 0.5 ml fractions were collected, air dried, and reconstituted for measurement of VP-IR.

VP content of the posterior pituitary decreased and plasma concentration increased significantly in the WR group. VP content of the magnocellular nuclei was not significantly altered by this treatment, nor was that of the OVLT, locus coeruleus, dorsal septum, or central grey. Outside the hypothalamus, lower VP content was measured in the ventral tegmentum and lateral and medial septum of WR rats. An increase was noted in samples from the medial amygdala. These responses to WR suggest that some VP-ergic neurons are not affected by this procedure.

In the radioimmunoassay, IR-VP extracted from hypothalamus, septum, and hippocampus was immunologically identical to the USP standard or synthetic arginine^{8}-vasopressin (AVP). The HPLC method separates AVP from oxytocin (OXY), arginine-vasotocin (AVT), pressin amide (PA), and proly-leucyl-glycinamide (PLG). Hypothalamic extract was resolved as a single peak of immunoreactive material which co-eluted with AVP. Extractant from extra hypothalamic brain tissue also contained primarily AVP co-elutable material, but in addition, a smaller peak of VP-IR was noted which did not co-elute with OXY, AVT, PA, or PLG. This VP-IR material may reflect another secretory product of certain nerve terminals or metabolism of synaptically released AVP.

8.8 BIOCHEMICAL CHARACTERIZATION OF RETINAL SOMATOSTATINS: SEQUENCE OF BIG SOMATOSTATIN IN BOVINE RETINA. D. Marshak*, J. Reeve*, J. Shively*, and T. Yamada* (Spon: G. Fain). Depts. of Anatomy and Medicine, UCLA School of Medicine and VA Wadsworth Medical Center, Los Angeles, CA 90073.

Previously we have identified somatostatin-like immunoreactivity (SLI) in a variety of vertebrate retinas and localized it to amacrine cells (PNAS 77:1691, 1980). In the present study we further characterized the biochemistry of retinal SLI. Extracts (3% acetic acid) of retinas from goldfish, frogs, chickens, rats, hogs, and cows were chromatographed Sephadex G50 in 0.1M ammonium acetate pH5.0 and eluted fractions were measured for SLI by radioimmunoassay. All of the extracts, with the exceptions of those from rat and cow retinas exhibited roughly equal distribution of SLI into peaks which co-eluted with somatostatin-14 (S14) and -28 (S28). Rat retinal SLI chromatographed in a single peak which co-eluted with S14. Bovine retina exhibited a major peak (>90%) which co-eluted with S28 and a minor peak which eluted in the column void. Re-chromatography of the bovine retinal extract in 8M urea resulted in disappearance of the void volume peak and appearance of a peak co-eluting with S14, suggesting that the latter was non-covalently attached to a larger molecule in the crude extract. Further purification for sequence analysis was practical only with bovine retinal SLI. Thus, extracts of 3000 bovine retinas were brought to pH5.0 with ammonium hydroxide and applied to an affinity column made by linking anti-S14 antiserum 1001 to Affi-Gel 10. The SLI which was eluted with 2% trifluoroacetic acid (TFA) was applied to reverse phase high pressure liquid chromatography (HPLC) on a C-18 column and eluted with a gradient of 0-30% acetonitrile in 0.1% TFA. The major SLI peak was further purified by HPLC twice on a phenyl column using a gradient of 25-30% acetonitrile in 0.1% TFA until a single clean A_{220} peak was found to correspond to the peak of SLI. The peptide sequence of this peak as determined by an automatic Edman degradation technique performed with a modified spinning cup sequenator was SANSNPAMAPRERKAG(C)KNFFWKTF(T)(S)(C), identical to S28. The amino acids in parentheses could not be determined directly but were deduced because 1) the purified peptide co-eluted with S28 on HPLC, 2) the purified peptide had complete immunoreactivity while immunoreactivity of peptides substituted in positions 17, 26, 27, and 28 was virtually abolished, and 3) all previously sequenced mammalian big somatostatins have this identical sequence.

We conclude that 1) SLI is present in 2 molecular forms in a variety of vertebrate retinas, 2) rat retina contains only one form of SLI which co-elutes with S14 on gel filtration, and 3) the sequence of big SLI in bovine retina appears to be identical to that of S28.

8.9 NON-MAMMALIAN LUTEINIZING HORMONE-RELEASING FACTOR (LRF) IN TADPOLE AND FROG BRAIN. W. Dale Branton*, L.Y. Jan and Y.N. Jan. Department of Physiology, University of California, San Francisco, CA 94143.

Adult bullfrog brain contains a large amount (approximately 25 ng) of mammalian LRF. Bullfrog sympathetic ganglia contain about 0.2-1.0 ng of an LRF-like neurotransmitter distinct from mammalian LRF. We have now found a second brain immunoreactive LRF (LRF II) which may be similar to the ganglionic LRF.

Brain LRF II is present at about 0.1-0.4 ng per animal from metamorphic tadpoles through adult frogs. It makes up most or all of the LRF immunoreactivity in tadpoles, but mammalian LRF predominates in post-metamorphic frogs and greatly predominates in the mature adult where the non-mammalian form is probably at most 1-2% of the total brain LRF.

The brain LRF II is clearly separable from mammalian LRF on reversed phase HPLC and adsorption chromatography on G-25 Sephadex. It also differs in the slope of its RIA dilution curve (Nett R-42 antiserum). On the other hand, we have not found any differences between the chromatographic or immunologic behavior of the non-mammalian brain LRF II (tadpole source) and the ganglionic LRF. This suggests a relative similarity between these peptides. It is interesting to note the difference in the regulation of amounts of mammalian vs. non-mammalian forms of LRF in the frog brain.

8.10 ISOLATION OF NOVEL, NEUROACTIVE, ELH-LIKE PEPTIDES FROM THE ATRIAL GLAND OF APLYSIA. B.S. Rothman†, R.O. Brown*†, E. Mayeri†¶, and J.E. Shively*§. †Dept. of Physiology, Univ. of Calif., San Francisco, CA 94143, ¶Dept. of Basic Sciences, Calif. College of Podiatric Medicine, San Francisco, CA 94115 and §Div. of Immunology, City of Hope, Duarte, CA 91010.

Egg-laying hormone (ELH) is a peptide synthesized by the bag cell neurons of Aplysia that very likely mediates two bag cell actions on neurons of the abdominal ganglion. Three peptides isolated by others from the atrial gland of Aplysia cause the bag cells to fire: peptides A & B, which are unrelated to ELH in amino acid sequence and a hybrid peptide which has a strong sequence homology to the N-terminal half of ELH and the C-terminal halves of peptides A and B. We have purified extracts of the atrial gland to explore further the neuroactive peptides in this tissue.

Atrial glands were homogenized in 0.5 M formic acid at 0°C and fractionated on G50 Sephadex in 0.5 M formic acid. Material with an apparant M_r of 3000-10,000 was lyophylized, applied to a Partisil 10-ODS high performance liquid chromatography (HPLC) column and fractionated with a linear gradient of n-propanol in 0.5 M pyridine formate, pH 3.0. Among the major peaks of eluted material, the following five peptides were identified (in order of elution): peptide B, peptide A, and three ELH-like peptides called C, D and E. The yield of each peptide per atrial gland was (mg): 0.70, 0.67, 0.32, 0.14 and 0.09, respectively. Peptides D and E were not completely separated by the first HPLC step and were repurified on Partisil 10-ODS under isocratic conditions.

Peptides A & B were identified by amino acid and sequence analyses. Peptides C, D and E cross reacted strongly in an enzyme linked immunosorbant assay with affinity purified rabbit antibodies to ELH, while peptides A & B did not cross react. Peptides C, D & E, but not A or B, caused the prolonged excitatory response characteristic of left lower quadrant cells exposed to ELH. The thresholds for the responses to peptides C, D & E ranged from 0.5 to 5.0 ug/ml, while the threshold for ELH was 0.1 ug/ml. Amino acid and partial sequence analyses indicated that the N-terminal halves of peptides C, D & E were identical or strongly homologous to the N-terminal sequence of ELH. The analyses also suggested that neither peptides C, D nor E is identical to the hybrid peptide. Furthermore, all three peptides eluted differently from ELH under isocratic conditions on HPLC.

These data show that there is a family of ELH-like peptides in the atrial gland distinct from the ELH found in the bag cells. In addition, they imply that the N-terminal halves of ELH and peptides C, D & E are responsible for their prolonged excitatory activity in the CNS.

8.11 PITUITARY CHOLECYSTOKININ (CCK)/GASTRIN PEPTIDES: CHARACTERIZATION BY HPLC AND RIA. M.C. Beinfeld* (SPON: J. Taylor). Dept. of Pharmacology, St. Louis Univ. Med. Ctr., St. Louis, MO 63104.

CCK/gastrin immunoreactive pituitary peptides were characterized by radioimmunoassay, gel filtration, and high pressure liquid chromatography (HPLC). The concentration of CCK-like immunoreactivity (CLI) was measured in whole and dissected pituitaries with a CCK radioimmunoassay (RIA) which cross-reacts 80% with human gastrin I. Whole human pituitaries contained the highest concentration of CLI: 518.7 ± 166.5 ng/g wet weight (N = 6). The neurointermediate (NI) lobes and the pituitary stalk (PS) from bovine and porcine pituitary contained the most CLI relative to the anterior lobe [bovine NI: 439.2 ± 86.8 (N = 7), bovine PS 107.4 ± 27.5 (N = 5); porcine NI: 14.4 ± 1.7 (N = 7) and porcine PS: 21.7 ± 2.7 (N = 6)]. In rat and frog pituitary the NI or neural lobe also contained the highest CLI concentration. This distribution is suggestive of a possible hypothalamic origin of the CLI in these species. In rat we have demonstrated that 60% of the neural lobe CLI originates in the paraventricular nucleus of the hypothalamus and that all of the CLI in the pituitary originates in the brain (Beinfeld et al. (1980), Nature 288:376-378).

Whole bovine and human pituitary gland extracts display a single peak of CLI on Sephadex G50 which co-eluted with CCK8 sulfate. Most of the CLI in extracts from bovine anterior lobe, neurointermediate lobe or pituitary stalk also co-migrated with CCK8 sulfate on HPLC. The observation that the bulk of CLI in bovine pituitary co-migrates with CCK8 sulfate differs from the results of Rehfeld (1980), Nature 271:771-778. Preliminary results with whole human pituitary extracts also indicate that the bulk of the CLI in these extracts co-elutes with CCK8 sulfate on HPLC.

In contrast, the CLI in porcine pituitary extracts eluted as two peaks on Sephadex G50, one which co-migrated with Gastrin 17 and one that precedes it, while no CCK was present. This result is in agreement with the work of Rehfeld ((1980), Nature 271: 771-778). On HPLC the bulk of the CLI in porcine pituitary extracts eluted with porcine antral gastrins, and separates from CCK8.

In summary, clear species differences exist in the CCK/gastrin pituitary peptides. This points out the necessity of careful chemical characterization of pituitary gastrin/CCK peptides prior to physiological or pharmacological experimentation.

8.12 POLYPEPTIDES IN LUNG: CONTENT AND SITE OF ACTION. J. Tang*, P. Panula*, J. Chou*, A.Z. Zhang, H.-Y.T. Yang and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

The lung contains many APUD-like cells, but the function of these cells is still unknown. With specific and sensitive radioimmunoassay coupled with gel filtration, HPLC and immunofluorescence we explored the presence and measured the content of met^5-enkephalin, β-endorphin, met^5-enkephalin-arg^6-phe^7 (YGGFMRF), bombesin and substance P in the lung. YGGFMRF content in lungs of rat, guinea pig and human was found to be 0.68±0.08, 0.76±0.12 and 0.63±0.14 pmol/mg protein, respectively. Histochemical studies detected cells exhibiting YGGFMRF-like immunoreactivity in lung; they were located in clusters or as single cells closely associated with the wall of small and medium size bronchioli. This immunostaining was diminished when the antiserum was preabsorbed with YGGFMRF but not with met^5-enkephalin. Biochemically little or no met^5-enkephalin (ME) and β-endorphin was detected in lung.

Using ^{3}H-etorphine binding assay we observed high affinity (K_D=5.0) binding (Bmax 40 pmol/mg protein) in rat lung membrane preparations. And this binding could be displaced by YGGFMRF with high affinity. However the recognition site for opiates located in rat lung membranes shows a number of peculiarities including a low affinity for ^{3}H-naloxone.

Bombesin and substance P were also measured in lung of rat and humans. Histochemically both bombesin and substance P were located in axons. The bombesin and substance P contents in rat lung were 0.94±0.14 and 1.9±0.06 pmol/mg protein. These data allow us to speculate that YGGFMRF may be released from APUD like cells and acts on axons to elicit important respiratory changes (J pulmonary receptor) in rate and depth of respiration. The stimuli that release YGGFMRF are not known at this time.

9.1 DEVELOPMENT OF SENSORY NERVES WITHIN THE WING OF DROSOPHILA MELANOGASTER: A LIGHT- AND ELECTRON- MICROSCOPE STUDY. H. Anderson. European Molecular Biology Laboratory, 6900 Heidelberg, West Germany.

The Drosophila wing is a simple structure bearing many sensory neurons which form an elementary pattern of nerves within the veins. This simplicity and the availability of many genetic mutants make the wing an attractive system for studying the formation of nerve pathways.

The wing develops during the pupal stage of fly development. A light- and electron- microscope study of developing wings at timed pupal stages was undertaken first to establish the time at which the different classes of sensilla differentiate and form axons, and second to determine the arrangement of tissues within the wing prior to, and during, axon outgrowth, in order to assess possible candidates for directing axon outgrowth.

Wing development was observed to pass through three main stages: at 6-12 hours after puparium formation the wing is flattened and secreting pupal cuticle; at 15-18 hours the wing is dramatically inflated but is still a simple epithelium secreting pupal cuticle; at 21-24 hours the wing collapses and begins to secrete adult cuticle and to differentiate adult structures.

Each bristle on the anterior margin of the wing and each campaniform sensillum on the blade of the wing is made from a group of cells (usually a shaft cell, a socket cell, one or more neuron sheath cells, and one or more sensory neurons) derived from the mitotic divisions of a single epithelial cell. Differentiation of the sensory neurons begins before differentiation of the other cells; axon bundles are first detected during the 15-18 hour stage prior to the pupal moult when the wing is still secreting pupal cuticle, but morphological differentiation of the shaft and socket cells does not begin until the 21-24 hour stage which is after the pupal moult when the wing is secreting adult cuticle.

Even at the earliest stages of development there appear to be no persisting larval nerves which might act as pioneers or pathfinders for the later developing neurons. The first axon bundles are detected at the stage when the wing is an inflated sac, without any veins or orderly arrangements of tracheae or obvious physical regularities which might mechanically channel axon growth. Rather axons appear to navigate along the inner surface of the wing epithelium rather like the pioneer axons found in the embryonic appendages of other insects.

9.2 IMMUNOCYTOCHEMICAL STUDIES OF NEURAL DEVELOPMENT IN DROSOPHILA. Efrain Aceves-Pina*, Sandra Barbel*, Louise Evans*, Yuh Nung Jan and Lily Yeh Jan (SPON: Cheryl Laffer Shusterman). Department of Physiology, University of California, San Francisco, CA 94143.

Monoclonal antibodies have been used extensively in developmental studies of vertebrates and invertebrates. Drosophila may may be a favorable organism for such studies because of its well-studied genetics and molecular biology. Here we describe some monoclonal antibodies that recognize various structures of the nervous system at different developmental stages. These monoclonal antibodies were induced by either injecting and boosting mice with Drosophila embryos at various developmental stages (0-4 hr, when neuroblasts appear; 7-10 hr, when central fiber pathways form; or 18-22 hr, the final stage of neural organization; in each of 3 fusions), or injecting mice with 7-10 hr Drosophila embryos and boosting with the grasshopper embryonic nervous system at a similar developmental stage (done in collaboration with Katherine Kotrla and Corey Goodman at Stanford University).

Embryogenesis of the nervous system in Drosophila has been studied using monoclonal antibodies which recognize neuronal nuclei or subsets of nerve fibers early during embryonic development. Further, an interesting developmental profile has been found for certain antigens. For instance, some monoclonal antibodies stained all nuclei in young embryos but preferentially neuronal nuclei plus a subset of nerve fibers later during development.

Although these monoclonal antibodies were raised against embryonic tissues, some serve to subdivide the visual system in adult flies. For instance, some antibodies preferentially stain (1) retina, (2) lamina and/or medulla, (3) cells in lobula and lobula plate, or (4) subsets of fibers in all optic ganglia. Immunocytochemical studies of visual mutants and mutations affecting early neural development in embryos will be described.

9.3 THE LABELING PATTERNS OF DEVELOPING LEECH CNS NEURONS WITH MONOCLONAL ANTIBODIES RAISED AGAINST ADULT NERVOUS TISSUE. R.R. Stewart[1], E.R. Macagno[1], and B. Zipser[2]. Columbia University[1], New York, NY 10027 and Cold Spring Harbor Lab[2], Cold Spring Harbor, New York, NY 11724.

Among the monoclonal antibodies (Mabs) raised against the adult nervous system of the leech Haemopis marmorata by Zipser and McKay (Nature 289:549-554, 1981), some label groups of neurons in each segmental ganglion, indicating that the same or a very similar antigen is expressed by different adult neurons. In the experiments we report here we have studied the pattern of labeling of CNS neurons at different development stages by two of these Mabs (Lan 3-1 and Lan 3-6). Our aims were, first, to describe the temporal sequence of expression of the antigens to these Mabs, and second, to determine how the development of segmental differences (particularly in the sex ganglia of body segments 5 and 6) correlate with the expression of segmentally different patterns of labeling with Mabs. In the adult, Lan 3-6 interacts with about 35 neurons (35±9, n=26 ganglia) in each segmental ganglion. Lan 3-1, however, labels only one pair of small neurons in each segmental ganglion except for 5 and 6, where it labels an additional, larger pair per ganglion. We used the same techniques to visualize antibody binding in embryos as were used by Zipser and McKay to study adults.

Embryogenesis in H. marmorata lasts about a month at 22-25°C. The first ganglia to form are observed at 4-5 days of development, and all the ganglia can be visualized, adjacent to one another, by 8-9 days. Within the next 2-3 days the first four ganglia fuse to form the subesophageal ganglion, the midbody ganglia separate as the connectives grow in length, and the posterior seven ganglia fuse to form the tail ganglion. Labeling with Lan 3-6 is first observed at 8-9 days, when a pair of neurons located postero-medially on the ventral side of each of the most anterior segmental ganglia is labeled. As a function of time after this stage we observe, first, that more neurons label in the anterior segmental ganglia, and second, that labeled neurons appear in increasingly more posterior ganglia. For instance, in an 8-9 day old embryo, ganglia 4-7, 10-13 and 17-20 show, on the average, 2, 1 and 0 labeled cells respectively. In an 11-12 day old embryo, the same ganglia show $6 \pm 1, 4 \pm 2$, and 2 ± 1 labeled cells. In a 12-13 days old embryo the corresponding values are 13 ± 5, 10 ± 1 and 6 ± 2. Labeling with Lan 3-1 is first observed at about 12 days of development, when all segmental ganglia show a pair of labeled neurons located postero-laterally on the ventral side. The additional pair of neurons in ganglia 5 and 6 that label in the adult do not label in 12 day embryos, nor in embryos up to 15 days old. Whether this delay in the labeling of cells specific to the sex ganglia correlates with our preliminary observation that the maturation of these ganglia is also delayed remains to be confirmed.

9.4 ANTIBODY STAINING OF EMBRYONIC LEECH MUSCLE, BLAST CELL MIGRATION AND NEURONAL PATHWAY FORMATION. Duncan K. Stuart, Ian Thompson*, David A. Weisblat and Andrew P. Kramer. Dept. of Molecular Biology, University of California, Berkeley, CA 94720.

Early differentiating muscle cells are located along pathways of embryonic blast cell migration and nerve tracts and, therefore may be important for guidance of cell migration and axonal growth. This suggestion has been investigated by staining the muscles in disected embryos of the leeches Helobdella triserialis and Haementeria ghilianii with the monoclonal antibody Lan 3-14 of Zipser and McKay (Nature 289, 549, 1981) which they have shown to react specifically with adult leech muscle.

The antibody does not stain blast cell precursors but only differentiated muscles. The first cells to stain in the germinal plate appear at stage 8 of development. There is one bilateral pair of such cells per segment. Oblong in shape, they extend transversely from the ventral midline to the lateral edge of the germinal plate. They correspond to circular muscles and define the border between segments. The next stainable cells appear at early stage 9; they form two bilaterally paired sets of about ten longitudinal muscle cells per segment, each cell extending from the circular cell defining the anterior border of the segment to that defining the posterior border. The positions of these longitudinal muscle cells are not evenly spaced across the segment. At about this time two pairs of cells which will become the longitudinal muscles of the connectives and a second pair of circular muscles (parallel to the first) also start to stain. This second set of circular cells are located two thirds of the way back from the anterior edge of the segment. Other longitudinal and circular muscles appear later in stage 9 and are initially thinner and less intensely staining. Subsequently, still more circular and longitudinal muscle cells appear adjacent to the preexisting ones so as to form specific muscle bundles. Oblique muscles develop later, in early stage 11.

The antibody stain has been used on embryos in which certain blast cells have been previously labeled with a cell lineage tracer (Weisblat et al, Science 209, 1538, 1980) or a tracer injected into developing, identified neurons. Specific muscle cells of a given type differentiate at different times. The earliest differentiating cells are spatially associated with pathways of blast cell migration and peripheral axon growth.

9.5 MUSCLE CELLS, GLIAL CELLS AND AXONAL GUIDANCE IN LEECH EMBRYOS. Andrew P. Kramer and Duncan K. Stuart. Dept. Molecular Biology, Univ. Calif., Berkeley, CA 94720.

Growing axons of central neurons in leech embryos may be guided initially by muscle or glial cells in the CNS and periphery. Every major axon tract in the leech nervous system develops in close spatial association with specific muscle or glial cells. First to form are the commissural tracts. The initial processes of central neurons grow toward the center of the ganglion, which is dominated by two giant neuropil glial cells aligned on the midline. The first commissural axons grow just dorsal to or exactly between the glial cells. Subsequently, axons grow between the ganglia to form the connective tracts. Before axonal outgrowth, the space between adjacent ganglia is bridged only by two pairs of connective muscle cells dorsally and a pair of connective glial cells ventrally. The first connective axons grow between the muscle and glial cells. Some follow the lateral connective muscle cells, to form the paired lateral connective nerves, and the rest follow the medial muscle cells, to form the unpaired Faivre's nerve. Finally, axons grow into the periphery, which at this stage is occupied by an orthogonal grid of longitudinal and circular muscles and also dorso-ventral flattener muscles. The first peripheral axons grow along these muscles, and identified axons predictably follow particular muscle pathways. This was ascertained by combining selective staining of muscle cells using an antibody (Lan 3-14; Zipser and McKay, Nature 289:549, 1981) and intracellular dye-filling of identified neurons that have peripheral axons. In these preparations, one can see a close spatial association between growing peripheral axons and muscle cells. This is true not only for axons of motor neurons but also for peripheral axons of central sensory neurons that innervate the skin. The dorsal (P_D) and ventral (P_V) pressure-sensitive mechanosensory neurons that appear to pioneer the MA and DP peripheral nerve tracts (Kuwada and Kramer, in press) reach their appropriate skin territory by growing along particular muscle cells before entering the epidermis. The P_D neuron, which innervates dorsal skin, grows along the medial bundle of flattener muscles, that is a bridge over ventral skin to dorsal skin territory. The P_V neuron grows along the grid of circular and longitudinal muscles in the ventral territory. Its axon initially grows laterally along circular muscles in the middle of the body segment and extends longitudinal branches as it passes over each of three specific longitudinal muscle cells. Each of these branches in turn extends lateral branches when it reaches circular muscles at the sides of the body segment. We suggest that the muscle cells at these branch points may be landmarks recognized by the P_V axon.

9.6 MONOAMINE-CONTAINING NEURONS OF THE LEECH AND THEIR TELOBLAST OF ORIGIN. S.S. Blair and D.K. Stuart. Dept. Molecular Biology, Univ. California, Berkeley, CA 94720.

The injection of tracer dyes into specific, identifiable blastomeres (teloblasts) in the early leech embryo leads to the reproducible staining of particular portions of the embryonic germinal plate, including the nervous system. Therefore, it has been proposed that specific neurons arrise only from the progeny of a particular teloblast. To test this hypothesis two types of studies have been performed, using either the ablation of identified teloblasts or the injection of dyes to trace cell lineages.

The monoamine-containing neurons of the leech CNS and body wall may be detected by using the glyoxylic acid technique. In this way each segment has been shown to contain on one side three serotonin-containing cells in the CNS and three dopamine-containing cells in the body wall. In the first type of study, adults have been reared from embryos in which particular teloblasts were ablated through the injection of DNase I. Adults in which one N teloblast was deleted lack those serotonin-containing neurons. Adults lacking one OP cell lack the two more lateral dopamine-containing neurons. Adults lacking the Q teloblast lack the medial dopamine-containing neurons. For the second type of study, glyoxylic acid staining was used on embryos in which selected teloblasts were injected with a rhodamine-labeled peptide. In this way it has been determined that, in agreement with the above results, the Q teloblast gives rise to the medial dopamine cell, the O teloblast to one lateral dopamine cell (LD2) and the P teloblast to the other (LD1). Work is currently underway to directly determine the teloblast from which the serotonin-containing neurons are derived by using antiserum against serotonin to identify these neurons in embryos similarly injected with tracer dyes.

9.7 DEVELOPMENT OF SWIMMING IN THE LEECH FOLLOWING ABLATION OF SEROTONIN-CONTAINING NEURONS. J.C. Glover* (Spon: W.B. Kristan, Jr.). Dept. of Biology, UCSD, La Jolla, CA. 92093

Leech embryos were treated with 5,7-dihydroxytryptamine, causing a selective and complete ablation of all serotonin-containing neurons. The embryos continued to develop and were examined for behavioral abnormalities at later stages. Particular attention was paid to swimming behavior, which is known to be stimulated by serotonin. Swimming behavior develops in a sequence of stages involving gradual refinement of more primitive movements, and this sequence begins about 2 weeks following the stage at which the ablations were performed.

In treated embryos, normal swimming behavior failed to develop. Under conditions which induced swimming behavior in control animals, treated animals produced weak dorsal-ventral flexions of the head and tail, but never produced the normal sinusoidal movement characteristic of swimming. However, within minutes after being injected with serotonin, these abnormal leeches swam normally. Thus, the neural circuitry underlying swimming had developed, but the expression of the behavior was disrupted in the absence of serotonin. The neural circuitry responsible for swimming therefore developed in the absence of 1) neurons containing a neurotransmitter essential for the expression of the behavior, and 2) the normal developmental sequence of swimming movements and resultant patterned sensory feedback.

Although the ablations were performed 2 weeks before swimming behavior developed, the serotonin-containing neurons were developing and contained serotonin for several days prior to the ablations. It is still possible that early events in swimming circuit development, preliminary to actual behavioral development, may be influenced by the absence of these neurons. Ablations of the serotonin-containing neurons around the time they first contain serotonin are currently being performed to address this possibility.

9.8 DENDRITIC GROWTH AND REORGANIZATION OF NEURONAL INTERACTIONS DURING INSECT METAMORPHOSIS, R.B. Levine and J.W. Truman. Dept. of Zoology NJ-15, Univ. of Wash., Seattle WA. 98195.

The nervous systems of holometabolous insects such as the moth, Manduca sexta, must mediate different behavior at different stages of life. They are therefore subject to a dramatic reorganization during metamorphosis. Our effort to understand this process has foccused upon the abdominal motorneurons, which we are able to identify as unique individuals. Metamorphosis is highly conservative with respect to these neurons, since all motorneurons present in the adult were also functional larval motorneurons. As described previously(Levine and Truman,Neuro. Abs. 6,1980), Some motorneurons die following the death of their targets after the pupal molt, but many survive the death of their larval target muscles and are retained to innervate new adult muscles. Larval neurons may possess bilateral or unilateral dendritic fields, depending upon the location of their target muscle. Regardless of larval morphology, however, all adult motorneurons possess bilateral dendritic fields even though this requires extensive growth on the part of unilateral neurons.

The behavior of the adult abdomen requires synergistic activity of motor neurons which were antagonists in the larva. This transformation is reflected in the synaptic inputs to bilaterally homologous motorneurons. In the larva for example, the motorneuron MN-1 has a unilateral dendritic field and is directly excited by an ipsilateral stretch receptor, while its contralateral homologue is indirectly inhibited. In the adult, both motorneurons have attained a bilateral dendritic tree and are directly excited by the same stretch receptor. The formation of the new excitatory pathway during adult development is correllated with dendritic growth of MN-1 in the region of the contralateral stretch receptor. Aquisition of common synaptic inputs by bilaterally homologous adult motorneurons is accomplished in this example not by growth of the presynaptic cells, but rather by elaboration if the motorneuron dendrites into areas occupied by its contralateral homologue.

The new excitatory pathway from stretch receptor to contralateral MN-1 forms during the latter part of adult development, and for a time coexists with the larval inhibitory pathway. Just prior to adult emergence stimulation of the receptor co-activates both pathways, but the inhibitory connection dominates. Within 30 minutes of emergence the inhibitory pathway has lost its influence on MN-1, and stimulation of the receptor causes pure excitation of the contralateral MN-1. The retension of the larval inhibitory pathway allows ongoing pupal behavior to persist undisturbed as the new excitatory pathway forms. Its rapid loss coincides with the onset of adult behavior patterns.

9.9 HORMONAL CONTROL OF STAGE-SPECIFIC ECDYSIS MOTOR PATTERNS DURING LARVAL AND PUPAL DEVELOPMENT IN MANDUCA SEXTA. Janis C. Weeks and James W. Truman. Dept. Zoology, Univ. of WA, Seattle, WA 98195.

The tobacco hornworm M.sexta molts 6 times between hatching and adulthood. The first 4 molts occur between larval instars, the next molt is from larva to pupa, and the final molt is to the adult moth. Each molt culminates in the shedding of the old cuticle, an event called ecdysis(or eclosion, in the case of adult emergence). Each ecdysis is accomplished by rhythmic, anteriorly-directed peristaltic abdominal movements which may be accompanied by stage-specific limb movements during stages when limbs are present. These behaviors propel the old cuticle posteriorly along the body to be cast off. This process takes 5 - 15 min. and depending on the animal's stage may be preceded by a period of stereotyped rhythmic pre-ecdysis behavior which loosens the old cuticle. These behaviors are normally triggered by a 8500 mw peptide hormone, eclosion hormone (EH), which is released from the CNS into the blood roughly 0.5 - 1.5 hour before ecdysis begins, or they can be elicited prematurely by injecting insects with EH extract. To examine the neuronal basis of these hormone-mediated behaviors, we developed a semi-intact, deafferented preparation which responds to EH extract by producing the appropriate stage-specific pre-ecdysis and ecdysis motor patterns. Using standard intracellular and extracellular recording techniques on this preparation, and by filming and making EMG recordings from intact insects, we have characterized the larval and pupal motor patterns of M.sexta. In particular, we have determined key features of the patterns which are diagnostic of each stage;e.g., during larval ecdysis the abdominal prolegs show a strong protraction-retraction cycle during peristalsis, whereas at pupal ecdysis these appendages have been lost and this behavior is absent. Despite such changes, however, the same hormone (EH) turns on the motor patterns at each ecdysis. The characterization of these normal motor patterns has provided the framework for examining the hormonal control of circuitry modification during the larval to pupal transformation. By treating final instar larvae with a juvenile hormone analog (ZR515) at critical times during the ecdysone-mediated pupal transformation, we generated "larval-pupal intermediates" which have varying degrees of mixed larval and pupal character in their body structures, nervous systems, and behaviors. Notably, we produced animals which generated inappropriate motor patterns at their next ecdysis. Electrophysiological and neuroanatomical investigation of these animals should provide insight into how CNS circuitry is modified hormonally during development.

9.10 TRANSPLANTED SENSORY NEURONS IN THE CRICKET TEST THE SIGNIFICANCE OF SOMATOTOPY. Jonathan Bacon and R.K. Murphey, Department of Biology, SUNY, Albany, NY 12222.

Last year in this space we reported that cercal wind-sensitive filiform neurons form a somatotopic projection within the cercal glomerulus of the terminal abdominal ganglion of crickets. The filiform hairs are of two types: "T" hairs (vibrating transversly to the long axis of the cercus) are located dorsal and ventral on the cercus and "L" hairs (vibrating longitudinally) are found medial and lateral. A single afferent neuron innervates each hair and the location of its terminal arborisation within the glomerulus is largely a function of the hair's circumferential position on the cercus: "T" hairs project dorso-laterally in the glomerulus and "L" hairs project ventro-medially.

Two large interneurons, MGI and LGI, receive predominantly "T", and not "L" hair, excitatory input to their major dendrites. These dendrites are situated in positions in the glomerulus where direct contact with "T" hair afferents is more likely. We therefore find a correlation between synaptic connectivity of sensory afferents with these interneurons and their dendritic location within the afferent projection.

However this correlation does not prove that these morphological relationships are determinants of connectivity. A direct way to investigate this is to perturb the relationship of the somatotopic cercal projection to the interneurons. To do this, we have employed the experimental paradigm first described by Edwards and Sahota (J. exp. Zool., 166:387, 1967) in which a cercus is transplanted to the mesothoracic leg stump and the filiform hairs generate sensory projections to the mesothoracic ganglion. Our observations show that the ingrowing neurons produce a well defined glomerulus. "T" hairs tend to project laterally (as they do in the terminal ganglion) and "L" hairs project more ventrally and medially: thus a somatotopic map is recreated in foreign neuropile. Since MGI and LGI (whose axons are situated in the Ventral Intermediate Tract) have medially directed branches in the thoracic ganglia, this manipulation alters the relationship of the filiform afferents to the giant neurons. "L" hair afferents, rather than those from "T" hairs, are now more likely to form direct contact with MGI and LGI. However stimulation of the ectopic cercus produced no spiking activity in these interneurons though other ascending units were activated by the stimulation. Support for the hypothesis that somatotopy is an important determinant of connectivity would now be provided by the demonstration that "L" hair afferents provide sub-threshold inputs to the giant neurons in the thoracic ganglia. We are at present recording intracellularly from the giants in the thorax to test this possibility.

9.11 NEURITE OUTGROWTH AND SYNAPSE FORMATION BY IDENTIFIED APLYSIA NEURONS IN DISSOCIATED CELL CULTURE. S. Schacher*, E. Proshansky*, and J. S. Camardo*. (SPON: R. Ambron.) Center for Neurobiology & Behavior, Depts. of Anatomy, Physiology, and Psychiatry, Columbia University, P & S, and N.Y. State Psychiatric Institute, New York, N. Y. 10032.

Dissociated cell culture techniques applied to identified central neurons of known properties and interconnections can provide an excellent system for examining factors which influence neurite outgrowth and specific synapse formation. We have succeeded in growing identified neurons from the abdominal ganglion of Aplysia californica in dissociated cell culture and have found that: 1) cells isolated with their axons remain essentially unipolar whereas cells without their original axonal process sprout numerous 'processes' each consisting of a fascicle of smaller neurites, 2) the number of fascicular sprouts and their thickness is dependent on the level of Aplysia hemolymph in the growth medium, and 3) the cholinergic interneuron L10 forms appropriate chemical synapses with three different follower cells.

Following enzymatic and mechanical dissociation, identified Aplysia neurons will attach and begin sprouting processes within 12 hrs when grown in medium containing Aplysia hemolymph. The nature of the neuritic sprouting is dependent on both the presence or absence of a cell's original axonal process and the level of Aplysia serum in the growth medium. When the initial axon is present, all neuritic sprouts emerge from the axon, leaving the cell in its original unipolar configuration. In contrast, cells lacking their original axon sprout numerous (5-15) processes from their cell bodies. At the electron microscope level, each 'process' consists of a fascicle of 4-10 smaller processes. The number of fascicular processes is reduced and their thickness increased when the level of Aplysia serum in the growth medium is reduced from 50% to 10%.

The cholinergic interneuron L10 will form chemical synapses with three different follower cells (LUQ, R15, and L7) by three days. The sign of the PSP is appropriate for each cell, so that firing of action potentials in L10 produces an IPSP in the LUQ cell, an EPSP in R15, and an EPSP-IPSP in L7. The chemical nature of the synapses was evident from the fact that there was no electrical connectivity, and that changing the membrane potential of the postsynaptic cell changed the magnitude of the PSP. The PSPs observed in culture tend to have prolonged rising and decay phases, and often repetitive firing of the presynaptic neuron is required to elicit a measurable response. Our data indicate that an identified neuron will form appropriate connections in culture with its usual target cells. It is not yet clear, however, to what extent this specificity is maintained, since it appears that cells may occasionally form synaptic connections which are not present in the ganglion.

9.12 THE ROLE OF ACTIVITY IN NEURONAL PLASTICITY IN THE COCKROACH S.F. Volman and J.M. Camhi. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

In the escape system of the cockroach *P. americana*, the normal behavior is to turn away from a wind source. The sensory organs for wind are the cerci, a pair of abdominal appendages covered with fine sensory hairs. When one of the cerci is cut off, animals make directionally specific mistakes in their escape behavior. After about 4 weeks, without regeneration, the behavior is substantially corrected. There is also a concomitant increase in the ability of afferents from the intact cercus to evoke action potentials in directionally selective giant interneurons (GI's) on the contralateral (deafferented) side, which helps to restore the GI's normal responses (Vardi and Camhi, Neurosci. Absts., 6).

Is the ability of the contralateral cercal afferents to mediate changes in behavior and in the nervous system dependent on their activity during the 4-week "recovery" period? To answer this question, we compared the behavioral and physiological responses of three groups of unilaterally deafferented animals: 1) deafferented one day before testing, 2) deafferented for 4 weeks, and 3) deafferented with the intact cercus covered for at least 4 weeks. To prepare the last group, we cut off one cercus from last instar nymphs, and covered the other cercus with adhesive to immobilize the hairs. When animals molted 28-40 days later, they had a new set of sensory hairs and could be tested with wind stimuli. Covered animals did not show corrected behavior after molting (Volman et al., Neurosci. Absts., 6). The lack of behavioral recovery was not due to damage caused by the adhesive because animals having an intact cercus covered with plastic tubing also did not have corrected behavior after 4 weeks.

Intracellular recordings were made from the 3 largest ventral GI's in response to wind on the contralateral cercus. We plotted the receptive fields as the number of action potentials vs. wind-stimulus angle. For all 3 GI's, the responses in animals whose cerci had been covered were smaller than those in animals not covered during the 4 weeks after deafferentation; in particular, responses were smaller for frontal winds which had produced the most mistakes in behavioral tests. However, the responses were also significantly greater than those in animals which had been deafferented only one day before recording.

These results suggest that the long term level of activity can influence the amount of change in the ability of the contralateral afferents to drive the GI's. However, specific wind-evoked activity is not necessary to get some degree of change.

9.13 HORMONAL CONTROL OF REGENERATION IN HYDRA

H. Chica Schaller *. Max-Planck-Institute for Medical Research, Dept. of Biophysics, Jahnstr. 29, 6900 Heidelberg, F.R.G.

We use hydra as a model system to understand how pattern formation, cellular growth and differentiation are controlled at the molecular level. We have found that four substances influence head and foot formation in hydra: an activator and an inhibitor of head formation and an activator and an inhibitor of foot formation. The two inhibitors are small molecules with molecular weights below 500 daltons, they have an overall positive charge, and they do not contain peptide bonds. The two activators have an overall negative charge, both are peptides, the foot activator has a molecular weight between 500 and 1000 daltons and the head activator of 1124 daltons. The head activator consists of 11 amino acids and has the sequence pGlu-Pro-Pro-Gly-Gly-Ser-Lys-Val-Ile-Leu-Phe. All four substances act at concentrations below 10^{-8} molar and their action is specific. At such low concentrations the head factors only influence head formation and the foot factors foot formation. Within the animal all four substances occur as gradients of sources, the head factors with a maximum in the head, the foot factors with a maximum in the foot region. The release from the structure-bound form is specific, and it determines the polarity of the tissue. Thus release of head factors is necessary to induce head regeneration, and that of foot factors to induce foot regeneration. In normal hydra all four substances are produced by and stored in nerve cells. We try to understand, how these substances act and interact to create the spatial and temporal pattern of growth and differentiation typical for hydra.

10.1 FURTHER CHARACTERIZATION OF BRAIN DOPAMINE RECEPTORS BY PHOTO-AFFINITY LABELLING AND DISC GEL ELECTROPHORESIS. K. Moroi* and L. L. Hsu (Spon: E. S. Barratt) Dept. of Psychiatry and Behavioral Sciences, Univ. of Texas Med. Branch, Galveston, Texas 77550.

We have previously reported on the purification and characterization of a dopamine (DA) receptor protein in brain synaptosomal membranes by affinity chromatography and disc gel electrophoresis. This purified DA receptor showed two polypeptide bands on SDS gel with apparent molecular weights of 40 K and 70 K daltons. In this study, we have examined the ligand specificity and binding properties of this DA receptor protein in rat synaptosomal membranes as well as in the microsomal fraction of the rat cortex using photo-affinity labelling and gel electrophoretic analyses. Crude mitochondrial membrane fraction including synaptosomes (P_{2M}) was prepared from rat cerebral cortex according to the procedure of De Robertes et al (J. Biol. Chem. 242:3489, 1967). Aliquots of P_{2M} were incubated with labelled DA, apomorphine (APO), spiroperidol, (SPD) haloperidol, (HAL), serotonim (5-HT) or acetylcholine (ACh) at 37°C for 40 min. in the absence or presence of fluorescent light. At the end of each incubation, an appropriate amount of cholic acid was added to the incubation mixture to a final concentration of 0.2% to solubilize the ligand labelled protein and this mixture was subsequently subjected to disc gel electrophoretic analysis. In another experiment, aliquots of cholate extract from P_{2M} were incubated with various labelled ligands described above and the incubation mixtures were subjected to disc gel electrophoretic analysis directly. After gel electrophoresis, one gel was stained with comassie blue R-250 for protein visualization and other gels were sliced into 12 equal pieces from origin to the dye marker. Each gel slice was mashed in a scintillation vial containing 1 ml of ethanol and 4.5 ml of Scintiverse counting solution for measurement of radioactivity.

Results indicated that, among all the ligands examined, only DA showed a radio binding peak at the protein band with a R_f value equivalent to the purified DA receptor protein. Furthermore, fluorescent light enhanced the DA binding peak in P_{2M} fraction 3 fold and the cholate extract showed much less photo affinity DA binding than P_{2M} pre-incubated with labelled DA under fluorescent light and subsequently extracted with cholic acid. The microsomal fraction showed similar results. Therefore this fast moving DA receptor protein seems to have ligand specificity towards DA only under our assay conditions. Whether it requires other components for SPD or HAL binding remains to be determined. The observation that cholate extract of P_{2M} exhibited much less photo-affinity labelling suggests that certain lipid component(s) in the P_{2M} membrane may be required for such irreversible DA binding. (This work was supported by a grant from R. A. Welch Foundation)

10.2 GTP-INDEPENDENT AND Na-DEPENDENT STEREOSPECIFIC BINDING OF ^{3}H-LISURIDE TO STRIATAL DOPAMINE RECEPTORS. P.F. Spano*, H. Usumaki*, S. Govoni, M. Memo*, V. Covelli, M. Carruba*, M. Trabucchi. (Spon: I. Hanbauer). Dept. of Pharmacology and Pharmacognosy, Univ. of Cagliari and Univ. of Milan, Italy.

Behavioral, pharmacological and clinical evidences indicate that lisuride can directly stimulate dopamine (DA) receptors in the brain and in the anterior pituitary. In vitro experiments using ^{3}H-lisuride indicate that this compound binds to central DA receptors. However, lisuride unlike apomorphine does not stimulate DA-sensitive adenylyl cyclase activity in rat striatal homogenates. To determine whether lisuride may interact with a specific subtype of DA receptors we investigated the effect of GTP and NaCl on ^{3}H-lisuride specific binding to rat striatum. The specific binding of ^{3}H-lisuride (26 Ci/mmol) to striatal membrane preparations was defined by 5×10^{-7} M d-butaclamol and appears to be saturable and stereospecific, both in presence or in absence of NaCl. In presence of 120 mM NaCl the B_{max} is increased by 40% (from 723±73 fmol/mg prot. to 1,035±80 fmol/mg prot.) and the K_D values remain unchanged. (1.8±0.4 nM without NaCl and 1.9±02 with NaCl). On the contrary, GTP up to 50 µM did not affect ^{3}H-lisuride binding characteristics in presence or in absence of NaCl. These findings are in contrast to those showing that the affinity of ^{3}H-apomorphine binding was decreased by one half in the presence of GTP.

The lack of effect of GTP on ^{3}H-lisuride binding characteristics seems to rule out the possibility that this ergot derivative is an agonist acting at the DA receptors linked to adenylyl cyclase (D_1). Moreover, the Na-dependency of ^{3}H-lisuride binding indicates that lisuride may bind to a Na-sensitive DA receptor (D_2).

10.3 RECOGNITION OF [^{3}H]SEROTONIN BINDING SITES IN RAT BRAIN BY ANALOGUES OF TRYPTAMINE. D. L. Nelson, W. Taylor* and B. Weck*. Dept. of Pharmacology & Toxicology, Col. of Pharmacy, Univ. of Arizona, Tucson, AZ 85721

In this study a series of structural modifications at the aminoethyl portion of tryptamine (TRYP) were examined to determine their effects on recognition by [^{3}H] serotonin ([^{3}H]5-hydroxytryptamine, [^{3}H]5-HT) binding sites in rat brain, i.e., those sites commonly classified as 5-HT_1 receptors. A standard ligand-binding assay was used to measure the binding of [^{3}H]5-HT to membranes prepared from rat cortex (Pedigo et al., J. Neurochem. 36: 220, 1981) except that ascorbate was not used and the antagonist metergoline (1 µM) was used to define nonspecific binding. Removal of the 5-hydroxy group of 5-HT to form TRYP resulted in a large decrease in potency at the 5-HT_1 sites (IC_{50}5-HT = 3-5 nM, IC_{50}TRYP = 100-200 nM). In addition, 20-25% of these [^{3}H]5-HT binding sites were resistant to inhibition by TRYP. This suggested that the 5-hydroxy group was necessary for recognition by these sites. However, alkylation of TRYP to form dimethyltryptamine (DMT) or diethyltryptamine (DET) resulted in compounds which could now inhibit all specific [^{3}H]5-HT binding. The inhibition curves produced by DMT and DET were shallower than that produced by TRYP, and while the IC_{50} values for the three compounds were very similar, at low concentrations (3-10 nM) DMT and DET appeared to be more potent inhibitors of [^{3}H]5-HT binding than TRYP. Synthesis of an analogue having even greater bulk on the amino group, i.e., diisopropyltryptamine (DIPT), produced a compound which had an overall potency that was much less than TRYP (IC_{50}DIPT = 800-1500 nM). However, this compound produced a biphasic curve for the inhibition of [^{3}H]5-HT binding such that at low concentrations (3-10 nM) it was more potent than TRYP while at higher concentrations (100-3000 nM) it appeared less potent than TRYP. Syntheses of compounds with more complex substitutions at the amino group were also carried out. When the amino group was replaced by a piperidyl or a morpholinyl group the resulting compounds produced inhibition curves which were essentially identical to DIPT. The present data indicated that modifications in the structure of 5-HT could significantly alter recognition by 5-HT_1 sites, resulting in discrimination between different populations of these sites. TRYP, DMT and DET are commonly classified as 5-HT agonists, and there is now preliminary evidence that DIPT also acts as an agonist. If high affinity [^{3}H]5-HT binding truly represents a class of receptors, then these data suggest the possibility of synthesizing 5-HT agonists which are relatively specific for certain 5-HT receptor subtypes. (Supported by NIH grant NS16605 and a PMA grant.)

10.4 COMPUTER-ASSISTED MICRODENSITOMETRY OF SEROTONIN RECEPTOR SUBTYPES IN RAT CENTRAL NERVOUS SYSTEM. P.P. Deshmukh, D.L. Nelson, A.S. Marathay* & H.I. Yamamura. Dept. of Pharmacology & Optical Sciences Center, University of Arizona, Tucson, AZ 85724

Computer-assisted image processing to analyze autoradiograms can provide precise quantitation of neurotransmitter receptors in micron-sized regions of the brain. In this study we have used computerized microdensitometry to analyze subtypes of serotonin receptors in rat central nervous system. A number of recent studies have proposed at least two broad classes of serotonin (5-hydroxytryptamine, 5-HT) receptors. One class, the 5-HT_1 receptor, is defined by the high affinity binding of [^{3}H]5-HT and the other, the 5-HT_2 receptor, is defined by the high affinity binding of [^{3}H]spiperone. It has also been shown that the 5-HT_1 sites can be further subdivided into two groups according to their affinity for the neuroleptic spiperone. These subtypes are called 5-HT_{1-A} (having high affinity for spiperone) and 5-HT_{1-B} (having low affinity for spiperone). The binding of ^{3}H-5-HT to rat brain slices was performed essentially as described by Young and Kuhar (Eur. J. Pharmacol. 62:237, 1980). Serial sections were incubated to give: 1) total 5-HT binding (in the presence of 2nM ^{3}H-5-HT); 2) non-specific binding where ^{3}H-5-HT is displaced by the addition of 1 µM metergoline and 3) binding to 5-HT_{1-B} sites where binding to 5-HT_{1-A} sites has been blocked by the presence of 1 µM spiperone in the incubating medium. After proper exposure and development the autoradiograms obtained on LKB-ultrofilm were scanned with a Perkin-Elmer microdensitometer that scans 65000 lines with 1024 pixels per line. A scanning aperture of 5 µm was used in this procedure. A Hewlett-Packard 2020 Tape drive with a 7-track reel tape was used to record the scanned information. This 7-track tape was then converted to a 9-track, 800 bits per inch format at the University of Arizona computer center. This 9-track tape was then processed at the Digital Image Analysis Laboratory (DIAL) where there is built-in software available for picture processing and display of processed images. A hard copy in psuedocolor can be produced on polaroid print film or on a 35mm Ektachrome format. Image processing brings out very subtle changes in receptor densities in minute areas that are too small for measurement by binding to homogenates. For example, septum and inner layers of frontal cortex show a preponderance of 5-HT_{1-A} sites while in the CA_1 area of the hippocampus and superficial layers of the superior colliculus the 5-HT_{1-B} sites predominate. The use of this technique should therefore, prove very useful for mapping and characterizing 5-HT receptor subtypes as well as other receptors within the central nervous system. (Supported by NIMH grant MH36861, H.I.Y. is supported by a RSDA from the NIMH.)

10.5 QUANTITATIVE AUTORADIOGRAPHY OF [^{3}H] DESMETHYLIMIPRAMINE AND [^{3}H] IMIPRAMINE BINDING SITES. T.C. Rainbow and A. Biegon. The Rockefeller University, New York, NY 10021.

We have used the recent LKB Ultrofilm method of autoradiography to localize high affinity binding sites for [^{3}H] desmethylimipramine (DMI) and [^{3}H] imipramine (IMI) in rat brain. The antidepressants DMI and IMI are, respectively, potent inhibitors of norepinephrine (NE) and serotonin (5HT) re-uptake, which recently have been shown to bind to high affinity sites in brain tissue. Our procedure was to label frozen 32μ thick brain sections in vitro with [^{3}H] DMI, [^{3}H] IMI or [^{3}H] nitroimipramine (NI), an irreversible inhibitor of 5HT uptake (Rehavi et al., Biochim. Biophys. Res. Comm. 99 1981). Brain sections were incubated at 4° with 1-10nM of [^{3}H] ligands in 50mM Tris buffer containing 300mM NaCl. Non-specific binding was measured by co-incubation with 100μM unlabeled DMI. The labeled sections were placed against LKB Ultrofilm as described (Rainbow et al., J. Neurosci. Methods 5 1982) to generate autoradiograms. The optical density readings were converted into the amount of binding site per mg of protein with tritium standards. We also analysed autoradiograms with computerized image processing. The properties of [^{3}H] DMI and [^{3}H] IMI binding to frozen sections corresponded closely to previous reports of high affinity tricyclic binding to membrane preparations. In sections removed for scintillation counting, each ligand was observed to bind to a single, specific site, with half-maximal binding occurring at 4-6nM.

The distribution of [^{3}H] tricyclic sites was in striking accord with the known distribution of monoamine terminals in rat brain. The anatomical location of DMI binding sites closely paralled the location of NE terminals, with high concentrations of binding sites found in the locus coeruleus, the ventral portion of the nucleus stria terminalis, the anterior ventral thalamus and the dorsomedial nucleus of the hypothalamus. There were low concentrations of DMI binding sites in the caudate putamen and substantia nigra, regions with a low content of NE. By contrast, the distribution of IMI and NI binding sites was in good agreement with the location of 5HT terminals in rat brain, with a high density of binding sites observed in the olfactory tubercle, the interpeduncular nucleus, the raphe nuclei and the nucleus of the facial nerve. There was a low content of IMI or NI binding sites in the ventral thalamus, a region with a low level of 5HT.

Our results support the hypothesis that the DMI and IMI binding sites correspond to some aspect of the presynaptic uptake site for monoamines and suggest that monoamine neurons might be important target sites for the clinical actions of antidepressants. It may be possible to use in vitro autoradiography with [^{3}H] DMI or IMI to quantify monoamine terminals in brain sections.

Supported by NS17435 and a Chaim Weizmann fellowship.

10.6 BINDING TO A SUBPOPULATION OF ^{3}H-IMIPRAMINE SITES BY ^{3}H-Ro 11-2465, A POSSIBLE IRREVERSIBLE LIGAND. A. Dumbrille-Ross and S.W. Tang. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Ontario, Canada M5T 1R8.

In order to examine whether the compound Ro 11-2465 (Ro) (a CN-derivative of imipramine) and imipramine (IMI) bind to the same site, characteristics of receptor binding of ^{3}H-Ro were examined in both rat cerebral cortex homogenates and human platelets. Competition of ^{3}H-Ro binding by various drugs, effects of raphe lesioning, sodium and temperature dependence of ^{3}H-Ro binding was examined and compared to that of ^{3}H-IMI binding.

Serotonin was the only neurotransmitter which competed for binding of both ^{3}H-Ro and ^{3}H-IMI (Ki 1.3 μM and 0.4 μM respectively). Drugs competed for the binding of both ligands with an order of potency similar to that in blocking serotonin uptake. Binding of ^{3}H-Ro and ^{3}H-IMI, similar to serotonin uptake, is sodium dependent. Raphe lesions decrease binding of both ^{3}H-Ro and ^{3}H-IMI.

^{3}H-Ro binds (23°) to cortical tissue with a K_d of 0.25 nM and B_{max} 250 fmol/mg protein. ^{3}H-IMI (4°) binds with K_d of 7.5 nM and B_{max} of 328 fmol/mg protein. In human platelets, ^{3}H-Ro binds to about 50% of the number of sites bound by ^{3}H-IMI (B_{max} 311 fmol/mg protein and 605 fmol/mg protein respectively). Binding characteristics of ^{3}H-Ro and ^{3}H-IMI are different at 4° from 23°. The B_{max} of ^{3}H-IMI decreases about 50% when incubated from 20 min to 24 hr at 23°, suggesting that a discrete population of sites may be susceptible to temperature degradation. However the B_{max} of ^{3}H-Ro binding is not temperature dependent, and the association time at 4° is slow, about 8 hr. If the tissue is incubated with ^{3}H-Ro at 4° for 16 hr, the binding becomes largely irreversible. After binding ^{3}H-Ro to cortical homogenates (4°) and thoroughly washing off the unbound ^{3}H-Ro, binding of ^{3}H-IMI is reduced by about 50%.

These results suggest that ^{3}H-Ro and ^{3}H-IMI label sites of similar characteristics with high affinity, and that ^{3}H-Ro may label a subpopulation of ^{3}H-IMI binding sites.

We thank Dr. W.P. Burkard for his gift of ^{3}H-Ro 11-2465. A. Dumbrille-Ross is supported by an Ontario Mental Health Foundation Studentship and Dr. S.W. Tang is an Ontario Mental Health Foundation Scholar.

10.7 PICROTOXIN BINDING SITES INTERACT WITH BOTH CATION AND ANION SITES IN BENZODIAZEPINE/GABA RECEPTOR COMPLEXES, R.F. Squires and E. Saederup*. Rockland Research Institute, Orangeburg, NY 10962.

Several picrotoxin-like convulsants increase the number of brain specific ^{3}H-flunitrazepam (^{3}H-FLU) or ^{3}H-CGS 8216 binding sites protected against heat inactivation (30 min, 60°C) in 200 mM NaCl. These convulsants include picrotoxin (EC_{50}=16 uM), anisatin (3.6), isopropylbicyclophosphate (15), isopropylbicyclophosphothionate (1.8), t-butylbicyclophosphate (4.4), tetramethylene disulfotetramine (51) and picrotoxinin (25). Picrotin was inactive at 100 uM. Picrotoxin decreased the concentration of NaCl required to provide 50% of its maximum protective effect and increased the Hill number for NaCl from 2 to 3. Hill numbers greater than one indicate positive cooperativity between separate binding sites, possibly for Na^+ and Cl^-, respectively. Picrotoxin (100 uM) and 5 mM $CaCl_2$ combined, but not individually, provide significant protection against heat inactivation, which is synergistically enhanced by 50 mM NaCl. Dialysis of rat brain P2 membranes, first against EDTA, then water, removes about 90% of the GABA which cannot be removed by dialysis against water alone. ^{3}H-FLU and ^{3}H-CGS 8216 binding site in such EDTA-water dialyzed membranes are partly protected against heat inactivation by GABA plus $CaCl_2$, but by neither substance individually. In the presence of 500 uM GABA, $CaCl_2$ provides 50% of its maximum protective effect near 600 uM. Mg^{2+}, Ba^{2+}, Sr^{2+} and Mn^{2+} also provide similar protection in the presence of GABA while eight other divalent cations were inactive. In the presence of 5 mM $CaCl_2$, ten GABA-A receptor agonists (β-aminopropane sulfonate, β-guanidinopropionate, imidazole acetate, muscimol, isoguvacine, piperidine-4-sulfonate, THIP, trans-4-amino crotonate, dihydromuscimol and d,l-beta-homoproline) can partly or entirely replace GABA with EC_{50} values in the 5-150 uM range. Using ^{3}H-FLU as radioligand, time courses of heat inactivation at 60°C in the presence of saturating $CaCl_2$ and GABA-A receptor agonists are polyphasic with slow components constituting about 45% of unheated control binding (Bo) for THIP, isoguvacine and P4S, 56% for imidazoleacetate, β-guanidinopropionate and aminopropane sulfonate, and 68% for GABA and muscimol, suggesting the presence of at least 4 subpopulations of BZ receptor complexes. Using ^{3}H-CGS 8216 the corresponding Bo value in the presence of 5 mM $CaCl_2$ and 500 uM GABA is 95%, suggesting that this ligand preferentially labels a subpopulation of ^{3}H-FLU binding sites. Picrotoxin does not modify the ability of GABA-A receptor agonists to enhance the protective effects of NaCl or $CaCl_2$. Taken together, these results indicate the presence of independent binding sites for cations, anions, GABA, picrotoxin and benzodiazepines in binding-site complexes.

10.8 LOCALIZATION OF RECEPTORS ON CHEMICALLY IDENTIFIED NEURONS IN CULTURE. Louis Terracio*, A.J. Beitz, W.E. Wells, and James Buggy (SPON: John J. Freeman). Depts. of Anatomy and Physiology, Univ. of S. Carolina, Colurbia, S.C., 29208.

The localization of specific receptors on chemically defined neurons within specific brain regions would be useful in addressing many problems in neurobiology. We have devised a technique using primary cultures of rat brain that permits characterization of neurons by immunohistochemistry and radiohistochemistry. Neuronal cells were isolated from 1-3 day old rat cerebellum (CER), brain stem (BS), and cerebral hemispheres (CH), using both mechanical and enzymatic digestion procedures. The isolated cells were plated at high density on glass coverslips with F12K plus 10% horse and calf sera and fed on days 4-7 in vitro with F12K-10HS-10CS plus 10mg/ml cytosine arabinoside. The resulting cultures from each of the three brain regions were composed of several populations of neuronal-like cells with few contaminating glial or fibroblast cells. Cultures from each region were first characterized immunohistochemically. Cultures of CH were tested for cholecystokinin (CCK)- and somatostatin (SOM)-like immunoreactivity. BS neurons were reacted with met-enkephalin (ME), serotonin (5HT) and neurotensin (NT) antisera, while CER cultures were reacted with angiotensin (AII) antisera. CH contained distinct populations of neurons that were positive for SOM and CCK. BS possessed neurons that were positive for 5HT, NT, and ME, while CER contained a population of neurons that had AII-like immunoreactivity. Receptor-binding autoradiography was performed using modifications of the procedure of Young and Kuhar (1979). Opiate receptors were demonstrated using ^{3}H-naloxone, β-adrenergic receptors (β-Ad) using ^{3}H-dihydroalprenolol (DHA) and muscarinic-cholinergic receptors (MCR) using ^{3}H-quinuclidinyl benzilate (QNB). β-Ad and MCR were demonstrated on neurons from all three regions. Opiate receptors were found on some neurons from BS and CH. The combined localization of peptides or neurotransmitters and receptors was accomplished for the ligands QNB and naloxone by first performing the radiohistochemical procedure followed by fixation of the cultures prior to immunohistochemistry. The fixation step did not retain DHA binding and therefore DHA radiohistochemistry was performed after immunohistochemistry. The results of this combined procedure indicate that in the CH cultures neurons could be found that had both SOM and β-Ad. In BS cultures there were neurons that possessed NT and opiates, NT and MCR and a few neurons with 5HT and opiates but no neurons with 5HT and MCR. The results of this study indicate that this combined technique may be a useful approach to characterizing neurons both chemically and pharmacologically from a variety of discrete brain regions.

10.9 BENZODIAZEPINE RECEPTORS ARE NOT EXCLUSIVELY LOCATED ON PURKINJE CELLS: A STUDY WITH THE PCD MUTANT MOUSE. F. M. Vaccarino*, B. Ghetti, M. A. Rea, and M. H. Aprison. Depts. of Psychiatry, Pathology and Biochemistry, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The benzodiazepine (BZ) action on the CNS has been linked to GABAergic mechanisms on the basis of biochemical and physiological evidence, however the distribution of the GABA and BZ receptors is not always parallel. In the cerebellar cortex of the mouse and rat, autoradiographic studies have shown that the BZ receptors are localized in the molecular layer, while GABA receptors are in the granular layer. To determine whether the binding noted in the molecular layer is associated only to Purkinje neurons and to measure the binding in a more quantitative manner, we used Purkinje cell degeneration (pcd) mutant mice. In these mice, Purkinje cells start to degenerate at 17 days of age until they are almost completely lost at 45 days. Granule cell loss begins after 50 days of age; morphological data in 1 year old pcd's indicate that more than 50% of the granule cells have degenerated. BZ binding in affected pcd mice, compared to control littermates, was measured at different ages with [^{3}H]Flunitrazepam (FNZ) and [^{3}H]ethyl β-carboline (BCC). Both ligands were employed at concentrations near to Kd. Since GABA and GABA agonists can increase the affinity at BZ receptors, we added Muscimol (10 μM) to maximally stimulate the latter receptors to avoid variations due to different levels of endogenous GABA. RO5-4864, an inactive BZ that binds to non-neuronal cells, is ineffective at 1 μM in displacing the above ligands, indicating that they are selective for neuronal cells. The binding data from affected pcd animals, 45 to 80 days old, show a 25% decrease for the two ligands; in animals 180 days old, the binding decreased by 45% for both ligands whereas in animals 300 days of age, FNZ and BCC binding decreased 50 and 60%, respectively. No difference in binding was detected at any age in the cortex and hippocampus of affected animals compared to controls. Scatchard analysis of BCC binding revealed that the above decreases were due to a loss of total receptor number without any change in their affinity. Scatchard plots of FNZ binding data appeared curvilinear, with a lower Bmax value in the affected animals. These results do not support an exclusive localization of BZ receptors on the Purkinje cell dendritic tree and suggest that this binding might also be associated with other cerebellar neurons (granule cells and/or neurons of the deep nuclei). -Supported in part by an International Rotary Foundation grant (F.M.V.) and a NIH research grant RO1-NS-14426 (B.G.).

10.10 SYNAPTIC LOCALIZATION OF SPECIFIC BINDING OF 125I-α-BUNGAROTOXIN IN THE RAT SUPERIOR CERVICAL SYMPATHETIC GANGLION. A. J. Smolen and T. Lindley*. Dept. of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

In the rat superior cervical sympathetic ganglion (SCG), α bungarotoxin (αBT) demonstrates binding that is saturable and inhibited by nicotinic ligands. However, αBT does not inhibit the physiological response of ganglionic neurons to preganglionic stimulation or to exogenously applied acetylcholine. Thus, the specificity of αBT for ganglionic nicotinic cholinergic receptors has been questioned. It has been proposed that in some regions of the central nervous system αBT may bind to cholinergic receptors without blocking transmission. To determine whether the morphological localization of the binding sites of αBT in the SCG is related to the distribution of cholinergic receptors sites, we undertook the present study.

Intact, desheathed SCGs were incubated for 30 min in 80nM 125I-αBT with or without 1mM of the nicotinic antagonist d-tubocurarine (d-TC). After the incubation, the ganglia were washed, fixed and assayed for bound radioactivity by gamma counting. These ganglia were subsequently processed for electron microscopic radioautography.

In the absence of d-TC, there was a total binding of 45 fmoles αBT/ganglion. With d-TC, the nonspecific binding was 18 fmoles/ganglion. The specific binding was calculated to be 28 fmoles/ganglion. For the electron microscopic analysis, a modification of the cross-fire method of Blackett and Parry was employed, in which the localization of real grains resulting from the non-specific and the specific binding was compared to a hypothetical grain distribution based on the geometrical properties of the tissue section. A computer minimizing routine was employed to adjust the relative weights of each of the potential sources of hypothetical grains until a "best-fit" with the real grain distributions occurred. The nonspecific binding of αBT was uniform across all tissue components, with the exception of a significant concentration on the membrane of the ganglion cell body. By contrast, the specific binding of αBT was highly localized to synaptic membranes and to a lesser extent to dendritic membranes.

The localization of the specific binding of αBT in the rat SCG is consistent with that of cholinergic receptors or with some other molecule located in the region of the synapse, and thus may be useful as a marker for the postsynaptic membrane.

10.11 AUTORADIOGRAPHIC LOCALIZATION OF HIGH AND LOW AFFINITY MUSCARINIC CHOLINERGIC BINDING SITES IN THE BRAIN AND SPINAL CORD. J. K. Wamsley, M. A. Zarbin* and M. J. Kuhar. Dept. of Psychiatry, Univ. of Utah, Salt Lake City, UT 84132 and Dept. of Neuroscience, Johns Hopkins Univ., Baltimore, MD 21205.

High and low affinity muscarinic cholinergic binding sites can be discriminated on the basis of their differing affinities for muscarinic agonists (Birdsall et al., Mol. Pharmacol., 14: 723, 1978). Autoradiographic techniques for the microscopic localization of receptors have been applied to differentially localize high and low affinity muscarinic cholinergic binding sites (Wamsley et al., Brain Res., 200: 1, 1980). We have now utilized this technique to map the distribution of high vs. low affinity muscarinic cholinergic binding sites throughout the brain and spinal cord.

Low affinity muscarinic cholinergic binding sites predominate in the forebrain. Such structures as the cortex, caudate-putamen, hippocampus, amygdaloid nuclei, and many of the structures in the thalamus and hypothalamus contain mostly low affinity sites. High affinity muscarinic sites could be identified in the medial septum, preoptic region, anterior hypothalamus, thalamic reticular nucleus, and in the lateral habenula. Clearly, the high affinity muscarinic cholinergic binding sites predominate in brainstem regions. Most of the muscarinic receptors identified in the superior and inferior colliculi, raphe nuclei, structures on the floor of the fourth ventricle, medial vestibular nucleus, cochlear nuclei, and in the facial and hypoglossal cranial nerve nuclei, were of the high affinity type. Low affinity muscarinic agonist binding sites predominate in the pontine nuclei and in the substantia gelatinosa of the spinal trigeminal nucleus. The most dramatic separation of high and low affinity sites was found in the spinal cord where only high affinity sites exist in the ventral horn and only low affinity sites are found in the dorsal horn.

Observations in the peripheral nervous system indicate the high affinity site is located in ganglionic cell bodies and is being orthogradely transported, whereas the low affinity site is localized in neuron terminals and is undergoing retrograde transport (Wamsley et al., Brain Res., 217: 155, 1981); Zarbin et al., J. Neurosci., in press). We hypothesize the same relationship may exist in the brain. The localization of high affinity sites in motor cranial nerve nuclei and in several white matter pathways in the brain, would support this hypothesis. High affinity muscarinic cholinergic sites may thus represent a marker for cholinergic cell bodies. These receptors diminish in the ventral horn of the spinal cord in patients with amyotrophic lateral sclerosis (Whitehouse et al., in preparation).

10.12 RECEPTOR-MEDIATED UPTAKE OF ACTH(1-24) IN RAT BRAIN SLICES. Frank S. LaBella, Gary Queen*, Douglas Stein* and Margaret Millar*. Dept. of Pharmacology and Therapeutics, Faculty of Medicine, University of Manitoba, Winnipeg, Canada.

(Phe^2, norleu^4)- ACTH(1-24) was labelled with 125I, and monoiodinated tyr^{23}- ACTH isolated by HPLC. Buckley et al (Endocrinol. 109:5, 1981) report that monoiodinated (phe^2, norleu^4)-ACTH(1-38) is as fully active as the natural peptide. Brain slices (0.2 x 0.2 x 0.6 mm) were incubated with 0.4 nM labelled ACTH in Krebs-Ringer-bicarbonate at 37°, in the presence or absence of competing ligands. The slices were filtered on a nylon screen, washed with cold buffer, scraped from the screen and dissolved in KOH. Aliquots were analyzed for 125I and protein. Specific binding was resolved into two components, one with Kd 50 nM and another, Kd 5 uM. Specific binding of ACTH to slices reached a maximum at 1 hr, was enhanced by added glucose, and reduced by 80% in the presence of ouabain, NaF, or dinitrophenol. Dissociation of ACTH was 50% complete at 30 min in metabolically inhibited slices and only 30% at 2 hr in non-inhibited tissue, suggesting metabolically dependent sequestration (internalization?) of specifically bound ACTH. The number of high affinity binding sites for ACTH in whole brain, estimated in the presence of inhibitors of sequestration, was 0.4 pmol/mg protein, and 16 pmol/mg protein for the low affinity sites. Specific binding of ACTH in decreasing rank order: hypothalamus, striatum, hippocampus, cerebral cortex, cerebellum, midbrain, brainstem. Potency of ACTH fragments in displacing ACTH(1-24) in decreasing rank order: 1-24, 11-24, 1-10, 4-10. This order of fragment potencies is similar to that found by us for binding of ACTH(1-24) to dispersed adrenal cells. Of a large number of opiate drugs and hormonal peptides, only metenkephalin and, to a lesser extent, beta-endorphin competed with ACTH(1-24). Snell and Snell (FEBS Lett. 137:209, 1982) have pointed to structural similarities between the N-terminal region of ACTH and the receptor conformation of enkephalin. Rat liver slices showed about one-third the level of specific binding estimated in brain, whereas none was detected in slices of heart, kidney, spleen, lung and intestine. The brain slice preparation has the potential to yield information on the turnover of ACTH receptors, receptor density on the neuron membrane, and receptor coupling to the biological transducer. This slice system promises, also, to provide information on the molecular basis for a putative role of ACTH in tolerance and dependence to opiates which may not be available from studies with brain homogenates or membranes. (Supported by MRC of Canada).

11.1 LESIONS OF CEREBELLAR NUCLEI ABOLISH THE CLASSICALLY CONDITIONED NICTITATING MEMBRANE RESPONSE. C.H. Yeo*, M.J. Hardiman*, M. Glickstein and I. Steele Russell*. MRC Unit on Neural Mechanisms of Behaviour, 3 Malet Place, London WC1E 7JG, U.K.

Extensive lesions of the cerebral cortex do not impair acquisition or retention of the classically conditioned nictitating membrane response (NMR) of rabbits (Oakley and Russell, Phys. Behav. 18: 931-937, 1977). A possible subcortical pathway is suggested by a recent study (McCormick et al. Bull. Psych. Soc. 18, 103-105, 1981) in which lesions of cerebellar cortex abolished the ipsilateral conditioned NMR.

The output of the cerebellum is exclusively via the deep cerebellar nuclei, so lesions of these nuclei alone should abolish the conditional response. We trained rabbits on daily sessions of 200 trials using 500 msec conditional stimuli of light or white noise interspersed in blocks through the session to give 100 daily trails of each. The unconditional stimulus was a brief, paraorbital electrical shock.

18 rabbits were pretrained with five sessions giving the shock to the right side. They were then subjected to suction or radio-frequency lesions of the right cerebellar nuclei, or control areas. Subjects were then given five training sessions to the right (ipsilateral) side followed by five sessions to the left (contralateral) side.

In six cases the lesion abolished conditional responses on the side ipsilateral to the lesion. All animals were unaffected contralaterally and unconditional responses were normal on both sides. Animals with abolished conditional responses had extensive damage to the interposed nuclei accompanied by some damage to medial parts of the dentate nucleus and small areas of overlying paramedian lobe. Damage to paramedian lobe and/or dentate nucleus alone failed to abolish conditioning.

We suggest that the interposed nucleus is a critical structure for NMR conditioning. If the cerebellar cortex is involved, then the relevant portion is most likely to be contained within the division C of Voogd.

11.2 EFFECTS OF ELECTROLYTIC LESIONS OF CEREBELLAR NUCLEI ON CONDITIONED BEHAVIORAL AND HIPPOCAMPAL NEURONAL RESPONSES. G. A. Clark*, D. A. McCormick*, D. G. Lavond*, K. Baxter*, W. J. Gray* and R. F. Thompson (SPON: K. A. Sigvardt). Dept. of Psychol., Stanford Univ., Stanford, CA 94305.

A critical issue for the biology of learning concerns the identification of brain structures essential for learning to occur. We report here that unilateral lesions of dentate and interpositus cerebellar nuclei abolish conditioned but not reflexive nictitating membrane (NM) responses in trained rabbits.

Rabbits were trained with standard procedures for classical conditioning of the NM response: a 350 msec tone conditioned stimulus (CS) was paired with a 100 msec airpuff to cornea, which elicited NM extension. Interstimulus interval was 250 msec, with a variable intertrial interval of 30 sec. Animals were trained to a behavioral criterion of eight conditioned responses out of any nine consecutive trials, then given one day of further training. Electrolytic lesions (2mA, 5 min.) were then made through mono- or bipolar electrodes previously implanted in dentate and interpositus cerebellar nuclei ipsilateral to the trained (left) eye. Animals were subsequently given four days of retraining, as well as a fifth session in which training was switched to the contralateral (right) side for the first half of the day, then switched back to the original (left) side.

In all animals (n=12) with damage to deep nuclei and surrounding fibers, lesions caused complete or near-complete abolition of conditioned responses on the ipsilateral side ($p < .001$). In contrast, lesions did not effect the amplitude of unconditioned responses to airpuff, indicating lesion effects were not due simply to motor disturbances or performance variables. When training was switched to the contralateral (right) eye, animals learned within the first few trials ($\bar{x} = 6$), but did not relearn when training was returned to the left (lesioned) side (cerebellar connections with other structures are primarily unilateral). The fact that animals learned the contralateral response so quickly rules out nonspecific lesion effects. Control animals in which lesions spared the deep nuclei showed no memory deficits.

Recordings of hippocampal neuronal unit activity during training indicated that nuclear lesions also abolished conditioned increases in neural activity normally evoked by the CS in this paradigm. As with the behavior, training on the contralateral side reinstated the conditioned neuronal response within the first few trials of training.

Present and previous studies thus indicate that disruptions of cerebellar circuitry at several points--cerebellar cortex, deep nuclei, and superior cerebellar peduncle--all abolish conditioned NM responses. Such convergence argues strongly that it is the cerebellum itself which is essential for the learned response.

11.3 BEHAVIORAL EFFECTS OF HIPPOCAMPECTOMY DEPEND ON INTER-EVENT INTERVALS. J.N.P. Rawlins*, J. Feldon* and J.A. Gray* (SPON: C. Blakemore). Dept. of Experimental Psychology, University of Oxford, South Parks Road, Oxford OX1 3UD, England.

Large hippocampal lesions abolish the partial reinforcement extinction effect (PREE) in the straight alley, when 48 acquisition trials are given at 6 trials/day with an intertrial interval (ITI) of 4-8 minutes (Rawlins, J.N.P., Feldon, J. and Gray, J.A., Exp. Brain Res., 38:273, 1980). The development of a PREE depends in part upon the animal's ability to remember on a rewarded trial that he was recently non-rewarded (e.g. Capaldi, E.J. and Minkoff, R., J.Exp.Psychol., 81: 56, 1969). The present experiments reduced the time over which the rats were required to associate events. In one experiment on the PREE, the ITI was reduced to a few seconds. A second experiment directly paired non-reward and reward by presenting a reward only after a delay in the goal box on 50% of acquisition trials, and measured the increased resistance to extinction that this produces (the partial delay extinction effect).

Rats with large hippocampal lesions (HC), or cortical control lesions (CC), or rats having had sham operations (SO) were trained to run down a 170cm straight alley for food. 48 acquisition trials were used at 6 trials per day. In experiment 1, the rats were rewarded on a random 50% of trials. On rewarded trials the rats were confined in the goal box while they consumed the food, and were then replaced in the startbox for the next trial. On non-rewarded trials the rats were confined in the goal box for an equivalent time, and then replaced in the startbox. The ITI was thus less than 3 seconds. In experiment 2 the rats were confined as before on rewarded trials, and then replaced in a waiting box. On delay trials, the rats were confined without food as for the non-reward trials in experiment 1, but food was then dropped via a tube into the goal cup. The ITI was 4-8 minutes, spent in a waiting box.

Both the partial reinforcement and the partial delay schedules used produced an increase in resistance to extinction, which was not blocked by hippocampectomy. This is consistent with the view that hippocampal damage does not prevent the formation and use of associations, so long as the interval between the events which must be associated is short enough. However hippocampectomy may retard the formation of associations between events which are separated by longer inter-event intervals.

J.N.P. Rawlins is Henry Head Research Fellow of the Royal Society, supported by the U.K. Medical Research Council, and the European Training Programme in Brain and Behaviour Research.

11.4 SELECTIVE KAINIC ACID LESIONS OF THE HIPPOCAMPAL FORMATION: EFFECTS OF SUBICULUM VS. CA3 CELL LOSS ON PLACE AND CUE LEARNING. Leonard E. Jarrard. Dept. of Psychol., Washington & Lee Univ., Lexington, VA 24450.

Recent research demonstrating different behavioral effects resulting from selective damage to either hippocampal cell fields or projections prompted the present investigation of the effects of damage to CA3 cell field or subiculum on performance of a complex place and cue task. Using a within-subjects design, rats were trained before the operations to run on an 8-arm radial maze with a procedure that involved two kinds of learning (place and cue) and two memory functions [reference memory (RM) and working memory (WM)]. In the place version of the task the same 4 arms were baited from trial to trial and room cues (door, rack of cages, overhead lights) remained in the same spatial location. In the cue task 8 removable inserts of different materials were placed in the arms but the location was changed from trial to trial in a random order -- 4 of the 8 cues were consistently baited.

After learning the tasks the rats were divided into two control groups (operated and unoperated) and 4 lesion groups. Kainic acid (KA) was injected bilaterally into either the CA3 cell field, the subiculum, or the lateral ventricles. Rats in the remaining group received extensive damage to the hippocampus (including all cell fields, dentate gyrus, and fimbria) using an aspiration technique. Following recovery the animals were retrained to approach the last 4 arms (and 4 cues) that had been learned before the operations, and then reversal training was carried out.

Analysis of the behavioral data indicated an impairment on the place task but not the cue task in animals with subiculum cell loss and those with extensive damage to hippocampus. Even though rats in the CA3 Group suffered extensive loss of pyramidal cells in the CA3 cell field, their performance did not differ from controls on either the place or cue task. Rats receiving intraventricular injections of KA were impaired on both tasks but were able to relearn to successfully perform the cue task. Analysis of the error data broken down by error type indicated no differences between RM and WM for any of the groups.

These results will be discussed as they relate to current theories of hippocampal function.

11.5 SEVERE RECOGNITION IMPAIRMENT AFTER COMBINED BUT NOT SEPARATE TRANSECTION OF THE FORNIX AND THE AMYGDALOFUGAL PATHWAYS. J.Bachevalier*, J.K.Parkinson, J.P.Aggleton and M.Mishkin (SPON: K.Macko). Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Two relatively independent limbo-diencephalic systems appear to contribute equally to recognition memory in the monkey (Mishkin and Saunders. Neurosci.Abstr. 5:1979). One is a hippocampo-diencephalic system interconnected by the fornix (Fx) and the other is an amygdalo-diencephalic system interconnected by amygdalofugal pathways (AFP) including both the ventral amygdalofugal pathway and the stria terminalis. To test further the postulated equivalence of these two parallel systems in recognition memory, we examined the effect of limbo-diencephalic disconnection on monkeys' visual memory by transecting the two pathways either alone or in combination.

Twelve cynomolgus monkeys were trained preoperatively in a one-trial recognition task in which they were required to distinguish a completely novel object from a sample object presented 10 sec previously (delayed nonmatching-to-sample). After achieving the criterion of 90 correct responses in 100 trials, three monkeys each underwent bilateral transection of either Fx, AFP, both, or neither. Fx transections were made by aspiration through a slit in the corpus callosum, while AFP transections were made by aspiration through dorsal amygdaloid tissue via an orbitofrontal approach. Following reattainment of criterion, the animals were given a performance test with longer delays (30 to 120 sec) and list lengths (3 to 10 objects). Whereas scores of the normal monkeys on this performance test ranged from 89 to 93%, and those of the monkeys with Fx or AFP transections were only slightly lower (range: 84-93% and 84-94%, respectively), the mean performance score of monkeys with combined Fx and AFP transections fell sharply (range: 69-74%). Histological examination indicated that the AFP lesions resulted in ischemic damage to part of the amygdaloid complex, and thus they cannot be characterized as transections only. Nevertheless, the additional damage to the amygdala yielded an impairment no more severe than that seen after Fx transection and was not sufficient by itself (AFP group) to produce the substantial memory deficit observed when a Fx transection was superimposed (Fx + AFP group).

The results suggest that disconnection of both the amygdala and the hippocampus from the diencephalon by combined transection of their diencephalic connections results in a memory impairment similar to (though less severe than) that following combined damage to the limbic structures themselves. The data thus provide additional evidence for the complementary participation of amygdalo-diencephalic and hippocampo-diencephalic circuits in recognition memory.

11.6 AMYGDALECTOMY BUT NOT HIPPOCAMPECTOMY IMPAIRS CROSS-MODAL DELAYED NONMATCHING-TO-SAMPLE IN MONKEYS, E. A. Murray and M. Mishkin. Lab. of Neuropsychology, NIMH, Bethesda, MD 20205.

After extensive pre- and post-operative testing on delayed nonmatching-to-sample (DNMS) in the tactual modality and, separately, in the visual modality, cynomolgus monkeys with ablations of either the amygdaloid complex or the hippocampal formation were tested on cross-modal DNMS. In the cross-modal task the animals were required first to touch and displace in the dark a sample object overlying the baited central well of a three-well testing board (sample presentation). Then, 10s later, the monkeys were presented with the sample object plus another one overlying the two lateral wells, but now in the light (test); the animals could obtain a reward by displacing the object that had not been touched 10s before, but they had to select it visually because a response was scored the moment either object was first touched. The animals were tested with a fixed set of 40 tactually distinctive objects that were randomly paired daily. These were the same objects that had been used in the pre- and post-operative intramodal DNMS testing, both in the light and in the dark (Murray and Mishkin, Neurosci. Abstr., 7: 237, 1981).

Although both groups of animals had previously achieved a high level of performance on each of the intramodal DNMS tasks with 10s delays between sample presentation and test (amygdalectomy: 90% and 98% correct responses in touch and in vision, respectively; hippocampectomy: 92% and 99% correct responses in touch and in vision, respectively), the performance of the two groups differed markedly on the cross-modal DNMS task. Monkeys with bilateral hippocampectomy performed well on the tactual to visual DNMS, averaging 88% correct responses across 500 trials. In contrast, monkeys with bilateral amygdalectomy averaged only 57% correct responses across the 500 trials. For both these groups there was little improvement with training; monkeys performed at about the same level over the last block of 100 trials as they had over the first block. These results suggest that amygdalectomized but not hippocampectomized monkeys are impaired in either (i) the ability to form an association between stimuli of different sensory modalities even though they are derived from the same external object or (ii) the ability to recall an object in one sensory modality given an input or trigger stimulus in another modality. These findings have broad theoretical import regarding the role of the amygdaloid complex in associative memory. Although it had been shown earlier that the amygdala is important for either forming or recalling object-reward associations (Speigler and Mishkin, Behav. Brain Res., 3: 303, 1981), the present results suggest that in fact the amygdala may be critical for the formation or recall of sensory-sensory associations in general.

11.7 A SELECTIVE MNEMONIC ROLE FOR THE HIPPOCAMPUS IN MONKEYS: MEMORY FOR THE LOCATION OF OBJECTS, J. K. Parkinson* and M. Mishkin. Lab. of Neuropsychology, NIMH, Bethesda, MD. 20205.

Six cynomolgus monkeys were trained by approximation to remember the particular locations occupied by particular objects on the basis of a single acquisition trial. Testing was conducted with trial-unique objects and a three-well stimulus tray in a Wisconsin General Testing Apparatus. In the final phase of preoperative testing, two different unbaited sample objects were presented on two wells selected at random, and the animal was required to displace both objects in order to receive a baited test trial 12 seconds later. On this test trial, one of the two previously presented samples was presented again on the well it had covered in the acquisition trial, while an exact duplicate of this object was presented either (a) on the other well that had been covered during acquisition or (b) on the third, previously uncovered, well. Choice of the sample object in its original position was rewarded. In the case of test trial (b) correct choice required memory of location only, whereas in test trial (a) it required memory of both the object and its location. There were 12 possible combinations of stimulus settings across acquisition and test trials, and each combination was presented twice daily for a total of 24 test trials per day.

After 25 days of testing on this final design, the six animals were divided into two groups of three matched on the basis of their preoperative performance and given bilateral ablations of either the amygdaloid complex or the hippocampal formation. Ten days postoperatively, the animals were retested on the final design of the task. The amygdalectomized monkeys reattained their preoperative performance levels of about 80% correct responses within 25-40 sessions. By contrast, the hippocampectomized monkeys continued to perform at chance levels through 75 sessions, the maximum presented. The scores for test trials (a) and (b) were about the same for a given animal at a given stage, suggesting that under the conditions of this experiment the animals treated the object and its location as a unit.

The present results contrast with previous findings both on object recognition, where hippocampal and amygdaloid lesions were found to yield equivalent though mild effects, and on object-reward association, where amygdaloid lesions were found to yield more severe effects than those of hippocampal lesions. The overall pattern of results suggests that the hippocampus in the monkey contributes selectively to the rapid memorization of the locations of objects.

11.8 SPATIAL MEMORY AND LONG-TERM RETENTION FOLLOWING MAMMILLARY BODY LESIONS IN MONKEYS. E.J. Holmes, S. Jacobson, B.M. Stein* and N. Butters. Lab. for Neurosurg. Neurobehav. Res., Boston VA Medical Ctr., Boston, MA 02130.

Although most of the experimental evidence indicates that surgical destruction or disconnexion of the mammillary nuclei does not affect the retention of information acquired before surgery, the dispute as to whether the mammillary nuclei are or are not key structures involved in the short-term retention of new information remains, for the most part, unsettled. It also remains unclear as to whether subjects with mammillary body (MB) lesions are more prone than intact control subjects to a retention loss of the solution to a previously acquired task following a prolonged period of time without practice. In the following study, we attempted to at least partially resolve these two questions.

The subjects were nine cynomolgus monkeys (M. fasicularis), all of which were equal in their previous training experience. Using a direct sub-temporal approach to the hypothalamus, three subjects had previously received bilateral lesions of the mammillary bodies, three subjects received surgical control lesions for the sub-temporal approach, and three subjects remained unoperated. In a previous experiment, all of the subjects had been trained on a delayed alternation (DA) task in which they were required to alternate responses between left and right reward sites from trial to trial with a 5 second delay between trials. The subjects were trained on the DA task for 50 trials per day until they reached a learning criterion of 90 correct responses in 100 consecutive trials. Approximately one year after initial training, the subjects were again trained to criterion on the DA problem as before, after which the demand on short-term memory in the task was increased by inserting a delay of 30 secs. between trials in place of the previous 5 secs.

In the first part of the experiment, all three groups were able to reattain criterion performance on the 5 sec. DA task with relative ease. That is, even after a time lapse of 12 months, the subjects with mammillary body (MB) lesions did not differ significantly from either the intact or operated control animals in relearning the original DA task. In the second part of the experiment, however, the subjects with MB lesions showed marked difficulty in attaining the new DA task which utilized a 30 sec. intertrial interval. Moreover, the performance of the MB lesion group was in marked contrast to the two control groups which displayed little or no difficulty in adapting to the increased delay. Hence, the results indicate that the mammillary nuclei in nonhuman primates play a significant role in the ability to retain or process information in short-term spatial memory, although these nuclei do not appear to be involved in the long-term retention of a previously acquired spatial skill.

11.9 TWO FORMS OF AMNESIA IN MONKEYS: RAPID FORGETTING AFTER MEDIAL TEMPORAL LESIONS BUT NOT DIENCEPHALIC LESIONS. S. Zola-Morgan,* and L.R. Squire. (SPON: R. Loy). VA Medical Center, San Diego, CA 92161 and Dept. of Psychiatry, UCSD Sch. of Med., La Jolla, CA 92093.

It has been known for a long time that amnesia can occur after damage in two different brain regions, the diencephalon and the medial temporal region. Recently, it has been suggested that diencephalic and bitemporal amnesia might be fundamentally different entities (Huppert and Piercy, 1978; 1979; Squire, 1981). These studies used a method designed to minimize the difficulty of comparing forgetting rates between normal and amnesic groups that already differ in level of acquisition, and demonstrated that amnesic patients with diencephalic damage exhibited a normal rate of forgetting, while those with bitemporal dysfunction exhibited an abnormal rate of forgetting. These results support a scheme for classifying amnesia based on behavior and the presumed underlying neuropathology. However, no neuropathological information for any of the amnesic cases is available. Studies using monkeys with circumscribed lesions of the critical brain areas could provide direct evidence for an association between nature of amnesia and site of lesion.

Monkeys with bilateral conjoint removal of the hippocampus and amygdala (A+H=4), those with bilateral medial thalamic removal including dorsomedial nucleus (DM=4), and a group of normal control monkeys (N=3) were first trained on the delayed non-matching-to-sample task, which is sensitive to amnesia in humans. On this task all groups received only single exposures to the sample stimulus. Next, following a procedure analogous to that used in the human studies, operated monkeys received repeated exposures to the sample stimulus in order to equate their retention performance to that of normal monkeys at 10 min after training (A+H: 12 exposures; DM: 10 exposures; N: 1 exposure). Forgetting was then assessed at 1 hr and 24 hr after acquisition. Our findings paralleled those observed in human amnesia. While both operated groups were impaired in the single exposure condition, in the multiple exposure condition monkeys with A+H lesions exhibited rapid forgetting while the monkeys with DM lesions exhibited normal forgetting rates. The results confirm the hypothesis that medial temporal and diencephalic brain regions normally contribute in different ways to the formation of memory. The significance of these findings to the development of an animal model of amnesia will be considered.

11.10 COMPARISONS AMONG FORMS OF AMNESIA: SOME DEFICITS ARE UNIQUE TO KORSAKOFF SYNDROME. L.R. Squire, N.J. Cohen,* and S. Zola-Morgan,* VA Medical Center, San Diego, CA 92161, Dept. of Psychiatry, UCSD Sch. of Med., La Jolla, CA 92093 and Dept. of Psychology, MIT, Cambridge, MA 02139

Certain features of abnormal memory, which have figured prominently in theoretical treatments of the amnesic syndrome, were assessed in patients with Korsakoff syndrome, case N.A., and patients receiving electroconvulsive therapy (ECT). Patients with Korsakoff syndrome differed from the other patients by 1) failing to exhibit release from proactive interference (PI); and 2) being disproportionately impaired in the ability to make judgments about the temporal order of recent events.

A number of considerations suggested that these deficits might be related to frontal lobe damage, and be superimposed upon a more basic memory disorder. To explore this possibility, three tests sensitive to frontal lobe dysfunction (card-sorting, word fluency, and an embedded figures test) were given to the Korsakoff patients and to case N.A., two examples of diencephalic amnesia. Whereas N.A.'s performance on these tests was average or above-average, the Korsakoff patients were impaired. Moreover, there was a significant correlation (r=.79) between their performance on the three tests sensitive to frontal lobe dysfunction and performance on those aspects of the memory tests purported to reflect frontal lobe dysfunction (the tendency to release from P.I. and the ability to make temporal order judgments). By contrast, there was not a significant correlation (r=.14) between their performance on these three tests and performance on those parts of the memory tests that gave difficulty to all the amnesic patients (trials 1-4 of the 5-trial P.I. test and recognition memory). These results indicate that the Korsakoff syndrome is unique to some extent, in that this syndrome is associated with cognitive deficits that occur together with amnesia and that can determine its character. Presumably critical diencephalic lesions, which cause the memory disorder, occur in this syndrome together with frontal lobe dysfunction. The frontal lobe dysfunction appears to superimpose additional cognitive deficits upon the basic memory disorder. Theories of amnesia, and inferences from amnesia about the organization of memory in the brain, must distinguish between the basic memory disorder in amnesia and other deficits that have no obligatory relationship to the basic disorder.

11.11 THE EFFECT OF PERIARCUATE AND PRINCIPALIS LESIONS ON THE PERFORMANCE OF A MOTOR CONDITIONAL ASSOCIATIVE-LEARNING TASK. Michael Petrides* (SPON: B. Milner). Dept. of Psychology and the Montreal Neurological Institute, McGill Univ., Montreal, Quebec, Canada, H3A 2B4.

It has been shown that patients who have sustained unilateral excisions from the frontal cortex are severely impaired in mastering conditional associative-learning tasks (Petrides, M. cited in Milner, B. Philos. Trans. R. Soc. Lond., in press). The frontal lobe is a large and heterogeneous area as shown by a number of neuroanatomical and behavioral investigations. Determining the critical area within the frontal lobe that gives rise to these deficits is difficult in work with patients because the therapeutic excisions overlap to a considerable extent. This problem can, of course, be overcome with experimental animals. The experiment reported here investigated the effect of selective frontal-lobe lesions in the monkey on a test modelled on one of the tasks used with patients.

Ten adult rhesus monkeys (Macaca mulatta) were used. Three animals served as unoperated controls. Three animals received bilateral ablations of the cortex lying within the sulcus principalis and the cortex lying immediately above it, and four animals received bilateral ablations of the periarcuate region.

In the main experiment, the monkeys were faced with a box covering the foodwell. The box had two manipulanda attached to it: a stick the monkey could grip and a button he could touch. After mastering these two movements, the monkeys were required to learn to perform one of the movements when object A was shown and to perform the other movement in the presence of object B. The objects were shown behind the test-board and outside the monkey's reach (at a distance of 26 cm). The periarcuate monkeys were severely impaired in learning to select the correct movement in response to the appropriate stimulus. In contrast, animals with lesions to the sulcus principalis region showed only a mild retardation in learning the task.

In a control task, the monkeys were trained to respond by gripping the stick when one object was shown but not to respond to the other object. There were no differences between the groups on this and various other control tasks requiring discrimination between stimuli similar to the ones used in the main experiment. In addition, the monkeys had learned the two movements before testing began and continued to perform both movements equally well throughout testing. These facts suggest that the deficit of the periarcuate monkeys cannot be reduced to a difficulty in discriminating between the stimuli or producing the responses. It appears, instead, to reflect an inability to learn to select consistently the correct movement in the presence of the appropriate stimulus.

11.12 PICTURE ENCODING IN THE AMNESIC PATIENT H.M. Elizabeth Grove,* Mary C. Potter,* and Suzanne Corkin (SPON: W.J.H. Nauta). Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139

Although it has been suggested that amnesic patients are deficient in the encoding of new information, their capacity to perform deeper level processing has been tested only with verbal material (Butters and Cermak, 1980; Corkin, 1982). Thus, it is not known whether memory impairment with nonverbal information is associated with an encoding deficit for that material. The present study used a procedure for assessing the conceptual processing of pictures, based on a task developed by Potter (1975,1976). This test was given to the patient H.M., who has been severely amnesic for both verbal and nonverbal material since undergoing a bilateral resection of medial temporal structures in 1953 (Scoville and Milner, 1957; Milner, Corkin and Teuber, 1968; Corkin, Sullivan, Twitchell and Grove, 1981).

H.M. and normal, age-matched control subjects were shown sequences of 16 color photographs at rates of 125, 167, and 250 msec per picture. In each sequence, subjects were asked to detect a target picture that had been specified in advance by presenting either the picture itself or a brief title for the picture (e.g., "people dancing"). In the picture-target condition, the viewer could select the target on the basis of physical features alone. In the name-target condition, detection depended on identifying the subject of each rapidly presented picture, in order to match it with the title. Each picture could be processed only while it was in view, since it was subject to visual and conceptual masking by the next picture in the sequence (Potter, 1976). H.M.'s ability to detect target pictures did not differ significantly from that of control subjects in either target condition, or at any rate of presentation. His normal performance with named targets indicated that he could process pictures at a conceptual level as rapidly as normal subjects his age. A second experiment compared the performance of H.M. and control subjects on a test of recognition memory. Two sequences of 16 pictures were presented at 500 msec per picture, a rate at which it is likely that all pictures were processed conceptually. A two-alternative forced-choice recognition test was administered immediately after the presentation of each sequence. Although control subjects recognized over 80% of the pictures, H.M.'s performance was at chance.

These results suggest that a severe impairment in memory for pictures can coexist with a normal capacity for processing pictures at a conceptual level. Experiments in progress are investigating possible distinctions between H.M. and patients with Korsakoff's syndrome in the encoding of new visual information.

11.13 CHRONIC GLOBAL AMNESIA AFTER RUPTURED ANEURYSMS OF THE ANTERIOR COMMUNICATING ARTERY. Neal J. Cohen* and Suzanne Corkin (SPON: William H. Sweet). Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139

Chronic global amnesia occurs as a result of lesions in either of two brain regions and possibly others: the medial portion of the temporal lobe, as seen in cases of encephalitis, anoxic encephalopathy, posterior cerebral artery occlusion, and surgical removal (i.e., the noted patient, H.M.); and the diencephalic midline, as seen in cases of Korsakoff's syndrome and third ventricle tumor. Although amnesias differing in etiology have traditionally been thought to comprise a single amnesic syndrome, careful neuropsychological assessment in recent years has demonstrated important differences in the severity and nature of memory impairments and in the presence of non-mnemonic deficits. An examination of the anatomical findings in relation to behavioral symptoms in patients with global amnesia enriches our understanding of the neurology and taxonomy of memory and memory disorders. Mild global amnesias sometimes accompany ruptured aneurysms of the anterior communicating artery. These amnesias are not well understood with respect to either their anatomical or behavioral correlates. In the present paper, we report preliminary findings on the status of cognition and affect in a group of such patients.

The group included 6 men, aged 48 to 61, and 1 woman, aged 37, who were examined 4 months to 18 years after rupture of an anterior communicating artery aneurysm. Neurological examinations revealed no deficits in 5 of the 7 patients. Of the two remaining patients, one had grasp reflexes bilaterally, and the other had a slight droop on the left side of the mouth. A review of the medical histories and psychiatric evaluations suggested personality change and loss of motivation following operation. The assessment of non-mnemonic cognitive functions showed a sparing of overall intelligence (Full Scale I.Q. range: 104-130), but an impairment of cognitive functions of the frontal lobes, including problem solving and verbal recency-discrimination. Memory-test results verified the clinical observations of a mild global amnesia. Measures of remote memory capacities indicated a brief retrograde amnesia. Tests of the ability to learn new material revealed deficits in recall or recognition of both verbal and nonverbal stimulus items after a delay, including memory for wordlists, prose passages, recurring verbal and nonverbal material, and complex geometric shapes. By contrast, capacities for perceptual and cognitive skill learning were intact. These findings contribute to our understanding of the patterns of deficit that characterize and differentiate amnesic syndromes.

12.1 THE FATE OF HOST AXONS IN NERVE ALLOGRAFTS AFTER ABOLISHING TOLERANCE IN RATS. A.A. Zalewski. Laboratory of Neurochemistry, NINCDS, NIH, Bethesda, MD 20205.

Nerve allografts (grafts between genetically different animals of the same species) are rejected by normal rats but not by rats that have been rendered immunologically tolerant to donor histocompatibility antigens. Since in such tolerant animals allogeneic Schwann cells survive and myelinate host axons, it was of interest to abolish tolerance and determine what would happen to the host axons when the allogeneic cells supporting them were now rejected. Inbred Lewis (LE) and Brown Norway (BN) rats which exhibit major and minor tissue histoincompatibilities were used. Normal LE and LE rats tolerant to BN antigens received 4 cm long BN nerve grafts. Normal rats rejected their allografts whereas the entire 4 cm allograft survived at three months in tolerant hosts. The allografts in tolerant animals had numerous host axons throughout, and they were myelinated presumedly by allogeneic Schwann cells. Tolerance was abolished (by the inoculation of LE lymphoid cells that were sensitized to BN antigens) in rats that had bilateral BN nerve grafts in residence for three months. Examination of one BN graft from twelve different hosts, four weeks after the immune cell transfer, revealed that the BN graft was rejected. All these grafts were virtually acellular and lacked axons except in their proximal portion where it appeared that the host axons were attempting to regrow through the connective tissue remnants of the rejected allograft. The extent of this second host axonal growth was investigated in the other BN nerve after five more months, and it was found that regeneration proceeded only for 1-1.5 cm. The distal portion of the rejected nerve apparently underwent autolysis and disappeared. It is concluded that viable allogeneic cells (Schwann, fibroblast, vascular) together with their connective tissue matrix provided the best way to aid host nerve fiber regeneration through a long nerve allograft.

12.2 EFFECT OF A NERVE CONDITIONING LESION ON THE RATE OF NEWT LIMB REGENERATION. C. E. Maier* and I. G. McQuarrie. Dept. of Anatomy, Sch. of Med., Case Western Reserve University, Cleveland, OH 44106.

Forelimb regeneration in the newt is a nerve-dependent phenomenon. We have employed a nerve conditioning lesion (CL) in an attempt to accelerate limb regeneration by accelerating nerve regeneration. The CL effect is obtained by making an axotomizing nerve lesion, waiting 2 weeks, and making a second or testing lesion (TL) proximal to the CL. This results in an earlier appearance of regenerating axonal sprouts and an increase in their rate of elongation compared to that seen after a TL alone (McQuarrie & Grafstein, Brain Res., 216: 253, 1981).

A CL was made on the 3 major nerves of one forelimb at the elbow joint. Two weeks later, bilateral TLs were made by amputating through the mid-humerus. Daily single-blind observations of experimental and control limbs were made to record the progress of regrowth as determined by an established staging system (Singer, Quart. Rev. Biol., 27: 169, 1952). (To ensure that the contralateral control was appropriate, contralateral sham CLs were employed in some groups.) Our results showed that limb buds on the CL side completed the earliest ("accumulation") phase of regeneration approximately 4 days (15-20%) sooner than contralateral controls, apparently because limb bud formation was initiated 4 days sooner than normal.

The extent of reinnervation in early limb buds was determined 2 weeks after amputation by counting silver-stained axons in serial cross-sections of the forelimb. The number of axons per $100\mu m^2$ of limb cross-section was determined at 750μm proximal (parent axons) and 250μm distal (daughter axons) to the amputation site. In a pilot study, the number of axons per $100\mu m^2 \pm$ SD was 5.14 ± 1.15 (daughter) and 4.70 ± 1.76 (parent) on the control side, and 12.80 ± 4.53 (daughter) and 4.67 ± 1.62 (parent) on the CL side. Thus, the ratio of daughter to parent axons was 2.5X greater when the amputation was preceded by a CL. This indicates that reinnervation of the limb bud occurs more rapidly if the neurons that were axotomized by amputation had been conditioned for growth. Thus, the threshold level of innervation that is required for the initiation of limb bud formation (Singer, Rzehak and Maier, J. Exp. Zool., 166: 89, 1967) would be reached sooner, accounting for the earlier onset of limb bud formation that we observed.

12.3 OBLIGATORY ROLE FOR POLYAMINES IN THE RESPONSE OF SYMPATHETIC NEURONS TO AXOTOMY. G.M. Gilad, Isotope Department, Weizmann Institute of Science, Rehovot, Israel

Recently, we have demonstrated that ornithine decarboxylase (ODC) activity - an indicator for polyamine biosynthesis - is rapidly enhanced within nerve cell bodies in the superior cervical ganglion (SCG) of adult rats after axotomy. This is the earliest biochemical change so far detected during the axon reaction. Presently we sought to determine: (a) whether the ODC response is specifically associated with the axon reaction or is it a nonspecific change associated with metabolic alterations of the neuron in general, and (b) whether the ODC response is an absolute requirement for the axon reaction to progress. In one set of experiments ODC activity was determined in the SCG 6h after: 1) postganglionic nerve cut (axotomy); 2) preganglionic nerve cut (denervation); 3) end organ removal, and 4) 6-hydroxydopamine treatment. The activity compared to controls was increased after all treatments by 310, 280, 150 and 170 percent respectively. In another set of experiments polyamine biosynthesis was specifically inhibited prior to, during and for 5d after axotomy was performed. When examined thereafter, this treatment resulted in an inhibition of the chromatolytic response and death of the injured neurons, while neurons of unlesioned ganglia remained intact. We conclude that in adult rats: (a) Increased ODC activity is a common feature of drastic neuronal metabolic alterations, and (b) Increased polyamine biosynthesis is obligatory for the progression of the axon reaction in SCG neurons.

12.4 PERIPHERAL NERVE REPAIR WITH DISTRIBUTED MECHANICAL SUPPORT. L. de Medinaceli and W. J. Freed* (SPON: R.J. Wyatt)*. Div. of Special Ment. Res., NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

The introduction of microsurgical techniques has improved peripheral nerve repair in terms of the precision of fascicular reunion. Nevertheless, histological observation of longitudinal sections made shortly after repair show a profound disorganization of axons directions at the reunion site. The gap itself is usually quite wide and contains extraneous material. The present study was made to test the possibility of improving the quality of sciatic nerve repair at the axonal level in animals through the use of distributed mechanical support. A method was developed in which transverse stresses were relieved by placing the nerve in a grooved chamber, and longitudinal stresses were relieved by suturing the nerve to a rubber sleeve. Histological studies of silver-impregnated specimens from rabbit sciatic nerve using this technique revealed that the tips of the axons were closely reconnected with minimal disruption in their direction or alignment and without extraneous material between the severed stumps. In the cases with the best histological appearance, transient electrical potentials could be evoked in the distal stump by stimulation of the proximal stump. These electrophysiological phenomena were further investigated in rat sciatic nerves by similar methods. The table below shows the relationship between the histological quality of repair and the appearance of stimulus-evoked potentials in the distal stump of the severed nerve.

HISTOLOGICAL CHARACTERISTICS OF NERVE RECONNECTION

Repair Type	Apposition of closest axon tips (means ± S.E.M.)	Intervening material in gap
Reconnection, transmission of potentials	13 ± 41 microns (n=7)	0
Reconnection, no transmission	141 ± 130 microns (n=9)	+
Suture, no transmission	380 microns 320 microns (n=2)	+++

It is suggested that improved mechanical support may lead to improvements in the histological manifestations of peripheral nerve repair, and that electrophysiological studies such as these may be used experimentally to obtain an immediate evaluation of the quality of peripheral nerve repair methods.

12.5 NODAL SODIUM CHANNEL NUMBER IN NORMAL AND REGENERATED NERVE FIBERS FROM VENTRAL LUMBOSACRAL SPINAL ROOTS OF CAT. H.W. Querfurth*, R.M. Herndon, and R.A. Armstrong* Center for Brain Research, University of Rochester, Rochester, NY 14642.

Sodium channel estimates for mammalian (rabbit) peripheral nerve nodes of Ranvier as determined by ^{3}H-STX binding (7.2×10^5 sites per node (Ritchie, Rogart PNAS 74:211, 1977)) and by gating current studies (upper limit 8.2×10^4 channels/node (Chiu, J. Physiol. 309, p. 499, 1980)) are discordant by an order of magnitude. To further elucidate this problem we studied binding of ^{3}H-STX to feline lumbosacral ventral root. The parameters from a computer-fitted binding curve for 2 normal cats, were b = 1.5, B_{max} = 10.6 ± 0.6 fmoles/mg-wet, K_d = 0.94 ± .25 nM. A similar determination on 7th lumbar ventral roots from of 2 other normal cats, yielded consistent results (b = 1.5, B_{max} = 11.5 ± 1.3 fmole/mg-wet, K_d = 1.5 ± .43nM).

To calculate the nodal number per mg. of ventral root, total fibre counts and diameter histograms were prepared for spinal levels L5, L6 and L7 and several hundred internodal lengths were measured from fibres of different sizes teased from each of the lumbosacral levels. From 2 cats, there were 4372 ± 704 nodes/mg wet for L5, 4729 ± 792 for L6 and 4018 ± 153 for L7. Using the weighted mean and given B_{max}, we calculate 1.5×10^6 STX receptors per node.

Five adult cats underwent cryogenic axotomy of ventral root levels, L5, L6, L7 and S1 on the left side. After regeneration for 16-45 weeks, binding parameters were determined. On the right (control) side binding was consistent with that in unoperated animals (b = 1.3, B_{max} = 10.2 ± .4 fmol/mg-wet, K_d = 0.6 ± .1 nM). However, the regenerated nerves showed a 3.6x increase in maximal binding (b = 1.3, B_{max} = 36.1 ± .5, K_d = .45 ± .04). Computer aided histologic analysis of the regenerated roots for 1 cat (19 weeks) revealed 1) a decrease in fibre size; 2) a significant decrease in internodal length for fibres in a given size class; 3) a 1.5x increase in total fibre count per root. These factors account for a 3.1x increase in nodes per mg wet. The number of STX sites per regenerated node was calculated to be 1.7×10^6.

It is concluded that 1) a very high number of STX receptors exists at the node of Ranvier of mammals; 2) Anterior horn cells possess the capability of synthesizing STX binding protein in response to injury; 3) the number of channels/node remains relatively constant in the regenerated fibers. Channel density remains unclear since effective nodal area and channel size are not as yet clearly known. A similar increase (2.7x) in channel number per unit length was seen in remyelinated peripheral nerve in rabbit (Ritchie, Rang, Pellegrino, Nature 294:257, 1981).

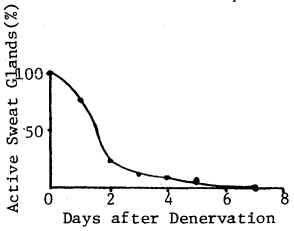
12.6 DENERVATION AND REINNERVATION OF SWEAT GLAND. W.R.Kennedy, M.Sakuta* Dept.of Neurology, Univ.of Minnesota, Minneapolis, MN 55455

PURPOSE We report the response of denervated mouse sweat glands (SG) to daily S.C. pilocarpine and the progress of their re-innervation by the saphenous nerve.

METHODS Two groups of animals were studied. In Group I, the sciatic and saphenous nerves were sectioned. In Group II only the sciatic nerve was sectioned. S.G. were activated by nerve stimulation or S.C. pilocarpine. Sweating was evaluated using a silicone elastic impression material that detected the number and distribution of active S.G.

RESULTS In the intact mouse electrical stimulation of the sciatic nerve activated all S.G. in the hind paw. Saphenous nerve stimulation activated a few S.G. on digits 1 and 2. Pilocarpine (SC) activated 90% of innervated S.G. In Group I the number of S.G. activated by pilocarpine declined daily to zero by day 7 (fig.). The latency from injection to onset of sweating progressively lengthened. In Group II by 2 to 3 weeks the number of active glands in the saphenous territory had increased and the territory enlarged far outside the original confines to other foot pads and digits. The spreading reinnervation ceased after 6-8 weeks. That the saphenous was the source of axons to the newly reinnervated S.G. was proven by their response to electrical stimulation of the nerve and by their subsequent failure to respond to pilocarpine one week after the saphenous nerve was sectioned. In animals where the sciatic nerve was allowed to regrow into the paw the extent of the collateral reinnervation of the saphenous nerve was inhibited.

CONCLUSIONS Mouse sweat glands do not develop denervation hypersensitivity. After sciatic nerve section the remaining intact saphenous nerve collaterally reinnervates 6 to 9 times the number of glands normally innervated. This increases the density and enlarges the area of the original sweat territory. The collateral reinnervation is inhibited by reappearance of the tibial nerve. The remarkable degree of regeneration by collateral sprouting is considered in relationship to the sprouting patterns of other sensory and motor axons.



12.7 REGENERATION AND MATURATION OF MAMMALIAN MYELINATED AXONS: INTRA-AXONAL STUDIES. J.D. Kocsis, S.G. Waxman, and C. Hildebrand*. Dept. of Neurology, Stanford Sch. of Med. and V.A. Med. Ctr., Palo Alto, CA. 94304; Dept. of Anat., Karolinska Inst., Stockholm, Sweden.

Several studies indicate that voltage-dependent potassium conductances (g_K) may be absent or minimal at mammalian nodes of Ranvier, but are present at internodal and on nonmyelinated axons. We studied the effects of the g_K blocking agent 4-aminopyridine (4-AP) on the waveform and firing properties of intra-axonally recorded action potentials from regenerating rat sciatic nerve, and compared these results to those obtained from myelinated fibers of young adult and mature rats.

Wistar rats were anesthetized with pentobarbital and their sciatic nerves crushed for 20 sec with fine forceps. The regenerating nerves were removed, desheathed, and placed in a recording chamber into which warmed (37 deg C) Ringer was continuously applied. The proximal end of the nerve was stimulated and the whole nerve response recorded at various points along the nerve. Intra-axonal impalements were obtained with glass microelectrodes filled with 2M KCL. The nerves were also studied ultrastructurally.

Early regenerating fibers (3 to 14 days) had conduction velocities ranging from 1-3 m/sec. These fibers were identified ultrastructurally as premyelinated and gave rise to numerous axonal sprouts extending into Schwann cell sheaths of the distal nerve segment. The predominant effect of 4-AP on these fibers was broadening of the action potential. After 3 mo of regeneration most of the fibers in the distal segment of the sciatic nerve were myelinated. Conduction velocities of these regenerated myelinated axons were similar to normal sciatic nerve (30-50 m/sec). When 4-AP was applied to the myelinated regenerated axons, the whole nerve response developed late negative components that gave a "rippled" appearance. Single axon recordings indicate that spike bursting occurred following a single stimulus, suggesting that the damped oscillations in the whole nerve response were due to repetitive firing, rather than to the addition of new fiber activity or a simple delay in repolarization. In mature rats (3 mo or more) 4-AP had virtually no effect on the myelinated component of the nerve response or on the waveform of single action potentials. But, when 4-AP was applied to myelinated fibers of young adult rats, the effects of 4-AP were similar to those observed for myelinated regenerating fibers, i.e., the elicitation of bursting.

These results indicate that the functional organization of regenerating myelinated axons is similar to that of myelinated axons of young adult rats, but differs from myelinated axons of mature rats.

12.8 REGENERATION OF PRESYNAPTIC ACTIVE ZONES AT THE FROG NEUROMUSCULAR JUNCTION. Chien-Ping Ko. Dept. of Biological Sciences. University of Southern California, Los Angeles, CA 90007

The active zone of the nerve terminal has a unique structure and is thought to be the site of transmitter release. However, it is not clear how this unique specialization is formed and at what stage in its morphogenesis, the active zone becomes functional. To answer these questions, reinnervation of neuromuscular junctions in the frog cutaneous pectoris muscle was studied by combining intracellular recording and freeze-fracture electron microscopy.

Around 11 days following nerve crush, reinnervation began. The percentage of junctions which showed evoked endplate potentials increased over a period of one week. During this period, some terminals were seen to make small synaptic contacts in the middle of the width of the gutters, which were otherwise occupied by Schwann cells. At these newly regenerated contacts, there were clusters of large intramembrane particles located just opposite to junctional folds. Some of these clusters already showed the typical orientation and two-double-row organization found at normal terminals. However, these primitive active zones were very short. If nerves were stimulated in dilute formaldehyde, dimples, which may represent openings of synaptic vesicles, were seen at these primitive active zones and even at regions of terminal membrane where there were only clusters of unorganized particles opposed to junctional folds.

Around 20 days post-denervation, every muscle fiber recorded had endplate potentials. Nerve terminals became larger and occupied most of the area of the junctional gutters. However, active zones were still not completely regenerated even at one month following denervation. Often there was more than one short segment of primitive active zones opposed to one junctional fold. Openings of synaptic vesicles were found along both sides of these discontinuous active zones, but were not found in the regions where active zones were interrupted. Later, these discontinuous short segments of active zone probably joined together and formed the normal mature active zone. About three months after nerve crush most active zones were indistinguishable from the normal.

This study suggests that transmitter release can occur even before active zone particles are organized into the adult pattern of two double rows and localization of the presynaptic active zone may be induced by the junctional fold.

12.9 EFFECT OF PRIOR COLLATERAL SPROUTING ON AXONAL REGENERATION. Janet R. Sparrow and Bernice Grafstein. Dept. Physiology, Cornell Univ. Med. College, New York, N.Y. 10021

It has repeatedly been shown that a faster rate of axonal regeneration occurs after the second of two nerve injuries (McQuarrie and Grafstein, Arch Neurol. 29:53, 1973; McQuarrie, Brain Res. 152:597, 1978). However it is not known whether the earlier "conditioning lesion" is effective because of injury to the axons per se or whether it is related to the axonal outgrowth which occurs after the first lesion. We have undertaken to induce prior outgrowth in the absence of a lesion and to determine whether an enhancing effect on subsequent axonal regeneration occurs.

Partial denervation of the muscles in the right hind limbs of young rats was performed by eliminating L4 and L6 spinal nerves. Control rats received a sham operation. Collateral sprouting of L5 axons was allowed to proceed for 7 days postoperatively, upon which the right sciatic nerve was crushed. The distance regenerated by the axons 8 days after crushing was measured by labeling the motor axons with radioactive fast transported proteins. ^{3}H-proline was injected into the lumbar ventral horns and 24 hours later the animals were killed and the sciatic nerves were removed. The radioactivity in consecutive 2 mm segments of nerve was measured by liquid scintillation and plotted as a function of distance from the site of crushing.

In nerves which had undergone prior sprouting the mean distance regenerated was significantly greater than in control nerves ($p < 0.01$). Conversely, the distance regenerated by the fastest growing axons (i.e. maximum outgrowth distance) was not increased.

It is concluded that prior axonal outgrowth, induced without injuring the axons, serves to accelerate the outgrowth of motor axons regenerating after a crush. The enhancement of regeneration is comparable to that induced by an earlier conditioning lesion: the mean rate of outgrowth is accelerated while the fastest growing axons are unaffected. Thus the conditioning lesion effect may be attributable at least in part to a mechanism which is associated with outgrowth and which is not dependent on axonal injury for its initiation.

12.10 DOES NEUROTOXIC CONDITIONING ACCELERATE NERVE REGENERATION? A.B. Sterman. Department of Neurology SUNY at Stony Brook, Stony Brook, NY 11794 and Northport VA Medical Center, Northport, NY.

We have recently shown that prototype neurotoxins, putatively directed exclusively at axons, produce a spectrum of cell body remodeling resembling chromatolysis (Sterman, 1981; in press). This study tested the hypothesis that "conditioning" by exposure to a prototype neurotoxin would accelerate the rate of regeneration of severed peripheral axons by evoking a reparative reorganization of the soma, analogous to the well-studied conditioning lesion phenomenon. Thirty-eight Sprague-Dawley rats were paired, and each pair member either exposed to 0.5% 2,5-hexanedione (2,5-HD) in drinking water (experimental) or received water without toxin (control). After six weeks, the rats were given a one week recovery period off toxin and then were subjected to experimental crush of the sciatic nerve, using the general methods of others (McQuarrie, 1977; Forman, 1978). Nerve regeneration was measured by the pinch test 5-13 days after crush. Results failed to show an accelerated rate of axonal outgrowth; however, there was a small but significant ($p < 0.05$) decrease in the initial delay from sciatic nerve crush to the start of outgrowth. Thus, despite morphological similarities between neurotoxin-induced cell body changes and chromatolysis, there are critical functional differences. Results provide a model (morphologically similar to chromatolysis but functionally divergent) which can be used to explore factors supporting nerve regeneration.

This study was supported in part by the Veterans Administration, NIRA ES02650, and MH36856.

12.11 FUCOSYL GLYCOPROTEIN DISTRIBUTION IN THE DEMYELINATED PERIPHERAL NERVE. I. M. Parhad, J. W. Griffin*, D. L. Price*, J. F. Koves*, and D. O. Kuethe*. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

The effect of demyelination on axonal transport has been incompletely studied. The problem is of interest because transported glycoproteins might be involved in remodeling the axolemma in demyelinated internodes or in influencing Schwann cells to divide or remyelinate. [^{3}H] fucose, when injected near nerve cell bodies, is incorporated into fucosyl glycoproteins. Fucosyl glycoproteins are carried predominantly by fast axonal transport; a portion of these glycoproteins become associated with axolemma. The present study was designed to assess whether there was altered retention of rapidly transported fucosyl glycoproteins in demyelinated internodes.

A 2% lysolecithin solution was applied directly to a segment of the sciatic nerve of Sprague-Dawley adult rats for ten minutes. Ten to thirty percent of fibers developed demyelination, mostly in the subperineurial area. One to five days after application of lysolecithin, [^{3}H] fucose was injected into the lumbar ventral horns and dorsal root ganglia (L4-L5). The sciatic nerves were fixed with glutaraldehyde 2-7 days after labeling when most of the rapidly transported material had moved past the site of demyelination. The tissue was embedded in Epon, and longitudinal sections of nerve were processed for light autoradiography. Area measurements were done using a digitizer. Both in the normal (myelinated) and in the demyelinated fibers, there was a marked increase in grain density in the constricted segment (node and myelin sheath attachment sites) of the axon. In the demyelinated internodes (DI), there was at all times an increase in the density of silver grains as compared to the normally myelinated adjacent internodes (MI) of the same axon (DI: 0.38±0.03 grains/μm^2; MI: 0.20±0.02 grains/μm^2; 23 matched pairs examined). The demyelinated internodes had a smaller caliber when compared to the normally myelinated adjacent internodes of the same axon (DI: 3.83±0.22μm; MI: 4.45±0.31μm).

These results showed a markedly increased retention of rapidly transported fucosyl glycoproteins in the constricted segments of both the normal and demyelinated axons. In the demyelinated internodes, there was increased retention of fucosyl glycoproteins as compared to the normally myelinated internodes. The increased retention of fucosyl glycoproteins may be due to local slowing of transport and/or to increase insertion in the axolemma.

12.12 INCOMPLETE GLYCOSYLATION OF A MYELIN GLYCOPROTEIN EXPRESSED BY SCHWANN CELLS IN THE DISTAL SEGMENT OF THE PERMANENTLY TRANSECTED NERVE. Joseph F. Poduslo, Carole T. Berg*, and Peter J. Dyck. Membrane Biochemistry Laboratory, Peripheral Nerve Center, Department of Neurology, Mayo Foundation, Rochester, MN 55905.

Glycoproteins have been implicated in Schwann cell-axon recognition events responsible for the initiation of myelination and probably for the maintenance of the integrity of the myelin sheath (Poduslo, in Peripheral Neuropathy, eds. Dyck, Thomas, Lambert, and Bunge, in press). The elucidation of the regulatory mechanisms by which Schwann cells express specific myelin proteins which are then assembled into the myelin membrane is an important area of research. Schwann cell expression of the major myelin glycoprotein, P_o, has been investigated using the permanent nerve transection model described by Spencer et al (Brain Res., 165, 119, 1979) where reinnervation and remyelination is prevented. Endoneurial fractions from a desheathed nerve distal to the permanent transection were compared with similar fractions from a crushed nerve at 7, 14, 21, 28, and 35 days after injury. The expression of P_o glycoprotein was evaluated after SDS-pore gradient electrophoresis by Coomassie blue and silver stain and by autoradiography after direct overlay of radioiodinated lectins (wheat germ agglutinin, gorse agglutinin, and concanavalin A). As evaluated by these parameters, the concentration of P_o after crush decreased and subsequently increased as a function of time after injury corresponding to the events of demyelination and remyelination. After permanent transection using Coomassie blue stain (sensitivity: ~100 ng), the P_o concentration decreased following the same time course found after crush. At subsequent time points, P_o could not be detected using Coomassie blue stain which supports the observations made by Spencer (in Aspects of Developmental Neurobiology, eds. Ferrendelli and Gurvitch, 1979). Similar results were obtained when P_o was evaluated using silver stain which has a ~50 fold greater sensitivity than Coomassie blue (~2 ng). Wheat germ agglutinin (sensitivity at the subnanogram level) (specificity: NeuNAc-Gal-GlcNAc) showed no binding to P_o glycoprotein by 21 days post-transection; however, both gorse agglutinin (specificity: Fuc) and concanavalin A (specificity: Man) showed low levels of binding to P_o. Radioactive precursor incorporation studies of endoneurial slices at 35 days post-transection revealed active synthesis of P_o glycoprotein by Schwann cells in this permanent transection model. In addition, differences in lectin binding and precursor incorporation studies suggest that this glycoprotein is incompletely glycosylated since we could not demonstrate addition of the terminal carbohydrates. The data suggest a post-translational regulation step in the synthesis of this glycoprotein and the subsequent regulation of myelination.

12.13 EFFECT OF XYLOCAINE APPLIED TO THE HYPOGLOSSAL AXOTOMY SITE ON 14C-2-DEOXYGLUCOSE UPTAKE IN THE HYPOGLOSSAL NUCLEUS. Philip A. Singer and Sharon Mehler*, Neuromuscular Histochemistry Laboratory, Veterans Administration Medical Center, Kansas City, MO 64128.

We (Singer and Mehler, Exp. Neurol. 69:617-626, 1980) and others (Kruetzberg and Emmert, Exp. Neurol. 70:712-716, 1980) have found markedly increased 2-deoxyglucose (2DG) uptake in the hypoglossal nucleus as early as 24 hours after hypoglossal axotomy. There is a question whether this increased uptake is caused by increased synthetic activity or perhaps increased numbers of action potentials. David and Aguayo (Neuroscience Abst. 6:439, 1980) have shown that increased 2DG uptake in the lumbar anterior horns is blocked by applying xylocaine to the axotomy site 13 days after the sciatic nerve was cut and placed in a polyethylene tube. Thus, presumably, action potentials were originating in a neuroma and invading the anterior horn cells. In order to test the possibility that a similar mechanism was producing the increased 2DG uptake in the hypoglossal nucleus after axotomy, the following study was undertaken.

Male 150-200gm Sprague-Dawley rats underwent bilateral hypoglossal ligation followed by axotomy distal to the ligation under nembutal anesthesia. The nerve was ligated so that the proximal cut end could be identified later. In animals destined for longer (15 days) survival, the hypoglossal was ligated and cut only on the left. At 24 hours, 3 and 15 days after the axotomy the left proximal hypoglossal stump was exposed under nembutal 50mgm/kg anesthesia and a cotton pleget soaked in 1% xylocaine applied around the nerve stump. 15μc/100gm 14C-2-deoxyglucose was then injected via the tail vein. Forty-five minutes later the brainstem was excised and frozen in freon. Later 20u sections were cut at -18° and applied to x-ray film for 2 weeks. The resultant autoradiographs showed no difference in glucose uptake between the xylocaine treated and control sides at 24 hours or 3 days and a definite increased uptake compared to the non-axotomized side at 15 days.

Our results suggest that electrical activity originating from the axotomy site is not a factor in producing increased 2DG uptake in the hypoglossal nucleus. The difference between our results and those of David and Aguayo may be explained by several differences in the preparation used. We did not encourage neuroma formation by placing the axotomized nerve into a plastic tube. Furthermore, the sciatic nerve contains a large number of sensory fibers which impinge either directly or indirectly on the anterior horn and whose reaction to injury may be different from motor fibers.

13.1 CAT SCAN MEASURES IN SCHIZOPHRENICS: CORRELATIONS BETWEEN BRAIN ATROPHY, MAO-B AND DIAGNOSTIC SUBGROUPS. A Kling, N. Kurtz*, K. Tachiki* and S. Connor*. Psychiatry Service, Vet. Admin. Med. Center, Sepulveda and UCLA Sch. of Med., Los Angeles, CA.

Recent studies have demonstrated that some schizophrenics have increased ventricular brain ratios (VBR), atrophy of the sylvian fissure and other morphological changes of the brain (Weinberger, D. et al., Arch. Gen. Psych. 36:935, 1979). Other studies have implicated MAO-B levels to be low in paranoid schizophrenia (Potkin, S.G. et al., N. Eng. J. of Med. 298:61, 1978) and high in brain atrophy associated with aging and Alzheimer's disease (Adolfson, R. et al., Life Sci. 27:1029, 1980).

This study examined specific brain changes by CAT Scan and whole blood MAO-B activity in DSM III subgroups of chronic schizophrenics.

CAT Scans of 26 chronic schizophrenics (12 residual, 12 paranoid and 2 undifferentiated) between ages 25 and 45 were measured for VBR, sylvian fissue widening, and asymmetry of the frontal lobes. MAO-B levels were obtained using a modified method of Marshall (Marshall, E.F. and Campbell, I.C., Bioch. Pharm. 26:353, 1977).

Paranoid schizophrenics were found to have significantly smaller VBRs than the non-paranoid group, 7.3±3.3 vs. 10.4±3.5 ($p<.025$). The schizophrenics were divided into two VBR groups: greater than 9 (2 s.d.above normal controls 4.75±2.0). Regression and analysis of variance between the two VBR groups, MAO-B and sylvian atrophy showed a multiple correlation of $R = .689$, $p < .01$. Age and length of illness did not account for the variance seen. Individual analyses showed that MAO-B means were higher in the greater than 9 VBR groups ($p<.05$) and that sylvian fissure atrophy was positively correlated with VBR 9 at $p < .01$. Reversed asymmetry of the frontal lobes was significantly correlated ($p < .01$) with VBR values of greater than 9 when controlled for age. The paranoid schizophrenics had significantly lower MAO-B activity when compared to the non-paranoid schizophrenics ($p < .001$) and an age matched normal control group ($p < .001$).

These data suggest that chronic residual schizophrenics have larger VBRs and increased MAO-B activity compared to age matched chronic paranoid schizophrenics. Sylvian fissure atrophy was positively correlated with increased ventricular size but not with MAO-B or diagnostic subgroups.

13.2 DEMENTIA PATHOPHYSIOLOGY: X-RAY COMPUTED TOMOGRAPHY AND DYNAMIC POSITRON EMISSION TOMOGRAPHIC STUDIES WITH 18-FLUORODEOXYGLUCOSE AND RUBIDIUM-82. R.P.Friedland, T.F.Budinger*, E.Ganz*, Y.Yano*, C.Mathis*, R.Huesman*, B.Knittel*, B.Moyer*, B.A.Thompkins-Ober* and B.Koss. Donner Laboratory, University of California, Berkeley, Ca. 94720, Dept. of Neurology, University of California, Davis and VA Medical Center, Martinez, Ca..

Positron emission tomography(PET) allows for the in vivo noninvasive regional quantitation in three dimensions of aspects of cerebral physiology in health and disease. Comprehensive neuropsychological testing, x-ray computed tomography and PET studies were performed on 16 demented subjects aged 52-82 with clinical diagnoses of Alzheimer-type dementia(N=10), multi-infarct dementia, communicating hydrocephalus, Creutzfeldt-Jakob disease and alcoholic dementia. PET studies of glucose metabolism and blood brain barrier permeability were performed on the Donner 280-crystal ring (resolution 9mm FWHM). 18-Fluorodeoxyglucose(FDG) was synthesized at the Lawrence Berkeley Laboratory using the 18-F F reaction with glucal. IV injection of FDG was followed by rapid sampling of arterialized blood using hand warming to 44 C and dynamic imaging of the head from the time of injection to 60 minutes after injection. Tomographic data were collected initially at 5 second intervals and later at longer intervals in order to calculate rate constants for transport and phosphorylation of FDG and dephosphorylation of FDG-6-Phosphate. Images taken 45 minutes after injection demonstrate an impairment in glucose utilization in the temporal cortex in the Alzheimer-type dements. One subject with clinically diagnosed Creutzfeldt-Jakob disease had a unique pattern of heterogeneous and asymmetrical radionuclide distribution throughout the brain.

Studies were also performed using generator produced rubidium-82 as an indicator of blood brain barrier integrity. No rubidium-82 uptake suggestive of increased blood brain barrier permeability was noted in 4 subjects (two Alzheimer-type, one multi-infarct and one communicating hydrocephalus).

Results of kinetic analysis of FDG uptake and metabolism will be presented and relationships between behavioral and x-ray computerized tomographic features of the dementia and metabolic parameters will be discussed.

13.3 THE PATHOGENESIS OF EARLY TRAUMATIC BRAIN DYSFUNCTION. O.R. Hubschmann and D. Kornhauser*. Neurological Surgery Section, University of Medicine and Dentistry of New Jersey-New Jersey Medical School, 100 Bergen Street, Newark, N.J. 07103 and Veterans Administration Medical Center, East Orange, N.J. 07019.

The clinical condition of closed head injury is associated with high morbidity and mortality in patients. The processes that participate in the development of the clinical presentations at the cellular level are not well understood. Using a hypothesis that the potassium is one of the primary inducing factors in the pathogenesis of cerebral swelling following head trauma, we have studied the early changes in potassium concentration following experimental head trauma. We have studied the dynamic changes in K+ and Ca++ activity in the cortical extracellular microenvironment in 15 cats where local SAH or intracerebral hematoma was produced by injecting 0.5 cc of autologous blood. The cellular response was monitored using extracellular K+ and Ca++ ion-specific microelectrodes, DC cortical potential and electrocorticogram.

The cellular response was characterized by a profound cellular depolarization, extracellular Ca++ depletion and extracellular accumulation of K+. The pre-hemorrhagic baseline K+ level averaged 3.17 ± 0.52 mM and was elevated to levels ranging between 16 and 31 mM. Ca++, normally maintained at 1.14 ± 0.11 mM was reduced to levels ranging between 0.4 and 0.7 mM. In most experiments, both K+ and Ca++ activity returned to normal limits within 5 minutes.

Experimental head trauma, either in the form of subarachnoid hemorrhage or intracerebral hematoma, is accompanied by the release of potassium into the extracellular space accompanied by concomitant extracellular calcium depletion and depression of electrical activity. This change is not dependent on intracranial pressure and it is not induced by ischemia. The potassium release which appears to be transient, in most instances, blocks neuronal transmission and causes increase in vascular resistance. It is combined with the decrease in extracellular calcium which change the cell permeability, decrease their metabolic activity and block synaptic transmission. We conclude that this process is the pathogenetically primary force in inducing secondary brain damage in head trauma.

13.4 ULTRASTRUCTURAL STUDY OF THE ASTROCYTIC CHANGES INDUCED BY SPONTANEOUS SPONGY DEGENERATION OF THE MOUSE BRAIN. N.A. Azzam, P.A. Cancilla*, J.V. Bready* and R.N. Azzam*. Faculty of Med., Kuwait Univ. and College of Med., The Univ. of Iowa, Iowa City, IA 52242.

A spontaneous spongy degeneration was discovered in the brain of the Swiss Webster mouse of the Charles River colony. The disorder is genetically transmitted in an autosomal recessive pattern of inheritance. Paraffin sections stained with H&E revealed extensive spongy degeneration affecting mainly the white matter. Ultrastructural studies confirmed the status spongiosus and localized the abnormality to the astrocyte. Astrocytic foot processes surrounding cerebral blood vessels were distended by accumulation of fluid. This caused the dispersion of cytoplasmic organelles of the foot processes which spread to include the astrocytic cell bodies. The vascular basal lamina remained intact inspite of the vacuolization. An extensive and elaborate system of hemidesmosomes appeared between the vascular basal lamina and the astrocytic foot processes. This seemed to be a reaction to help prevent the disruption of the blood brain barrier. Arterioles and capillaries remain suspended in the vacuoles by thin strands of the cytoplasmic remains of the astrocytes. Reactive astrocytes were observed in the subependymal layer. Some had large foot processes surrounding capillaries. Their nuclei were larger and cerebriform. The nuclear envelope was thrown into marked convolutions. The karyoplasm was of different densities, with few electron-dense clumps of varying sizes irregularly dispersed. The cytoplasm contained dense bodies of varying sizes, a well developed Golgi complex and several mitochondria. The most prominent feature was the presence of membrane-bound bodies with granular densities which seemed to be transverse sections of fibrils. These were widely dispersed in the cytoplasm and between the folds of the nuclear envelope. The membrane surrounding some of these bodies was ruptured and the contents were dispersed into the cytoplasm. Some bodies seemed to have merged and coalesced with other bodies. These astrocytes were held together by gap junctions and by a ball and socket type junction. Inspite of the spongy degeneration, the vascular basal lamina remains impermeable to intravenous horseradish peroxidase. However, a 5 mm spot freeze injury applied to the brain through the intact skull disrupted the blood brain barrier. An animal model is established which regularly produces affected offspring for further investigation, aimed at gaining insight into the pathogenesis of human neurologic disorders; In particular, Canavan's spongy degeneration, which bears similar patterns of inheritance and morphological abnormality.

Supported by the University of Kuwait Research Council Grant MA014 and by NIH Grants HL-01712 and NHLT 14230.

13.5 TO WHAT EXTENT IS TRAUMATIC PARAPLEGIA A DEMYELINATIVE DISEASE? A. R. Blight. Depts. Neurosurg. and Physiol. & Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016.

It has been assumed that the cause of chronic paralysis following mechanical injury to the spinal cord is a total or near total destruction of axons at the trauma site. Several other causes of irreversible dysfunction are possible, and prominent among these is demyelination of surviving white matter. It is essential to know the relative importance of such extra-axonal pathology in considering possible therapeutic approaches to this intractable condition.

The experimental model used was contusion of the cat spinal cord with a 20g weight dropped 20cm onto the exposed dura at T7/8. Axons surviving at the injury site were examined with light and electron microscopy and in vitro intracellular recording of conduction. Animals which remained paraplegic at 7-14 months post injury were compared with animals from the 10-20% which recover the ability to stand and walk with relatively mild deficits. All animals suffered destruction of the gray and 80-95% of the white matter at the injury site. There was an overlap between paralyzed and walking animals in the number of axons surviving in the outer 150-300 um of the ventral tracts. The proportion of large caliber axons (more than 5 um) and the thickness of their myelin sheaths was greater in the walking animals. There was a clear difference between the ability of axons in the two groups to conduct through the lesion site in vitro. Impaling axons 6-7 mm either side of the middle of the lesion in dorsal, ventral and lateral tracts, the proportion capable of action potential conduction through the lesion site was determined at 22-25°C. The proportions were 13% (of 150 axons) for paralyzed, 65% (of 134 axons) for walking chronic animals, and 70% (of 233 axons) for uninjured controls.

When axons were challenged by raising the temperature, it was found that conduction failed below 36°C in 70% of axons in the paraplegic sample, compared with 7% in control and 10% in the chronic walkers. This temperature sensitivity of conduction in the paralyzed cats is consistent with morphological signs of sustained poor myelination. The evidence currently suggests that paraplegia in the model is the combined result of a critical loss of axons and persistent demyelination. Other factors, including obvious vascular occlusion, may contribute to deficits in individual cases. More attention to the cellular basis of paraplegia may open possibilities for treatment more accessible than functional axonal regeneration. (Supported by the Steven Camhi Fund for Spinal Cord Injury Research & USPHS grant NS10164 from NINCDS).

13.6 Measurement of Myelin Basic Protein and of Anti-Basic Protein Antibodies by ELISA Utilizing Biotinylated Antibodies. L. Spatz*, L. Whitman*, M-J. Messito*, G. Nilaver, S. Ginsberg* and N. Latov* (SPON:E.A. Zimmerman). Dept. of Neurology, Columbia U., New York, N.Y. 10032.

Myelin Basic Protein (MBP) is the target antigen in Experimental Allergic Encephalomyelitis and may be important in the pathogenesis of Multiple Sclerosis. Its concentration is elevated in CSF of patients with active demyelination and anti-MBP antibodies are detected in patients with Multiple Sclerosis. We compared ELISA systems for mesuring antibodies to MBP and developed a two-site ELISA capable of mesuring as little as 0.1 ng/ml of MBP.

To measure anti-MBP antibodies, microplate wells were coated with human MBP and incubated with increasing dilutions of affinity purified rabbit anti-human MBP antibodies. Binding was measured by incubating with either peroxidase-conjugated anti-rabbit IgG or Protein A, or biotinylated anti-rabbit IgG and avidin-peroxidase. O-phenelenediamine was added as substrate and the reaction products measured at 450nm. The three assay systems were equally sensitive and capable of measuring as little as 1.5ng/ml of specific antibody.

To measure concentration of MBP, wells were coated with affinity purified rabbit anti-MBP antibodies and incubated with increasing dilutions of MBP. The bound antigen was measured by incubating with biotinylated anti-MBP antibodies and avidin-peroxidase, and then with O-phenylenediamine. Reaction products were measured at 450nm. In this assay, as little as 0.1 ng/ml of MBP could be detected. The assay is significantly more sensitive than previousely described radio-immune assays for MBP and is preferable to the competitive inhibition ELISA for detecting fragments of MBP.

13.7 CAPRINE β-MANNOSIDOSIS: NEURONAL AND MYELIN ABNORMALITIES. Kathryn L. Lovell and Margaret Z. Jones. Pathology Dept., Michigan State Univ., East Lansing, MI 48824.

Morphological changes were delineated in the central nervous system of goats affected with β-mannosidosis in order to determine the extent and distribution of neuronal and myelin abnormalities associated with this inherited glycoprotein metabolic perturbation. Coronal sections of the cerebral hemispheres, sagittal sections of the cerebellum, and transverse sections of the brainstem of 3 affected goats and 3 age-matched controls, ranging in age from 0-16 weeks, were embedded in paraffin, sectioned at 6 μm and stained with Hematoxylin and Eosin and with Luxol fast blue-Periodic acid Schiff-Holmes stains. Tissues from selected areas were embedded in Epon-Araldite, sectioned at 2 μm and stained with toluidine blue. Thin sections were stained with uranyl acetate and lead citrate.

Lysosomal storage vacuoles, probably representing storage of uncleaved oligosaccharides, were present to various extents in different neuronal cell types. Cell types most severely affected included cortical pyramidal cells, hippocampal pyramidal cells, caudate neurons, and cerebellar Purkinje and Golgi II cells. Other populations, e.g. granule cells from the hippocampus and cerebellum, showed less vacuolation. The size of cytoplasmic vacuoles varied among cell types and, in some cases, vacuolation appeared more severe in the oldest animal. Homogeneous, eosinophilic axonal spheroids, like those noted in α-mannosidosis, were present throughout the white matter. They were most numerous in the cerebellum and cerebral hemispheres of the 16 week old affected goat. Ultrastructural examination revealed accumulation of dense bodies and membranous material in the spheroids.

Unlike related storage disorders, gross examination revealed severe deficiency of myelin in the cerebral and cerebellar hemispheres of all animals. In contrast, the brainstem appeared unremarkable, as noted previously for the 1 day old affected animal (Jones, et al., 1979, Soc. Neurosci. Abst., 5:513). Light and electron microscopic examination, however, showed a reduction in myelinated fibers in most white matter areas, including the brainstem.

Central nervous system lesions correlated with severe neonatal neurological deficits, characteristic of β-mannosidosis. The precise role of β-mannosidase deficiency and accumulation of oligosaccharides in the pathogenesis of the neuronal and myelin abnormalities remains to be established.

Supported by NIH Grant NS 16886 to M.Z.J.

13.8 SERIAL CHANGES IN NMR IMAGES OF ACUTE EXPERIMENTAL CEREBRAL ISCHEMIA: TIME COURSE AND EFFECTS OF DEXAMETHASONE, MORPHINE AND NALOXONE. Robert M. Levy*, David Baskin*, Leon Kaufman* and Yoshio Hosobuchi* (SPON: Nancy Lee). Department of Neurosurgery and Radiologic Imaging Laboratory, University of California, San Francisco, CA 94143.

Following unilateral carotid artery ligation, about 40% of gerbils will evolve hemispheric strokes due to insufficient collateral cerebral blood flow. Baskin and Hosobuchi (1981) have demonstrated that naloxone reverses the neurologic deficit following cerebral ischemic insults in two patients and in gerbils following carotid artery ligation. Morphine was shown to precipitate stroke symptoms in asymptomatic animals. We have employed nuclear magnetic resonance (NMR) imaging to evaluate intracerebral changes over time after unilateral carotid artery ligation and the effects on these images of dexamethasone, morphine and naloxone. Gerbils were anesthetized with pentobarbital and underwent right carotid artery coagulation and sectioning. Animals were allowed to recover from anesthesia and were then tested for neurologic deficit. Both stroked and asymptomatic animals were then scanned at time points ranging from 3 to 24 hours following surgery. Symptomatic animals were then given intraperitoneal injections of either naloxone 2 mg/kg or dexamethasone 5 mg/kg and rescanned at either 5-10 minutes or 60-90 minutes later, respectively. Asymptomatic animals were injected with 10 mg/kg morphine sulfate IP and rescanned 90 minutes later. Signal intensity, T1 and T2 times were then averaged over each hemisphere of the NMR images.

The results indicate that asymptomatic animals exhibit no differences between the occluded and control hemispheres with respect to any of the above variables. Symptomatic animals, on the other hand, demonstrate significant differences between hemispheres in both T1 and T2 times. T1 times appear to be increased by 15% until 24 hours when the T1 time on the occluded side rises to 136% of the control side. T2 times appear to rise in a linear fashion over 24 hours, at which time the ischemic hemisphere demonstrates a T2 time of about 71 msec vs. a control of 57 msec.

Neither naloxone, administered to stroked animals, nor morphine, administered to asymptomatic animals, had any effect on the NMR images obtained at any time point over the 24 hours following surgery. Dexamethasone, given to symptomatic gerbils, had no effect on the NMR images obtained at either 6-8 hours or 24 hours after surgery. Of interest is that dexamethasone appears to negatively influence 24 hour survival following this cerebral ischemic insult. Thus, cerebral ischemia following unilateral carotid artery ligation in symptomatic gerbils appears to be reflected in both T1 and T2 times, and these changes appear to increase over time within the first 24 hours after surgery. None of the drugs tested appear to effect these post-ischemic changes in NMR images.

13.9 A UNIQUE PROTEIN ASSOCIATED WITH THE SCRAPIE AGENT. D.C. Bolton*, M.P. McKinley* and S.B. Prusiner, Departments of Neurology and Biochemistry and Biophysics, University of California, San Francisco, CA 94143.

The scrapie agent causes a degenerative neurological disease of sheep and goats. One infectious unit appears to induce the synthesis of 10^9 ID_{50} (mean infectious dose) units in the brain of an infected hamster over a 120 day period. The agent has been substantially purified by a method using detergent extraction, polyethylene glycol precipitation, nuclease and protease digestion, ammonium sulfate precipitation and sedimentation into a discontinuous sucrose gradient. The specific infectivity (ID_{50} units/mg protein) of the aggregated agent in a fraction from the 25%/60% interface of the sucrose gradient was increased 100- to 1,000-fold above that found in homogenates of infected hamster brain. The agent is hydrophobic and contains a protein which is required for infectivity. Attempts to demonstrate the dependence of infectivity on a nucleic acid present within the agent have been unsuccessful. The agent is resistant to ribonucleases, deoxyribonucleases, psoralen photoadduct formation, Zn^{++} catalyzed hydrolysis and chemical modification by hydroxylamine. A new term, "prion", has been introduced to describe and identify these small proteinaceous, infectious particles which are resistant to most procedures that modify nucleic acids.

A unique protein was identified in substantially purified fractions containing the scrapie agent. This protein was observed by radiolabelling of the purified fraction with N-succinimidyl 3-(4-hydroxy, 5-[^{125}I]-iodophenyl) propionate or [^{14}C]-diethylpyrocarbonate and subsequent analysis by SDS polyacrylamide gel electrophoresis. It migrated as a diffuse band with an apparent molecular weight between 27,000 and 30,000 daltons. The protein was uniquely resistant to digestion by proteinase K prior to denaturation. This property was used to demonstrate that the protein was distinct from others of similar molecular weight found in normal brain. Heating the scrapie-associated protein to 100°C for 2 min in the presence of 1.25% SDS and 1.25% β-mercaptoethanol rendered it sensitive to digestion by several proteases. The protein was degraded by proteinase K, pronase and *Staphylococcus aureus* V-8 protease under these conditions, but was apparently resistant to digestion by α-chymotrypsin. Whether this protein is a pathological product of scrapie infection or a structural component of the agent remains to be established. In support of the latter, the protein and the infectious scrapie agent copurified. In addition, preliminary results suggested that in substantially purified fractions the amount of this protein correlated with the titer of the scrapie agent.

13.10 INFUSIONS OF TRITIATED THYMIDINE INTO THE BRAIN INCREASES SURVIVAL OF BDF MICE FOLLOWING (CNS) B-16 MELANOMA IMPLANTS. M.S. Kaplan* and R.H. Selinfreund* (SPON: W.G. Dail, Jr.). Anatomy Dept., Univ. of New Mexico, Sch. of Med., Albuquerque, NM 87131.

10^5 cells of B16 melanoma were injected directly into the brains of 41 BDF female mice. Four days later a cannula was placed just above the implanted tumor. The next day infusions of either tritiated thymidine, "cold" thymidine, sterile saline, or ^{125}IUdR were administered. Total infusions of 440 μc of tritiated thymidine or ^{125}IUdR were administered over four 36-hour periods such that: 110 μc were delivered, the animals were removed from the infusion for 36 hours, 110 μc infused for another 36 hours, etc. Animals received 440 μl (total volume) of their respective agent during the four infusions.

Mice that received infusions of tritiated thymidine had a 15% increase in survival beyond those that received infusions of sterile saline or "cold" thymidine. These results were confirmed as statistically significant ($p \leq 0.01$) by Duncan's multiple range test for variable time and by least square means. Analysis of radioactivity in individual organs demonstrates that slow infusions of tritiated thymidine (3.0 μl/hour) into the brain do not effectively incorporate into organs beyond the brain. This procedure may then be valuable for the selective treatment of patients with brain tumors without jeopardizing the normal proliferative organs.

This work was supported by a grant from the research allocation committee of the University of New Mexico.

14.1 LOCALIZATION OF THE CIRCADIAN PACEMAKER IN THE EYE OF BULLA. G.D. Block and S.F. Wallace*. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

The eye of Bulla gouldiana, like that of Aplysia, expresses a circadian rhythm (CR) in optic nerve compound action potential (CAP) frequency. The Bulla retina contains fewer and larger cells than its Aplysia counterpart and there is better spatial separation between morphologically distinct cell populations. These attributes provide an opportunity for employing long term intracellular recording and selective surgical reduction as techniques for pacemaker localization.

We find that the organized photoreceptor layer is not involved in generating the CAP circadian rhythm. Long term (>24 hr) intracellular recording from photoreceptors fails to reveal membrane potential fluctuations which could account for the simultaneously measured CR in the optic nerve. In most preparations there are small (±2mV) membrane fluctuations, but these appear random and are not statistically correlated with CAP frequency.

Surgical reduction of the retina confirms intracellular results. Paring the retina to its extreme base by removal of the photoreceptor layer does not affect the expression of the CR. Importantly, the period of the CR in the reduced retina (23.9 hr; ±.45) is identical to the CR period of the intact eye (23.8 hr; ±.35), even though only 30-50 cells remain in the fragment. This result supports a similar finding in Aplysia (Strumwasser, 1973) and demonstrates that the CR is generated within individual or small groups of cells and is not due to the mutual interactions of a large population of non-circadian pacemakers as suggested for Aplysia by Jacklet and Geronimo (1971).

Surprisingly, even though the organized photoreceptor layer is removed, retinal fragments remain photosensitive and the pacemaker can be phase shifted by light cycles. Six hr light pulses delivered at Circadian Time 18 cause a 1.1 hr mean phase advance which is similar to the 1.5 hr advance observed in intact eyes. Thus, both a competent circadian pacemaker and its entrainment pathway reside among a small group of cells at the base of the retina. Supported by NS15264 to G. Block.

14.2 ELECTROPHYSIOLOGICAL INVESTIGATION OF CELLS AT THE BASE OF THE BULLA RETINA. S.F. Wallace* and G.D Block (SPON: P. Best) Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

The eye of Bulla gouldiana expresses a circadian rhythm in spontaneous optic nerve impulse frequency (Block & Friesen, 1981). Both the circadian pacemaker(s) and its entrainment pathway reside among a small group of cells at the base of the retina (Block & Wallace, this volume).

We have begun preliminary electrophysiological study of cells at the retinal base. Our first efforts have been directed toward surveying the types of neurons present at the base of the eye with the underlying goal of identifying cells which comprise the circadian pacemaker system.

Intracellular recordings were obtained from isolated Bulla eyes maintained in artificial buffered seawater. To facilitate electrode penetrations, the retina was reduced to its base by removing the lens and then carefully cutting away the surrounding photoreceptor layer. Neurons in the remaining fragment of tissue were impaled with glass microelectrodes (20-40 MΩ) while optic nerve impulse activity was recorded with a suction electrode.

We observed several types of cell responses in the retinal fragment. Most recorded units were spontaneously active (~75%) and responded to illumination with an increased impulse frequency. Spikes from these units were correlated 1-for-1 with compound action potentials in the optic nerve and presumably, were contributing units to the compound optic nerve response. We less frequently observed other cell responses including: 1) a unit which was spontaneously active and hyperpolarized upon illumination; 2) regular beating neurons which did not respond to illumination; and 3) normally quiet cells which responded to illumination with a depolarization accompanied by 2 or 3 spikes which were not correlated with optic nerve impulses.

We also recorded from a non-spiking cell which exhibited a slow 15 mV depolarization in response to illumination. However, unlike intracellular responses from the organized photoreceptor layer, this unit did not rapidly repolarize during sustained illumination. The tonic nature of the reponse makes this cell a candidate for an entraining light-receptor, since the Bulla circadian cell pacemaker can only be phase shifted by long light pulses (>4 hr). Additional intracellular recording using pairwise techniques should reveal the functional relationships between the various cell types at the base of the retina. Supported by NS15264 to G. Block.

14.3 ORGANIZED PHOTORECEPTOR LAYER IS NOT REQUIRED FOR LIGHT RESPONSES IN THREE OPISTHOBRANCH EYES. D.G. McMahon and G.D. Block. Dept. of Biol., University of Virginia, Charlottesville, VA. 22901.

Several opisthobranch eyes have been shown to respond to light with compound action potentials (CAPs) (Aplysia-Jacklet, 1969; Bursatella-Block and Roberts, 1981; Bulla-Block and Friesen, 1981; Navanax-Eskin and Harcombe, 1976). These eyes also express a circadian rhythm in spontaneous CAP frequency. The eyes of another opisthobranch, Haemonea vesicula, exhibit similar behavior. The functional organization of the opisthobranch retina, and specifically the pathways by which light reaches the circadian pacemakers in these retinas is of special interest in the study of biological rhythms (Eskin, 1977; Strumwasser, 1973).

Audesirk (1973) has proposed a model for Aplysia retinal organization in which higher order neurons, driven by photoreceptors are responsible for light-induced CAPs. We were intrigued by evidence in Bulla that higher order cells are, themselves, photosensitive (Block and Wallace, this volume). In order to investigate the role of photoreceptors in the light response we obtained electrophysiological data from three opisthobranch eyes (Aplysia, Bulla, Haemonea).

We find two types of evidence excluding input from the organized photoreceptor layer as critical for the light-induced CAP response. First, simultaneous intracellular recordings from photoreceptors and the optic nerve indicate that the response characteristics of photoreceptors do not match the response in the optic nerve. During a long light pulse (∿30s) receptors first depolarize and then gradually repolarize while CAPs continue at an elevated frequency. Termination of the light pulse has no immediate effect on the receptor membrane potential, but CAPs cease. Similar results were obtained in all three opisthobranchs tested. Second, following surgical reduction of the retina both spontaneous and light-induced CAPS persist (for Aplysia also see Sener, 1972). Histological examination of Aplysia and Bulla retinal fragments reveals that the pigmented layer and all distal segments associated with photoreceptors are absent with only a small number of neurons remaining at the retinal base. Histological analysis of Haemonea retinal fragments is incomplete. These results suggest a reexamination of the present model for opisthobranch retinal organization. Supported by NS15264 to G.D. Block.

14.4 DEMONSTRATION OF IN VIVO AND IN VITRO COUPLED PACEMAKERS IN BULLA GOULDIANA. M.H. Roberts and G.D. Block. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

Bilaterally distributed circadian pacemakers have been identified in a number of organisms. These include the rodent, cockroach, crayfish and several marine gastropods including Aplysia californica (for review see Aschoff, 1981). Many of these organisms have been used to study the properties of pacemaker-pacemaker interactions. However, to date it has not been possible to study a coupled circadian pacemaker system in vitro. We now provide evidence that the two ocular pacemakers of Bulla gouldiana are mutually coupled and that their interactions can be observed in vitro.

Our study of in vitro coupling was prompted by our observations that Bulla, when compared to Aplysia, generally exhibit more coherent and sustained free-running locomotor behavior. Previous work by Lickey et. al. (1980) had shown that poor quality Aplysia free runs were often associated with desynchrony between the two ocular rhythms. We reasoned therefore, that the Bulla eyes, as controlling pacemakers, may always remain in phase, unlike their Aplysia counterparts. In a test of this hypothesis, we determined that even after a month of darkness, the Bulla ocular rhythms were never separated by more than 4 hours. In contrast, results in Aplysia from Lickey's laboratory indicate that ocular phase separations of up to 9 hours appear in as little as two weeks (Hudson, 1978).

This ability of Bulla to maintain ocular pacemaker synchrony in constant darkness can also be demonstrated in vitro. By applying a 12 hour cold pulse to a single eye of an intact Bulla nervous system maintained in vitro, it is possible to induce a 10 hour phase separation between the two ocular rhythms. If the eyes are then allowed to interact through the optic nerves and cerebral ganglion for 36 to 48 hours, the ocular phase separation gradually diminishes to about 4 hours. When a similar cold pulse is applied to a single eye of an intact Aplysia nervous system the 10 hour phase separation remains, even after a number of days of interaction. It appears therefore, that unlike Aplysia, the Bulla ocular pacemakers are tightly coupled and any induced phase difference is quickly reduced.

This is the first demonstration of a coupled circadian pacemaker system in vitro. It should now be possible to investigate directly the dynamics of pacemaker-pacemaker interactions. Supported by NS15264 to G. Block.

14.5 CIRCADIAN PACEMAKER OF BULLA EYE: ELECTRON MICROSCOPY, DYE INJECTION, INTRACELLULAR RECORDING. Jon W. Jacklet and William Colquhoun*. Department of Biology, SUNYA, Albany, NY 12222.

The isolated eye of Bulla gouldiana, the marine bubble snail, contains a circadian pacemaker since the isolated eye expresses a circadian rhythm of compound action potentials (CAP) frequency (Block & Friesen, 1981), similar to the eye of Aplysia. Our electron microscopy of the eye shows it contains about 2500 photoreceptors of 3 types: a large (90 x 30 μm) electron-dense type replete with dense aggregates of 600 Å cytoplasmic vesicles and a large microvillous distal segment; a large clear type with fewer cytoplasmic vesicles and a distinctively different distal segment with larger diameter microvilli; a small slender spindle-shaped receptor with short microvilli and lacking vesicles present in the larger receptors. There are about 70 secondary neurons (20 μm dia), lacking photoreceptor specialization, clustered around the extensive neuropile at the base of the eye. Each secondary neuron has a broad clear axon extending to the optic nerve and neurites branching to the neuropile. Neurons contain rough ER, golgi, dense-core 1000 Å vesicles, and neurotubules similar to secondary neurons of Aplysia eye. Gap junctions between receptors and glial cells, secondary neurons and glial cells, receptor neurites and receptor neurites, and secondary neurites and secondary neurites are common. The optic nerve contains about 2600 axons, perhaps in 1:1 correspondence with the number of receptors and neurons in the eye. Intracellular recording and Lucifer yellow injection show photoreceptor responses of at least 3 types: light induced depolarization without spikes, depolarization with spikes, and depolarization/hyperpolarization with spikes. Dye injections show these responses are from retinal photoreceptors and each has an axon in the optic nerve. Unitary spikes in the photoreceptors are not correlated with the optic nerve CAP but appear in the optic nerve as unitary spikes. The spikes of secondary neurons are correlated 1:1 with the spontaneous and light evoked CAP. Dye injection shows these neurons are clustered at the base of the eye and each has an axon in the optic nerve similar to neurons of the Aplysia eye (Jacklet et al., J. exp. Biol., in press). Secondary neurons of Bulla may be driven to spike by direct current injection, which causes other secondary neurons to fire also and produces an optic nerve CAP. This suggests the secondary neurons are a population of electrically coupled neurons. The neurons are the output neurons of the circadian pacemaker in the eye and very favorable for continued intracellular recording combined with experimental techniques to explore the mechanisms of circadian rhythms. Supported by NSF BNS11154.

14.6 LIMULUS VISUAL THRESHOLD VARIATIONS MEASURED BEHAVIORALLY: DAILY AND SEASONAL EFFECTS. Gerald S. Wasserman. Dept. of Psychological Sciences, Purdue University, West Lafayette, IN 47907.

Limulus ventral eye visual thresholds were measured psychophysically over a period of almost one year. A 12:12 LD schedule was maintained; all testing was done in the afternoon. A seasonal trend was found: In Summer, thresholds clustered around one value. In Winter, thresholds clustered around another value that was 2 log units higher. In Spring and Fall, thresholds were more widely distributed between the two values. This finding suggested but did not prove that two different states exist, that one or the other state prevails in the Summer or Winter, and that both states are present in Spring and Fall. This suggestion was tested by examining response latencies which were also season dependent: In both Summer and Winter, latency followed Pieron's Law and was a declining logarithmic function of intensity with the Summer function shifted toward lower intensities relative to the Winter function. But in Spring and Fall, latencies first declined as intensity was increased, then rose at intermediate intensities, and then fell again at high intensities. This confirms the suggestion that the Spring and Fall results do not come from a single population because a mixture of the Summer and Winter populations should produce a nonmonotonic latency versus intensity function. This mixed function would follow the Summer pattern at low intensities because these would be below the threshold for the Winter type of animal. However as the intensity is raised to the point where Winter type animals do begin to respond, then their average would rise towards the Winter value. Once all animals were recruited, then the function would once again follow a declining pattern. Individual animals exhibited threshold variations that were comparable to the overall group variation. This was true whether one examined data from freshly delivered animals or whether one examined data from animals which had been tested repeatedly in our laboratory for several months. In all seasons, individual animals also exhibited threshold variations from day to day that were as large as the mean difference between Summer and Winter thresholds. A signal detection method was used to examine these day-to-day variations within animals. Large and statistically significant within animal day-to-day variations in signal detectability were found. These data suggest that there are two visual states, that most of the animals are in the more sensitive state in the Summer, that most of the animals are in the less sensitive state in the Winter, and that animals are more evenly distributed between the two states in Spring and Fall. The daily results suggest that any individual can be in either state at any time of the year but that the probability that an animal is in a given state varies with the season.

14.7 REGENERATION OF THE OPTIC TRACTS AND CIRCADIAN PACEMAKER ACTIVITY IN THE COCKROACH. Terry L. Page, Dept. Gen. Biol., Vanderbilt University, Nashville, TN 37235.

It is well established that bilateral severence of the optic tracts (OT) of the cockroach Leucophaea maderae disrupts the circadian locomotor activity rhythm. I found, however, that rhythmicity in DD consistently reappeared in 3-5 weeks (27±5.5 days, N=11) after OT section. After its reappearance the freerunning period (τ) of the rhythm was strongly correlated with τ before surgery (r=0.91), but on the average was slightly longer ($\overline{\Delta\tau}$ = 0.2±0.35h). Also, the phase of the freerunning rhythm (ϕ), projected back to the day of surgery, was correlated with ϕ of the pre-operative rhythm (r=0.77). The average of the absolute values of the differences in phase was 3.4±2.29h (95% conf. limits). It was also found that exposure of animals to light cycles during the first 10 days after OT section (leaving connections between the OL and compound eyes intact) shifted the phase of the subsequent rhythm.

Several observations suggest the return of rhythmicity after OT section is likely due to regeneration of neural connections between the optic lobes (OL) and the midbrain. (1) After removal of the OL, aperiodicity persisted indefinitely (>100 days, N=13). (2) Insertion of a piece of glass coverslip between the OL and the midbrain to slow regeneration prevented return of rhythmicity in 6 animals (>75 days) and delayed it in 3 animals (46±14.9 days). Insertion of the coverslip elsewhere in the head capsule had no effect on the reappearance of the rhythm (N=6). (3) Histological examination of brains following return of rhythmicity showed regeneration of structural connections between the OL and the midbrain. (4) Extracellular recording several weeks after OT section and ocelli ablation showed the return of light evoked activity in axons of the cervical connectives. This activity was abolished if the OT were re-cut. (5) The time course of the return of the light evoked activity paralled the return of behavioral rhythmicity.

These results are consistent with the view that the circadian pacemaker that drives the activity rhythm resides in the OL and controls rhythmicity via neural connections with the midbrain. They also suggest that the oscillation persists in the optic lobe after optic tract section, that it can be entrained by light, and that it is capable of regenerating those connections with the midbrain that are necessary to drive the activity rhythm.

(Supported by PHS-NIH grant GM30039 and BRSG grant PHS-NIH 2-507-RR07201-02).

14.8 NEUROFUNCTIONAL MAPPING OF THE EFFECTS OF ELECTRICAL STIMULATION IN THE SUPRACHIASMATIC NUCLEUS. A.M. Rosenwasser, E. Yadin, N.T. Adler. Dep't of Psychology, University of Pennsylvania, Philadelphia, PA 19104.

The suprachiasmatic nucleus (SCN) of the hypothalamus has been implicated in the control of circadian rhythmicity in a wide variety of neural, endocrine, and behavioral systems. These widespread effects of SCN damage on circadian rhythms are consistent with the neuroanatomical evidence regarding SCN efferents, which appear to be similarly widespread.

Schwartz and coworkers have used the 14C-2-deoxyglucose method of autoradiography to demonstrate the presence in the SCN of a circadian rhythm in neurofunctional activity (Science 205, 723, 1979). Such circadian metabolic rhythms were not seen outside the SCN. On the other hand, electrophysiological studies reveal SCN-dependent rhythms in electrical activity in a number of brain areas. In the present study, we explored the functional connectivity of the SCN by combining 2DG autoradiography with electrical stimulation of the SCN. Chronic stimulating electrodes were aimed unilaterally at the SCN of rats. 30-40 μCi of 14C-2DG were injected ip and stimulation (100-200μA; 0.1 ms pulses at 100 pps) was delivered throughout the 45 min survival period. Animals were sacrificed and their brains were removed and sectioned on a cryostat for autoradiography (10-14 days exposure to x-ray film). Following autoradiography, the sections were stained with cresyl violet or thionin. The results were analyzed using a computer-assisted image processing system (Drexel-Penn system) which allowed the direct super-imposition of radiographic and histological information. Control brains included those in which the electrode placements were found to be outside the SCN as well as similarly treated but unstimulated brains.

Thus far we have analyzed primarily the intrahypothalamic effects of unilateral SCN stimulation by comparing the 2DG uptake of several bilaterally paired nuclei. Increases in 2DG concentration of 10-20% were seen in the anterior hypothalamic nucleus, the paraventricular nucleus, the ventromedial and dorsomedial nuclei, the lateral hypothalamus, and the posterior hypothalamic nucleus on the stimulated side of the brain relative to the unstimulated side. On the other hand, decreased 2DG uptake was noted in the arcuate nucleus on the side of SCN stimulation. These radiographic effects corresponded closely to histologically defined nuclear regions, and were not observed in the control brains. THese results complement and add to the results of SCN connectivity studies using transport of labeled amino acids. It is hoped that by elucidating the functional consequences of SCN stimulation we will help clarify the role of this area in circadian organization.

14.9 ROLE OF THE INTER-CONNECTIONS OF THE SUPRACHIASMATIC NUCLEI IN THE HAMSTER CIRCADIAN SYSTEM. Cheryl L. Sisk and Fred W. Turek. Dept.Neurobiol.& Physiol., Northwestern Univ., Evanston, IL 60201.

The splitting of the circadian rhythm of activity of rodents into 2 separate components provides evidence for multiple oscillators within the mammalian circadian system. In hamsters exhibiting a 2-component split activity rhythm, unilateral lesions of the suprachiasmatic nucleus (SCN) reinstate a single-component activity rhythm. This suggests that an oscillator or population of oscillators within a single SCN can control a single activity component. Neurons within each SCN project to the contralateral nucleus and their axons cross the midline within the underlying optic chiasm. The function of these SCN inter-connections is unknown. To determine if these fibers provide neural coupling between putative circadian oscillators, midsagittal knife cuts which severed the SCN reciprocal connections were made in male golden hamsters which had developed a split activity rhythm during prolonged exposure to constant light. Preoperatively, each of the split activity components consisted of a dense band of activity usually 1-2 hr in length. Following the knife cut, it was frequently observed that the 2 activity components became more diffuse and of longer duration, consisting of many small activity bouts per component with a total activity duration of up to 5 hr per component. In other hamsters, the postoperative phase relationship between the 2 components was noticeably different from the characteristic preoperative 180° antiphase. Other consequences of the knife cut which were observed included changes in phase of the 2 components with respect to time of day, and either an increase or a decrease in period of the components. Importantly, postoperatively the 2 components were never seen to free run with differing periods and were always stably in phase with each other. This range of responses was observed in hamsters in which the knife cut was on the midline and had resulted in minimal or no damage to either of the SCN. Complete abolition of the split activity pattern occurred only in hamsters found to have sustained substantial unilateral SCN damage. These results suggest that (1) the neural connections between the SCN participate in the integration of individual activity bouts into unified activity periods which are under circadian control, (2) the connections may be involved in regulating certain parameters of coupled circadian oscillators such as period and phase, and 3) in the absence of the SCN-SCN neural connections which traverse the optic chiasm, other neural or hormonal pathways exist which allow for the stable coupling of the 2 activity components in the split circadian system.

Supported by a grant from the Whitehall Foundation.

14.10 PERINATAL ENTRAINMENT OF HAMSTER CIRCADIAN RHYTHMS. Fred C. Davis* and Roger A. Gorski. Laboratory of Neuroendocrinology of the Brain Research Institute & Department of Anatomy, UCLA School of Medicine, Los Angeles, California 90024.

Study of the development of the neural mechanisms which underly circadian rhythm generation should contribute to a more general understanding of this important biological problem. A useful approach to this question is to determine when during development circadian mechanisms first become functional. The present study demonstrates that the activity/rest rhythm of hamster pups is entrained by maternal rhythmicity at some age prior to weaning (postnatal day 18), and suggests that this entrainment actually begins before birth. Wheel-running activity was recorded from hamster pups following weaning at 18 days of age. Continuous recording of activity for several weeks in constant dim light (dim LL, < 1 lux) provides a precise determination of the phase of activity onset on the day of separation from the mother. Pregnant hamsters were maintained in dim LL throughout gestation and lactation, with some hamsters receiving 10% heavy water (D_2O) for drinking water. The D_2O was used to lengthen freerunning period in some of the mothers. At weaning four pups from each of four litters (2 H_2O and 2 D_2O) were individually isolated in wheel-running cages. Phases of activity onset of the 16 pups occured at widely scattered "clock times" (probability of random distribution >0.1, Rayleigh test). The scatter, however, is related to differences in the mothers' phases of activity onset resulting from differences in their freerunning periods. Relative to "mother time" pups were found to be synchronized ($P<.001$), phase leading their mothers by an average of 1.6 hr. This relationship between mother and pup onsets could have been established prenatally, postnatally or during both times. To test if maternal entrainment of pup rhythms occurs before birth, mothers were maintained on one of two 14/10 light/dark cycles with lights off 180° out of phase. Pups from these mothers were raised in dim LL by foster mothers from only one of the prenatal LD cycles. If the pups possessed entrained rhythmicity at birth, the groups would be either "in phase" or "out of phase" with their foster mothers. At weaning, "in phase" pups (n=12) were synchronized ($P<.001$) either with respect to "clock time" or "foster mother time", phase leading the mothers by an average of 1.7 hr. "Out of phase" pups were not synchronized ($P>.1$) either with respect to clock or foster mother time. The synchronization among "in phase" pups suggests an entraining influence by the foster mothers which did not occur with the "out of phase" pups. This difference can only be attributed to the difference in prenatal phase, suggesting that entrainment of rhythmicity in the pups occurs before birth. Supported by NRSA HD05916 to FCD and NIH grant HD01182 to RAG.

14.11 CIRCADIAN RHYTHMS OF BODY TEMPERATURE AND WHEEL RUNNING IN THE TURKISH HAMSTER(Mesocricetus brandti). H. E. Albers, D. S. Carter*, J. M. Darrow* and B. D. Goldman*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545

Much of the empirical base for current views of the functional and physiological organization of the mammalian circadian timing system has been obtained from studies using the Syrian (golden) hamster (Mesocricetus auratus). In view of the lack of data in other hamster species we have begun to examine the circadian system in the closely related Turkish hamster (Mesocricetus brandti). In each of 8 male Turkish hamsters entrained to LD 16:8, core body temperature was telemetrically recorded at hrly intervals for 27 consecutive hr and wheel running was continuously monitored on an event recorder. Body temperature varied between 36.3 ± 0.1 and 38.4 ± 0.1°C over the 24 hr day. The initial rise in temperature tended to anticipate the 8 hr dark phase while activity began shortly after dark onset. The acrophase of the activity rhythm occurred ~2.5 hr after dark onset, while temperature maxima were consistently found 1.74 ± 0.12 hr later into the dark phase, as determined by a least squares sine wave fitting technique. To determine the characteristics of the free-running circadian activity rhythm records were obtained from 14 male and female hamsters initially maintained in LD 16:8 and subsequently exposed to constant light (LL; 40 lux) for 2 months. Several hamsters displayed precise free-running circadian patterns of activity similiar to those reported for the Syrian hamster; however, the activity rhythms of the remaining hamsters were less regular displaying spontaneous changes in period and/or phase. Time series analyses indicated that the activity pattern of each hamster had a statistically reliable period within the circadian range (24.38 ± 0.14 hr). Following 30 days of re-entrainment to LD 16:8, all hamsters were blinded and castrated to determine if the spontaneous changes in the free-running patterns were produced by either LL exposure or endogenous changes in gonadal steroids. Activity records for the 2 months following surgery suggested that free-running rhythms were more disrupted than during the previous LL exposure. Time series analyses revealed 2 different statistically reliable circadian periods within the activity records of each of 8 hamsters. In summary, Turkish hamsters maintain precise circadian patterns of both body temperature and activity when entrained to an LD cycle. However, under constant conditions the activity rhythm exhibits spontaneous perturbations which are not the simple result of the disruptive effects of LL or changing levels of gonadal steroids. These data emphasize the importance of comparative studies of circadian organization and suggest that functionally important differences may exist in the circadian system of even closely related species.

14.12 SPLIT FREE-RUNNING ACTIVITY RHYTHMS IN THE GOLDEN HAMSTER: DIFFERENTIAL RESPONSES OF THE TWO COMPONENTS TO SINGLE 6-HOUR DARK PULSES. Jodi G. Lees* and John D. Hallonquist. Dept. of Zoology, University of Toronto, and Dept. of Psychiatry, Mount Sinai Hospital, Toronto, Ontario, Canada.

The phenomenon of splitting of the locomotor activity rhythm in the golden hamster has been well documented. Splitting is generally considered evidence for the presence of two mutually coupled oscillators underlying this rhythm. Conditions that result in splitting are well known (eg., environmental lighting, hormonal milieu of the subject), however, little is known regarding the formal properties of the two components while in the split condition. Phase shift experiments may reveal certain characteristics of the underlying pacemaker system(s).

Eleven male golden hamsters were maintained in constant light (LL) of 100-175 lux to encourage splitting. Six of these subjects displayed split wheel-running activity rhythms after 60 to 122 days in LL. Five subjects (2 split, 3 non-split) were first exposed at various circadian times to a single 2-hr. pulse. The effects of this pulse were minimal, therefore all 11 subjects were subsequently exposed to a single 6-hr. dark pulse at various circadian times after 128 to 137 days in LL. A second 6-hr. dark pulse was presented 6 wk. after the first 6-hr. pulse, allowing sufficient time for the rhythms to stabilize.

The 6-hr. dark pulses had profound effects on the split rhythms. These effects appeared to depend on the time of pulse presentation relative to activity onset, as well as an interaction between the two components. Of greatest interest were the differential responses of the 2 components of split rhythms. Components often shifted in opposite directions. Components shifting in the same direction did so by different amounts. In some cases, immediate and steady-state phase shifts of a single component occurred in opposite directions. Occasionally these shifts were as large as 7 hr. In most cases transients resulted in the reestablishment of the pre-pulse phase relationship. In a few instances a single split component was not expressed for 1-17 days post-pulse. Another effect was the merging of 2 split components as a result of unequal phase shifts followed by changes in periodicity from $<$ 24 hr. to $>$ 24 hr. Effects of 6-hr. dark pulses on non-split rhythms included phase shifts, temporary splitting lasting up to 38 days post-pulse, or no effect at all. Transients were smaller in size and persisted for fewer days in non-split rhythms.

Compared to well-integrated non-split rhythms, split rhythms appear to be more labile in their response to dark pulses. The differential response of the split components provides further evidence for multioscillator control of the circadian locomotor activity rhythm in the golden hamster. (NSERC grant to N. Mrosovsky, Dept. of Zoology, U of T, & NSERC graduate award to JGL.)

15.1 RECOVERY TIME AND TACTILE LEARNING FOLLOWING SM-1, SM-2 AND SM 1+2 LESIONS IN THE RAT. S. Finger, T. Hart* and E. Jones*. Psychol. Dept., Washington Univ., St. Louis, MO 63130.

In an earlier study from this laboratory (Finger & Reyes, Physiol. Beh., 15:289, 1975) rats with simultaneous bilateral lesions of Sml+2 were tested for acquisition of a series of 5 tactile discriminations. The animals with ablations performed worse than sham operated rats (and comparably to each other) whether given weeks, months or 1-2 years for recovery.

The question asked in the present study was whether persistent deficits would also be witnessed after lesions restricted to just Sm-1 or just Sm-2, or whether there would be observable recovery over time after these "subtotal" sensorimotor cortex lesions. To answer this question, 52 rats with bilateral lesions of Sm-1, and 47 with bilateral lesions of Sm-2, were tested on the same battery of tactile discriminations that was used previously. The surgeries were performed when the animals were 3-4 mo. of age. Some rats were given 1 or 2 weeks for recovery; some were allowed 1 or 6 mos. for recovery; and some remained in their home cages for 1 or 2 yrs. before starting testing.

The rats with Sm-1 lesions performed poorly when the recovery period was 1 yr. or less, but scored within the control group range in the 2-yr. recovery condition. Sm-2 animals also did poorly with the shorter recovery periods, but their learning scores appeared "normal" in both the 1 and 2 yr. recovery conditions.

These data suggest that the capacity for rapid tactile learning after Sm-1 lesions is dependent upon Sm-2 remaining intact and vice-versa. Whether the animals adapted new strategies (e.g., rubbing a stimulus a bit harder), or whether they were exhibiting "true recovery," however, could not be discerned under the conditions of this experiment. Nor is it clear at the present time why such extensive recovery periods were required before the postoperative learning scores of the Sm-1 and Sm-2 rats descended into the control group range.

15.2 DEFINITION OF SOMATOSENSORY TRANSITIONAL ZONES (TR) IN THE SENSORIMOTOR (SI-MI) CEREBRAL CORTEX OF RATS. Wally Welker, Kenneth J. Sanderson, and Georgia M. Shambes. Department of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Details of afferent and efferent projections to and from somatosensory cortex in rats have not yet been defined precisely. We examined light touch somatosensory afferent and movement-elicited efferent projections of SI, MI and the transitional (TR) zones between them. Subjects were albino rats anesthetized with ketamine hydrochloride. Tungsten ball-tip microelectrodes (impedances of 0.3-1.0 MΩ) (a) recorded single- or multiple-unit responses in SI,TR & MI evoked by punctate threshold mechanoreceptive stimulation of body parts and (b) electrically stimulated laminae V & VI to evoke body movements (15-25 msec biphasic pulse trains, each pulse=100 μsec; via optical stimulus isolators at 2 trains/sec; thresholds=4-250 μA). In-depth microelectrode micromapping techniques at high puncture densities yielded micromaps of receptive fields (RF's) and movement fields (MF's). Recording and stimulating sites (marked by microlesions) were verified microscopically on frozen thionin-stained sections. RESULTS: The TR zones lie between the cell dense patches in SI that receive projections from head & forelimb and from forelimb & hindlimb, as well as between granular SI cortex and agranular MI cortex. The RF's in any portion of TR are similar in general body location to those in adjacent SI. Compared to RF's in MI & SI, TR RF's have intermediate: (1) force-amplitude-velocity thresholds, (2) size, (3) sharpness of their boundaries, (4) degree of somatotopy, and (5) cortical depth of best activation of multiple units. TR latencies to mechanical stimulation overlap those to SI & MI (for hand: SI=14-18 msec; TR=13-18 msec; MI=13-20 msec). MI "motor" maps are similar to those of Hall & Lindholm (Brain Res. 66:23-38,1974) and Donoghue & Wise (Neuroscience Abstracts, 5: 18,1981), exhibiting detailed musculotopy. Afferent inputs to MI and the rostral forelimb motor area (Neafsey & Sievert, Brain Res.232:151-156,1982) derive from RF's that are similar to the movement fields elicited from these same cortical regions. SI projections were similar to those of C. Welker (Brain Res. 26:259-275,1971). But, considerable individual variations occurred in somatotopic projections to SI and musculotopic projections from MI. SI afferent projections (at mean depths of 630μ) partially overlap MI efferent projections (at mean depths of 1320μ) in hindlimb and forelimb regions, confirming Hall & Lindholm (1974) and Donoghue & Wise (1981). These studies contribute further information to the many ongoing studies of finer projectional details of connections and functions of sensorimotor systems.

15.3 SIGNIFICANCE OF TOPOGRAPHY AND SUBMODALITY IN THE ORGANIZATION OF BRODMANN'S AREA 1 IN SmI OF MACACA. Mary Carlson, Shao Dianhua* and Xu Bingxuan*. Institutes of Physiology and Brain Research, Academia Sinica, Shanghai, PRC and Dept. of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

The representation of the cutaneous input from the hand in the postcentral gyrus in Macaca has been variously described. Paul et al.('71) proposed separate hand projections aligned serially in areas 3 and 1, and with the digit tips pointing rostral; Kaas et al.('79, '80) also proposed separate hand zones for 3 and 1, but organized as mirror images with digit tips at the 3a-3b and 1-2 borders('71); Whitsel et al.('71) proposed a single cutaneous core zone within 3 and 1. The relative position of the digit receptive fields(RFs) in area 1 remains the most disputed issue in the topographic organization of the hand area/areas.

In an attempt to resolve this issue we recorded in several species of Macaca, using anesthetized and unanesthetized preparations and multi- and single neuron techniques. We found that the glabrous surface of the digits projected to area 3 and the hairy digit RFs projected to area 1 but not to area 3. RFs on the digit tips projected to the 3a-3 border, the area 1-2 border and also to the 3-1 border. However, RFs from both proximal and distal digits were frequently interspersed throughout area 1 in the anteroposterior plane. RFs on distal hairy digits projected to the area 3-1 border and proximal digit RFs to the area 1-2 border. Although RFs of glabrous digits were frequently adjacent to those on the dorsal, hairy surface of the same distoproximal location in area 1, the topography of hairy RFs was more evident than for glabrous RFs. In studies of awake Macaca we found neurons in area 1 responded to either glabrous or hairy digit skin or to joint manipulations, in close proximity in single perpendicular penetrations. The organization of submodalities in area 1, as in area 2, appears more important than topography.

Our studies of Macaca SmI are in agreement with some components of all previous studies but differ in emphasizing the heterogeneity of the representation in area 1. We conclude that 1) cytoarchitectural distinctions between areas 3 and 1 in primates are associated with different projections of glabrous and hairy skin and 2) glabrous RFs in area 1 of primates represent an ectopic projection within the original hairy RFs, both in Macaca and the prosimian, Nycticebus (Carlson and FitzPatrick, '82)

15.4 CALLOSAL CONNECTIONS OF POSTCENTRAL SOMATOSENSORY CORTEX IN OWL AND MACAQUE MONKEYS: I. THE RELATION OF TERMINATIONS AND PROJECTING CELLS TO THE SEPARATE BODY MAPS IN AREAS 3b, 1 AND 2. H.J. Gould, III, C.G. Cusick*, T.P. Pons, H.P. Killackey, and J.H. Kaas. Dept. of Psych., Vanderbilt Univ., Nashville, TN 37240, Dept. of Psychobiol., Univ. of Calif., Irvine, CA 92717, and Dept. of Anat., LSU Med. Ctr., New Orleans, LA 70112.

Recently, it has become apparent that each of the four architectonic fields of the traditional "First Somatosensory Area" of monkeys corresponds to a separate representation of the body (e.g. Kaas et al., [Science, 204: 521, 1979]). The goal of the present study was to see how callosal connections relate to these separate representations. Axonal terminations and cells of projection were revealed by horseradish peroxidase (HRP) histochemistry following multiple injections (.04 to .2 μl typically at 0.5 to 1.5 mm spacing) of the tracer into postcentral parietal cortex of one hemisphere and extensive microelectrode mapping (350 to 575 recording sites) of the body representations in Areas 3b, 1, and 2 of the other hemisphere. Reference microlesions were placed to facilitate correlation of recording sites with body cytoarchitecture and locations of labeled neurons and axon terminations. Brains were cut in the parasagittal plane or flattened and cut parallel to the surface. The flattened brains allowed the two dimensional surface view of the connection pattern to be directly appreciated.

The results lead to several major conclusions. 1) The connection patterns for New and Old World monkeys were roughly similar. 2) The separate representations differed markedly in the overall magnitude of callosal connections. Callosal connections were sparse for Area 3b, moderate for Area 1, and very dense for Area 2. 3) In all three Areas, projecting and receiving areas were correlated, although projecting regions tended to be somewhat more broadly distributed. 4) The connections were unevenly distributed across body parts in the three representations. For Area 3b, the most dense connections were largely restricted to the representations of the trunk and parts of the face. However, scattered labeled cells were found elsewhere even occasionally in the representation of the glabrous hand. In Area 1, the pattern was similar, but the limb regions generally contained more label than in Area 3b. In Area 2, more densely labeled regions included all major body parts including the hand and foot. Since the representations in Areas 3b, 1, and 2 are serially connected, the results suggest that the callosal transfer of information is largely delayed until it reaches the Area 2 representation, where transfer occurs for all body parts. More limited transfer concentrated on some body parts occurs for the representations in Areas 3b and 1. Supported by NIH Grant NS16446.

15.5 CALLOSAL CONNECTIONS OF POSTCENTRAL SOMATOSENSORY CORTEX IN OWL AND MACAQUE MONKEYS: II. LAMINAR AND AREAL DISTRIBUTION PATTERNS. C.G. Cusick*, H.J. Gould, III, T.P. Pons, H.P. Killackey, and J.H. Kaas. Dept. of Psych., Vanderbilt Univ., Nashville, TN 37240, Dept. of Psychobiol., Univ. of Calif., Irvine, CA 92717, and Dept. of Anat., LSU Med. Ctr., New Orleans, LA 70112.

In the previous abstract callosal connections were related to the separate body representations in Areas 3b, 1 and 2 (Gould et al.). Two further aspects of the organization of callosal projections are laminar patterns of origin and termination, and the tangential clustering of connected regions within architectonic areas. These features of the somatic callosal connections were studied in the material described previously. The projecting cells had similar laminar locations in each of Areas 3b, 1 and 2. Most labeled neurons were found in the lower part of layer III, fewer were found in upper layer III, and an occasional one in layer V. The great majority of callosally projecting neurons were pyramidal cells. The basal dendrites of well-defined cells showed a variety of morphologies. In some cases, basal dendrites formed a radiating field around the soma, in others, basal dendrites extended horizontally in the lamina of the cell body, and still other neurons had basal dendrites descending below the level of the cell body. There was no clear preponderence of one type of dendritic morphology. The distribution of anterograde HRP label was also similar in the 3 architectonic fields. Anterograde label was densest in layer IV, decreased in density in the lower part of layer III and extended to layer I. The anterograde label appeared strongest in a region traditionally considered to be part of Area 2. In this heavily labeled region, the terminal field in layer IV was very conspicuous, and it was clear that the dense terminal layer was spatially separate from the layers containing projecting cells.

The areal pattern of distribution was reconstructed from parasagittal sections and was directly apparent in the flattened sections. In the trunk region, 3-4 elongated patches were seen, one of which appeared to be roughly associated with the 3b/1 border as defined physiologically and anatomically. Patches of input were also seen in the face region of areas 3b and 1, but evidence for a regular pattern was lacking. These findings suggest that: 1) although the origin and termination zones roughly correspond in their tangential distribution, the laminar patterns are not precisely homotypic. The presence of a dense terminal field in layer IV suggests that stellate cells found in this layer form a synaptic link in the interhemispheric transfer of information. 2) The bands or patches of callosal neurons and terminations do not form simple repeating shapes but may be complexly organized in relation to peripheral receptive fields and cytoarchitectonic areas. Supported by NIH Grant NS16446.

15.6 STIMULUS-EVOKED METABOLIC ACTIVITY IN THE VENTROBASAL THALAMUS OF MONKEYS. S.L. Juliano, B.L. Whitsel & P.J. Hand. Dept. Physiol. & Dental Res., Univ. of N. Carolina, Chapel Hill, NC and Dept. Animal Bio., Sch. Vet. Med., Univ. of PA, Phila., PA.

Although much information exists regarding the body representation in the somatosensory thalamus, neurophysiological investigations of this region have not provided maps possessing the fine grain of those available for the somatosensory cortex. The (^{14}C)2-deoxyglucose (2DG) technique provides an excellent means, in the same animal, for studying the detailed relationship between the peripheral mechanoreceptor sheet and its representation in both the ventrobasal complex (VB) of the thalamus and in the cortical fields which receive VB projections. The experiments in this study mapped the 2DG activity evoked in VB by precisely controlled mechanical stimuli applied to different regions of the body. Five Cynomolgous monkeys were used; details of the method have been reported previously (Juliano, et al., J. Neurophys., 46, 1981). Different modes of somatic stimuli were applied unilaterally to varying proximo-distal regions of the upper and lower limbs. These stimuli were servo-controlled: flutter vibration (15 hz), brush strokes (27 cm/sec) and joint rotation (12^{o}/sec). The VB labeling of all animals exhibited certain common attributes. 1) The labeling was dorsoventrally extensive, and occupied a crescent-shaped territory. 2) Within the crescent of label, fluctuations in optical density exist, revealing regions of dense metabolic activity embedded in larger territories of more diffuse labeling. 3) The stimulus related labeling occupies long antero-posterior distances (1-1.5 mm). The distribution of 2DG labeling shifted systematically within the medio-lateral dimension of VB as the locus of stimulation changed from one body region to another. The topographic relationships indicate that the lower extremity is represented most laterally, the face most medially, and the hand in a central position surrounded both medially and laterally by the arm. For 3 animals, the 2DG patterns were compared to the distribution of HRP labeled cells in VB obtained from injections into functionally characterized fields within SI. This comparison revealed that injections of HRP into an SI region representing the body part stimulated in a 2DG experiment retrogradely labeled cells in a territory of VB closely matching that labeled in the 2DG experiment. The significance of the arrangement of the 2DG label into intermittent dense cores embedded within crescents of less dense label is not immediately apparent. The possibility exists that the dense core labeling corresponds to aggregates of VB neurons whose receptive fields (RFs) were maximally engaged by the stimulus employed, while the surrounding less dense field of activation corresponds to neuron aggregates whose RFs are less completely engaged by the same stimulus. (Supported by NS 10865 and DE 02668)

15.7 ARE THERE INTERNEURONS IN THE THALAMIC SOMATOSENSORY PROJECTION NUCLEUS IN THE RAT? J. Wells, T. J. Mathews* and M. A. Ariano. Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Evidence has been accruing that the thalamic projection nucleus for the somatosensory system in the rat (ventral posterolateral nucleus - VPL) contains no interneurons. Confirmation of the absence of interneurons is important for at least two reasons. Since other projection nuclei have interneurons, it would indicate that the rat VPL must have developed unusual mechanisms for the maintenance of somatotopy and modality specificity. Secondly, the lack of interneurons may play a role in the reactive synaptogenesis that occurs in VPL following lesions to its afferent innervation. We have attempted to show the presence of interneurons in the rat VPL by injecting the cortex with HRP in order to determine if there is a population of unlabeled neurons in VPL. In addition, since there is a high concentration of GABA receptors in VPL which might indicate GABA-containing interneurons, we have stained VPL with an antibody to glutamic acid decarboxylase (anti-GAD) to determine if there is a special population of GAD-containing neurons within VPL.

Following injections of HRP into SI cortex, Saporta and Kruger (J. comp. Neur. 174:187, 1977) found all neurons appeared labeled within a coherent band of VPL and suggested there were no neurons intrinsic to VPL. We have modified their experimental paradigm by using thinner sections so that unlabeled neurons would not be obscured by heavily labeled neurons or by the antegrade transport of HRP from cortical neurons, and by using large injections into both SI and SII cortex. When we used 10-15 µm thick sections after large HRP injections of cortex stained by the tetramethyl benzidine method, all of the neurons appeared to contain reaction product. A few neurons remained equivocal, however, in 1-2 µm sections randomly selected throughout VPL and stained by the glucose oxidase-diaminobenzidine method there again appeared to be no unlabeled neurons within the labeled zone of VPL. Therefore, if unlabeled neurons do exist, they must form a very small population.

After staining with anti-GAD there were many neurons which appeared darkly labeled. These neurons were randomly scattered throughout VPL and were the size and shape of typical VPL projection neurons. There were too many neurons stained by the anti-GAD reaction to account for the unlabeled or equivocal population observed after HRP injections. Thus, there may be a subpopulation of VPL neurons that perhaps use GAD for the synthesis of transmitters such as glutamate. These studies further support the evidence that the VPL in the rat does not contain interneurons. Supported in part by PHS 5429-17-3 to J.W and BNS 81-02648 to MAA.

15.8 PATTERNS OF CORTICAL PROJECTION UPON THE VENTROBASAL THALAMIC COMPLEX OF CAT, E. Ramon-Moliner, Department of Anatomy and Cellular Biology, Shool of Medicine, University of Sherbrooke, Sherbrooke, Québec, Canada, J1H 5N4.

Following injections of labelled aminoacids in various points of the frontal lobe of cat, the following patterns were found: (1) The pericruciate cortex as a whole sends fibers to VA and rostral VL, to ventral LP, to medial VPM, to VPLm (but not to VPLl, unless rostrolateral sigmoid cortex is included), to CL (profusely), to CM (sparsely), to the perifascicular region and to certain unnamed islands within the pretectal region (see below). (2) Following multiple microinjections in pericruciate (anterior, lateral and posterior sigmoid) gyrus, the lack of projections to caudal VL and lateral VPM results in a dark, negatively outlined area, surrounded by a "white halo" of labelled fields, when using dark field illumination. Its shape is ovoid and lies within the VB complex. It could be partially due to failure to inject the deeper intracruciate cortex. It is present, though less extensively, following single injections in intracruciate, coronal and anterior ectosylvian cortices. (3) The lateral sigmoid cortex projects to caudal VL, VPL, lateral VPM, caudal CL and medial n. ruber. The lateral sigmoid projection to caudal VL also outlines a nonlabelled oval field within which certain circumscribed spherical labelled fields ("ventrobasal islands") can be seen. (4) An injection confined to the cortex within the depth of the cruciate sulcus resulted in labelling of ventral LP, caudal VL, CL, CM, and the intermediate perifascicular region. A negatively outlined area, devoid of afferents, also resulted from this intracruciate injection. (5) The rostral interhemispherical cortex, including gyrus proreus and genualis, projects selectively to MD, centralis medialis, dorsomedial LD and paratenialis. (6) All the injected areas in the rostral forebrain send fibers to the perifascicular region and to some unnamed scattered small fields in the pretectal region. This projection takes place by means of collaterals of the cerebral peduncle which form the bundle of Ramón y Cajal (Trab. Lab. Invest. Biol. 25: 129-143, 1928) or prerubral bundle (Brain Res. 170:1, 1979; and 194: 484, 1980). The proreus-genualis, medial precruciate, and lateral pericruciate (sigmoid) cortices project respectively to dorsal, intermediate, and ventral perifascicular regions. (Supported by grant MA6820 from the National Research Council of Canada).

15.9 GAD IMMUNOREACTIVE NEURONS IN THE VENTRAL POSTERIOR NUCLEUS OF CAT AND GALAGO. G.R. Penny, D. Fitzpatrick*, D. Schmechel* and I.T. Diamond. Depts. of Psychology and Neurology, and Neurobiology Program, Duke University, Durham, NC 27706.

This report is a companion to our abstract on the lateral geniculate nucleus in this volume. In this study we use the presence of glutamic acid decarboxylase (GAD) immunoreactivity to identify neurons in the ventral posterior nucleus which presumably use the inhibitory neurotransmitter GABA. GAD immunoreactivity was demonstrated by PAP and avidin-biotin immuno-peroxidase methods. We find that these neurons form a distinct class of thalamic cells on the basis of their size and morphology. In both the cat and the prosimian Galago GAD positive cell bodies are found distributed throughout the nucleus. Counts of the relative number of GAD positive cells and unlabeled Nissl stained neurons indicate that the GAD containing neurons make up about 25-30% of the neurons in the ventral posterior nucleus of both species. In addition, the ventral posterior nucleus is characterized by a dense population of GAD terminals and is divided by GAD-free fiber lamellae. The GAD positive neurons are significantly smaller than the unlabeled, Nissl stained neurons in the same regions. In the cat, a sample of GAD cells has a mean soma area of 150 um^2 and unlabeled Nissl stained neurons in the same area have a mean size of 308 um^2. In the Galago the mean size of a sample of GAD cells is 90 um^2 and unlabeled Nissl stained neurons in the same region have a mean size of 178 um^2. Although most of the unlabeled, Nissl stained neurons are larger than the GAD positive neurons, it is of interest to note that there are some non-GAD neurons that are small and are in the size range of the GAD positive neurons. We have previously reported that neurons of this size-class may project to the superficial cortical layers. The GAD positive neurons display few primary dendrites (2-4), and these dendrites tend to be oriented parallel to the fiber lamellae which transect the ventral posterior nucleus. The similarities in size and proportion of GAD positive neurons in the ventral posterior nucleus and the lateral geniculate nucleus of these species, supports the idea that GABAergic inhibitory neurons are a consistent feature of the organization of sensory relay nuclei in the mammalian thalamus. Whether GAD positive neurons are, in fact, local circuit neurons is currently being tested by combining retrograde labeling with immunocytochemistry.

(Supported by NSF research grant BNS-79-15780 and NIMH grant 04849 (ITD), and NIMH predoctoral fellowship 08312 (GRP)).

15.10 SOMATOTOPIC ORGANIZATION OF THE VENTROPOSTERIOR NUCLEUS OF THE SQUIRREL MONKEY (Saimiri sciureus). R. J. Nelson, J. H. Kaas, M. M. Merzenich, R. W. Dykes and M. Sur*. Depts. of Psychology and Anatomy, Vanderbilt Univ., Nashville TN 37240.

To determine the detailed somatotopic organization of the ventroposterior nucleus of the thalamus in squirrel monkeys, we used multi-unit recording techniques to record in each of the three cardinal planes because reconstructions made from penetrations in any one plane yield incomplete topographic sequences of the body surface representation.

Multi-unit responses to natural stimulation were characterized for recording sites at 50 um intervals under ketamine anesthesia. Receptive fields were mapped for sites responding to tactile stimulation. Subsequent histological reconstruction of electrode tracks in each case confirmed that sites responding to cutaneous stimulation were confined to thalamic nuclei VPL and VPM. Cells at recording sites dorsal and ventral to VPL were activated by non-cutaneous input.

Results show that there is a single systematic representation of the contralateral body surface in VP although there is also a submodal segregation in this region of the thalamus (Dykes et al., Neuroscience 6(8):1687-1692, 1981). The dorso-caudal portion of VPL receives input from the axial body where body surface locations from cranial to caudal on the trunk are represented from medial to lateral. Ventral to the trunk representation, the proximal extremities and the dorsal surface of the hand and foot are represented. Most of the ventral and rostral portions of VPL are occupied by the representation of the glabrous hand and foot. Each digit of the hand and foot is represented in a smaller region which, when reconstructed, appears disc-shaped, elongated in the antero-posterior dimension and internally concave, conforming to the external curvature of VPL. The volar pads are represented dorsal to the representation of the digits for both hand and foot. VPM receives input from the face with the lips represented ventrally and rostrally while the remainder of the face and head represented dorsally and caudally adjacent to the trunk representation in VPL.

Reconstructions of VP in each plane show that no single cardinal plane contains a strictly continuous representation of the body surface; there are discontinuities in the representation in each cardinal plane, which result in abrupt shifts in the receptive field sequence for sites recorded as little as 100 um apart. These abrupt shifts are most likey to occur in the medio-lateral plane. When discontinuities do occur in the thalamic representation of the body surface they correspond with naturally occurring body surface discontinuities such as those between the digits of the hand and foot.

Supported by NIH grant NS-16446 to J. H. Kaas.

15.11 CORTICO-LIMBIC PATHWAY FOR TOUCH: CONNECTIONS VIA SOMATOSENSORY CORTICAL FIELDS IN THE LATERAL SULCUS OF THE MONKEY, D. P. Friedman, E. A. Murray and M. Mishkin. Lab. of Neuropsychology, NIMH, Bethesda, MD 20205

Combined damage to the amygdala and hippocampus results in a severe tactual memory deficit in monkeys (Murray, E. A. and M. Mishkin, Neurosci. Abstr., 7: 237, 1981). Yet the pathways by which somatosensory information could reach these limbic structures and thereby account for their participation in tactile memory processes have not been established. In a search for such pathways, single- and multi-unit recording techniques were used to identify the specific cortical fields in the parietal lobe and the lateral sulcus of macaques that are activated by somatic input. These fields include the first and second somatic sensory areas (SI and SII), areas 5 and 7b, the retroinsular area (Ri) and the granular and dysgranular insular fields (Ig and Id). After a particular field was mapped, an injection of either tritiated amino acids or horseradish peroxidase was made into the hand or digital representation within it to trace its connections.

The anterograde and retrograde axonal transport experiments together demonstrate reciprocal connections between SII and Ri, SII and area 7b, SII and Ig and Id, and Ri and Ig. We have confirmed the previously reported reciprocal connections of SI with SII, and demonstrated reciprocal projections between area 5 and both Ri and area 7b.

The laminar pattern of termination of these projections suggests the sequential order in which the somatic sensory fields process information. In the visual system, "forward" cortico-cortical projections (i.e., projections directed away from striate cortex) are characterized by a heavy input to layer IV, while "backward" projections completely avoid layer IV and instead have a characteristically heavy input to layer I. By analogy with the visual system, an analysis of the laminar pattern of termination in our material indicates that the forward sequence of projections is: SI to SII and area 5, area 5 to Ri and 7b, 7b and Ri to SII, and SII and Ri to Ig; SII also projects to Id. Finally, we have confirmed previously reported projections from Ig and Id directly to the amygdala and indirectly to the hippocampus via the rhinal cortex.

These data demonstrate, for the first time, a series of parallel tactile processing pathways that converge on the insular cortex, via which somatosensory information can then reach the limbic structures of the temporal lobe. The entire set of connections could serve as a hierarchically organized cortico-limbic pathway for tactile perception and memory.

15.12 CENTRAL REPRESENTATION OF A SPECIALIZED MECHANORECEPTOR ARRAY IN THE WING OF THE BAT. J.M. Zook and B. C. Fowler*, Coleman Lab. University of California, San Francisco, Ca. 94143.

The bat's wing is an elaborated hand in which the elongated digits and arm support six web membranes. For more than a century prior to the discovery of echolocation it was commonly believed that a special tactile sensitivity of the wings enabled bats to fly and navigate in the dark.

We have begun to investigate the nature and distribution of wing cutaneous receptors and their representation in the central nervous system by recording within somatosensory cortex and by histological examination of the wing. Primary somatosensory cortex was mapped with closely spaced microelectrode penetrations in anaesthetized bats of the species Antrozous pallidus.

These experiments reveal a number of unique features both of the cortical representation of the wing and of the mechanoreceptor population within the wing. More than a fifth of the body surface representation in somatosensory cortex is devoted to a representation of the wing. Although the membranous web is very thin, both dorsal and ventral wing surfaces are completely represented. The alternating order of digits and web membranes across the wing surface is not maintained in the cortical representation, i.e. digits are represented in one area and webs in another. However, within each of these areas, the topographic order of the relevant surface is maintained. Most units within the area of web representation are characterized by slowly adapting response. Optimal stimuli for the wing surface were light touch or puffs of air. Cutaneous receptive fields were centered around Haarscheiben (Pinkus domes) which are found in a prominent array on both ventral and dorsal surfaces. These raised dome structures are aligned in single file rows which form a distinctive geometric pattern across the wing. This pattern is consistent within any one species but varies between species. Histological examination reveals identifiable Merkel cells within these Haarscheiben.

These findings reveal a highly specialized somatosensory system in which peripheral receptors are of a single type (Haarscheibe) arranged in an elaborate geometrical array. The central representation of these receptors consists of a segregated population of slowly adapting units. The importance of this system to the bat is suggested by the relative size of the representation in somatosensory cortex and the preserved representation of both dorsal and ventral wing surfaces. The unique anatomical and physiological features of this system appear well suited to provide specialized sensory feedback from the wing, e.g. to indicate changes in air flow or pressure across its surfaces during flight.

16.1 DEVELOPMENT OF THE AUDITORY ORGANS OF THE BULLFROG: A LIGHT AND SCANNING ELECTRON MICROSCOPIC STUDY. W.P. Shofner and A.S. Feng. Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL 61801

We have previously demonstrated that during development, physiological changes occur in the peripheral auditory system of the bullfrog (Shofner and Feng, 1981). In particular, the distribution of best excitatory frequencies of intermediate and high frequency selective primary auditory fibers shift downward. The changes in frequency selectivity of these two populations of auditory fibers during development presumably reflect in part morphological changes in the amphibian and basilar papillae. The development of these two auditory organs was investigated using light and scanning electron microscopy.

Otic capsules of anesthetized adult (13-17 cm snout -vent length) and juvenile (3-4.5 cm snout -vent length) bullfrogs were opened and gently perfused with buffered 4% glutaraldehyde. Following fixation, entire otic capsules were decalcified, dehydrated, cleared and embedded in paraffin. Serial sections (15 u) were stained in hematoxylin and eosin for light microscopy. For scanning electron microscopy, the auditory organs were excised following fixation and subsequently dehydrated, critical point dried and mounted on aluminum stubs. The mounted specimans were sputtered coated with Au/Pd. Quantitative measurements were made from serial reconstructions of camera lucida drawings of hematoxylin and eosin stained sections and stereopair scanning electron micrographs.

During development, there is a dramatic increase in the volume of the basilar papilla lumen. In addition, the tectorial membranes of the basilar and amphibian papillae increase in size during this period of development. These changes are accompanied by increases in the size of the sensory epithelia and number of hair cells. The morphological changes observed in the basilar and amphibian papillae presumably alter the frequency selectivities of these organs during development.

16.2 ULTRASTRUCTURAL DEVELOPMENT OF THE EAR IN THE TOADFISH, OPSANUS TAU. Bernd Sokolowski* (SPON: A. B. Butler), Department of Anatomy, Georgetown University, Washington 20007.

Fishes are the only vertebrates in which inner ear hair cells appear to proliferate throughout life. Consequently, fishes are a potential model system for understanding the mechanisms involved in hair cell growth and regeneration in vertebrates. However, since previous studies of the teleost ear have dealt solely with the function and morphology of the adult sensory epithelium, little is actually known about the development of the ultrastructure of these sensory cells. Thus, before we can gain further insights into the mechanisms involved in hair cell proliferation in the adult we need to learn about the ontogeny of the sensory epithelium, particularly with regard to hair cell development and the formation of the different hair cell orientation patterns.

In the present study, ultrastructural development of the saccular macula of the toadfish, Opsanus tau, was studied in the adult and at early ages from an embryo to two weeks post-hatching, using scanning and transmission EM. The adult toadfish saccule has a typical teleost four quadrant hair cell orientation pattern with two vertically oriented and two horizontally oriented hair cell groups. TEM of embryonic tissue shows that the centriole precursors to the kinocilia are present at the 12 somite stage, while kinociliary buds are seen by the 25 somite stage. The initial kinociliary buds are centrally located on the surface of the sensory cell and are seen prior to the development of the stereocilia. The saccular sensory epithelium in the one-day post-hatched animal (approximately 10-12 days post-fertilization) has cells with a single kinocilium, as well as other cells with a kinocilium and a few small stereocilia. Cells with only a kinocilium are of two types. One type has a kinociliary bud that is centrally located on the apical portion of the cell while the other has a more developed kinocilium located to one side. The fully developed hair cell ciliary bundles are first encountered at one end of the developing saccular macula and as growth continues they are found over the whole epithelial surface. Individual sensory cells appear to have their adult orientation as soon as their kinocilium and stereocilia are recognizable. This is particularly noticeable by 7 days post-hatching. By 10 to 14 days post-hatching, the shape of the saccular sensory epithelium approximates that of the adult. At these ages there are a large number of hair cell ciliary bundles over the entire surface of the macula although bundles are still forming. (Supported by NSF grant BNS 80-0943 and by a grant from the Lerner-Gray Fund for Marine Research of the American Museum of Natural History).

16.3 POSTNATAL DEVELOPMENT OF SPIRAL GANGLION CELLS IN THE RAT COCHLEA A.M. Schwartz, M. Parakkal*, and R.L. Gulley. NIH, NINCDS-LNO, Bethesda, MD 20205.

The postnatal development of the spiral ganglion in the albino rat was studied using light and electron microscopy. The morphological characteristics distinguishing type 1 from type 2 spiral ganglion cells were defined and the critical period for distinguishing the two types of cells was identified. Twenty-eight OM strain rats divided into eight age groups (newborn,2,4,6,8, 10,14, and 30 postnatal days) were used. At birth, the spiral ganglion consists of a homogenous population of small, densely packed spherical cells, which have large nuclear/cytoplasmic ratios. The cell somas are surrounded by a single layer of glia. No synapses were observed on the spiral ganglion cell bodies at this or any subsequent age. During the first postnatal week, the cells mature slowly. The spiral ganglion cell exhibits numerous filopodial extensions of the membrane, and the developing myelin extends long glial fingers which can be seen wrapped around the filopodia. By the end of the first postnatal week, the myelin sheath generally consists of a few layers of loose myelin. By postnatal day 8, the two types of spiral ganglion cells can be distinguished. The type 2 cells are often found in clusters of two or three and are usually, but not exclusively,located at the periphery of the ganglion. Using phase contrast light microscopy, on toluidine blue stained semithin sections, the type 2 cell is smaller than the type 1. Its cytoplasm stains less intensely compared with the type 1 cell, while its nucleus often appears darker with a fine rim of dense material along its edge. In the electron microscope, the most characteristic features of the type 2 cells are the dense packing of neurofilaments but marked sparsity of other cytoplasmic organelles, especially rough endoplasmic reticulum. Type 2 cells generally are ensheathed by multiple layers of loose myelin that even retain small amounts of glial cytoplasm in the lamellae, while type 1 cells have compact myelin surrounding the soma. By day 14, spiral ganglion cells are morphologically mature based on cell size, packing density, nuclear/cytoplasmic ratio, lack of filopodia, and full complement of cytoplasmic organelles. The myelin sheath, however, continues to thicken after this age. The results are in good temporal agreement with previously observed findings on the morphological maturation of the organ of Corti and the electrophysiological development of the auditory system in the rat.

16.4 THE ORGANIZATION OF THE SACCULE OF HELOSTOMA TEMINCKI. William M. Saidel* and Arthur N. Popper, Department of Anatomy, Georgetown University, Washington, D.C. 20007

The complex structure of the saccule of H. temincki (the kissing gourami) was investigated with several techniques. The hair cell orientation pattern was studied with SEM; the nerve innervation pattern, by the reduced silver stain of Winkelmann and Schmitt; acoustic frequency mapping by intense sound destruction of hair cells; and electrophysiological performance by microphonic and axon recordings. The results suggest that this saccule is organized along a 'pseudo place-like' mechanism.

Three types of hair cells were seen with SEM. Hair cells with a long kinocilium and a few, short stereocilia border the sensory epithelium. The bulk of the epithelium is covered by hair cells with a graded ciliary bundle. A type intermediate in structure is found between these two hair cell types. The hair cells are distributed into four orientation groups, the anterior two are oriented along the fish's horizontal axis, and the posterior two, along the fish's vertical axis.

The reduced silver preparations revealed a pattern of innervation onto the saccular sensory epithelium by eighth nerve fibers that followed certain rules: i) the anterior saccular branch innervates only the horizontally oriented cells and the posterior branches innervate the vertically oriented cells; ii) fibers appear to innervate hair cells of specific types; and iii) fibers may individually innervate hair cells in a single orientation group or opposite orientation groups. Innervation of hair cells in orthogonally polarized orientation groups has not been seen.

Use of intense tonal stimulation demonstrated that pure sine wave stimuli destroy hair cells in large and reproducable loci on the saccular sensory epithelium. The distribution of frequency specific loci is not linearly tonotopic. Support for frequency responsive loci has also been derived from microphonic recordings and responses of single axons known to innervate specific epithelial regions.

This organization is simultaneously useful in providing input for sound localization, and in the analysis of the acoustic signals to the fish. We propose that the response of the hair cells on the saccular epithelium will be dictated by the motions of the otolith relative to the epithelium. This motion will be in the form of an 'orbit' within the saccular chamber due to the modes of stimulation of the teleost ear, and that each 'orbital' will depend upon the characteristics (i.e., direction, spectral components) of the stimulating signal.

16.5 SIMILAR NUMBERS OF STEREOCILIA ON BOTH LARGE AND SMALL APICAL SURFACES OF HAIR CELLS IN THE GOLDFISH VESTIBULAR SYSTEM.
C. Platt and J. D'Andrea*. Dept. Biological Sciences, Univ. Southern California, Los Angeles, California 90007.

Fishes, unlike mammals, have only vestibular Type II cylindrical hair cells as sensory receptors in their inner ears. Yet this single type exhibits wide diversity in the form of the ciliary bundle that extends from the apical surface of each cell. Each bundle consists of one true cilium, the kinocilium, at one end of an array of several stereocilia. Since the recent work of Hudspeth and co-workers has shown that the stereocilia mediate the mechanosensory transduction process, we wanted to examine the numbers of stereocilia present in some of the different bundle forms.

The utricle is the gravistatic otolith organ of the ear, and has a dished sensory macula. Anteriorly, a region called the striola contains large hair cells that have much larger apical surfaces and thicker, taller ciliary bundles than those found in the floor of the macula, the cotillus. After conventional aldehyde fixation and osmium post-fixation of goldfish inner ear tissues, we used a sonication bath for 5-30 sec to shear off the ciliary bundles from the utricular maculae. After dehydration and critical-point drying, scanning electron microscopy then showed the base of each bundle as an array of dots on the apical surfaces of the sensory cells. We measured the length, width and stereociliary number of the arrays on large cells sampled from the striola and small cells from the cotillus of utricles from 6 goldfish.

The mean lengths of the arrays are roughly 1.5 μm for the small bundles and 2.0 μm for the large bundles; the mean widths of the arrays are roughly 0.8 μm for the small and 1.2 μm for the large bundles. The differences between small and large are significant, for both lengths and widths. If the area covered by the array is approximated by a rectangle, the small arrays sampled occupy a mean area of less than 1.5 μm^2, but the large arrays occupy roughly 2.5 μm^2. Surprisingly, the stereociliary number found in both large and small arrays was close to 40, the small cells averaging roughly 38 and the large cells roughly 43.

These results show that the large cells have almost twice the spatial area of the stereociliary array on their surfaces, but only about 10% more stereocilia in that array than the small cells. If the stereociliary number is important to the magnitude of the receptor potential, this similarity suggests that the small cells may be as mechanosensitive as the large cells. If this difference partly represents growth, it suggests that many small cells already have a full complement of cilia, which then thicken and spread apart slightly during development.

16.6 MOTION OF HAIR-CELL STEREOCILIA IN THE AUDITORY RECEPTOR ORGAN OF THE ALLIGATOR LIZARD.
T. Holton* and A. J. Hudspeth (SPON: M. E. Olds). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

In vertebrate auditory organs, hair cells are thought to transduce mechanical displacements of their hair bundles into receptor potentials. In the auditory receptor organ of the alligator lizard, the basilar papilla, hair cells rest on a basilar membrane which moves in response to sound. The motion of this membrane differs from that of the mammalian membrane in that it is not tonotopically organized; that is, the frequency selectivity of motion does not vary with longitudinal position along the organ (Peake, W. T. and Ling, A. L., J. Acoust. Soc. Am., 67:1736, 1980). However, responses of cochlear-nerve fibers innervating the basal portion of the papilla are tonotopically organized (Weiss, T. F., Peake, W. T., Ling, A. L. and Holton, T., Evoked Electrical Activity in the Auditory Nervous System (Naunton, R. F. and Fernandez, C., eds.), Academic Press, 1978, p. 91). In this region, the hair bundles protrude into fluid unencumbered by overlying tectorial structures and have heights that vary monotonically with position along the organ. We have sought to determine whether tonotopic organization exists at the mechanical input to the hair cells, that is, whether hair bundles in different positions along the organ move maximally in response to stimuli of different frequencies.

We have observed the motion of individual hair bundles in response to mechanical stimulation in an in vitro preparation of the lizard's basilar papilla. The organ is cemented across a perforated partition separating two fluids, a high-K^+ saline bathing the top (hair-bundle) surface of the organ and a high-Na^+ saline bathing the bottom (basilar-membrane) surface. Motion of the organ, induced by driving the fluid in the bottom compartment with a piezoelectric bimorph element, is observed under differential-interference-contrast optics with xenon-flash stroboscopic illumination and recorded on 35mm film or videotape.

The main finding is that the motions of the distal tip of a hair bundle and of the top surface of its hair-cell body are different, frequency-dependent functions of longitudinal position. As a result, the relative motion between these structures, which constitutes the effective mechanical stimulus to the cell, is frequency-selective and tonotopically organized: the longest hair bundles move preferentially at low frequencies (∿ 1.5 kHz), while the shortest hair bundles move preferentially at high frequencies (∿ 4 kHz). Thus, tonotopic organization of hair-bundle motion and neural response are correlated, suggesting that receptor-organ micromechanics partly determines such neural response properties as frequency selectivity and tonotopic organization.

16.7 MECHANICAL PROPERTIES OF HAIR BUNDLES OF RECEPTOR CELLS IN THE GUINEA PIG COCHLEA.
D. Strelioff and Å. Flock*, Division of Head and Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024 and Dept. of Physiology II, Karolinska Institutet, S-104 01 Stockholm, Sweden.

The static mechanical properties of hair bundles (HB) on sensory hair cells were investigated and the stiffness of the HB were measured in an isolated preparation of the guinea pig cochlea. The preparation consisted of about three-quarters of a coil of the second (T2), third (T3) or fourth (T4) cochlear turn which was carefully dissected free and maintained in tissue culture medium (Leibowitz, L15) at room temperature. Removal of the stria vascularis and the tectorial membrane permitted access to the apical surfaces of the hair cells. The coil was mounted in a microscope chamber where it was held horizontally and could be rotated to provide proper alignment of the HB with respect to a probe of known stiffness. The tips of the stereocilia of a hair cell and the probe were viewed with differential interference contrast optics while the probe, a vertical quartz glass fiber about 1 μm in diameter and 500-700 μm in length, was used to displace the row of stereocilia by 1 μm. From measurements of the bending of the probe, the stiffness of each HB was determined.

It was found that the cilia within each HB are attached to one another, that the cilia do not bend but pivot at their attachment to the hair cell and that both attachments of the cilia are irreversibly damaged by horizontal deflections greater than 2 μm (≈ 25°). The HB stiffness (defined as the force required to deflect the tips of the HB by 1 μm) was 0.90±0.35 dynes/cm for the first row of outer hair cells in T4, increased toward the base of the cochlea (3.48±0.38 dynes/cm for the first row of outer hair cells in T2) and decreased radially for the three rows of outer hair cells. On the basis of measurements of the lengths of the hair bundles we suggest that the longitudinal variation in stiffness is due mainly to the decrease in the length of the HB from apex to base. Another significant finding was that the HB are approximately twice as stiff in the excitatory direction (toward the basal body) as in the opposite direction.

The longitudinal stiffness variation may play an important role in the tuning properties of the cochlear partition. In addition, the asymmetric stiffness may account for some of the nonlinear properties of cochlear mechanics, receptor potentials and neural responses recorded in the mammalian auditory system.

16.8 MOTION OF BASILAR PAPILLA AND HAIR CELL STEREOCILIA IN THE EXCISED COCHLEA OF THE ALLIGATOR LIZARD: RELATION TO FREQUENCY ANALYSIS.
L.S. Frishkopf, RLE, MIT, Cambridge MA 02139, D.J. DeRosier* and E.H. Egelman*, Rosenstiel Center, Brandeis U., Waltham MA 02254.

The basilar papilla in the alligator lizard is an elongated auditory receptor organ containing hair cells attached to the basilar membrane which vibrates in response to sound. The axis of symmetry of the stereociliary bundle of each hair cell - presumably the sensitive direction for displacement - is perpendicular to the long axis of the papilla. CF's of nerve fibers are between 0.2 and 4 kHz and vary systematically with location in the nerve (Weiss et al in Evoked Electrical Activity in the Auditory Nervous System, Naunton and Fernandez, eds., 91, 1978). Yet measurements of basilar membrane velocity suggest that the frequency response does not vary from one part of the basilar membrane to another and thus does not provide a basis for the observed variation of nerve fiber CF (Peake and Ling, J. Acoust. Soc. Am. 67: 1736, 1980). Where then does frequency analysis take place? One possibility is that, within the basilar papilla, modes of motion may occur which are not evident in the measurements of basilar membrane motion. It has also been suggested that the gradual variation in maximum length of the free-standing stereocilia in the posterior two-thirds of the organ, from 30 μm in the 1 kHz region to 12 μm in the 4 kHz region, may provide a micromechanical basis for frequency analysis over this range of CF (Weiss et al, loc cit).

To address these issues, the motion of the basilar papilla and of the free-standing hair cell stereocilia that results from acoustic stimulation has been observed under a microscope. The cochlear duct was excised and the basilar papilla with its supporting limbus was mounted in a drop of lizard Ringer's solution across an opening in an air-filled chamber; the organ was stimulated with tones (0.2 - 6 kHz; 110 - 130 dB SPL) and viewed stroboscopically at 400 - 800X. Results are: (1) the papilla rocks about an axis parallel to its length in the direction of symmetry of the stereociliary bundles, i.e. in the direction of sensitivity of the hair cells; (2) the papilla moves in phase along its entire length, consistent with Peake and Ling's findings; (3) above 3 kHz, the displacement of the high-CF region exceeds that of the rest of the papilla, perhaps providing a partial basis for frequency analysis; (4) the stereociliary bundles move relative to the underlying cuticular surface in the direction of presumed hair cell sensitivity; the phase angle of the relative movement of the stereocilia tips is a function of frequency and of the position of the hair cell along the basilar papilla; these findings are consistent with an explanation of frequency analysis in the papilla based on length-dependent mechanical tuning of stereociliary bundles.

16.9 THE LEAKY INTEGRATOR MODEL OF THE SPIKE GENERATION MECHANISM SIMULATES THE BEHAVIOR OF UTRICULAR AFFERENTS. E. Soto*, R. Budelli*, M. T. González-Estrada* (SPON: M. M. Rodríguez-Budelli). Unidad de Investigaciones Cerebrales, Instituto Nacional de Neurología y Neurocirugía. México, D. F. and Universidad Autónoma de Puebla. Puebla, México.

The leaky integrator model simulates the phase-locking of the discharges from several sensory afferents. There is a group of utricular afferents (Type I from Budelli & Macadar, 1979) which shows phase-locking; so, these afferents can be simulated by a leaky integrator. Another group of afferents (Type II) does not show phase-locking, so it might be assumed that the behavior of these afferents can not be simulated by the leaky integrator. Nevertheless we would expect from a model to reproduce the behavior of every type of afferents by an adequate selection of the parameters. The leaky integrator always shows phase locking for stimulus with frequencies closed to the spontaneous firing rate and small intensities. There is a chance that if certain model parameters are chosen, the range of frequencies within which phase-locking is apparent can be very small. This would reduce the probability of finding phase-locking experimentally. We were able to determine the frequencies and amplitudes range within which the phase-locking is produced for different time constants of the model. We found that, for values of the time constant (τ) similar or shorter than the period (ρ) of the spontaneous firing, the range of the stimulus parameters where the model produces phase-locking is relatively wide, as it is observed for Type I afferents. For $\tau >> \rho$ the range vanishes giving a result similar to that of Type II afferents. If we select the parameters in a way such that the model produces phase-locking, it, also, reproduces the relation frequency of stimulus-rate of firing and the gain curves of Type I afferents. On the other hand, if we select the parameters in order not to produce phase-locking, the model reproduces the curves of Type II afferents. This shows that quantitative changes in the time constant of the model produce qualitative changes in the behavior of the simulated afferents.

Budelli & Macadar (1979): Statoacoustic properties of utricular afferents. J. Neurophysiol. 42:1479.

16.10 EFFERENT MODULATION OF HAIR CELL TUNING IN THE TURTLE COCHLEA. J.J. Art*, A.C. Crawford*, R. Fettiplace* and P.A. Fuchs. Physiological Lab., Cambridge Univ., Cambridge CB2 3EG, England.

Most major features of frequency selectivity of turtle hair cells can be described in terms of a parallel resonance which correctly predicts their responses to acoustic stimuli and current injection (Crawford, A.C. & Fettiplace, R., J. Physiol. 306:79, 1980; ibid, J. Physiol. 312:377, 1981). This frequency selectivity is decreased following efferent stimulation. Intracellular records from hair cells show that there is a direct synaptic input onto these cells which controls both their mean membrane potential and their tuning properties.

A long-lasting hyperpolarization (50-300 ms) is recorded from hair cells following electrical stimulation of the vestibular branch of the eighth nerve. In response to a single shock the inhibitory post-synaptic potential (IPSP) has a rise time of about 25 ms and decays exponentially with a time constant of about 50 ms. The amplitude of the IPSP facilitates strongly with multiple shocks so that eight shocks separated by 4 ms may produce IPSPs which are as large as 25 millivolts in cells with resting potentials of between -45 and -58 millivolts. When hair cells are hyperpolarized by injecting currents in excess of -300 pA, the IPSP is reversed in polarity, indicating that the synaptic potential arises from an increase in membrane conductance to ions whose equilibrium potential is approximately 30 mV negative to the resting potential.

The evidence for a damping of the hair cell resonance during the efferent IPSP is as follows: a. a decrease by 1.6-25 fold in the amplitude of the receptor potential at the best or characteristic frequency (CF); b. a broadening of the frequency selectivity of the filter as measured by an increase in the half-power bandwidth of the linear tuning curve with little change in the CF; c. a faster decay of the oscillations in hair cell membrane potential in response to acoustic clicks or steps of injected current.

We reported previously a large efferent inhibition and resultant loss of frequency selectivity in the auditory afferents of this species (Art, et al., J. Acoust. Soc. Am. 69:S52, 1981). We believe that the combined effect in the hair cells of the long lasting hyperpolarization and the frequency selective desensitization following efferent stimulation is sufficient to account for both of these observations.

16.11 IMMUNOCYTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE-LIKE IMMUNOREACTIVITY IN OLIVOCOCHLEAR FIBERS IN THE GUINEA PIG COCHLEA. J. Fex, R.A. Altschuler, M.H. Parakkal*, and F. Eckenstein*. Lab Neuro-otolaryngology, N.I.H., Bethesda, MD 20205 and Max-Planck-Institute, D-8033 Martinsried, FRG.

There is considerable biochemical, physiological and pharmacological evidence that olivocochlear efferent fibers are cholinergic. With the recent reorganization of this system into lateral and medial components (Warr 1980), it has become obvious that most of this evidence pertains only to the medial component ending primarily by outer hair cells. In this study we used immunocytochemical techniques to determine the localization of choline acetyltransferase (ChAT)-like immunoreactivity in the guinea pig cochlea. Choline acetyltransferase serves as an excellent marker for cholinergic neurons, fibers and terminals.

The indirect immunofluorescence technique of Coons and the PAP technique of Sternberger were both utilized on cryostat sections through the cochlea and on whole cochlea with the bony shell removed, respectively. Antiserum to ChAT from pig brain, raised in mouse and antiserum to a ChAT-mouse IgG complex, raised in rabbit were used in this study. Both gave identical results. ChAT-like immunoreactivity was seen in the inner spiral bundle, tunnel spiral bundle and by the bases of inner hair cells, corresponding to the lateral system of efferents, and in tunnel crossing fibers and patches by the bases of outer hair cells corresponding to the medial system of efferents. This indicates that both systems of olivocochlear efferents are cholinergic. We have previously demonstrated enkephalin-like immunoreactivity in olivocochlear fibers. Studies are now in progress to determine if there is co-localization of ChAT and enkephalin-like immunoreactivities.

16.12 MULTIPLE RESERVOIR MODEL OF NEUROTRANSMITTER RELEASE BY A COCHLEAR HAIR CELL, H.A. Schwid* and C.D. Geisler. Department of Neurophysiology and of Electrical and Computer Engineering, University of Wisconsin-Madison, Madison, Wisconsin 53706.

A probabilistic model is described for transmitter release from cochlear hair cells and for primary auditory neuron EPSP's and discharge patterns. The present model assumes that several reservoirs of neurotransmitter exist, having individual probability-of-release functions centered at successively higher stimulus intensities. Refilling of the reservoirs, a crucial process, is not uniform but is from the highest intensity reservoir downwards. The model accurately mimics the adaptation of successive EPSP amplitudes of the afferent neuron of the goldfish sacculus, and, for mammalian auditory-nerve fibers, the adaptation of neural discharge rate, the saturation of onset and steady-state neural rate versus intensity, and the change in neural rate in response to incremental stimuli. The model also produces realistic interval and period histograms. Contrasting characteristics of previous single-reservoir models will also be presented. The data to be shown support the hypothesis that multiple populations of neurotransmitter are involved in the afferent hair-cell synapses.

This research was supported by NIH Program Project Grant NS-12732.

16.13 "NEUROTRANSMITTER SYNTHESIZING ENZYMES IN THE DEVELOPING CHICK INNER EAR: A MODEL FOR CELLULAR LOCALIZATION OF PUTATIVE CHEMICAL MEDIATORS IN THE VESTIBULAR SENSORY PERIPHERY". °G. Meza; °P. Cuadros*, °I. Lopez* and +M. Ruiz*, °Dept. Neurociencias, CIFIC, UNAM and +Dept. Histología, Fac. Medicina, UNAM, México, D.F.

Neurotransmission in the sensory periphery of the vestibular system is chemical in nature; the efferent neurotransmitter is apparently acetylcholine; strong evidence favors GABA as the afferent mediator. We have reported that glutamate decarboxylase (GAD), the GABA synthesizing enzyme, is present in a homogenate of isolated chick vestibular cristae and took it as evidence for GABA participation in the system; however, we were not able to say in which cells this activity was located. The chick vestibular embryogenesis is well known: the sensory epithelium develops prior to the arrival of nervous fibers. If afferent neurotransmission were GABAergic, GAD activity would be found and measurable in hair cells at a stage in embryogenesis before the fibers arrive to it; if acetylcholine were the efferent neurotransmitter its synthesizing enzyme, cholineacetyltransferase (CAT) should be detectable when efferent fibers reach the neuroepithelium. We investigated these possibilities and give the results obtained. Homogenates of vestibular cristae from chick embryos of 13,17,19 days, of the day of hatching and of 1-day old chicks were obtained and GAD and CAT activities were measured. Morphological features were followed by light and EM microscopy. We found that in the 13-day old embryo, GAD activity was already a 60% of that present in the 1 day-old chick and it reached the level of the latter at the day of hatching; whereas CAT activity in the earlier stage studied was barely detectable increasing slowly along development. The morphological studies showed that hair cells, as early as in the 13-day old embryo present some of the characteristics of the mature cell i.e., hair tufts in the apical part; typical afferent and efferent connections were not present at this stage but appeared slowly as ontogenesis proceeded. These results show that GAD activity is detectable in vestibular cristae of chick embryo before the sensory epithelium receives any connections implying that this activity is located in a cell type of this structure most probably the hair cell. On the other hand, the activity of CAT is measurable later in development in coincidence with the arrival of efferent fibers; thus CAT activity must be located in efferent terminals.

Although additional evidences are needed to proof the cellular source of the neurotransmitter candidates in the vestibular sensory periphery these results altogether can be taken to support the GABAergic nature of afferent neurotransmission and suggest that most probably the efferent mediator is acetylcholine.

16.14 ULTRASTRUCTURAL STUDY OF DEVELOPMENT OF SYNAPTIC ORGANIZATION IN THE VESTIBULAR SYSTEM OF THE CHICKEN. K. D. Peusner. Dept. of Anatomy, Geo. Washington Univ. Sch. of Med., Washington, D.C. 20037.

The tangential nucleus comprises a part of the avian lateral vestibular complex in the medulla. The embryonic bodies of the principal cells of the nucleus are contacted by large vestibular nerve afferents, the colossal fibers, by means of very large spoon-shaped synapses in a one-to-one relationship. Previous ultrastructural studies showed that the spoons attain their largest size in the late embryo, followed by atrophy postnatally (Peusner, 1980,1981). Concomitantly, small synaptic terminals seemed to increase in numbers that contact the principal cell body.

The current goal was to quantify these developmental changes in synapses. Montages were made at 31,000X magnification of 15 principal cell bodies at each of 3 stages of spoon transformation: at 15 embryonic days (time of onset of gap junctions), at hatching (when vesicular synapses disappear, although gap junctions persist), and at 3 years (when spoons have electron-dense axoplasm). The selection of bodies for the montages was random with regard to the region of the tangential nucleus and the plane of section through the body, but was dependent on the visibility of the entire perimeter of the somata, their adequate preservation, and their contact by a spoon profile.

The amount of linear surface of the somata covered by all types of synaptic terminals is constant at about 55% at all the ages studied. The spoon occupies a diminishing linear surface, on the average, from embryos (40%) to hatchlings (12%), which is retained in 3 year olds (12%). The average length of the spoons in the montages was 27.7 um in embryos (range: 13.7-38.2 um), 7.9 um in hatchlings (range: 1.7-21.1 um), and 9.0 um in 3 year olds (range: 2.6-19.6 um). In contrast, the small synaptic terminals occupy an increasing linear surface, on the average, from embryos (16%) to hatchlings (42%), that persists in 3 year olds (44%). This increase in linear surface covered by small synaptic terminals may be attributed in part to an increase in the average lengths (1.2 um in embryos, 1.6 um in hatchlings, and 2.1 um in 3 year olds) and to a fluctuation in the number of synaptic terminals per 100 um of linear surface (14.3 in embryos, 27.1 in hatchlings, and 21.6 in 3 year olds). In summary, birth marks a time for major developmental changes in synaptic endings in the avian lateral vestibular complex. In hatchlings, spoons have atrophied from their embryonic form. In addition, the surface of the principal cell body in the vicinity of a shrinking spoon is filled in by small synaptic terminals of unknown origins, that allow for a constancy in the amount of somatic surface membrane covered by synaptic profiles. (Supported by USPHS grant 5 R01 NS15633 and 7 R01 NS18108.)

16.15 DISTRIBUTION OF SENSITIVITY VECTORS IN CENTRAL VESTIBULAR UNITS RESPONDING TO LINEAR ACCELERATION, N. Daunton and G.Melvill Jones. Biomedical Res. Div., NASA Ames Res. Centre, Calif. 94035 and AMRU, Dept. of Physiol., McGill Univ., Montreal, PQ, Canada.

A population of 639 neural units responding to natural vestibular stimulation has been examined in 26 decerebrate cats by conventional extracellular microelectrode recording in a brainstem region deemed likely to receive primary afferent inputs from the otolith organs (W. Mehler). The animals were located in a stereotaxic device (22° head down) mounted on a platform suspended from the ceiling by either three parallel springs (for vertical stimuli), or three parallel steel cables (for horizontal stimuli). All units were first tested 'audibly' for qualitative assessment of response to 3-D rotational and linear acceleration. 304 units (48%) responded to rotation, but not linear acceleration, of which 171 were selectively horizontal canal dependent (91 Type I, 80 Type II), 89 vertical canal dependent (76 Type I, 13 Type II) and the remainder (44) received a variety of convergent canal inputs. Of those responding to linear acceleration (52%), 81 units were successfully recorded and averaged during 60 cycles of sinusoidal oscillation in each of the three orthogonal x (side-to-side), y (fore-aft) and z (up+, down-) directions, at 0.15 'g' amp. and 0.59 Hz. The magnitude and direction of individual resultant sensitivity vectors were subsequently calculated with the object of mapping their polar distribution relative to the skull. Mean 'spontaneous' activity in the stationary animal was 12.3 (SE 1.2) AP/sec, with no significant differences in subpopulations responding primarily in x, y and z directions; nor between those excited in +z and -z directions. The latter finding implies a neural bias opposing the DC effects of gravity on the peripheral otolith organs. There was no correlation between resting level and neural gain (r=0.06). Mean sensitivity (neural gain) of resultant vectors was 196 AP/sec/g (SE 19; range 25-1150) the only significant segregation being between those excited by contralateral (227±26 AP/sec/g) and ipsilateral (111±15) acceleration along the x axis. The directions of sensitivity vectors were not clustered along the x, y, z axes. Rather, when projected on the x-y (horizontal) plane they tended to concentrate along diagonal axes close to the planes of the vertical canals. Additional concentrations were found close to the horizontal plane. These directional trends suggest that central representation of both rotational and linear vestibular information tends to be coordinated within the same three orthogonal planes, namely those of the canals. In line with this is the fact that those 'otolith' units which selectively received H-canal input, had linear sensitivity vectors oriented close to the horizontal plane.

16.16 EVOKED FIELD POTENTIALS MEASURED IN THE VESTIBULAR NUCLEI BEFORE AND AFTER UNILATERAL PARTIAL LABYRINTHECTOMY. Janet F. Ott. Dept. Biol., Univ. Southern Calif., Los Angeles, CA. 90007.

To test for possible physiological changes involved in compensation, the plastic process allowing recovery of function after ablation of the utricle and semicircular canals unilaterally, evoked field potentials were measured in the vestibular nuclei ipsi- and contralateral to the remaining ear. Two - four goldfish each were tested at one day, two weeks, and two months post-op, in addition to several control fish having both ears. Recordings were made in lightly anesthetized fish with exposed utricles.

Recordings were made on the surface of the brain along the midline from the fourth ventricle to the rostral edge of the vagal lobes every 200 microns. At the place of the highest amplitude response, a lateral series was recorded at right angles to the midline on the ipsilateral (stimulated) side. Response amplitudes increased, then decreased with distance from the midline. At the highest amplitude response, a depth profile was made recording again at every 200 microns. Except in two cases, this was the point where a unique waveform change was noted at some particular depth. Recordings were then made at points 200 microns rostral, caudal, medial and lateral to this point and at the corresponding points on the contralateral side.

A point of unique waveform change was always noted on the ipsilateral side, generally directly beneath the point of highest response amplitude on the surface. Points surrounding the unique waveform had responses that increased, then decreased in amplitude with depth, but showed no change in waveform. These ipsilateral responses do not change after unilateral partial labyrinthectomy. However, the contralateral side shows changes. Control and day one fish show a small response on the surface at the point corresponding to the unique waveform approximately one-tenth to one-fourth the size of the ipsilateral surface wave. There is no change in waveform with depth. Beginning at approximately two weeks, the surface waveform increases in amplitude and the waveform changes with depth corresponding to the change on the ipsilateral side. This change is not seen in all two week post-op fish and may be related to the fact that the behavior is variable during this period also (Ott, 1981). At two months, all fish show some change on the contralateral side. This is similar to findings by Dieringer and Precht in the frog (1979). This work was supported by a Grants-in-Aid for Research by Sigma Xi.

16.17 OTOACOUSTIC EMISSIONS IN MAN AND DOG: ASSOCIATION WITH COCHLEAR PATHOLOGY. M.A. Ruggero, B. Kramek* and N.C. Rich*. Depts. of Otolaryngology and Veterinary Clinical Sciences, Univ. of Minnesota, Minneapolis, MN 55455.

Spontaneous and evoked oto-acoustic emissions (OAEs) are reported to be common in seemingly normal-hearing humans. However, cases have been noted where spontaneous OAEs (SOAEs) existed at frequencies near which audiometry indicated hearing deficits. We present here data on one human ear and one dog ear, both of which produce SOAEs. In both cases, the SOAE is associated with audiometric abnormalities. Review of our data and the related literature has led us to formulate a simple hypothesis to explain the origin of both spontaneous and impulsively evoked OAEs; we propose that both phenomena arise from sharp spatial transitions in the organ of Corti, between areas of outer hair cell (OHC) loss or other pathology, and areas of relative normality.

The first author's right ear produces a SOAE at 7529 Hz and 16 dB SPL. An external continuous tone is able to suppress the SOAE. The 3 dB iso-suppression curve is broadly tuned and displaced, relative to the SOAE, toward higher frequencies. Impulsive stimuli (clicks and short tone pips) are able to synchronize the SOAE. In contrast to the suppressive effect of continuous tones, impulsive stimuli can synchronize the SOAE only if they possess sufficient energy at the SOAE frequency. An audiogram notch exists at frequencies just below that of the SOAE.

An intense SOAE (9000 Hz, 47 dB SPL) has been recorded from one ear of a young dog. Its suppression tuning curve is broadly tuned and displaced toward lower frequencies. BSER audiometry indicates severe high frequency hearing loss, sharply sloping toward normality near the SOAE frequency.

We explain the occurrence of both SOAEs and impulsively evoked OAEs in terms of disruption of active feedback mechanisms of the OHCs upon basilar membrane vibration. Each OHC feeds back positively upon its segment of basilar membrane and negatively upon adjacent segments. Normally, the two feedbacks largely cancel each other, leaving a small positive effect: the "stimulus frequency acoustic emissions" demonstrated by Kemp and Chum (in Studies in Hearing, van den Brink and Bilsen, eds., 1980). However, if a patch of OHC loss exists, adjacent segments will be released from the negative feedback and will respond to an impulsive stimulus with exaggerated oscillations at their resonance frequencies, thus producing OAEs. At particularly sharp transitions between normal and abnormal regions of the organ of Corti SOAEs will be generated. (Supported by NIH Grant NS12125)

16.18 RIPPLE NOISE PROCESSING BY THE GOLDFISH AUDITORY SYSTEM. R.R. Fay*, W.A. Yost* and S. Coombs. Parmly Hearing Institute, Loyola University of Chicago, Chicago, IL 60626.

Goldfish were classically conditioned to discriminate between complex acoustic signals called rippled noise. Ripple noise produces a pitch sensation for man and has been used to describe the filtering properties of the auditory periphery. This signal may be produced by taking a broadband noise with a flat power spectrum, delaying it (t sec) and adding it back to its undelayed version, resulting in another broadband noise with a "rippled" power spectrum -- power varying sinusoidally with frequency. The frequency spacing between spectral peaks and the spectral location of the first peak is equal to the reciprocal of the delay (t^{-1} Hz). As t increases, the spacing between peaks decreases, resulting in increasing ripple densities.

The minimum detectable change in spectral spacing (Δt^{-1}) was measured for rippled noises with spectral peak spacings at 800, 400, 200, and 100 Hz (t values of 1.25, 2.5, 5 and 10 msec). Results from 5 animals showed that the smallest detectable spacing (Δt^{-1}) remained approximately constant at about 5% of t^{-1}. These results are in close agreement with those from humans (Yost et al, J. Acoust. Soc. Am. 63: 1166, 1978), despite large differences between humans and fish in the mechanical filtering properties of the auditory periphery. These data will be compared to other psychophysical results using ripple noise as well as to neurophysiological findings on the processing of ripple noise by single units in the eighth nerve of the goldfish. These results will be discussed in terms of the temporal and spectral mechanisms responsible for the processing of this complex stimulus. (Work supported by NIH and NSF).

16.19 EXAMINATION OF THE NEURAL NATURE OF THE FREQUENCY FOLLOWING RESPONSE IN CATS. R.L. Snyder and C. Schreiner, Epstein Lab., University of California, San Francisco, CA. 94143.

Two different sets of sustained AC signals can be recorded from the auditory system in response to low frequency (below 4kHz) tones. The first is the well characterized cochlear microphonic (CM), which is generated by structures in the cochlea--primarily outer hair cells. The second is the less well defined frequency following response (FFR), whose generators are presumably neurons central to the cochlea. The FFR, usually recorded with scalp electrodes, is often dismissed as a remote recording of the CM. However, in the course of an examination of the FFR, we have been presented with a number of properties of the FFR which clearly separate it from the CM.

In anesthetized cats a platinum-iridium ball electrode was placed at the edge of the round window, and a pair of similar electrodes placed straddling the auditory nerve as it exits the internal meatus. In addition silver wire electrodes were inserted through the skin at the vertex and below each pinna. The CM was recorded differentially from the round window electrode and one of the electrodes at the internal meatus. The FFR was recorded either by recording differentially via the the auditory nerve electrodes (AN-FFR) or via the skin electrodes (S-FFR).

The intensity-response (I/O) function, the frequency-response (transfer) function, the adaptation properties, and the influence of masking stimuli were examined in the CM, the AN-FFR, and the S-FFR. The amplitude of the CM was a linear function of the input stimulus intensity up to high levels (110 dB SPL) and its phase was relatively constant. The amplitude of the AN-FFR and the S-FFR saturated or showed a marked inflection at moderate stimulus intensities (70-90 dB SPL). The phase of the FFR's was constant and different from the phase of the CM except after the inflection where it approximated that of the CM. In the transfer function the amplitude of the FFR's was relatively larger at low frequencies (below 2kHz) than the comparable CM. Moreover, the FFR transfer function displayed the expected interference dips at higher intensity levels which were unseen in the CM transfer function. In the averaged response to tone bursts the CM showed no signs of adaptation or an offset response. In contrast the FFR's showed marked adapatation and a pronounced offset response. The time course of the FFR adaptation closely matches the time course of neural adaptation seen in the auditory nerve. Non-simultaneous masking has no effect upon the CM, while forward pure-tone maskers profoundly supress the FFR's. Finally, section of the auditory nerve or injection of TTX into the cochlea greatly diminish the FFR's, while they leave the CM unaffected or only slightly decreased.

From these results we conclude that the FFR at low to moderate stimulus levels is largely a neural response whose generators are central to the cochlea and separate from those for the CM. cochlea. (Supported by the Deafness Research Foundation and a NASA grant #NCA2-OR665-003).

17.1 SYNAPTIC GAIN CONTROL IN INSECT PHOTORECEPTORS.
S. R. Shaw* (SPON: I. A. Meinertzhagen). Psychology Dept., Dalhousie University, Halifax, N.S., Canada B3H 4J1.

The first synaptic relay in the insect visual pathway is the site of amplification of small signals from photoreceptors, and of gain control during light adaptation. Despite the availability of a complete qualitative description of neural connections in the columns (cartridges) of the synaptic zone in Diptera (flies), it is unclear how gain control is exercised. Large field potentials complicate intracellular recording from the synaptic zone,or lamina, which lies inside a part of the blood-brain barrier.

To overcome field potential contamination, responses from the receptor terminal have been monitored intracellularly back in the cell body, by antidromic cable conduction up the axon. Responses from the other terminals in a cartridge then become accessible, via electrical connections between next neighbors, established by multiple gap junctions (Shaw, S.R. & Stowe, S., J. Cell Sci. 53, 115-141, 1982). A single fiber optic probe moved to the appropriate facet lens stimulates each terminal individually, because each originates from a cell under a different facet. The attenuated terminal response so recorded discloses a fast transient wave of inhibitory feedback, starting just after the direct photoresponse. Thus a brief surge of high gain afferent output can escape from the terminal, before suppression follows. The polarity of the feedback signal recorded in the soma, and the disposition of diffusion barriers around the cartridge, now rule out direct electrical interaction between pre- and postsynaptic cells as an explanation for the feedback. Instead, chemical synaptic action seems to be responsible. This is local in origin, since feedback is centered spatially upon the terminal stimulated. In addition, the total loop delay (1.5-2.0 msec, which has to include the two chemical synapses), leaves negligible time for synaptic processing outside the cartridge itself.

Two particular follower neurones make reciprocal connections back to receptor terminals within the same cartridge, and are well placed to originate the feedback. Quantitative counts of the numbers of their synapses revealed an initially perplexing result. Neither neurone comes close to matching the number of reciprocal synapses driving it directly from the receptors (~200 per terminal), seeming not to indicate a powerful gain control system. However, when the known amplification of the primary afferent synapse is taken into account, only a small percentage of the number of afferent synapses is needed in the feedback arm of the circuit, to obtain total transient suppression of receptor output. Correctly balancing the relative numbers must be an important function of the developmental program, in a system like this using high gain synapses. (Supported by NSERC grant A9593).

17.2 RPE BASAL MEMBRANE HYPERPOLARIZATION FOLLOWS LIGHT-EVOKED, K^+-DEPENDENT, APICAL MEMBRANE HYPERPOLARIZATION. Edwin R. Griff* & Roy H. Steinberg. Depts. of Physiol. & Ophthalmol., Univ. of Calif., San Francisco, CA 94143.

The response of vertebrate photoreceptors to light leads to a decrease in $[K^+]$ in the subretinal space between the neural retina and the retinal pigment epithelium (RPE). This decrease in $[K^+]$ hyperpolarizes the RPE apical membrane and, therefore, increases the trans-epithelial potential. We have recently observed in gecko retina that the subsequent recovery (decrease) of the trans-epithelial potential is not caused solely by a repolarization of the apical membrane, but rather by a hyperpolarization of the RPE basal membrane. In the cat, a similar sequence of RPE membrane potential changes occurs. Thus, absorption of light by photoreceptors leads to a hyperpolarization of the RPE apical membrane followed by a hyperpolarization of the basal membrane.

We have further studied this basal event in the perfused, isolated RPE of gecko. We mimicked the light-evoked K^+ decrease by changing $[K^+]$ in the apical bathing solution. Decreasing $[K^+]ap$ from 5 to 2 mM first hyperpolarized the apical membrane, and this was followed by a hyperpolarization of the basal membrane. The basal membrane response was more easily studied by increasing $[K^+]ap$. Increasing $[K^+]ap$ from 2 to 5 mM depolarized the apical membrane and this was followed by a depolarization of the basal membrane. Increasing $[K^+]ap$ from 5 to 20 mM, however, depolarized only the apical membrane. Addition of ouabain to the apical solution caused a depolarization of the apical membrane but no subsequent basal response. Similar results were obtained by increasing apical $[Mg^{++}]$. Thus, the basal membrane event was not triggered solely by polarizing the apical membrane. The basal depolarization produced by increasing $[K^+]ap$ from 2 to 5 mM was blocked by replacing apical $[Cl^-]$ with isethionate or methyl sulfate, suggesting that K^+ must enter the cell to produce the basal depolarization. We propose that the interaction between changes in $[K^+]ap$ and the response of the basal membrane involves a change in intracellular $[K^+]$.

17.3 EVIDENCE THAT LOCALIZED LASER-PRODUCED LESIONS CAN RETARD THE PROGRESS OF RETINA DEGENERATION IN RCS RATS.
D. Bowyer*, M.M. Behbehani, J. Ruffalo & G. Kranias* (Spon: G. Khodadad) Dept. of Physiology, Dept. of Anatomy and Dept. of Ophthalmology. Un. Cincinnati Coll. Med., Cincinnati, OH 45267.

RCS rats develop a degenerative disease that begins at age 19 days and progesses rapidly, causing blindness by age 2 months. These animals have been used as a model for retinitis pigmentosa. It has been shown that in these animals the phagocytosis of the rod outer segment disks by the pigment epithelium is abnormal. Since laser-produced lesions of the retina can increase phagocytosis, we tried to find out if laser lesions can retard the progress of retina degeneration. 19-day old RCS rats that were kept in total darkness from birth were anesthetized by morphine and fitted with contact lenses. 500 micron laser spots at 100 mw were used to produce 12 lesions in the retina of one eye. The other eye was used as control. Electroretinograms (ERG) were recorded from these animals at weekly intervals, beginning one week after the lesion. When the ERG recorded from the normal and the lesioned eye showed a significant difference, both eyes were removed and prepared for histological examination. The results of these experiments showed that the ERG recordings from the lesioned side display a prominent "a" wave for up to three weeks after the "a" wave of the ERG of the non-lesioned side has been abolished. Histological examination showed that there is an increase in number of phagosomes in the laser-lesioned retina as compared to the non-lesioned side. Since the persistence of the "a" wave in the ERG is an indication of the function of the photoreceptors, these studies indicate that the progress of the retina degeneration can be retarded by laser surgery. (Supported by a grant from the Ohio Lions)

17.4 LIGHT ADAPTATION OF ROD AND CONE PATHWAYS IN THE GOLDFISH. Robert Paul Malchow and Stephen Yazulla. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

The sensitivity changes of cells in the outer retina of the goldfish produced by steady, monochromatic backgrounds were investigated using an isolated retinal preparation. The extracellularly recorded, aspartate-isolated PIII response was used to monitor the responses from rods and cones. Intracellular techniques were used to examine the responses of rod horizontal cells, which contact only rods, and H1 horizontal cells, which receive input predominantly from red cones. Response vs. intensity (RvI) curves were generated using hyperbolic tangent functions as used by Naka and Rushton (1966), followed by the construction of increment threshold curves. Test flashes consisted of 100ms, monochromatic wide field light and were substituted for backgrounds. Responses were first obtained from the dark adapted preparation, followed by backgrounds near threshold intensity, which were then increased in 0.5 log unit increments.

Backgrounds just above threshold caused a compression of the PIII RvI curve, with more intense backgrounds resulting in a lateral shift along the intensity axis. A clear rod-cone break in the increment threshold curve was not apparent. The rod contribution to the increment threshold curve was obtained by isolating dark adapted goldfish retinas at midnight, a procedure by which all cone outer segments are stripped away with the pigment epithelium while leaving the rods intact. Such a preparation yields a PIII response that has a normal dark adapted sensitivity. Background illuminations now result primarily in response compression of the PIII, with a complete suppression of response at higher backgrounds. Rod horizontal cells also adapt to background illuminations by a compression of their RvI curves, with a concommittant narrowing of the curve's width, and intense backgrounds also lead to complete response suppression. H1 horizontal cells have a higher absolute threshold than the PIII or rod horizontal cells and have a much broader response range in the dark. Moderate backgrounds cause a response compression of these cells, as well as a narrowing of their response range. More intense backgrounds result in a lateral shift of these cells' RvI curves along the intensity axis.

This study, comparing light adaptation of rod and cone pathways in the distal retina of a single species, has shown how the rod system approaches saturation as background illumination becomes more intense, while the cone pathway remains able to respond by laterally shifting its RvI curve along the intensity axis. We are currently examining the convergence of these pathways at the level of the mixed rod-cone bipolar cells.

This study was supported by NIH Grant EYO 1682.

17.5 A SPECIES COMPARISON OF PEANUT LECTIN BINDING TO SPECIFIC PHOTORECEPTOR CELLS AND SYNAPTIC REGIONS IN THE RETINA. J. C. Blanks and L. V. Johnson*. Doheny Eye Foundation and Departments of Ophthalmology and Anatomy, University of Southern California, Los Angeles, CA 90033.

Although lectins have been used to study surface oligosaccharides of rod and cone photoreceptor cells in intact retinas and dissociated retinal cells, no lectin has been reported that binds preferentially to cones versus rods. We have found that application of FITC-conjugated peanut lectin (PNA) to cryostat sections of mouse retina results in binding that appears to be confined to a subpopulation of photoreceptor cells. PNA has carbohydrate binding activity highly specific for D-galactose-B-(1→3)-N-acetyl-D-galactosamine. The developmental appearance of PNA binding in postnatal mouse retinas coincides with the appearance of the outer synaptic layer (OSL) and the formation of photoreceptor inner and outer segments. PNA binding within the OSL appears in discrete patches, possibly associated with large synaptic pedicles of cone photoreceptor cells.

To further investigate the possibility that PNA binds specifically to cones, we have extended our study to include the cone dominant retinas of goldfish and chicken. Additional studies of PNA binding in rabbit, monkey and human all suggest that, indeed, PNA binding is specific for cone photoreceptor cells. To obtain optimum morphology, the tissue was fixed in 4% paraformaldehyde, embedded in acrylamide, frozen and cryostat sections were cut at 6-8 um. After application of FITC-PNA to the sections, binding could be detected associated with some photoreceptor cell bodies and cellular processes, that often could be traced to the patchy fluorescent areas in the OSL.

Electron microscopic investigations are underway to establish the identity of PNA-positive photoreceptor cells and specific regions of synaptic layers, as are biochemical characterizations of PNA-binding molecules in the retina.

17.6 ULTRASTRUCTURAL STUDIES OF SYNAPSES IN THE OUTER PLEXIFORM LAYER OF RETINAS OF WILD TYPE (C57BL/6J +/+) AND PEARL MUTANT (C57BL/6J pe/pe) MICE. M.A. Williams*, J. Gherson*, L.J. Fisher, L.H. Pinto. Department of Biological Sciences, Purdue Univ., W. Lafayette, IND. 47907, and Department of Ophthalmology, Henry Ford Hospital, Detroit, MI 48202

The synaptic zone of outer plexiform layer of eight mice was examined for the number and anatomical characteristics of the ribbon synapses. Three of the animals were pearl mutants and five of the animals were wild type.

Electron-dense, bulbous thickenings with diameters ranging from circa 100 to 240 nanometers were found in association with the ribbon lamellae. The electron-dense thickenings were either swellings of the ribbon lamellae near one end of the ribbon, or were discrete electron-dense spheres of similar dimensions near the ribbons. The thickenings were found only in rod spherules. Some spherules contained as many as three separate electron-dense spheres. Eleven per-cent of the ribbons in the retinas of the pearl mutants had associated swellings (247 ribbons examined). Less than 0.6% of the ribbons from the wild-type animals had associated swellings (498 ribbons examined). The spherules which contained swellings were often seen clustered throughout the retina in discrete foci of three to four neighboring or nearly-neighboring terminals.

All animals were light-adapted, anesthetized with ether, perfused intracardially with formaldehyde and glutaraldehyde, and the eye-cups processed for electron microscopy. The animals had been on a twelve hour light/twelve hour dark cycle and were sacrificed between 1100 and 1400 hours.

A similar nodular enlargement of the synaptic ribbon of rods has been reported in retinas of albino rats after excessive exposure to bright fluorescent light (Kuwabara, T. and M. Funahashi, 1976). The accompanying extensive mitochondrial damage that was observed in these rats however, was not present in the pearl retinas.

These anatomical observations suggest that the bulbous swellings may be related to the demonstrated sensitivity deficit of the pearl visual pathway, (Balkema et al, 1981).

17.7 THE GUINEA PIG RETINA CONTAINS BOTH MET- AND LEU-ENKEPHALIN. Judith L. Mosinger*, Douglas W. Hoffman and Joanne C. Gutierrez*. [SPON: M. Martin]. LNO, NINCDS, NIH, Bldg. 36, Rm. 5D-32, Bethesda, MD 20205.

This laboratory has recently published the first report of enkephalin-like immunoreactivity in a mammalian retina (Altschuler, Mosinger, Hoffman and Parakkal, PNAS, 79: 2398, 1982). Enkephalin-like immmunoreactivity has previously been reported in the non-mammalian vertebrate retina (Brecha, et. al. PNAS, 76: 3010, 1979; Eldred and Karten, Soc. Neurosci. Abstr., 7: 277, 1981). In all cases this immunoreactivity has been confined to amacrine cells and their processes in the inner plexiform layer. However, enkephalin-like immunoreactivity has not been seen in other mammalian species examined; e.g., the albino (OM) rat. To identify the molecular forms of the enkephalins in retina, extracts of guinea pig retina were analyzed by high pressure liquid chromatography (HPLC) and radioimmunoassay (RIA) for content of enkephalin-related peptides.

Retinal sonicate was centrifuged, and the supernatant injected directly onto a Waters microBondapak octadecylsilane (10 micron) column equipped with a guard column filled with C_{18}/Corasil. Fractions were isocratically eluted with 0.05% trifluoroacetic acid in 25% acetonitrile at 0.6 ml/min. One min. fractions were collected in a liquid N_2 bath, and then lyophilized to dryness. Samples were reconstituted in a phosphate-BSA buffer for RIA. RIA's were performed using two commercially available antisera raised against met-enkephalin, demonstrating significant cross-reactivity to leu-enkephalin. The use of these antisera coupled to these HPLC conditions permitted the assay of both met- and leu-enkephalin in one short (20 min.) chromatographic run and subsequent immunoassay.

Both met- and leu-enkephalin were found in the guinea pig retina, as was a third substance, which was neither met- nor leu-enkephalin but shared immunochemical characteristics with both. The identity of this third immunoreactivity moiety is not known, but it behaved chromatographically in the same manner as the enkephalin-immunoreactive substance seen in guinea pig cochlea and hippocampus, in which enkephalins are also found.

17.8 SYNAPTIC CONTACTS OF ENKEPHALINERGIC AMACRINE CELLS IN THE RETINA OF TURTLE (PSEUDEMYS SCRIPTA). W.D.Eldred and H.J.Karten. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, New York 11794

Antiserum directed against enkephalin (Chang, Burroughs-Wellcome) labels specific bistratified amacrine cells in the retina of turtle. We have examined these labeled amacrine cells (outside the visual streak) at the ultrastructural level to determine the nature and location of their synaptic contacts and the intracellular localization of enkephalin-like immunoreactivity (ELI) within these neurons. Throughout the cytoplasm there was diffuse DAB reaction product which coated the external surfaces of all organelles. The labeled neuronal profiles contained three classes of vesicles: 1) numerous small unlabeled clear-core vesicles (60 nm in dia.) which were clustered at conventional chemical synaptic release sites; 2) scattered large unlabeled dense-core vesicles (130 nm in dia.); and 3) scattered large labeled vesicles (130 nm in dia.) filled with a core of electron-dense reaction product.

These bistratified amacrine cells with ELI arborize in two strata within the inner plexiform layer (IPL); one wide stratum in the proximal IPL and a second narrow stratum in the distal IPL near the inner nuclear layer. Amacrine cells with ELI receive conventional chemical synaptic contacts from other unlabeled amacrine cells and ribbon synaptic contacts from unlabeled bipolar cells in both the proximal and distal strata of the IPL. In the proximal stratum of the IPL, amacrines with ELI make conventional chemical synaptic contacts onto unlabeled cell processes which lack synaptic vesicles and are probably from ganglion cells. Small unlabeled clear-core synaptic vesicles are clustered at these release sites. Our results suggest that enkephalin-like substances co-exist with at least one other neurotransmitter in these neurons. These bistratified amacrine cells integrate information from bipolar and amacrine cells in both the proximal and distal IPL and relay information to ganglion cells in the proximal IPL. Physiological studies are needed to determine the significance of the synaptic contacts in visual processing. This research supported by EY03801 to WDE and by EY02146 to HJK.

17.9 **BAR SYNAPSES ARE MADE BY THE INTERSTITIAL AMACRINE CELL OF THE CICHLID FISH RETINA,** **R. P. Zimmerman, Departments of Neurological Sciences and Physiology, Rush University, Chicago, IL 60612.**

The inner plexiform layer (IPL) of the retina of the cichlid fish *Astronotus ocellatus* has been shown to have an orderly three-dimensional structure (Hibbard,E.,*Exp.Eye Res.*,*12*:175,1971; Zimmerman, R.P.,*Invest.Ophthalmol. Vis.Sci. 22(Suppl.)*:112, 1982). The IPL is divided into approximately equal thirds by proximal and distal grids of neuronal processes. A roughly square pattern is imposed by the array of radial processes of the Mueller glial cells which run perpendicular to the plane of the retina.

Of particular interest is an unusual type of amacrine cell which has its cell body and processes restricted to a narrow 10 - 15 µm sublamina within the proximal grid. These *INTERSTITIAL AMACRINE CELLS* (following the terminology used by Cajal for the mammalian retina) have a triangular cell body 20 µm long and 10 - 12 µm in diameter at the widest point. The three primary processes of the interstitial amacrine (IA) branch at angles of 90 - 100 degrees; all branches remain within the plane of the sublamina.

The interstitial amacrine cell of the *Astronotus* retina is the first reported instance of processes of an identified class of amacrine cell in the vertebrate retina containing presynaptic dense specializations. The IA's contain dense presynaptic bars which are approximately cylindrical, about 60 nm in diameter and 0.22 - 0.75 µm in length. This presynaptic bar is often opposed by two postsynaptic profiles in a dyad arrangement. The postsynaptic components of the dyad may be a bipolar cell and an amacrine cell process, or two amacrine cell processes. IA's receive direct synaptic input from bipolar cell terminals as well as from other classes of amacrine cells, and are presynaptic to bipolar terminals (at reciprocal synapses), amacrine cells and ganglion cell dendrites. In addition, IA's make large gap junctions with adjacent IA's, but not with any other class of retinal cells. These gap junctions suggest the possibility of electrical coupling between IA's.

17.10 DISTRIBUTION AND MORPHOLOGY OF DOPAMINERGIC NEURONS IN THE RETINA Clyde W. Oyster, Nicholas C. Brecha and Ellen S. Takahashi. School of Optometry, University of Alabama in Birmingham and Center for Ulcer Research and Education, UCLA.

Dopaminergic neurons in the retinas of several species have been labeled by an immunohistochemical method employing antisera directed to tyrosine hydroxylase. The peroxidase-antiperoxidase technique, in modified form, shows the complete dendritic morphology of the immunoreactive neurons in flat-mounted retinas.

In rabbit retina, the dopaminergic neurons are amacrine cells. Their somata are confined to the inner nuclear layer and the dendrites ramify in the outer portion of the inner plexiform layer. The cells are sparsely and non-randomly distributed. In spite of the low density (19 cells/mm^2), the dendritic fields overlap extensively; each retinal point lies within at least three dendritic fields.

The dopaminergic neurons in pigeon retina are also amacrine cells; their morphology is quite similar to those in rabbit retina. In the cat retina, however, some of the dopaminergic amacrine cells have somata in the ganglion cell layer. These displaced amacrine cells give rise to a single process which extends up to stratum 1 of the inner plexiform layer. Here, the dendrites of the displaced amacrines ramify along with those of the main amacrine cell population. Even when these two amacrine cell populations are considered separately, however, the dendritic overlap is still significant.

This and other studies have found dopaminergic neurons in the retinas of all species which have been examined. The type of dopaminergic neuron varies between species, but the various dopamine systems share some general characteristics; they are composed of low density, non-randomly distributed cells having extensive, sparsely branched dendrites.

We thank Drs. A.W. Tank and N. Weiner for antisera. This work was supported by USPHS Grants EY02207, EY04067, EY03895, and EY03039 (CORE).

17.11 SYNAPTIC ORGANIZATION OF DOPAMINERGIC INTERPLEXIFORM CELLS IN GOLDFISH RETINA: AN EM-IMMUNOCYTOCHEMICAL/AUTORADIOGRAPHIC ANALYSIS. Charles Zucker and Stephen Yazulla, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Long Island, NY 11794.

Evidence suggests that in goldfish, the spatial properties of horizontal and bipolar cells are modified by dopaminergic interplexiform cell(DA-IPC) input. All synaptic inputs to DA-IPCs are located in the inner plexiform layer(IPL), while output occurs in the outer plexiform layer (OPL) as well as in the IPL. In this study, this synaptic organization was analyzed by combining EM-immunocytochemical localization of the biosynthetic enzyme tyrosine hydroxylase (TOH) with autoradiographic locolization of ^{3}H-GABA and ^{3}H-Glycine as well as the nicotinic- and muscarinic-cholinergic ligands ^{125}I-α Bungarotoxin (αBTX) and ^{3}H-Propylbenzilylcholine mustard (PBCM). Following one hour of glutaraldehyde and 18 hours of paraformaldehyde fixation at a pH of 10.4, sodium borohydride and buffered ethanol treatments were used to restore antigenicity and allow immunologic reagents to penetrate throughout tissue blocks. Comparison of labeling pattern of anti-TOH with other studies using either the Falck-Hillarp method or the accumulation of the biogenic amine precurser 5,6-dihydroxytryptamine indicates that we are selectively labeling the DA-IPC. DA-IPC cell bodies are found among those of amacrine cells in the proximal inner nuclear layer and send processes to both plexiform layers forming dense plexes in the OPL and the most proximal IPL and a plexus of much lower density in the distal IPL. DA-IPCs make synaptic contact with amacrine cell processes, rarely with bipolar terminals and never with other DA-IPCs. GABA accumulating pyriform Ab amacrine cells ramify in the proximal IPL making many synaptic contacts with bipolar and amacrine cells and frequent en-passant contacts with labeled DA-IPC processes. GABA accumulating processes are also seen contacting the DA-IPCs in the distal IPL. Binding of ^{125}I-αBTx indicates that the DA-IPC receives no nicotinic input. Studies utilizing ^{3}H-PBCM and ^{3}H-Glycine are presently under way. In the OPL, DA-IPCs make numerous synaptic contacts with GABA accumulating H1 horizontal cells and bipolar cells. Similar contacts, not previously described, are also made onto type H2 and H3 cone horizontal cells. The double labeling technique we have employed is a powerful tool to study the geometry of an identified neuron in regard to its specific transmitter inputs. These data when correlated with electrophysiological studies provide much needed information about the synaptic interactions involved in receptive field formation and modulation.

17.12 AMACRINES RECIPROCAL TO THE ROD BIPOLAR IN CAT RETINA ARE GABA-ACCUMULATING. M.A. Freed* and P. Sterling, Dept. Anatomy, School of Medicine, Univ. of Pennsylvania, Philadelphia, PA 19104.

At least four types of amacrine accumulate exogenous ^{3}H-GABA, but specific circuits involving these neurons have not been identified. We have examined the rod bipolar axon terminal, identified by its dark cytoplasm and unbranched, scalloped form, to learn whether any of its amacrine inputs are GABA-accumulating. In each of several cats one eye was injected with 100uCi ^{3}H-GABA; the animal was perfused 3.5 hours later with a buffered mixture of aldehydes and the retina prepared for EM autoradiography. From a series of 110 consecutive EM autoradiograms we identified three classes of amacrine varicosity associated with the rod bipolar. The AII amacrine, identified by its large mitochondrion, absence of synaptic vesicles, and presence of ribbon contact from the rod bipolar, was non-specifically labeled (0.03±0.02 grains/um^2) as was a second class (0.08±0.06 grains/um^2) identified by its synaptic input to the rod bipolar and lack of a reciprocal contact. A third class, identified by its reciprocal contacts with the rod bipolar invariably showed specific labeling (0.21± 0.03 grains/um^2).

Two types of amacrine, A_{13} (hyperpolarizing) and A_{17} (depolarizing) have been shown by Kolb and Nelson (Vis. Res., 21: 1625, 1981) to receive ribbon contacts from rod bipolars, and we (McGuire et al., 1982) have determined that every amacrine varicosity with such a ribbon contact is reciprocal. This implies that both A_{13} and A_{17} are reciprocal to the rod bipolar and, therefore, are GABA-accumulating. Indeed, A_{13} resembles morphologically our type 1 GABA-accumulating amacrine and A_{17} resembles our small, spherical GABA-acumulating amacrine (Freed et al., Neurosci. Abstr., 1981). Thus, two types of amacrine with opposite responses to light may both provide GABA-ergic feedback to the rod bipolar axon terminal and constitute a dual mechanism for regulating its sensitivity.

17.13 A GOLGI AND AUTORADIOGRAPHIC STUDY OF (^{3}H)MUSCIMOL-LABELED AMACRINE CELLS IN THE CAT RETINA. R. G. Pourcho and D. J. Goebel*. Dept. of Anatomy, Wayne State Univ., School of Medicine, Detroit, MI. 48201.

Five morphologically distinct subpopulations of neurons located in the amacrine portion of the inner nuclear layer (INL) of cat retina have been shown to label with both (^{3}H)gamma-aminobutyric acid (GABA) and the GABA agonist, (^{3}H)muscimol (Pourcho, R.G., Brain Res., 215:187, 1981). In order to provide further information about the dendritic ramification of these cells within the inner plexiform layer (IPL), Golgi impregnation has been combined with electron microscopic autoradiography. Retinas were preloaded with (^{3}H)muscimol and then processed for Golgi impregnation according to the method of Mariani in Kolb, H. et al. (J. Comp. Neurol., 189:31, 1980). After selected cells were photographed and drawn with a camera lucida, the same cells were thin sectioned for autoradiography. In order to prevent chemographic exposure of the nuclear emulsion by dichromate salts, the sections were covered with a formvar film prior to dipping into emulsion.

This technique has been used to characterize four types of amacrine cell with somas in the INL and one type with its soma displaced to the ganglion cell layer which accumulate (^{3}H)muscimol. The interplexiform cell was also found to be labeled, confirming the finding of Nakamura, Y., et al. (Proc. Nat. Acad. Sci., 77:658, 1980) that this cell in the cat may be GABAergic. Among the amacrine populations were a cell with a dendritic field of less than 100μm whose processes are confined to strata 1 and 2 of the IPL, a cell with a dendritic field of 180μm and branches in strata 2-5, and a cell whose dendrites ramify over an 800μm field in strata 4-5. All of these cells exhibited prominent varicosities on their dendritic processes. Another amacrine which ramified exclusively within stratum 2 was also labeled. The displaced amacrine had varicose processes in strata 3-4 of the IPL. Preliminary electron microscopic analysis of the synaptic relationships of these cells indicates that several participate in reciprocal synapses with various classes of bipolar cells.

The combination of Golgi and autoradiographic techniques offers the opportunity to obtain new information regarding the circuitry of neurochemically characterized cells and should aid in understanding the role of these neurons in retinal function.

17.14 RETINAL GABA NEURON LABELLING WITH (3H)-ISOGUVACINE IN DIFFERENT SPECIES, E. Agardh and B. Ehinger. Dept of Ophthalmology, University of Lund, Lund, Sweden, S-22185.

Retinas from goldfish, chicken, rat, guinea-pig, rabbit and humans were exposed to (^{3}H)-isoguvacine either by intravitreal injection in vivo or by incubation in a balanced salt solution and the distribution of radioactivity was then studied with autoradiography. The substance labelled a set of presumed amacrine cells in all types of animals. The inner plexiform layer was well demarcated and a variable amount of ganglion cells was marked. In goldfish and chicken, radioactivity could also be seen in horizontal cells, particularly so when the retina had detached from the pigment epithelium. Even 24 hours after an intraocular injection there was a significant amount of radioactivity left in nerve cells. Only little glial labelling could be seen at any time. Since the distribution of labelled neurons was similar to that of GABA neurons and since isoguvacine is a potent GABA agonist, it seems reasonable to presume that (^{3}H)-isoguvacine labels GABA neurons. The uptake is selectively neuronal with strong binding to presumed GABA storage sites.

17.15 EFFECTS OF ASPARTATE AND GLUTAMATE ANALOGUES ÓN AMACRINE AND GANGLION CELLS IN MUDPUPPY RETINA. P.D. Lukasiewicz* and J.S. McReynolds. Dept. of Physiology, Univ. of Michigan, Ann Arbor, MI 48109.

GABA and glycine have been shown to act as inhibitory transmitters in the inner plexiform layer (IPL) of mudpuppy retina, but the excitatory transmitters in the IPL are still unknown. Here we show the effects of three aspartate/glutamate analogues on transient amacrine cells and ON-center ganglion cells in intracellular recordings from superfused mudpuppy eyecups.

Application of 250 μM 2-amino-4-phosphonobutyric acid (APB) eliminated light-evoked responses in depolarizing bipolar cells and ON-center ganglion cells, as well as the ON response of transient amacrine cells, as reported previously by Slaughter & Miller (Science 211: 182, 1981). When synaptic transmission was blocked by 1 mM cadmium (Cd), APB produced no voltage or conductance changes in either transient amacrine cells or ON--center ganglion cells, although it still caused a hyperpolarization and conductance decrease in depolarizing bipolar cells.

250 μM N-methyl-dl-aspartate (NMDLA) produced a depolarization and conductance increase in both transient amacrine cells and ON-center ganglion cells. When applied in the presence of Cd, NMDLA produced the above effects only in transient amacrine cells.

100 μM kainic acid (KA) produced a depolarization and conductance increase in ON-center ganglion cells, also in the presence of Cd; its effect on transient amacrine cells has not been determined.

These results suggest that transient amacrine cells have receptors activated by NMDLA (KA not yet tested) and that ON-center ganglion cells have receptors activated by KA but not by NMDLA. The findings are consistent with the notion that one or more amino acids related to aspartate or glutamate is used as an excitatory transmitter in the mudpuppy IPL, and that if only one such substance is endogenous its receptor sites are pharmacologically different on transient amacrine cells and ON-center ganglion cells. Neither of these cell types has the kind of glutamate/aspartate receptor site found at the synapse from photoreceptors to depolarizing bipolar cells.

Supported by NIH grants EY01653 and EY07022.

17.16 DISTRIBUTION OF L-ASPARTATE AND L-GLUTAMATE SYNAPTIC RECEPTORS IN MEMBRANES FROM CHICK RETINA, A.M. López-Colomé and F. Somohano*. Departamento de Neurociencias, Centro de Investigaciones en Fisiología Celular, UNAM; 04510 - México, D.F.

L-Glutamate (Glu) and L-Aspartate (asp) have been considered as strong neurotransmitter candidates in the vertebrate retina. It has been proposed that both amino acids could act as transmitters at photoreceptor cell (PR) synapses, as well as at other excitatory synapses in the inner retina. We have attempted to discriminate between Glu and Asp as the PR transmitter by determining the kinetic and pharmacological characteristics of Asp and Glu receptors measured through the binding of ^{3}H-Asp and ^{3}H-Glu to synaptic membranes from both retinal plexiform layers in conditions reported to expose synaptic receptors (Enna and Snyder (1976), Brain Res, 115:174-179).

As we have previously reported for Glu (López-Colomé (1981), Neurochemical Res, 6: 1019-1033), we found saturable, high affinity ^{3}H-Asp binding in membranes from both plexiform layers which exhibited a K_D=40nM for outer plexiform and K_D=12nM for inner plexiform layer and B_{max}=0.666 and 0.4 pmoles/mg protein respectively. In contrast with ^{3}H-Glu binding which is evenly distributed in both plexiform layers, ^{3}H-Asp receptors were found to concentrate in membranes from outer plexiform layer compared with membranes from whole retina. Binding of ^{3}H-Asp was effectively inhibited by Asp analogues N-methyl-DL-aspartate and DL-alpha-amino-adipate whereas the Glu antagonist glutamate-diethyl ester had no effect.

Kainic acid has been shown to destroy amacrine cells and to a less extent, horizontal and bipolar cells, in the chick retina when injected intravitreally at a dose of 60 nmoles/eye (Morgan, I., and Ingham C.A. (1981) Neurosci Lett, 21: 275-280). When ^{3}H-Asp and ^{3}H-Glu binding was measured in these lesioned retinas, a significant increase in the number of receptors (around 100% over control) was observed for both amino acids, although following a different time course.

Our results indicate the presence of different synaptic receptors for Glu and Asp in both plexiform layers of the chick retina, which can be distinguished by means of kinetic constants, some pharmacological characteristics, and the effect of kainate.

17.17 ULTRASTRUCTURE OF THE INNER NUCLEAR LAYER OF THE RETINA OF XENOPUS LAEVIS LARVAE. George J. Kokoris and Leslie J. Fisher. Neuroscience Program, University of Michigan, Ann Arbor, Mich. 48109, and Dept. Ophthalmology, Henry Ford Hospital, Detroit, Mich. 48202

As part of an ongoing study investigating the patterns of proliferation and differentiation of cells within the inner nuclear layer (INL) of the central retina of Xenopus laevis larvae, an ultrastructural analysis of retinal cell types was undertaken using electron microscopy (EM). Tissue was obtained from larvae at various stages of metamorphosis and processed for EM using gluteraldehyde fixation.

Unlike the adult amphibian retina, cells of the larval INL are not stratified according to type within this structure. Horizontal cells, frequently identified by their flattened oblong nuclei, low nucleus/cytoplasm ratio, abundant microtubules, and clumped Nissl material, are the exception, the position of their nuclei always being at the scleral border of the INL, as in the mature retina.

Bipolar cells tend to have a high nucleus/cytoplasm ratio, the envelope of cytoplasm closely following the contours of the nucleus. Their cytoplasm appears electron-lucent, with few organelles aside from large ovoid mitochondria. Bipolar nuclei tend to be large and spherical, with a moderate density of evenly distributed chromatin.

The perikarya of mature Muller fibers often lie in the median stratum of the INL, with dark-staining processes that insinuate and ramify: horizontally, between other cell types in the INL, and radially, from the level of the photoreceptor nuclei to the vitreal border of the ganglion cell layer. The vitreally directed processes contain numerous filaments arranged in bundles, an abundance of smooth endoplasmic reticulum (SER), and widely distributed glycogen granules. Mitochondria are usually observed in scleral portions of Muller fiber cytoplasm.

Amacrine cells are identified by their electron-dense nuclei, which display frequent cytoplasmic inclusions. Their cytoplasm is also electron-dense, and is distinguished by long rills of SER arranged concentrically about the nucleus. Amacrine cells also extend thick processes, containing mitochondria at their origin and vesicles along their length, into the inner plexiform layer.

In addition, a number of cells that seem to be in various phases of the mitotic cycle, including several cells that appear to include two partially formed nuclei within a single cytoplasmic envelope, were observed. This tentative conclusion awaits confirmation with serial sectioning techniques, but is in accord with our autoradiographic data demonstrating mitotic activity within the INL of the differentiated central retina of larval Xenopus laevis.

17.18 GIANT GANGLION CELLS IN THE SKATE RETINA. P. Witkovsky and W.J. Brunken*. Depts. of Ophthal. and Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016 and Dept. of Anat. Sci., SUNY, Stony Brook, NY 11794.

We have demonstrated the existence of giant ganglion cells in the retina of the skate (Raja, spp.), similar in all respects to those found in the dogfish, Mustelus (Stell & Witkovsky, JCN, 148:1, 1973). Giant ganglion cells are identified on the basis of their extensive, elliptical dendritic arbors (1.0 x 1.5 mm) and their large, polygonal cell bodies, measuring 35-45 µm in the longest axis. These neurons can be divided into three classes on the basis of the location of the perikaryon: superficial (ganglion cell/optic fiber layer); intermediate (within the inner plexiform layer); displaced (inner plexiform/inner nuclear layer border). The dendritic arborizations of each cell class are isoplanar, i.e., confined to a narrow horizontal band of inner plexiform layer adjacent to the perikaryal position. Each class of giant ganglion cell forms an irregular matrix over most of the retinal surface with a cell to cell spacing of about 800 µm.

Retrograde transport of HRP was used to demonstrate that the superficial layers of the optic tectum are at least one site of termination for giant ganglion cell axons. Preliminary electrophysiology measures indicate that the superficial class of giants is of the on-center variety. Data on the synaptic connections of giant ganglion cells will be presented.

Supported by NEI Grant EY03570 to P.W.

17.19 A MODEL FOR THE EVOLUTION OF CENTRAL RETINAL SPECIALIZATIONS M.H. Rowe and B. Dreher School of Anatomy, Univ. of New South Wales & Department of Anatomy, Univ. of Sydney, Sydney, AUSTRALIA

Retinal specializations subserving high acuity vision involve a potential conflict between two fundamental requirements; the neural requirement of high receptor and post-receptor neuron density in the specialized region, and the optical requirement of an unobstructed light path to the receptors. The fovea, found in a variety of vertebrates, is a structural solution to this problem which involves the displacement of all post-receptor retinal neurons away from the specialized region. However, even in animals lacking a fovea, such as the domestic cat, some of the inner retinal neurons, the ganglion cells, are displaced away from the center of the high acuity specialization in a pattern which may illustrate the early stages of foveal evolution.

Most beta (X) cells near the area centralis (a.c.) of the cat, as seen in whole mount preparations and visualized following HRP injections into one optic tract, have a single primary dendrite. At the center of the a.c. these dendrites typically descend vertically through the inner plexiform layer (IPL) and give rise to a dendritic tree which is directly beneath the soma. For cells between 100 and 700 microns from the center of the a.c., however, most dendrites descend obliquely through the IPL resulting in a dendritic tree which is laterally displaced from the soma by as much as 40-50 microns. For many of these cells, the trajectory of the dendrites is such that the somas are systematically displaced away from the center of the a.c., while for other cells, the direction of the displacement seems random with respect to the location of the a.c.

This balance between random and systematic variation in the pattern of ganglion cell soma displacement is unaffected by monocular deprivation. However, in Siamese cats, although central beta cells with laterally displaced somas are as common as in normal cats, the direction of the displacement is predominantly random. Thus, the degree of randomness in the pattern of ganglion cell soma size displacement can vary between strains of cats and appears to be under fairly direct genetic control.

These observations suggest that early stages of foveal evolution involved a transition from a random to a systematic pattern of dendritic displacement among ganglion cells near the area centralis. Thus the presence of random variation in neural populations may be an adequate substrate for natural selection, and the transition from random to systematic variation in the characteristics of a neural population may be a general mechanism of nervous system evolution.

17.20 MORPHOLOGY OF RETINAL GANGLION CELLS IN A TURTLE, PSEUDEMYS SCRIPTA. E.H. Peterson School of Anatomy, University of New South Wales, Sydney AUSTRALIA

The ganglion cell layer of Pseudemys retina is highly differentiated with a horizontally aligned visual streak and a peak density area in the approximate center of the retina (Peterson & Ulinski, '79). Moreover, there is substantial variation in ganglion cell size as a function of retinal locus and some evidence that ganglion cells of different size have idiosyncratic patterns of retinal distribution (Peterson & Ulinski, '82). In the present study I have begun to characterize the morphology and spatial properties of Pseudemys ganglion cells using Golgi impregnation techniques and retrograde transport of horseradish peroxidase applied to the optic nerve or tract.

A majority of the ganglion cells observed to date can be assigned to one of three groups. Type I cells are the largest ganglion cells with somata in peripheral retina greater than 25um and dendritic field diameters of 700-900um. They show little variation in soma or dendritic field size as a function of distance from the streak; e.g. one cell in or just above the peak density area had a 22um soma with a dendritic spread of 500um. They appear to be monostratified with two variants arborising approximately in strata 1 or strata 5 of the IPL. Type II cells have smaller somata and dendritic fields (17-19um and 250-250um in peripheral retina). They typically have relatively numerous pedunculated appendages on the distal dendrites, and somata which are eccentrically placed within the dendritic field, but their dendrites are displaced randomly with respect to the visual streak. In Nissl material, cells of this same relative size tend to occur in pairs as described for alpha cells in cat retina. Type III cells have a characteristic 'lacy' appearance with dendritic branches having fine beaded appendages which descend through the IPL to terminate in a single, well defined layer. In the periphery, Type III cells have radially symmetrical dendritic fields (200-300 um) and relatively small somata (10-12um). Closer to the streak both somata and dendritic fields are markedly smaller (8-10um; 60-80um) and dendrites are displaced toward the streak. In one retina, two Type III cells were impregnated in or very near the peak density area with somata approximately 150um apart, one above and one below the streak. These cells have narrow dendritic arbors only 20um in width which are displaced sharply toward the streak. Thus dendritic field size in Type III cells decreases by a factor of 10 from peripheral retina to the streak in contrast to Type I cells in which the change with eccentricity is much less marked. These cells appear to correspond to Type B cells of Marchiafava & Weiler ('80) and probably form the small cell peak seen in soma size histograms of Pseudemys retina (Peterson & Ulinski, '82) which is most pronounced in the visual streak.

17.21 A MONOCLONAL ANTIBODY AGAINST RETINAL GANGLION CELLS IN THE MOUSE. U.C. Dräger and C.J. Barnstable. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

Balb/c mice were immunized with the ganglion cell layers of formalin-fixed retinas from C57BL/6J mice. Spleen cells from immune mice were fused with P3-x63 Ag8.653 plasmacytoma cells, and hybrid cells were selected in HAT medium. Supernatants of growing cultures were screened on cryostat sections of formalin-fixed C57 retinas, using indirect immunofluorescence. Antibodies of one of the hybridoma lines that were cloned, R3, stained fiber bundles in the ganglion cell layer and processes in the outer plexiform layer. With Triton X-100 added, a network of fine fibers in the inner plexiform layer and, rarely, the outlines of a cell in the ganglion cell layer became visible. This pattern was indistinguishable from the staining we saw with a known antibody against neurofilaments (Wood, J.N. and B.H. Anderton, Biosci. Rep. 1:263-268, 1982).

In developing retinas R3 bound at the earliest age tested, the day of birth, although the staining was not as bright as in adults. A few cell bodies in the ventricular zone and in the ganglion cell layer were stained, in addition to what appeared to be optic fiber bundles. Several days later cells with long processes at the level of the developing outer plexiform layer became positive.

The spatial distribution of the staining in the adult retina was studied in whole mounts. A tangle of thick, sparsely branching processes with small cell bodies was seen in the outer plexiform layer; this may represent a class of horizontal cells known to be rich in neurofilaments. Most of the processes in the ganglion cell layer appeared to be optic axons: they converged on the optic disk and a few could be seen to emerge from large ganglion cells. The identity of other fibers was not clear: a few in every retina formed a loop with both ends heading into the direction of the optic disk, and an occasional fiber could be seen to give off branches. When the eye was injected with colchicine, the overall intensity of the staining increased and many more ganglion cells became visible on account of dense filamentous material in soma and dendrites. All the stained cells were large in diameter, 18 μm on average, which is about twice the size of the bulk of ganglion cells in the mouse; and 6% were displaced ganglion cells, as compared with 1% in the population overall. They formed a small fraction of all ganglion cells, in the best preparation so far between 2-3%. Whether the distribution of the R3 antigen in ganglion cells correlates with functional or projectional characteristics, similar to the neurofibrillar staining restricted to α-type ganglion cells in the cat, is not clear. (Supported by EY01938 and EY03735).

17.22 SOME SPIKES ARE WORTH MORE THAN OTHERS: CONSEQUENCES OF STIMULUS AND ADAPTATION CONFIGURATION. B. Pöpel* Institute of Physiology, Free University Berlin, W.-Berlin, F.R.G.

Center and periphery of cat retinal ganglion cell receptive fields (RF) were stimulated with white light modulated in time by Gaussian quasi-white noise (GWN). The σ-contrast (σ= s.d. of GWN) was 0.27 and was kept constant throughout the experiments, bandwidth was 100 Hz. The adaptation of the unmodulated RF-part was either dark, low photopic (equal to the GWN-mean) or high photopic. Stimuli were uniform discs of center size and large fields minus the discs. Disc diameters were chosen to produce as far as possible pure center and surround responses as estimated from first order kernels under "mean" adaptation ("medium situation").

Without going into theoretical details (R.Eckhorn and B.Pöpel, Vis. Res. 21,435-443 (1981)) the rate of transinformation, T'(bit/s), is taken as a coupling measure denoting the information transfer of a ganglion cell spike train with respect to the stimulus. Dividing T' by the average discharge rate, $\bar{R}$ (spikes/s), gives a new quantity, $\eta = T'/\bar{R}$ (bit/spike), which yields the information represented by a single spike of this response. η denotes the "economy" of the system in achieving a certain information transfer.

Results reported here refer mainly to brisk sustained ganglion cells because of the better possibility of separating the center and surround mechanisms. Response coupling per se (derived, for example, from T' or the total spectral response power) varies across adaptation in these units and is strongest in the "medium situation".This holds for the majority of on- and off-center cells for both center and peripheral modulation.Also, a substantial part of the average discharge is evoked by the dynamic stimulus.However, in only about 25% of our cells do the changes in discharge rate $\bar{R}$ follow the changes in coupling (i.e.,$\bar{R}$ should not be used to estimate coupling). On the other hand, in off-center cells, the "economy"η of the center responses increases for decreasing adaptation level of the surround, and η of the surround increases for increasing adaptation level of the center.Although η should not be taken as a coupling this result means that the antagonistic inhibition of the unmodulated RF-part tends to suppress more the uncoupled spikes. No such clear-cut result emerged from on-center cells.

In the "medium situation" both coupling and $\bar{R}$ are normally slightly higher for the surround (total surround stimulated!).However,η is larger for the center: with a center stimulus, the single spike carries more information than with a surround stimulus. Finally, a result concerning the brisk sustained (BS)/transient (BT) dichotomy. With diffuse dynamic stimuli, BS-units normally yield weaker coupling and η ($\eta \leq 0.5$) compared to BT-units ($\eta > 0.5$). This supports the idea of BT-units being especially sensitive to luminance changes in time.

17.23 EFFERENT CONTROL OF PATTERN VISION IN LIMULUS. R. Batra* and R. B. Barlow, Jr. Institute for Sensory Research, Syracuse Univ., Syracuse, NY 13210.

Efferent optic nerve activity from a circadian clock modulates responses of the Limulus lateral eye. Previous studies show that at night the efferent input to the retina changes the structure and sensitivity of retinal photoreceptors. Here we describe the effects of efferent activity on optic nerve responses generated by stationary step patterns of illumination on the retina. One half of the eye was brightly illuminated and the other half dimly illuminated. Optic nerve responses of a single photoreceptor located near the center of the eye were recorded for various positions of the step pattern relative to the photoreceptor.

Lateral inhibition enhances the optic nerve response when the photoreceptor is located in the bright region of the pattern near the edge and depresses the response when the photoreceptor is in the dim region near the edge. These maxima and minima in optic nerve responses correspond to Mach bands: they enhance contrast in the illumination pattern. The width of the Mach band, which reflects that of the underlying inhibitory field, is conveniently measured as the distance between the step and the photoreceptor when the Mach band is half maximum amplitude. During the day the width is about 4 photoreceptor diameters in the antero-posterior direction and 2 photoreceptor diameters in the dorso-ventral direction. These measurements correspond to an inhibitory field extending 6 photoreceptors antero-posteriorly and 3 photoreceptors dorso-ventrally from the center. At night the width of the Mach band does not change significantly, but the optic nerve response increases for fixed levels of excitation. Apparently at night the total strength of lateral inhibition decreases with no corresponding change in the size of the inhibitory field. Also, a second inhibitory process, self-inhibition, appears reduced at night.

In sum, these and other results indicate that the efferent input to the retina at night increases excitatory effects and decreases inhibitory effects. During the day, physiological changes in the retina maintain contrast enhancement under bright light without saturation of optic nerve responses. Thus the retina appears to be adapted for low levels of illumination at night and high levels during the day.

17.24 TRANSFER FUNCTION BETWEEN RECEPTOR POTENTIAL AMPLITUDE & OPTIC NERVE SPIKE FREQUENCY IN LIMULUS IN DARK & LIGHT ADAPTATION. L. T. Wang* and G. S. Wasserman (SPON: H. B. Nudelman). Dept. of Psychological Sciences, Purdue University, W. Lafayette, IN 47907.

Using one microelectrode inserted into a Limulus retinular cell, simultaneous recordings were made of the receptor potential evoked by light falling on that retinular cell and of the optic nerve action potentials generated in the eccentric cell coupled to that retinular cell. The transfer function for sensory quantity was thereby determined directly at the first postreceptor stage over the entire operating range of the retinular cell from resting potential to saturation; this is a more extended range than previous studies had covered. The transfer function had strong nonlinearities which were discontinuous and it could best be described by a tripartite piecewise linear fit. Light adaptation induced a non-parallel shift of the transfer function.

These properties of the postreceptor transfer function produce a number of differences in the way in which the receptor responds to light (I-V function) in comparison to the way in which the optic nerve fiber responds to light (I-SF function): The I-SF function is both steeper and more sensitive than the I-V function. Similar changes have been seen before using indirect techniques in both invertebrates (Laughlin, 1981) and vertebrates (Green and Powers, 1982). Their interpretation has sometimes been problematic because of the indirect nature of the measurements. The fact that the present results were obtained with a single microelectrode which saw all of the responses at the same time suggests that these differences are genuine. A third effect is that the I-SF function exhibits a greater degree of light adaptation than the I-V function because of the extra light adaptation induced by the postreceptor stage. A fourth effect is that the I-SF function cannot be described by the Naka-Rushton function nor by any continuous function. The sharp discontinuities of the postreceptor transfer function yield corresponding discontinuities in the I-SF function although the latter discontinuities are less noticeable because they are riding on a curvilinear background.

Is postreceptor adaptation mediated by a mechanism that is similar to that which mediates receptor adaptation? The present data show certain phenomenological similarities which might have supported the suggestion that the mechanisms are indeed the same. But important differences exist: In addition to the postreceptor discontinuties, the postreceptor transfer function is expansive at low response levels and compressive at high levels while the receptor function only exhibits a compressive nonlinearity. The effect of this dual nonlinearity is to yield a narrow range of intensities over which small changes in light intensity produce large changes in the sensory signal.

17.25 ANALOGUE MODEL OF THE CHROMATICITY AND LUMINOSITY CHANNELS IN THE GENERALIZED VERTEBRATE CONE RETINA. R. Siminoff. Institut für Physiologie der Freien Universität Berlin, F.R.G.

A prototype of the generalized vertebrate cone retina was built using operational amplifiers to simulate retinal neurons. Each retinal neuron consisted of 2 components, a Summator to add inputs and a Leaky Integrator to simulate the synaptic delay for the output. Inverters and gain controls were used to give the proper magnitude and sign to the output voltage. The dynamic characteristics of the model were determined by the frequency-dependent Leaky Integrators, which are low-pass filters, with the major determining factor being the interplay of antagonistic center and surround field inputs to the bipolar cells (BC). Negative feedback from horizontal cells (HC) to cones and its potentiation by electrical coupling of HCs reinforced the effects of the surround field on decreasing the static levels of tonic ganglion cells (GC), as well as increased the transient ON and OFF phases of phasic GCs. The cone mosaic was simulated by a 25 X 21 grid of 525 phototransistors with color-sensitivity produced by color filters placed in fron to the cones. A trichromatic retina was organized into red unit hexagons (UH) as described in my theoretical paper (Siminoff, J. theor. Biol. 86: 673, 1980). Besides phasic and tonic units, there were color-coded (C) and non-color-coded (L) channels with a full compliment of retinal cells as specified in my theoretical paper. At the HC level, the L-HC acted as the path for the surround field of the L-BC, as well as negative feedback for the cones, while the biphasic C-HCs formed the surround fields for the single and double opponent C-BCs. Color-coded GCs reflected the C-BCs and formed concentric receptive fields with the antagonistic color pairs, red and green or blue and yellow (red plus green). The phasic GCs were formed by the convergence of depolarizing-center (DPBC) and hyperpolarizing-center (HPBC) BCs with the HPBC input having an extra "synaptic delay" and negative feedback reinforced the OFF discharge of the phasic GC. Stray light effects, electrical coupling of like-cones and electrical coupling of like-HCs were simulated by a form of positive feedfoward and along with negative feedback from the L-HCs to the cones played important roles in the development of the spatial and chromatic properties of retinal neurons. The analogue model has a number of physiological correlates. X- and Y- cells are both tonic cells with the X-cells having a minimum of surround field input, while the Y-cells having a strong surround field input. For the C-channel, color-coding was improved by negative feedback and electrical coupling in spite of the sloppy filter characteristics of the cones.

This work was done while the author was a Fellow of the Fritz Thyssen Foundation.

17.26 MODEL OF ELECTRORETINOGRAM b-WAVE GENERATION: TESTING THE K^+ HYPOTHESIS. Eric A. Newman and Louis L. Odette.* Eye Research Institute of Retina Foundation, Boston, MA 02114 and Boston University, Boston, MA 02215.

The K^+ hypothesis of electroretinogram b-wave generation holds that increases in extracellular K^+ concentration ($[K^+]_o$) depolarize Müller cells, leading to the generation of radially directed current flow and a transretinal potential. Several questions have been raised concerning this hypothesis. 1) If $[K^+]_o$ increases drive both Müller cell depolarization and b-wave currents, why is the Müller response much more prolonged than the b-wave? 2) Why do the K^+ ejection experiments of Yanagida and Tomita (1982) lead to intraretinal potential profiles different from those of the b-wave? 3) Why are distal $[K^+]_o$ increases measured in some experimental preparations smaller than those needed to generate the b-wave?

We have investigated these objections to the K^+ hypothesis by simulating b-wave generation with a computer model representing relevent retinal structures. The model incorporates the following components. 1) Two time-dependent K^+ sources representing the light-evoked $[K^+]_o$ increases in the inner and outer plexiform layers, 2) a time and $[K^+]_o$ dependent K^+ sink representing the $[K^+]_o$ decrease in the rod inner segment layer, 3) diffusion of released K^+ through extracellular space, 4) active and passive K^+ re-uptake, 5) spatial variations in the K^+ diffusion coefficient and the volume fraction of extracellular space, 6) an extraretinal shunt resistance. Müller cells are modeled with 1) internal resistance, 2) spatial variations in membrane K^+ permeability, and 3) a membrane potential specified by the Nernst equation and transmembrane current flow. $[K^+]_o$ distributions in time and retinal depth are computed from imposed K^+_o source-sink densities. Based on these computed $[K^+]_o$ distributions, Müller cell potentials, current source-density profiles and intraretinal potentials are calculated.

Imposed $[K^+]_o$ distributions similar to those measured experimentally during the b-wave lead to the generation of a transient b-wave response and a prolonged Müller response in the model system. Current source-density distributions and intraretinal potentials generated by the model match experimental results closely. In addition, the model generates a realistic slow PIII potential in response to prolonged $[K^+]_o$ decreases in the distal retina and reproduces the K^+ ejection results of Yanagida and Tomita accurately. Simulations also suggest that tissue damage caused by K^+-selective micropipettes in experimental preparations may lead to a serious underestimation of the distal $[K^+]_o$ increase. The simulations demonstrate that the spatio-temporal properties of intraretinal b-wave voltages and Müller cell responses can be generated according to the K^+ hypothesis, by passive Müller cell depolarization driven by variations in $[K^+]_o$. 17.27 K^+ SOURCES IN AMPHIBIAN RETINA, C. J. Karwoski, C. Nicholson, & L. M. Proenza. Vision Research Laboratory, Univ. Georgia, GA, and Department of Physiology and Biophysics, NYU Medical Center, NY.

There is presently some question concerning the number and location of light-evoked K^+ sources in the retina, and what role their associated K-increases play in the generation of field potentials, specifically the b-wave. In particular, at the level of the outer plexiform layer, a light-evoked K^+ source (distal K^+ increase) remains an elusive phenomenon. Here, we begin to provide quantitative detail from depth-profiles in frog and mudpuppy retinas.

Two forms of analysis were useful for resolving a distal K^+ increase which, nevertheless, could not be seen in all cases:

(1) Plots of K-increase latency vs. depth show relative minima distally, at the OPL, and proximally, at the IPL. Both distal and proximal K-increases show a strong "surround turndown" -- responses to diffuse stimuli are ∿65% smaller than those to 250 μm spots. Individual K-increases in the distal retina usually reach, at most, only ∿25% of the amplitude that can be observed proximally, while the total distal K-increase is only 5-10% of that seen proximally.

(2) Increases in $[K^+]_o$ are generated by K^+ sources, but the spatial distribution and time course of these sources are obscured because of diffusion. However, a source distribution, $Q(x,t)$, can be computed from knowledge of the time and space derivatives of the concentration by using a diffusion equation that includes the volume fraction (α) and tortuosity (λ) of extracellular space (Nicholson and Phillips, 1981, J. Physiol., 321: 225-257): $Q = \alpha[\partial c/\partial t - (D/\lambda^2)(\partial^2 c/\partial x^2)]$. Such calculations cannot indicate whether K^+ arises from neurons or glial cells, nor can they reveal K^+ sources in equilibrium with K^+ sinks (e.g., clearance mechanisms). Nevertheless, these ion source density calculations are useful and have been initiated in amphibian retinas.

Taken together, these analyses indicate that the profile of light-evoked changes in $[K^+]_o$ consists of: (1) a slow K^+ sink in the photoreceptor layer; (2) a distinct, but small, on-source near the OPL; (3) a large on-source throughout the IPL; (4) an off-source at the IPL, which peaks slightly distal to the on-source; and (5) separate on- and off-sources in the ganglion cell layer. Although evidence for the distal K^+ increase can be obtained from most depth profiles, its amplitude seems too small for it to play the dominant role in b-wave generation.

17.28 LOCAL CIRCUIT FEEDBACK LOOP IN NEURONS OF THE OCELLAR RETINA. Susan L. Stone* and Richard L. Chappell. Dept. of Biological Sciences, Hunter College, New York, N.Y. 10021.

Anatomical[1], electrophysiological and pharmacological studies suggest that synaptic feedback from second order neurons (L-neurons) onto receptor terminals plays a role in transforming the sustained depolarizing response of the photoreceptor into the phasic hyperpolarizing response of the L-neuron in the ocellar retina of the dragonfly. The hyperpolarizing off transient in the receptor response and the depolarizing off transient in the L-neuron are thought to reflect such feedback. Curare eliminated both the L-neuron response and the off transient in the receptor, while picrotoxin modified only the off transients suggesting that the receptor and L-neuron (feedback) transmitters may be acetylcholine and GABA, respectively.[2]

We have recently found evidence which suggests that lateral synaptic interactions between adjacent photoreceptors and L-neuron dendrites may also contribute to the intracellular response waveform of ocellar neurons. Edrophonium, eserine and carbachol reduce the L-neuron light response suggesting that lateral synaptic interactions between photoreceptors may be inhibitory. A conductance increase associated with the depolarizing off transient in the L-neuron indicates that lateral synaptic interactions between L-neurons may be excitatory. The simple model, neglecting such lateral interactions, is no longer sufficient to account for these observations. Consequently, we have developed a more comprehensive model (below). This model is consistent with the original hypothesis that the receptor transmitter (filled circles) may be acetylcholine and the L-neuron transmitter (open circles) might be GABA. According to the model, the receptor transmitter is inhibitory to L-neurons and adjacent receptor terminals, while the L-neuron transmitter has an excitatory effect on the receptor terminals and adjacent L-neuron dendrites. The local circuit is such that a dynamic equilibrium is established at any given light intensity or in the dark, while the response to changes in intensity is enhanced. (Supported by NIH Grant EY-00777.)

18.1 β-ENDORPHIN MODULATES THE DOPAMINE INHIBITION OF PROLACTIN SECRETION AT THE ANTERIOR PITUITARY. C.Y. Cheung. Div. of Perinatal Biology, Dept. of Physiology, Loma Linda University, School of Medicine, Loma Linda, CA., 92350.

The endogenous opiate β-endorphin (B-EP), has been implicated in the regulation of prolactin secretion. Intravenous administration of B-EP in rats increases prolactin secretion, and the effect is reversible by naloxone. The mechanism by which B-EP stimulates the release of prolactin is not well understood. The present study was undertaken to determine whether B-EP stimulates prolactin secretion by a direct action at the anterior pituitary. Experiments were performed on dispersed anterior pituitary cells in culture. Anterior pituitaries from ovariectomized rats were dispersed using 0.3% collagenase and plated in Ham's F-10 medium containing 15% horse serum and 5% fetal calf serum. At the onset of the experiment the medium was changed to Ham's F-10 containing 20% serum substitute, and the cells were preincubated for 48 hours. The medium was then collected and replaced with fresh medium, or medium containing dopamine, B-EP, or dopamine and B-EP. Ascorbic acid was used to prevent the autooxidation of dopamine, and bacitracin was added to prevent the enzymatic degradation of B-EP. The in vitro effects of B-EP on prolactin release and on the dopamine inhibition of prolactin release were studied over a 24 hour period with sampling of the medium at 1, 3, 5, and 24 hours. The amount of prolactin released into the medium was measured by radioimmunoassay. B-EP at 10^{-6}M, did not significantly alter the release of prolactin into the medium, although small increases of 13%, 15%, 35%, and 17% were observed at 1, 3, 5, and 24 hours respectively. A lower dose of 10^{-8}M B-EP again showed no effect on prolactin release. Dopamine at 10^{-6}M, significantly inhibited prolactin release by 55%, 43%, 48%, and 49% at 1, 3, 5, and 24 hours respectively. However, when the cells were incubated with 10^{-6}M dopamine in the presence of 10^{-6}M B-EP, the inhibitory effects of dopamine at 1, 3, and 5 hours were completely reversed by the opiate. But by 24 hours, the B-EP effect was no longer observed. To investigate whether endogenous B-EP released from the anterior pituitary played a role in maintaining the in vitro release of prolactin, the cells were treated with 10^{-6}M naloxone for 24 hours to block any effects of the opiate before testing with dopamine. Naloxone did not affect the basal release of prolactin, nor the inhibition of prolactin release by 10^{-6}M dopamine up to 24 hours of incubation. Thus, B-EP of pituitary origin may not be released in adequate amounts to affect prolactin secretion from pituitary cells in vitro. The major finding from these studies suggest that although B-EP may not directly stimulate prolactin release from the anterior pituitary, it could modulate the release of prolactin by reversing the inhibitory effects of dopamine.

18.2 EVIDENCE FOR DEGENERATION OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS IN AGING RATS WITH PROLACTIN SECRETING PITUITARY TUMORS, D.K. Sarkar*, P.E. Gottschall* and J. Meites* (SPON: R.A. Bernard), Neuroendocrinology Laboratory, Physiology Department, Michigan State University, East Lansing, Michigan 48824.

The activity of tuberoinfundibular dopaminergic neurons (TIDA) was determined biochemically and with fluorescent histochemistry in young female rats (diestrous, 3-4 mo) and in old rats (anestrous, 24-28 mo) with or without prolactin (PRL) secreting pituitary tumors. Old rats with PRL secreting tumors showed elevated levels of PRL (702±78; n = 19) in the blood as determined by RIA when compared to levels in old (129±12; n = 12), and young (54±7; n = 17) females without tumors. Pituitary weights in situ of rats with tumors (41.4±11.3; n = 11) were significantly higher than in old (12.2±0.5; n = 10) and young (9.2±0.4; n = 16) rats without tumors. Estimation of dopamine content by radioenzymatic assay revealed that there was a significant reduction of dopamine content in the median eminence in rats with tumors (37±2; n = 6), as compared to old (55±4; n = 8) and young (127±22; n = 8) rats without tumors. Dopamine content in the median eminence of old rats also was significantly lower than in the median eminence of young rats. The fluorescent intensity of catecholamines in the external layer of the median eminence was reduced in old animals and the reduction was particularly marked in old females with PRL secreting tumors.

Both tumor and non-tumor bearing old rats showed signs of histological degeneration, as was evident by the presence of punctate autofluorescent lipofusin, and distorted fibers in the arcuate nucleus. These data indicate that there is a loss of dopaminergic neurons during aging and the loss becomes greater as old animals develop spontaneous PRL secreted pituitary tumors. (Aided by NIH research grants AM04784 from the National Institute of Arthritis, Diabetes, Digestive and Kidney Diseases, CA10771 from the National Cancer Institute, and AG00416 from the National Aging Institute to J. Meites).

18.3 SHORT-LOOP NEGATIVE FEEDBACK EFFECT OF PROLACTIN ON THE SUCKLING-INDUCED PROLACTIN RESPONSE AND ON THE PROESTROUS SURGE OF PROLACTIN. Michael Selmanoff, Karen A. Gregerson* and Phyllis M. Wise*. Department of Physiology, Univ. of Maryland, School of Medicine, 660 West Redwood Street, Baltimore, Maryland 21201.

Prolactin (PRL) is thought to exert at the hypothalamus a short-loop negative feedback effect on its own secretion. We tried to block the suckling-induced PRL response and the proestrous PRL surge with sc injections (4mg/kg) of oPRL. The injection of oPRL resulted in the following plasma levels (ng/ml) in these female rats (n=16): Time 0 (undetectable), 0.5h (809±65), 1 (1515±156), 1.5 (2094±200), 2 (2015±248), 3 (1840±231), 4 (958±99), 5 (638±72), 6 (420±42) and 8 (118±40). In 10 day postpartum rats oPRL or vehicle was injected at 6h or 12 and 6h before the onset of suckling at Time 0. Pups were separated from their mothers 4h prior to Time 0 and were allowed to suckle for 40 min. It may be seen from the data that 12 or 6h of prior exposure to high levels of oPRL blunts the suckling-induced rPRL response.

	0'	10	20	30	40	60	90	120
Vehicle	4±	125±	193±	224±	313±	77±	17±	6±
(n=11)	1	35	40	34	23	20	6	2
oPRL-12h	2±	56±	103±	118±	180±	50±	30±	8±
(n=8)	1	19	46	42	47	16	15	3
oPRL-6h	3±	73±	128±	106±	179±	37±	5±	4±
(n=10)	1	21	38	34	37	12	1	1

There is a significant suppression at both 30 and 40 minutes of suckling for both oPRL-treated groups. Considering the area under the curves, the 6h area is 17% less and the 12h area 15% less than controls. In a second experiment in lactating rats (pups removed), oPRL administration was unable to suppress the already low morning basal secretion of rPRL. In 4 day cycling rats, oPRL was injected every 8h starting at 0900h on diestrous day 1. This oPRL treatment totally abolished the proestrous PRL surge and significantly suppressed basal secretion determined in the morning hours.

	0900h	1030	1200	1300	1400	1500	1600	1700	1800	1900
Vehicle	9±	4±	5±	47±	107±	100±	167±	179±	214±	157±
(n=6)	3	1	2	28	60	28	37	46	53	26
oPRL	3±	1±	1±	1±	1±	1±	3±	4±	4±	7±
(n=11)	1	0	0	0	0	1	1	1	1	1

The data indicate that elevated PRL levels dramatically inhibit the hypothalamic mechanism mediating the proestrous PRL surge while having a lesser effect on the mechanism mediating the suckling-induced PRL response. (Supported by NIH grants NS-14611 and AG-02224).

18.4 DIETHYLSTILBESTROL-INDUCED PITUITARY TUMORS: A MODEL FOR THE STUDY OF CONTROL MECHANISMS IN HUMAN PROLACTINOMAS. C. Phelps* and W. C. Hymer*, (SPON: A. Carrillo) Biochemistry Program, The Pennsylvania State University, University Park, PA 16802.

Marked increases in pituitary weight, DNA content and PRL synthesis result from chronic estrogen (DES) treatment in Fischer 344 female rats (Wiklund et al., Endocrinology 109:1700, 1981). In order to further characterize such tumors, we have determined total cell number, PRL content, PRL secretory rates in culture, cell separation, DNA synthetic rates by flow cytometry and effects of subsequent treatment with the dopamine agonist, bromocryptine (BC). Pituitaries from DES-treated (9-10 mg silastic implants) animals increased from 157% at day 8 to 3410% (437 mg) of control weights by 150 days; total cell yields increased from 125% to 5890% (113.7×10^6 cells) of controls over the same treatment period. Chronic DES increased the proportion of PRL cells from 33% to 50% as revealed by immunocytochemistry. Intracellular PRL levels ranged from 1.95 to 9.40 times that of controls ($p<.05$). In addition, beyond 8 days of DES, PRL release in vitro from the experimental cell group was significantly ($p<.05$) and consistently greater than controls in 12 experiments. All these DES effects were more pronounced among ovariectomized rats. Some PRL cells in DES-treated rats had greater sedimentation velocities at unit gravity, suggesting increased cell size and/or density; moreover, 30% or more of the tumor cells (and none of the controls) sedimented through Ficoll-Hypaque ($1.08 g/cm^3$). Even though approximately equal proportions of PRL cells were recovered from the upper and lower Ficoll fractions, cells from the upper region released 3-4x more PRL in vitro. Bromocryptine treatment (4 mg/day/5days) in rats bearing 22-, 35-, 44- or 90-day tumors reduced pituitary weights, cell number, PRL content, and PRL release in vitro; the latter BC effect was more pronounced among the less dense PRL cells. Cell cycle analyses showed that the percentage of cells in $S+G_2$ ranged from 5 to 31% in ovariectomized controls and 28 to 52% in tumors. Bromocryptine treatment did not affect the $S+G_2$ population. Information obtained on 6 individual human prolactinoma cell suspensions (courtesy of M. Thorner and G. Tindall) consistently showed a high percentage of cells in G_2+S ($\bar{x}$=46%). In patients on BC therapy, this distribution was not altered. On the basis of these data we conclude that the DES-induced tumor offers a reasonable model for studying dopaminergic influence on cell growth and secretion in human prolactinomas. Supported by NIH grant CA 23248.

18.5 FAILURE OF PLASMA PROLACTIN LEVELS TO RISE AFTER A SECOND INJECTION OF SULPIRIDE. POST-RECEPTORIAL REFRACTORINESS? R. Collu and H. Cohen*. Neuroendocrine Research Laboratory, Pediatric Research Center, Hôpital Ste-Justine, Montreal, Quebec H3T 1C5, and INSERM Unité 34, Hôpital Debrousse, Lyon, France.

It is now well established that the secretion of prolactin (PRL) is under a tonic inhibitory control exerted through specific pituitary receptors by dopamine (DA). Some clinical as well as experimental data have indicated that previous exposure to neuroleptics may modify the PRL response to either antagonist or agonist dopaminergic drugs. This may indicate that treatment with neuroleptics has changed either the sensitivity of dopaminergic receptors or PRL metabolism. We have recently performed "in vivo" and "in vitro" studies in order to verify whether a previous single exposure to an antidopaminergic agent might modify pituitary DA receptors as well as the PRL response to a second challenge by the agent. For this purpose, adult male Sprague-Dawley rats, 250-300 g body weight, bearing a chronic indwelling catheter in the jugular vein were utilized. While a first injection of the antidopaminergic, substituted benzamide drug sulpiride 1 mg/kg induced a large rise of plasma PRL levels, a second injection given 2 h later was totally inactive although the pituitary content of the hormone was still 76% of the initial values. When the second injection was given 8 h after the first it was slightly effective, but when administered 24 h later it was as effective as the first. The second of two consecutive injections of haloperidol 5 mg/kg given at 2 h interval, or an injection of morphine 10 mg/kg given 2 h after sulpiride, were incapable of inducing a release of PRL. Two h after an injection of sulpiride 1 mg/kg, a 30 min period of immobilization stress as well as a second injection with larger doses (5, 10 or 20 mg/kg) of sulpiride induced a significant rise in plasma PRL levels. Apomorphine 0.1, 1.0 or 5.0 mg/kg was at least as effective an inhibitor of PRL secretion when given 2 h after sulpiride than when injected after saline. "In vitro" studies of dopaminergic binding sites with [^{3}H]Spiroperidol ([^{3}H]SPIR) revealed that in pituitary glands the apparent dissociation constant (K_D) and maximal number of binding sites (B_{max}) of [^{3}H]SPIR as well as the inhibitory constant (K_i) of two DA antagonists (haloperidol and sulpiride) and one DA agonist (bromocriptine) were not significantly modified by the drug. These data suggest that the only plausible explanation for the ineffectiveness of the second of two consecutive injections of sulpiride is the development of a state of refractoriness of the mechanisms that subserve the release of PRL induced by suppression of the inhibitory dopaminergic tonus.

18.6 OVARIAN STEROIDS MODULATE THE DENSITY OF ANTERIOR PITUITARY {^{3}H}-SPIPERONE BINDING SITES IN OVARIECTOMIZED RATS. Nancy S. Pilotte, David R. Burt and Charles A. Barraclough.* Depts. of Physiology and Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD. 21201.

Ovarian steroids affect the release of prolactin (PRL) into the peripheral circulation through 1) modulation of the release of hypothalamic dopamine (DA) into the hypophysial portal blood, 2) a direct stimulatory action on the anterior pituitary gland, and 3) desensitization of the anterior pituitary gland to the inhibitory action of DA. To clarify the mechanism(s) by which steroids affect the pituitary release of PRL, we tested whether the administration of estradiol (E_2) and/or progesterone (P) to ovariectomized (OVX) rats alters the number of available dopaminergic binding sites within the anterior pituitary gland.

All rats were OVX 7 days prior to the s.c. implantation of 2 30-mm Silastic capsules containing oil or 150 µg E_2 in oil. Forty-eight hr later, 2 30-mm Silastic capsules containing oil or 50 mg P in oil were implanted sc. At approximately 2, 6, 24 or 30 hr after the administration of P or oil, (48-76 hr after E_2), the anterior pituitary glands were removed, homogenized and stored at -20°C 1-4 weeks. The number of {^{3}H}-spiperone binding sites in the homogenate was assessed by incubation with 0.4 nM {^{3}H}-spiperone in the presence or absence of 10^{-6} M (+)-butaclamol for 15 min at 37°C. The incubation was terminated by addition of 3 ml of ice-cold 0.15 M NaCl. Bound radioactivity was separated from the free by rapid vacuum filtration through Whatman GF/B filters followed by 3 successive 3-ml rinses. The filters were equilibrated 12-16 hr in Liquifluor and counted.

No differences were observed in the specific binding of {^{3}H}-spiperone from the glands of OVX and OVX-E_2-treated rats removed 48-76 hr after E_2/oil treatment or from E_2P-treated rats removed 2, 6 or 30 hr after the administration of P (specific binding: 25.81 ± 4.48 (mean ± SE) to 33.66 ± 2.35 fmol/mg protein). However, the number of binding sites from the pituitary glands of E_2P-treated rats removed 24 hr after P was significantly increased ($p < .02$) to 43.50 ± 3.36 fmol/mg protein. In contrast, the peripheral levels of PRL are low in OVX rats, are moderately elevated in the mornings and rise sharply in a surge-like manner in the afternoons following E_2 or E_2P treatment. These findings suggest that, although there is a steroid-mediated change in the number of anterior pituitary receptors for DA, the availability of recognition sites for DA does not necessarily control the release of PRL. Other substances, perhaps stimulatory, may be more important in the regulation of PRL release under certain circumstances.

18.7 DISSOCIATION OF ESTROGEN RECEPTOR BINDING AFFINITY AND CONVERSION TO CATECHOL ESTROGENS: A PROBE FOR THE MECHANISM OF ACTION OF ESTROGENS IN THE CNS. D.G. Pfeiffer*, E. Barnea*, N.J. MacLusky*, L.C. Krey*, D.L. Loriaux*, and G.R. Merriam. Developmental Endocrinology Branch, NICHD, Bethesda, Md. 20205; Yale Univ., New Haven, Conn. 06510; and Rockefeller Univ., New York 10021.

Estrogens are metabolized in hypothalamus, pituitary, liver, and other tissues to 2- or 4-hydroxy catechol estrogens, which are able to interact with enzymes of catecholamine synthesis and degradation and possibly with membrane catecholamine receptors. It is not known whether this conversion plays an important role in mediating the physiological effects of estrogens in the CNS. To use as probes in the study of this problem, we sought to identify natural and synthetic estrogens which were impeded in conversion to catechol estrogens but had high estrogen receptor affinities, or which were readily converted to catechols but were poor receptor ligands. Of several estrogens tested, four--17α estradiol, 2- and 4-fluoroestradiol, and 11-β-methoxy-ethynyl estradiol (R2858) --appeared especially promising. Female Sprague Dawley rats, 200 g, were oophorectomized 5-7d before study. Cytosol estrogen (E) receptor affinities in hypothalamus-preoptic area-amygdala (HPA), pituitary, and uterus were studied at 4° and 25°C, using LH-20 columns to separate bound and unbound ligands. At 25°C, 17αE_2 had much lower E receptor affinity than the other estrogens.

IC-50's (pM) for displacement of [^{3}H]E_2 at 25°C (m±SE, n=3)

Compound	HPA	Pituitary	Uterus
17βE_2	0.39 ± 0.1	1.1 ± 0.2	1.2 ± 0.1
17αE_2	28.3 ± 4.3	64.6 ± 8.9	48.5 ± 6.4
4FE_2	0.9 ± 0.4	1.5 ± 0.3	1.5 ± 0.4
2FE_2	2.6 ± 0.8	10.6 ± 2.3	6.6 ± 0.8
R2858	4.0 ± 2.4	2.7 ± 0.8	3.6 ± 1.0

Conversion of these estrogens to catechol estrogens was studied in microsomes from HPA, pituitary, and liver, using a methylation system (catechol-O-methyltransferase, [^{3}H]S-adenosylmethionine) to convert newly synthesized catechol estrogens to stable [^{3}H]methyl ethers. [^{3}H]products were separated by HPLC. Conversion rates differed markedly. In liver, values were: 17βE_2: 40.6 pmol/min/mg microsome protein; 17αE_2: 176.5; 4FE_2: 31.6; 2FE_2: 11.5; R2858: 8.9. In HPA and pituitary, conversion rates were much lower; e.g., in HPA, rates were: 17βE_2: 1.08; 17αE_2: 1.48; other estrogens < 0.4. Thus 17αE_2 is readily converted to catechol estrogens but is a relatively poor E receptor ligand, while 2FE_2, 4FE_2, and R2858 are quite potent ligands but poorer substrates for catechol formation. If catechol estrogen formation is obligatory for expression of some CNS estrogen actions, one would expect 2FE_2, 4FE_2, and R2858 to be impeded in those actions, while 17αE_2 might retain potency despite reduced E receptor affinity.

18.8 CATECHOL ESTROGEN FORMATION IS NOT ESSENTIAL FOR ESTROGEN STIMULATION OF GONADOTROPHIN RELEASE AND FEMALE SEXUAL BEHAVIOR IN THE RAT. N.J. MacLusky*, L.C. Krey*, G.R. Merriam, B. Parsons* and F. Naftolin*, (SPON: A. Van den Pol). Yale University School of Medicine, New Haven, CT 06510; Developmental Endocrinology Branch, NICHD, Bethesda, MD 20205; and Rockefeller University, New York 10021.

Estrogens are extensively converted in the brain and pituitary gland to 2- and 4-hydroxylated "catechol" estrogens (CEs). The physiologic significance of these metabolic pathways remains uncertain. Since CEs can interact directly with pathways of catecholamine synthesis and metabolism, it is possible that local CE formation could participate, together with estrogen receptor mediated events, in estrogen actions on the CNS. One way of dissecting apart the contributions from estrogen receptor and catechol-mediated effects is to utilize structurally modified estrogens which have either a reduced receptor affinity [e.g. estradiol 17α (17αE_2)] or a reduced ability to act as substrates for catechol formation [e.g. 2- and 4-fluoroestradiol (2 and 4FE_2) and R2858] (Pfeiffer, et al, this meeting). We have used this approach to examine the role of CEs in the control of cyclic gonadotrophin release and feminine sexual behavior female Sprague-Dawley rats exhibiting regular 4-day estrous cycles were ovariectomized on the evening of diestrus 1. Twelve hours later (10am "diestrus 2") they were implanted subcutaneously with Alzet 2001 osmotic minipumps containing either 17βE_2, 17αE_2, 2FE_2, 4FE_2, R2858 or the infusion vehicle alone (propylene glycol; 0.1% ascorbic acid). The 17βE_2 infusion rate (0.025 ug/h) was chosen to reproduce the effects of the proestrus estrogen surge. Infusion rates for R2858, 2FE_2 and 4FE_2 were adjusted to give the same levels of cell nuclear estrogen receptors (ERn) in the brain and pituitary as those produced by the 17βE_2 infusion. 17αE_2 was infused at rates of 0.025 and 0.25 ug/h; neither of these 17αE_2 treatments significantly increased brain and pituitary ERn concentrations. Tail vein blood samples were withdrawn from all animals at 12 noon, 2, 4, and 6pm on the expected day of "proestrus" and assayed for LH. The animals were then injected s.c. with 1 mg progesterone in propylene glycol and tested for lordosis and proceptive behaviors 5 h later.

Treatment ug/h	N	LH at 6pm ng/ml±SEM	Lordosis Quotient % ± SEM	Proceptivity Frequency
Vehicle	7	77±18	0	0/7
17αE_2, 0.025	7	53±16	0	0/7
17αE_2, 0.25	7	44±9	0	0/7
17βE_2, 0.025	7	435±69	94±69	5/7
2FE_2, 0.1	7	645±221	84±9	6/7
4FE_2, 0.025	7	445±121	92±3	4/7
R2858, 0.05	7	475±98	87±2	6/7

All of the estrogens except 17αE_2 elicited LH surges and proceptive and lordosis behaviors. These results suggest that local CE formation is not an obligatory step in the mechanism by which estrogens induce LH release and female sexual behavior. (Supported by NIH grant HD13507).

18.9 REMOVAL OF THE NEUROINTERMEDIATE PITUITARY RESULTS IN AN EFFECTIVE INCREASE IN CORTICOID FEEDBACK. K. Fagin*, S. Wiener*, J. Shinsako* and M. Dallman* (SPON: M. Mangiapane). Dept. of Physiol., UC San Francisco, CA 94143 and Dept. Psychiatry, Stanford University, CA 94305.

We have reported that rats in which the neurointermediate pituitary had been removed (NX) have a selective deficit in their ability to increase plasma ACTH and corticosterone (B) following a noise ("neurogenic" or exteroceptive) stimulus compared with controls (NC). Plasma ACTH and B increases after 15 ml/kg hemorrhage ("systemic" or interoceptive) stimulus are similar in NX and NC rats (Endo Soc Abstr #838, 1982). We investigated here the cause of the selective deficit in ACTH and B secretion. Ability to perceive a neurogenic stimulus, indicated by latencies to pawlicking and jumping in a heat platform test were identical in NX and NC rats, but NX rats demonstrated the predicted deficits in plasma B elevations after the heat test as well as in a novel environment compared with NC rats ($p<0.05$). Since AM plasma B levels in NX rats are significantly higher than in NC rats, such levels might impose an increased negative feedback signal to ACTH secretion following neurogenic stimuli. We determined in cannulated rats that the elevated B levels did not indicate the lack of a diurnal rhythm; significant rhythms in plasma B and in water intake were present both in NX and in NC rats ($p<0.05$).

	ACTH (pg/ml)				B (µg/dL)			
(h)	1930	0230	0830	1430	1930	0230	0830	1430
NC	65±8	66±12	30±3	46±3	16.2±1.8	3.1±0.4	1.4±0.1	6.5±2.7
NX	59±6	63±17	56±15	58±9	15.1±1.6	5.4±1.1	11.2±1.5	14.3±2.0

(lights on 0830-2030 h. mean±SEM. NX n=5; NC n=4)

Adrenal sensitivity to ACTH appeared to decrease at 0230 h in both groups; however, B levels were elevated in NX rats by 0830 h, suggesting that by that time the normal diurnal rhythm in hormone levels was overridden by other factors. Since mean plasma B over 24 h was 1.7-fold higher in NX vs. NC rats ($p<0.05$), we thought that this chronic elevation in mean plasma B might attenuate the plasma ACTH increase after adrenalectomy, a low-intensity stimulus known to provoke a B-sensitive ACTH response. The increase in plasma ACTH 1 h after adrenalectomy was significantly less in NX rats compared with NC rats. Thus, NX rats have normal perception of and behavioral reactions to a neurogenic stimulus, a normal diurnal drinking rhythm, and capacities both for a rhythm in adrenal sensitivity to ACTH and to secrete large amounts of ACTH. The attenuated increase in ACTH after adrenalectomy indicates that the deficit in plasma B responses to neurogenic stimuli may result in part from a corticosterone negative feedback signal that is chronically elevated. Supported by AM28172 and MH15091.

18.10 CORTICOTROPIN RELEASING FACTOR ELICITS RESPONSES CHARACTERISTIC OF STRESS REACTION IN PRIMATES H.M. Schulte*, G.P. Chrousos*, P.W. Gold*, E.H. Oldfield*, G.B. Cutler* and D.L. Loriaux* (Spon: F.K. Goodwin) Developmental Endocrinology Branch, NICHD, Psychobiology Branch, NIMH, and Surgical Neurology Branch, NINCDS, NIH, Bethesda MD 20205

A 41 amino acid peptide possessing ACTH releasing activity has recently been isolated from ovine hypothalami. It has greater corticotropin (ACTH) releasing potency than any previously identified endogenous or synthetic peptide in pituicyte cultures in vitro and, in rats, subhuman primates and man in vivo. We report that in addition to its corticotropin releasing effects, corticotropin releasing factor (CRF) stimulates the secretion of growth hormone (GH) and prolactin (PRL) and influences the cardiovascular system as well. Intravenous CRF administered to pituitary stalk-sectioned cynomolgus macaques in graded doses (0.01 to 40 µg/kg, n= 26 stimulation tests) stimulated cortisol secretion with an ED_{50} of 0.5 µg/kg. It also released GH and PRL at all doses above 1 µg/kg. Plasma TSH and LH concentration were not altered. CRF (10 µg/kg iv bolus) also caused significant GH and prolactin release in rhesus monkeys with intact hypothalamic-pituitary units ($p < 0.05$). It did not influence TSH and LH secretion in these animals. In the same animals heart rate and blood pressure were measured at 1 minute intervals for 30 min before and for 2 h after CRF administration. CRF induced a marked transient increase in heart rate, with a peak at 5 min (193 + 7 vs 158 + 15, $p < 0.025$). Heart rate returned to control values by 50 min. No discernible changes in mean arterial blood pressure were noted. Thus, peripheral administration of CRF elicited several responses characteristic of the stress reaction in primates: cortisol secretion, GH and PRL release, and tachycardia. Work from other laboratories suggests that the increased heart rate results from a CRF-induced release of catecholamines. We conclude: 1. In the primate, CRF releases GH and PRL as well as ACTH; 2. The hormonal response to CRF is that usually associated with stress; 3. CRF causes an immediate and prominent increase in heart rate. These findings suggest that several aspects of the stress response may be mediated by CRF.

18.11 GNRH RELEASE FROM PERIFUSED MURINE HYPOTHALAMI, L. M. Johnson*. Divn. of Pediatric Endocrinology, U. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

A study of in vitro release of GnRH from murine hypothalmi is in progress. Such tissue provides less GnRH per animal than does rat tissue, but the much smaller tissue size facilitates diffusion of gasses to maintain cellular integrity. Brains of the mice were dissected on ice immediately after decapitation. Hypothalamic borders extended rostrally to include preoptic area, caudally to the mamillary bodies, laterally 1.0 mm from midline and dorsally 2 mm. Each hypothalamus was bisected through the midline and halves were placed in separate perifusion chambers. Each chamber held 2 halves. 0.5 ml fractions were collected over a 6 minute period into RIA tubes. Kelch anti-GnRH (10-15) was used. A sensitivity of 0.5 pg/tube was achieved in most assays using a procedure of overnight (4 C) incubation with unlabelled hormone plus anti-hormone, 3 hr (25 C) incubation with labelled hormone and rapid charcoal separation. The Kreb's buffer slightly depressed binding and was, thus, used in standards also.

Baseline release was measured over a 2 hr period for 0, 5 and 20 mM glucose. No release occurred without glucose. At 5 mM glucose, release varied, being only occasionally detectable in 2 intact mice but variable between 5 and 10 pg/fraction for 3 other intact, young adult male mice. For 2 hypothalami placed in 20 mM glucose, release was between 20 and 40 pg/fraction, with 4 pulses each in 2 hrs. Addition of 15 mM mannitol to 5 mM glucose did not enhance release.

Baseline release in young adult, ovariectomized mice varied from undetectable to 3 pg/fraction compared to release during 60 mM KCl stimulation that was 8 - 10 pg/fraction. Baseline release in 4 old (1.7 yr) mice (ovx at age 5 wk, as the others) was $\leq$2 - 2.7 pg/fraction (20 mM glucose) or $\leq$0.5 pg/fraction (5 mM glucose), but only one chamber (20 mM) contained slightly increased GnRH during potassium stimulation.

It appears that for murine hypothalami in vitro (1) 20 mM glucose supports higher baseline GnRH release than 5 mM glucose, (2) that release may be pulsatile under some conditions and (3) respond well to potassium stimulation in young but not in old ovariectomized mice.

18.12 IMMUNOCYTOCHEMICAL EVIDENCE FOR GONADOTROPIN RELEASING HORMONE NEURONAL AUTONOMY IN THE PRIMATE MEDIAL BASAL HYPOTHALAMUS. Paul C. Goldsmith, Lisa R. Brezina* and Yu-Chih Jao*. Dept. of Ob, Gyn and Repro. Sci., Univ. of California, San Francisco, CA 94143.

In order to determine the neuroanatomical basis for the reported gonadotropin releasing hormone (GnRH) autonomy of the deafferented primate medial basal hypothalamus (MBH), we studied the distribution and contacts between GnRH neurons within the intact MBH. Immunofluorescence and the PAP technique were performed on frontal vibratome sections from 5 male and 5 female neonatal baboons. The GnRH cell body (CB) and fiber distribution was identical for both sexes. At the optic chiasm, bilateral groups of about 20 CBs appeared dorsal to and partly within each supraoptic nucleus. More posterior CBs, along with those spilling over the medial border of each optic tract (OT) gave rise to a distinct fiber pathway extending to the infundibular lip (IL) which we have designated the ventral hypothalamic tract (VHT). In its lateral third, VHT CBs were dispersed and aligned within the tract. At the midpoint, CBs became scarce, but axons formed a loose bundle parallel to the ventral hypothalamic surface. More medially, VHT fibers condensed as they came to lie close to the ventral surface. Some vertically oriented bipolar CBs, perpendicular to the VHT, appeared amidst the granular cell layer at the ventral surface. Their axons ascended dorsally only to contact or join VHT fibers, while their ventral dendrites vanished into the pia. Occasional CBs within the VHT sent axons ventrally, or dendrites to contact nearby capillaries. At the IL, bilateral groups of about 10 GnRH CBs again appeared, primarily aligned within the VHT. These CBs were always lateral and/or ventral to the arcuate nucleus, but not within the nucleus itself. Compact VHT axons turned ventrally to enter the infundibulum (INF) from its perimeter. Beaded fibers gave rise to radiating collaterals, all of which terminated in a dense GnRH plexus in the palisade zone of the median eminence, covering the entire INF. Posterior to the INF, CBs were rare, but fibers accumulated near the small capillary network on the ventral surface.

The most interesting findings were GnRH intercellular contacts of diverse type and complexity. Close contacts between CBs occurred within the VHT, especially at the IL. Their proximity suggested electrotonic coupling rather than synaptic interaction. In addition, polygonal axo-axonic formations with terminal boutons were observed between 2 or 3 contributing, but more widely dispersed, CBs at the IL. Together, these contacts may recruit GnRH neurons into a phasic firing pattern and may help amplify pulsatile GnRH release. CBs within the MBH together with their prevalent contacts may be sufficient to ensure concerted circhoral GnRH secretion into portal blood, and to maintain basal gonadotropin levels in the primate, provided the VHTs and ILs are intact.

Supported by USPHS Grant HD 10907 and the Mellon Foundation.

18.13 ENDOGENOUS OPIATES DO NOT MEDIATE A SIMPLE TONIC INHIBITION OF GONADOTROPIN RELEASING HORMONE SECRETION IN THE MALE RAT. M. A. Miller*, D. K. Clifton*, D. M. Dorsa*, W. J. Bremner*, and R. A. Steiner* (SPONSOR: D. M. Bowden). Depts of Ob-Gyn, Psychology, Physiology and Biophysics, and Medicine, University of Washington and VA Medical Center, Seattle, WA 98195

Recent studies have shown that opiate antagonists enhance LH release and imply that endogenous opiate pathways tonically inhibit episodic gonadotropin releasing hormone (GnRH) secretion. We hypothesized that if this were true, then a continuous blockade of opiate receptors should result in a sustained increase in LH pulse frequency and/or amplitude. To test this hypothesis we examined the effect of continuous exposure to the opiate antagonist naloxone (NAL, Endo Labs) on LH pulse frequency and amplitude in the intact male rat.

Young adult male, Sprague-Dawley rats were implanted with jugular catheters under ether anesthesia. Beginning at 0900h on the next day, blood samples (400 µl) were taken every 10 min for 5 hours. After each sample, animals received an equal volume of a blood replacement mixture. Following sample #6, animals in the experimental group (n=8) received a bolus injection of 2 mg/kg NAL (IV) as well as an additional 0.2mg NAL every 5 minutes over the subsequent 4 hours. The control group (n=7) received saline in place of naloxone. Plasma LH levels were measured with NIAMDD rat LH RIA reagents.

Three of 7 control animals exhibited spontaneous LH pulses at apparently random intervals during the injection period. NAL effected an immediate (within 20 min) pulsatile release of LH (from preinjection levels of 9±2 to 42±5 ng/ml) in 7 of 8 animals, whereas none of the control animals exhibited an LH pulse for at least 30 minutes following saline injection; the two groups were significantly different by this 30 minute cut-off criterion ($p<0.01$). This stimulated LH release was not sustained during chronic opiate blockade. Average serum LH levels during the last 2 hours of NAL treatment ($\bar{X}$=7±1 ng/ml) did not differ significantly from pretreatment levels. Although animals receiving the NAL treatment exhibited a greater number of LH pulses during the treatment period, the difference in frequency between the groups was not significant (control: 0.32±0.18 vs experimental: 0.66±0.10 pulses/hour, $p>0.1$).

Conclusion: Although endogenous opiates may interact with the GnRH system, these opiate pathways do not exert a simple tonic inhibition of pulsatile GnRH output.

18.14 PLASMA β-ENDORPHIN (βEND), β-LIPOTROPIN (βLPH) AND ACTH RESPONSES TO STRESS IN INTACT AND ADRENALECTOMIZED RATS. Errol B. De Souza and Glen R. Van Loon. Departments of Physiology and Medicine, University of Toronto, Toronto, Ontario, Canada and Department of Medicine, University of Kentucky and Veterans Administration Medical Center, Lexington, KY.

It has been proposed that βEND, βLPH and ACTH are concomitantly secreted from the pituitary gland in an equimolar ratio in response to a variety of stimuli including stress and adrenalectomy. The parallel secretion of these peptides probably relates to their common origin and biosynthesis from a larger precursor glycoprotein referred to as proopiomelanocortin. The present study was designed to compare the plasma concentrations of βEND, βLPH and ACTH under basal conditions and following application of a 2 min restraint stress both in intact and chronically adrenalectomized adult male rats. In intact rats, application of a 2 min restraint stress produces rapid, parallel increases in plasma concentrations of radioimmunoassayable βEND/βLPH and ACTH, peaking at 2.5 to 5 min following onset of the stress and returning almost to basal concentrations by 30 min. The antibody used in the βEND/βLPH radioimmunoassay detects βEND and βLPH equally on a molar basis. In order to determine the relative amounts of βEND and βLPH that are present in plasma of control, nonstressed rats and the amounts that are secreted in response to stress, we separated the peptides by gel exclusion chromatography prior to assay of the peptides by radioimmunoassay. Plasma obtained from control, nonstressed rats contains more βEND than βLPH. Equal amounts of βEND and βLPH are present in plasma of intact rats 5 min after the onset of a 2 min restraint stress as assessed by gel exclusion chromatography and radioimmunoassay. Rats adrenalectomized nine days earlier have significantly higher basal plasma concentrations of βEND/βLPH and ACTH than are present in intact rats. Furthermore, the plasma responses of both βEND/βLPH and ACTH to stress are markedly enhanced in adrenalectomized rats when compared to the corresponding responses in intact rats. Gel exclusion chromatography revealed that both the higher basal concentration and the enhanced plasma βEND/βLPH response to stress in adrenalectomized rats result primarily from increases in the βLPH component with lesser increases in the βEND component. In summary, the data of the present study demonstrate that following application of a 2 min restraint stress, equal amounts of βEND and βLPH are secreted in intact rats whereas, greater amounts of βLPH than βEND are secreted in chronically adrenalectomized rats. Thus, different mechanisms appear to regulate the βEND and βLPH responses to stress in the normal state and following removal of glucocorticoid negative feedback.

18.15 PROLACTIN INCREASES THE ACTIVITY OF TUBEROINFUNDIBULAR AND NIGRONEOSTRIATAL DOPAMINE NEURONS: PROLACTIN ANTISERUM INHIBITS THE HALOPERIDOL-INDUCED INCREASES IN DOPAMINE SYNTHESIS RATES IN MEDIAN EMINENCE AND STRIATUM OF ADULT MALE RATS. Glen R. Van Loon, Andrew Shum*, Susan R. George* and Seon Shin*. Departments of Medicine, University of Toronto, Toronto, Canada, and University of Kentucky and Veterans Admin. Medical Center, Lexington KY, and Department of Physiology, Queen's University, Kingston, Canada.

Important differences in the regulation of tuberoinfundibular and nigroneostriatal dopaminergic neurons have been proposed. For example, neuroleptics such as haloperidol increase striatal dopamine synthesis and release promptly through a dopamine-receptor mediated negative feedback mechanism. In contrast, haloperidol increases median eminence dopamine turnover only after a prolonged latent period; it has been postulated that this haloperidol effect is mediated by prolactin since it is not present in hypophysectomized animals. The present study was designed to provide conclusive evidence for this thesis, and to assess further a possible effect of prolactin to alter striatal dopamine turnover. We examined the effect of prolactin antiserum on the haloperidol-induced increases in median eminence and striatal dopamine synthesis rates in adult male rats. Our prolactin antiserum generated in rabbits effectively precipitated prolactin, but not other anterior pituitary hormones. Following iv administration, a large excess of circulating prolactin antibody could be demonstrated, even 24 hours after haloperidol administration. Groups of rats received haloperidol 2.5 mg/kg or tartaric acid vehicle sc twice, 22 h and 12 h before measurement of brain dopamine turnover. Comparable groups of haloperidol or vehicle-treated rats received either prolactin antiserum iv or normal rabbit serum. Dopamine synthesis turnover rate was estimated by measurement of accumulation of L-dihydroxyphenylalanine following inhibition of L-aromatic amino acid decarboxylase with m-hydroxybenzylhydrazine. Haloperidol increased median eminence dopamine synthesis rate, and prolactin antiserum completely prevented this effect. Prolactin antiserum did not alter basal median eminence dopamine synthesis rate in male rats. In addition to its effect in median eminence, prolactin antiserum blunted the haloperidol-induced increase in striatal dopamine synthesis rate, suggesting that the haloperidol-induced increase in nigroneostriatal dopamine turnover is mediated in part by prolactin. Neither haloperidol nor prolactin antiserum altered serotonin synthesis rate in mediobasal hypothalamus or striatum. The data provide further evidence that the haloperidol-induced increase in activity of tuberoinfundibular dopamine neurons is mediated by prolactin, and further support for a mechanism by which prolactin can regulate its own secretion.

18.16 ANGIOTENSIN II RECEPTORS IN BRAIN POTENTIATE THE STIMULATORY EFFECT OF ENDOGENOUS OPIOID NEURONS ON CENTRAL SYMPATHETIC OUTFLOW. Nathan M. Appel and Glen R. Van Loon. Departments of Physiology and Medicine, University of Toronto, Toronto, Ontario, Canada and Department of Medicine, University of Kentucky and Veterans Administration Medical Center, Lexington, KY.

Endorphins, endogenous opioid peptides, appear to have neurotransmitter or neuromodulator function in brain, mediating a wide variety of effects. We have reported that intracisternal administration of synthetic human β-endorphin increases plasma concentration of catecholamines, presumably by acting at unknown brain site(s) to increase sympathetic outflow to the adrenal medulla and sympathetic nerves. The β-endorphin-induced increase in plasma catecholamines was prevented by ganglionic blockade with chlorisondamine and by bilateral adrenal denervation. Subsequently, we provided evidence for the involvement of central cholinergic, noradrenergic and somatostatin neurons in the mediation of this endorphin-induced stimulation of sympathetic outflow. A variety of other neurotransmitters may be involved. In the present study we examined the possibility that angiotensin II, acting in brain, modulates endorphin-induced catecholamine secretion. Synthetic human β-endorphin, 1.45 nmoles administered intracisternally, increased plasma epinephrine and norepinephrine concentrations 10-30 minutes later when compared to the response in animals receiving saline vehicle. Simultaneous administration of angiotensin II, 1.0 nmole intracisternally together with β-endorphin, potentiated the plasma epinephrine and norepinephrine responses to intracisternal β-endorphin. In contrast, simultaneous administration of the angiotensin II receptor antagonist [Sar^1,Val^5,Ala^8]-angiotensin II (saralasin), 1.1 nmoles intracisternally together with β-endorphin, blunted the plasma epinephrine and norepinephrine responses to β-endorphin. These data are consistant with the hypothesis that activation of angiotensin II receptors in brain potentiates the endorphin-induced stimulation of central sympathetic outflow. It remains to be demonstrated whether angiotensin II acting in brain to modulate activity of opioid neurons is synthesized in brain or is derived peripherally.

18.17 RELEASE OF VASOPRESSIN AND β-ENDORPHIN INDUCED BY ANGIOTENSIN IN THE CONSCIOUS RAT: STUDIES ON THE MECHANISM OF ACTION.
W. Knepel*, U. Beuers*, D. Nutto*, and D.K. Meyer*. (SPON: A. Raines). Dept. of Pharmacology, Univ. of Freiburg, Hermann-Herder-Str.5, D-7800 Freiburg i.Br.

Intravenous infusions of angiotensin I and II induce release of β-endorphin from the anterior lobe and of vasopressin from the posterior lobe of the pituitary gland. Captopril, a converting enzyme inhibitor, abolishes the effect of angiotensin I, whereas saralasin blocks the action of angiotensin II.

(i) A fornix lesion anterior and ventral to the subfornical organ inhibits the effect of angiotensin II on vasopressin release, but does not effect the release of β-endorphin. (ii) In rats with hereditary lack of vasopressin the angiotensin II-induced release of β-endorphin was diminished as compared to controls. (iii) When rat medial basal hypothalami were incubated in vitro angiotensin II increased the release of β-endorphin.

We conclude that blood-borne angiotensin II releases the pituitary hormones via different routes: vasopressin release from the posterior lobe may be mediated by the subfornical organ; in contrast, β-endorphin release from the anterior lobe may be due to a direct effect of angiotensin on the adenohypophysis as well as to an enhanced release of vasopressin from the external layer of the median eminence which then acts as a β-endorphin releasing factor.

18.18 HISTAMINE LEVELS ARE SELECTIVELY DECREASED IN THE POSTERIOR PITUITARY LOBE OF BRATTLEBORO RATS LACKING VASOPRESSIN.
H.H. Holcomb§, P.M. Gross§§, M. Kadekaro§§, and J.M. Saavedra§§§. Biological Psychiatry Branch§, Laboratory of Cerebral Metabolism§§, and Laboratory of Clinical Science§§§, National Institute of Mental Health, Bethesda, Maryland 20205.

Histamine may have an important role in modulating the secretion of vasopressin in normal animals. Its levels in the posterior pituitary lobe are high (Saavedra, J.M., et al., J. Neurochem., 25:257, 1975), and intracerebroventricular administration of histamine causes a marked increase in circulating levels of vasopressin (Dogterom, J., et al., Experientia 32:659, 1976; Tuomisto, L., et al., Eur. J. Pharmacol., 63:15, 1980).

Our demonstration of high histamine methyl transferase activity in the posterior pituitary lobe of normal rats (apparent activity: 50±7.9 pmoles/μg protein/h; mean±SE, n=6) suggests a rapid rate of histamine turnover. In marked contrast, the intermediate lobe exhibits no detectable histamine methyl transferase activity (n=6) despite high histamine content.

We studied histamine metabolism in homozygous (DI) and heterozygous (HZ) Brattleboro rats deficient in vasopressin. We demonstrate a marked reduction in posterior pituitary histamine content of DI rats in comparison with HZ controls. Conversely, histamine levels were not different in the intermediate pituitary lobe of DI and HZ rats.

	Histamine Levels (ng/mg protein)	
	DI	HZ
Intermediate Lobe (n=4)	3.3 ± 1.0	3.5 ± 0.27
Posterior lobe (n=9)	4.9 ± 0.65	14.8 ± 2.72*

* $p < 0.001$

Our results suggest that these marked differences in histamine content in the posterior pituitary lobe may reflect its role in modulating vasopressin secretion and water balance.

18.19 SELECTIVE INCREASE IN THE RATE OF GLUCOSE UTILIZATION BY THE NEUROHYPOPHYSIS DURING DEHYDRATION FROM SALINE INGESTION.
P.M. Gross, M. Kadekaro, H.H. Holcomb§, L. Sokoloff, J.M. Saavedra§§. Laboratory of Cerebral Metabolism, Biological Psychiatry Branch§, and Laboratory of Clinical Science§§, National Institute of Mental Health, Bethesda, Maryland 20205.

Dehydration is associated with increased synthesis and elaboration of vasopressin from the hypothalamo-neurohypophysial tract. Previous studies in this laboratory with the 2-[^{14}C]deoxyglucose method used qualitatively provided autoradiographic evidence that chronic saline ingestion activated metabolism in the neurohypophysis but not in the hypothalamic nuclei of origin of this tract (Schwartz, W.J., et al., Science, 205:723-725, 1979). In the present studies we have essentially repeated those earlier studies but with the quantitative 2-[^{14}C]deoxyglucose method to assess the magnitude of the changes in glucose utilization. Male Sprague-Dawley rats (318-371 g initial weight) were provided water or 2% saline (n=5 in each group) ad libitum over a 5 day period. Animals which drank saline had an average 18% loss in body weight and an increase in plasma osmolality of 20 mosm/l over controls. Values for glucose utilization in selected structures of conscious animals were (means ± SE in μmoles/100 g/min, * $p < 0.05$):

Structures	Water	Saline	S-W % Diff
N. paraventricularis	63 ± 3	62 ± 3	-2
N. supraopticus	71 ± 4	72 ± 4	+1
N. suprachiasmaticus	71 ± 7	70 ± 6	-1
Area retrochiasmaticus	58 ± 4	52 ± 4	-7
Neurohypophysis	45 ± 9	102 ±10*	+127

The results confirm that dehydration from chronic saline ingestion causes a dramatic increase in metabolic activity in the neurohypophysis but not in hypothalamic nuclei that synthesize or store vasopressin.

18.20 MOTILIN STIMULATES GROWTH HORMONE RELEASE IN VITRO AND IN VIVO.
M.D. Lumpkin*, W.K. Samson* and S.M. McCann, Dept. of Physiol, Univ Tex Health Sci Ctr Dallas, Dallas, Texas 75235.

The peptide motilin has been localized to the anterior pituitary gland and hypothalamus-median eminence, as well as the gut, by immunohistochemistry and radioimmunoassay (Jacobowitz et al., O'Donohue et al., respectively, Peptides 2; 1981). These findings suggested a role for motilin in anterior pituitary function. In a previous report by us (Samson et al., Brain Research Bulletin 8; 1982), a single dose (10^{-6}M) of motilin released growth hormone (GH) from rat hemipituitaries and dispersed anterior pituitary cells. This result led us to seek here a dose-related ability of motilin to release GH from dispersed anterior pituitary cells and, as well, an action to release GH in vivo. In 2 experiments, anterior pituitaries from adult male rats were dispersed and cultured overnight. The dispersed cells were incubated with synthetic motilin (Peninsula) at log and half-log doses ranging from 5×10^{-8}M to 10^{-5}M. The minimal effective dose of motilin which caused a significant release of GH was 10^{-7}M. Increasing doses of motilin produced a linear, dose-related increase in GH release ($p<.02$ to $p<.001$). By contrast, TRH in the same system only stimulated GH release slightly at 10^{-6} or 5×10^{-6}M doses. Motilin also was incubated with dispersed anterior pituitary cells from ovariectomized estrogen-progesterone-primed rats. Again motilin increased the secretion of GH into medium at doses of 10^{-6} ($p<.001$) and 10^{-5}M ($p<.01$) in a dose-related fashion. In vivo, the intravenous (iv) injection of 1 or 10 μg of motilin into conscious adult male rats bearing jugular cannulae produced variable results, while 100 μg motilin iv significantly elevated plasma GH 2-fold 5 min post-injection.

Finally, microinjection of motilin (5 μg) into the 3rd ventricle of conscious adult male rats paradoxically lowered plasma GH 5 min post-injection ($p<.05$) when compared to preinjection values. This paradoxical effect may indicate that an ultrashort-loop feedback mechanism exists whereby exogenous motilin may decrease hypothalamic motilin secretion, thereby reducing the motilin stimulus for GH release. The specificity of the motilin effect on GH was attested to by the failure of motilin to alter significantly PRL, TSH and LH in each paradigm. We conclude that motilin may act physiologically on cells of the anterior pituitary at various doses to release GH specifically and in a dose-related fashion and that it might be involved in ultrashort-loop feedback to reduce its GH-releasing action. (Supported by NIH Grants HD-07062, HD-09988, and AM-10073).

18.21 MULTIPLE OPIATE RECEPTOR REGULATION OF PROLACTIN AND GROWTH HORMONE SECRETION. J.I. Koenig*, M.A. Mayfield* and L. Krulich* (SPON: J.G. Parnavelas). Dept. of Physiol., Univ of Texas Hlth. Sci. Ctr., Dallas, TX 75235.

Opioid peptides, as well as morphine have been shown to stimulate the secretion of both prolactin (PRL) and growth hormone (GH). However, receptor binding studies indicate that these compounds exhibit different affinities for the various opiate receptors. The present study was undertaken to determine whether specific opiate receptor subtypes mediate opiate-induced PRL and GH secretion. Adult male Sprague-Dawley rats (300-350 gm) were used in all the following experiments. Third cerebral ventricle (IVT) injections were performed through cannulae which had been implanted one week previously. Blood samples were obtained from chronic jugular cannulae which were implanted 48 hrs. before experimental use. Morphiceptin (MPC) was used as a rather selective ligand of the mu receptors, while delta receptor peptide (DRP) and [D-Ala^2, D-Leu^5] enkephalin (DADLE) were used as delta receptor agonists, respectively and bremazocine was used to stimulate the kappa receptors. The IVT injection of MPC, DRP and DADLE all dose dependently increased plasma PRL 15 min following injection over a dose range of 100 ng to 10 µg. These effects were all significantly reversed by naloxone (0.6 mg/kg, iv) given 15 min before the IVT injection. Bremazocine also elevated PRL in a dose dependent fashion over a range of 0.0125 to 0.5 mg/kg, i.v. The PRL-releasing effect of 0.125 mg/kg of bremazocine was not reversed by 0.6 or 6.0 mg/kg of naloxone or MR 2266, a specific kappa receptor antagonist. The opiate influence on GH secretion exhibited different characterisitics. Bremazocine regardless of the dose had no effect on GH secretion. DRP stimulated GH over the dose range of 100 ng to 10 µg and except for the 100 ng dose the effect was not attenuated by naloxone (0.6 mg/kg). DADLE stimulated GH at a dose of 500 ng which was not blocked by naloxone, similar to DRP. These results indicate that the secretion of PRL may result from activation of mu or delta receptors because naloxone inhibited the effect of MPC but also the effect of DADLE or DRP, which is a rather specific delta agonist. The PRL releasing effect of bremazocine, not blockable by naloxone implies an entirely different mechanism. GH secretion seems to be controlled predominantly by the delta receptors, since naloxone is ineffective against DADLE or DRP and since MPC is effective only at high dose which may also activate the delta receptor. Kappa receptors are probably not involved either since bremazocine did not stimulate GH secretion. Supported by NIH Grant #HD 09988.

18.22 A POSSIBLE ROLE FOR OXYTOCIN IN THE CONTROL OF PROLACTIN RELEASE. W.K. Samson*, M.D. Lumpkin*, G.P. Kozlowski and S.M. McCann. Dept. of Physiology, UTHSCD, Dallas, Texas 75235.

Recently, we have reported the potent stimulatory action of oxytocin (OXY) on the in vitro release of PRL from rat hemipituitaries and dispersed cell preparations (Lumpkin et al., Endocrine Society, 1982). In order to further elucidate the possible role of OXY in PRL release, attempts were made to 1) correlate fluctuations in serum levels of both hormones after estrogen priming, 2) examine a possible depletion of neural lobe OXY during steroid-induced PRL secretion and 3) examine the effect of passive immunoneutralization of endogenous OXY on basal PRL secretion. Antiserum raised in rabbits to synthetic OXY (GPK936) was used for RIA purposes and generally binds 30% of total at a final dilution of 1: 25,000. No cross-reactivity was demonstrated to twenty other known hypothalamic and/or pituitary peptides in doses as high as 1 ug/tube, except in the case of vasopresin (AVP) where 1 ug AVP cross-reacted with the equivalency of 28 pg of OXY. Ovariectomized (OVX) rats were injected s.c. with 5 µg estradiol benzoate (EB) and sacrificed at 10 AM, noon, 1 and 2 PM two days later. A significant rise in serum PRL levels was observed following the 10 AM sampling time (10.26 ± 4.95 ngm PRL/ml) with highest values being detected at 1 pm (33.07 ± 8.82). A similarly significant rise in serum OXY with levels peaking at 1 pm (39.15 ± 1.5 pg OXY/ml) was seen. Serum OXY levels also were elevated significantly when compared to the 10 AM sampling (33.36 ± 1.02) at noon (37.90 ± 1.33) and 2 PM (38.70 ± 1.02).
In a second experiment OVX rats were decapitated hourly from 10 AM to 2 PM, 48 hrs. after EB injection. Serum PRL levels again were elevated significantly at 1 PM (33.13 ± 1.63) over those at 10 AM (20.2 ± 3.83). Neural lobe OXY content (ngm OXY/mg tissue) declined in a linear fashion from 11 AM (139.03 ± 13.34) to lowest values at 2 PM (81.70 ± 6.68, $p<.01$). Anterior lobe OXY content increased after 10 AM (2.82 ± 0.54 pg/ng tissue) with significantly higher values present at 1 pm (5.31 ± 0.77). Finally, antiserum to OXY (100 µl) was injected into freely moving, intact male rats through an implanted jugular cannula. Plasma PRL levels did not differ significantly in normal rabbit serum or anti-OXY treated rats at any sampling time (0-120 minutes). We have demonstrated previously the potent in vivo and in vitro PRL-releasing activity of OXY. Additionally, we have observed immunostaining for OXY in the external layer of the anterior median eminence, suggesting delivery of the peptide into the portal capillaries. Our data suggests a temporal correlation between OXY release from neuronal elements and steroid-induced PRL secretion. A role for OXY in basal PRL release seems unlikely however due to the failure of immunoneutralization of endogenous serum OXY levels to alter PRL secretion.

18.23 THE EFFECTS OF MORPHINE INJECTIONS DURING PREGNANCY IN THE RAT ON PLASMA LEVELS OF TSH AND PROLACTIN AFTER BIRTH. W.J. Litto*, J.P. Griffin*, and J. Rabii, Department of Biological Sciences and the Bureau of Biological Research, Rutgers University, Piscataway, New Jersey 08854.

The administration of opiates has been shown to lead to acute alterations in pituitary hormone secretion. Relatively little attention has been given to the possible long-term effects of opiate exposure on neuroendocrine systems. We have studied the influence of morphine sulfate (MS) injections, on days 5-12 of pregnancy, on TSH secretion in the offspring and on prolactin (PRL) release in the lactating dam. Pups born to MS or saline treated dams were sacrificed by decapitation at 5-day intervals between 5 and 35 days of age. Both male and female offspring of either MS or saline treated mothers exhibited a peak in their plasma TSH concentrations at 20 days of age. Plasma TSH levels before 20 days of age tended to be lower in the MS exposed pups as compared to the saline controls. TSH levels after day 20, on the other hand, were generally higher in MS treated animals. When the acute response of TSH to MS injection was studied in pups born to MS or saline treated dams, marked decreases in TSH release were seen in both sexes of either treatment group. No significant differences were apparent between the prenatally MS and saline exposed pups in their response to a single postnatal injection of MS. Pups were separated from their mothers between days 5 and 10 postpartum. Blood samples were obtained from the dam immediately before and at times after the return of the pups to the cage. Pups were returned after a 6-hour separation. The MS and the saline injected dams were both able to exhibit a significant PRL release in response to the suckling stimulus. The response of the MS group, however, was markedly lower than that of the saline controls. These experiments suggest that, at least in the 5 to 35 day old pups, there are apparent influences of prenatal exposure to MS on basal TSH release but not on the MS-induced acute inhibition of TSH secretion. Furthermore, MS injections during pregnancy appear to be capable of lowering the magnitude of the PRL secretion in response to suckling. Supported by National Institute of Drug Abuse Grant DA02227.

18.24 ADENOHYPOPHYSEAL DOPAMINE CONTENT DURING PHYSIOLOGIC AND PHARMACOLOGIC-INDUCED CHANGES IN PROLACTIN SECRETION. **K.T. Demarest, G.D. Riegle*, and K.E. Moore. Depts. of Pharmacol./Toxicol. and Physiol., Michigan State Univ., East Lansing, MI 48824.**

Dopamine (DA) released from terminals of tuberoinfundibular neurons is transported via hypophyseal portal blood to the anterior pituitary gland (AP). Here, the DA is either bound to receptors on cell membranes and/or is internalized and bound to prolactin containing granules within the lactotroph (Endocrinology 107: 30, 1980). It has been suggested that incorporation of DA into the AP is functionally related to the regulation of prolactin secretion. Studies were undertaken to characterize the relationship between AP DA and changes in prolactin secretion which occur in selected physiologic states and following drug treatments. Surges of prolactin secretion which occur on the afternoon of proestrous, during suckling, early pregnancy and restraint stress are all accompanied by a decrease in AP DA content. On the other hand, the increases in serum prolactin concentrations which are observed in aged rats or following water deprivation are accompanied by a dramatic increase in AP DA content. These results demonstrate that there is not a simple inverse relationship between AP DA and alterations in prolactin secretion.

An analysis of pharmacologic manipulations which alter prolactin secretion support this contention. DA agonists (apomorphine and bromocriptine) which decrease serum PRL do not alter AP DA. d-Amphetamine and L-DOPA, drugs which increase DA in the hypophyseal portal blood and decrease serum PRL, increase AP DA. Haloperidol and estradiol both increase serum PRL and decrease AP DA. α-Methyltyrosine (αMT), γ-butyrolactone (GBL) and reserpine, drugs which increase serum PRL by decreasing DA in the hypophyseal portal blood by interfering with the synthesis, release or storage of DA in tuberoinfundibular neurons, all decrease AP DA. The αMT- and GBL-induced increase in serum PRL and decrease in AP DA are blocked by pretreatment with bromocriptine or L-DOPA. The reserpine-induced increase in serum PRL but not the reduction of AP DA are blocked by bromocriptine or L-DOPA, suggesting that reserpine has a direct effect on the storage of DA in the AP. In addition, these data suggest that the ability of DA to inhibit PRL secretion is independent of the incorporation of this amine into the AP. (Supported by USPHS grant AG2644 and a MSU College of Osteopathic Medicine Biomedical Research Grant.)

18.25 ROLE OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS IN THE DIURNAL-NOCTURNAL SURGES OF PROLACTIN SECRETION DURING EARLY PREGNANCY. G.D. Riegle*, K.E. Moore and K.T. Demarest (SPON: J.L. Bennett). Depts. of Pharmacol./Toxicol. and Physiol., Michigan State Univ., East Lansing, MI 48824.

A diurnal nocturnal pattern of tuberoinfundibular dopamine (TIDA) nerve activity occurs out of phase with the diurnal-nocturnal surges of prolactin secretion during early pregnancy (Neuroendocrinology 34: 229, 1982). Since increases in serum prolactin concentrations stimulate TIDA neuronal activity (Frontiers in Neuroendocrinology 7: 161, 1982) the role of prolactin feedback in initiating and timing the biphasic patterns of TIDA nerve activity and prolactin secretion was considered. Studies were undertaken to determine the effect of manipulating the surges of prolactin on the biphasic changes in TIDA nerve activity during day 6 of pregnancy. TIDA nerve activity was estimated by measuring the in vivo rate of DA synthesis in the median eminence (the rate of DOPA accumulation 30 min after a decarboxylase inhibitor, NSD 1015, 100 mg/kg, ip). In vehicle-treated pregnant rats a diurnal-nocturnal pattern of prolactin secretion was observed with peaks at 600 and 2100 h and nadir at 1200 h. A biphasic pattern of TIDA nerve activity was also observed with a peak at 1200 h and nadirs at 300-600 h and 1800-2100 h. Pretreatment with haloperidol (2.5 mg/kg, s.c.) 24 h prior to sacrifice maintained high serum prolactin concentrations (700-800 ng/ml) throughout the day; DOPA accumulation in the median eminence was also increased, and the diurnal-nocturnal pattern was still maintained. Similarly, intracerebroventricular infusion of prolactin (1 µg) 12 h prior to sacrifice increased DOPA accumulation in the median eminence and the diurnal-nocturnal pattern was still observed. In these animals, the magnitude of the surges of prolactin secretion were reduced, probably reflecting increased TIDA neuronal activity. Pretreatment with bromocriptine (3 mg/kg, s.c.) 24 and 12 h prior to sacrifice reduced serum prolactin concentrations (<25 µg/µl) throughout the day; DOPA accumulation in the median eminence was also reduced but the diurnal-nocturnal pattern was lost. These results suggest that the prolactin-induced activation of TIDA neurons is not the cause of the daily changes in the activity of these neurons. Prolactin-induced activation of these neurons does, however, appear to be required during pregnancy for maintenance of "basal" TIDA nerve activity. (Supported by USPHS grants NS09174 and AG2644.)

18.26 PLACENTAL LACTOGEN MIMICS PROLACTIN IN ACTIVATING TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS. N.J. Duda*, K.T. Demarest, G.D. Riegle* and K.E. Moore (SPON: T.M. Brody). Depts. of Pharmacology/Toxicology and Physiology, Michigan State Univ., East Lansing, MI 48824.

During the first half of pregnancy in rats tuberoinfundibular dopamine (DA) neurons exhibit a daily biphasic pattern of activity which appears to be temporally related but out of phase with the diurnal-nocturnal surges of prolactin (Neuroendocrinology 34: 229, 1982). By day 13 of pregnancy the surges of prolactin cease and tuberoinfundibular neuronal activity is continuously maintained at an elevated level; these could be mediated by the increased secretion of placental lactogen which occurs at midpregnancy. The present experiments were undertaken to determine if placental lactogen can stimulate tuberoinfundibular DA neurons. The activity of these neurons was estimated from the in vivo rate of DOPA accumulation in the median eminence after the administration of 3-hydroxybenzylhydrazine (100 mg/kg, i.p.). An initial study was undertaken to determine if a factor in the serum of pregnant rats could stimulate tuberoinfundibular DA neurons. Female Long-Evans rats, ovariectomized for two weeks, were administered pregnant rat sera (collected on day 13-16 from pregnant rats) 3 ml, i.p. at 24, 18, 12 and 6 h prior to sacrifice. For comparison rat prolactin (RP-2-B, 10 µg/10 µl) was administered by intracerebroventricular (icv) infusion 12 h prior to sacrifice via previously implanted cannula guides. The pregnant rat sera, like the icv prolactin infusion, significantly increased the rate of DOPA accumulation in the median eminence. Thus, some factor in pregnant rat sera, perhaps placental lactogen, is capable of activating tuberoinfundibular DA neurons. Studies were undertaken to characterize the action of placental lactogen on tuberoinfundibular DA neuronal activity using human placental lactogen (HPL) since purified rat placental lactogen was unavailable. Tuberoinfundibular DA neurons were activated with 10-100 µg HPL when measured 12 h after icv infusion, while no effect was seen after 3 µg. Following icv infusions of HPL (10 µg) the rate of DOPA accumulation in the median eminence was accelerated at 12 and 16 h, but was without effect at earlier times (4 and 8 h). Thus, HPL exhibits a delayed onset of action similar to that seen with icv prolactin (Brain Res. 195: 236, 1980). These data indicate that placental lactogen can stimulate tuberoinfundibular DA neurons and this process could play a role in terminating the surges of prolactin at midpregnancy. (Supported by USPHS grant NS09174 and a College of Osteopathic Medicine Biomedical Research Grant.)

18.27 CALCIUM IONOPHORE A-23187 STIMULATES CYCLIC AMP AND PROLACTIN RELEASE IN ANTERIOR PITUITARY CELLS: ANTAGONISM BY DOPAMINE OR PENFLURIDOL. G. Schettini,* R.M. MacLeod* and M.J. Cronin (SPON: R.J. Krieg). Depts. of Medicine and Physiology, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908.

In many systems a relationship exists between Ca^{2+} and cyclic AMP (cAMP) to regulate cellular events. Both messengers are involved in the control of prolactin (PRL) release, although the association between Ca^{2+} and cAMP at the pituitary level is not clear. Dopamine (DA) inhibits PRL secretion, but the post-receptor mechanism of action of DA is poorly understood. We investigated the effect of Ca^{2+} ionophore A-23187 (CaI) on cAMP cellular content and PRL release in primary cultures of anterior pituitary cells from male rats. The effects of DA or penfluridol (PF), a neuroleptic that inhibits calmodulin biological activity, on basal or CaI-stimulated cAMP accumulation and PRL release were examined. cAMP (pmole/well) and PRL (ng/well) were measured by RIA. The cells were pretreated with isobutylmethylxantine (0.2 mM) for 2 h before the experiments, which lasted 15 min. CaI (1,5,10 µM) stimulated cAMP accumulation (control 3.6 ± 0.4; CaI 1 µM 5.8 ± 0.8, $p<0.05$; CaI 5 µM 10.0 ± 1.1, $p<0.001$; CaI 10 µM 9.9 ± 1.4, $p<0.01$) and PRL release. DA (0.5, 1, 5, 10 µM) and PF (0.5, 1, 10 µM) both inhibited basal cAMP accumulation and PRL release ($p<0.05$ to $p<0.01$). The table presents the results of another experiment in which the cells were simultaneously exposed to DA or PF with or without CaI. Both compounds show a clear ability to reduce both basal and CaI-stimulated accumulation of cAMP and PRL release.

	- A-23187		+ A-23187 10 µM	
	cAMP	PRL	cAMP	PRL
Control	31 ± 3	173 ± 14	104 ± 8**	300 ± 22**
DA 1 uM	22 ± 2*	117 ± 11*	69 ± 10*	229 ± 13*
PF 1 uM	23 ± .8*	119 ± 5*	51 ± 15*	206 ± 12*
PF 10 uM	16 ± 1**	55 ± 12**	38 ± 2**	79 ± 9**

*= $p<0.05$; **= $p<0.01$ by ANOVA compared to the respective control.

These results indicate that an enhanced calcium influx activates cAMP accumulation in pituitary cells. The ability of CaI to stimulate PRL release may be, at least in part, due to the enhanced lactotroph cAMP content, because DA inhibited both basal and ionophore-stimulated cAMP accumulation and PRL release. The PF inhibition of ionophore-stimulated cAMP accumulation and PRL release suggests that calmodulin participates in these responses in the lactotroph. Thus, PRL release may be modulated by Ca^{2+}-calmodulin-dependent processes that positively interact with the cAMP system, and the inhibitory action of DA may be produced by interacting with this system. Supported in part by USPHS Grant CA-07535 (RMM), RCDA 1KO4 NS00601 and AM22125 (MJC).

18.28 DOPAMINE INHIBITS THE INCORPORATION OF $^{32}P_i$ INTO PHOSPHATIDYLINOSITOL OF ANTERIOR PITUITARY GLANDS. P.L. Canonico,* C.A. Valdenegro,* S.B. O'Dell* and R.M. MacLeod*. (SPON: J.H. Johnson). Dept. of Internal Medicine, University of Virginia School of Medicine, Charlottesville, VA 22908.

Dopamine (DA) has a major function to inhibit prolactin (PRL) secretion from anterior pituitary gland, whereas it does not seem to be directly involved in regulating secretion of other pituitary hormones. Neurotransmitters and peptide hormones have been found to increase phosphatidylinositol (PI) cleavage and turnover in a variety of cell types, including endocrine cells.

We studied the effect of DA and DA antagonists on $^{32}P_i$ incorporation into PI, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) in the anterior pituitary gland of female rats. Incubation of the glands for 30 min with 50 uCi/ml $^{32}P_i$ Na_2HPO_4, and DA at concentrations of 0.5, 5 and 50 µM caused a significant ($p<0.01$) reduction in the incorporation of $^{32}P_i$ into PI, while, in contrast, no change occurred in ^{32}P-PC or -PE labelling. This effect was also studied as a function of the incubation period. The inhibition produced by 0.5 uM DA was observable after 20 min (-47%), was maximal at 30 min (-55%) and was still present after 60-120 min (-41 and -35% respectively). These concentrations of DA caused rapid and significant inhibition in PRL release. Haloperidol and pimozide (50 nM) did not modify the incorporation of $^{32}P_i$ into PI, PC and PE by themselves, but completely abolished the inhibition of $^{32}P_i$ incorporation into PI produced by DA. The incorporation of $^{32}P_i$ into PI, PC and PE was also investigated in the pituitary gland of female rats injected with a specific inhibitor of catecholamine synthesis α-methyl-p-tyrosine (αMpT) (200 mg/kg i.p.) 2.5 hrs before sacrifice. Serum PRL levels in αMpT treated rats were considerably higher (641 ± 117 ng/ml) than in saline injected rats (16 ± 3). The glands from these animals, incubated for 30 min with $^{32}P_i$, showed a significant increase (+130%) in the incorporation of the radiolabelled P_i into PI, but not into PC or PE. When 0.5 uM DA was added in vitro to pituitary glands from αMpT treated rats, the stimulation of $^{32}P_i$ into PI induced by αMpT was completely inhibited. To verify whether the chronic effect of DA on the PI cycle is also present in vivo conditions, we utilized female rats bearing the transplanted PRL secreting tumor MtTW15. The high serum PRL levels produced by the tumor stimulate the synthesis and release of DA from tuberoinfundibular dopaminergic neurons which suppress pituitary gland prolactin synthesis and release. When these pituitary glands were incubated for 30 min with $^{32}P_i$, an accompanying inhibition (-44%) of incorporation into PI but not into PC and PE was observed in comparison with non-tumor bearing animals.

Our results suggest that the inhibition of PI turnover may represent a biochemical event related to the stimulation of pituitary DA receptors responsible for the inhibition of PRL secretion. (Supported in part by USPHS Grant CA-07535 from the National Cancer Institute)

18.29 LONG-TERM TREATMENT WITH ESTRADIOL ATTENUATES THE PROLACTIN-INDUCED ACTIVATION OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS. M.K. Pryal*, G.D. Riegle*, K.E. Moore and K.T. Demarest (SPON: J.E. Thornburg). Depts. of Pharmacol./Toxicol. and Physiol., Michigan State Univ., East Lansing, MI 48824.

Previous studies have demonstrated that short-term treatment with large doses of estradiol benzoate (25 µg/kg, sc for 3 days) stimulates the synthesis and turnover of dopamine (DA) in the terminals of tuberoinfundibular neurons in the median eminence (Endocrinology 106: 463, 1980). This action of estradiol is thought to be mediated by increased circulating levels of prolactin. The present studies were undertaken to compare serum prolactin concentrations and tuberoinfundibular DA neuronal activity in ovariectomized, estradiol-treated rats. The activity of these neurons was estimated by measuring the rate of DOPA accumulation in the median eminence 30 min after the administration of an inhibitor of aromatic L-amino acid decarboxylase (NSD 1015, 100 mg/kg, i.p.). Female rats, ovariectomized for two weeks, were implanted with silastic capsules containing estradiol benzoate, which maintained serum concentrations of this hormone in the range of 60-80 pg/ml. Following the implantation of the estradiol-containing capsule serum prolactin concentrations were markedly increased 6 and 18 days later. The rate of DOPA accumulation in the median eminence was significantly increased at 6 days but not at 18 days after the initiation of estradiol treatment. Interestingly, the concentration of DA in the median eminence declined at 6 days after estradiol treatment and a further decline was noted after 18 days despite the fact tha serum prolactin concentrations were still elevated. This suggests that long-term estradiol treatment in ovariectomized rats reduces the responsiveness of tuberoinfundibular DA neurons to prolactin. This was confirmed by direct experimentation. In sham-implanted rats, the rate of DOPA accumulation in the median eminence was increased 12 h after the intracerebroventricular infusion of prolactin (10 µg/10 µl); this effect was not seen in estradiol-treated rats. These results suggest that long-term treatment with estradiol attenuates the prolactin-induced activation of tuberoinfundibular DA neurons. (Supported by USPHS grant NS9174.)

18.30 ACUTE EFFECTS OF ESTRADIOL ON THE TURNOVER OF SEROTONIN IN DISCRETE BRAIN REGIONS AND ON PITUITARY HORMONE SECRETION. M.D. Johnson*, L.C. Terry, and W.R. Crowley, Dept. of Pharmacology, Univ. of Tennessee, Memphis, TN 38163 and VA Medical Center, Ann Arbor, MI 48105.

Central serotonin (5-HT) systems may participate in the regulation of luteinizing hormone (LH) and prolactin (PRL) secretion from the anterior pituitary gland. These studies employed analysis of 5-HT turnover and discrete 5-HT denervations to test whether the acute effects of estradiol on LH and PRL are mediated by changes in activity of specific 5-HT systems. Ovariectomized female rats received oil vehicle or estradiol benzoate (EB; 50µg) three hours prior to decapitation. Each hormone group was subdivided further so that one third received saline and the remainder received 75 mg/kg of the monoamine oxidase inhibitor, pargyline HCl, 15 or 30 min prior to decapitation. Plasma concentrations of LH, PRL, GH, and TSH were determined by double antibody radioimmunoassays. Brains were frozen, sectioned in a cryostat, and eight individual nuclei were microdissected. Concentrations of 5-HT and its metabolite, 5-hydroxyindole acetic acid (5-HIAA), were measured by liquid chromatography with electrochemical detection. In other animals, the content of LH releasing hormone (LHRH) was measured in the median eminence by radioimmunoassay.

Administration of EB produced a gradual decline of LH and rise of PRL within the three hour period but did not change GH or TSH, or median eminence levels of LHRH. While estrogen treatment did not change steady state levels of 5-HT, the hormone did elevate 5-HIAA concentrations, suggesting enhanced 5-HT release, in the medial preoptic, ventromedial and cortical amygdaloid nuclei. Furthermore, estrogen-treated animals showed a potentiation of the accumulation of 5-HT and enhanced decline of 5-HIAA following pargyline in these three nuclei, suggesting increased turnover. No changes of 5-HT turnover were noted in the median eminence or in the stria terminalis, periventricular, dorsomedial or lateral amygdaloid nuclei. In further studies, whole brain 5-HT depletion produced by systemic p-chlorophenylalanine (400 mg/kg) did not prevent either the decrease of LH or increase of PRL after EB, and also did not affect GH or TSH. However, preliminary observations in desmethylimipramine-pretreated, ovariectomized rats show that microinjections of the 5-HT neurotoxin, 5,7-dihydroxytryptamine, into the cortical amygdala attenuated the rise of PRL observed after EB, without modifying the decrease of LH or basal levels of either hormone.

These results suggest that estradiol acutely elevates PRL, in part, via increased serotonergic activity in the cortical amygdala, and possibly, other discrete nuclei.

18.31 LOCALIZATION OF SEROTONIN AND SOMATOSTATIN FIBERS IN THE RAT ADENOHYPOPHYSIS. Karin N. Westlund and Gwen V. Childs*, Department of Anatomy, The University of Texas Medical Branch, Galveston, Texas 77550.

The anterior pituitary contains receptors for both serotonin and somatostatin (Johns et al. and Enjalbest et al., Endocrinol. 110, 1982). In addition, the pituitary contains measurable amounts of serotonin and somatostatin. The objective of this study was to determine if serotonin or somatostatin fibers could be traced to specific sites in the adenohypophysis. We initially compared a variety of fixation, embedding and immunocytochemical staining techniques. Male rats were perfused with warm saline, followed by cold buffered 4% paraformaldehyde (PF), and then cold buffered 30% sucrose. Horizontally or sagittally cut (15µm) frozen sections were stained with one of two immunocytochemical methods: (1) 1:20,000 dilution of anti-serotonin or 1:5,000 dilution of antisomatostatin and the peroxidase antiperoxidase (PAP) technique. The PAP complex was localized with diaminobenzidine chloride (DAB) intensified with nickel ammonium sulfate (Hancock, Histochem. Abst., 1982), or (2) 1:75,000 dilution of antiserotonin or 1:25,000 dilution of antisomatostatin and the avidin biotin peroxidase complex (ABC) technique (Childs and Unabia, J. Histochem. Cytochem. 30, 1982) intensified with nickel ammonium sulfate. A second set of male rat pituitaries were immersion fixed in 1% glutaraldehyde (Gl) or 4% PF and embedded in Araldite 6005. A third set of pituitaries was freeze fixed in the Boyne Rapid freezing apparatus, followed by freeze drying *in vacuo*, and embedding in Epon (Dudek et al., J. Histochem. Cytochem. 30, 1982). Thick and ultrathin plastic sections were cut and stained for serotonin or somatostatin with the ABC technique (Childs and Unabia, J. Histochem. Cytochem. 30, 1982). In the frozen, unembedded sections, fibers and varicosities staining for serotonin and somatostatin were observed to enter the rostral zone or "nasale Umschlagszone" of the adenohypophysis with blood vessels and split into fine, varicose fibers in deeper portions of the anterior lobe, in agreement with ultrastructural studies of Kurosumi and Kobayashi (Arch. hist. jap. 43, 1980). Fibers staining either for serotonin or somatostatin were along the periphery of the anterior and posterior lobes especially at the poles and along the surface of the anterior lobe adjacent to the cleft. Fine, varicose fibers were also scattered throughout the intermediate lobe. In the freeze fixed, plastic embedded sections, staining for serotonin appeared in collections of fibers or processes extending from the periphery of the gland into the first 2-3 cell layers. These studies suggest that fiber systems containing serotonin or somatostatin innervate the adenohypophysis and can be detected with most sensitive methods (ABC-Intensified DAB). Supported by the Kempner Foundation.

18.32 EFFECT OF SEROTONIN AGONISTS AND PRECURSORS ON PITUITARY HORMONE SECRETION IN MAN. H.Y. Meltzer, N.Nash*, G. Manov*, B.J. Tricou*, and V.S. Fang*. Departments of Psychiatry and Medicine, University of Chicago Pritzker School of Medicine and the Illinois State Psychiatric Institute, Chicago, IL. 60637

The role of serotonin (5-HT) in the secretion of prolactin (PRL), growth hormone (GH) and cortisol in man has been quite controversial. The precursor of 5-HT, 5-hydroxytryptophan (5-HTP), has been most frequently employed as a stimulus to examine this question, with very mixed results. Quipazine, a direct acting 5-HT agonist, has been reported to stimulate cortisol secretion, but not that of PRL or GH, in normal volunteers.

We have administered the indole hallucinogen, N,N-dimethyltryptamine (N,N-DMT), 0.7 mg/kg intramuscularly (i.m.) or saline, to 8 volunteers, after pretreatment with placebo or cyproheptadine (Cyp), a putative 5-HT antagonist, 4 mg t.i.d. for 3 days. Experimental days were at least 1 week apart, the conditions were randomly presented to each subject, and the experimenters were blind concerning the pretreatment and injection schedule. Three of the subjects were also tested in a fifth condition: pretreatment with haloperidol (Hal), 0.5 mg, i.m., 60 min before DMT. Subjects had an indwelling venous catheter to permit multiple blood samples from 30 min before to 3 hr after DMT.

Serum PRL, GH and cortisol increased in most but not all subjects after placebo-DMT. The increase in PRL and cortisol peaked 30 min after DMT whereas GH peaked at 60 min. Cyp pretreatment blocked the GH increase but had minimal effect on PRL and cortisol. Hal did not affect the GH increase. Cyp and Hal had only slight effects on the psychotomimetic effects of DMT.

In a separate study, 5-HTP, 200 mg p.o., was administered to 10 normal volunteers, unmedicated patients with mania (N=10) or depression (N=10) and to the latter, following two-three weeks treatment with lithium or tricyclic antidepressants (TAD). Results to date indicate that 5-HTP tended to increase serum cortisol levels in the patients with affective disorders but not the normal controls. Treatment with TAD appeared to diminish the cortisol response to 5-HTP whereas lithium treatment appeared to enhance the response. However, the number of subjects studied to date is insufficient for these findings to be conclusive. 5-HTP had no consistent effect on PRL or GH levels. Supported, in part, by USPHS MH 30059.

18.33 DIURNAL CHANGES IN THE UPTAKE OF SEROTONIN AND NOREPINEPHRINE IN NUCLEAR REGIONS DURING THE ESTROUS CYCLE AND THE EFFECTS OF NEUROTOXIN LESIONS ON ESTROUS CYCLICITY. Donald C. Meyer, and Jyoti Singh, Department of Physiology and Biophysics, University of Louisville School of Medicine, Louisville, Kentucky 40292.

The temporal pattern of hypothalamic and limbic aminergic activity during the estrous cycle in the regularly cycling female Sprague Dawley rat has been investigated by measuring the changes in serotonergic and noradrenergic neuronal uptake during the regular estrous cycle (0500-1900 L). Significant changes ($P < .05$) in the saturation uptake of ^3H 5-HT and ^3H NE were recorded in the suprachiasmatic nuclei (SCN) at 1200 hours on proestrus. Significant changes ($P < .05$) in the uptake of ^3H 5-HT in the preoptic area (POA) were found at 1200 hours on both diestrus and proestrus while ^3H 5-HT showed a significant peak ($P < .05$) in the median eminence (ME) only during proestrus. In the amygdala (AMYG) ^3H 5-HT uptake was significantly different at 1200 hours on diestrus and proestrus, while ^3H NE uptake was significant ($P < .05$) at 1200 hours only during proestrus. During these experiments the plasma proestrus luteinizing hormone surge as measured by radioimmunoassay occurred at 1700 hours.

To further assess the role of serotonin in ovulation and estrous cyclicity, 5,7-dihydroxytryptamine lesions (5,7-DHT) were placed in the SCN, POA, ME, and AMYG. 5,7-DHT was stereotaxically injected thru a 30 gauge needle in concentrations of 5-10 µg/ul over a time period of one minute. In the SCN 4 or 5 day estrous cyclicity was interrupted by diestrus for average periods of up to 15 days; in the POA for periods of 10 days; in the median eminence for periods of 13 days; and in the amygdala for periods of up to 6 days. Following these periods of acyclicity rats resumed normal cycles.

These lesion effects and patterns of uptake suggest a common timing mechanism utilizing both serotonin and possibly norepinephrine for neuroendocrine control. Lesions with the serotonin neurotoxin disturb estrous cyclicity in all four brain regions, but the greatest delays occur in the SCN and ME, regions which are particluarly critical to intrinsic neuroendocrine rhythms. The patterns of change in reuptake capacity in all four regions occur 3 hours prior to the critical period for the plasma LH surge and may be an important mechanism for many types of neuroendocrine events including ovulation.

18.34 ACUTE ESTROGEN NEGATIVE FEEDBACK: TEMPORAL CORRELATION BETWEEN ESTRADIOL UPTAKE AND NUCLEAR TRANSLOCATION AND NOREPINEPHRINE, DOPAMINE AND 5-HYDROXYTRYPTAMINE METABOLISM IN DISCRETE PREOPTIC AND HYPOTHALAMIC REGIONS. C.A. Johnston, M. Tesone* and A. Negro Vilar, Dept. of Physiology, Univ. of Texas Health Science Center, Dallas, TX 75235.

This study was designed to examine the cellular mechanisms by which estradiol exerts its negative feedback effects upon gonadotropin secretion in gonadectomized animals. The uptake of estradiol by cytosol receptors and the subsequent translocation of the estradiol receptor to the nucleus in preoptic (POA) and hypothalamic (HYP) regions were correlated with changes in neuronal activity of norepinephrine (NE), dopamine (DA) and 5-hydroxytryptamine (5-HT)-containing neurons of the suprachiasmatic (SCN), medial preoptic (MPO) anterior (AN1) and posterior (AN2) arcuate and dorsomedial (DMN) nuclei, as well as in the median eminence (ME), in ovariectomized (OVX) rats. Ten days following OVX, rats received either oil or estradiol benzoate (Eb) (20 µg/rat, s.c.) a treatment which resulted in a marked drop in the castration-induced elevation of serum luteinizing hormone (LH) concentrations within 3 h of injection. Cytosolic (CER) and nuclear (NER) estrogen receptors were measured using an exchange assay at various times following Eb injection in POA, HYP and anterior pituitary (AP) tissues. The activity of the NE, DA and 5-HT neuronal systems in discrete regions within those brain areas was estimated concurrently by measuring the concentrations of NE, DA, and 5-HT and their major metabolites: 3-methoxy-4-hydroxyphenylglycol (MHPG), 3-4-Dihydroxyphenylacetic acid (DOPAC) and 5-hydroxyindoleacetic acid (5-HIAA) respectively, utilizing high performance liquid chromatography with electrochemical detection. Eb stimulated nuclear translocation of the receptor by 3h in both HYP and AP, while NER levels in POA were already increased at 1h, slightly preceding the first detectable drop in serum LH concentrations. Following OVX, NE metabolism increased in the SCN, MPO and DMN, and decreased in the AN2 when compared to diestrous controls. These changes were completely reversed 3 h after Eb, at a time when effective increases in NER had taken place. Similarly, changes in DA and 5-HT concentrations (but not metabolism) observed after OVX were also reversed by Eb. The results indicate that acute nuclear translocation of estradiol receptors in POA and HYP effectively modifies NE metabolism in several discrete nuclei reportedly involved in the regulation of LHRH/LH release, support the concept that rostral noradrenergic neuronal systems are involved in the negative feedback of estrogen upon LH secretion and suggest the possibility that some NE neurons within the mediobasal hypothalamus may play an inhibitory role in the regulation of LH release. Supported by NIH 09988-06, Project III.

18.35 ANALYSIS OF STEROID-MONOAMINE FEEDBACK INTERACTIONS IN DISCRETE BRAIN REGIONS USING AS A MODEL THE MONOSODIUM GLUTAMATE (MSG) LESIONED RAT. M. Tesone*, C.A. Johnston and A. Negro-Vilar, Dept. of Physiology, Univ. of Texas Health Science Center, Dallas, Tx 75235.

Neurodegenerative lesions induced by neonatal treatment with MSG elicit a number of endocrine and behavioral deficiencies such as hypogonadism, sluggish gonadotropin responses to gonadectomy, irregular cycling in females and impaired lordotic responses. Previous studies from our laboratory (Endocrinology 110: 835, 82) indicate that the mechanism(s) that normally triggers LHRH release is defective in these animals. The present studies were undertaken to determine whether the reported deficiencies in monoamine input to selected preoptic and hypothalamic regions affect steroid receptor kinetics in those areas. Moreover, steroid negative and positive feedback effects were evaluated and the responses compared to those of normal controls. Adult female rats, injected neonatally with either MSG or hypertonic saline were used for these experiments. Analysis of dopamine, norepinephrine and serotonin metabolism by HPLC with electrochemical detection, revealed substantial decreases in the metabolism of all three amines in the arcuate nucleus, as well as reduced dopamine and serotonin metabolism in the suprachiasmatic nucleus. Measurement of estradiol receptors in preoptic (POA), hypothalamic (HYP) and anterior pituitary (AP) tissues from MSG-treated and control rats killed during diestrus or 2 weeks after ovariectomy (OVX), revealed no difference in either cytosolic (CER) or nuclear (NER) estrogen receptor levels. Priming of OVX rats with estradiol for 2 days induced similar levels of NER for both groups in all three areas. Evaluation of cytosolic progestin receptors (CPR) using R-5020 as ligand, revealed no differences between control and MSG unprimed-OVX or estradiol-primed rats. Both the negative and positive feedback effects of estradiol, as well as pituitary responsiveness to LHRH were not significantly impaired in MSG rats. These results indicate that the MSG-induced damage to dopaminergic, serotonergic and noradrenergic elements within several preoptic and hypothalamic nuclei does not impair estrogen and progestin receptor kinetics; nor does it prevent adequate negative or positive steroid feedback responses, if appropriate steroid regimens are employed. Supported by NIH 09988-06, Project III.

18.36 STRAIN DIFFERENCES IN NUMBER OF HYPOTHALAMIC DOPAMINE NEURONS: RELATIONSHIP TO PITUITARY STORAGE AND RELEASE OF PROLACTIN H. Baker, A.F. Sved, S. Alden*, L.W. Tucker* and D.J. Reis. Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

There are fewer dopamine (DA) neurons in all dopamine cell groups of the hypothalamus of mice of the BALB/cJ strain as compared to those of the CBA/J strain. Some of these neurons, specifically the tuberoinfundibular (TI) DA neurons (A12 group), act to inhibit the synthesis and release of prolactin (PRL) from the anterior pituitary (AP). We sought to determine whether the differences between the number of DA neurons was reflected by an appropriate variation in the content and release of PRL in male mice of the two strains. PRL, measured by radioimmunoassay, was higher in the serum in CBA/J as compared with BALB/cJ mice (9.8 ± 0.6 and 7.8 ± 0.6, $\bar{x}$ ng/ml + SEM, respectively; $n = 10$; $p<.05$) and in the pituitary (CBA/J, 2.03 ± 0.06; BALB/cJ, 1.62 ± 0.05; $\bar{x}$ µg/gland + SEM; $n = 10$; $p<.05$); thus, the strain with more DA neurons has less PRL. To establish the cytochemical basis for the strain differences in pituitary PRL content, pituitaries from mice of each strain were immunocytochemically stained with antibodies to PRL using the peroxidase antiperoxidase method. Sections were examined using a computer assisted image analysis system. Quantitative immunocytochemical staining was carried out under linear reaction conditions with diaminobenzidine (DAB) as the chromagen (Benno et al., Br. Res., 1982). The average optical density (AOD) of the DAB reaction product, a measure of the density of staining averaged over an entire tissue section, was determined at low power (2.5x) throughout the pituitary. AOD was greater in CBA/J than BALB/cJ mice (0.054 ± 0.003 vs. 0.036 ± 0.002, $\bar{x}$ OD units + SEM, $n = 4$-5; $p<.05$). This difference in AOD could result from either greater staining intensity in the same number of pituitary cells or differences in the total number of cells containing PRL. Since the AOD of the darkest staining tissue, measured at high power (40x), did not differ significantly between strains, the variation in AOD was not a result of differences in staining intensity in similar numbers of cells. However, with comparable staining conditions, within any field there were more cells containing PRL in CBA/J than in BALB/cJ mice. The average number of acidophils stained by the Pearse trichrome method, representing lactotrophs (containing PRL) and somatotrophs (containing growth hormone), did not differ between strains. Thus, either CBA/J mice have more lactotrophs or some lactotrophs in BALB/cJ mice do not contain sufficient PRL to be demonstrable with the antibody technique. The strain difference in the number of PRL-containing cells in the AP suggests that genetic variation in the number of hypothalamic TI DA neurons is reflected by appropriate functional differences in the storage and release of PRL from the pituitary.

18.37 THE EFFECT OF HALOPERIDOL ON OVINE REGIONAL CEREBRAL AND MEDIAN EMINENCE BLOOD FLOW. J. Townsend*, R. M. Bryan, R. W. Brennan*, R. B. Page*. Dept. of Surgery (Div. of Neurosurgery), Dept. of Medicine (Div. of Neurology), Dept. of Physiology and Dept. of Anatomy, M. S. Hershey Medical Center of the Pennsylvania State University, Hershey, PA 17033.

Dopaminergic axons terminate near blood vessels in the median eminence. To test the hypothesis that dopamine regulates median eminence blood flow, we measured regional cerebral and median eminence blood flow before and after infusion of haloperidol, a dopamine antagonist. Five female non-pregnant sheep were anesthetized with pentobarbital, intubated, and passively ventilated. Right and left femoral arteries were cannulated for injecting drugs, withdrawing blood, and monitoring blood pressure. After a left thoracotomy, a double lumen cannula was inserted into the left atrium by passing it directly through the atrial wall and was used for injecting microspheres. Blood gases and pH were measured from arterial blood samples and maintained within normal range by adjusting the respirator. Blood flow was measured twice in each sheep, once before and once after an I.V. infusion of haloperidol (0.5 mg/kg over 30 minutes). After haloperidol infusion blood flow decreased in all regions measured: subcortical white 17%, cortical gray 18%, neural lobe 21%, caudate nucleus 23% and median eminence 33% ($P < .02$). Renal blood flow fell 29% on average. Mean arterial blood pressure did not change with haloperidol infusion. Since dopamine is locally released in the median eminence under physiological conditions and haloperidol, a dopamine antagonist, significantly decreased median eminence blood flow, we conclude that the local release of dopamine is a mechanism for regulation of blood flow in the median eminence.

18.38 THE RELEASE OF DOPAMINE (DA) INTO HYPOPHYSIAL PORTAL BLOOD IN THE MALE HYPERPROLACTINAEMIC RAT. A. Brar*, V. Kapoor*, A. McNeilly*† G. Fink (SPON: D.W. Lincoln). MRC Brain Metabolism Unit, Department of Pharmacology, 1 George Square, Edinburgh, U.K., and †MRC Reproductive Biology Unit, 37 Chalmers Street, Edinburgh, U.K.

Studies in vitro and the measurement of DA in the hypothalamus have suggested that prolactin (PRL) may increase DA release into hypophysial portal vessel blood and thereby invoke a negative feedback system. We have investigated this possibility by measuring DA in hypophysial portal vessel blood in control adult male rats and in male rats made hyperprolactinaemic by transplanting two pituitary glands under the kidney capsule. Hypophysial portal vessel blood was collected (Fink, G. and Jamieson, M.G., J. Endocrinol. 68: 71, 1976) for 30 min before, during and after the application of an electrical stimulus (30 sec trains of biphasic square wave pulses, 60 Hz, 1mA peak to peak and 1 mA duration) to the median eminence. The portal blood was collected into Trasylol (20,000 KIU/ml) and EDTA (5.4 mM l^{-1}) at 4°C. The concentrations of DA and DOPAC were measured in plasma extracts using HPLC with electrochemical detection (Plotsky, M. et al, Endocrinology 102: 1887, 1978).

Concentration of DA and DOPAC in hypophysial portal plasma (ng/ml, mean ± S.E.M.)

	Pre-stimulation	Stimulation	Post-stimulation
CONTROLS (n=6)			
DA	3.62 ± 0.55	2.66 ± 0.98	2.20 ± 0.07
DOPAC	7.20 ± 0.24	4.60 ± 0.28	7.00 ± 1.98
HYPER-PRL (n=5)			
DA	4.48 ± 0.34	4.56 ± 0.39	-
DOPAC	9.47 ± 1.32	12.20 ± 1.10	-

The table shows that DA and DOPAC levels were slightly higher in the hyperprolactinaemic group than in the control group, although the differences were only significant in the sample collected during stimulation. These results suggest that long-term elevations in plasma PRL (approx. 120 ng NIH-RP-1/ml) elevate the turnover rate of the tuberoinfundibular DA system without significantly affecting the DA concentration in portal blood. Furthermore, despite a 47% depletion of DA concentration in the median eminence (ME) produced by long-term hyperprolactinaemia (Simpkins, J.W. et al, Life Sci. 30: 1249, 1982), electrical stimulation of the ME can augment the PRL-induced elevation of DA turnover while keeping DA concentration constant.

18.39 DOMPERIDONE SELECTIVELY ALTERS THE RATE OF DOPAMINE SYNTHESIS IN THE MEDIAN EMINENCE AND POSTERIOR PITUITARY IN THE RAT. J.M.Farah, Jr.*, K.T.Demarest, G.P.Mueller, and K.E.Moore (SPON: D.J. Pettibone). Department of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814, Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

Blockade of dopamine receptors in the central nervous system with haloperidol (HAL) is associated with increased dopamine synthesis which is thought to accompany increased dopaminergic neuronal activity. Another dopamine receptor antagonist, domperidone (DOM), is frequently used to study dopaminergic physiology outside the central nervous system because of the reported inability of systemically administered DOM to cross the blood-brain barrier (Laduron & Leysen, 1979, Biochem. Pharmacol. 28:2161). To further characterize the peripheral versus possible central effects of DOM, we compared the effects of DOM with those of HAL on the rate of dopamine synthesis in dopamine neurons thought to terminate outside the blood-brain barrier (i.e., in the median eminence and posterior pituitary) and those which are located within the blood-brain barrier (i.e., striatum, nucleus accumbens, and olfactory tubercle). Rate of dopamine synthesis was estimated in adult, male, Long-Evans rats by the accumulation of DOPA 30 min after administration of a DOPA-decarboxylase inhibitor (NSD 1015, 100 mg/kg, ip). DOPA was measured by radioenzymatic assay of 0.2 N $HClO_4$ tissue extracts from animals treated with 2.5 mg/kg DOM or HAL sc either 2, 8, or 16 h before sacrifice; efficacy of dopamine receptor blockade in the periphery was estimated by plasma levels of pituitary hormones thought to be tonically inhibited by dopamine (prolactin, α-melanotropin, and β-endorphin-like immunoreactivity).

DOM, like HAL, increased DOPA accumulation in the median eminence only after a delay of 16 h, and increased posterior pituitary DOPA accumulation 2, 8 and 16 h after administration. Unlike HAL, which increased DOPA accumulation in the striatum, nucleus accumbens, and olfactory tubercle 2, 8, and 16 h after injection, DOM had no effect on dopamine synthesis in either the striatum or nucleus accumbens, and only moderately increased DOPA accumulation in the olfactory tubercle. In non-NSD-treated rats, DOM increased plasma levels of α-melanotropin and β-endorphin-like immunoreactivity 2 h and 4 h after injection, and plasma prolactin was markedly increased over control values 1 h after DOM and remained elevated for up to 16 h. The present findings demonstrate that DOM selectively increases the rate of dopamine synthesis in dopamine neurons which terminate in the median eminence and posterior pituitary but not those which terminate in the striatum, nucleus accumbens and olfactory tubercle. (Supported by USPHS Grant NS 15911 & USUHS Grant RO7632)

18.40 COMPARISON OF IONIC CURRENTS IN VOLTAGE-CLAMPED PITUITARY TUMOR CELLS IN CULTURE. J. M. Dubinsky and G. S. Oxford*. Neurobiology Program and Physiology Department, University of North Carolina, Chapel Hill, NC 27514.

Ionic currents have been identified in voltage-clamped cells from the GH3 and GH4 rat pituitary tumor cell lines. Individual cells (10-17um) were voltage-clamped using the new patch clamp technology (Hamill et al., Pfluger's Arch. 391:85, 1981). Patch pipets were gently apposed to the cell membrane and with the application of suction a "gigohm" seal was formed between the pipet and the cell. Additional suction ruptured the membrane under the pipet and permitted intracellular recording and internal dialysis of the cell cytoplasm. Resting potentials averaged -43.0 ±13.6mv. Membrane resistance was in the range of 0.5 - 5 Gohm. When voltage steps were applied from -50mv to -70mv holding potentials, both inward and outward currents were present. Series resistance was partially compensated and capacitative transients and leakage currents were corrected by computer subtraction of hyperpolarizing control pulses.

A fast inward current which inactivated had the voltage- and time-dependence of Na current and was blocked by tetrodotoxin (TTX). For large depolarizations this current became outward and its reversal potential shifted as expected from the Nernst relation for changes in external [Na^+]. Another inward current which did not appear to inactivate had a slower onset, was blocked by external Co^{++}, Zn^{++}, Mn^{++}, and Cd^{++}, and was sensitive to the external [Ca^{++}]. Ba^{++} could substitute for Ca^{++}as the current carrier.

The outward current appeared to have three components: (a) one sensitive to external 4-aminopyridine (4AP) and internal Cs^+, (b) one sensitive to external Co^{++}, internal Cs^+, or EGTA, and (c) one insensitive to all of these agents. K^+ appears to be the major ion carrier of the first two types of outward current. Inactivation of the first type of outward current was observed during 185ms pulses and resulted in a use-dependent decrease in outward current with repeated pulses. The second type of outward current was slower in onset and continued to increase steadily with time.

Thus it appears that the GH3 and GH4 cell membranes possess several voltage-dependent ionic channels selective for sodium, calcium, and potassium as well as a calcium-activated K channel. While both cell types contained all of these currents, the relative proportions of Na and Ca currents and the two types of outward K currents varied greatly between the GH3 and GH4 cell lines. The functional implications of these findings will be discussed.

18.41 THREE-DIMENSIONAL RECONSTRUCTION OF THE MORPHOLOGY OF NERVE-GLIA RELATIONSHIPS IN THE NEURAL LOBE OF THE PITUITARY. W. Gregory, M. R. Park and C. D. Tweedle. Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

Previous reports have shown that pituicytes, specialized glial cells of the neural lobe of the hypophysis, can encapsulate neurosecretory nerve endings and that the extent of the glial containment is a function of rate of hormone release (Neurosci. 5, 661-667; Brain Res. 192, 555-559). As the surrounding of neurosecretory nerve endings is a plastic process, it seemed profitable to precisely reconstruct the three-dimensional arrangement of these elements from serial electron micrographs.

A system of programs has been developed on the PDP-11 computer for the reconstruction, display, and analysis of morphological data. From serial electron micrographs, the outline of each profile considered to be of interest is entered into the computer as a series of x, y coordinates, using a digitizing pad (Bitpad). The third coordinate (z) is a function of section number and is entered by the operator. The mass of x, y, z coordinates can be manipulated by the computer, rotated according to the rules of analytical geometry, and drawn by a graphics plotter. A critical step in reconstruction is the accurate placement of fiduciary marks on each micrograph which establish the origin and orientation of the Cartesian coordinate system used and which orient adjacent serial sections to each other. This step is performed manually. Experience has shown that the eye and judgement of the investigator are the most efficient for detecting and aligning ultrastructural features useful in placing these reference marks.

The membrane and cytoplasm of that portion of a pituicyte adjacent to a neurosecretory ending can be seen, in the serial reconstruction, to be thrown first up into ridges which become progressively higher and finally completely encircle the nerve ending. Additional ridges can form from the thin rim of cytoplasm surrounding one nerve ending to engulf another. Numerous neurosecretory endings can be contained within a localized region of a single pituicyte. The geometric arrangement of membrane around neurosecretory processes cannot be topologically described as a single unbroken surface. This is evidenced by the presence of fenestrations along sheaths encircling a neurosecretory process and the observation of processes which enter and then leave an ensheathing portion of pituicyte. To have formed complex geometrical arrangements, both fusion and cleavage of adjacent cytoplasmic extensions must have taken place. The observation of the transition in space which results in the encircling of a process, though static, suggests a means by which neurosecretory processes are actively engulfed. 18.42 PRESENCE OF CRF-LIKE IMMUNOREACTIVITY IN HYPOPHYSIAL PORTAL BLOOD. D.M. Gibbs and W. Vale. Dept. Repro. Med., UCSD Sch. Med., La Jolla, CA 92093 and The Salk Institute, La Jolla, CA 92138.

Recently a 41 amino acid ovine hypothalamic peptide with potent CRF activity in vivo and in vitro has been isolated, characterized, and synthesized (Vale et al., Science 213: 1394, 1981). We now describe the presence in rat hypophysial portal plasma of a substance which is bound by an antiserum raised against synthetic ovine CRF (oCRF).

Hypophysial portal blood was collected from Nembutal-anesthetized male rats by the parapharyngeal technique of Porter. Immunoreactive CRF was extracted from plasma by adsorption to ODS silica cartridges (Bond Elut) and elution with acetonitrile-TEAF. Immunoreactivity was measured in an RIA consisting of antiserum raised against oCRF, oCRF standard and iodinated oCRF trace. The limit of detection was 25 pM.

The mean concentration of CRF-like immunoreactivity (CRF-LI) in portal plasma from 9 rats was 104.9 ± 9.7 pM ($\bar{x}$ + SEM) while the mean concentration in peripheral plasma was $27.5 ± 0.8 pM ($p < 0.0001$). Inhibition curves for synthetic ovine CRF, highly purified rat CRF, and portal blood CRF-LI were parallel, but the affinity of the antiserum for rat CRF was about 5-fold less than for ovine CRF. Therefore, portal blood CRF-LI levels expressed in terms of oCRF standard were probably underestimated by about 5 times.

An amount of oCRF equivalent to the concentration of CRF-LI found in rat portal blood has been shown to produce a 300% increase in ACTH secretion by pituitary cells in primary culture. This suggests that the concentration of CRF-LI in rat portal blood is sufficient to stimulate ACTH secretion and supports the hypothesis that oCRF, or a very similar molecule in the rat, is a physiologic hypothalamic releasing factor.

18.43 CORTICOTROPIN RELEASING FACTOR (CRF)-INDUCED STIMULATION OF PROTEIN CARBOXYLMETHYLATION AND ACTH RELEASE IN MOUSE PITUITARY CELLS. S. Heisler*, V.Y.H. Hook*, and J. Axelrod (SPON: L. Larochelle). Section on Pharmacology, Laboratory of Clinical Science, NIMH, Bethesda, MD 20205 and Unite de Bioregulation Cellulaire et Moleculaire, Centre Hospitalier de 'Universite Laval, Quebec G1V 4G2 (SH)

Hormonal stimulation of several secretory organs is associated with an increase in the formation of protein methyl esters. Methyl groups can be transferred from S-adenosylmethionine to free carboxyl groups of protein substrates by the enzyme protein carboxylmethylase. Neutralization of negative charges of substrates localized on the surface of secretory vesicles could increase the probability of collision between the vesicles and the negatively charged plasma membranes thereby promoting intermembrane fusion and exocytotic secretion. The involvement of the protein carboxylmethylation reaction in CRF-stimulated ACTH secretion was investigated in the At-T-20/D16-16 mouse clonal pituitary cell line. Protein carboxylmethylation activity and ACTH secretion were both increased as a function of the concentration of extracellular CRF. Methylation was maximally increased by 40% and ACTH secretion by 400% at 10^{-8}M CRF. The half-maximal concentration for ACTH release and carboxylmethylation was about 3nM. CRF-stimulated ACTH release and protein carboxylmethylation activity were linear and temporally parallel for 50 to 90 minutes in the AtT-20 cells. The 21-methoxy derivative of CRF (10^{-7}M) had a similar effect on protein carboxylmethylation and ACTH release as 10^{-8}M CRF. The C-terminal free acid of CRF had no effect on either ACTH secretion or formation of protein methyl esters (10^{-9} to 10^{-6}M). A combination of 3-deazaadenosine and L-homocysteine thiolactone, inhibitors of the carboxylmethylation reaction, reduced CRF-stimulated carboxylmethylation by 55% and CRF-induced ACTH secretion by 37%. Dexamethasone (10^{-9} and 10^{-8}M; 20 hr pretreatment), known to inhibit both ACTH secretion and synthesis, had a marked inhibitory effect on ACTH release in the CRF-stimulated cells (80-90% reduction). Protein carboxylmethylation was less markedly, but significantly affected by dexamethasone (50% reduction). Post-translational modification of protein structure by protein carboxylmethylation appears to be a functionally important feature of hormone-stimulated secretion from several endocrine and exocrine glands. The data supports a similar relationship between protein carboxylmethylation and ACTH secretion in mouse pituitary cells.

18.44 EFFECT OF CORTICOTROPIN-RELEASING FACTOR ON PHOSPHOLIPID METHYLATION AND ACTH SECRETION IN MOUSE PITUITARY TUMOR CELLS. V.Y.H. Hook*, S. Heisler*†, and J. Axelrod. Section on Pharmacology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, Md. 20205 and †Unite de Bioregulation Cellulaire et Moleculaire, Centre Hospitalier de l'Universite, Laval, Quebec, Canada G1V 4G2

Our laboratory has shown that the 41-residue synthetic ovine corticotropin releasing factor (CRF) stimulates ACTH and β-endorphin release in AtT-20/D16-16 mouse pituitary tumor cells. The response of these cells to CRF makes this homogeneous cell population a good model for investigating the biochemistry of CRF-receptor mediated molecular events required for ACTH and β-endorphin secretion. Phospholipid methylation of phosphatidylethanolamine to phosphatidylcholine with S-adenosylmethionine as methyl donor has been shown in several cellular systems to be involved as a possible membrane transduction mechanism for receptor-induced events. CRF increased phospholipid methylation by 30-50% at concentrations (10^{-9} to 10^{-8}M CRF) which also stimulated ACTH secretion. Both processes increased linearly with time up to 90 minutes incubation with CRF. The methionine sulfoxide derivative of CRF was less potent than CRF in stimulating both phospholipid methylation and hormone secretion, and the COOH-terminal free acid derivative of CRF had no effect on either process. CRF-induced increases in phospholipid methylation and ACTH secretion were reduced when cells were treated with the phospholipid methyltransferase inhibitors 3-deazaadenosine and L-homocysteine thiolactone. These CRF-stimulated effects were also blocked by the glucocorticoid dexamethasone. We have found that the AtT-20 cells also show changes in cAMP and protein carboxylmethylation in response to CRF. These findings suggest that phospholipid methylation in conjunction with other biochemical processes may be involved in CRF-receptor mediated stimulation of ACTH release.

18.45 FAILURE OF NEUROACTIVE AMINO ACIDS TO INFLUENCE LUTEINIZING HORMONE RELEASE FROM ISOLATED RAT OR MONKEY PITUITARY. J. TAL*, M. T. PRICE and J.W. Olney (SPON: R. Burde). Dept. of Psychiatry, Washington Univ. Sch. Med., St. Louis, MO 63110.

Glutamate (Glu) and certain of its structural analogs excite central neurons when tiny amounts are applied iontophoretically to their dendritic or somal surfaces. When larger amounts are applied, neurons are destroyed, apparently by an excitatory mechanism. Systemic administration of these "excitotoxic" agents results in destruction of neurons in brain regions that lack blood brain barriers such as the arcuate-median eminence (AH-ME) region of the hypothalamus. We have shown in adult male rats that subcutaneous (sc) injection of a subtoxic dose of glutamate (Glu) or N-methyl-aspartate (NMA), a potent excitotoxic analog of Glu, results in a rapid (7 1/2 min) tenfold increase in serum luteinizing hormone (LH). Pretreatment with sc GABA prevents NMA-induced LH release as does removal of neurons from AH-ME by sc Glu treatment in infancy. These findings suggest that the LH releasing action of Glu or NMA may involve excitation by these agents of AH neurons with consequent secretion of luteinizing hormone releasing hormone (LHRH) into the portal system. Consistent with this hypothesis, Schainker et al. (Brain Res., 184:425, 1980) reported that LH levels remain unchanged in isolated rat hemipituitaries incubated with NMA. R.C. Wilson and E. Knobil (personal communication) recently demonstrated that intravenous administration of NMA (15 mg/kg) to adult female rhesus monkeys induces a rapid elevation of serum LH and follicle stimulating hormone. Here we report that neither NMA nor Glu causes LH release from in vitro preparations of either rat or monkey pituitaries.

Hemipituitaries from male adult rats or 1/8 anterior pituitary from male pigtail monkeys were allowed to equilibrate at 37° for 30 min in constantly oxygenated Gibco medium #199. Incubation fluid was then replaced with fresh medium with added test agents and pituitaries were gently oscillated for 3 hr. LH was assayed by radioimmunoassay and agents were tested in concentrations from 10^{-8} to 10^{-3}M with or without LHRH. The only pituitary preparations from either rat or monkey that had significant elevations of LH were those that included LHRH; Glu, NMA or GABA, when incubated either with or without LHRH, failed to influence LH release. Our findings suggest that excitatory amino acids release LH not by a direct action at the pituitary level but by acting through AH-ME neurons which control LHRH secretion into the portal vascular system. Moreover, a suprasellar locus of action apparently also characterizes the inhibition by GABA of NMA-induced LH release. Supported by USPHS grants NS-09156, DA-00259 and RSA MH-38894 (JWO).

18.46 PULSATILE LH AND FSH SECRETION IN LONG-TERM OVARIECTOMIZED RATS: EVIDENCE FOR DIFFERENTIAL CONTROL MECHANISMS. T.P. Condon*, D.I. Whitmoyer and C.H. Sawyer. Anatomy Department and Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Long-term (3-4 wks) ovariectomized (OVX) Sprague-Dawley rats were maintained under standardized lighting and temperature conditions. Unanesthetized, freely-moving animals were bled sequentially at 5-min intervals for 5 hr via indwelling atrial cannulas. From the same plasma samples both LH and FSH secretory patterns were determined by radioimmunoassay. A reconstituted whole blood preparation, consisting of 45-48% rat red blood cells suspended in 5% human plasma protein fraction (Plasmanate, Cutter Laboratories) was infused after each sample was taken to maintain blood volume, hematocrit and osmotic homeostasis. Distinct pulses of LH were observed with a periodicity of about 30 mins, excursions of 200-400 ng/ml/pulse and a half-life (15-20 mins) consistent with that described by other investigators. However, in most animals pulses of FSH were less well defined with a periodicity of approximately 50 mins, excursions of 100-300 ng/ml/pulse and a half-life consistently shorter than the 110 min previously reported by other investigators. Although at times LH and FSH peaks occurred simultaneously, differential secretion patterns were usually observed.

The effects of intracerebroventricular (3V) infusion of catecholamines on the pulsatile secretion of gonadotropins were also tested in these animals. Intraventricular infusion of 0.3 µmoles norepinephrine (NE) in 2 µl over 2 min resulted in rapid and complete inhibition of pulsatile LH secretion, with LH values falling by 85-95%, while FSH levels were affected to a much lesser extent. In most animals plasma FSH values declined after 3V infusion of NE, but the gradual decline did not seem to reflect a mere half-life disappearance of FSH from the plasma. The pulsatile pattern of FSH secretion appeared to continue even though pulses of LH were eliminated. In addition, 3V infusion of 0.3 µmoles clonidine, an α_2-adrenergic agonist, resulted in a biphasic LH response consisting of a transient elevation followed by a prolonged depression in plasma LH but relatively little effect on FSH secretion patterns.

The differences in basic pulsatile rhythm as well as in responsiveness to catecholamines suggest that LH and FSH secretion patterns in OVX rats are under differential control mechanisms. These mechanisms may reside at the levels of GnRH neurons in the brain, gonadotropic cells in the hypophysis, and/or catecholamine receptors in the hypothalamus.

18.47 PROGESTERONE AND 20α-HYDROXYPROGESTERONE STIMULATE THE IN VITRO MEDIOBASAL HYPOTHALAMIC RELEASE OF LHRH. D.D. Rasmussen* and S.S.C. Yen* (SPON: D. Gibbs). UCSD Sch. of Med., Dept. of Reproductive Medicine, La Jolla, CA 92093.

Circulating levels of progesterone (P) and 20α-hydroxyprogesterone (20α-OHP) increase prior to or concomitantly with the preovulatory LH surge. This in vitro superfusion study examined whether these increases in P and/or 20α-OHP may induce or augment the LH surge by stimulating the release of LHRH from the mediobasal hypothalamus (MBH). Adult ovariectomized rats were implanted with silastic capsules containing 17β-estradiol to simulate the estrogen environment of proestrus. After 3 days the rats were decapitated (1000-1030 h) and MBH fragments from 2 rats were placed in each 0.5 ml superfusion chamber, perfused (0.5 ml/10 min) by oxygenated Media 199 (Gibco) containing 0.05% bovine serum albumin. Following a 90 min stabilization period, effluents were collected at 10 min intervals for 250 min. P or 20α-OHP were dissolved in ethylene glycol or ethanol respectively, and then diluted 1:1000 in superfusion media to a final concentration of 10 ng/ml. Experimental chambers were perfused with 5 pulses (10 ng/ml for 10 min) of P or 20α-OHP at 20 min intervals following an initial 1 hour baseline period, while control chambers were infused with control media only. At 220 min 150 µl of a solution of perfusion media containing 125 mM KCl was injected into each chamber to produce a K^+ concentration of 60 mM after dilution. LHRH was determined in effluent fractions by radioimmunoassay. Mean (±SE, n-6) LHRH release (pg/10 min) in response to both P (9.0 ± 0.5) and 20α-OHP (7.9 ± 0.3) treatment was significantly ($p < 0.01$) greater than that of control treatment (5.3 ± 0.4). The first significant ($p < 0.01$) increase of LHRH release in response to the steroid treatments occurred at 120 min, following the second pulse infusion. The response to KCl stimulation was similar for all treatments. These data demonstrate that in vitro administration of P or 20α-OHP stimulates the release of LHRH by MBH tissue from the adult ovariectomized estrogen-primed rat, an established model for proestrus. It is significant that this effect occurs in tissue fragments containing only the MBH, without the preoptic area. These results suggest that the in vivo increase of circulating P or 20α-OHP associated with the initiation of the preovulatory LH surge may play a role in regulating the timing or amplitude of this surge by directly stimulating the release of LHRH from the MBH. (Supported by NIH grant HD 07203).

18.48 THE ROLE OF SEROTONIN IN THE STEROID INDUCED RELEASE OF PITUITARY LUTEINIZING HORMONE IN OVARIECTOMIZED RATS. S. Iyengar* and J. Rabii (SPON: C. Page). Dept. of Biological Sciences and the Bureau of Biological Research, Rutgers University, Piscataway, NJ 08854.

The role of brain serotonin in the regulation of luteinizing hormone (LH) secretion has become the focus of attention over the last few years. An unequivocal role, however, has not as yet emerged for this neurotransmitter in the hypothalamic control of LH secretion. We have used the estrogen/progesterone induced LH release paradigm as a model for a neuropharmacological approach to this question. Bilaterally ovariectomized adult female rats of the Sprague- Dawley strain were used 2 weeks after castration. On day 1 of the experiment, each rat was injected with an 8 µg dose of estradiol benzoate. This was followed by an injection of progesterone (1.5 mg) on day 3 of the experiment. Blood samples were obtained by venipuncture in the morning of days 1-4 as well as in the afternoon of the 3d day. This steroid injection schedule results in a plasma LH peak 6 hours after the progesterone injection. Treatment of rats with p-chlorophenylalanine (PCPA; 250 mg/kg), the inhibitor of serotonin biosynthesis, in the morning of day 1, led to complete inhibition of the LH surge. At the dose used in this study, 5-hydroxytryptophan (100 mg/kg), the immediate precursor of serotonin, when given at the time of progesterone administration, significantly elevated the LH levels in PCPA pretreated animals, but did not re-establish the expected peak. Similar observations were made with two serotonin receptor agonists, quipazine (30 mg/kg) and N-N-dimethyl-5-methoxy-tryptamine (10 mg/kg). When the serotonin receptor antagonist cyproheptadine (10 mg/kg) was injected at the time of progesterone administration, it was effective in blocking the expected LH surge. Similar results were obtained with two other serotonin receptor blockers. Cinanserin (5 mg/kg) and 2-chloro-2-[3-(dimethylamino)propyl]thio-cinnamanilide-HCl (SQ-10,631; 10 mg/kg) were both effective in inhibiting the steroid induced LH surge. Methysergide (2.5 mg/kg), another presumed blocker of serotonin receptors, on the other hand, was only able to reduce the magnitude rather than block the expected LH surge. We conclude from these observations that serotonin has a stimulatory role in the central nervous system regulation of LH secretion. Supported by funds from the Bureau of Biological Research of Rutgers University.

18.49 CORRELATION BETWEEN INCREASED HYPOTHALAMIC MULTI-UNIT ACTIVITY AND ENDOGENOUS LUTEINIZING HORMONE PULSES IN THE OVARIECTOMIZED RHESUS MONKEY. T. Uemura*, T. Akema*, R. Wilson, J. Kesner* and E. Knobil*. Department of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

In the rhesus monkey, as in all mammals studied to date, the secretion of pituitary gonadotropic hormones occurs in pulsatile fashion. Each pulse is thought to be the consequence of a packet of hypothalamic LHRH reaching the pituitary by way of its portal circulation. We have recently reported the results of preliminary experiments which demonstrated increases in hypothalamic multi-unit activity (MUA) that corresponded with plasma LH pulses. The present experiments were designed to extend these observations and, to develop techniques for reproducibly recording neural activity associated with LH release.

Using ventriculography and roentgenographic guidance for improved precision in electrode placement, single recording electrodes were placed acutely or multielectrode arrays were implanted chronically at various sites within the medio-basal hypotnalamus (MBH) of 29 ovariectomized rhesus monkeys. For each animal, MUA and LH secretion were analyzed during repeated 8 hr recording sessions. To avoid alterations in hypothalamic activity and LH release coincident with periodic arousal from anesthesia, the animals were maintained on continuous thiopental infusion with EEG monitoring.

In 4 monkeys we recorded MUA increases which were selectively associated with plasma LH pulses. These MUA increases began abruptly just prior to initiation of the LH rise, lasted 30-50 min corresponding to the rising phase of the LH pulses, and terminated near the time of the LH peak. The reproducibility of this association was exemplified in one monkey bearing chronic electrodes in which the MUA-LH coupling was maintained through 5 recording sessions over 8 weeks. Histological analysis in 2 monkeys indicated that electrodes recording MUA-LH correlations were selectively located in the arcuate nucleus region and in the subjacent median eminence. These results confirm our earlier reports (Dufy, J. Physiol. Paris 75:105, 1979; Knobil, Biol. Reprod. 24:44, 1981) of a temporal correlation between activation of neural elements in the arcuate area and the pulsatile release of LH. Additionally, they demonstrate that this coupling can be electrophysiologically monitored over the extended time periods required for analysis of hormonal and neural factors that may modulate this neuroendocrine control system.

18.50 RAPID AND DELAYED CHANGES IN PULSATILE LH RELEASE FOLLOWING OVARIECTOMY IN THE RAT. Robert E. Leipheimer* and Robert V. Gallo* (SPON: Marianne Steele). Department of Physiology, University of California, San Francisco, School of Medicine, San Francisco, CA 94143.

LH release is pulsatile during periods of low level LH secretion in the rat estrous cycle (Gallo, Biol. of Reprod. 24: 771, 1981). The purpose of the present study was to determine the time course of the changes - both rapid and delayed - in LH pulse amplitude and frequency that occur after ovariectomy in the rat. Animals which showed at least two consecutive 4 day estrous cycles were used in these experiments. Unanesthetized rats with jugular cannulae were bled continuously the morning of diestrus 1 (0900-1200 h) or at various times following ovariectomy. Blood samples were taken at 5 to 10 minute intervals, and each rat was only bled once. Ovariectomies were done the morning of diestrus 1 (0830-0900 h), and rats were subsequently bled for a 3 h time period for analysis of pulsatile LH release. Intact diestrous 1 rats demonstrated pulsatile LH secretion with mean blood LH levels of 18 ng/ml whole blood. Following ovariectomy, blood LH levels did not increase by either 10 or 17 h. However, by 1 day post ovariectomy blood LH levels increased to 59 ng/ml whole blood due to an increase in both LH pulse amplitude and frequency. Between 1 and 2 days post ovariectomy blood LH levels remained stable, although some changes occurred in the LH pulse generating mechanism; pulse amplitude increased while frequency decreased, accounting for no net change in mean blood LH levels. Between 2 and 8 days post ovariectomy, a 2½ fold increase in blood LH levels occurred, values reaching 159 ng/ml whole blood. While no further change in LH pulse amplitude occurred during this time, pulse frequency accelerated thereby causing this increase in blood LH levels. Lastly, between 8 days and 3 weeks post ovariectomy an additional 3 fold increase in blood LH levels occurred. However, during this time period LH pulse frequency remained stable but LH pulse amplitude increased. Therefore, these studies demonstrate that: 1) blood LH levels increase rapidly within one day post ovariectomy due to increases in both LH pulse amplitude and frequency; 2) by 8 days following ovariectomy LH pulse frequency reaches a rate that is maintained through 3 weeks, while LH pulse amplitude continues to increase during this time period. Supported by NIH grants HD05577 and AM07265.

18.51 FACILITATORY ROLE OF α-ADRENERGIC MECHANISM IN PULSATILE LH RELEASE IN OVARIECTOMIZED FEMALE GUINEA PIGS. J.A. Keller-Halbe* and Ei Terasawa (SPON. J.W. Kemnitz), Wisconsin Regional Primate Research Center, University of Wisconsin, Madison, WI 53715-1299

Control mechanisms of the pulsatile release of LH, presumably the pulsatile release of LHRH, in ovariectomized (OVX) animals have not been clarified. Previously, we have reported on the dramatic inhibition by opiate neurons and indirect facilitation by serotonergic neurons on the pulsatile release of LH in the OVX guinea pig (Endocrinology suppl. 108: 290, 1981). The present experiment was performed to further investigate the control mechanism of pulsatile LH release: specifically the possible involvement of catecholamines was tested using antagonists and agonists of α_1 and α_2 adrenergic receptors and dopamine receptors. In order to obtain frequent blood samples from unrestrained and unanesthetized animals, a catheter was implanted in the jugular vein of long-term OVX female guinea pigs (n=33). A day later a 0.5 ml blood sample every 5 min was obtained for the 1 h control period and continued for 3-3.5 h after drugs or vehicles were injected. Plasma LH was established by RIA.

The pulsatile rhythm of LH established in control experiments with and without vehicles, consisted of a pulse duration of 27.0 ±1.4 min, and a pulse amplitude of 621±60 ng/ml at the level of 898±57 ng/ml. Corynanthine (4 mg/kg, ip), an α_1 receptor blocker significantly decreased the mean LH level ($p < 0.005$) and prolonged the pulse duration (48±14 min) 30 min after the drug injection. Prazosin (4 mg/kg, ip), another α_1 receptor blocker, completely suppressed the pulsatile rhythm and the mean LH level 30 min after the drug injection, which was retained for the remaining sampling period ($p < 0.025$). Yohimbine (2-4 mg/kg, ip) an α_2 antagonist, also substantially suppressed the pulsatile rhythm and decreased the mean LH level ($p << 0.001$) 15 min after the drug injection for the remaining sampling period. In contrast, clonidine (0.3 mg/kg, sc) an α_2 agonist, though inducing a slight suppression in LH levels around 20 min, induced a significant increase in mean LH levels and pulse amplitude at 75 min after drug injection, which continued to increase throughout the remaining sampling period ($p < 0.005$). Both haldol (0.5 mg/kg, im), a dopamine antagonist, and bromocryptine (1, 2 and 5 mg/kg, im), a dopamine agonist, did not significantly alter the pulsatile rhythm.

Therefore, it seems that stimulation of both α_1 and α_2-adrenergic receptors facilitates pulsatile release of LH, presumably by interacting with LHRH neurons, while dopamine does not seem to directly affect the release of LH. (Supported by NIH grants RR00167, HD11355, HD15433.)

18.52 WHICH OF THE FOLLOWING CONTROLS CYCLIC RELEASE OF LH IN BABOONS: HYPOTHALAMIC LHRH OR ESTROGEN? N. Hagino, J.W. Lee*, and A. Arimura*. Dept. of Anatomy, Univ. TX Health Sci. Ctr. at San Antonio, TX 78284 and Labs. for Molecular Neuroendrinol. and Diabetes, Depts. of Med. and Anat., Tulane Univ. Sch. of Med., New Orleans, LA 70112.

Previous studies in our laboratory demonstrated that neural signals having 24 hr. periodicity which are located in the forebrain-preoptico region and brain stem travel the diffused forebrain-preoptico tuberal paths, medial forebrain bundle-tuberal paths, and brain stem-tuberal paths to reach hypothalamic LHRH neurons. Circulating estrogen modulates not only neural signals which control hypothalamic LHRH release and the effect of LHRH on LH release, but also potentiates the effect of progesterone on neural signals which control LH release in baboons. However, the physiological role of hypothalamic LHRH in the regulation of cyclic release of LH is not clearly defined.

In this experiment, 6 normally cycling female baboons (papio cynocephalus, 5-7 yrs. old) were injected with anti-LHRH serum to reveal the physiological role of LHRH in cyclic release of LH. Normal circulating levels of estradiol (E_2), LH and progesterone were determined by RIA during the entire period of menstrual cycle preceding the following experiment: In 3 baboons, 10 ml of normal sheep serum was injected through femoral vein under ketamine sedation on a day of peak concentration of E_2 (serum levels of E_2 were determined daily) and injections were given for 5 days to cover the entire period of LH release and ovulation (LH release appears on a day of peak concentration of E_2, reaching a peak on the following day). After 3 months, 10 ml sheep anti-LHRH serum was injected on a day of peak concentration of serum E_2 in these same baboons, and injections were given for 5 days.

Injections of normal sheep serum had no demonstrable effect on serum levels of estradiol and cyclic release of LH, whereas injections of anti-LHRH serum blocked cyclic release of LH without altering estradiol levels. In the second experiment, 10 ml anti-LHRH serum was injected only for 2 days in another 3 baboons; on a day of peak concentration of serum E_2 and the next day. Again, anti-LHRH serum blocked cyclic release of LH. It is suggested that hypothalamic LHRH may play a primary role in the regulation of cyclic release of LH, and that estrogen may modulate this process in baboons. 18.53 PROGESTERONE INDUCED LH RELEASE REQUIRES A TIME INTERVAL AFTER ESTROGEN PRIMING IN FEMALE RHESUS MONKEYS. R.R. Yeoman, N.J. Schultz*, W.E. Bridson* and E. Terasawa, Wisconsin Regional Primate Research Ctr., Univ. of Wisconsin, Madison, WI 53715-1299.

Previously we have reported in rhesus monkeys that a progesterone (P) injection after estradiol benzoate (EB) readily induces an LH surge with a short latency (7h) and a short duration (24h). This LH release with P is quite different from an LH surge (latency 28-48h; duration 48-72h) induced by EB alone. In addition the P-, but not the EB-, induced LH surge, can be blocked by pentobarbital, indicating P stimulates release of LH through the brain, presumably facilitating the release of LHRH. In the present study the interval of EB conditioning for P effectiveness was examined. Long term ovariectomized rhesus monkeys (n=10) received a small estradiol-17β implant 2 wks prior to the experiments. Four experiments were repeatedly performed in which the time of P (2.5 mg) injection was either 0,12,24 or 30h after 10μg EB. Blood samples were obtained through femoral puncture every 3 to 6h. A 4 week minimum rest period was allowed between the experiments. Plasma LH was measured in duplicate with a heterologous double antibody RIA. Administration of P 30h after EB induced a typical LH release with short latency (6.7±0.5h) and duration (22.0±1.5h) in all animals. Similarly, P injection 24h after EB induced an LH release in all animals, which is almost identical to the above (latency; 7.4±0.4h, duration; 25.1±1.9h). The amplitude of the P-induced LH release in both 30 or 24h groups is also similar (P-30h; 65.0±18.7, P-24h; 59.8±24.4 ng/ml). In contrast administration of P 12h or 0h after EB resulted in inducing an LH release in only 50% (P=0.016) and 30% (P=0.0015) of animals, respectively. Furthermore, the amplitude of the LH release in animals responding to P 12h (31.7±20.6 ng/ml) or P 0h (18.7±6.0 ng/ml) was smaller than that of P 30h or P 24h ($P<0.01$). However, the latency and duration of the LH release in animals responding to P 12h (latency; 8.9±0.7, duration; 22.2±2.9h) or P 0h (latency; 7.8±0.2, duration; 15.0±1.7h) were similar to those in animals treated at P 30 and P 24h. These results are interpreted that 1) P injection 24 or 30h after EB reliably induced the LH surge with a short latency and duration and 2) effects of P 0 or 12h after EB are essentially negligible, although some animals responded to P 0 or 12h after EB with low LH amplitude. This is probably due to the effect of an estradiol implant prior to EB injection. It is, therefore, concluded that effects of P in inducing the LH surge in ovariectomized rhesus monkeys requires EB priming more than 12h, but less than 24h, prior to P administration. This interval of estrogen conditioning for progesterone effectiveness is consistent with data reported in rodents on LH release as well as lordosis behavior. (Supported by NIH grants RR-00167, HD11355, HD15433).

18.54 HOW FAST IS PULSATILE LH SECRETION UNLEASHED FOLLOWING CASTRATION? Gary B. Ellis and Claude Desjardins*. Institute of Reproductive Biology, Department of Zoology, The University of Texas at Austin, Austin, TX 78712.

Tonic LH release in the normal male rat is best described as a series of irregular, low-amplitude pulses having a variable frequency. In contrast, long-term castrated rats exhibit regular, high-amplitude, high-frequency LH pulses. In this study, we chart the development of these LH pulses as a function of the time elapsed after removal of the testes. In doing so, we dissect the hypothalamic-pituitary response to castration into neural and endocrine components.

Adult male rats (age >15 wks; wt >450 g) were fitted with an indwelling atrial cannula and loosely tethered to a valve mounted outside the cage. Four days after cannulation, blood samples (0.2 ml) were obtained at frequent intervals (2½-5 min). Withdrawn blood was replaced by a mixture containing 48% rat red blood cells suspended in a human plasma protein fraction. This intensive blood sampling routine was imposed upon castrated rats at 8 time intervals after castration. Blood sampling began at hour 0 (castration occurring during blood sampling); at hours 19, 43, 62, and 120; and on days 21, 80, and 140. At each time interval, 2-4 rats were sampled for 3-7 hours.

The results (values are mean ± SE):

Time after castration	LH pulse peak (ng LH /ml)	Nadir to peak (ng LH /ml)	Interpulse interval (minutes)
0- 7 hr	23.3 ± 2.8	15.9 ± 1.5	161.7 ± 53.3
19- 23 hr	76.5 ± 3.6	37.6 ± 2.6	27.5 ± 2.5
43- 47 hr	133.5 ± 2.2	62.1 ± 3.9	23.2 ± 1.0
62- 65 hr	121.0 ± 5.9	58.1 ± 4.3	29.2 ± 5.9
120-124 hr	145.7 ± 2.8	74.0 ± 4.8	24.4 ± 1.5
21 days	364.2 ± 9.1	127.9 ± 7.8	18.8 ± 1.3
80 days	638.4 ± 18.4	310.8 ± 12.7	21.1 ± 1.0
140 days	792.2 ± 16.1	378.9 ± 30.5	26.3 ± 1.9

The pattern of LH release through 7 hours after castration closely resembles that observed in intact male rats. From 19 hours through 140 days post-castration, the amplitude of LH pulses rises steadily; peak LH levels increase and the pulses grow increasingly pronounced. This graded elevation in LH pulse amplitude is likely a reflection of the remodeling of pituitary gonadotropes that occurs following removal of the testes.

In contrast to amplitude, the frequency of pulsatile LH release is remarkably static from as early as 19 hours post-castration through 140 days. The sudden appearance (<1 day after castration) and uniform frequency of high-frequency LH pulses suggests that in the normal rat an intrinsic, ~25-minute neural periodicity exists and is hidden by testicular influences. [NIH HD-13470]

18.55 LONG-TERM GONADECTOMY ELIMINATES THE EFFECTS OF OPIATES ON LH SECRETION IN THE RAT. R. Bhanot and M. Wilkinson. Depts. of Physiol. Biophys. & Obstet. Gynecol., Dalhousie Univ., Halifax, Canada.

Gonadal steroids have powerful negative feedback effects on LH secretion. Part of this influence is exerted via the hypothalamus, probably through involvement of endogenous opiates. We now show that the inhibitory effects of the opiate peptide FK 33-824 (FK) on LH secretion, and conversely the stimulatory influence of naloxone, are dependent upon recent exposure to gonadal steroids.

Female Sprague Dawley rats were OVX at day 24 and the LH response to naloxone (2.5 mg/kg sc) determined 2,7 and 21 days post-OVX. Naloxone significantly increased serum LH levels (ng/ml; 15 min) from 400±50 (saline) to 780±80 ($p<0.005$) in 2-day OVX rats. This response was attenuated 7 days post-OVX (LH increased from 314±39 to 384±30 $p<0.1$) and was absent in rats OVX for 21 days (LH was 589±47 for controls and 672±75 for the treated group (ns)). These results demonstrate an absence of endogenous opiate suppression of LH release coincident with the disappearance of ovarian negative feedback control.

We subsequently tested the effect of OVX (at day 24) on the ability of FK to inhibit LH release. FK (1 mg/kg, 1.5 hr post-injection) suppressed serum LH by >80% in rats OVX for 2 or 7 days, but was ineffective in animals OVX for 21 days: LH values were 589±47 for controls compared with 700±71 for the FK-treated group (ns). An effect of age was discounted by determination of FK responses in 45-day old rats OVX for 2 days: FK reduced LH levels to 32±13 compared with 125±19 for saline controls ($p<0.005$). Similar results were obtained in males. We therefore determined the effect of testosterone propionate (TP) (1.2 mg/kg/day; x 2 days) on the response to FK in long-term castrates (20 days). FK failed to affect LH secretion in oil-treated controls: serum LH in the oil + FK group was 104±9% of control values. In contrast FK reduced LH levels to 53±13% in TP-primed animals ($p<0.025$ compared with TP + saline). We interpret these findings to indicate that the hypothalamic opiatergic system is serially involved in mediating the regulatory influence of sex steroids on LH secretion. These responses further suggest that the coupling of the opiate receptor to LH regulatory mechanisms is dependent upon gonadal steroids. However, since we have been unable to show any influence of steroids or gonadectomy on hypothalamic opiate binding sites (Wilkinson et al., in 'Steroid Hormone Regulation of the Brain', Eds. Fuxe et al., Pergamon 1981) we conclude that the reversible alteration in opiate involvement in LH release involves another neurotransmitter system. (Supported by Canadian MRC grant to MW).

18.56 MULTIPLE COMPONENTS OF TRH-LIKE IMMUNOREACTIVITY IN RAT HYPOPHYSIAL PORTAL BLOOD. W.J. Sheward*, A.J. Harmar* and G. Fink (SPON: H.W. Kosterlitz). MRC Brain Metabolism Unit, Department of Pharmacology, 1 George Square, Edinburgh, U.K.

In a number of tissues differences between the immunoreactive material (IR) measured by TRH radioimmunoassay and authentic TRH, have been reported (Youngblood et al., 1979). Using reverse phase high performance liquid chromatography (HPLC) combined with a sensitive radioimmunoassay, we have examined the IR material found in rat hypophysial portal blood. Alcoholic extracts of portal blood were evaporated to dryness, reconstituted in buffer and loaded on to the HPLC column. Fractions eluting from the column were dried, redissolved in assay buffer and TRH-like IR determined using ovine anti-TRH serum. Three peaks of immunoreactive material were present in the portal blood, the first of which co-eluted with synthetic pGlu-His-ProNH_2. A single IR peak was obtained from acid or alcoholic extracts of rat hypothalamus and from rat peripheral blood to which synthetic TRH or hypothalamic extracts had been added. Peripheral blood extracts themselves contained little or no immunoreactive material.

Hypophysial portal blood, therefore, contains at least two additional IR substances other than TRH which since they are absent from the hypothalamus are not stored precursors of TRH released into portal blood. However a non-immunoreactive precursor, when released from the hypothalamus, may be degraded to produce intermediates in TRH biosynthesis which do cross react with the antiserum used. Since there is no appreciable cross reaction (<0.1%) between the antiserum and known TRH metabolites and no additional IR peaks were produced after addition of synthetic TRH to peripheral blood, the extra peaks of IR material are unlikely to be TRH metabolites.

(The TRH antiserum was a gift from Dr. H.M. Fraser, MRC Reproductive Biology Unit, Edinburgh).

Youngblood, W.W., Humm, J. and Kizer, J.S. (1979) Brain Research. 163 101-110.

18.57 SOMATOSTATIN INHIBITION OF GROWTH HORMONE RELEASE IS BLOCKED BY PERTUSSIS TOXIN. M. Cronin, A. Rogol*, L. Dabney*, G. Myers*, and E. Hewlett*. Depts. of Physiology & Internal Medicine, Univ. of Virginia Sch. Med., Charlottesville, Va. 22908.

A protein toxin from Bordetella pertussis induces many biological effects including the annulment of dopamine agonist inhibition of prolactin release in vitro (Cronin et al, 1982 Endocrine Society Meeting, abstract 857). To determine whether other inhibitory hormones acting at the anterior pituitary can be influenced by this pertussis toxin (PT), we studied the decrease of basal and stimulated growth hormone (GH) release by somatostatin (33 nM), a physiological GH inhibitory hormone. The PT was prepared from the culture medium of B. pertussis by affinity chromatography on haptoglobin-sepharose (BBA 580:175, 1979). Anterior pituitaries from adult male rats were enzymatically dispersed and plated (500,000 cells/well) for at least 4 days in RPMI-1640 medium supplemented with serum (2.5% fetal calf & 7.5% horse) and antibiotics. The cells were maintained in a humidified chamber with 95% air/5% CO_2 at 37C. Prior to study, cells were exposed to PT for 24 h, a time which allowed maximal toxin effects in other systems. After this treatment, the cells were washed and then exposed to serum-free medium with various combinations of somatostatin and or a GH releasing factor (GRF) (Fed Proc 41: 1488, 1982) for 4 h. Secreted GH was determined by RIA. The PT was able to totally reverse the inhibitory effect of somatostatin on basal GH release without affecting the basal release itself (Table). Furthermore, the PT prevented the somatostatin antagonism of GRF-stimulated GH release (Table) in a dose dependent manner (0.23-230 ng PT/ml). This toxin protein reduces or abolishes inhibitory adenosine, cholinergic, alpha-adrenergic, dopaminergic and now somatostatin receptor effects in a variety of cells. We hypothesize that PT may act at a common, obligatory step involved in the action of these inhibitory receptors.

	Growth Hormone (µg/well; mean ± SEM)			
	− PT	n	+ PT (23 ng/ml)	n

18.58 A COMPARTMENTALIZED ORGAN-CULTURED HYPOTHALAMO-NEUROHYPOPHYSIAL SYSTEM FOR THE STUDY OF VASOPRESSIN RELEASE. Christine M. Gregg* and Celia D. Sladek. (Spon: E. Hibbard) Dept. of Biology, Pennsylvania State Univ., Univ. Park PA 16802 and Depts. of Anatomy and Neurology, U. Rochester Sch. of Medicine and Dentistry, Rochester, NY 14642.

An organ-cultured compartmentalized hypothalamo-neurohypophysial system (CHNS) has been developed in order to test whether substances affecting vasopressin release act on hypothalamus (HT) or directly on posterior pituitary (PP), or both. Hypothalamic explants containing supraoptic nuclei, median eminence, and PP were removed from decapitated male Sprague-Dawley rats (175-200g). Hypothalamus and pituitary were maintained in organ culture in separate compartments and the intact infundibular stalk passed through a small opening in the fluid-tight barrier which separated the 2 sides. The only communication between the compartments is neuronal. Thus, either side may be selectively stimulated and the locus of action on VP release determined. VP was measured by radioimmunoassay.

The amount of VP released from PP on 4 successive days was 2007±23, 1156±83, 1058±81, and 451±38 pg/24 hr. Respective values for HT side were 175±16, 96±13, 149±17, and 118±11 pg/24 hr. Values do not include a correction for simultaneous degradation which can approach 100pg/hr on PP side.

Experiments were done on days 2 & 3. PP VP release was measured during a control hour and again during a subsequent test hour during which a stimulus was administered on HT side. VP release during the test hour is expressed as a % of the control hour release.

Stimulus to HT side	none	↓ Osm 6 mOsm	↓ Osm 15 mOsm	↑ Osm 15 mOsm	+ Ach 10^{-5} M
PP VP release (% of control)	85%±13%	46%±6%	29%±7%	708%±342%	140±11%
(n)	(6) *p=.29	(5) p<.001	(6) p<.001	(5) p=.07	(5) p<.025

osm=osmolality Ach=acetylcholine *paired t-test

Basal PP release rates during the control hour for these experiments was 194±43 pg/hr.

Four day old explants stained for VP neurophysin showed immunoreactivity in supraoptic neurons, fibrous zone of median eminence, and PP.

The organ-cultured CHNS responds appropriately to known stimuli for VP release and should prove to be another useful tool for the study of VP release. Supported by NIH grant NS 17300.

18.59 CHARACTERIZATION AND LOCALISATION OF NEUROTENSIN IN THE RAT ANTERIOR PITUITARY GLAND. M. Goedert, P.C. Emson and S. Lightman (SPON: M. Hanley). MRC Neurochemical Pharmacology Unit, MRC Centre, Hills Road, Cambridge, England.

Using both amino- and carboxy-terminal specific neurotensin antisera we detected neurotensin-like immunoreactivity (NTLI) in the rat anterior pituitary (80 pmol/g). This NTLI could not be distinguished from synthetic neurotensin on gel or high-performance liquid chromatography. The NTLI is localised to a specific population of cells in the rat anterior pituitary from which it can be released by depolarization. The neurotensin content of the anterior pituitary in vivo was dramatically reduced by propylthiouracil (PTU) treatment. Within one week of PTU treatment the neurotensin content of the anterior pituitary decreased by more than 90%. The effect of PTU could be reversed or prevented by treatment with L-tri-iodothyronine (T_3) suggesting that the fall in neurotensin content was attributable to a fall in thyroid hormone induced by PTU treatment. In agreement with this suggestion thyrotropin releasing hormone (TRH) treatment (Alzet minipump 50µg/kg/day) also produced a 90% decrease in neurotensin content. This data suggests a functional relationship between pituitary neurotensin and the thyroid although the nature of this relationship is unclear at present.

18.60 EFFECTS OF URETHANE ON PITUITARY-ADRENAL FUNCTION. W.N. Hamstra*, S. Orr*, D. Doray*, and J.D. Dunn. Dept. of Anatomy, Oral Roberts University., Sch. of Med., Tulsa, OK 74171.

Urethane anesthesia is frequently used in studies concerned with testing neuronal responsiveness to a variety of stimuli including hormonal administration. However, little is known about its mechanisms of action or its effect on hormonal systems, particularly pituitary-adrenal function. Since both ACTH and adrenal corticosteroids have marked effects on neural activity of various CNS sites, we undertook a systematic evaluation of the effect of urethane on pituitary-adrenal function.

Urethane (1.35 gm/Kg, i.p.) or saline was administered to variously treated adult female rats and timed blood samples were taken from an exposed jugular vein or via rapid decapitation. Plasma levels of corticosterone (Cpd B), an index of pituitary-adrenal activity, were determined fluorometrically.
Urethane produced a rapid and sustained increase in Cpd B levels both in the AM and PM. Initial corticosterone levels of non-injected control rats showed marked AM-PM differences, but by 10 min post-injection morning Cpd B levels were increased such that AM-PM differences were not observed. By 30 min post-injection, afternoon plasma Cpd B levels had increased significantly but AM-PM differences were still abolished. AM and PM Cpd B levels remained elevated for at least 4 hrs. Saline injected controls showed the expected response to stress; plasma Cpd B levels were significantly increased at 10 min but were back to baseline by 30 min. Dexamethasone (100 µg/Kg, s.c.) markedly suppressed both AM and PM urethane stimulated Cpd B levels, but diurnal differences in dexamethasone suppression were noted; increased dexamethasone (250 µg/Kg) administration abolished the diurnal difference. Neither AM or PM infusions (10 min) of exogenous corticosterone (8 µg/ml/min, i.v.) significantly altered plasma Cpd B levels. Hypophysectomy abolished the urethane induced adrenocortical activity, and plasma Cpd B levels of non-anesthetized, hypophysectomized ACTH-primed and injected rats were not different from those similarly treated and anesthetized with urethane. Urethane-stimulated plasma Cpd B levels were significantly reduced 15 min after intravascular infusion of atropine (0.8 mg), but urethane-induced increases in Cpd B were not affected by hypothalamic deafferentation.

Collectively, these data indicate that urethane evokes a sustained increase in pituitary-adrenal activity, that the increased activity is dexamethasone and atropine sensitive and that the site of action is the hypothalamo-hypophyseal complex. Extrahypothalamic CNS sites may be influenced by urethane anesthesia but urethane-induced increases in pituitary-adrenal activity do not necessitate extrahypothalamic neural influences.

18.61 SECRETAGOGUE-INDUCED THYROTROPIN RELEASE IS DECREASED BY PENFLURIDOL: A POSSIBLE ROLE FOR CALMODULIN. A.M. Judd,* G. Schettini* and R.M. MacLeod*. (SPON: F.E. Dreifuss). Dept. of Internal Medicine, Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

We have studied the effects of penfluridol (PF), a potent neuroleptic, on basal and secretagogue-induced thyrotropin (TSH) release. Stimulus secretion coupling in various cells is known to involve calcium-dependent mechanisms, and calcium is thought to have its effect via binding to and thereby activating the protein calmodulin (CM). Several pharmacological agents, including neuroleptics, in addition to their effects on neurotransmitter receptors, have been reported to bind to and inhibit CM. To determine the effect of PF on basal TSH release, female rat hemipituitaries were incubated in Medium 199 under a 95% O_2, 5% CO_2 atmosphere for 5 hrs at 37° and the TSH content of the gland and medium determined by radioimmunoassay. PF (100 μM) had no effect on unstimulated total, glandular or medium TSH content. The inability of PF to modify basal TSH release may be explained by the observation that basal TSH release seems to be a Ca^{2+}-independent process, whereas the stimulus-related release of TSH seems to be a Ca^{2+}-dependent process. To investigate the effect of PF on secretagogue-induced TSH secretion, a second series of experiments was carried out in a manner analogous to the first, except the hemipituitaries were treated with vehicle or PF for the first 2.5 hrs and then the medium was removed and the pituitaries incubated for 30 min in fresh medium containing secretagogue and either vehicle or PF. PF (0.1 - 10 μM) had no effect on basal TSH release but decreased in a dose-related manner the release of TSH due to either 70 nM thyrotropin releasing hormone (TRH), 50 mM K+, 10 μM calcium ionophore A-23187, 3 mM dibutyryl cAMP, or 5 mM theophylline. Since all of these secretagogues affect TSH secretion via Ca^{2+}-dependent mechanisms, the PF effect may be due to inactivation of CM.

If the PF effect occurs via inactivating CM, then it should be reversible. To test this hypothesis, enzymatic dispersed pituitaries were intermittently perifused with Medium 199 containing vehicle or PF (1 μM) and the release of TSH due to 70 nM TRH determined. TRH induced a marked increase in TSH release (250%), which was completely blocked by PF. The responsiveness of the cells to TRH returned subsequent to withdrawal of the PF. Further exposures to PF blocked TRH-induced TSH release, with the recovery of the TSH response to TRH following the withdrawal of each PF perifusion.

In conclusion, although PF does not affect basal TSH secretion, it decreases TSH release caused by a number of secretagogues. In the case of TRH, the PF effect is reversible. These observations are consistent with the hypothesis that PF inactivates the calcium-CM system, and suggests that CM may play a role in the secretagogue-induced secretion of TSH. (Supported in part by USPHS Grant CA-07535 from the National Cancer Institute)

18.62 NEONATAL ADRENAL TRANSPLANTATION ALTERS NORMAL PITUITARY-ADRENOCORTICAL RELATIONSHIPS. W.C. Engeland*, C. Wilke* and S. Feeley* (SPON: C. Allen-Rowlands). Div. of Biol. Med., Brown Univ. and Rhode Island Hosp., Providence, RI 02902.

To define the effect of disruption of adrenal nerves on the development of the rhythms of plasma corticosterone (B) and of plasma ACTH, adrenals from neonatal (day 1) rats were transplanted unilaterally into the anterior chamber of the eye (NTE) of adult bilaterally adrenalectomized recipients. Groups of rats were sacrificed by decapitation in the AM and in the PM at 1,3,5, 7 and 9 weeks after transplantation. Control rats, littermates to adrenal donors, were sacrificed at 1,3,5,7 and 9 weeks of age. Plasma B and ACTH concentration were determined by RIA. Plasma B in the PM was significantly greater ($p<0.05$) than in the AM at 5,7 and 9 weeks in both the NTE and intact groups. In the AM and in the PM, there was no difference ($p>0.05$) in plasma B between intact and NTE rats at any time. Plasma ACTH in the AM and the PM was not different ($p>0.05$) at any time in the NTE and intact groups. However, plasma ACTH in NTE rats was significantly greater ($p<0.025$) than in intact rats at all times. To determine whether or not differences in plasma ACTH following transplantation were related to the site of transplantation or to the age of the transplanted adrenal, plasma ACTH and B were determined in the PM in groups of adult rats at 5 weeks after either NTE, unilateral neonatal adrenal transplantation to the kidney capsules (NTK), unilateral adult adrenal transplantation to the kidney capsule (ATK), or unilateral adrenalectomy and sham transplantation to the kidney capsule (STK). There was no difference in adrenal weight ($p>0.1$) or in plasma B ($p>0.1$) between groups. Whereas plasma ACTH in STK and in ATK groups was not different ($p>0.5$), plasma ACTH in both NTE and NTK groups was significantly greater ($p<0.025$) than that in the STK and ATK groups. Thus, transplantation of the neonatal adrenal into an adult recipient results in elevated plasma ACTH and normal rhythmicity in plasma B. These findings suggest that adrenal transplantation neonatally prevents the maturation of a neural or humoral mechanism that is necessary for the normal development of the pituitary-adrenocortical system. (Supported in part by BRSG 7655 and NIH AM 26831).

19.1 SEXUAL DIFFERENTIATION OF BRAIN FUNCTION : THE ROLE OF GONADAL HORMONES IN ELECTROCONVULSIVE SHOCK,
C-A. Hardy*, Z. S. Dolinsky, P. J. Donovick, and R. G. Burright* (SPON: E. Shaskan, Dept of Psychiatry, UCONN, Farmington). Dept. of Psychology, SUNY-Binghamton, Binghamton, N.Y. 13901.

The duration and severity of transcorneally-induced electroshock seizures of 93 HET male and female mice was assessed at 63 days of age following removal of the gonads or sham-operations at either 21 days of age or 42 days of age. An additional group of 24, 60-65 day old intact non-surgical female mice was tested exclusively to determine the relationship between the phases of the estrous cycle and transcorneally-induced seizure susceptibility. The duration and severity of behavioral seizures was similar for intact males and intact females. However, intact females classified as being in estrous or proestrous were more likely to seize following electroconvulsive shock than those intact females classified as in metestrous or diestrous. This finding suggests that when circulating levels of estrogens are high, young adult female mice have a heightened susceptibility to electroshock seizures, presumably due to the central effects of estrogens. However, gonadectomized animals, on the average, tended to have somewhat longer behavioral seizures than intact animals, suggesting that heightened susceptibility to electroshock seizures is not simply a function of the level of circulating estrogens. Also, mice operated on at 21 days of age tended toward longer behavioral seizures than those mice operated on at 42 days of age.

All mice were sacrificed following testing and brain, pituitary, liver, adrenals, kidneys, spleen, and ovaries, or seminal vesicles and testes were removed wherever possible, and weighed. Marked effects of gonadectomy were noted for spleen, kidney, seminal vesicle, brain, and adrenal weights. Furthermore, intact male and female organ weight differences were noted, as well as organ weight changes for each of the four classified phases of estrous in the intact females. In conclusion, while gonadectomy produced pronounced peripheral organ weight changes, it is unclear what effect gonadectomy has on brain seizure mechanisms, and further investigation is warranted.

19.2 ADRENALECTOMY AND METOPIRONE DISRUPT ACQUISITION OF ACTIVE AVOIDANCE BEHAVIOUR.
R. J. Bialik*, B. A. Pappas and D. C. S. Roberts (SPON: T. Picton). Unit for Behavioural Medicine and Pharmacology, Dept. of Psychology, Carleton University, Ottawa, Canada, K1S 5B6.

Investigations into the role that adrenal steroids play in active avoidance learning have yielded conflicting results. These studies have usually employed bilateral adrenalectomy to reduce corticosterone levels in plasma. One problem encountered when using adrenalectomized rats is that the corticosterone levels are not completely reduced, often remaining at 20 to 30% of controls. Another is that these rats require a week or longer to recover following surgery. Testing this long after surgery allows for compensatory changes in steroid uptake in the brain or increased extra adrenal synthesis of corticosterone, thereby complicating interpretation of the results.

To test the effect of acute corticosterone depletion on avoidance behaviour the corticosterone synthesis inhibitor Metopirone was used here. Injection of Metopirone (50 mg/kg ip) resulted in plasma levels of corticosterone which were reduced to 40% of control values two hours after injection. Two hours following Metopirone injection, rats showed a deficit in the acquisition of a shuttle-box avoidance response like that seen three weeks following adrenalectomy. Administration of Metopirone to adrenalectomized rats also caused a further avoidance deficit and corticosterone depletion. This Metopirone-induced avoidance deficit was dose dependent over the range of 0, 10, 25 and 50 mg/kg. The deficit could be attenuated but not completely reversed by subcutaneous implantation of pellets containing corticosterone or dexamethasone. The seventh daily injection of Metopirone (50 mg/kg ip) reduced avoidance performance and corticosterone levels similar to that of a single injection of the drug, thus indicating an absence of tolerance to its behavioural and endocrinological effects.

Metopirone is used clinically to test for anterior pituitary dysfunction. That there is a behavioural impairment after acute and chronic Metopirone in the rat suggests that the behavioural effects of this drug in humans should be explored. (Supported by MRC and NSERC)

19.3 PSYCHONEUROENDOCRINE EFFECTS OF SEPTAL AND STRIATAL DAMAGE IN THE RAT.
T.R. King* and D.M. Nance (SPON: J.A. Armour). Department of Anatomy, Dalhousie University, Halifax, N.S., B3H 4H7.

With respect to female sexual behavior, electrolytic septal lesions increase sensitivity to sex steroids. This facilitation in lordosis behavior is associated with changes in brain dopomine (DA) and GABA (Brain Res. Bull. 2:341, 1977). Here we report the effects of neurotoxic lesions in the septum and striatum induced by 6-hydroxydopamine (6-OHDA) or kainic acid (KA) on body weight (BWt), ovarian compensatory hypertrophy (OCH) and lordotic behavior. The 6-OHDA was injected bilaterally into the lateral septum (8 µg in 1.0 µl) and striatum (16.0 µg in 2.0 µl). Likewise, KA was injected into the septum (0.5 µg in 1.0 µl) and striatum (1.0 µg in 2.0 µl). Electrolytic (DC) septal lesion rats (2mA/20") as well as vehicle and sham operated controls were included. Effectiveness of 6-OHDA injections was subsequently verified by measuring brain DA levels using HPLC and electrochemical detection. Relative to controls, septal injections of 6-OHDA selectively reduced septal levels of DA by 60%. Striatal injections of 6-OHDA reduced striatal levels of DA by 77%, septal levels by 30% and had no effect on DA levels in the accumbens. Brain histologies indicated that the DC lesions bilaterally destroyed the lateral and occasionally medial septum. The KA septal lesions reduced the overall size of the septal area (primarily lateral region), but otherwise the septum appeared remarkably normal at the light microscopic level. However, there was extensive neuronal cell loss in hippocampal areas CA3 and CA4. KA-striatal injections were found to be lethal with only 1 survivor. Behavioral and endocrine effects of these various lesions were, relative to controls; 1) KA in the septum increased and 6-OHDA in the striatum decreased BWt, 2) 6-OHDA in the striatum reduced ovarian weight and KA in the septum increased OCH, 3) DC septal lesions increased whereas KA septal lesions decreased female sexual behavior. Also, 6-OHDA septal lesions reduced lordotic behavior. These results suggest that decreases in brain DA associated with DC septal lesions are not causally related to the increased female sexual behavior. The opposite effects of DC and KA septal lesions on lordotic behavior were unexpected and possibly related to the extensive hippocampal damage associated with the KA injections. Likewise, the increase in OCH by the KA septal rats may also be related to the hippocampus, a region proposed to exert inhibitory control over gonadotropin release. Supported by MRC Grants #MA-6807 and MA-6956.

19.4 IMMUNOREACTIVE SOMATOSTATIN LEVELS IN BRAIN REGIONS OF ELECTRICALLY KINDLED VS CHEMICALLY KINDLED RATS.
T. Higuchi*, K.R. Shah*, N. Kato, M. West*, J.A. Wada* and H.G. Friesen*, Department of Physiology, University of Manitoba, Winnipeg, Manitoba, and Health Sciences Center Hospital, The University of British Columbia, Vancouver, B.C.

The kindling phenomenon has become a useful model for studying partial seizures and epileptogenesis. Although there have been many biochemical findings in kindled animals, in many instances these findings reflect not the basic mechanism of kindling but the consequences of kindled seizures. Somatostatin has been shown to induce epileptic-like EEG activity and generalized seizures (GS) in rats.

In the present study, we investigated immunoreactive somatostatin (IRS) levels in brains of rats after electrical and chemical kindling. Electrical kindling: Fourteen Long-Evans male rats (250-300 g) were implanted stereotaxically with electrodes in both amygdala. Stimulation was administered through left amygdala once daily with 1 second trains of 6.0 Hz sine wave at an intensity of 150 µA. Stimulation was stopped after five stable stage 5 (GS) were elicited. It took 9.7 days (average) to develop stage 5. After 2 months of establishment, kindled rats and controls were killed by microwave irradiation and brains dissected into 7 regions (Amygdala, Sensorimotor Cortex, Hippocampus, Piriform Cortex, Entorhinal Cortex, Hypothalamus, Cerebellum). Tissues were extracted in 0.1 N acetic acid and the supernatant was stored at -70°C until IRS assay. Chemical kindling: Sixteen male SD rats (246 ± 11 g) were given subthreshold doses of Lidocaine (60 mg/kg) by I.P. route once daily. Administration of Lidocaine was continued until the onset of G.S. within 5 min. (kindling). In 7 out of 16 rats, the kindling was established after an average of 27 (7-40) Lidocaine injections. After 1-3 weeks of establishment, the same dose of Lidocaine was administered again and the kindling effect was confirmed. One week later the kindled rats (7), non-kindled rats (9) which did not show GS after chronic injection of Lidocaine, and control rats were killed and the brain tissues assayed for IRS in a similar fashion to electrically kindled rats. Results: In electrically kindled rats, a significant increase of IRS was found in Amygdala*** (119% of controls), Entorhinal Cortex* (32%), Piriform Cortex**** (63%), and Sensorimotor Cortex**** (37%). In chemically kindled rats, IRS showed a significant increase in Amygdala** (56% of controls) and Entorhinal + Piriform Cortex* (50%). In non-kindled rats, IRS increased significantly only in Amygdala** (58%). (*P< 0.5, **p< .02, ***p< .01, ****p< .001). The results suggest that somatostatin may be associated with both electrically and chemically induced kindling.

19.5 INDEPENDENT EFFECTS OF ESTRADIOL ON FEEDING AND DRINKING. J.A. Czaja*, P.C. Butera* and T.A. McCaffrey* (SPON: F.R. Brush). Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907.

Six experiments examined the effects of estradiol on feeding and drinking in female guinea pigs. Estradiol treatment was found to reduce water intake independently of its actions on food intake and body weight.

Initial observations indicated that intact female guinea pigs display a cyclic variation in feeding, drinking and body weight across their ovarian (estrous) cycles. Minimum intake and body weight coincided with rupture of the vaginal membrane, the estimated time of ovulation. Compared to the midluteal phase of the cycle, the periovular depression averaged 15.1 ± 1.9% for food intake, 11.3 ± 4.9% for water intake and 1.7 ± 0.2% for body weight. In a second experiment utilizing ovariectomized females, injections of 3 µg estradiol benzoate per day significantly depressed food intake by 24.9 ± 0.4%, water intake by 17.6 ± 4.1% and body weight by 2.0 ± 0.6% compared to oil injections. Neither during the estrous cycle nor following estradiol injections did the ratio of water intake per gram food intake change significantly. This suggested that the reduced drinking might be a consequence of the reduced feeding. To test this hypothesis, food rations were reduced to 30 percent below ad lib levels in experiment #3. This partial reduction in feeding by itself had no significant effect on drinking. In experiment #4, therefore, ovariectomized females were first placed on a food ration 30 percent below ad lib levels and then injected with either 3 µg per day estradiol benzoate or oil. Compared to oil injections, these estradiol injections significantly reduced water intake by 21.0 ± 6.0% while food intake declined insignificantly by only 0.2 ± 0.1%. In these experiments, the reduction in food intake was therefore neither a sufficient nor a necessary condition for the estradiol induced suppression of water intake.

The last two experiments verified that estradiol has independent actions on feeding. The daily water ration was reduced to 30 percent below ad lib levels in experiment #5 with no significant effect on food intake. In the sixth experiment, the water ration of ovariectomized females was first reduced to 30 percent below ad lib levels. Females were then injected with either oil or 3 µg per day estradiol benzoate. With this reduced water ration, the estradiol significantly suppressed food intake by 11.3 ± 4.1% while producing only minimal and insignificant changes of 0.2 ± 0.6% in water intake.

Our findings establish that estradiol can independently influence water intake and food intake in the guinea pig, thereby indicating that estradiol operates through different mechanisms to produce these two effects.

19.6 EFFECTS OF STEROID HORMONES ON THE CNS AND ITS RESPONSIVENESS TO VAGINOCERVICAL STIMULATION, T. O. Allen, Y. Gomita*, and N. T. Adler. Dept. of Psychology, University of Pennsylvania, 3815 Walnut St., Philadelphia, PA 19104.

Stimulation of the female rat's vaginal cervix by the male during coitus (or by copulomimetic stimulation) has several behavioral and physiological consequences, for example potentiation of the lordotic posture, and initiation of twice-daily surges of prolactin necessary for pregnancy. Gonadal hormones facilitate these effects. We have continued to investigate the nature of the central nervous system mediators of copulatory stimulation (Allen et al., Science, 1981, 211:1070). We have expanded our investigation to assess the influence of steroid hormones (estrogen & progesterone) on the brain's response to copulomimetic stimulation. For our study of hormonal mediators, 24 female rats were bilaterally ovariectomized and injected with either a) no exogenous hormones, b) estrogen only, c) progesterone only, or d) sequential estrogen and progesterone. Half of the rats in each group were given vaginocervical stimulation during incorporation of 14C deoxyglucose. The other half did not receive vaginocervical stimulation.

Computerized image-processing of 47 brain nuclei revealed that in females not receiving vaginocervical stimulation estrogen generally increases uptake of 2DG (36/47 structures) and progesterone decreases uptake (39/47 structures). Treatment with estrogen and progesterone produced variable patterns of 2DG uptake across the 47 brain areas analyzed.

In females treated with estrogen and progesterone, vaginocervical stimulation increased uptake of 2DG in 41/47 brain areas. Similarly, in females receiving either progesterone or no hormone, vaginocervical stimulation also produced increased metabolism. However, in females receiving only estrogen, vaginocervical stimulation did not increase brain activity.

There were correspondences between the 2DG map of functional activity in this study and maps of steroid-hormone concentrating cells (e.g. Pfaff & Keiner, J. Comp. Neurol. 151:121). Previous reports (Moguilevsky and Malinow, Amer. J. Physiol. 1964, 206: 855; Schiaffini & Marin, 1975, Excerpta Med. Int. Congr. Ser. 374:123) of metabolic changes in the hypothalamus during the estrous cycle may be related to changing titers of steroid hormones.

19.7 PRENATAL HORMONAL INFLUENCES ON TAIL POSTURE ASYMMETRY IN NEONATAL RATS. G.D. Rosen*, A.S. Berrebi*, D.A. Yutzey, and V.H. Denenberg. Dept. Biobehavioral Sci., U. of Conn., Storrs, CT 06268.

Ross, Glick and Meibach (PNAS, 78: 1958, 1981) demonstrated a sexually dimorphic pattern of asymmetry in the tail posture of neonatal Sprague-Dawley rats. A sexually dimorphic pattern of tail posture has been reported for Purdue-Wistar rats as well (Denenberg et al., Dev. Br. Res., 2: 417, 1982): males and females were biased to the left with females more biased than males. Also, more males had a neutral tail posture than females. The question addressed here was whether exogenous prenatal hormones could influence the asymmetry pattern of tail posture in the rat.

On days 16-21 of gestation, pregnant Purdue-Wistar rats were injected with testosterone proprionate (TP), dihydrotestosterone proprionate (DHTP), sesame oil, or received no injection. At birth, tail posture was assessed and then sex was determined. There was no difference between the oil-injected and the non-injected groups and the data were pooled. The results are summarized in Table 1.

The control animals replicated our previous work with both males and females biased to the left and more males with neutral tail postures than females. The TP-injected females were significantly different from the control females ($p < 0.01$) but were not different from the control males ($p > 0.10$). Females receiving DHTP were no different from control animals ($p > 0.10$) but were significantly different from TP-injected females ($p < 0.02$).

The population pattern of neonatal tail posture asymmetry can be affected by TP but not DHTP injected prenatally. DHTP has no effect on the sexually dimorphic pattern of tail posture asymmetry. DHTP is a non-aromatizable androgen having peripheral effects. The conversion of testosterone to estrogen in the brain has been hypothesized to underlie sexual differentiation in the rat. Thus, the difference between the TP- and the DHTP-injected groups in this study suggests a central mechanism for tail posture asymmetry.

TABLE 1

Number of Animals with Tail Posture
(percentages in parentheses)

	LEFT	NEUTRAL	RIGHT
MALES	92 (55.8)	20 (12.1)	53 (32.1)
FEMALES	116 (66.3)	6 (3.4)	53 (30.3)
FEMALES + TP	17 (37.8)	8 (17.8)	20 (44.4)
FEMALES + DHTP	59 (62.8)	5 (5.3)	30 (31.9)

19.8 THE ABILITY OF PROGESTERONE TO RELEASE LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) IN VITRO FROM IMMATURE FEMALE RAT HYPOTHALAMIC FRAGMENTS IS NOT RELATED TO CYTOPLASMIC PROGESTIN RECEPTOR LEVELS. T. W. Jasper and V. D. Ramirez. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801.

We have reported that intermittent but not continuous infusion of progesterone (P) stimulates LHRH release in vitro from hypothalamic fragments from ovariectomized, estrogen-primed immature rats (Kim and Ramirez, Endocrinology, 1982, in press). The following study was conducted to examine the possible relationship between cytoplasmic progestin receptor (PRc) levels and the ability of P to stimulate LHRH release in vitro from the immature female rat hypothalamus.

Immature 28-day-old female rats were ovariectomized and implanted sc with silastic capsules containing estradiol-17β (10 mm length, 1.6 mm width id, 235 µg/ml oil). (This estrogen dose stimulated hypothalamic-preoptic area PRc levels nearly 10-fold versus ovariectomized-only immature rats by 30 days of age; 11.17±1.06 versus 1.23±0.74 fmol/mg protein, respectively.) At 30 days of age, the rats were decapitated and the mediobasal hypothalamic-anterior hypothalamic-preoptic area (HPOA) fragments were removed, placed in superfusion medium on ice, and subsequently transferred to superfusion chambers maintained at a constant temperature. At various times during the superfusion, HPOA fragments were removed from the chambers and placed in superfusion medium on ice for the duration of the experiment. After superfusion, the fragments were homogenized in assay buffer and PRc levels were measured in the 45,000 g x 60 min supernatant using ^{3}H-R5020, a synthetic progestin, as the specific ligand.

Incubation of the HPOA fragments at a temperature of 37C resulted in a rapid exponential decrease in PRc levels (the calculated half-life was 6 min). At 30C, the exponential decrease in PRc levels was greatly reduced, and the corresponding half-life of PRc decay was calculated to be 55 min. However, the reported ability of P to release LHRH in vitro from the HPOA fragments was markedly reduced when the units were superfused at 30C versus 37C (see Kim and Ramirez, Endocrinology, 1982, in press). Infusions of norepinephrine, a possible mediator of estrogen stimulation of PRc levels in female rats (Nock et al., Brain Res. 207: 371-396, 1981), were ineffective in preventing the loss of PRc at 37C. The loss of PRc is apparently not the result of nuclear translocation, as extraction of the 45,000 g x 60 min pellet with KCl did not yield detectable PR at the end of the superfusion period.

These data are inconsistent with the hypothesis that the in vitro effect of P to stimulate LHRH release is mediated by a genomic mechanism involving PRc binding, and an alternative mechanism of action for P must be considered.

19.9 MODULATION OF LOCAL CEREBRAL GLUCOSE METABOLISM BY ESTROGEN AND PROGESTERONE IN THE HYPOTHALAMUS OF OVARIECTOMIZED FEMALE RATS. L. Porrino*, H. Namba*, A. Crane*, J. Jehle*, L. Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda MD 20205.

The gonadal hormones, estrogen and progesterone, have been shown to have potent influences in the central nervous system, particularly in the hypothalamus. The 2-deoxyglucose autoradiographic method was used to identify the neural circuits upon which these hormones act to regulate sexual behavior in the female rat. Three groups of female Sprague-Dawley rats ovariectomized (OVX) 2-3 weeks prior to study were used: 1) OVX control; 2) OVX implanted subcutaneously with Silastic capsules containing 10% estradiol (E2) for 48 hours; and 3) OVX, implanted as group 2, injected with 500 µg progesterone (P) 4 hours before the start of the experiment. Local cerebral glucose metabolism (LCGU) was studied by the deoxyglucose method with particular emphasis on the nuclei of the hypothalamus. E2 treatment significantly increased LCGU in the anterior, ventromedial, lateral and posterior hypothalamic areas when compared to OVX controls. No significant changes were seen in any other hypothalamic region. In contrast, in animals receiving E2 + P treatment, LCGU was reduced in the lateral preoptic, magnocellular portion of the preoptic area and suprachiasmatic nucleus, as well as in the anterior hypothalamus in comparison to metabolism in either OVX-control or E2-treated rats. P injections did not alter LCGU's in the ventromedial, lateral or posterior nuclei, areas which showed increases following E2 alone.

These data demonstrate an anatomical separation of the effects of gonadal steroids in the hypothalamus. E2 facilitates neural activity in the mid and posterior portions of the hypothalamus, while E2 in combination with P suppresses activity in the anterior-preoptic region. The two distinct patterns of alteration of LCGU in the anterior and posterior regions of the hypothalamus may reflect differential involvement in feminine sexual behavior.

19.10 CONTROL OF FEMININE SEXUAL BEHAVIOR WITH INTRAVENTRICULAR INFUSION OF CHOLINERGIC AGENTS. P.J. Barr*, G.P. Dohanich, and L.G. Clemens. Hormones and Behavior Laboratory, Michigan State Univ., East Lansing, MI 48823.

Sexual behavior in the female rat is regulated by the ovarian hormones, estrogen and progesterone. Evidence indicates that this behavior, characterized by the postural lordosis response to a mount by a male, may be mediated within the brain by cholinergic mechanisms. The experiments reported further analyze cholinergic influences on lordosis.

Ovariectomized female rats were implanted with bilateral cannulae in the lateral ventricles. In the first experiment, females were primed intramuscularly with 0.13 µg estradiol benzoate (EB) for 3 days prior to intraventricular infusion of carbamylcholine chloride (carbachol), a cholinergic agonist. This estrogen regimen by itself fails to activate sexual behavior in female rats. A dose-related facilitation of lordosis was observed over the 4 concentrations of carbachol used (0.125, 0.25, 0.5, 1.0 µg/cannula in 0.5 µl volumes). Highest levels of response were observed 15 minutes after intraventricular infusion. This facilitation was completely prevented by systemic pretreatment with 2 mg atropine sulfate, a muscarinic receptor blocker. In a second experiment, ovariectomized females were primed with 0.13 µg EB for 3 days and intraventricularly infused with eserine sulfate, an acetylcholinesterase inhibitor. Facilitation of lordosis occurred in a dose-dependent manner over 3 concentrations (2.5, 5.0, 10.0 µg/cannula in 0.5 µl volumes). Highest responses were observed 15 minutes after infusion. In the third experiment, females were primed with 0.25 µg EB for 3 days and 0.5 mg progesterone on day 4. This estrogen-progesterone regimen by itself activated a high level of feminine sexual behavior. Five hours following progesterone treatment, scopolamine HCl, a muscarinic receptor blocker, was infused intraventricularly. Infusion of scopolamine resulted in a transient, dose-related reduction in lordosis over the 3 concentrations used (5.0, 7.5, 10.0 µg/cannula in 0.5 µl volumes). Greatest reductions were observed 15 minutes after infusion.

These results lend further support to the concept that cholinergic brain mechanisms may mediate hormonal influences on sexual behavior in female rats.

This research was funded under USPHS Grant HD-06760.

19.11 INTRACEREBRAL ANISOMYCIN BLOCKADE OF PROGESTERONE FACILITATED ESTROUS BEHAVIOR IN RATS IS SITE SPECIFIC. Jeffrey H. Glaser*, Susan C. Cislo*, and Ronald J. Barfield* (SPON: A. Hyndman). Department of Biological Sciences, Livingston Campus Rutgers University, New Brunswick, NJ 08903

The mechanism of progesterone (P) action in the facilitation of estrous behavior in estrogen-primed rats is not known. The existence, however, of estrogen-induced progestin receptors that translocate to the nucleus following P administration suggests that P may act via a genomic protein synthetic mechanism. Furthermore, whereas evidence for the neural site of P action in estrous behavior implicates the ventromedial hypothalamus (VMH), other sites including the preoptic area (POA) and the midbrain (MB) have also been implicated. Recently, Rainbow et al. (Br. Res. 233,1982) reported that VMH implants of the protein synthesis inhibitor anisomycin (ANI) inhibited the P facilitation of estrous behavior; these authors, however, did not investigate other brain sites, nor were nonspecific behavioral effects assessed. The present study was carried out in order to examine the effects of intracerebral implants of ANI in the VMH, POA, and MB on the facilitation of estrous behavior by progesterone.

Female Long-Evans rats (220-250g) were stereotaxically outfitted with 23 gauge bilateral guide cannulae directed towards the VMH (N=24), POA (N=8), and MB (interpeduncular nucleus, N=9). Following ovariectomy and insertion of sc 5% estradiol 17-beta silastic capsules for estrogen priming, animals received two tests in a counterbalanced design. Thirty minutes following the lowering of 28 gauge inner cannulae, which were either filled with ANI or blank, all animals were injected with 500 ug P sc. Cannulae were removed 2 h after P, and at 3 h several animals from each group were given a general activity test. At 4 h all animals were tested for estrous behavior with a vigorous male. Lordosis quotients (LQ) and solicitation scores (SS = # of darts and hops/ 10 mount test) were recorded.

Results showed that the anisomycin blockade of the progesterone activation of estrous behavior is site specific. Animals with ANI placed in the VMH showed little sexual behavior 4 h following P treatment (LQ=30.5±5.8; SS=1.8±.64; 29% proceptive). In contrast, animals with ANI placements in the POA (LQ=77.5±7.3; SS=15.6±3.0; 100% proceptive) and the MB (LQ=87.8±4.0; SS=10.2±2.1; 89% proceptive) were relatively unaffected. All animals appeared to be healthy, and no deficits in general activity were observed. Findings from any behavioral study using protein synthesis inhibitors must be viewed with caution. Nevertheless, the results of this study provide additional support for the essential role of the VMH as the primary site of P action, and they are consistent with the hypothesis that P acts to promote estrous behavior via a protein synthetic mechanism.

19.12 NORMAL DIFFERENTIATION OF SEXUAL BEHAVIOR IN MALE FERRETS DESPITE NEONATAL INHIBITION OF BRAIN AROMATASE OR 5α-REDUCTASE ACTIVITY. M. J. Baum, J. A. Canick*, M. S. Erskine*, C. A. Gallagher*, and J. G. Shim*. Dept. of Nutrition, M.I.T., Cambridge, MA 02139 and LHRRB, Harvard Medical School, Boston, MA 02115.

Male ferrets received s.c. implants of silastic capsules containing either the aromatase inhibitor, androst-1,4,6-triene-3, 17-dione (ATD), the 5α-reductase inhibitor, testosterone-17β-carboxylic acid (17βC), or no hormone for 15 days beginning at birth; an additional group of females received empty capsules during the same neonatal period. All animals were gonadectomized at 11 weeks and then were tested for masculine sexual behavior after a counterbalanced sequence of treatments with testosterone, estradiol, and 5α-dihydrotestosterone. Regardless of the neonatal treatment received, all groups of male ferrets displayed significantly higher levels of neck grip, mounting, and pelvic thrusting behavior than control females in adult tests. The three groups of males as well as the females all showed equivalent, dose-dependent increments in receptive behavior after administration of estradiol benzoate. Additional groups of newborn male and female ferrets were implanted s.c. with capsules containing ATD, 17βC, or no hormone, and were later killed on postnatal day 7. Administration of ATD, but not 17βC, strongly inhibited aromatase activity in hypothalamus + preoptic area (H + POA). The activity of 5α-reductase was very low in both H + POA and in cerebral cortex regardless of neonatal treatment. Neonatal administration of 17βC, but not ATD, caused a further reduction of 5α-reductase activity in cortex. Plasma concentrations of testosterone were equivalent on postnatal day 7 in males given ATD, 17βC, or no hormone at birth. The results suggest that behavioral defeminization fails to occur in ferrets of either sex whereas behavioral masculinization occurs in the male in response to the neonatal action of testosterone itself, as opposed to its estrogenic or 5α-reduced androgenic metabolites.

19.13 ANDROGEN AND ESTROGEN RECEPTORS IN DEVELOPING FERRET BRAIN. C. C. Vito, M. J. Baum, T. O. Fox, C. A. Gallagher* and M. S. Kindy*. Dept. of Neuropathol., Harvard Med. Sch., Boston, MA 02115 and Dept. of Nutrition, M.I.T., Cambridge, MA 02139.

Sexual differentiation of ferret brain appears to be developmentally and behaviorally distinct from that of rodents (mice, rats, hamsters) in that organization of male coital behavior is primarily modulated by testosterone rather than estrogen. In ferrets, the "critical period" of behavioral differentiation appears to be entirely neonatal, and sex hormones affect only masculinization, not defeminization, of adult coital behavior (Baum et al., Endocrinology, in press, 1982).

We investigated the possibility that the sex hormone receptor mechanisms in ferret brain are biochemically and/or developmentally distinct from that in rodents. Using DNA-cellulose affinity chromatography (Vito and Fox, Dev. Brain Res. 2: 97-110, 1982), we have characterized androgen and estrogen receptors in ferret brain 5 days before birth (42-day gestation period), at postnatal days 7 and 15, and in adulthood. Biochemically, both the androgen- and estrogen-binding activities in cytosol extracts of anterior hypothalamus-preoptic area, medial basal hypothalamus, temporal lobe and cortex at all ages tested are similar to those in rodent brain: Androgen-binding activities exhibit elution maxima at 120 - 140 mM NaCl while estrogen-binding activities exhibit elution maxima at 200 - 220 mM NaCl, and putative adult androgen receptors bind both dihydrotestosterone and testosterone while estrogen receptors bind both estradiol and diethylstilbestrol.

In contrast, the developmental profiles of androgen and estrogen receptors in ferret brain appear to differ from those in rodent brain. In ferret hypothalamus and preoptic area (H + POA), androgen receptor concentrations are relatively high prenatally and remain high through the "critical period" and into adulthood, whereas in mice and rats androgen receptor concentrations are lower at prenatal ages and increase gradually to similar levels in adulthood. Likewise, estrogen receptor concentrations in ferret H + POA are high prenatally and remain high through early postnatal ages (see also Holbrook and Baum, in press, 1982); these levels are higher than those detected at any age in either mouse or rat H + POA. In ferrets, estrogen receptor concentrations are higher than those of androgen receptor at prenatal and early postnatal ages while both approach more similar levels in adulthood. To date, we have not detected sex differences in either receptor system.

The persistently high concentration of androgen receptors, together with the changing ratio of estrogen to androgen receptor, in postnatal H + POA may contribute to the ferrets' high responsiveness to testosterone and to the timing of its neonatal "critical period."

19.14 COMPETITION FOR ANDROGEN RECEPTOR SITES BY FLUTAMIDE AND ITS METABOLITES. B. Gladue* (SPON: R.E. Whalen). Long Island Research Institute, SUNY at Stony Brook, NY 11794.

Flutamide (FLU; 4'-nitro-3'-trifluoromethylisobutyranilide), the non-steroidal antiandrogen has been shown to interfere with testosterone-induced behavioral sex differentiation (Clemens, et al. Horm. Behav. 10,40,1978) and adult sexual behavior (Gladue, B.A. and Clemens, L.G. Endo. 106,1917,1980). Yet, in vitro studies demonstrate poor inhibitory properties of FLU upon androgen binding to steroid receptors. Possibly FLU action upon CNS tissues may require in vivo conversion to a more active metabolite with greater inhibitory properties. To test this hypothesis, metabolites of FLU were evaluated for their relative effectiveness at competing with ^{3}H-DHT for androgen receptor sites in hypothalamic-preoptic area (HYPOA) and cerebral cortex (CTX) tissues of adult short-term castrated male rats.

Cytosol extracts were incubated (4° C) for 18 hrs with 2 nM ^{3}H-DHT alone or with 200 nM DHT, FLU, the hydroxy metabolites of flutamide, SCH 16423 (α,α,α-trifluoro-2-methyl-4'-nitro-m-lactotoluidide) and RU 23908 (5,5-dimethyl-3-[4-nitro-3-(trifluoromethyl)phenyl-2,4-imidazolidine-dione). For comparison, a steroidal antiandrogen R 2956 (17β-hydroxy-2,2,17-trimethyloestra-4,9,11-triene-3-one) was also evaluated for its ability to compete for ^{3}H-DHT. Bound ^{3}H-DHT was measured after separation with Sephadex LH-20 chromatography. Percentage inhibition was computed on the basis of relative effectiveness to that of 200nM DHT, which was arbitrarily designated as 100%.

COMPETING SUBSTANCE	HYPOA	CTX

These data demonstrate that the metabolites of Flutamide are more effective at competing for androgen receptor sites than that of Flutamide itself, in both HYPOA and CTX. Therefore, the antiandrogenic actions of FLU may require in vivo metabolism to a more active form suggesting that FLU interference with testosterone-mediated processes may result from one of its metabolites.

20.1 OPIOID PEPTIDES MAY MEDIATE THE IMMUNOSUPPRESSIVE EFFECT OF STRESS. Y. Shavit, J.W. Lewis, G.W. Terman*, R.P. Gale*, and J.C. Liebeskind. Departments of Psychology and Medicine, UCLA, Los Angeles, CA 90024.

A number of studies indicate that stress can modulate the responsiveness of the immune system (see review by Solomon and Amkraut, 1981). Several findings suggested to us that this modulatory effect may be mediated by opioid peptides released during stress. Inescapable, but not escapable, stress causes opioid mediated analgesia in rats (Maier et al., 1980). Inescapable, but not escapable, stress can also enhance tumor development in animals (Sklar and Anisman, 1979; Visintainer et al., 1982). In addition, opiate antagonists were found to inhibit tumor growth and prolong survival of animals given tumors (Aylsworth et al., 1979; Zagon et al., 1981). Taken together, these results suggest the involvement of opioid peptides in the development of tumors, possibly via modulation of the immune system. To test this hypothesis we employed two types of footshock stress, one shown to induce an opioid, the other a nonopioid, form of analgesia (Lewis et al., 1980; 1981). We examined the effects of these stressors on the reactivity of the immune system to two different lymphocyte mitogens.

Rats were subjected to either the opioid (2.5 mA, 1 sec every 5 sec, for 20 min) or the nonopioid (2.5 mA, for 3 min continuously) footshock stress paradigms. Two or 24 hrs after stress, rats were exsanguinated by heart puncture. The whole blood was separated by Ficoll-hypague gradient centrifugation and the mononuclear cell fraction was recovered. 2×10^5 cells were cocultivated with the lymphocyte mitogens Con A (1 µg) or PHA (1:20), and cell proliferation (DNA synthesis) was determined 72 hrs later by the incorporation of ^{3}H-thymidine.

The opioid stress paradigm significantly decreased the response to both mitogens (to ca. 35% of control values) in cells obtained 2 hrs after stress. The response of cells obtained 24 hrs later was slightly elevated compared to controls (143% for con A, 134% for PHA). In contrast, the response of cells obtained 2 hrs after the nonopioid stress paradigm did not differ from the control response. Finally, preliminary data indicate that the immunosuppressive effect of the opioid type of stress is blocked by the opiate antagonist naltrexone (10 mg/kg). These results provide evidence that the immunosuppressive effect of stress is mediated, at least in part, by opioid peptides. (Supported by a gift from the Brotman Foundation.)

20.2 AUTONOMIC INNERVATION OF THYMIC/LYMPHOID TISSUE IN THE THORACIC CAVITY OF NUDE MICE. A. Lapa*, M. Teiche*, K. Bulloch. Dept. of Neurology, SUNY-Stony Brook. Sch. of Med., Stony Brook, NY 11794

During the perinatal period, the development of integrity in the function of the thymus gland is crucial to the formation of a competent immune system and the neuroendocrine axis. Recent studies now indicate that differentiation of the thymus occurs after it is innervated by fiber of the vagus nerve suggesting a role for innervation in the development of this gland. To test this hypothesis, we have examined innervation of rudimentary structures of putative thymic origin within the thoracic cavity of nude mice. This mutant was chosen because alterations in thymic development occur at a time concomitant with the innervation of the gland by vagal fibers. Acetylcholinesterase (AchE) histochemistry was used to demonstrate parasympathetic terminals in the nude thymic rudiment and sympathetic innervation was shown by glyoxylic acid fluorescence histochemistry techniques. Routine histology was used to examine the relationship of peripheral fibers and ganglia to lymphoid tissue.

Nude mice have a polycystic organ and numerous aberrant lymphoid accumulations (LA) and lymph nodes (LN) within the thoracic cavity. The lymphoid tissue is always found in close association with ganglia, nerve fibers, or both. This association also is found in wild type mice. In many cases,the morphology of the LA resembles that of the LN,however, they fail to demonstrate lymphatic afferent drainage. The sympathetic (CA) and parasympathetic (AchE) innervation of nude LN is similar to the wildtype mouse. CA fibers are evident within the capsule, along the vasculture and in discrete areas within the interior of the nodes. Cholinergic fibers are also present in the capsule along the vasculature and "in transit" along the outer parenchama of the node. Very few CA and cholinergic fibers are found within the stroma of LAs in either nude or wildtype mouse. The nude polycystic organ also demonstrates very limited innervation by CA or AchE histochemical techniques. No fibers are evident among the cells of the cyst nor are any present in its outer boarders. The lack of cholinergic innervation in the polycystic organ and those LA reported to be thymic rudiments (Holub, 1975) is in accord with the view that vagal innervation plays a role in thymic development. In addition, the observation that many LN and LA tissue develop in association with ANS fibers and ganglia suggest the organization of other immune system tissue also may be dependent on the nervous system.

20.3 BINDING CHARACTERISTICS OF A NOVEL CHOLINERGIC RECEPTOR SITE ON MURINE LYMPHOCYTES. John J. Grayhack*, Samir F. Atweh, and David P. Richman*(SPON: M.A. Hollyday) Dept. of Neurology, The University of Chicago, Chicago, IL 60637.

Following observations of cholinergic receptors on lymphocytes we have shown contrasting functional responses of these cells to carbamylcholine (Richman, D.P. and Arnason, B.G.W., Proc. Natl. Acad. Sci.USA 76, 4632). The stimulatory response is blocked by muscarinic antagonists and the suppressive response by nicotinic antagonists. In light of these findings, we have investigated a cholinergic binding site on isolated adult mouse spleen lymphocytes, demonstrated with the use of the muscarinic antagonist ^{3}H-quinuclidinly benzilate (^{3}H-QNB). This binding site has shown affinities and specificity differing from muscarinic receptor sites in rat brain tissue. In our mouse spleen lymphocytes, binding was displaceable by both muscarinic and nicotinic antagonists. In view of this unusual specificity we were led to investigate the kinetics and displacement of this binding site.

Lymphocytes were prepared from the spleens of Swiss mice, and the red cells were separated either by ammonium chloride lysis at 4°C or by centrifugation on a Ficoll-hypaque discontinuous gradient. Adherent cells were removed by incubation on plastic. The lymphocyte fraction was incubated with 2nM ^{3}H-QNB in phosphate buffered saline for 30 minutes at room temperature and free ligand removed by either filtration or centrifugation. 80-90% of the ^{3}H-QNB binding was displaceable by cholinergic ligands. The possibility of QNB uptake was discounted by the demonstration of binding to membrane preparations and by the rapid rate of dissociation of the bound ligand. Multiple cholinergic ligands competed for binding with ^{3}H-QNB including atropine, scopolamine, acetylcholine, α-bungarotoxin, and d-tubocurarine. Unlabeled QNB competed for binding in a biphasic manner suggesting two binding sites with IC_{50}'s of 0.1µM and 5µM respectively. Atropine and d-tubocurarine displaced ^{3}H-QNB with IC_{50}'s of 50µM and 70µM respectively. Under similar conditions, binding of ^{3}H-QNB to rat brain membranes was displaced with unlabeled QNB and atropine with IC_{50}'s of 1 and 7nM while d-tubocurarine had an IC_{50} of 10µM.

In summary, we have demonstrated a QNB binding site on splenic murine lymphocytes which is competed for by several cholinergic ligands. It differs from classical muscarinic sites by its relatively low affinity to QNB and by the fact that muscarinic and nicotinic antagonists are almost equipotent in displacing ^{3}H-QNB. The lymphocytic receptor is of unknown physiological significance but any such receptor may be functionally relevant and provide a means of selective pharmacological control of immunologic response or pathology. This consideration is especially true in the case of myasthenia gravis, in which an autoimmune response against receptors is associated with reduced suppressor cell function.

20.4 INCREASED β-ADRENERGIC RECEPTORS ON SPLEEN LYMPHOCYTES FROM MICE LACKING PERIPHERAL SYMPATHETIC NERVOUS SYSTEM. K. Miles*, G. Otten*, S. Atweh*, E. Chelmicka-Schorr* and B. Arnason. Dept. of Neurology, Univ. of Chicago, Chicago, IL 60637.

A role for the sympathetic nervous system in regulating the murine immune response in vivo has been demonstrated previously. We reported a significantly enhanced antibody forming cell response to 2 thymus-independent antigens in mice treated with 6-hydroxydopamine to destroy peripheral sympathetic nerve endings (axotomy). (Miles, K. et al, J. Neuroimmunol. 1:101, 1981).

Recently we studied lymphocyte β-adrenergic receptors to probe the cellular events responsible for this increased antibody production in axotomized mice. β-adrenergic receptors on axotomized and control A/J male mouse spleen lymphocytes were quantitated using ^{3}H-dihydroalprenolol (DHA). Whole cells, nonadherent to plastic culture dishes to exclude macrophages and erythrocyte depleted either by NH_4Cl lysis at 4°C or by centrifugation on a Ficoll-hypaque gradient, were incubated with ^{3}H-DHA in phosphate buffered saline for 30 minutes at 25°C. The cells and bound ligand were then separated either by rapid filtration or by centrifugation. Specific binding, displaceable by 10^{-4}M propranolol, accounted for 80% of the total binding. Spleen lymphocytes from axotomized animals show a 40-60% ($p < .01$) increase in ^{3}H-DHA binding. Scatchard analysis reveals an increase in the number of binding sites.

To examine the correlation between receptor density and lymphocyte function, we separated control mouse spleen lymphocytes into B and T subpopulations on nylon wool columns and then measured β-adrenergic receptors. A 2-3 fold enrichment of specific binding was detected on the B compared to T cell populations. We attempted to distinguish whether axotomized mouse lymphocytes have more receptors per cell or whether a population shift occurred in the direction of more B cells which could also explain the increased number of binding sites. We labeled the B cells of spleen lymphocytes with fluoresceinated goat anti-mouse Ig. Using flow cytometry to detect and quantitate small positive cells, we report a 25% decrease in the number of B cells present in axotomized mouse spleen lymphocyte populations.

The reduction of the higher density receptor B cell population in axotomized mice further enhances the significance of the difference in receptor number of axotomized compared to control mouse lymphocytes. Recent data suggests that both T and B cells in axotomized mice have increased receptor sites. We postulate a denervation hypersensitivity event occurring after axotomy. These findings illustrate a further link between sympathetic nervous system activity and immune function.

20.5 A LIGHT AND ULTRASTRUCTURAL ANALYSIS OF INNERVATION OF THE THYMUS GLAND DURING THE PERINATAL PERIOD. K. Bulloch. Dept. of Neurology School of Medicine. SUNY at Stony Brook, Stony Brook, NY 11794.

Recent studies reveal the thymus receives direct projections from the CNS prior to birth. (Bulloch & Moore, 1981, Bulloch & Loy, 1981). In order to further characterize this innervation, a qualitative light and ultrastructural analysis of the thymus of the C57BL/6J mouse during embryonic and perinatal development was undertaken. Routine light and ultrastructural histology was used to examine the development of the thymus from E-13 - P-3.

Light and ultrastructural analysis revealed that the thymus is innervated by the Vagus prior to E-13. The nerve penetrates the thymus in the cervical area and descends with the gland into the thoracic cavity. Fibers are distributed throughout, terminating in areas that define the future cortico-medullary boundaries and to a discrete layer of cells adjacent to the capsule. Growth cones, most likely derived from the Vagal fibers, are common within the thymus through E-18, and become less frequent as the mouse approaches P-3. Some of these cones form synapses with each other and contain clear spherical vesicles 40-50 nm at presynaptic terminals. Other fibers are found to form synapses with processes and soma of thymic stroma cells. Two cell types are associated in areas of dense synaptic contacts. A large, clear cytoplasmic cell at the developing cortico-medullary boundary and a dense "reticular-like" cell located at the outer perimeter of the developing cortex. Vescicular content of the fibers and boutons associated with these cells vary. Large dense core vesicles 100 nm, lucent pleomorphic 50-60 nm by 25 nm vesicles as well as the clear spherical vesicle are found in synaptic profiles. Large dense core vesicles predominantly are found in boutons containing small clear spherical vesicles. All three types of vesicles are evident in various combinations in either clear or osmophilic axons and terminals. No pattern of synaptogenesis on any given cell type is apparent though synaptic contacts are more common on cell processes and other axons than on cell soma.

The temporal and terminal distribution of vagal fibers within the thymus precedes its morphological and functional differentiation. These data suggest a role for the nervous system in thymic development.

21.1 FUNCTIONAL MAPPING OF VAGAL TRUNK NEURONS IN THE DECENTRALIZED STELLATE AND MIDDLE CERVICAL GANGLIA OF THE DOG USING [^{14}C] 2-DEOXYGLUCOSE. D.R. Kostreva, J.A. Armour* and Z.J. Bosnjak. Depts. Anesthesiol. and Physiol., Med. Col. Wis. and Wood VA Med. Ctr., Milw., Wis. 53193 and Dept. Physiol., Dalhousie U., Halifax, Nova Scotia B3H 4H7.

Recent extracellular and intracellular electrophysiological and HRP studies of the stellate (SG) and middle cervical ganglia (MCG) of the cat and dog indicate that some cardiopulmonary reflexes may be mediated by these thoracic ganglia. (Bosnjak, Am. J. Physiol. 242:R237-R243, 1982; J. Physiol. 324:273-283, 1982), (Armour, J. Comp. Neurol. 202:169-184, 1981; Cardiol. 61:309-328, 1976). The functional neuroanatomical mapping technique of Sokoloff using [^{14}C] deoxyglucose (DG) was used to determine if focal changes in DG uptake could be elicited in the decentralized SG and MCG during electrical stimulation of the cut central end of the left vagus at the level of the heart. Adult dogs 3-4 kg were anesthetized with sodium pentobarbital (35mg/kg i.v.), intubated and placed on positive pressure ventilation. Systemic blood pressure and electrocardiogram were recorded using a polygraph. The left SG and MCG were decentralized by sectioning all of the vagal and sympathetic neural connections with these ganglia except for the ansae subclaviae and cardiopulmonary nerves caudal to these ganglia. The left vagal trunk sectioned just above the heart, was partially desheathed and the central end was stimulated electrically using bipolar electrodes at a frequency of 10 Hz, 0.5 ms pulse width, and a current strength of 5 mA. Prior to the initiation of stimulation, a single bolus injection of DG (Pathfinders Labs; 110 uCi/kg) was administered i.v. Periodic stimulation of the vagal trunk, one to two minutes on and one minute off, was continued throughout the 45 minute experimental period. The SG and MCG were then removed together and frozen sections were made at 20 micron increments. The sections were then covered with film for autoradiography. After a 12 day exposure, the films were developed and selected corresponding sections were Nissl stained. The results demonstrate that electrical stimulation of the cut central end of the left vagal trunk at the level of the heart can produce focal increases in DG uptake within the SG, but not within the MCG. However, in one animal, a cluster of ganglion cells located outside of the MCG had markedly increased DG uptake as compared to the MCG. It is not possible in this study to determine whether the increases in DG uptake of the SG are due to the orthograde activation of afferent or to retrograde activation of efferent neurons. However, this data does strongly suggest a functional connectivity of the SG with the vagal trunk caudal to the MCG, without a functional connectivity with the MCG. (Supported by the Dept. Anesthesiol. Medical College of Wisconsin and the Wood VA Medical Center).

21.2 DIFFERENCES IN SPONTANEOUS AND REFLEX ACTIVITY AMONG RENAL, CARDIAC, AND SPLENIC SYMPATHETIC NERVES FOLLOWING HIGH CERVICAL SPINAL CORD TRANSECTION. R.L. Meckler, H.K. Fry*, and L.C. Weaver. Dept. of Physiol., Mich. State Univ., E. Lansing MI 48824

Spontaneous activity of sympathetic nerves is depressed initially following high cervical spinal cord transection but gradually increases with time. Uniformity of the effects of spinal cord transection on basal discharge of different sympathetic nerves has not been investigated. In addition, although increasing systemic blood pressure is known to cause changes in sympathetic discharge in spinal animals, the homogeneity of such responses in different sympathetic nerves has not been assessed. Therefore, uniformity of sympathetic responses was evaluated in alpha-chloralose anesthetized cats in which the IXth and Xth cranial nerves had been severed. Sympathetic activity was recorded simultaneously from pairs of nerves (renal and cardiac, renal and splenic, cardiac and splenic) during and after spinal transection at the 1st cervical segment. Blood pressure was maintained at not less than 70 mm Hg by intravenous infusion of phenylephrine when necessary.

Immediately following spinal transection, renal nerves were completely quiescent in 11 of 13 cats evaluated. In the remaining 2 cats renal nerve activity was depressed to less than 50% of control discharge. In contrast, splenic nerves ceased firing after transection in only 1 of 7 cats, activity was depressed to less than 50% in 3 cats and was unchanged or increased in 3 cats. Similarly, cardiac nerve activity was abolished immediately in only 1 of 9 cats, was depressed to less than 50% in 4 cats and was unaffected or increased in 4 cats. Recovery of spontaneous discharge also differed among the 3 populations of nerves.

Increasing systemic arterial pressure from 78±3 to 124±8 mm Hg by injection of pressor agents in 6 Cl spinalized cats produced a 57% decrease in cardiac sympathetic activity but only a 25% decrease in renal nerve discharge. The differences in these responses could not be attributed to unequal rates of spontaneous discharge in the 2 nerves. The sympatho-inhibition may have originated in part from activation of cardiac spinal afferent neurons. In 3 spinal cats stimulation of epicardial receptors by bradykinin caused 39% inhibition of cardiac nerve activity whereas renal nerve activity was excited or unaffected by this stimulus.

These results indicate that cardiac, splenic and renal sympathetic nerves are not dependent to the same extent upon supraspinal drive for basal excitability. Moreover, in spinal cats, cardiac and renal nerves were unequally sensitive to inhibitory influences initiated by increasing systemic arterial pressure.

21.3 VENOUS AFFERENT CONTRIBUTION TO DISTRIBUTED NEURAL CONTROL OF THE MUSCLE-TONUS VENOPRESSOR MECHANISM. F.J. Thompson and B.J. Yates*. Dept. of Neuroscience, Univ. of Fla. Coll. of Med., Gainesville, FL 32610.

A problem of major significance in the neural control of the cardiovascular system is how the central nervous system controls venous return during and subsequent to changes in posture. The CNS mediated change in skin and visceral venous capacitance in response to central baroreceptor inputs has emphasized a dynamic role for these two venous components in the regulation of circulation. Understanding of the role of peripheral venous afferents in the neural control of circulation has been prevented by the lack of details regarding their properties and connections in the CNS.

Although it is known that orthostasis leads to blood pooling in the long limb veins and subsequently, to volume pooling in skeletal muscle veins, reflex control of the capacitance of the skeletal muscle venous reservoir has not been described in the classical literature.

Yandel Henderson and colleagues revealed that venous pressure in general and intramuscular venous capacitance in particular was supported by muscle tonus, and described this functional relationship as the venopressor mechanism. They recognized that the central nervous system controlled muscle tonus, but were unable to identify an input variable which was specifically related to this mechanism.

Recently, details of a peripheral venous afferent input to the spinal cord (Thompson and Barnes, 1979) to the cerebral cortex (Thompson, Lerner, Fields and Blackwelder, 1980) and to somatic motoneurons (Thompson, Barnes and Wald, 1982) were reported. The connections revealed in these studies provide the neural substrate for venous afferent elicited influences on skeletal muscle tone.

In experiments carried out on decerebrate cats spinal at T_{10}, we have observed that electrical stimulation of femoral venous afferents produced a marked increase in hindlimb skeletal muscle tone measured by recording both intramuscular pressure and muscle contraction tension.

In addition we have observed that distention of segments of limb veins in decerebrate spinal cats produced facilitation of lumbar motor neurons. Limb vein distention was also shown to elicit activity of neurons in the cerebral cortex with the principal focus in the limb motor cortex in cats anesthetized with α-chloralose.

The authors propose that the venous afferents form a major contribution to the central integration and control of intramuscular venous capacitance. The ogranization of venous afferent CNS connections as a distributed system will be discussed.

21.4 DIFFERENTIAL SYMPATHETIC REFLEXES INITIATED BY DISTENSION OF THE URINARY BLADDER AND DUODENUM. H.K. Fry* and L.C. Weaver (SPON: J.R. Hoffert). Dept. of Physiol., Mich. State Univ., E. Lansing MI

Distension of the urinary bladder and duodenum stimulates visceral afferent neurons to elicit sympathetic reflexes. This study was undertaken to determine the uniformity of responses in splanchnic sympathetic outflow to these visceral afferent stimuli. Renal and splenic sympathetic reflexes were investigated in alpha chloralose anesthetized cats in which carotid sinus and aortic depressor nerves had been severed. Activity of these multifiber sympathetic efferent nerves was recorded simultaneously. Balloon-tipped catheters were inserted into the urinary bladder and duodenum through small incisions. Reflex responses to distension of these organs were compared prior to and following vagotomy. Distension of the urinary bladder caused pressor responses and excitation of renal nerve activity whereas, splenic nerve activity was either excited or inhibited by this stimulus. Excitation of renal nerve discharge was greater than or equal to the increase observed in splenic nerve activity. The excitatory response to bladder distension was observed in both sympathetic nerves following vagotomy suggesting that this reflex was initiated at least in part by spinal afferent neurons. Distension of the duodenum initiated pressor responses and excitatory or inhibitory reflexes in renal and splenic nerves. Opposite responses were sometimes but not always observed in the two nerves. Excitation of renal nerve activity tended to be greater than that of splenic nerve activity and reciprocally, splenic nerve activity tended to be more inhibited by duodenal distension than was renal sympathetic discharge.

In summary, distention of the urinary bladder and duodenum tended to cause greater excitation of renal than splenic sympathetic discharge. These findings can be contrasted with results obtained in previous studies completed in our laboratory in which stimulation of other visceral afferent neurons caused greater excitation of splenic than renal nerve activity (Meckler et al., Neurosci 7:366, 1981). Thus, these results provide further evidence that the sympathetic nervous system is capable of non-uniform discharge and that variations in specific reflex patterns depend upon the source of afferent initiation. Support: NIH grant HL21436.

21.5 CENTRAL ORGANIZATION OF CAROTID BARORECEPTOR AND CHEMORECEPTOR PROJECTIONS IN THE CAT. S. Donoghue*, R.B. Felder*, D. Jordan* and K.M. Spyer* (SPON: M. Stewart). Department of Physiology, Royal Free Hospital School of Medicine, London, England and the Cardiovascular Center, University of Iowa, Iowa City, Iowa.

Afferent fibers in the carotid sinus nerve are known to terminate centrally in the nucleus of the tractus solitarius (NTS). However, the organization within the NTS of axons and terminal beds of specific types of afferent fibers from the carotid sinus nerve has not previously been studied.

In anesthetized artificially ventilated cats, we obtained extracellular recordings from single baroreceptor or chemoreceptor cell bodies in the petrosal ganglion. Baroreceptor units were identified by pulse rhythmical activity which was abolished by ipsilateral common carotid occlusion; chemoreceptor units were identified by increased activity in response to 30 seconds of ipsilateral common carotid occlusion or to increasing end-tidal CO_2. The brain stem projections of cells having a stable signal:noise ratio were systematically investigated using antidromic stimulation techniques previously established in this laboratory (Donoghue, S., Garcia, M., Jordan, D. and Spyer, K.M., J Physiol 322:337-352, 1982).

Baroreceptors with myelinated axons (n=6) and nonmyelinated axons (n=3) projected to medial and lateral subnuclei of NTS between 0-3 mm rostral to obex. Chemoreceptors with unmyelinated axons (n=6) terminated mainly in medial subnuclei of NTS 1.5-3.5 mm rostral to obex. Myelinated chemoreceptor units were not observed. Chemoreceptors were characterized by discrete terminations close to the main axon, while baroreceptors had widespread areas of branching and termination.

The differences in pattern of projection of carotid sinus baroreceptors and chemoreceptors suggest that these two groups of sensory receptors influence different cell populations within the NTS.

21.6 NEURONS IN THE DOG'S AREA POSTREMA ARE ESSENTIAL FOR ITS SYMPATHOFACILITATIVE CARDIOVASCULAR ACTIONS. Karen L. Barnes and Carlos M. Ferrario. Cleveland Clinic Research Division, Cleveland, OH 44106.

We have previously shown that electrical stimulation of the dog's area postrema mimics the pressor response produced by intravertebral infusion of low-dose angiotensin II, causing an increase in mean arterial pressure associated with onset tachycardia and increased peripheral resistance (Barnes, K.L., Ferrario, C.M. and Conomy, J.P.: Circ. Res. 45: 136, 1979). In order to show that this pressor mechanism is initiated by neurons localized within the area postrema it was necessary to eliminate the possibility that the pressor pathway within the area postrema consisted of efferent fibers of passage from some distant pressor region. Thus we examined the characteristics of the area postrema pressor response before and after: 1) surgical transection of the brainstem at the midcollicular level, and 2) microinjection of kainic acid into the area postrema. In morphine-chloralose anesthetized dogs the area postrema was stimulated with 20 sec trains of 0.2 msec pulses at 50 Hz and 20, 50 and 80 μA (threshold 10 μA). Midcollicular transection in 3 dogs did not alter resting mean arterial pressure or heart rate (before: 118 ± 9 mmHg, 55 ± 6 beats/min; after: 110 ± 7 mmHg, 60 ± 9 beats/min) or the magnitude of the area postrema pressor responses at 20, 50 and 80 μA. Peak increases in mean pressure were 19 ± 1, 30 ± 3 and 40 ± 4 mmHg in the intact state and 20 ± 1, 32 ± 3 and 46 ± 6 mmHg after transection; peak heart rate increases were 15 ± 4, 31 ± 7 and 50 ± 10 beats/min before and 18 ± 6, 26 ± 5 and 42 ± 5 beats/min after transection. In 4 other dogs kainic acid (10 nmoles in 1 μl phosphate buffered saline) was microinjected into the right area postrema, and 1 μl vehicle into the left area postrema. Mean arterial pressure rose to 227 ± 7 mmHg, and heart rate to 97 ± 3 beats/min, but returned to control values during the next two hours. When electrical stimulation was repeated, the pressor responses were unaltered in the left area postrema (vehicle) and abolished in the right area postrema after kainic acid. The site and extent of damage produced by the kainic acid were histologically verified. These results provide evidence that the area postrema pressor pathway is initiated by neurons within the area postrema, rather than by fibers of passage from other pressor centers. Supported by grants from NHLBI (HL-6835) and the Reinberger Foundation.

21.7 CARDIOVASCULAR RESPONSES ELICITED BY ELECTRICAL STIMULATION OF MIDLINE NEOCORTEX AND THE MEDIODORSAL AND ANTERIOR THALAMIC NUCLEI OF THE CONSCIOUS RABBIT. Shirley L. Buchanan, and D. A. Powell, Neuroscience Lab., VA Hospital and Univ. of South Carolina, and James Buggy, Dept. of Physiology, Univ. of South Carolina School of Medicine, Columbia, S.C.

Previous studies revealed that electrical stimulation of midline neocortex (precentralis agranularis) in conscious rabbits elicited pronounced bradycardia and vasodepressor responses. The bradycardia was abolished by atropine but was unaffected by propranolol or phentolamine. In the present study, stimulation subsequent to the injection of 1.6 mCi/kg of ^{3}H-2-deoxyglucose resulted in increased metabolic activity, ipsilateral to the electrodes, in both anterior and mediodorsal nuclei of the thalamus. Other experiments mapped the dorsal thalamus, especially the MD and anterior nuclei, for cardiovascular responses elicited by electrical stimulation. Responses were assessed as a function of train duration, pulse frequency, and stimulus intensity. Respiration, EMG and gross motor activity were also recorded.

Electrical stimulation of the MD and anterior nuclei of the thalamus resulted in pronounced bradycardia, in some cases preceded by a brief heart rate acceleration. The accompanying BP response was in some cases a pressor response. Administration of atropine and/or propranolol suggested that although this response is primarily vagally mediated it may be at least partially determined by sympathetic inhibition. It was also shown that the bradycardiac response was not due to elicitation of the baroreceptor reflex, since α-receptor blockade (phentolamine) abolished the BP response but left the bradycardiac response intact. Stimulation in other regions of the thalamus (usually more anterior) resulted in monotonic BP depressor responses and HR decelerations. Again, the HR decelerations were atropine dependent, but were unaffected by propranolol or phentolamine. These cardiovascular responses were in all cases accompanied by increases in respiration frequency and decreases in depth. At stimulus parameters which elicited pronounced cardiac and vascular changes, no movement occurred.

These studies suggest that the bradycardia and depressor responses elicited by anterior midline cortical stimulation are related to pathways from the anterior cingulate to the anterior and MD nuclei of the thalamus. Other types of cardiovascular responses are generated in MD nuclei, but the nature and behavioral significance of these responses is unclear at the present time.

21.8 CENTRAL CONTROL OF THE CARDIOVASCULAR AND RESPIRATORY COMPONENTS OF THE CEREBRAL ISCHEMIC RESPONSE (CIR). James R. Haselton*, Howard H. Ellenberger*, Philip M. McCabe, and Neil Schneiderman. Program in Behavioral Medicine, Dept. Psych., Univ. of Miami, Coral Gables, FL 33124.

The CIR consists of elevated arterial blood pressure, profound bradycardia, apnea, and isoelectric cortical EEG. We have reliably reproduced this pattern in rabbits using bilateral occlusion of the vertebral and common carotid arteries. Each vertebral artery was occluded by packing cotton dental pellets into the transverse foramen of the C2 vertebra. The common carotid arteries were temporarily occluded to induce brief episodes of cerebral ischemia (CI).

Cervical vagotomy transformed the bradycardia component into tachycardia, indicating that the bradycardia is vagally mediated. Aortic nerve section attenuated, but did not abolish, the bradycardia component, suggesting that at least part of the cardiodeceleration is a centrally mediated primary bradycardia. Neither of these nerve sections altered the blood pressure or respiratory components of the CIR. Artificial ventilation and neuromuscular blockade failed to alter the heart rate and blood pressure components, demonstrating that these components are not secondary to the apnea. Previous work has shown that the CIR persists after pontomedullary transection, whereas spinal cord section at C1 abolishes the reflex hypertension. These observations indicate that the CIR is organized in the medulla. Extracellular recordings were made of medullary neurons before, during, and after repeated brief episodes of CI. Inspiratory neurons were found in the dorsal medulla that responded to bilateral vertebral and carotid occlusion with a decrease or cessation of firing. Conversely, cardiovascular-related neurons were found in the dorsal vagal nucleus that increased their discharge rate during the four-vessel occlusion.

CI episodes are a common risk following cardiac arrest or during profound hypotension. The four-vessel occlusion technique appears to be clinically interesting insofar as it permits venous drainage of the head to remain uncompromised. Present experiments directed towards understanding the neuronal control of the circulation in response to CI and its sequelae should be useful in elucidating the role of circulatory adaptations in reestablishing cerebral perfusion following CI.

21.9 ALPHA ADRENERGIC RECEPTOR SITE BINDING IN THE FOREBRAIN AND BRAINSTEM OF THE DAHL RAT MODEL OF HYPERTENSION. E. Edwards*, J. McCaughran, Jr., R. Friedman*, J. Iwai* and N. Schechter. (Spon. A. Orr). Long Island Research Institute and Department of Psychiatry, SUNY at Stony Brook, NY 11794

The Dahl model of hypertension consists of two lines of rats: a salt sensitive or DS line which remains normotensive unless exposed to a high salt diet and a salt resistant or DR line which shows no change in blood pressure irrespective of salt intake. We determined the number and affinity of the α-adrenergic (α_1 and α_2) receptor sites in cortex, medulla and hypothalamus in DS and DR rats on both high and low salt diets. In addition, drug inhibition studies were performed to pharmacologically characterize the receptors.

After three weeks on their respective diets and following blood pressure determination, brain regions from DR and DS rats were homogenized and aliquots were incubated in the presence of ^{3}H-clonidine for α_2 receptors and ^{3}H-WB4101 for α_1 receptors. Non-specific binding was determined by parallel incubations with 10 μM and 100 μM (-) -norepinephrine respectively. A detailed method has been previously described (Mol. Pharmacol., 16, 1979, 57-60).

The high salt diet resulted in significant elevation in blood pressure in DS rats but not in DR rats. In the low salt condition where both lines are normotensive the DS rats had 40% fewer α_1 binding sites than DR rats in the hypothalamus. The DS rats fed high salt had even fewer α_1 binding sites than the low salt DS rats in the hypothalamus. There were no differences in the binding of the α_1 adrenergic ligand in any other brain regions. ^{3}H-clonidine binding to α_2 receptors showed no differences in any area examined in the four line x diet groups.

The affinity of both α_1 and α_2 receptors for ^{3}H-clonidine and ^{3}H-WB4101 was unaffected in all four groups. K_d values obtained from Scatchard plots were 2.84 ± .22 nM for clonidine and 0.46 ± .02 nM for WB4101. Pharmacological characterization of the α_1 adrenergic receptor revealed that the displaceability of ^{3}H-WB4101 is consistent with the specificity of the non-labeled ligand to react with α_1-receptors. IC_{50} values obtained from displacement curves followed the order: WB4101 > oxymetazoline > yohimbine > clonidine > propanolol. We have previously reported (Neuroscience meeting, 1981) an enhanced activity of the cholinergic system in the DS rats. The noradrenergic data presented here lead us to speculate that interactions between cholinergic and noradrenergic systems may play a role in the blood pressure regulation of DS and DR rats.

22.1 SPECIFICITY OF HYPOTHALAMIC-AUTONOMIC CONNECTIONS. C. B. Saper, Dept. of Neurology, Washington Univ. Sch. Med., St. Louis, MO 63110

Hypothalamic neurons project directly to preganglionic cell groups in the medulla and spinal cord, but the functional specificity of these connections is not unknown. Electrophysiological studies indicate that certain functionally specific preganglionic pools (e.g., pupillodilator, vasoconstrictor, vesicoconstrictor) may be innervated by particular subsets of hypothalamic neurons. The specificity of hypothalamic-autonomic connections has therefore been investigated by the use of retrograde fluorescence double-label methods in the rat.

Microinjections of fast blue and nuclear yellow were placed through the dorsal column into the intermediate gray matter at different levels of the thoracic spinal cord in the rat. Only injections limited to the spinal gray matter of a single segment were considered. Absence of double-labeled neurons in the red nucleus, indicating lack of uptake of dye by lateral column fibers of passage, was verified in all cases. Retrogradely labeled neurons were seen in the paraventricular and dorsomedial hypothalamic nuclei and in the lateral hypothalamic area. Small groups of neurons projecting to one labeled spinal level were interspersed with small groups projecting to the second labeled level, but no double labeled neurons were seen unless the injections were placed into adjacent spinal levels. There was no simple topographic pattern to the retrograde labeling, but hypothalamic neurons appeared to project almost exclusively to single spinal levels.

These data indicate that, like the functionally specific preganglionic neuron pools of the medulla and spinal cord, the hypothalamic-autonomic cell pools are intermixed, but have anatomically distinct targets. This organizational principle appears to underlie the functional specificity of descending hypothalamic-autonomic projections and explains the difficulty of previous investigations in identifying an organizational pattern.

22.2 **BRAINSTEM AREAS WHICH PROJECT TO CARDIAC REGIONS OF THE NUCLEUS AMBIGUUS IN RAT.** S.E. Fish, S.L. Stuesse, and K.S. Powell.* Neurobiology Program, N.E. Ohio College of Med., Rootstown, OH 44272.

The nucleus ambiguus (NA) is a brainstem structure which sends projections through the vagus nerve to the viscera, primarily heart, lung, and gut. The anatomical relationship among the NA and other brainstem structures has not been elucidated nor has the cardiac region been identified physiologically in rats. We have attempted to clarify which areas of the NA are cardioinhibitory and to determine other regions of the brainstem which send direct projections to this physiologically identified cardiac region. Stimulating electrodes were positioned sterotaxically in the medulla of anesthetized rats. Small currents (25-30ua/.2ms) were passed through the electrodes to locate regions in the ventrolateral medulla which slowed heart rate. In each rat, the area found was small (less than 200 um in diameter) very specific, and located in the most rostral portion of the NA just caudal to the facial motor nucleus. Microquantities of horseradish peroxidase (HRP Sigma type VI) were then iontophoretically ejected into this brainstem area. 24-72 hours following the HRP injection, the rats were processed for HRP reaction product using the tetramethybenzidine method. The only well-identified area from midbrain to upper cervical spinal cord which sent projections to the rostral NA was the ipsilateral medial subnucleus of the solitary tract (mnTS) HRP-filled cell bodies in the mnTS were found 1000um to 100um above the obex. A few labeled cells were found in the ipsilateral ventrolateral subnucleus of the solitary tract at the level of the obex and in the reticular formation. Control injections in reticular areas surrounding the rostral NA showed no label in the mnTS. These results are consistent with the interpretation that some of the mnTS cells project to cardioinhibitory regions of the NA. Since this NA area is also surrounded by cells with activity correlated with respiration, we can not rule out the possibility that some of these direct projections may subserve pulmonary functions. Supported by NIH HL23964 and a grant from the American Heart Association, Akron District Branch.

22.3 ASCENDING FASTIGIAL PROJECTIONS IN THE BEAGLE. R.J. Person, K. J. Dormer, and J. A. Andrezik. Depts. of Physiol. and Biophys. and of Anat. Sci., Univ. of Okla. HSC. Oklahoma City, OK 73190.

In the dog electrical stimulation of the cerebellar fastigial nucleus (FN) evokes a stimulus-bound pressor response (FPR) and baroreceptor-modulated bradycardia. Chronic stimulation in awake dogs also elicits a stimulus-bound stereotyped pattern of oral behavior of compulsive licking or grooming directed towards the forelimbs. Preliminary investigation of FN efferent pathways in the beagle was initiated using autoradiographic procedures. Beagles (10-12 kg) were anesthetized with α-chloralose (115 mg/kg); ECG electrodes and femoral artery cannulae were placed to record heart rate and blood pressure. Concentric electrodes were placed in the rostral FN and stimulation current (100-500 μA, 80 Hz) passed to localize the site eliciting maximal FPR and tachycardia. The electrode was replaced with a micropipette and a 1:3 mixture of ^{3}H-leucine and proline (60-120 μC/μl) injected in volumes of 30-120 nl. Dogs recovered for 10-14 days. The brain was processed for autoradiography using standard techniques. A description of the brain stem projections identified in these dogs was reported recently (Fed. Proc. 41:1517, 1982). Analysis of injection sites showed that significant numbers of ascending labeled axons were seen only with spread of protein label to middle and caudal FN. Injection material confined to the rostral FN resulted in labeling of fibers extending only to the substantia grisea centralis at the level of the oculomotor nucleus. With middle and caudal FN injections ascending labeled fibers were primarily contralateral to the injected FN. Fibers in transit were seen as a diffuse contingent ascending lateral to the borders of the substantia grisea centralis and oculomotor nucleus. Terminal areas were found in the deep layers of the superior colliculus bilaterally, the ipsilateral side receiving fibers decussating through superior collicular and posterior commissures. Passing the caudal pole of the thalamus the contingent splits ventral to the central medial thalamic nuclei and enters the thalamus with (1) a small decussating projection terminating diffusely in the ipsilateral ventromedial (VM) and ventrolateral (VL) nuclei, (2) a small dorsally-directed projection terminating in the contralateral medial dorsal nucleus, and (3) a larger projection to the contralateral VM and VL. Sparse labeling was observed in the centrolateral, paracentral, and central medial nuclei. It may be that the oral behavior directed to the forelimb may be an attempt to investigate or relieve odd sensation resulting from the convergence of FN and sensory projections on thalamic neurons involved in forelimb posture control. Supported by in part by USPHS grants HL 24082 and NS 16868.

22.4 PATHWAYS FROM THE FASTIGIAL PRESSOR AREA IN RAT. A. Del Bo, D.A. Ruggiero, C.A. Ross, R. Wiley and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

We sought to map projections from neurons of the rostral fastigial nucleus (FN) at sites from which electrical stimulation elicits a fastigial pressor response (Miura and Reis, Brain Res. 13, 595, 1969). Anterograde tracers, horseradish peroxidase-wheat germ agglutinin and ^{3}H-amino acids were microinjected into pressor sites of rostral FN in rats anesthetized with halothane and identified by the TMB method and autoradiography, respectively. With injections that selectively involved cells in rostral FN, anterograde transport was confined to the hindbrain and distributed primarily via two trajectories: a) the contralateral uncinate fasciculus (UF) and, b) the ipsilateral juxtarestiform body (JRB). A few additional fibers projected into the ipsilateral UF, superior medullary velum and cerebellar vermis.

The UF projections decussate within the cerebellum arch rostrally over the contralateral dorsal parabrachial n. and caudally over the dorsal convexity of the superior cerebellar peduncle. The UF passes ventrally along the lateral border of the superior vestibular n. (SVN), arches medially and traverses a ventral strip of the rostral lateral vestibular n. (LVN). At the level of SVN-LVN fibers of the UF follow two courses: 1) One group splits into a series of descending fascicles, which lie between SVN-LVN and the inferior cerebellar peduncle, are traversed by entering rootlets of the vestibular nerve, and descend caudally throughout lateral aspects of the entire vestibular complex. These give rise to a thin medially directed fiber sheet primarily traversing and terminating in ventral parts of inferior (IVN), and medial (MVN) vestibular n., perihypoglossal structures, and throughout n. parasolitarius (NPS). 2) The second group terminates throughout ventral LVN and also gives rise to fibers which leave LVN and spray ventromedially into the dorsal pontine tegmentum to terminate primarily within specific subdivisions of gigantocellular, paramedian and lateral reticular n., and n. ventralis.

The fastigial contingent of the JRB is ipsilateral and traverses SVN and LVN. It contributes to the terminal fields of the UF within LVN and IVN, but does not appear to enter the reticular formation.

Thus, the effects of FN stimulation upon blood pressure, release of vasopressin (Del Bo et al., Fed. Proc., 1982) or cerebral blood flow (Nakai et al. Brain Res., 1982) are either mediated by polysynaptic pathways or by excitation of fibers passing through the rostral FN. Projections from neurons in pressor sites of FN do not extend rostral to the hindbrain, nor descend to autonomic segments of spinal cord. The autonomic responses, therefore, may be subserved by polysynaptic pathways synapsing in hindbrain. Another possibility is that stimulation of the rostral FN excites fibers of passage originating from other regions of cerebellum.

(Supported by NIH Grant HL 18974.)

22.5 INSULAR AND MEDIAL FRONTAL CORTEX PROJECTIONS TO THE AMYGDALOID CENTRAL NUCLEUS IN THE RABBIT. B. S. Kapp, J. S. Schwaber[1], and P. A. Driscoll-Mendes*. Dept. of Psychology, The Univ. of Vermont, Burlington, VT 05405, and [1]Dupont Central Research Neurobiology Group, Glenolden, PA 19036.

Recent evidence in the rabbit has demonstrated that (1) the amygdaloid central nucleus projects directly to the nucleus tractus solitarius and the dorsal motor nucleus of the vagus nerve (Schwaber et al., 1980, 1982), (2) electrical stimulation of the central nucleus elicits bradycardia and depressor responses (Kapp et al., 1982), and (3) lesions or pharmacological manipulations within the central nucleus attenuate vagally-mediated conditioned bradycardia (Kapp et al., 1979; Gallagher et al., 1980, 1981). These data suggest a role for the central nucleus in cardiovascular regulation. As one of a series of studies designed to further elucidate the nature of this role, we are investigating the afferentation of this nucleus in the rabbit. The present study examined central nucleus projections originating in the frontal cortex.

Twenty-two rabbits received pressure injections of HRP (25-50%; 10-50nl) or the retrograde fluorescent tracers, Bisbenzimide (5-10%; 10-60nl) or Nuclear Yellow (5%; 15nl), delivered via a glass micropipette (40-60 μm tip diameter) or 26 gauge syringe needle and aimed at the central nucleus. Animals were sacrificed from six hours to three days following the injection. The HRP-injected brains were processed using the TMB procedure (Mesulam, 1978), while those injected with BB and NY were examined using fluorescence microscopy.

Central nucleus injections produced significant numbers of labeled neurons located in the lateral insular and medial frontal cortex. Those located in the insular cortex were primarily restricted to layer V of the agranular insular cortex at more rostral levels. At more posterior levels the labeled neurons were located in layers II-III as well as layer V and extended dorsally into layer V of the ventral portions of the granular insular cortex. Injections of HRP into the insular cortex resulted in anterograde labeling within the central nucleus, thereby confirming the direct cortico-central nucleus projection. Labeled neurons located in the medial frontal cortex were located primarily in layer V of the prelimbic cortex (Area 32) and were scattered throughout layers II-V of the indistinctly laminated infralimbic cortex (Area 25). While the exact terminal distribution of these cortical projections within the central nucleus has yet to be determined, the present results nevertheless demonstrate a significant cortical influence on the amygdala central nucleus and possibly on those neurons which project to medullary cardiovascular regulatory nuclei. Supported by PHS NS 16107.

22.6 DIRECT PROJECTIONS TO AUTONOMIC CENTERS OF FOREBRAIN AND BRAINSTEM FROM A CORTICAL VASOPRESSOR AREA IN RAT. S. Mraovitch, D.A. Ruggiero, C.A. Ross and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

A region of nucleus tractus solitarius (NTS) upon which cardiopulmonary afferents terminate (Ross et al. Brain Res. 223, 402, 1981) is innervated by a major projection from insular cortex (areas 13-14 of Krieg, 1946). In the present study, we sought to a) determine whether electrical stimulation of this region elicits cardiovascular responses, and b) trace anatomical pathways from active sites. Electrical stimulation of insular cortex (8 sec train, 100 μA, 50 Hz, 0.5 msec pulse duration) in anesthetized (60 mg/kg chloralose) paralyzed rats (n=5) increased arterial pressure (AP) and heart rate (HR). At active sites, threshold current was 50 μA. At optimal frequencies (50-300 Hz), and at 100 μA cortical stimulation increased AP $\leq$ 50 mm Hg and HR $\leq$ 40 bpm. Most responsive sites were concentrated between claustrum and rhinal fissure and corresponded to the insular area of Krieg. Wheat germ agglutinin-horseradish peroxidase was injected into areas corresponding to active sites, and sections processed with the TMB method. Anterogradely labeled fibers were mapped. Projections from cortex were distributed throughout brain, particularly in thalamocortical and limbic-autonomic structures. In forebrain, major unilateral projections end in n. stria terminalis, central amygdala n., lateral pallidal segment, ventral striatum. Less intense projections end in lateral and basal amygdala n., medial pallidal complex and substantia innominata. In thalamus, major projections end primarily in ventrobasal-ventromedial n., intralaminar-midline n., medial-dorsal and medial geniculate n. There were relatively weak terminals in hypothalamus, with minor projections to zona incerta, supra- and tuberomammillary n., and lateral hypothalamic fields. In midbrain and hindbrain, corticobulbar fibers heavily innervate autonomic regions of central grey, Edinger-Westphal n., parabrachial and solitary tract n., A5 area and ventrolateral medulla. Other projections were to substantia nigra, precerebellar and trigeminal n. There were no projections to spinal cord. In NTS, terminals lie primarily in gustatory zones and also overlap the baroreceptor-vagal innervation. Retrograde transport data indicate that cortical cells projecting to NTS-cardiopulmonary subdivisions are topographically distinct — lying ventral to and in a more restricted location from the origin of projections to reticular formation and gustatory NTS. Cortical control of the autonomic nervous system has traditionally been viewed as mediated by hypothalamic and corticospinal tracts. However, these results demonstrate the presence of numerous direct projections from autonomic cortex to other widely distributed autonomic areas throughout brain. These direct cortico-autonomic pathways may regulate circulatory and other autonomic functions.
(Supported by NIH Grant NS 03346.)

22.7 IDENTIFICATION OF NEURONAL POPULATIONS PROJECTING FROM THE VENTRAL MEDULLA TO OTHER NUCLEI WHICH REGULATE AUTONOMIC FUNCTIONS. J.A. Andrezik, S.R. Holmes,* S.R. Anderson* and M.W. Halterman,* Department of Anatomical Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190

The nucleus paragigantocellularis lateralis (PGCL) and the nucleus gigantocellularis, pars alpha, (GCα) project to the intermediolateral cell column of the rostral thoracic spinal cord and to other nuclei which influence the autonomic nervous system (Loewy et al., Br. Res. Rev. 3:63-80, 1981). The diverse connections of these reticular nuclei and their hetrogeneous cell populations (Andrezik et al., Anat. Embryol. 161:355-371, 1981) suggested further studies be made as to which neurons of the ventral medulla (VM) project to other autonomic nuclei and as to whether or not the same neuron sends axons to more than one nucleus.

Sprague-Dawley rats were injected with the fluorescent dye Fast Blue (FB), and one of the dyes Nuclear yellow (NY) or Bisbenzimide (BB). The injections (30-60 nl) were asymmetrical and in terminal areas of VM axons, i.e. the parabrachial nucleus (NPB), dorsal medulla (DM, including the solitary and dorsal vagal nuclei), paraventricular nucleus of the hypothalamus (PVH), periaqueductal gray (PAG), zona incerta (ZI), and intermediolateral nucleus of the thoracic spinal cord (IML). These sites were used in a variety of combinations to form pairs which were analyzed for double-labeling and for cell populations.

Neurons projecting to NPB are found bilaterally but primarily ipsilateral in the caudal PGCL; medium-sized and large triangular neurons, and some large round neurons are labeled. PVH injections result in only a few neurons labeling in the ipsilateral PGCL, while ZI injections label neurons mainly in the contralateral dorsal PGCL. These neurons are separate populations from those that project to NPB. With PAG injections the labeling is bilateral and confined to the medial PGCL and lateral GCα caudal to the facial motor nucleus. Spindle-shaped cells, as well as medium-sized and most of the large triangular neurons are labeled. Injections into DM label neurons in the caudal PGCL of both sides. Projections to the IML and spinal cord below the rostral thoracic segments originate in the ipsilateral GCα; only a few cells in the ventral PGCL contribute to this pathway.

For the most part, individual populations of neurons in VM project to separate "autonomic nuclei." In all our cases only about 10% of all labeled neurons contain both dyes; the majority of the double-labeled neurons project to PAG and DM. (Supported by USPHS grant NS-16868.)

22.8 PREGANGLIONIC NEURONS AND VISCERAL AFFERENT FIBERS IN THE RAT PELVIC NERVE. I. Nadelhaft and A.M. Booth. VA Medical Center & Depts. of Neurosurgery and Pharmacology, University of Pittsburgh, School of Medicine, Pittsburgh, PA.

The location and morphology of preganglionic neurons of the sacral parasympathetic nucleus (SPN) and the central distribution and organization of related visceral afferent fibers running in the rat pelvic nerve was determined using the horseradish peroxidase (HRP) tracing technique. HRP was applied to the central portion of the transected pelvic nerve of adult female Sprague-Dawley rats (about 450 gm) which were sacrificed two days later. The SPN was located ipsilaterally in S1 and L6 and formed a continuous column of about 850 cells extending 3.7mm rostrocaudally. In transverse sections, cells were found in a pocket about 100μm in diameter along the lateral gray-white border at the base of the dorsal horn. Cells were round, triangular and spindle shaped (average size: 11x20μm) and were oriented in all directions. Dendrites extended into the dorsolateral funiculus, the lateral marginal zone of the dorsal horn, and horizontally into the dorsal gray commissure. Axons ran along the lateral gray-white border.

Afferent fibers transported HRP to the ipsilateral dorsal root ganglia (DRG) and from there to the spinal cord. Labelled cells (average size: 19x29μm) were found in S1 and L6 DRGs in numbers proportional to the numbers of SPN neurons found in corresponding cord segments. Centrally, afferent fibers entered Lissauer's tract (LT) via the S1 and L6 dorsal roots and were observed in LT rostrally as far as L2, and caudally to S3. Afferent collateral fibers from LT formed two groups: a prominent lateral projection located along the lateral margin of the dorsal horn and which entered the SPN region, a less prominent medial projection extending along the dorsal margin of the dorsal horn and alongside the dorsal columns to the dorsal gray commissure. When observed in horizontal sections, these collateral groups were seen to be organized into periodically spaced fiber bundles (average center to center distance: ∿100μm).

An unexpected bundle of afferent fibers was observed just below the ventral border of the central canal. It was 10μm in diameter and was observed to run continuously from S3 to L2. The source of these fibers was not determined.

In summary, with the exception of this unusual afferent bundle, the organization of pelvic nerve afferents and efferents in the rat paralleled the results of similar studies in cats and monkeys. Features in common were: 1) the location of the SPN, the number of preganglionic neurons and their dendritic patterns, 2) the division of afferent collaterals into strong lateral and weaker medial projections and the periodic organization of these collaterals, 3) the relationships among collateral projections, preganglionic neurons, and dendrites.

22.9 THE ORIGIN OF RENAL SYMPATHETIC EFFERENTS, AND THE CENTRAL PROJECTION OF RENAL AFFERENTS IN CAT. D.C.Kuo, W.C.deGroat, I. Nadelhaft, T.Hisamitsu*, and M.G.Backes*. Dept.of Pharmacology, Univ. of Pittsburgh, Sch. of Medicine and VA Medical Center, Pittsburgh, PA 15261

The cells of origin of renal efferents, and the segmental distribution and central projection of renal afferents in adult cats and kittens were studied by the technique of retrograde and anterograde transport of horseradish peroxidase (HRP). Nerves on the surface of the left renal blood vessels were transected near the hilum of the kidney, and the central cut ends exposed to HRP. Sympathetic efferent neurons were labeled centrally along the renal nerve, in the superior mesenteric ganglion, and in the ipsilateral sympathetic chain ganglia (T12-L3). HRP was not detected in preganglionic neurons in adult animals but a few of these cells were labeled in the spinal cord of kittens. The results show that the sympathetic efferent innervation of the kidney is derived from both paravertebral and prevertebral ganlia. In the latter (superior mesenteric ganglion), renal afferent neurons exhibited a topographic distribution. Labeled cells were localized in the caudal pole of the ganglion near the origin of the renal nerves.

Retrograde transport of HRP labeled renal afferent perikarya in the ipsilateral dorsal root ganglia (DRG) from T12 to L4. A few labeled cells were also discovered in contralateral DRG. Transganglionic anterograde transport of HRP successfully labeled renal nerve afferent fibers (RNAF) in the spinal cord of kittens. RNAF were found between T11-L6, with the greatest concentration in L1, L2, and L3. Fibers traveled rostrocaudally in medial and lateral Lissauer's tract; some collaterals could be traced into and through lamina I. In the transverse plane, a medial (MP) and a lateral (LP) renal projection within the dorsal horn margins could be readily discerned. A large number of fibers in LP passed medially into Lamina V at the base of the dorsal horn. In some sections LP could be followed ventrally into the lateral portion of upper lamina VII where the intermediolateral nucleus is located. Fibers in MP and LP could also be traced across the midline in the dorsal commissure. In the contralateral spinal cord RNAF were largely seen in Lamina V. These results demonstrate that RNAF project into regions containing spinothalamic tract cells, and therefore may reflect sites of termination of renal nociceptive pathways. These afferents as well as other projections into autonomic nuclei may be involved in spinal sympathetic reflexes to the kidney. Supported in part by NSF Grant PCMF9O6093, Clinical Research Grant MH30915, NIMH Grant 5430, NIH Grant 1-F32-NSO7006, National Spinal Cord Injury Foundation, and Western Pennsylvania Heart Association.

22.10 SPINAL ORGANIZATION OF RESPIRATORY INFLUENCES ON SYMPATHETIC NERVE DISCHARGE PATTERNS IN CATS. C. A. Connelly*, R. D. Wurster. Department of Physiology, Loyola University of Chicago, Stritch School of Medicine, Maywood, Illinois 60153.

Sympathetic nerve discharges exhibit respiratory rhythmicity. Descending pathways which alter sympathetic activity originate in the brainstem and are located primarily in the dorsal and ventrolateral regions of the spinal cord. Those fibers affecting phrenic and intercostal motor nerves are located in the ventrolateral spinal cord. The purpose of this study was to 1) determine if fibers responsible for the respiratory rhythmicity in sympathetic nerves are also localized in the ventrolateral spinal cord and 2) determine the laterality of descending respiratory influences. Inferior cardiac sympathetic, phrenic and intercostal nerve activities were recorded and integrated in vagotomized, alpha-chloralose anesthetized cats which were paralyzed and artificially ventilated. Respiratory rhythmicity was assessed by comparing the sympathetic discharge with phrenic nerve activity. Intercostal nerve activity served to assess the lesion of descending spinal respiratory pathways. Progresive lesions in the C6 and C7 segments of the spinal cord were made below the C5 level of phrenic motor outflow. The following results were obtained: 1) Bilateral lesions of the ventral cord interrupted the respiratory activity of the intercostal nerve while the phrenic and sympathetic nerves remained in phase. 2) Ipsilateral hemisections attenuated but did not eliminate the respiratory rhythm in the inferior cardiac sympathetic nerve discharge. 3) Bilateral dorsal spinal cord section was necessary for complete elimination of the respiratory rhythm in sympathetic nerves. It is concluded that the rhythmic nature of sympathetic discharges is primarily due to bilaterally descending influences located in the dorsal spinal cord. (Supported by NIH Grant HL 08682 and The Potts Foundation.)

22.11 VAGAL AND GASTRIC CONNECTIONS TO THE CENTRAL NERVOUS SYSTEM DETERMINED BY THE TRANSPORT OF HORSERADISH PEROXIDASE. F. C. Barone, S. L. Scharoun, B. B. Falk,* P. A. McGrattan* and M. J. Wayner. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210.

Pure horseradish peroxidase (HRP, Sigma Type VI) crystals were encased in a parafilm envelope and applied to the transected central ends of the left and right cervical vagus nerves and the anterior and posterior esophogeal vagus nerves of adult male hooded rats. Injections of HRP (30%) were made into the muscle wall of the fundus and antrum regions of the stomach. After a 48 hr survival time, animals were perfused intracardially with a phosphate buffer plus sucrose wash followed by glutaraldehyde and paraformaldehyde fixative. The brain stem, spinal cord segments and corresponding dorsal root ganglia, the superior cervical sympathetic ganglion, and the nodose ganglion were removed and cut into 50 µm sections. All tissue was processed with TMB and counterstained with neutral red for the blue reaction according to Mesulum . Sequential sections were examined under a microscope. Labeled neurons and nerve terminals were identified using bright and dark field condensers and polarized light. In tissue from animals that had HRP applied to the cervical vagus nerves, retrogradely labeled neurons were identified ipsilaterally in the medulla located in the dorsal motor nucleus of the vagus (DMN) and in the nucleus ambiguus (NA). Labeled cells extended from the DMN into the spinal cord in laminae X of cervical segments. Many bipolar neurons were labeled in the nodose ganglion. Anterogradely labeled terminals were observed throughout and adjacent to the solitary nucleus (SOL) dorsal to the DMN and intermixed among labeled neurons located in the DMN. In tissue from animals that had HRP applied to the esophogeal vagus nerves, similar labeling was observed. However, fewer neurons were identified in the NA, the nodose ganglion, and in the cervical spinal cord. Also, very little terminal labeling was observed in and adjacent to the SOL. Labeled neurons in tissue from animals that had HRP injected into the stomach wall were observed bilaterally in the DMN, nodose ganglion, and only at the C_1 level of the spinal cord. However, labeled bipolar neurons were observed in the dorsal root ganglia of the thoracic cord. These data indicate that cervical cord and NA neurons are more important in the supradiaphragmatic motor innervation by the vagus. Also, many afferents to the SOL originate above the diaphragm. In addition, some afferents from the stomach enter the central nervous system via the thoracic spinal cord.

(Supported by NINCDS USPHS Grant No. 13543.)

22.12 SKIN RESISTANCE LEVEL IDENTIFIES LATERALIZED AUTONOMIC DEFICIT. R.L. Bruno*, L.J Cote and J.A. Downey*. Research Labs., Dept. of Rehabilitation Med., College of Physicians and Surgeons, Columbia Univ., N.Y., N.Y. 10032.

Autonomic dysfunction is often seen in patients with Parkinson's Disease (PD). For example, patients frequently exhibit diminished sweating on the trunk and limbs (Appenzeller and Goss, 1971). However, it is unclear whether the diminution in sympathetic cholinergic activity which underlies such anhydrosis is attributable to peripheral neuropathic changes (which have been demonstrated in PD patients (Aminoff and Wilcox, 1971)) or to the central degenerative process which underlies the disease.

The skin resistance level (SRL) is a sensitive measure of the degree of hydration of the stratum corneum of the skin, and thus of sympathetic cholinergic efferent activity (Edelberg, 1972). The greater the sympathetic cholinergic outflow to the sweat glands and corneum, the greater the hydration of the skin and the lower the SRL. The SRL of both hands was recorded at rest in 18 dextral PD patients who had asymmetric symptoms, i.e. their overall symptoms and their upper extremity tremor or rigidity were greater on one side of the body. The patients separated equally into those with predominant left- or right-sided involvement; they were receiving anticholinergic agents and/or L-Dopa at the time of testing. It was found that the mean SRL was 46.5% higher in the hand on the more involved side of the body ($d=239$ Kohms; $t=2.06$; $p<.05$) and that the SRL of the right hand was significantly correlated with the severity of the rigidity in that hand ($r=.702$; $p<.05$).

The higher SRL on the more affected side of the body and the correlation between SRL and rigidity demonstrate a diminution in sympathetic cholinergic activity in these patients, the magnitude of which is related to the distribution and severity of the PD symptoms. These SRL findings strongly suggest that the sympathetic cholinergic deficit in PD is attributable to a central autonomic disorder related to the motor symptoms, rather than to degenerative changes in the peripheral autonomic nervous system.

22.13 EFFECTS OF FOOD DEPRIVATION ON LIVER AND HEART ADRENERGIC RECEPTOR MECHANISMS DURING ONTOGENY. C.M. Kuhn, M.K. McMillian*, G.E. Evoniuk* and S.M. Schanberg. Dept. of Pharmacology, Duke University Medical Center, Durham, NC 27710.

We have reported previously that in preweanling rat pups food deprivation (FD) causes a selective loss of liver responsivity to alpha adrenergic agonists. We now report that FD affects both liver and heart responsivity to adrenergic stimuli but that the mechanism responsible for altered responsivity changes during ontogeny. Short term FD (2 hrs) of 10 day old rat pups decreases liver ornithine decarboxylase (ODC) responsivity to both the alpha adrenergic agonist phenylephrine (PHE) and the beta adrenergic agonist isoproterenol (ISO). However, the number of hepatic $alpha_1$ and beta receptors as determined by measuring the binding of ^{3}H-prazosin and ^{125}I-pindolol to crude membrane preparations is not changed. In addition, heart ODC responses to PHE and ISO are not affected by short term FD. Long term FD (12-24 hrs) of 10 day old pups also is associated with decreased liver responsivity to PHE and ISO that is dissociated from changes in receptor number: beta receptor number actually increases although responsivity is decreased, and $alpha_1$ receptors do not change.

In adults, short term FD affects neither liver ODC responses to adrenergic agonists nor receptor number. However, long term FD (24-48 hrs) causes an increase in beta receptor number and a decrease in $alpha_1$ receptor number which are accompanied by a parallel increase in liver ODC responsivity to ISO and a decrease in responsivity to PHE. Heart responsivity to both PHE and ISO is decreased following long term FD of adult rats, and the decrease in responsivity to these adrenergic agonists is accompanied by a decrease in both $alpha_1$ and beta receptor number.

These results suggest that nutrition plays an important role in regulation of peripheral adrenergic receptor mechanisms. However, the duration of FD required to change responsivity and the mechanism by which the changes occur are different in neonates and adults. The effects of FD in neonates occur after only 2 hrs of FD, and seem to be mediated by postreceptor mechanisms, while altered responsivity in adults only occurs after 24-48 hrs of FD, and altered responsivity can be explained by changes at the receptor level. Finally, FD has opposite effects on beta receptor mechanisms in liver and heart: beta responses in liver are potentiated by FD, while those in heart are suppressed.

22.14 STREPTOZOTOCIN DIABETES-INDUCED CHANGES IN AUTONOMIC RECEPTOR SENSITIVITY IN THE RAT BLADDER. Michael C. Gerald and Malak G. Kolta.* Division of Pharmacology, College of Pharmacy, The Ohio State University, Columbus, OH 43210.

Urinary bladder dysfunction is a chronic complication of diabetes mellitus. This autonomic neuropathy is characterized by progressive bladder paralysis with urinary retention. The present study was designed to test the hypothesis that diabetes alters the sensitivity of the detrusor and sphincter + trigone (Sph+T) smooth muscles of the bladder to cholinergic and/or adrenergic (α,β) activation, autonomic influences that normally control bladder function.

Diabetes was induced with streptozotocin (40 mg/kg, i.v.) in adult, male Sprague-Dawley rats and tissue sensitivity to autonomic drugs was assessed 6 wks later. Average plasma glucose levels and percent changes in initial body weight in control and diabetic rats were 104±3 and 497±23 mg %, and +44% and -5%, respectively. At the time of sacrifice, visual inspection revealed that bladders obtained from diabetic rats were much more distended than controls. Preliminary studies indicated that, while the contractile response of control and diabetic intact bladders to KCl was equivalent, diabetic bladders were 2-fold more sensitive to acetylcholine (ACh). Subsequent studies compared the sensitivity of the detrusor and Sph+T smooth muscles from control and diabetic rats to KCl and the cumulative addition of: ACh, phenylephrine in propranolol-pretreated tissues, and isoproterenol in phentolamine-pretreated tissues. Results were analyzed as a percentage of the maximal response to KCl. Control and diabetic tissue sensitivity to KCl was equivalent. Although ACh produces relaxation in the human Sph+T, contraction was observed in rats. Diabetic detrusor and Sph+T muscles were 4- and 100-fold more sensitive, respectively, to ACh-induced contractions. The maximum contractile response to phenylephrine (α-adrenoceptor agonist) was 2.5-fold greater in the diabetic detrusor, while no difference was observed in the Sph+T. While the diabetic detrusor was more sensitive to isoproterenol-induced relaxation, the diabetic Sph+T was less responsive to relaxation by this β-agonist than corresponding controls.

These results suggest that the diabetic state induces selective alterations in cholinergic and/or adrenergic receptor sensitivity and support the hypothesis that diabetic urinary bladder dysfunction may result from β-mediated enhanced detrusor relaxation and/or from a marked enhancement of the sensitivity of the Sph+T to cholinergic contraction.

22.15 Effects Of Glucose And Osmotic Pressure On Temperature-Sensitive Neurons In Hypothalamic Tissue Slices. N.L. Silva* and J.A. Boulant. Department of Physiology, Ohio State Univ., Columbus, Ohio 43210.

Previous studies have demonstrated the existence of temperature-sensitive single units in the preoptic area and anterior hypothalamus (PO/AH) in both *in vivo* and *in vitro* preparations. Nearly one half of the PO/AH neurons may be classified as temperature-sensitive; i.e., warm-sensitive cells increase their firing rates with increasing preoptic temperature; and cold-sensitive cells increase their firing rates with decreasing preoptic temperature. Other studies have suggested that certain PO/AH units may respond to alterations in either glucose or osmotic pressure. The purpose of the present study was to characterize the specificity of *in vitro* PO/AH neurons for their responses to temperature, low glucose and hyperosmolarity.

PO/AH tissue slices (300-400 μm thick) were maintained in a humidified chamber which was constantly perfused with an oxygenated nutrient media (7.4 pH, 300 mOsm/kg, 10 mM glucose). The medium perfusing the slices was maintained at 37°C, but could be rapidly changed between 32°-42°C. Low glucose media (1-3 mM glucose) or hyperosmotic media (307-309 mOsm/kg) could also be switched to perfuse the chamber. Following the determination of a single unit's extracellular response to changes in temperature (impulses/second/°C) the normal media was replaced by either the low glucose or hyperosmotic media. The spontaneous firing rate and temperature sensitivity were again examined during these experimental perfusions.

The primary effect seen in the cold-sensitive cells was an inhibition produced by the low glucose and hyperosmotic media. Within the temperature-insensitive cell group the majority of units were not affected by either media, however, 30% of these units were inhibited by either one or both media. Of the warm-sensitive cells studied, approximately 10% were facilitated by one or both media; and the remaining warm-sensitive neurons were not affected by either media.

(Supported in part by grants from NIH (5-R01-N514644) and the American Heart Association).

22.16 DELAY AND PARTIAL REVERSAL OF NEUROENDOCRINE REPRODUCTIVE DYSFUNCTION BY OVARIECTOMY IN MIDDLE-AGED AND OLD C57BL/6J FEMALE MICE. C. Mobbs*, D. Gee* and C. E. Finch. Andrus Gerontology Ctr., Univ. of So. Cal., Los Angeles, CA, 90007.

Reproductive senescence in C57BL/6J female mice 12 to 18 months of age is characterized by cessation of ovarian cycles and onset of persistent vaginal cornification (PVC). Mice with PVC have moderately elevated and sustained plasma estradiol (E2), show major impairments in the E2-induced LH surge ($p<.001$), and can sustain fewer estrous cycles when given young ovarian grafts ($p<.001$), as compared to 6-month-old cycling mice. Middle-aged (12 months) but still cycling mice also show these impairments, although to a less extent ($p<.05$). If 18-month-old mice were ovariectomized (OVXed) two months previously, after the onset of acyclicity and correlated neuroendocrine dysfunctions, the E2-induced LH surge and the ability to support cycles given young ovaries were both partially restored ($p<.01$) (see table below). Furthermore, if the 18-month-old mice had been OVXed 12 months earlier, while still young and cycling, there was no significant loss of function in the regulation of LH. However, if middle-aged but still cycling mice were OVXed for 2 months, there was no significant restoration of function in either regulation of LH or ability to support cycles.

Age[a]	Time OVXed[b]	LH(ng/ml) (n)	# cycles[c] (n)
6 mo.	4 days	200±45 (13)	17±1.6 (18)
6 mo.	2 mo.	300±50 (16)	....
12 mo.	4 days	90±20 (16)	7.1±3.1 (16)
12 mo.	2 mo.	120±30 (15)	5.9±2.6 (17)
18 mo.	4 days	20±5 (18)	1.6±0.8 (18)
18 mo.	2 mo.	120±30 (20)	7.6±1.2 (17)
18 mo.	12 mo.	190±50 (16)	....

[a]Age at grafting of young ovaries or induction of LH surge.
[b]Length of time OVXed before grafting of young ovaries or induction of LH surge.
[c]Total number of estrous cycles of host after ovaries were removed and replaced with 6-month-old ovarian grafts.

We conclude that ovariectomy of young cycling mice can prevent or delay loss of neuroendocrine reproductive function as they age; furthermore, 2 months of OVX in 18-month-old mice can partially restore reproductive function. However, OVX does not seem to affect the neuroendocrine dysfunctions of middle-aged mice. These data indicate that there may be a biphasic ovary-dependent component to reproductive senescence.

22.17 THE EFFECT OF INTRACRANIAL SELF-STIMULATION (ISS) ON THE RESPONSE TO COLD STRESS AMONG AGED MICE. M. Talan* (Spon.: N. Buckholtz) Gerontology Research Center, National Institute on Aging, Baltimore, MD, 21224.

Informal observation in my former laboratory (Pavlovian Institute, Leningrad, USSR) suggested that animals which were allowed to electrically self-stimulate their brains in so called reward areas also appeared more vigorous in settings outside of the test chamber. In order to test this impression further, the following study was carried out. In experiment 1 electrodes were implanted in the medial forebrain bundle in 30, C57BL/6J mice aged 30 mos. All animals were able to produce ISS after a short shaping procedure. They were divided in two groups of 15 mice each. After 10 days all animals were exposed to a 10°C cold stress for 3 hr while rectal temperature was recorded every 30 min. After three weeks all animals were retested. Between the two tests animals in the first group (+ISS) received daily sessions of ISS for 30 min. Animals in the second group (-ISS) were placed in the ISS chamber every other day for 30 min but were not allowed ISS. Data were analyzed by computing individual slopes of rectal temperature during the cold stress for each test. These regression coefficients then were compared using a repeated measures analysis of variance. The results showed that there was no difference between groups of test 1, F (1,28) =.00058, but at test 2 the -ISS group had significantly poorer tolerance to the cold stress than the +ISS group, F (1,28) = 20.16, p <.001. This difference occurred because cold tolerance in the -ISS group fell significantly from test 1 to test 2, F (1,28) =23.37, p<.001; whereas the +ISS group showed no deterioration in performance, F (1,28) =.102.

In experiment 2 electrodes were implanted in 6, 30 mo. old mice which were tested for tolerance to cold stress as described above. Then they were retested twice at 3 week intervals. Between test 1 and test 2 they remained in their home cages; between test 2 and test 3 they received 30 min/day sessions of ISS for 3 weeks. The results showed a significant test effect, F (2,10) =9,23, p < .01, body temperature fell significantly more during test 2 than test 1, F (1,10) =9.19, p <.01. However, during test 3 the temperature response to cold stress was not different from test 1, F (1,10) = 1.3, but was significantly better than during test 2, F (1,10) = 17.42, p<.01.

These data suggest that ISS may facilitate the ability of old mice to cope with cold stress.

23.1 EFFECTS OF LEAD ADMINISTRATION ON POSTNATAL DAY 5 OR DAY 15 OF LIFE ON LITHIUM-INDUCED POLYDIPSIA, STRIATAL ^{3}H-SPIPERONE BINDING AND DOPAMINE METABOLISM IN ADULT RATS. R.B. Mailman, D.L. DeHaven and M.R. Krigman. Biol. Sci. Res. Ctr. and Depts. of Pharmacol., Psychiat. and Pathol., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514

Lithium-induced polydipsia (LIP) has been shown to be increased in adult rats who were treated with lead (Pb) from day 3 to day 30 of life (Mailman et al., Science, 201:637, 1978). This effect is permanent, is not caused by higher doses of lead administered from days 30-60 of life and is not due to differences in circulating renin or angiotensin or other renal changes. Lithium-induced polydipsia has also been shown to be dependent upon an intact nigrostriatal dopaminergic system, but not any other monoamine system. The present experiments have narrowed the range of ages during which Long-Evans rats are sensitive to lead-induced changes in LIP, and have also examined the function of the nigrostriatal dopamine system. In the first study, rats were treated by oral gavage with 200 mg/kg/day of lead (as the acetate) or with sodium acetate vehicle during days 3-10, 11-20 or 21-30 of life (birth = day 1). At 60 days of age, testing for LIP was initiated. Significant increases in LIP were seen in the groups treated from days 3-10 and 11-20, but not those treated on days 21-30. In the second experiment, rats were treated with a single dose of lead (200 mg/kg) or vehicle on either day 5 or day 15. A within-litter design was used such that each sex within a litter received one of the four treatments. Testing for LIP began when the rats were ca. 60 days of age, and the same rats were sacrificed for neurochemical analyses when ca. 6 months of age. Individual Scatchard analyses of ^{3}H-spiperone binding were performed for each rat's striata using unlabeled spiperone as displacer. Concentrations of dopamine, DOPAC and HVA were quantified using HPLC with EC detection (Kilts et al., J. Chromatog., 225:337, 1981). Administration of Pb on either day 5 or day 15 caused a significant increase in LIP compared to controls. However, when the animals were sacrificed after thorough washout of lithium, there was no difference between Pb-treated and control groups in the affinity or number of receptors for ^{3}H-spiperone in the striatum. Moreover, concentrations of DA, DOPAC and HVA in striatum were also unchanged. These data indicate the gross alterations of nigrostriatal DA function are not observable in treated rats who have significant alterations of LIP. However, differences between Pb and control groups might be evident if these same parameters were compared while the rats were being treated with lithium. In any event, the fact that a single dose of 200 mg/kg of lead causes a change in LIP of similar magnitude to that induced by dosing from days 3-30 suggests that this effect is a sensitive monitor of lead exposure during development. (Supported in part by ES-01104, ES-02087 and HD-03110).

23.2 EVIDENCE THAT LOW-LEVEL DEVELOPMENTAL LEAD EXPOSURE PRODUCES TOXIC AMBLYOPIA. D.A. Fox and A.A. Wright*. Div. of Toxicology, Univ. of Texas Med. Schl., Houston, TX 77025.

Clinical reports of children poisoned by inorganic lead (Pb) describe irreversible impairments in spatial resolution properties of the visual system. Experimental work from our laboratory and that of others suggests that deficits are confined to higher spatial frequencies and preferentially occur at scotopic, in contrast to photopic, levels of luminance. These changes have been reported to occur at all levels of the visual system (Fox et al., Tox. Appl. Tox.40:449,1977 and Neurobehav. Tox.1:101,1979; Fox and Sillman, Science 206:78,1979; Bushnell et al., Science 196:333, 1977; Impelman et al., Neurosci. Abs.8:in press,1982). To determine if the spatial resolution limit, visual acuity, of the adult rat's (100 days of age) visual system was altered following low-level neonatal Pb exposure, electrophysiological and psychophysical studies were conducted at mesopic and scotopic levels of luminance. Female neonatal Long-Evans hooded rats were exposed to Pb (or no Pb) from parturition to weaning (days 0-21) via the milk of dams consuming 0.2% Pb acetate (or water) solutions. Checkerboard pattern-reversal cortical evoked potentials (temporal freq. 0.94 Hz) were recorded in chronically implanted awake rats and used to estimate visual acuity by a modification of the extrapolation technique (Campbell and Maffei, J. Physiol.207:635,1970). Visual acuity psychometric functions were obtained utilizing sine-wave gratings (0.1-1.3 c/deg) in a conditioned suppression paradigm.

Results in control and Pb-exposed rats reveal a close correspondence between electrophysiologically and psychophysically determined spatial resolution limit. The maximal spatial resolution in control rats was approx. 1.3 c/deg under scotopic and mesopic conditions. These acuity values are in good agreement with those of Birch and Jacobs (Vis. Res.19:933,1979) and Lennie and Perry (J. Physiol.315:69,1981). Pb-exposed rats exhibited a 25-50% decrease in visual acuity with greater deficits being observed under scotopic, than mesopic, conditions. Decreases in spatial resolution were observed at all spatial frequencies greater than 0.25 c/deg in Pb-exposed rats. In addition to the decreased P2N2 amplitudes, which account for the decrements in spatial resolution, increases in P2 and N2 latencies were observed in the Pb group.

These data provide evidence that low-level neonatal Pb exposure produces toxic amblyopia. They also extend the findings that the scotopic system is more vulnerable to the toxic actions of Pb than the mesopic/photopic system and provide further support for the idea that all levels of the visual system are affected by developmental Pb exposure. Further experiments to determine the specific site(s) and mechanism(s) of action are in progress. Supported by grants ES 02713 and OH 07085.

23.3 CENTRAL EFFECTS OF LOW LEVEL DEVELOPMENTAL LEAD EXPOSURE ON OPTIC NERVE CONDUCTION AND THE RECOVERABILITY OF GENICULOCORTICAL RESPONSES IN HOODED RATS. D. Impelman*, C.L. Lear*, R. Wilson*, and D.A. Fox (Spon. B. Brooks). Div. of Tox. Univ. Texas Med. Schl,. Houston, TX 77025.

Long-term effects on visual functions in rats, following low-level neonatal lead (Pb) exposure suggest that clinical reports of irreversible impairments in spatial and temporal resolution properties of the visual system in children are partly due to changes in bioelectric properties of the optic nerve (ON) and in recoverability of visual cortical responses. Following neonatal Pb exposure latencies of the retinogeniculate and retinocollicular responses of flash visual evoked cortical potential (VECP) in adult rats are increased (Fox et al., Tox. Appl. Pharm. 40:449, 1977 and Neurobehav. Tox. 1:101, 1979). Latency increases in these pathways may reflect a decrease in the conduction velocity and excitability of the ON fibers since postnatal exposure to Pb produces hypomyelination and a decrease in fiber diameters of the ON (Tennekoon et al., Ann. Neurol. 5:558, 1979). Conduction velocities and chronaxy values obtained for the three ON conduction groups and the postsynaptic response latencies were measured in electrically evoked potential recordings from the LGN, superior colliculus (SC), and the striate cortex (CX) in adult control and Pb treated Long-Evans hooded rats. Female rats were exposed to Pb (or no Pb) from parturition to weaning (days 0-21) via the milk of dams consuming 0.2% Pb acetate solutions (or water). Electrical evoked recovery responses to double pulse stimulation of the ON were recorded because the similarity of electrical and flash evoked recovery functions suggested that Pb effects might be centrally mediated. Conduction velocities of the high (H) and middle (M) conduction groups were decreased in the Pb group with ranges of 9-15 m/sec vs 13-15 m/sec (Pb vs C) for the H group and 4.2-5.6 m/sec vs 5.2-7.0 m/sec for the M group. Chronaxy values for the same conduction groups were higher in the Pb group with ranges of 68-130 μs vs 39-59 μs for the H group and 125-148 μs vs 53-69 μs for the M group. Postsynaptic response latencies for the H and M conduction groups recorded form the LGN, SC, and CX were also increased but increases in the recovery response latencies and their amplitudes only occurred in the cortical recovery functions. Latency increases in the response components of the VECP recorded in Pb-exposed rats appear to be the result of a decrease in the conduction velocity and excitability of the fast and medium conduction groups in the ON. Increases in latency and amplitude of the recovery responses of the retinogeniculate component do not occur in the LGN which suggests that neonatal Pb exposure affects the cortical recovery mechanism. Supported by grants ES 02713 and OH 07085.

23.4 BEHAVIORAL DEFICITS IN MONKEYS EXPOSED TO LOW LEVELS OF LEAD SINCE BIRTH. Deborah C. Rice *and Steven G. Gilbert* (Spon: B. Weiss). Toxicology Research Division, Bureau of Chemical Safety, Food Directorate, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario, Canada K1A 0L2.

Monkeys (Macaca fascicularis) were dosed orally from birth with 0, 50, or 100 ug/kg/day of lead as lead acetate. Blood lead levels peaked at 16 or 22 ug/dl by 100 days of age for the two treated groups respectively, and decreased after weaning at 200 days of age to 12 ug/dl in both groups. Blood lead levels for control monkeys were always below the level of detection of the analytical procedure (5 ug/dl). When the monkeys were approximately three years old, they were tested on a two-choice discrimination and series of reversals paradigm. The monkeys faced a panel on which were a tube for delivery of fruit juice and two clear plastic response disks that could be backlit with various stimuli. The stimulus display consisted of a two-dimensional form (square or triangle) and color (red or green) on each disk. During the first part of the experiment, both disks were always backlit with red, and the monkey was required to respond on the disk displaying the square in order to receive a small amount of apple juice. The disk on which the correct stimulus appeared was varied randomly from trial to trial. When the monkey had learned the task (at least 9 out of 10 correct in a 10-trial block), the correct stimulus became the previously incorrect one, and the monkey had to relearn the task. A total of 20 such reversals were performed. For the two following tasks, the form and colors were displayed independently of each other, with one disk displaying one color and form, and the other disk the other possible pair. For the second task the monkey was required to attend to the colors on the disk and ignore the forms (initially red correct), while for the third task the forms were the relevant stimuli and the colors irrelevant (initially triangle correct). Twenty reversals were performed on each task. For each task, there were monkeys in the two treated groups whose performances were outside of control range on the reversal series, taking longer to learn the reversals and making more total errors than controls.

23.5 EFFECTS OF CHRONIC LOW LEVEL LEAD EXPOSURE ON THE PHYSIOLOGY OF INDIVIDUALLY IDENTIFIABLE NEURONS. Gerald Audesirk and Teresa Audesirk. Div. Biol. Sci., U. Missouri, Columbia, MO 65211.

Although chronic exposure to low levels of lead has been shown to be associated with behavioral deficits and neurochemical changes within the mammalian brain, relatively little is known of chronic lead's electrophysiological effects. Lead influences EEG measurements (Benignus, et al., 1981), suppresses evoked visual responses (Fox, et al., 1977), and inhibits spontaneous spiking in Purkinje cells of cerebellar grafts maintained in oculo (Palmer, et al., 1981). The present study utilized the nervous system of the pond snail Lymnaea stagnalis, with its individually identifiable neurons, as a model system in which to study lead effects on neuronal electrophysiology.

Juvenile Lymnaea were exposed to 1000 ug/l lead acetate in their aquarium water for 6 to 10 weeks; controls were identically reared but without lead. Isolated brains were dissected and pinned out in lead-free Ringer's. Intracellular recordings were made from the identifiable neurons RPeD1, VD1, and LP1; the pair VV1/VV2; and several (usually 3) neurons of the B and F clusters in each brain. Measurements were made of resting potential; action potential, overshoot, and undershoot amplitudes; action potential duration; rate of recovery of the undershoot; input resistance; time constant; spontaneous activity; and spike frequencies elicited by several intensities of intracellular current injection.

Multivariate analysis of variance of all parameters and all neuron types indicates that there is a significant overall effect of lead exposure ($p=0.0001$). Lead decreases spontaneous activity; reduces excitability to injected current (spontaneous activity subtracted out); decreases the input resistance; slows the rate of return of the spike undershoot to resting level; and increases the resting potential. Within these overall effects there is also a significant interaction between lead and neuron type ($p=0.02$). All neuron types in lead-exposed snails show, to some extent, a slowed rate of recovery of the undershoot and reduced spontaneous activity. However, B, F, and LP1 neurons are markedly less excitable when lead exposed, while the RPeD1 and VV1 neurons show no excitability change. The VV1 neurons also show no change in resting potential or input resistance.

These studies indicate that (1) characteristic changes occur in the electrophysiology of individual neurons as a result of in vivo lead exposure, and (2) different types of neurons differ in their response to chronic lead exposure. Further studies of affected and relatively unaffected neurons may lead to a more definitive understanding of the mechanism of action of chronic lead on the nervous system. (Supported by NIEHS grant 1 R23 ES02641-01.)

23.6 BIOCHEMICAL EFFECTS OF TRIETHYL TIN IN DEVELOPING RATS. R. Rocco and V. Sapirstein (spon: J. Blumberg) Dept. of Pharm. and Toxic Northeastern Univ., Boston, MA and Dept. of Biochem. E.K. Shriver Center, Waltham, MA.

Administration of triethyl tin (TET) to young animals induces a general retardation in growth, brain weight and a hypomyelination. The relative specificity of this toxin for oligo membrane formation suggests that the metabolic specialization of these cells, namely lipid synthesis, may contribute to their susceptability. These cells are enriched glucose 6P dehydrogenase (G6PDH) a function of which is to provide NADPH for fatty acid synthesis; glycerol P dehydrogenase, (GPDH).which provides glycerol phosphate for phospholipids; mouse mutant studies suggest that NADPH dependent fatty acid chain elongation is also enriched in these cells. Other enzymes highly enriched in oligos are CA and CNPase. We studed these and related enzyems in 21 day old rats that had received 3 consecutive IP injections of either distilled water or TET sulphate (2 mg/kg) on days 5,6 and 7. The TET treated animals had body and brain weights 85.5% and 49.6% of controls. The total protein /gm wet weight was 116% of control. The first two enzymes of the pentose shunt, G6PDH and 6P gluconate DH were unchanged in the TET animals. However, transketolase (TK) a rate limiting step in the non-oxidative portion of the shunt was reduced to 63% of control values. Because TK is a major source of glyceraldehyde 3 P which provides the substrate for GPD this enzyme was also measured. The activity in control animals was 61.0 + 3.2 nmoles/min/mg prot. while in the TET treated animals it was 45.9 + 3.2. The effects on TK and GPD imply a decreased capacity for glycerol-3-phosphate synthesis but no effect on the NADPH producing portion of the pentose shunt. We also measured levels of NADPH dependent isocitrate DH+NADPH-linked C18 fatty acid elongating activity but found no change from control values. CNPase was increased to 119% of control values but CA was significantly decreased in the TET animals (68% of control). We have found that inhibition of CA activity in brain slices by methazolamide decreases the labelling of lipids by 30% by $^{14}C\ HCO_3$. Decreases in this enzyme may compromise the ability of oligos to fix HCO_3 for the synthesis of lipids. None of the enzymes whose activities were found to be reduced are directly inhibited by TET in vitro.

These results indicate that TET causes a selective inhibition in activity of certain oligo enzymes required for lipid synthesis. The marked reduction in TK and GPD suggest that TET may exert an effect which results in the reduction of the non-oxidative limb of the pentose shunt, especially at the level of G3P incorporation into phospholipids. Supported by NS16186 and HD05515

23.7 TRIMETHYLTIN REDUCES BASKET CELL INHIBITION IN THE DENTATE GYRUS. R. S. Dyer, W. F. Wonderlin, T. J. Walsh*, and W. K. Boyes*†. Neurophysiology Branch, Neurotoxicology Division, Health Effects Research Laboratory, U. S. Environmental Protection Agency, Research Triangle Park, North Carolina 27711.

Systemic administration of trimethyltin chloride (TMT) produces a pattern of neuronal loss in the limbic system similar to that produced by kainic acid. The time course of TMT-induced changes is more prolonged than kainic acid, and the seizures which follow injection do not occur for at least 3 days in rats. Because of the similarity in pathology, the mechanisms of action of these two substances may be similar. One proposed mechanism of kainic-acid-induced damage to pyramidal neurons in the hippocampal CA3 field involves increased activity in the mossy fiber-CA3 pyramidal cell pathway. Sloviter and Damiano (Neuropharmacol. 20: 1003, 1981) have shown that kainic acid reduces basket cell recurrent inhibition of the dentate granule cells, thereby increasing mossy fiber activity despite constant perforant path (PP) input. We investigated the influence of TMT upon this pathway. Adult male Long-Evans hooded rats were implanted with bipolar stimulation electrodes in the PP and a monopolar recording electrode in the hilus of the dentate gyrus (referred to frontal sinus). Following a week of postsurgical recovery, baseline recordings were obtained in awake unrestrained rats. A mean of 32 responses was obtained following stimulation of the PP electrodes at an intensity that was supramaximal for appearance of the dentate granule cell population spike. To assess the amount of recurrent inhibition, stimuli were presented in pairs, with a 20 msec interstimulus interval within the pair, and a 2 sec interval between pairs. In control rats, recurrent inhibition greatly reduced the amplitude of the population spike produced by the second of the pair of stimuli. In TMT-treated rats, however, recurrent inhibition was attenuated within 2 hrs after an i.p. injection of 6 mg/kg and almost completely abolished within 3 days. PP stimulation occasionally produced multiple granule cell population spikes in TMT-treated rats. Thus, the mechanism of TMT neurotoxicity may parallel that of kainic acid: reduction of basket cell recurrent inhibition, resulting in an increase in mossy fiber activity and consequent damage due to overstimulation of CA3 pyramidal cells. The rapid onset of these changes suggests a pharmacological effect of TMT, perhaps by blocking the GABA receptors of the recurrent inhibitory pathway (Matthews et al., Neuropharmacol. 20: 561, 1981).

23.8 NEURAL AND BEHAVIORAL TOXICITY OF TRIMETHYLTIN IN DEVELOPING RATS. Patricia H. Ruppert, Karen F. Dean* and Lawrence W. Reiter. Neurotoxicology Division, Health Effects Research Laboratory, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Acute exposure to triethyltin (TET) on postnatal day 5 produces preweaning deficits in rope descent, a decrease in both brain and body weight, and an increase in motor activity which persists through adulthood (Reiter et al., Neurobehav. Toxicol. Teratol. 3: 285-293, 1981). In subsequent studies, we found reduced milk bands in TET-dosed pups, and a reduction in the adult acoustic startle response. To extend our investigations on the developmental toxicity of trialkyltins, we examined the effects of trimethyltin (TMT) on these variables. On day 5, rat pups (LE) received a single intraperitoneal injection of either 0 (saline), 4, 5, or 6 mg/kg TMT-hydroxide as the base. A within-litter design was used for dosing: one male and one female from each litter received each dose and, therefore, each litter contained all treatments. The size of the milk bands (a measure of milk consumption) was significantly reduced in 6 mg/kg TMT pups 48-96 hr after dosing, while in 5 mg/kg TMT pups, milk bands were reduced 96 hr after dosing only. During the preweaning period, dosages of 5 and 6 mg/kg TMT also produced growth retardation (with recovery by day 30) and impaired performance in rope descent. As adults, motor activity in a figure-eight maze was increased for 6 mg/kg TMT animals. The startle response to an acoustic stimulus (a 13kHz, 120dB(A) pure tone) was also affected by TMT treatment when measured both during ontogeny and in adulthood. During development, on days 10-21, all dosages of TMT reduced the number of responses during a 30 trial session in both males and females. The amplitude of positive responses was significantly reduced for the 6 mg/kg dose on days 12, 18, and 20. As adults, the amplitude of startle was decreased at all dosages for males but not for females. These behavioral changes were accompanied by decreases in adult brain weight for both sexes. Whole brain weight was decreased following 4 (4%), 5 (7%), and 6 (16%) mg/kg TMT. The weight of the olfactory bulbs was also reduced by 4 (8%), 5 (9%), and 6 (13%) mg/kg TMT. Hippocampal weight was decreased following 5 (22%) and 6 (39%) mg/kg TMT, while decreased cerebellar weight (8% at 6 mg/kg TMT) was not significant due to variability. Although the neuropathology produced by TET and TMT in adults is dissimilar, these alterations in behavior, body weight, and brain weight parallel those produced by TET on postnatal day 5.

23.9 **RELATIVE REFRACTORY PERIOD OF NERVE AXONS AS A DISCRIMINATOR OF NEUROTOXICITY.** R.J. Anderson. Dept. Pharmacology, George Washington Univ., Washington, DC 20037.

Because the relative refractory period is a logarithmic function, it has been a difficult measurement to handle statistically. Most investigators have limited their assessment to (1) determining the absolute refractory period and/or (2) the duration of the entire relative refractory period. We present here a simple method for conversion of the relative refractory period to a linear representation, which is more easily handled statistically and which may have particular utility in assessing neurotoxic agents.

The rat sciatic nerve was stimulated with twin pulses at intervals from 0.8 to 10 msec to evoke a pair of compound action potentials, the second of which fell within the relative refractory period. The decrement in amplitude and area of this response was used to generate the best fitting refractory period line according to the equation:

$$Y = A \exp(BX)$$

where Y is the decremented action potential at each interval, X, and A and B are coefficients found by solving the equation for stimulus intervals yielding responses between 20 and 80% of the control response. A straight line is then fitted using the calculated coefficients (A and B) and Y values of 25, 35, 50, 65, and 75% and their corresponding interstimulus intervals. The slope and intercepts of this straight line therefore define the complete characteristics of the relative refractory period and can be compared between control and test groups. Since variations in this line are quite small among control animals (for a given strain, weight and age), deviations from the control line are easily recognized and interpreted.

Acrylamide, phenol, trichlorfon and erythrosin were used as test compounds because each produces a different type of neurotoxicity. Phenol, a demyelinating agent, greatly prolonged the refractory period, the slope of which correlated with the degree of histopathology. Trichlorfon, an organophosphate which induces delayed neuropathy, showed a progressive shift in the refractory period during the development of the neuropathy. Acrylamide, an agent whose first neurotoxic effects are at the nerve terminal, showed no change in refractory period until the axon itself was structurally damaged. Erythrosin, an agent which seems to increase neuroexcitability, showed changes in relative refractory period which suggest an enhancement of axonal excitability particularly to high frequency neurotransmission.

These results suggest that the linear representation of the relative refractory period can serve as a sensitive, discriminative and quantitative measure for detecting neurotoxicity. (Supported by NIEHS.)

23.10 ORAL DOSING OF RATS WITH POLYCHLORINATED BIPHENYLS INCREASES URINARY HOMOVANILLIC ACID LEVELS. Richard F. Seegal, K.O. Brosch* and Brian Bush*. Center for Laboratories and Research, New York State Department of Health, Albany, New York 12201.

Polychlorinated biphenyls (PCBs) are widespread environmental contaminants demonstrated to produce adverse health effects in both man and animal (Fishbein, 1974; Hutzinger et al., 1974). Nervous system involvement includes disturbances in motor performance (Tilson et al., 1979), increased frequency of convulsions and neuropathological change in mouse spinal cord and limbic system structures (Chou et al., 1979) and alterations in whole brain catecholamine concentrations (Heinz et al., 1980).

4-hydroxy-3-methoxyphenylacetic acid (HVA), one of the major end products of dopamine (DA) metabolism in the rodent brain, can be used to estimate dopamine turnover (Westerink, 1979). When measured in the periphery, it co-varies with central changes following pharmacological, and electrophysiological manipulation (Sternberg et al., 1981).

Adult male Sprague-Dawley rats weighing between 250-300 g were singly housed in metal rodent metabolism cages. Animals received either a single oral dose of a mixture of Aroclor 1254 and 1260 (total dose = 500 or 1000 mg/kg) or corn oil vehicle and were followed for 21 days post-gavage. Food and water consumption, body weight and urinary HVA concentrations were measured every 3 days. HVA levels were determined by HPLC with electrochemical detection.

No significant differences in body weight, food and water consumption, urine volume or 24 h urinary HVA production were noted between any of the groups prior to gavage. Following treatment, there were transient reductions in body weight, and food and water consumption in the high PCB-exposed group. No significant changes in any of these measures were noted in the low-PCB or corn oil exposed groups. 24-h urinary HVA production was increased by approximately 175% in the low-PCB group, but returned to control levels after 6 d. 24 h HVA production increased by 215% in the high-PCB exposed group and remained elevated throughout the experiment. No significant differences in 24 h urine production were noted following treatment.

These results demonstrate a dose-dependent long-term change in dopaminergic function following a single oral exposure to a complex mixture of PCB congeners and are consistent with results obtained by Rosin and Martin (1981). These authors found a dose-dependent stimulation of release and inhibition of uptake of DA and other neurotransmitters in PCB-treated mouse brain synaptosomal preparations. Thus, peripherally obtained measures of DA-ergic function may serve as a practical, sensitive and objective index of exposure to PCBs and other putative neurotoxins.

23.11 LONG TERM STABILITY OF FUNCTIONAL DEFICIT IN LISSENCEPHALIC FERRETS PRODUCED BY A SINGLE PRENATAL INJECTION OF METHYLAOZXY-METHANOL ACETATE (MAM Ac). R. Haddad, R. M. Dumas* and A. Rabe. Neuroteratology Laboratory, NY State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

The ferret has a gyrencephalic brain, but the normal convolutional development can be prevented by giving the pregnant jill a single injection of MAM Ac (15mg/kg, IP) on gestation day (GD) 32 (mating = GD 1). (Full term is 42 days.) All the progeny are then lissencephalic, i.e., smooth brained, and hydrocephalic.

Lissencephalic ferres, tested at about one year of age (sexual maturation is 7-8 months) have been shown to be severely impaired in their performance on several maze learning tasks (Haddad et al., 1979, Neurotoxicology, 1, 171). Neuropathologic examination of the brains of these animals showed a severe hydrocephaly which led us to question whether the functional deficits found reflected degenerative brain changes rather than, or as much as, a developmental deficit. For this reason, a new group of treated and normal ferrets were evaluated at weaning (6-7 weeks of age). The lissencephalic weanlings displayed deficits comparable to those found in the adult (Haddad et al., 1980, P. 171 in FDA Symposium on the Effects of Foods and Drugs on the Development and Function of the Nervous System, HHS Publication No. (FDA) 80-1076).

Most of the latter group of ferrets were subsequently implanted with screq electrodes for chronic EEG recordings. They were operated between one and two years of age. EEG abnormalities were found in the lissencephalic ferrets (Lee et al., 1981, Teratology, 24, 13A). They were also found to differ in their seizure threshold and to be less responsive to anticonvulsant drugs (Majkowski et al., in preparation).

After completion of these tests, at about three years of age, all of the implanted ferrets were given another maze learning test. Additional unimplanted lissencephalic and normal ferrets of comparable age that had had neither previous testing nor any drug treatments were also tested. The performance of the three year old lissencephalic and normal ferrets was comparable to that of those previously tested at weaning and at one year of age. The lissencephalic ferrets again differed sharply from the normal animals ($p < .001$), making many more errors, while the range of errors for both the treated and normal groups was similar to that of the animals tested at younger ages.

The lissencephalic ferret thus provides an animal model for one form of mental retardation that should be useful for pharmacologic investigations since the functional deficit appears to be quite stable over a period of years.

23.12 A HISTOLOGICAL AND ELECTROPHYSIOLOGICAL CHARACTERIZATION OF GENTAMICIN INDUCED HINDLIMB PARALYSIS IN THE RAT. J.M. Tolliver* and J.E. Warnick. Department of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD 21201.

The intracisternal administration of gentamicin (GEN) to a patient and to rabbits induces similar histological lesions with tetraplegia occuring in rabbits (Ann. Neurol. 4:564, 1978). To further define the neurotoxic actions of GEN, the effect of subdural administration of GEN sulfate (GEN-S) on the rat spinal cord and extensor digitorum longus (EDL) muscle was investigated. A laminectomy was performed at L_1 under ether anesthesia and a fine glass capillary micropipette was inserted through the dura. Either GEN-S (3 μ moles in 20 μl) or physiological saline (20 μl) was injected under the dorsal roots. The incision was closed and animals recovered from anesthesia in about 30 min, upon which a flaccid hindlimb paralysis lasting about 3 h was observed. Muscle tone then gradually returned and within 15 h mobility was normal. Between 24 and 36 h after injection, a period of hyperexcitability characterized by hindlimb tremors and lower spinal seizures was evident. This was followed within 24 h by flaccid hindlimb paralysis that appeared to be permanent. In contrast, control animals receiving physiological saline showed no signs of motor abnormalities at any time after injection. Within 24 h of injection, a proliferation of small phagocytic cells was noted in the lumbar spinal cord. By 48 h axonal swelling, breakage and end bud formation had started to appear. From 3 to 7 days after injection, extensive chromatolysis of motoneurons was observed. With the exception of an occassional inflammatory response, spinal cords from control rats were histologically normal. For up to two days after injection, resting membrane potentials (RMP) in EDL muscles of sham-operated control and treated rats were similiar. At 4 and 7 days, RMPs in EDL muscles of GEN-S treated rats had decreased from -78 mV to -62 mV and -58 mV, respectively. In contrast, the RMP for EDL muscles of sham-operated controls was -77 mV. At 7 days after injection miniature endplate potentials could not be detected and tetrodotoxin resistant action potentials and extrajunctional acetylcholine sensitivity were present in EDL muscles of treated rats. These signs of functional denervation were not found in control EDL muscles up to 7 days after injection. GEN-S thus produces a profound spinal cord neuropathy with subsequent skeletal muscle denervation. The initial paralysis may result from GEN-S induced blockade of transmitter release in the cord whereas the final paralysis may reflect a neuronal-glia interaction. (Supported in part by U.S. Army Contract DAMD-17-81-C-1279.)

23.13 ACUTE DOSES OF NICOTINE INDUCE DEGENERATION IN REUNIENS NUCLEUS OF THALAMUS, R. C. Switzer IV* and R. C. Switzer III. Knoxville, TN, and Comparative Animal Research Laboratory, Oak Ridge Associated Universities, Oak Ridge, TN 37830.

Nicotine is a well-known stimulant of the CNS, while another nicotinic acid analog, 3-acetyl pyridine, has been shown to destroy specific neuronal populations such as inferior olive and lateral geniculate. We report here the specific destruction of neurons in reuniens nucleus of thalamus in rat following a single dose of nicotine. Each of six male Sprague-Dawley rats (200-250 g) was given a single intraperitoneal injection of a nicotine solution (2 mg/ml) at one of the following doses: 0.5, 1.0, or 2.0 mg/kg. After three days the rats were perfused under heavy pentabarbitol anesthesia, and their brains sectioned and processed according to the cupric-silver procedure of de Olmos.

Degeneration as revealed by argyrophilic cell bodies and surrounding dendritic fragments was found throughout the entire rostro-caudal extent of reuniens; however, not all cells were affected. At the coronal level where reuniens is widest, degenerated cell bodies were present as bilaterally symmetric groups, suggesting that a specific subpopulation of reuniens was affected. Degenerating axons could be traced from reuniens following the efferent pathways described by Herkenham (J. Comp. Neurol., 177:589-610, 1978). The rat receiving 0.5 mg/kg of nicotine displayed no degeneration.

Although it remains to be established if lower doses given chronically would yield the same destruction, these results reveal the reuniens nucleus as particularly susceptible to nicotine. Lower doses (less than 1 mg/kg) may not be lethal to neurons of reuniens but the physiology of these neurons may be perturbed to a greater extent than neurons in other CNS areas. Such an effect is of particular interest because of the role reuniens appears to play in moderating ascending neural activity from organs of the viscera, such as heart and lung, en route to limbic areas. The importance of thalamic influence on the viscera has been indicated by the findings that bilateral destruction in thalamus causes myocardial necrosis (McGeer and McGeer, CRC Crit. Rev. Toxicol., 10:1-47, 1982).

23.14 NEUROTOXICITY OF TUBULIN BINDING AGENTS IN RAT HIPPOCAMPUS. Richard B. Goldschmidt*, John H. Gilmore*, S. Scott Lasher* and Oswald Steward. (SPON: Christine Phillips). Depts of Neurosurgery & Anatomy, University of Virginia School of Medicine, Charlottesville, VA 22908

Injection of colchicine into the dentate gyrus of adult rats preferentially destroys dentate granule cells (Goldschmidt & Steward, PNAS 77: 3047, 1980). In an effort to elucidate the mechanism of action of colchicine, we have tested several tubulin binding agents and the non-binding analogs of colchicine - β and γ lumicolchicine, and observed whether they also induce preferential destruction of granule cells.

The drugs to be tested were prepared in equimolar concentrations to the usual dose of colchicine (about 9.5 nmoles/injection). Colchicine, colcemid, vinblastine and vincristine were dissolved in deionized water, while podophyllotoxin and β and γ lumicolchicine were dissolved in .95ml water and .05ml 75% ethanol. Adult male rats were given a single injection (.7µl) into the dorsal hippocampus and allowed to survive between 2 and 30 days.

Vincristine proved to be extremely toxic even at half the initial concentration. It killed neurons of all kinds for several mm from the injection site. Vinblastine was relatively selective in damaging granule cells, but was not as potent as colchicine in that the effect spread less than a mm from the injection. Colcemid and podophyllotoxin caused very little if any damage. Lumicolchicine injections and control injections of the vehicle containing ethanol caused no cell damage beyond the mechanical effects of inserting the syringe.

This ordering of the effects of these related drugs appears to correlate with the persistence of their binding to tubulin (Dustin, Microtubules, 1978). This suggests that granule cell death may be related to the length of time tubulin molecules are bound. However, it is also possible that differences in permeability to these different drugs might account for our results.

23.15 ON THE MECHANISMS OF GLUTAMATE NEUROTOXICITY. N. Brookes, R.C. Wierwille* and A. Boyne. Dept. of Pharm. & Exp. Ther., Univ. of MD Sch. of Med., Baltimore, MD 21201.

It is possible that glutamate is an endogenous neurotoxin in degenerative diseases of the CNS or that it mediates effects of exogenous neurotoxins. However, the way in which glutamate kills neurons is unclear. Monosodium glutamate (MSG) at 0.2 mM or more selectively destroys spinal cord (SC) neurons in primary cell cultures derived from the spinal cords of fetal mice (Brookes and Burt, Dev. Neurosci. 3:118, 1980). Neuronal death was quantitated by the reduction in uptake of [^{3}H]2-deoxyglucose (2-DG) by the cultures (Brookes and Burt, Soc. for Neurosci. Abstr. 6:180, 1980). MSG-susceptible neurons accounted for 50-75% of TEA-stimulated 2-DG uptake in suitable control cultures. This component of 2-DG uptake ('neuronal 2-DG uptake') was eliminated by addition of MSG 1 mM either for 10 min immediately before 2-DG uptake measurement or during the 20 min uptake period itself. On the other hand, a 1 min exposure to MSG 1 mM did not affect neuronal 2-DG uptake whether measured immediately or 2 days later. MSG did not accelerate the short-term leakage of 2-DG from pre-loaded SC cultures, yet no conditions were found in which an initial phase of MSG-induced neuronal excitation was demonstrable as increased 2-DG uptake.

The neurotoxic action of MSG 1 mM persisted in the presence of TTX 0.1 µM and in a calcium-free salt solution containing EGTA 1 mM. However, substitution of choline chloride for sodium chloride protected SC neurons against MSG. This appears to be an effect of choline rather than low sodium concentration since neither substitution with sucrose nor HEPES was protective. To determine whether short-term depolarization alone is sufficient for neurotoxicity, SC cultures were exposed to a solution containing 100 mM potassium. Initial studies reveal comparable neurotoxic effects of MSG 1 mM and 100 mM potassium as judged by 2-DG uptake, light and electron microscopy. The extent of comparability requires further examination.

Ultrastructural correlates were obtained by quick-freezing SC cultures on glass discs followed by freeze-substitution in tetrahydrofuran. Glial cells and dorsal root ganglion neurons appeared unaffected whereas other neuronal cells developed swollen endoplasmic reticulae and were extensively vacuolated 3 hr after a 20 min exposure to MSG 1 mM. During the first 10 min, mitochondria of affected cells became loaded with apparent calcium deposits which grew progressively larger. A similar loading occurred in neurons when the cultures were exposed to solutions containing 100 mM potassium. (Supported by USPHS grant MH29011 and U.S. Army contract DAMD 17-81-C-1279.)

23.16 NEUROCHEMICAL AND TOXICOLOGIC EFFECTS OF ANTICONVULSANT DRUGS ON CEREBRAL CORTICAL CULTURES. Elaine A. Neale, Phyllis K. Sher* and Phillip G. Nelson. Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20205

Anticonvulsants are commonly used for the treatment of major and minor motor seizures in young children, yet there is little consensus as to their mechanism of action or their toxicity to the developing nervous system. In an attempt to evaluate these issues, we have exposed dissociated cell cultures obtained from fetal mouse cerebral cortex to six drugs at approximately twice the high serum therapeutic concentration between days 9 and 20 in culture: phenytoin (PY) 40 µg/ml; phenobarbital (PB) 80 µg/ml;carbamazepine (C) 24 µg/ml; valproic acid (V) 200 µg/ml; diazepam (D) 5 µg/ml; and ethosuximide (E) 200 µg/ml. Following drug exposure, cultures were assayed in situ for ^{125}I-tetanus toxin labeling (TET), high affinity uptakes of ^{3}H-GABA and ^{3}H-β-alanine, choline acetyltransferase (CAT) activity, ^{3}H-benzodiazepine (BDZ) binding, clonazepam displaceable (CLO) BDZ binding, total protein and neuronal cell counts. Results for drugs used primarily to treat major motor seizures (PY, PB, C) indicated that PY-treated cultures evidence greater neuronal toxicity than PB or C (cell counts: 53 ± 3.7, 63 ± 3.9, 88 ± 4.7; CLO: 64 ± 2.9, 86 ± 4.9, 92 ± 7.7 percent of control ± SEM, respectively). For those drugs used to treat minor motor seizures (V, D and E), V and D showed greater neuronal toxicity than E (cell counts: 74 ± 2.9, 79 ± 3.2, 94 ± 6.3 percent of control ± SEM, respectively). In the latter group of drugs, CLO was non-detectable for D-treated cultures, 47 ± 3.9 for V-treated cultures and 79 ± 4.4 percent of control for E-treated cultures. This disproportionate reduction in both specific BDZ and CLO binding following V, D, or E exposure may relate to the mechanism of action of this group of drugs as such a reduction was not present in PY, PB, or C-treated cultures. Similarly, β-alanine uptake, largely a marker of GABA uptake into non-neuronal cells, was significantly depressed relative to neuronal GABA uptake in V-treated cultures and slightly depressed in D-treated cultures, but was not depressed in PY, PB, C, or E-treated cultures. CAT activity, and to a lesser extent, TET and CLO (at least for PY, PB and C) most accurately reflected variations in neuronal cell counts. Each of these parameters was thus depressed in proportion to the presumed relative toxicity of each drug. Results with this experimental system demonstrate a different profile of effects for the two groups of anticonvulsants, and suggest a hierarchy of toxicity within each group.

23.17 NEONATAL CHLORDECONE EXPOSURE ALTERS LEARNING/RETENTION OF ACTIVE AVOIDANCE IN THE RAT. C.F. Mactutus and H.A. Tilson. Lab. Behav. Neurol. Toxicol., NIEHS, Research Triangle Park, NC 27709.

Neonatal exposure of rats to chlordecone, during a period of neuroendocrine differentiation, alters cognitive and affective measures of passive avoidance behavior, particularly in male rats (Neurosci. Abst., 7:892, 1981). To the extent that a true associative deficit underlies the previous observation, interference with acquisition and retention of active avoidance should also be observed.

Fischer-344 rat pups were administered a single s.c. injection (20 µl) of either dimethylsulfoxide (DMSO) or 1 mg/pup of chlordecone dissolved in DMSO on postnatal day 4. Body weights were slightly, but significantly, depressed for chlordecone-exposed males on day 14 (9.9%) and for chlordecone-exposed males and females on days 21 (9.3% and 6.5%) and 35 (6.8% and 6.6%). Half of the pups were trained (day 18) on one-way avoidance (OWA). Chlordecone treatment increased the number of trials needed to attain the acquisition criterion; an effect most pronounced in the female pups. A retention test after a 72-hr interval indicated a trend for more rapid responding by chlordecone-exposed females relative to controls, with no difference between the male groups. Acquisition of two-way avoidance (TWA, days 28-30) found little influence of chlordecone treatment among pups which had no prior OWA experience. However, prior OWA training increased avoidance responding of chlordecone-exposed males and decreased avoidance responding of chlordecone-treated females, relative to vehicle-injected siblings. Perhaps most importantly, vehicle control pups demonstrated a directional bias to make an avoidance response from a small to a large compartment, while chlordecone-treated pups executed their avoidance responses in both directions at the same rate. These latter two observations also characterized TWA performance when a "reversal" procedure was used. A final extinction test indicated that chlordecone-treated pups made fewer responses both during and between trials, with the latter difference significantly greater between the female treatment groups than between the male groups. Plasma steroid levels of male and female chlordecone-treated pups were 15-16% higher than vehicle control values when the animals were sacrificed 5 min after the extinction test.

In summary, the unidirectional response bias in the TWA procedure by the vehicle control pups which had prior OWA training indicated retention of previous training which was not observed in the chlordecone-treated pups. The greater plasma steroid levels of chlordecone-treated pups over vehicle controls is consistent with the hyper-responsiveness previously noted following such exposure and indicates that increased "emotionality" also played a role in the expression of the observed behavior.

23.18 ALTERED BRAIN GROWTH IN BENZENE EXPOSED RAT PUPS, F. Petracca* and J. Diaz. (SPON: S. R. Burchfield) Dept. of Psychology, University of Washington, Seattle, Washington, 98195.

Benzene is an aromatic hydrocarbon frequently encountered in the workplace and home. Toxic effects of this chemical have been well documented in adults, and the National Institute of Occupational Safety and Health has established standards for regulation of workers' exposure to this substance. However, controversy remains regarding the effects of benzene on the developing organism (Mehlman, M., et. al., J. Env. Pathol. Toxicol., 4:123, 1980.; Tilson, H., et. al., Neurobehav. Toxicol., 2:101, 1980.). The purpose of this study was to determine possible effects of benzene when administered during the stage of most rapid brain growth in the rat pup. This stage, called the brain growth spurt (Dobbing, J. & Sands, J., Arch. Dis. Childhood, 48:757, 1973.), occurs pre- and postnatally in humans but entirely postnatally in rats.

4-day-old male Long-Evans rat pups were weighed and culled to litters of 8 and assigned to one of the following groups: 1) pups receiving 550 mg/kg of benzene, on days 7 through 11; 2) pups receiving 225 mg/kg of benzene, on days 7 through 11; 3) pups receiving corn oil vehicle, on days 7 through 11.

From days 4 through 18, pups were weighed daily and were administered a battery of reflex tests, including righting, negative geotaxis, cliff avoidance and free-fall righting. The appearance of teeth and eye opening were noted. On each of days 7 through 11, pups received a subcutaneous injection of either dose of benzene or corn oil vehicle. On day 17, all animals were tested in an open field apparatus. On day 18, each animal was sacrificed. The brain, liver, kidney, and spleen were removed and weighed.

There was a significant decrease in whole brain weights and cerebellar weights for the two benzene treated groups compared to controls ($p<.005$). No significant differences were seen in day 18 body weights, nor in liver, kidney, and spleen weights.

Behaviorally, the benzene treated groups showed indicators of intoxication within 30 minutes after injection. However, no significant differences were seen in ontogeny of reflexes, nor were they seen in day 17 open field measures.

The results of the present study suggest that benzene may have specific toxic effects on neural development. Peripheral organ weights were not affected by either dose of benzene, but whole brain and cerebellar weights were decreased in the two benzene exposed groups. Furthermore, these data suggest that the long term behavioral effects of early benzene exposure documented by Tilson et. al. (Neurobehav. Toxicol. 2:101, 1980) may be mediated by disruptions in CNS development.

23.19 DESTRUCTION OF GABA NEURONS IN THE AMYGDALA AND PYRIFORM CORTEX BY FOLIC ACID INJECTIONS INTO THE SUBSTANTIA INNOMINATA. P. L. McGeer, E. G. McGeer, T. Nagai* and P. T.-H. Wong. Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver, B. C., V6T 1W5.

Unilateral lesions were induced in the substantia innominata (SI) of rats by three methods: electrocoagulation; injection of kainic acid (KA) (2 nmol); injection of folic acid (FA) (50-200 nmol). Histological examination by cresyl violet and GABA-transaminase staining and biochemical evaluation, by glutamic acid decarboxylase (GAD) and choline acetyltransferase (ChAT measurements, and by [^{3}H]QNB and [^{3}H]benzodiazepine ([^{3}H]BZD) binding studies, were undertaken of the SI and several remote areas. Injections of FA into the SI produced much less local but more severe distant neuronal damage than did injections of KA, as previously reported by Olney et al.[1] Both produced sustained epileptiform activity. Electrolytic lesions, on the other hand, produced only local neuronal damage and no epileptiform activity. Biochemical measurements of GAD and histochemical staining for GABA transaminase indicated many of the neurons in the distant areas affected following FA injections were GABAergic, but cholinergic neurons were relatively spared. Damage to the cortical areas was heaviest in the superficial layers. The most severe distant damage after FA was noted in GAD in the amygdala and pyriform cortex, and to a lesser extent in the frontal, entorhinal and temporal cortices, and in the thalamus. The striatum and hippocampus were spared. The distant damage, except in the thalamus, seemed to parallel the density of cholinergic innervation from the SI as revealed by relative drops in ChAT following KA injections into the SI. Reduction in both seizures and remote damage was brought about by pretreatment of the animals with valium (20 mg/kg) or scopolamine (50 mg/kg). The protective action of scopolamine is further evidence that cholinergic neurons may mediate much of the remote damage to GABA neurons although they themselves are little affected. Falls in [^{3}H]QNB but not [^{3}H]BZD binding in the affected areas are consistent with such a mechanism. Distant effects of injections of FA into the amygdala or striatum were comparable in kind but much less in magnitude to those after SI injections.

23.20 EFFECTS OF CHRONIC PRENATAL AMPHETAMINE EXPOSURE ON CENTRAL DOPAMINERGIC AND SEROTONERGIC SYSTEMS IN THE RAT. E. Snowhill-Gisclon* and J.W. Gibb. (SPON: S. Stensaas) Dept. of Biochemical Pharmacol. and Toxicol., Univ. of Utah, Salt Lake City, UT 84112.

Administration of amphetamine (AMPH) or methamphetamine (METH) to adult male rats has been shown to produce significant decreases in the activities of tyrosine hydroxylase (TH) and tryptophan hydroxylase (TPH) (Hotchkiss and Gibb, JPET, 214:257, 1980; Bakhit et al., Neuropharm., 20:1135, 1981). Enzyme activities are depressed as long as 110 days after chronic or subacute drug administration (Ellison et al., Science, 201:276, 1978; Hotchkiss et al., Life Sci., 25:1373, 1979).

This study was designed to monitor similar neurochemical changes that might be expected in the dopaminergic and serotonergic systems of offspring of female rats exposed chronically to AMPH during gestation.

Timed-pregnant rats were injected chronically with AMPH under the following regimen: 0, 0.5, 2.0, or 5.0 mg/kg, s.c. every 12 hours from day 7 of gestation until term. Dosing was stopped 12-18 hours before expected delivery time. Control and treated groups did not differ in length of gestation or in body weights of 3-week old offspring. Male offspring were sacrificed by decapitation between 2 and 8 weeks of age and brain areas (cerebral cortex, neostriatum, hypothalamus, and hippocampus) were dissected out for neurochemical analysis.

TPH activity was measured by a $^{14}CO_2$-trapping method (Hotchkiss et al., ibid.); TH activity was measured by the method of Nagatsu et al. (Anal. Biochem., 9:122, 1964). Neurotransmitters and metabolites were quantitated using high performance liquid chromatography with electrochemical detection (K.E. Moore, personal communication), measuring DOPA, dopamine, DOPAC, HVA, 5-HTP, 5-HT, and 5-HIAA simultaneously in a single brain homogenate sample.

At 5 weeks postpartum, dams showed depression of the dopaminergic system, with dopamine decreased to 73%, DOPAC to 75%, and HVA to 72% of respective controls. 5-HT and 5-HIAA in treated dams were not different from controls. Animals allowed to recover until 12 weeks postpartum showed both transmitter systems at normal levels. Two-week old offspring showed significant dose-dependent decreases in TPH to 69% and 54% of control for 2 mg/kg and 5 mg/kg doses, respectively. Corresponding TH activities were 85% and 80% of controls. By 8 weeks of age these activities had returned to normal, and neurotransmitter levels were not different from control.

24.1 ALTERATIONS IN THE POWER SPECTRA OF KINDLED HIPPOCAMPAL SEIZURES IN ADULT RATS EXPOSED TO LEAD NEONATALLY. M. McCarren*, G. A. Young and C. U. Eccles. Dept. of Pharmacology and Toxicology, Univ. of Maryland School of Pharmacy, Baltimore, MD 21201.

The present study was designed to detect long-term effects on hippocampal function following a brief postnatal lead exposure and to compare the sensitivity of this test with others. Previous work in our laboratory (McCarren, M. and Eccles, C.U., Soc. Neurosci. Abst. 289:15, 1981) demonstrated that acute hippocampal afterdischarges are altered in lead-treated animals. It was of interest whether lead could affect kindling of hippocampal seizures. Power spectral analysis of the kindled seizure was utilized because of the sensitivity of this technique in other investigations of central nervous system function.

Sprague-Dawley rats were exposed postnatally to lead indirectly via the dam's milk. Dams' drinking water contained 1.0, 2.5, or 5.0 mg/ml of lead acetate or 1.25 mg/ml of sodium acetate. Pups were weaned to tap water at 22 days of age. At 3 months of age, adult males were prepared with chronic indwelling bipolar hippocampal and monopolar cortical electrodes. Animals were kindled by stimulating in the hippocampus at twice threshold (2 sec train of 50 Hz, 0.1 msec biphasic square wave pulses) at hourly intervals. Seven stimulations were applied per day, and this continued daily until the rat experienced his first stage 4 convulsion (forelimb clonus with rearing). From that time on, the animal received only one stimulation per day. Spectral analysis (Fast Fourier Transform) was performed only on stable, stage 5 (forelimb clonus with rearing and falling) kindled seizures; the data were normalized with respect to afterdischarge duration. Power in selected frequency bands was expressed as percent of total power during the primary afterdischarge.

No significant differences in kindling rates were detected among the groups, although there was a tendency for lead animals to kindle more slowly. Spectral analysis revealed that a greater percentage of total power resides in the lower frequency bands in lead animals (1-3 Hz, 3-5 Hz, 5-7 Hz) as compared to controls. The reverse is true at higher frequencies, where controls had higher percentages of power (13-15 Hz, 15-17 Hz, 17-19 Hz, 19-21 Hz, 21-23 Hz, 23-25 Hz). These data indicate that power spectral analysis is a sensitive technique for detecting subtle lead toxicity.

24.2 KINDLED MOTOR SEIZURES ARE ABOLISHED BY MICROINJECTION OF MUSCIMOL INTO VENTRAL MIDBRAIN TEGMENTUM. J. McNamara, M. Iadarola, L. Rigsbee*, and M. Galloway*. Epilepsy Center, Depts. of Med. and Pharm., Duke Univ. and VAMC, Durham, NC 27705.

The term kindling refers to a phenomenon whereby repeated periodic administration of an initially subconvulsive electrical stimulus results in progressively increasing seizure activity, culminating in generalized seizures. Elucidating the network of neural circuits responsible for kindling is essential to understanding the basic cellular and molecular mechanisms. Activation of brain stem structures parallels the appearance of motor seizure activity. Analysis of brain stem structures in 2-deoxyglucose autoradiographs of kindled seizures discloses increased metabolic activity in the substantia nigra (SN). Microinjection data implicate SN as a key site of GABA mediated anticonvulsant activity in other seizure models. Systemic administration of gamma vinyl GABA, an irreversible GABA transaminase inhibitor, blocks the motor component of kindled seizures. We therefore hypothesized that pharmacologic enhancement of GABA-ergic synapses in SN would abolish motor kindled seizures.

Male rats underwent stereotaxic implantation of electrodes in amygdala and guide cannulas in several brain structures. Electrode and cannula placements were histologically verified in all animals. Electrical stimulations were administered until motor seizures of constant duration were reliably elicited.

The effects of microinjection of saline and muscimol (M) (a GABA agonist) on motor seizure duration were determined. Animals were gently restrained during injection. M injections into SN induced stereotypies and turning behavior which were well developed by 30 min. after injection. Therefore drug effects were monitored by stimulation administered 30 min. after injection. Motor seizure duration was not altered by microinjection of saline into midbrain (x seconds $\pm$ SEM, baseline 30.5 $\pm$ 1.0, saline 31.7 $\pm$ 2). By contrast, microinjection of M (50 ng in 0.5 µl of saline) bilaterally into SN abolished motor seizures in every animal tested (baseline 27.6 $\pm$ 1, M 0 $\pm$ 0). This M effect was highly significant. M's abolition of motor seizures was parallelled by dramatic suppression of limbic seizure activity and afterdischarge. The seizure suppressant effect was reversible with a time course parallelling disappearance of stereotypies. Induction of stereotypies with apomorphine did not suppress motor seizure duration. Microinjection of M into several other brain regions did modify the seizures.

We conclude that the ventral midbrain tegmentum, and most likely the SN, is a key site in the propagation of kindled seizure activity triggered by amygdala stimulation. Pharmacologic enhancement of GABA-ergic synapses in this area is an effective method of suppressing these seizures.

24.3 Spontaneous hippocampal interictal spikes: behavioral correlation and effect of scopolamine. L. Stan Leung, Dept. Psychology, University of Western Ontario, London, Canada, N6A 5C2.

Steel wire electrodes were implanted in the CA1 alveus (surface) and the fissure (deep) of both dorsal hippocampi and in the neocortex of rats. Following recording of normal spontaneous activity, each rat was given 10 sec stimulation trains of 50 Hz, 100 - 300 µA, 0.1 msec pulses delivered bipolarly to the right hippocampus. Stimulation trains were given at 1 - 2 hour intervals and not more than 3 times a day. After a few stimulation trains, various abnormal electrical activity could be observed after the high amplitude afterdischarge that immediately followed the stimulation. One example was an increase in fast waves (30 - 70 Hz) by up to 10 fold for a period of 5 - 30 min post-stimulation. By use of Fourier spectral analysis, surface and deep hippocampal fast activities were shown to be highly coherent and 180° phase shifted. After 3 - 10 stimulation trains, spontaneous interictal spikes (SIS) of several mV could be detected visually or discriminated after high-pass filtering. No gross behavioral seizure was observed at this stage. SIS frequency increased with the recovery of the EEG amplitude (1 - 10 min. post-stimulation) and then subsided in one to several hours. SIS were various magnitudes and waveforms but mainly consisted of two types: 1. those with a surface negative, deep positive early phase followed by a late phase of reversed polarity and 2. those with a surface positive, deep negative early phase. Type 1 and 2 correspond to the waveform of the potentials evoked by the stimulation of the basal and apical dendrites of CA1 region respectively (Leung, L. S. Brain Res. 176: 49, 1979). SIS were usually synchronous on both left and right hippocampi. Its frequency varied with the behaviors of the rat, with the highest rate during slow wave sleep (SWS) and the lowest during active movements (walking, rearing, turning) and paradoxical sleep (PS); waking immobility was accompanied by an intermediate SIS rate. Scopolamine (5 mg/kg i.p.) increased the SIS rate across all waking behaviors. SIS were not detected in animals not stimulated by kindling trains.

The variation of the SIS frequency across behaviors resembles the irregular slow activity (ISA) or the theta rhythm of the hippocampus. ISA was largest and theta smallest during SWS when SIS rate was highest; ISA was smallest and theta largest during PS and active movements when SIS rate was lowest. A common mechanism may underlie the generation of hippocampal EEG and SIS - both activities may depend on an ascending brain stem input which includes a muscarinic cholinergic component. Scopolamine increased hippocampal ISA (and reduced relative power of theta) and SIS rate perhaps by blocking the cholinergic input. (Supported by NSERC grants).

24.4 MODULATION OF PENICILLIN-INDUCED INTERICTAL SPIKES BY CHOLINERGIC AGENTS AND MEDIAL SEPTAL LESIONS. Jeffrey H. Goodman* and R.M. Lebovitz. Department of Physiology, University of Texas Health Science Center at Dallas, Dallas, TX 75235.

There is strong evidence that the medial septal nucleus (MSN) projects cholinergic fibers, through the fornix that terminate throughout the hippocampus. Acetylcholine (ACH) released from these fibers may act as a neuromodulator of normal pyramidal cell activity. However, acetylcholine's role in the hippocampus during penicillin epilepsy has not been defined.

We used two approaches to investigate the possible role of the septo-hippocampal cholinergic system in penicillin epilepsy. The first was to pharmacologically test the effect of the cholinergic agents, carbachol and physostigmine, on the rate of penicillin-induced interictal spikes (IS). The second was to lesion the MSN and observe the effect on the IS rate.

The left hippocampus of Long-Evans male rats was exposed under Nembutal anesthesia. Sodium penicillin was topically applied to the dorsal surface of the CA1 region of the hippocampus and covered with warmed mineral oil. Once the focus became established, the hippocampus was superfused with artificial cerebrospinal fluid (CSF) and a baseline IS rate determined. The hippocampus was then superfused with the test agent dissolved in CSF. The concentrations of carbachol tested ranged from 10^{-6}M to 10^{-4}M. It was observed that carbachol, in doses of 10^{-5}M and greater, significantly increased the IS rate in a dose-dependent manner. Physostigmine, tested at a dose of 10^{-3}M, also caused a significant increase in the IS rate.

In a separate series of experiments, radiofrequency lesions were placed in the MSN of 300-350 g Long-Evans rats. These animals were allowed to recover a minimum of two weeks at which time the left hippocampus was exposed and penicillin was applied. The exposure was covered with warmed mineral oil. Once interictal spiking began, the spike rate was measured for a period of one hour. At the conclusion of each experiment the brain was removed and the location of the lesion was verified histologically. Non-lesioned controls were surgically prepared and examined in the same manner. We observed that the IS rate in the lesioned animals was significantly slower than the spike rate in the control animals. For example at 30 minutes the mean inter-interictal spike interval for the lesioned animals was 12.77 + 0.72 (SEC $\pm$ SEM) compared to 9.6 $\pm$ 0.56 for the controls ($p<0.005$).

The results suggest that removal of the tonic excitatory cholinergic input to the hippocampus results in a decreased level of excitability within the penicillin focus and that the IS rate can be accelerated by the cholinesterase inhibitor, physostigmine, or by the cholinomimetic carbachol.

24.5 COMPARISON OF IPSP RESPONSES IN THE CONTROL AND KINDLED HIPPOCAMPAL SLICE PREPARATION. M.W. Oliver* and J.J. Miller (SPON: J.P. Pinel). Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Previous studies have suggested that a loss of neuronal inhibition, particularly the inhibitory postsynaptic potentials (IPSP's) mediated by γ-aminobutyric acid, contributes to the generation of epileptiform activity. Although several experimental models have been used to examine this possibility, there is little information available concerning the inhibitory processes present in neuronal tissue predisposed to seizure activity. In the present study, we have utilized the in vitro hippocampal slice preparation to investigate the IPSP's from control and commissural-kindled rats.

Intracellular IPSP's, evoked by stimulation of alveus, were examined in hippocampal CA-1 pyramidal neurons from control and commissural-kindled rats. The potency, resiliency and membrane characteristics of this response was determined by assessing: 1) the duration of inhibition evoked by subthreshold alvear stimulation on spontaneous activity; 2) the effectiveness of the alvear-evoked IPSP to inhibit spontaneously active cells during tetanic stimulation at 5, 10 and 20 Hz; and 3) the conductance changes associated with the IPSP both during and following repetitive alvear stimulation.

The membrane properties of CA-1 neurons were essentially the same in control and kindled slices with their respective values being: RMP, -70, -68 mV; spike amplitude, 96, 91 mV; resting resistance, 27.5, 25.2 MΩ; input resistance during IPSP, 15.8, 18.8 MΩ. Furthermore the duration of inhibition of spontaneous or depolarization-induced neuronal activity ranged from 45-300 msec for controls and 60-350 msec for kindled slices. In both groups, tetanic stimulation at 5, 10 and 20 Hz, for varying durations could result in complete inhibition of spontaneous cellular discharge; interestingly, this occurs when the amplitude of the IPSP is reduced. That is, the amplitude and to a lesser degree the conductance associated with the IPSP are reduced during, but not immediately following, tetanic stimulation. Thus, the apparent effectiveness of the IPSP persists even though its amplitude decreases. Moreover the reduction of the IPSP, irrespective of group, differs at varying frequencies such that the decrease at 5<10<20 Hz.

These data suggest that neuronal tissue predisposed to epileptiform activity maintains the integrity of its inhibitory processes and further that the mechanism(s) subserving kindling and possibly other epileptogenic phenomena are not related to disinhibition, rather, to events that directly promote cellular excitability.

24.6 TRANSFER BETWEEN ELECTRICAL KINDLING OF THE AMYGDALA AND INTRACEREBRAL CARBACHOL OR PENTYLENETETRAZOL. Donald P. Cain. Dept. of Psychology, Univ. of Western Ontario, London, Canada. N6A 5C2.

The repeated administration of a variety of convulsant agents in initially subconvulsant amounts results in the gradual kindling of seizures. We and others have demonstrated that subjects kindled using one convulsant agent can be rendered thereby more susceptible to other such agents, but the mechanism by which this transfer facilitation occurs is not well understood.

Bidirectional transfer has been demonstrated in our laboratory between electrical kindling of the amygdala and peripherally administered pentylenetetrazol (PTZ). However, it was not clear whether kindling with peripherally administered PTZ represented a true CNS kindling effect or was merely an artifact of peripheral administration (changes in peripheral metabolism of the drug), and whether transfer would occur between intracerebrally administered PTZ and electrical kindling. In the present study kindling was clearly demonstrated when generalized seizures gradually developed after approximately 14 bidaily infusions into the rat amygdala of 0.4 mg PTZ in a 1.0 µl volume. Subsequent electrical kindling of the contralateral amygdala through a previously implanted electrode resulted in significantly faster kindling than in a control group. Another group of electrically kindled rats also demonstrated significantly faster chemical kindling when PTZ was subsequently infused into the amygdala. These results demonstrate that intracerebral PTZ can kindle seizures, and that bidirectional transfer occurs between electrical and PTZ kindling.

In a second experiment, transfer between electrical and carbachol kindling of the amygdala was studied. Both a transhemispheric (cannula in one hemisphere, electrode in the other) and an intra-hemispheric test (using a chemitrode) were made. In each case the result was the same: subjects previously kindled with one agent kindled significantly faster with the other agent. Thus, significant bidirectional transfer occurs with these agents. The convulsions produced by the agents were nearly identical. These results indicate that the agents are about equally effective in primary and transfer kindling, and are consistent with the idea that electrical kindling may depend, in part, on activation of muscarinic cholinergic neurons.

24.7 EFFECTS OF A SINGLE EPINEPHRINE INJECTION ON AMYGDALA SEIZURES AND KINDLING. K.A. Welsh*, L. Kingslow*, and P.E. Gold. Dept. of Psychology, Univ. of VA., Charlottesville, VA., 22901.

Repeated application of electrical stimulation to specific brain areas can lead to progressively intensified EEG and behavioral seizures. This phenomenon, termed "kindling", may be a useful model for studying both epileptogenesis and memory. Because peripheral epinephrine is a potent modulator of memory storage processes, we examined the effects of a single epinephrine injection on the development of kindled seizures.

In male Sprague Dawley rats, electrodes were implanted bilaterally in the basolateral nuclei of the amygdala. One week after surgery, afterdischarge (AD) thresholds were determined using unilateral stimulation trains (monophasic square waves, 1 msec, 60 Hz, 1 sec duration) of ascending intensity. Animals then received IP injections of epinephrine (1.0 mg/kg) or saline and AD thresholds reassessed 30 minutes after injection. AD durations were also measured following a fixed suprathreshold intensity (250 uA) stimulation train. This current intensity was then applied once daily (no further drug injections) and EEG and behavioral seizures were recorded after each train.

Thirty minutes after injection, epinephrine-treated rats had AD thresholds 30% lower than those of controls. Despite this increased sensitivity observed shortly after the epinephrine injection, on the next trial (24 hr later) suprathreshold stimulation (250 uA) resulted in ADs which were shorter (by 50%) in epinephrine-treated rats than in saline controls. Remarkably, the attenuation of AD duration observed after the single epinephrine injection was still evident up to 10 days later; epinephrine-treated animals had shorter ADs during kindling than did saline injected rats. Furthermore, epinephrine-treated rats required fewer trials before exhibiting behavioral clonus than did saline animals.

These results demonstrate several points: 1) A peripheral epinephrine injection reduces the AD threshold in the amygdala. 2) An epinephrine injection reduces the AD duration following suprathreshold amygdala stimulation; this effect is evident long after the injection. 3) A single epinephrine injection is sufficient to attenuate the rate of electrophysiological and behavioral kindling. These central effects of peripheral epinephrine may have potential importance for understanding the mechanisms by which epinephrine modulates memory. In addition, these findings suggest that peripheral adrenergic activity may influence epileptogenesis.

24.8 NORADRENERGIC ABNORMALITIES IN TWO INDEPENDENTLY DEVELOPED STRAINS OF GENETICALLY EPILEPSY-PRONE RATS. P.C. Jobe, H.E. Laird, T.W. Woods* and J.W. Dailey. Vet. Adm. Med. Ctr. and Depts. of Pharmacology and Psychiatry, LSU Med. Sch., Shreveport, Louisiana 71130 and Dept. of Pharmacology and Toxicology, Univ. of Arizona, Tucson, Arizona 85721.

The seizure prone state of genetically epilepsy-prone rats (GEPR) is characterized by susceptibility to hyperthermic seizures (Jobe et al., Fed. Proc. 41: 1560, 1982) and to sound-induced seizures (Jobe and Laird, Biochem. Pharmacol. 30(23): 3137, 1981). In addition, the GEPR exhibits abnormally low electroshock, pentylenetetrazol and bicuculline seizure thresholds. Two strains of the Sprague-Dawley derived GEPR have been independently developed, one at the Veterans Administration Medical Center in Shreveport, LA and the other at the University of Arizona in Tucson. The Shreveport strain typically exhibits seizures of moderate intensity, whereas the Arizona strain exhibits severe seizures. The Arizona colony was established in about 1957 and the Shreveport colony was independently initiated approximately 16 years later. Originally, seizures exhibited by the Arizona colony were of relatively moderate intensity, overtly identical to those which now characterize the Shreveport colony. Pharmacologic studies support the concept that a noradrenergic deficit may be an etiologically important determinant of seizure susceptibility and intensity in both GEPR strains.

The purpose of the present investigation was to compare innate noradrenergic abnormalities existing within the CNS of both the Tucson and Shreveport colonies. In all CNS areas except the cerebellum, norepinephrine levels were significantly ($P < 0.01$) less in the Shreveport GEPR than in non-epilepsy prone controls. The mean percentage decrement was 24.9%, with a range of 17.9% to 30.9%. The mean decrement in Tucson GEPRs was 37% (Range, 36-39%) with the cerebellum excluded. Norepinephrine levels in the cerebellum were increased by 16% in the Shreveport GEPR, whereas in the Tucson GEPR the levels were decreased by 30%. The existence of norepinephrine decrements which are widespread throughout most of the CNS in both the Shreveport and Tucson GEPRs provide additional support for the concept that one determinant of seizure susceptibility in the two strains in a decrement in noradrenergic transmission. Seizures in the Tucson GEPRs may be more severe than those of the Shreveport GEPRs because of the occurrence of cerebellar differences between these two strains. The increment in norepinephrine levels in the cerebella of Shreveport GEPRs may protect against severe seizures, whereas the norepinephrine decrements in the cerebella of Tucson GEPRs may augment seizure intensity. Alternatively, seizures of Tucson GEPRs may be more severe because of greater norepinephrine decrements in brain areas other than the cerebellum.

24.9 BRAIN NOREPINEPHRINE AND THE GENETICALLY-DIRECTED CONVULSIONS OF THE TOTTERING MUTATION IN THE MOUSE, P.J. Syapin, M. Basura*, S.R Snodgrass, and L. Erinoff*. Dept. of Neurology, University of Southern California School of Medicine, Los Angeles, CA 90033.

The autosomal recessive mutation tottering (tg) is identified by the occurance of "spontaneous" stereotypic behavioral convulsions and a characteristic degree of ataxia. Stereotypic convulsions identical to those seen "spontaneously" are also induced by doses of pentylenetetrazol (PTZ) which are subconvulsant in heterozygote (tg/+) and normal (+/+) mice of the same strain (C57Bl/6J This action of PTZ is antagonized by benzodiazepines but not by other common antiepileptic drugs (Syapin, in press). Levitt and Noebels reported increased brain norepinephrine (NE) levels arising from the locus coeruleus of (tg/tg) mice when compared to (+/+) mice (P.N.A.S., 78:4630, 1981). We now report on the role of the noradrenergic system in "spontaneous" and PTZ-induced stereotypic convulsions of (tg/tg) mice.

Regional brain levels of dopamine, NE, and 5-HT in (tg/tg), (tg/+), and (+/+) mice from our colony are being determined by HPLC to confirm and extend the finding of Levitt and Noebels. To determine whether the noradrenergic system is involved in the expression of stereotypic convulsions, (tg/tg) mice were treated i.p. with α or β-adrenergic drugs 30 min prior to induction of stereotypic convulsions with 30 mg/kg PTZ. Treatment with (+)propranolol (4 mg/kg), phentolamine (10 mg/kg), prazosin-HCl (2 mg/kg), or d-amphetamine (10 mg/kg) had no effect on the induction of convulsions in (tg/tg) mice. Treatment with 1 mg/kg clonidire, however, completely blocked PTZ-induced stereotypic convulsions (N=8). 0.1 mg/kg clonidine was ineffective. Treatment with 1 mg/kg clonidine caused sedation in both (tg/tg) and (tg/+) mice. The protection by clonidine was antagonized by 50% in mice treated with 4 mg/kg yohimbine 15 min prior to clonidine. Alone, yohimbine had only weak anticonvulsant activity.

When forebrain NE was reduced by 80% in adult (tg/tg) mice by i.c.v. injection of 100 µg 6-hydroxydopamine (6OHDA) the ability to have "spontaneous" and PTZ-induced stereotypic convulsions was not changed. Results from an ongoing study show that treatment of 40 day old (tg/tg) mice with 150 µg 6OHDA i.c.v. at least 10 days prior to the onset of behavioral symptoms did not influence the presence of "spontaneous" convulsions or the ataxia used to identify (tg/tg) mice.

These data imply that the noradrenergic system of the (tg/tg) mouse brain is not responsible for the onset of stereotypic convulsions but is perhaps involved in the expression of the behavioral convulsions via α-adrenergic mechanisms. (Supported by a grant from the Epilepsy Foundation of America and grant NS 16314)

24.10 SUBCLINICAL EPILEPTIFORM ACTIVITY AND MORPHOLOGICAL DAMAGE IN THE STRIATUM OF RATS AFTER TRANSIENT FOREBRAIN ISCHEMIA. P.S. Lacy*, W.A. Pulsinelli, Dept. Neurology, Cornell Univ. Med. Coll. New York, N.Y. 10021 (SPON: S.S. Winans)

We have reported that the number of morphologically damaged medium-sized striatal neurons progressively increases for hours after 30 min of severe forebrain ischemia in the rat (Ann Neurol 11:491, 1982). Late changes in arterial blood pressure or oxygenation did not occur in these animals, nor were there signs of postischemic (PI) seizures. We sought to determine (1) if epileptiform activity, defined in this study as spike/sharp-and-slow wavy complex (SW) was present in PI rats without behavioral signs of seizures and (2) if occurrence of SW could be related to the progression of ischemic damage in the striatum.

Tungsten microelectrodes (200 µ) were implanted in the left dorsal-lateral striatum of adult rats 7 to 10 days prior to subjecting the animals to 30 min of severe forebrain ischemia. Forebrain ischemia was produced by occluding the common carotid arteries for 30 min; the vertebral arteries were permanently occluded 24 hr earlier (Stroke 10:267, 1979). The electroencephalogram (EEG) was recorded prior to, during and serially after the ischemic insult. The animals' brains were perfused-fixed with FAM (formaldehyde:methanol:acetic acid, 1:1:8) at 24 to 72 hr after restoration of carotid artery blood flow. Serial sections were examined with the light microscope for ischemic neuronal damage. SW activity was visually identified and defined as spikes (duration < 80 msec) and sharp waves (duration > 80 msec) found to be associated with a slow wave of greater duration. The negative deflection of SW was further characterized according to Ktonas et al. (EEG and Clin. Neurophysiol 51:237, 1981) for amplitudes A and B, and subdurations A and B. On the basis of morphological studies of the striatum, animals were divided into Group I (few neurons damaged, n=3) and Group II (many-majority neurons damaged, n=3). Although SW was arrhythmic, the peak frequency, calculated from 3 min epochs randomly chosen at 30 min intervals, occurred in both groups between 1 to 2 hr PI. The peak frequency in Group I was 28/min and in Group II it was 20/min. The duration of SW from onset at 15 min PI to its termination at 10 hr PI was similar in both groups and was replaced by spindle activity after SW ceased. Amplitude A peaked between 0.5 and 1 hr PI in Group I and between 1 to 2 hr PI in Group II. Amplitude B peaked between 1 to 2 hr PI in Groups I and II. SW could also be detected from other regions of the brain including the neocortex and hippocampus. The results indicate that although striatal SW activity occurred in all rats subjected to forebrain ischemia, there was no apparent correlation between the severity of striatal damage and the frequency or amplitude of SW activity recorded in this region.

24.11 DIFFERENTIAL CONDITIONING EFFECTS OF ENVIRONMENTAL CUES ON KINDLING. F.G. Freeman and P.J. Mikulka*. Psychology Dept., Old Dominion University, Norfolk, VA 23508

Much anecdotal evidence exists suggesting that nonphysiological variables may affect seizures. However, there is relatively little experimental investigation of environmental and behavioral variables which might increase or decrease the probability of seizures. The present experiment investigated the effect of discrimination training on seizures within the kindling paradigm. Male Long-Evans hooded rats were kindled in the amygdala. Group 1 Ss received stimulation in an illuminated chamber with white walls; these Ss were also placed in a darkened chamber with black walls for two minutes either 1/2 hour before or after the kindling stimulation. Group 2 Ss underwent the same treatment except they were kindled in the black chamber and placed but not kindled in the white chamber. Group 3 Ss were kindled in the black chamber and not exposed to the white chamber while Group 4 Ss were kindled in the white chamber and not exposed to the black one. Upon reaching a stage 5 seizure all Ss were threshold tested in both the black and white chamber. They were then given 10 more days of training and retested in chambers.

Subjects kindled in the white box kindled significantly faster than those kindled in the black box ($p < .05$). Subjects in the white-discrimination condition kindled significantly faster than the black discrimination ($p < .01$) while the control groups did not differ. No significant differences in thresholds were found. However, on the final test there was a tendency for the discrimination Ss to have a higher threshold in the box in which they were kindled compared to their "nonkindled" box. Finally, discrimination Ss had significantly shorter AD durations than the control Ss for the threshold tests.

24.12 DIFFERENTIAL RECOVERY OF SIMPLE AND COMPLEX BEHAVIORS FOLLOWING KINDLED SEIZURES IN RATS. S. Caldecott-Hazard, N. Yamagata*, J. Hedlund*, J.C. Liebeskind. Dept. Psychology, University of California, Los Angeles, CA. 90024.

Few studies, either clinical (Escueta et al., 1977; Morrell, 1979) or experimental (Myslobodsky, 1981), have quantitatively evaluated changes in behavior following a seizure. The present study therefore assessed the performance of rats on a variety of behaviors immediately following a kindled seizure and continuing until the behaviors recovered to pre-seizure baselines. Kindling was produced by daily amygdala stimulation until fully generalized (stage 5) seizures were elicited on 3 days. Following a seizure, rats were tested for responses to painful tail shocks, fixed ratio bar pressing for food, free access to food, ability to cling to a vertical grid, latency to first step, and for duration of postictal EEG depression (PID). Each rat was tested on every task, and some rats also received naloxone in order to assess the possible involvement of opioid peptides. One week intervals separated tasks. Tail shocks (100 msec train, 60 Hz, 1 msec square wave pulses, 0.1-10 mA) were given at 10 sec intervals following the cessation of the seizure afterdischarge (AD) and thresholds for a tail flick, single squeak, and multiple squeaks were recorded. Postictally the threshold for multiple squeaks was significantly elevated and remained so for approximately 6 min. Thresholds for tail flick and single squeaks were not significantly changed. Bar pressing for food was abolished for approximately 8 min. Consumption of freely available food was arrested by the seizure but resumed approximately 5 min later. Similarly, the duration of the EEG postictal depression was approximately 5 min. Grid clinging was abolished for approximately 3 min. following the seizure, and the latency to the first step was approximately 2 min. Naloxone pretreatment (10 mg/kg given twice at 15 min. intervals immediately preceding the seizure) shortened the recovery time for the multiple squeak response, for grid clinging, and for the first step. Postictal recovery times for bar pressing, acquisition of freely available food, and PID were not significantly altered by naloxone. These data suggest that simple behaviors such as grid clinging and ambulation recover more quickly following a seizure than do appetitive or pain elicited vocalizations. Complex, learned behaviors such as bar pressing appear to recover most slowly. Furthermore, kindled seizures may release opioids that are involved in the production of analgesia and catatonia, but not in the disruption of learning or food acquisition.

24.13 KINDLING A SLEEP AND SEIZURE DISORDER. M. N. Shouse* and M. B. Sterman (SPON: D. J. McGinty). Neuropsychology Research, V.A. Medical Center, Sepulveda, CA 91343.

Although prevalent in various epilepsies, sleep pathology is typically viewed as a secondary or incidental complication of seizure activity. We re-evaluated this interpretation by documenting changes in sleep and waking states throughout as well as one month after the development of stimulation induced seizures through basolateral amygdala kindling. Ten cats were experimental subjects. Following recovery from stereotaxic surgery, afterdischarge (AD) thresholds were established using a standard method of limits procedure (Shouse, M. N. and Sterman, M. B., Exp. Neurol., 71: 550, 1982). Stimulation (1 sec, 60 Hz biphasic square waves, 1 msec pulse duration at minimal AD-eliciting intensity) was applied daily until stage 6 generalized tonic-clonic convulsions were obtained. Stage 6 seizure thresholds were established at the end of kindling and after a one month respite from amygdala stimulation, using the same threshold procedure as before. Twelve-hr polygraphic recordings of the sensorimotor cortical electroencephalogram, electrooculogram (eye movements) and electromyogram (neck muscle) were obtained before, during and at the end of kindling as well as on the day preceding seizure threshold determination one month later. An average of 25.6 AD stimulations were required to elicit stage 6 seizures. Progressive slow-wave-sleep and rapid-eye-movement sleep deficits accompanied the development of kindled convulsions, as previously reported (Shouse, M. N. and Sterman, M. B., Exp. Neurol., 71: 563, 1982). Moreover, these deficits persisted one month after kindling procedures were discontinued. Since no overt seizure activity occurred during the interim, non-stimulation period, post-kindling sleep deficits may not be viewed as a simple or transient side effect of seizure pathology. Further, the magnitude of sustained sleep deficits predicted subsequent seizure susceptibility ($r = .82$, $p < .05$). This correlation indicated a more fundamental link between the two pathologies than was previously suspected. Sleep deficits are clearly as persistent as the seizure disorder after kindling, suggesting the "kindling" of a sleep disorder which occurs in addition to and may be a determinant of the seizure disorder.

24.14 LEARNING DEFICITS IN AMYGDALOID-KINDLED JUVENILE RATS. K. J. Ebersole* and R. F. Berman. Department of Psychology, Wayne State University, Detroit, MI 48202.

The present study examined the development and behavioral effects of amygdaloid kindling in juvenile rats. Several lines of research have suggested a relationship between certain types of epilepsy and learning deficits. In particular, infantile seizures (occurring before 2 years of age) are associated with a high rate of mental retardation. An animal model of infantile epilepsy was developed to investigate this problem.

Five groups of young (18-56 days of age) male Long-Evans rats were stereotaxically implanted, bilaterally, in the amygdala with bipolar electrodes 5-7 days prior to the initiation of kindling. Each group differed in the age at which kindling began (25-27, 30-31, 35-36, 40-41, or 49+ days of age). Afterdischarge thresholds (AD) were determined and subjects were unilaterally stimulated once daily (100 Hz, biphasic, square wave, 0.1 msec pulse duration) for 5 sec at threshold until 3 consecutive Stage 5 seizures had been elicited. Development of kindling in juvenile animals was found to be similar to that previously reported for adult rats in spite of extremely high AD thresholds ($\bar{X}$=699 $\pm$ 36 S.E. microamperes) in the young animals. Permanence of kindling was tested 2 weeks to 2 months later and was demonstrated in every animal tested.

Between 12-14 weeks of age 3 groups of animals; a kindled group (n=11), a non-stimulated control group (n=13), and a non-operated control group (n=6), began training on a shock avoidance task. Animals were first water deprived and then trained to run from a start chamber to a goal chamber in which water was available. Training occurred once per day until animals entered the goal box and began drinking in less than 10 sec for 2 consecutive days. There were no significant differences among groups in the number of days required to reach this criterion. The next day each rat was given a brief scrambled footshock (3 milliamperes for 3 sec) upon entering the goal box. Rentention of training was examined 24 hours later by measuring the animal's latency to enter the goal box and begin drinking. The kindled rats showed impaired retention of the shock avoidance training compared to the control groups. Footshock sensitivity was ascertained for all subjects in order to ensure that the observed shock avoidance deficits were not due to an alteration in shock perception. No differences in shock sensitivity were detected among the groups. At the end of the experiments, implanted subjects were sacrificed and precise electrode placements were verified histologically.

These results suggest that while the brains of young rats support kindling, the long range behavioral consequences of this procedure are more profound than those reported for adult kindled animals.

24.15 DEVELOPMENTAL CHANGES IN POST-ICTAL INHIBITION IN THE KINDLED RAT. Bruce J. Albala and Solomon L. Moshé*. Depts. of Psychiatry and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461

Our recent data indicate that amygdaloid kindled rat pups (15-18 days) have faster generalization of focally elicited seizures than adult rats and kindling can be induced in rat pups even after the application of electrical stimuli which either markedly retard or fails to produce kindling in their adult counterparts. This data supports the notion that the immature CNS is more susceptible to the development and initiation of the kindled convulsions, though it does not address any developmental issues once the brain has been "kindled". The present study utilizes the "recycling" technique in an attempt to determine whether the degree of neural maturation affects the extent of post-ictal inhibition.

Fourteen 13 day old rat pups and six 120 day old adult rats were implanted with a bipolar electrode in the left amygdala. Three days later the adults and half the pups were kindled until generalized motor convulsions were elicited. Recycling was used to test the extent of post-ictal inhibition with the delivery of 8 separate stimulations (400 µAmp, 60 Hz, 1 sec) every 2 min. while the depth EEG and behavior was continuously monitored. The electrodes were then removed from the fully kindled (FK) and implanted non-stimulated (NON-STIM) pups which were allowed to grow. At 90 days the surviving rats were reimplanted with a bipolar electrode in the cortex and each amygdala. At 140 days the FK and NON-STIM rats were kindled daily in the right amygdala. The left amygdala was then stimulated until kindled motor convulsions were reliably elicited and the rats were then "recycled" at 5 and 7 months of age.

The results of the first recycling experiment indicates that the rat pups and adults differed significantly for both the behavioral seizure index (pups $\bar{X}$=3.1, adults $\bar{X}$=2.0, $p < 0.05$) and the afterdischarge (AD) seizure index (pups $\bar{X}$=48.8 sec, adults $\bar{X}$=27.5 sec, $p < 0.01$). The surviving 5 FK rats required significantly fewer stimulations to develop generalized convulsions than the 4 surviving NON-STIM rats when first kindled on the right side as adults (FK $\bar{X}$=1.8 stims., NON-STIM $\bar{X}$=5.8 stims., $p < 0.05$). These two groups of kindled animals were not statistically ($p > 0.05$) different in terms of either the first or second adult recycling trial. However, the 4 FK rats that were successfully recycled at 3 different ages had a statistically significant difference ($p < 0.05$) between the behavioral seizure index when they were rat pups ($\bar{X}$=3.2) as compared to their two later adult recycling trials at 5 months ($\bar{X}$=1.7) and 7 months ($\bar{X}$=1.6) of age.

The present study indicates that immature rats are capable of having longer and more severe seizures following delivery of repeated stimuli during the immediate post-ictal period. This increase in post-ictal inhibition with age appears to be a maturational event that is independent of previous epileptic experiences.

24.16 AMYGDALO-THALAMIC INTERRELATIONS IN EXPERIMENTAL TEMPORAL LOBE EPILEPSY. T.E. Hoyt*, P. Rinaldi, J.A. Kusske. Division of Neurosurgery, UCI School of Medicine, Irvine, CA 92714.

The patterns of seizure spread were investigated in rabbits with afterdischarge induced by electrical stimulation of the amygdala. Following surgical procedures, carried out under halothane anesthesia, the animals were immobilized with gallamine triethiodide and ventilated to maintain normal pO_2 and pCO_2. Stereotaxically placed tungsten microelectrode recordings of waves and extracellular unit activity were obtained from the dorsomedial nucleus of the thalamus, both ipsilateral and contralateral to the amygdala being stimulated and from the contralateral amygdala and ipsilateral hippocampus. In one group of rabbits the anterior commissure was left intact. In a second group, prior to inducing afterdischarge by amygdala stimulation, the anterior commissure was electrolytically lesioned. When convulsive activity developed at the focus in preparations with intact anterior commissures there followed a rapid and stereotyped development of ictal activity first detected in the contralateral amygdala and then in the thalamus and finally in the ipsilateral hippocampus. Stereotaxic electrolytic lesions, confirmed histologically, in the anterior commissure were followed by striking disorganization of the spread of ictal activity. In these preparations the duration of seizures was markedly reduced and the amplitude of ictal activity was significantly lessened. The implications of these findings relative to the treatment of patients with intractable temporal lobe seizures may be significant. These studies indicate that further investigations of stereotaxic lesions in the commissural systems connecting limbic structures are warranted to define new approaches to clinical therapy of otherwise intractable seizures arising from the amygdala complex in humans.

24.17 AMYGDALA KINDLING AND NOCTURNAL LOCOMOTION FOLLOWING MIDDLE CEREBRAL ARTERY LIGATION IN THE RAT. J.M. Schwartz*, C.L. Ehlers*, A.J. Mandell, and F.E. Bloom. A.V. Davis Center, The Salk Institute and the Dept. of Psychiatry, UCSD, La Jolla, CA.

Seizures and behavioral deficits are known to occur as sequelae to cerebral cortical infarction in human patients. In the present study we investigated whether alterations in locomotor behavior, and the development of amygdala kindled seizures could be detected following experimental cerebral infarction in the male Wistar rat. Experimental infarction was accomplished under chloral hydrate anesthesia by performing a right (n=12) or left (n=12) fronto-parietal craniotomy and ligating the middle cerebral artery with ophthalamic suture. These ligations resulted in a fronto-parietal cortical lesion 1-3 mm in diameter. Sham rats (n=10) sustained right or left craniotomies and dural puncture. In a second surgical procedure the ligated and sham animals were anesthetized and stereotaxically implanted with electrodes in the amygdala on the side contralateral to the ligation (n=16) or the side ipsilateral (n=8). Two weeks following the surgical procedures locomotion was assessed by monitoring spontaneous nocturnal activity in cages equipped with photocell beams. Ligated and sham rats were tested 30 days post-ligation for threshold to afterdischarge and then kindled daily (1 sec, 60 Hz, bipolar square waves, 200 μA) until 3 fully kindled convulsions were noted.

No gross motor deficits were noted in any of the rats by 72 hours following the ligation. Analysis of nocturnal locomotor activity by ANOVA did not reveal significant group or group x time effects betwen any of the groups (rt vs lf, rt vs shams, lf vs shams, ligated vs shams). However, analysis of the patterns of locomotor activity over time using spectral analysis did uncover significant frequency differences in locomotion. Activity patterns of lesioned animals showed a higher frequency of fluctuation compared to shams irrespective of whether the lesion was on the left or right ($p < .05$ Mann Whitney U-test). Differences in afterdischarge (AD) thresholds and rate of amygdala kindling were also found. Mann Whitney U-test revealed a significant increase in AD threshold ($p < .01$) and kindling rates ($p < .02$) in rats kindled in the amygdala contralateral to the ligation as compared to shams. A non-significant decrease in thresholds and kindling rates was found in animals kindled ipsilateral to the lesion. Thus, it appears that unilateral middle cerebral artery ligation may induce increased inhibitory mechanisms on the contralateral side. These results suggest that cerebral infarction induces complex electrophysiologic and behavioral changes in rats. (Supported by the Klingenstein Foundation and USPHS Grant MH 07899.)

24.18 UNCOUPLING OF HIPPOCAMPAL METABOLISM AND BLOOD-FLOW DURING AMYGDALA-KINDLED SEIZURES IN RATS. R.F. Ackermann, J.L. Lear*, W. Meredith*, and J. Engel, Jr. Reed Neurological Research Center, and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Utilizing the Sokoloff ^{14}C-2-deoxyglucose (2DG) method, we have previously shown that generalized amygdala-kindled seizures are associated with hippocampal hypermetabolism. Those results were replicated in the present study. In addition, two different blood-flow markers, ^{14}C-iodoantipyrene or ^{123}I-N-isopropyl-p-iodoamphetamine (IAM) were administered (i.v.) during, or up to 60 min after, amygdala-kindled seizures. The most salient result was a decrease in hippocampal blood-flow relative to surrounding structures, as indicated independently by both flow markers, during and up to 60 min following the seizures. Several animals with partial seizures (stage 3, Racine) were double-labeled with ^{14}C-2DG and ^{123}IAM. The resulting autoradiographs showed greater 2DG uptake in the ipsilateral hippocampus than the contralateral. In contrast, the IAM autoradiographs from the same animals showed less IAM uptake in the ipsilateral hippocampus than the contralateral. Numerous previous studies have demonstrated global increases in cerebral blood-flow during seizures. The present results suggest that, at the least, such increases are not distributed uniformly; the blood supply to certain structures may actually decrease. Previous workers have attempted to account for hippocampal neuronal loss following prolonged seizure conditions in terms of damage from 'overexcitation', despite the fact that it has been repeatedly shown that 'overexcited' neurons merely cease firing temporarily. The present study's results suggest that a more likely mechanism for progressive hippocampal neuronal death associated with repeated seizures may be that of episodic mismatches between hippocampal metabolic demand and blood supply.

24.19 RETARDATION OF AMYGDALOID KINDLING IN HOMOZYGOUS DIABETES INSIPIDUS RATS. Bonnie J. Gillis* and Donald P. Cain (SPON: C.H. Vanderwolf) Department of Psychology, University of Western Ontario, London, Ontario N6A 5C2.

There is recent evidence to suggest that arginine vasopressin (AVP) plays a role in CNS functioning. Several investigators have demonstrated that AVP fibres project from the hypothalamus to many parts of the brain including medial, central, lateral and basal amygdala, and that electrical stimulation of the amygdala results in increased levels of AVP at the site of stimulation. Kasting et al (1980) described a sensitization process whereby intracerebral ventricular injections of AVP initially caused short periods of immobility, and myoclonic-myotonic convulsions after a second injection two days later. The present study examined electrical kindling of the amygdala in homozygous diabetes insipidus rats, a Long Evans strain that genetically lacks the ability to synthesize AVP. It is of theoretical interest and of clinical significance to determine whether AVP plays a role in the production of generalized seizures.

Adult male homozygous diabetes insipidus (DI) and normal Long Evans (N-LE) rats were implanted with bilateral electrodes in the basolateral amygdala. Kindling stimulation consisted of a 1-sec train of biphasic square wave pulses at 60 Hz delivered once a day at 200 μA. The N-LE subjects kindled to a stage 5 generalized seizure after a mean of 14.0 afterdischarges (ADs). After 20 ADs the DI subjects had progressed to a mean seizure stage 1 (immobility and chewing). Half of these subjects were continued on the 200 μA stimulation and they kindled after a mean of 28.7 ADs. The remaining DI subjects were stimulated at 400 μA for 3 d., followed by stimulation at 800 μA for 3 d., after which the experiment was terminated. These latter DI subjects progressed to a mean seizure stage 1 after 26 ADs. Thus, the rate of kindling in the DI subjects was significantly retarded relative to that of the N-LEs ($p < .01$). There was no difference between the DI and N-LE subjects with respect to AD threshold or generalized seizure threshold (minimum current intensity necessary to elicit a generalized seizure in a fully kindled rat) in those subjects that kindled.

These preliminary data suggest that AVP may play a role in the kindling of seizures from the amygdala of normal LE rats, and that the significant retardation of kindling in the DI subjects may have been due to their lack of AVP. A variety of studies are being conducted to test this hypothesis more directly.

24.20 ROLE OF CENTRENCEPHALIC SYSTEM IN EPILEPSY. G.H. Fromm, C.F. Terrence* and A.S. Chattha*. Dept. of Neurology, Univ. of Pittsburgh Sch. of Med. and Neurology Service, V.A. Hospital, Pittsburgh, PA 15261.

It is now generally accepted that seizures originate in the cerebral cortex rather than in the centrencephalic system. However, there continues to be controversy as to whether seizure activity spreads primarily via the corpus callosum and cerebral commissures or via the centrencephalic system (reticular formation of diencephalon and midbrain). A number of investigations have indicated that anticonvulsants prevent the spread of seizures through subcortical pathways, suggesting that these structures do play an important role in seizure spread and generalization.

We have found the various inhibitory and excitatory mechanisms in the trigeminal nucleus of cats to be a useful model for studying the mechanism of action of anticonvulsant drugs. Petit mal drugs selectively depress inhibitory mechanisms in this model, while grand mal drugs primarily depress excitatory mechanisms. We have now compared the effect of anticonvulsant and non-anticonvulsant drugs on the periaqueductal and periventricular inhibition of the trigeminal nucleus to further elucidate the role of the reticular formation in the spread and in the control of seizure activity.

The i.v. injection of 5-20 mg/kg carbamazepine depressed the periventricular and the periaqueductal inhibition to the same extent that it depressed excitatory transmission in the trigeminal nucleus. As in previous experiments, these doses of carbamazepine facilitated the segmental inhibition in the trigeminal nucleus. The i.v. injection of 0.5-2.0 mg/kg baclofen also depressed excitatory transmission in the trigeminal nucleus, but in contrast to carbamazepine facilitated the periventricular and periaqueductal inhibition, as well as the segmental inhibition.

Baclofen thus resembles carbamazepine in depressing excitatory transmission and facilitating the segmental inhibition. Baclofen also resembles carbamazepine in being an effective drug for the treatment of trigeminal neuralgia. On the other hand, baclofen does not depress the periventricular and periaqueductal inhibition, and it does not have anticonvulsant properties either. Our experiments therefore indicate that the ability to depress the reticular formation is an important characteristic of anticonvulsant drugs. This suggests that the centrencephalic system is indeed involved in the spread and generalization of seizures.

25.1 THE EFFECT OF IMMOBILIZATION STRESS AND OPIATE RECEPTOR BLOCKADE ON RAT SUBSTANTIA GELATINOSA ACTIVITY DEMONSTRATED WITH CYTOCHROME OXIDASE HISTOCHEMISTRY. G.S. Hamill and N.J. Lenn. Depts. of Neurol. and Pediat., and Clinical Neurosci. Research Center., University of Virginia, Charlottesville, VA 22908.

The substantia gelatinosa (SG) is a complex area of interaction between primary afferents, projection cell dendrites, spinal interneurons, and descending pathways. Zeiss Zonax microdensitometer scans of cytochrome oxidase histochemical reaction (COx) in cervical spinal cord sections were corrected for staining variations based on dorsal funiculus, and control SG values amongst batches. Twelve rats were stressed by immobilization (IS) for one hr between 0900 and 1500 daily for 2 weeks; 5 of these also received naloxone HCl (Nal) in increasing dosage of 0.27 to 0.40 mg/kg s.c. 3 times daily. Five rats not immobilized received standard care, and 2 received naloxazone (nal) 20 mg/kg i.v. alternate days for 4 doses.

Visually apparent differences in staining intensity amongst the 4 experimental groups were confined to SG. The control animals had a mean COx density in SG of 360±28, while daily IS resulted in a 53% increase to 550±51 ($p<.02$). IS+Nal resulted in COx 29% less than IS only, 390±32 ($p<.05$), not significantly different than controls ($p>.2$). Nal was similar to control. IS+Nal rats were docile when handled compared to IS only.

There is evidence that COx is proportional to neuronal activity, analogous to 2-DG uptake, but with a time constant of days to weeks. The increased COx with IS in the present study might result from the effect of IS on brain. However, the effect of IS on brain is enhanced by Nal and attenuated by morphine (Nal reversible). In contrast Nal reverses the effect of IS on SG activity, suggesting a direct effect of IS and/or Nal on SG. Furthermore that IS gives greater COx than control, IS+Nal and nal only suggests that Nal interacts with the IS effect, possibly at a common site. Since these are net measures of activity direct effects on SG, and via multiple brain sites cannot be further distinguished, and very different component contributions of several sites may result in similar values.

In addition to providing evidence for interactive effects of IS and opiates on SG activity, we have provided further support for the use of COx for spatial resolution of physiological and pharmacological alteration of neuronal activity. Supported by NIH grant NS 16882. Naloxazone courtesy of Dr. G. Pasternak.

25.2 ROLE OF PEPTIDES, SUBSTANCE P AND ENKEPHALINS, IN ACUPUNCTURE ANALGESIA: IMMUNOCYTOCHEMICAL STUDY IN RAT SPINAL CORD. L. L. Vacca, N. Eric Naftchi, Guan Xinmin*, and Ai Minkang*. Department of Anatomy, University of Kansas Health Science Center, Kansas City, Kansas 66103, Laboratory of Biochemical Pharmacology, N.Y.U. Med. Ctr., New York, NY 10016, and Acupuncture Anesthesia Research Department, Wuhan Medical College, The People's Republic of China*.

Using immunocytochemistry, we are investigating the effect of acupuncture on the peptides substance P (SP) and methionine and leucine enkephalins (ME and LE, respectively) in the rat spinal cord. The peptides are thought to play a role in spinal pain processing. That is, SP seems to be involved in nociception, and the enkephalins, which bind stereospecifically to opiate receptors, have a role in analgesia. Our experiments so far show that acupuncture, like morphine (Vacca, L.L., Abrahams, S.J., Naftchi, N.E., Brain Research, 182:229, 1980), causes the increase of intraneuronal SP in the dorsal horn substantia gelatinosa of the rat spinal cord. The SP increase varies in proportion to the increase in pain threshold after acupuncture. Treated rats which show a great increase in pain threshold also exhibit a dramatic increase in SP; treated rats with a smaller increase in pain threshold after acupuncture exhibit little to no increase in SP.

Among treated animals, immunologic staining for ME varies according to the antisera species. Slight reductions appear variably in the dorsal horn of treated rats which show a great increase in pain threshold; no change occurs when acupuncture causes a smaller increase in pain threshold.

Compared with ME, LE exhibits greater reductions in the dorsal horn after acupuncture. However, once again the results vary between experiments, and change in proportion to the increase in pain threshold after acupuncture.

Despite the variations, we interpret the data to mean that acupuncture may cause the release of LE and may also block the release of SP from nearby afferent processes. Current hypotheses suggest enkephalin interneurons synapse with the preterminal endings of SP afferents and regulate SP release through an interaction with the opiate receptor. Conceivably acupuncture first causes the release of LE which then binds to preterminal opiate receptors and subsequently blocks SP release. Using our antisera species, ME does not change dramatically. Therefore LE and ME may have different functions and responses in vivo.

Acknowledgements: The work was supported by a grant from the Committee to Combat Huntington's Disease (LLV); Acupuncture treated rats were prepared and fixed by Drs. Minkang and Xinmin; anti-LE graciously provided by Dr. Richard Miller.

25.3 INTRATHECAL DYNORPHIN INDUCES ANTINOCICEPTION AND PARALYSIS. B.H. Herman. Addiction Research Foundation, 701 Welch Road, Palo Alto, CA 94304.

Previously, we found that intraventricular administration of the partially sequenced dynorphin peptide (dynorphin-(1-13) induced antinociception in rats (Herman, B.H., Leslie, F. & Goldstein, A., Life Sci., 27: 883, 1980). In contrast with other opioids, high naloxone doses were required to antagonize these effects. These results as well as others have suggested that dynorphin may preferentially interact with a unique type of opiate receptor in brain.

Here we determined if intrathecal (IT) administration of dynorphin induces antinociception in rats. We also compared dynorphin with morphine (a mu ligand) and (D-Ala2, Leu5) enkephalin (DADLE, a delta ligand) to determine the type of opiate receptor that dynorphan interacts with in spinal cord.

IT dynorphin (ED_{50} = 6.16 nmol, N = 9) was 14 times less potent than morphine (ED_{50} = 0.44 nmol, N = 9) and 103 times less potent than DADLE (ED_{50} = 0.06 nmol, N = 11) in the tail flick test (50% maximum possible effect). On hindlimb clip vocalization and flexion tests, antinociceptive potency of the three drugs were similar, although ED_{50}s were orders of magnitude higher than in the tail flick test. In these tests, the potency of dynorphin-(1-13) was similar to dynorphin while (Leu)enkephalin produced no effect in doses up to 50 nmol.

IT dynorphin doses greater than 10 nmol also induced hindlimb paralysis. Such paralysis was not reversible if the dynorphin dose was greater than 20 nmol. Neither IT morphine or DADLE produced similar paralysis, although doses of DADLE that were 100 times the ED_{50} for tail flick did induce a waxy flexibility of the hindlimbs.

Naloxone (1 mg/kg, s.c.) completely antagonized the antinociceptive effects of morphine (0.88 nmol) and DADLE (0.12 nmol) but not dynorphin (6.00 nmol) on tail flick. High naloxone doses (32 mg/kg, s.c.) did antagonize dynorphin's effects.

These results suggest that in spinal cord, dynorphin may have a role in antinociception and in some aspect of motor function. These data also raise the possibility that more than one opiate receptor type may modulate pain in spinal cord.

25.4 MODULATION OF THE SOMATOSENSORY RESPONSES OF SPINAL CORD DORSAL HORN NEURONS IN THE CAT BY ELECTRICAL STIMULATION OF THE RED NUCLEUS. Jonathan O. Dostrovsky and Bruce G. Gray. (SPON: H.C. Kwan). Department of Physiology, University of Toronto, Toronto, Canada, M5S 1A8.

Previous studies on the role of the red nucleus in descending control systems have found that this structure is important in modulating motor related responses. However anatomical studies have shown that the rubrospinal tract terminates in laminae V-VII, a region also known to contain neurons which relay somatosensory information. Such a pattern of termination would seem suited for modulating dorsal horn neurons which respond to cutaneous stimuli. Thus it was decided to investigate the effects of electrical stimulation delivered to the red nucleus on the responses of neurons receiving somatosensory inputs.

Experiments were performed on chloralose anesthetized cats. Single unit recordings were obtained from the lumbar spinal cord using glass-coated platinum-plated tungsten microelectrodes. A bipolar stimulating electrode was stereotaxically implanted in the red nucleus and the stimulation site subsequently verified histologically. A total of 26 neurons was studied. These neurons were identified according to standard criteria as low threshold mechanoreceptive, wide dynamic range or nociceptive specific by a careful sensory examination. Most of these neurons were located in laminae IV and V of the dorsal horn. To test for inhibitory effects from the brainstem the neurons were excited at just suprathreshold levels by electrical skin stimulation applied to the cutaneous receptive field. The brainstem conditioning stimulus was delivered 130 ms prior to the peripheral stimulus and consisted of a 100 ms 500 Hz train of 0.1 ms pulses (maximum current 400uA). 10/14 low threshold mechanoreceptive, 9/10 wide dynamic range and 2/2 nociceptive specific cells were inhibited with mean currents of 104uA, 121uA and 59uA repectively. A preliminary analysis of stimulation sites in or around the red nucleus revealed that those placed more caudally were most effective. These results indicate that the red nucleus may exert some modulatory influence on the transmission of somatosensory information in addition to its role in motor control. The inhibitory effects are presumably mediated by the rubrospinal tract, although the involvement of the rubro-bulbospinal pathway whose spinal component is thought to be the dorsal reticulospinal tract can not be ruled out.

Supported by Canadian MRC.

25.5 ASCENDING AND DESCENDING PROJECTIONS OF N.R. MAGNOCELLULARIS (NMC) AND N.R. GIGANTOCELLULARIS (NGC): AN AUTORADIOGRAPHIC AND HRP STUDY. Frank P. Zemlan, Michael Behbehani and Robert M. Beckstead. Psychobiology Division and Dept. of Physiology, Univ. of Cin. Sch. of Med., Cincinnati, OH 45267 and Dept. of Anatomy, Univ. of Va. Sch. of Med., Charolettesville, VA 22908.

The localization and density distribution of NMC and NGC cell bodies projecting to the spinal cord were determined in HRP experiments in the rat. Spinal cord hemisections with subsequent HRP application were performed at C_4 and T_{10}. The greatest density of NGC HRP labeled cells was found in the dorsorostral extent of NGC, while the greatest density of NMC HRP labeled cells was observed in caudal NMC. This seperation of NGC- and NMC-spinal neurons allowed highly selective labeling of these two systems in autoradiogrpahic experiments. Microiontophoretic deposits of ^{3}H-amino acids were made in the dorsorostral aspect of NGC in the rostral medulla, while NMC deposits were made in the caudal aspect of NMC in the caudal medulla.

Descending NGC projections were observed to the ipsilateral lateral vestibular nucleus, n. VII, XII; the contralateral inferior olive and ventral aspect on n. cuneatus. At cervical levels NGC-spinal fibers coursed through the ventral columns bilaterally with projections to laminae VII, VIII and X. Ascending NGC projections were observed to the ventral aspect of the periaqueductal gray, largely excluding raphe dorsalis; the deep and intermediate layers of the superior colliculus, the intralaminar nuclei, Fields of Forel and the dorsal and lateral hypothalamic nuclei.

Descending projections from NMC were observed to the lateral reticular nucleus, d.m.n. X, n. XII, n. commisuralis and intercalatus. At cervical levels NMC fibers coursed through the ipsilateral lateral columns, and were most numerous dorsally. Projections were observed to laminae IV, V, VI ipsilaterally, and bilaterally to VII and VIII. A similar pattern of labeled fibers was observered at caudal levels of the cord including a projection to the ipsilateral intermediolateral columns. No projection to the substania gelatinosa was observed after either microiontophoretic or large pressure injections of label to NMC. Although substantial descending projections were found with small microiontophoretic injections of label to NMC; ascending projections were limited to the ventromedial aspect of the pontine reticular formation. When large pressure injections were made to NMC, which spread into NGC, ascending projections were similar to those observed after NGC injections, and similar to those reported by others for the cat and opposum employing pressure injections.

25.6 CATEGORIES OF AXONS IN VENTRAL ROOTS OF THE CAT. B. Ferguson and D. Emery. Dept. of Zoology, Iowa State University, Ames, IA 50011

Unmyelinated axons in human ventral spinal roots are distributed uniformly throughout all spinal segments (Coggeshall et al., Brain 98:157-166. 1975.) In contrast, ventral roots in the rat (Coggeshall et al., J. Comp. Neurol. 173:175-184. 1977) and frog (Vance et al., J. Comp. Neurol. 164:117-126. 1975) show a variable distribution of unmyelinated fibers with some spinal segments containing large populations of unmyelinated axons and other spinal segments containing very few unmyelinated axons. One of the purposes of this study was to determine if the distribution of unmyelinated fibers in ventral roots of the cat is variable as in the frog and rat or uniform as in human ventral roots.

Ventral roots L_1-L_6 of the cat were examined with the electron microscope to determine the numbers of myelinated and unmyelinated fibers. All lumbar ventral roots contain sizeable populations of unmyelinated axons (Table 1). Levels L_1-L_4, which are part of the visceral outflows contain large populations of small myelinated fibers which are believed to be preganglionic. However, levels L_5 and L_6 do not contain large populations of small myelinated fibers, supporting the assertion that these segments in the cat are between the visceral outflows. Thus, the large populations of unmyelinated axons in L_5 and L_6 ventral roots are not preganglionic fibers.

Counts of axons after ventral rhizotomies and dorsal root ganglionectomies showed that most of the unmyelinated axons in ventral root L_6 are of dorsal root ganglion origin. These results are similar to findings by other workers that ventral roots between the autonomic outflows contain primarily unmyelinated sensory and myelinated efferent fibers. The distribution of unmyelinated axons in ventral roots of the cat is similar to the uniform distribution of unmyelinated axons in humans, but differs from the variable distribution of unmyelinated axons in the rat and frog.

The number and percentages of myelinated and unmyelinated fibers in ventral roots of the cat are presented below:

Table 1. Lumbar spinal segments

	Myelinated	Unmyelinated
L_1	2142(82.1%)	466(17.9%)
L_2	3106(82.5%)	657(17.5%)
L_3	2699(78.6%)	736(21.4%)
L_4	3115(71.4%)	1249(28.6%)
L_5	4321(71.4%)	1733(28.6%)
L_6	4819(68.7%)	2194(31.3%)

Table 2. Ventral root L_6

Cat	Myelinated	Unmyelinated
2	4819(68.7%)	2194(31.3%)
4	5657(77.4%)	1648(22.6%)
6	4704(71.7%)	1861(28.3%)
7	4530(82.6%)	952(17.4%)
8	5445(79.7%)	1384(20.3%)
9	3608(76.8%)	1093(23.2%)
	$\bar{X}$=4794(75.9%)	$\bar{X}$=1522(24.1%)

25.7 THE PRE AND POSTNATAL DEVELOPMENT OF FLAME-SHAPED HAIR FOLLICLE PRIMARY AFFERENTS IN THE RAT DORSAL HORN: A GOLGI STUDY. J.A. Beal. Dept. of Anatomy, Louisiana State University Medical Center, Shreveport, LA 71130.

Primary afferent collaterals which enter the head of the dorsal horn from its ventral aspect have been described in newborn animals as the "large" or "deep" fibers (Ramon y Cajal, S., Histologie du Systeme Nerveux, 1909) and as "flame-shaped" arbors (Scheibel, M.E. and A.B. Scheibel, Brain Res. 9:32-58, 1968). These same afferents have been identified in the adult and physiologically characterized as A-delta hair follicle afferents (A.G. Brown et al., J. Physiol. 272:779:797, 1977). Some structural differences, however, between the newborn and adult patterns have been noted. Studies on the newborn have demonstrated that "flame-arbors" form narrow lobules which extend through both the inner and outer zones of the substantia gelatinosa (SG) and that some give rise to collaterals to more than one lobule. Studies in the adult, on the other hand, have shown that these afferents extend dorsally no farther than the inner zone of the SG and have no interlobular collaterals. These discrepancies prompted the present study on the development of the "flame-shaped" hair follicle afferents. Sequential stages at close intervals were examined from 15 days gestation to 20 days post-partum. The hair follicle afferents can first be identified at 19 days of gestation. In transverse sections at this stage, small caliber fibers are seen leaving the dorsal funiculus in an arched pattern passing down into the neck then swinging upward into the head of the dorsal horn. At this stage the afferents have few branches and extend dorsally no farther than lamina III. Mechanisms directing the growth of these afferents is not yet clear but it has been observed that the growing afferents closely follow the vascular pattern and may be growing into spaces provided by regressing glial processes. At birth, the afferent arbors begin to branch and take on the characteristic flame-shaped lobular appearance. In addition to dorsal branches which by now enter the inner zone of the SG, many arbors also give rise to short ventral twigs which extend deep into lamina IV several micra below the arch of the incoming afferent fiber. By 10 days post-partum the hair follicle afferents have nearly attained their adult appearance. A few afferents at this and later stages have one or two branches which enter the outer zone of the SG, but these represent only a small percentage. In no case did branches of the hair follicle afferents enter more than one lobule. Thus, the integrity of each afferent lobule is established early in development. (Supported by NIH Grant #NS16642-02.)

25.8 DEVELOPMENT AND MATURATION OF NEURONS IN THE SUBSTANTIA GELATINOSA (SG) OF THE RAT SPINAL CORD: A GOLGI AND ELECTRON MICROSCOPIC STUDY. H. Ryan Bicknell* and John A. Beal (SPON: J.E. Penny), Dept. of Anatomy, Louisiana State Univ. Medical Center, Shreveport, LA 71130.

Although a considerable amount of data has been amassed, the developmental pattern of the SG is not clear. Ramon y Cajal (Histologie du Systeme Nerveux, 1909) followed the development of SG neurons and described the early prenatal formation of three general cell types ("centrale", "limitrophe", and "transversaux" cells) which display long axons and lengthy, but relatively simple dendritic arbors. In early postnatal material, however, Cajal noted drastic changes in the appearance of the cells. Axons now had collaterals but could no longer be followed into the white matter and the number of drendrites had increased, yet they were shorter and covered with numerous "fine filaments".

In order to further elucidate and more precisely describe these developmental changes, the present study was initiated. SG neurons in the rat lumbar spinal cord were examined at short-intervaled sequential stages from 15 days of gestation to 20 days post-partum. Our results suggest that Cajal's pre- and postnatal descriptions involve two separate populations of developing cells rather than variations within the same population. Using the Golgi technique, most cells in prenatal developmental periods appear to be "centrale", "limitrophe", or "transversaux" cells with long axons. These neurons have relatively simple dendritic arbors which lengthen throughout the developmental period and are thought to be Golgi type I projection or propriospinal neurons. Postnatally, a distinctly different group of cells begin to develop. These neurons develop several collaterals and display numerous short radiating dendrites. Close examination of various stages of development indicate that these neurons undergo a gradual dendritic metamorphosis and develop into an assortment of various Golgi type II interneurons. Both light and electron microscopic data suggest that these interneurons represent a large population of cells as indicated by a marked increase in the mean size of neuron cell bodies and an increase in the number of small diameter axons and dendrites during the postnatal developmental period.

In conclusion, the present study shows that SG neurons are heterogeneous and develop in two major waves. Golgi type I neurons essentially mature prenatally while Golgi type II interneurons mature postnatally, and make up the largest portion of the SG population.

25.9 ELECTRON MICROSCOPIC ANALYSIS OF PRIMARY AFFERENT FIBER TERMINALS FROM SLOWLY ADAPTING (TYPE I) RECEPTORS. K. Semba, P. Masarachia*, S. Malamed*, M. Jacquin, S. Harris*, G. Yang* and M. D. Egger. Dept. of Anat., UMD-Rutgers Med. Sch., Piscataway, NJ 08854.

Using the intra-axonal horseradish peroxidase (HRP) technique, we have previously described characteristics of terminals in the dorsal horn of primary afferent fibers innervating Pacinian corpuscles (PAC) in the glabrous skin of the cat's hindpaw (Semba et al., Neurosci. Abstr., 7(1981):528). The aim of the present study was to analyze terminals from another type of low-threshold mechanoreceptor, i.e., slowly adapting (SA) Type I receptors, and to compare these with PAC afferent terminals.

Analysis of electron micrographs from Rexed's laminae IV-VI indicated that: (1) HRP labelled boutons contained clear, round synaptic vesicles. Their longest dimensions ranged from 0.9-2.9 μm, somewhat less than those of PAC afferent terminals. About 13% of the perimeter was devoted to synaptic specializations. (2) About 70% of the synaptic contacts made by labelled boutons were with dendrites, about half on spines and half on shafts. Unlike PAC afferent terminals, contacts were frequently seen on dendrites near the soma. We observed no axosomatic contacts. Ninety percent of axospinous and axodendritic contacts were asymmetrical; subsynaptic bodies were often visible postsynaptically. Some postsynaptic dendritic spines contained a few dense core vesicles. We observed one spine with pleomorphic vesicles apparently presynaptic to a labelled bouton. (3) The remaining 30% of the synaptic contacts were with unlabelled axons. Most of these were postsynaptic to the labelled boutons. In 70% of these postsynaptic unlabelled axons, postsynaptic densities characteristic of asymmetrical synapses were visible. We also observed several unlabelled axons apparently presynaptic to labelled boutons, one of which formed a reciprocal synapse with a labelled bouton. (4) Lengths of synaptic specializations with axons (0.12-0.56 μm) tended to be less than those with dendritic spines (0.17-0.93 μm) or with dendrites proper (0.18-0.78 μm). (5) Labelled boutons often formed glomeruli involving several structures, some of which in turn were synaptically interrelated. (6) We found no systematic differences in the morphology of the labelled boutons among laminae IV-VI.

The predominance of synapses on dendrites, some at their proximal portions, combined with the presence of clear, round vesicles in the labelled boutons, suggests that impulses from SA receptors in the glabrous skin of the cat's hindpaw produce strong excitation of dorsal horn cells.

25.10 ANATOMICAL STUDIES OF LAMINA X IN THE RAT. R.L. Nahin and G.J. Giesler, Jr., Dept. of Neuroscience, University of California, Los Angeles, CA. 90024 and Dept. of Anatomy, University of Minnesota, Minneapolis, 55455.

Previous studies of Lamina X have not provided a reliable quantitative description of its lateral boundary. Using Nissl-stained material from the rat spinal cord, measurements of neuronal size, type, and density were obtained for several regions of the gray matter surrounding the central canal. Neuronal packing density was found to be relatively uniform throughout Lamina X. However, within a region of 190-260 microns (mean=232.6, S.D.=24.0) from the center of the central canal in the lumbar enlargement, an abrupt increase in cell density and cell size was observed. We believe these differences comprise a useful definition for the lateral boundaries of Lamina X. In a similar manner, boundaries of Lamina X in the cervical enlargement (mean=293.4, S.D.=23.5) and the mid-thoracic spinal cord (mean=184.1, S.D.=16.8) were determined. The vast majority of neural peptides and opiate receptors known to be present in the area around the central canal are confined to Lamina X as defined here.

The ascending projections of Lamina X neurons were studied by use of the retrograde transport of horseradish peroxidase (HRP). Predominately contralateral labeling of Lamina X neurons appeared following large injections of HRP into the medulla, pons and midbrain. Large numbers of cells within Lamina X were labeled following HRP injections into the medullary reticular formation. Far fewer cells were labeled with injections into the pons or midbrain. Labeled cells were categorized according to their shape as pyramidal, stellate or fusiform. For all injections stellate cells were the most frequently encountered. Pyramidal and stellate cells were distributed uniformly throughout Lamina X. Fusiform cells were found predominently in the dorsal-most region of Lamina X. Following medullary and pontine injections, Lamina X cells labeled in the lumbar enlargement were significantly larger than those labeled in the cervical enlargement. This difference was apparent across all three cell types. These data suggest Lamina X neurons not only contribute to local nociceptive processing as indicated by Honda and Perl (1981), but also contribute significantly to long ascending pathways including the spinoreticular tract. (Supported by NIH grants NS07628 and NS17540.)

25.11 IMMUNOCYTOCHEMICAL ANALYSIS OF SEROTONIN AXONS IN LAMINAE I AND II OF THE LUMBAR SPINAL CORD OF THE CAT. M.A. Ruda, J. Coffield*, and H. Steinbusch*[1]. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205; [1]Free University, Amsterdam, The Netherlands.

Serotonin (5HT), a monoamine neurotransmitter originating from brain stem cell groups, is in part responsible for descending modulation of the response of dorsal horn neurons to noxious input. To identify the site of action of 5HT in the dorsal horn, we employed the PAP immunocytochemical technique of Sternberger to characterize 5HT axons and terminals at the light (LM) and electron microscopic (EM) level. Adult cats were perfused with 4% paraformaldehyde in 0.1 M phosphate buffer. Glutaraldehyde (0.2%) was added to the EM perfusate. Fifty μm transverse and sagittal sections were cut with a Vibratome. For LM, 0.75% Triton X100 was added to the 1^{o}, 2^{o} and PAP to improve penetration while no detergents were added to the EM material. The characteristics of the 5HT antisera were as previously described (Steinbusch et al., Neurosci., 3 (1978) 811).

Immunoreactive 5HT axons were most numerous in lamina I, decreased somewhat in lamina IIa and were fewest in lamina IIb. In laminae I and II, the predominant orientation of the varicose 5HT axons was rostro-caudal. An occasional branching of the varicose strand was found. At the LM level, at least three different types of immunoreactive axons could be determined based on the size of their varicosities. At the EM level, 5HT endings synapsed primarily on dendritic shafts, and occasionally on spines and cell bodies in both laminae I and II. Dendrites which received 5HT synapses varied with respect to their cytoplasmic density and the presence or absence of vesicles. Most synapses were slightly asymmetrical with only a slight accumulation of dense material on the postsynaptic side. Immunoreactive 5HT endings were never observed as part of axoaxonic synapses. The 5HT varicosities contained either a mixture of flattened and small oval agranular vesicles, or a relatively homogeneous population of oval vesicles. A few dense core vesicles were present in most 5HT endings. The PAP reaction product coated the agranular vesicles, dense core vesicles and outer mitochondrial membranes. Since 5HT endings synapsed on cell bodies in laminae I and II as well as on different morphological types of dendrites, it is likely that 5HT modulates the response properties of different types of neurons in the superficial dorsal horn. Additionally, the presence of numerous 5HT synaptic contacts on dorsal horn neurons suggests that 5HT modulation of nociceptive information occurs predominantly through synapses on dorsal horn neurons themselves, rather than on incoming primary afferent axons.

25.12 SEROTONERGIC INNERVATION OF DORSAL COLUMN POSTSYNAPTIC SPINOMEDULLARY (DCPS) NEURONS IN THE CAT AND MONKEY. N. Nishikawa*, M.A. Ruda, G.J. Bennett and R. Dubner (SPON: R. Dionne). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Bulbospinal serotonergic (5HT) neurons are known to modulate the activity of spinal cord projection neurons. It is unclear whether this modulation is presynaptic, postsynaptic, or both. It has recently been shown that DCPS neurons in cats and monkeys constitute a major somatosensory projection that is as large as the feline spinocervical system. We have examined the 5HT innervation of DCPS neurons with a combined retrograde labeling and immunocytochemical method.

Lumbosacral DCPS neurons were retrogradely labeled by placing HRP on their cut axons in the thoracic dorsal columns. Retrogradely transported HRP was developed with $CoCl_2$-DAB to yield a reaction product consisting of black granules dispersed throughout the cell's soma and proximal dendrites. The tissue was subsequently counterstained with an anti-5HT antibody by the PAP method. 5HT profiles were stained an homogenous reddish brown. Immunocytochemical controls were all negative.

In the cat, 5HT varicosities were present in great numbers throughout the grey matter. Retrogradely labeled DCPS neurons were found in laminae IV, medial V-VI, and dorsomedial VII. Every DCPS neuron was surrounded by 5HT varicosities that appeared to make direct contact with the cell. Counts of the varicosities impinging on 20 consecutive DCPS neurons showed an average of 61 contacts per cell.

In the monkey, 5HT varicosities were far less numerous than in the cat. DCPS neurons were concentrated in laminae III-IV and scattered in laminae V, VI, VII, and X and also in the dorsolateral white matter. Almost all of the monkey's DCPS neurons had 5HT varicosities contacting their perikarya or proximal dendrites. These contacts were generally not as numerous as in the cat. An average of 18 contacts per cell was found on 20 consecutive DCPS neurons.

These light-microscopic observations indicate that the cat's and monkey's DCPS projections are modulated by bulbospinal 5HT systems and that this control is at least partly postsynaptic.

25.13 ELECTRICAL ACTIVITY AND NEUROPEPTIDE LOCALIZATION IN THE LUMBAR DORSAL HORN AFTER DORSAL ROOT AVULSION AND RHIZOTOMY IN THE CAT. J. Ovelmen Levitt*, B. Blumenkopf*, R. Sharpe*, K. H. Lee* and B. S. Nashold. Div. Neurosurgery, Duke Un. Med. Ctr., Durham, N. C. 27710

A feline model of lumbar plexus avulsion has been developed with unilateral extradural avulsions of 4-5 roots of the lumbar enlargement performed. These preparations were studied acutely and up to 6 months post-denervation. Dorsal rhizotomized animals were also studied and experimental results compared. Electrophysiological experiments were performed under light barbiturate anesthesia. In chronic denervations there was an increased amplitude and duration, although prolonged in latency, of the response to electrical stimulation of receptive areas of adjacent intact segments into the denervated zone as compared to the intact side. This involved both late negative and positive slow wave components of the cord dorsum response. The effect on the positive wave was especially pronounced when stimuli preferential for small diameter fiber activation were used. Response modalities, receptive fields and latencies for 248 isolated cells were determined using natural and electrical stimuli. The spontaneously firing of cells on the avulsed side, located at a mean depth of 1600 microns in the mid to lateral dorsal horn of the L6 or L7 could be influenced from the ipsilateral flank (L3-L4) and/or the contralateral flank and limb. This was often an inhibition. Spontaneous spike interval and post-stimulus histograms were made. Chronically avulsed cells often fired very regularly with a mean interval of 104.4 msec. The mean interval for all observed spontaneously active cells (36) in intact and control dorsal horns was 586 msec. Cells influenced from superficial receptive fields usually had irregular firing patterns, while cells having non-noxious deep receptive fields typically fired more regularly. The mean depth for cutaneous activated neurons in the mid to lateral intact dorsal horn was 1570 microns while that for deep activated cells was 2000 microns. To date no studied cell on the denervated side has been antidromically activated from the thalamus. Naloxone reversible decrease in spontaneous activity after 2.5 mg/kg Morphine has been observed in denervated cells. By immunohistochemistry, the neuropeptides met-enkephalin (ME), somatostatin (SS) and substance P (SP) have been studied at the level of injury. SP was substantially decreased through four weeks in avulsed preparations, but returned somewhat by 12 weeks. ME appeared essentially unchanged in the upper lamina of the avulsed preparation through 4 weeks, decreased by 6 weeks and remained so through 12 weeks. SS was also unchanged at 4 weeks, decreased at 6 weeks, but was returning somewhat at 12 weeks. Results from rhizotomized cords have indicated a different imbalance.

25.14 SHORT TERM CHANGES OF DORSAL HORN CELL RECEPTIVE FIELDS FOLLOWING DORSAL RHIZOTOMY IN CAT. C. J. Hodge, Jr., A. V. Apkarian and R. T. Stevens. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Changes of the patterns of response and receptive fields of dorsal horn cells were examined in chloralose anesthetized cats following dorsal rhizotomy. Dorsal roots L2 through L6 were cut unilaterally in cats. Single unit recordings were then made in superficial dorsal horn (i.e. not deeper than 2 mm). Segments L7 through L4 were examined bilaterally with a series of regularly spaced electrode penetrations. Records from 211 cells form the basis of this report. In the immediate post-rhizotomy period the receptive field organization of all the cord segments was the same as is seen in animals with intact dorsal roots with the exception that there were fewer cells found per penetration ipsilateral to the rhizotomies in segments 4 through 6.

In the period beginning 6 - 10 hours after rhizotomy there was a striking change in the receptive field characteristics of some dorsal horn units both in the denervated portion of the spinal cord and in the non-denervated areas of the cord. A large number of cells with either bilateral or only contralateral receptive fields were found. In the immediate period only 4 of 95 cells had bilateral or contralateral receptive fields while in the later period (i.e. 6 or more hours after rhizotomy) 39 of 116 cells were found to have contralateral input. These cells had large receptive fields and almost exclusively responded to noxious stimuli. They were found proportionately more frequently in the lateral dorsal horn and at a greater depth than cells with purely ipsilateral receptive fields. These changes were as prominent in the non-denervated segments of the cord (L7) as in the denervated segments. With this exception, the somatotopic organization of the dorsal horn remained unchanged. The findings suggest that there exists extensive bilateral input into the dorsal horn, and that much of the input from the dermatomes of the contralateral side of the animal are suppressed. The mechanism by which rhizotomy unmasks this contralateral input is not yet clear.

25.15 PRIMARY NEURONS MAINTAIN THEIR CENTRAL AXONAL ARBORS IN THE DORSAL HORN FOLLOWING PERIPHERAL NERVE INJURY. T. Sugimoto* and S. Gobel. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

This study was designed to examine whether the cell bodies and central processes of primary neurons in adult cats survive up to 3 months after their peripheral branches are cut and prevented from regenerating. One superficial radial nerve was transected in the mid-forearm and capped with a polyethylene tube sealed at one end (experimental side) while the superficial radial nerve on the other side (control side) was left intact. Either 1 month or 3 months later, both nerves were transected again in the mid-forearm. Both nerves had HRP applied to their proximal stumps and were capped. Three days later the C_6-C_8 dorsal root ganglia and corresponding spinal cord segments were processed for HRP reaction product using the TMB method.

At each survival time, many cell bodies were labeled in C_6-C_8 ganglia on the experimental side as well as on the control side. The frequency distribution of labeled cell diameters (average of long and short diameters) was similiar in experimental and control sides at both survival times. The diameter of labeled cells ranged from about 10 μm to about 100 μm and about 60% of these cells fell between 20 and 40 μm in diameter. The distribution of HRP reaction product in the central axonal processes in the spinal cord was similar on the experimental and control sides at both survival times. The HRP-labeled central axonal projection extended throughout the full depth of the dorsal horn from the rostral part of C_6 through the caudal part of C_8. Most of the projection lay medial to an imaginary line extending between Lissauer's tract and the ventromedial part of lamina VI and did not fully extend to the medial border of the dorsal horn. The projection was heaviest in the head of the dorsal horn across laminae I-IV of the C_7 segment. HRP-labeled primary axonal endings throughout laminae I-IV on the experimental side of the C_7 dorsal horn were examined with EM at one month after nerve transection. All HRP-labeled primary axonal endings were apparently healthy. They were packed with synaptic vesicles and normal mitochondria and were not blackened. These primary axonal endings most commonly were presynaptic to dendritic spines and sometimes postsynaptic to other synaptic vesicle containing processes.

In conclusion, primary neurons of all sizes survive transection and capping of their peripheral processes in the superficial radial nerve for 3 months in adult cats. These injured primary neurons are capable of transganglionic transport of HRP into their central axonal arbors which maintain their normal topographic position across laminae I-VI of the C_6-C_8 dorsal horn. They remain morphologically intact and maintain their synaptic vesicles and some of their synaptic connections.

25.16 CONVERGENCE ONTO INTERNEURONS MEDIATING PAD FROM GROUP I MUSCLE AFFERENTS. EE.Brink, E.Jankoswka*, B.Skoog*, Dept. of Physiol., Univ. of Göteborg, Göteborg, Sweden.

Group I muscle afferents produce primary afferent depolarization (PAD) in different classes of afferents, depending on whether the source afferents are 1a or 1b, and whether from flexors or extensors.Notably, 1a afferents depolarize only other 1a afferents, which may also be depolarized only by 1b afferents (cf Schmidt, Ergebn.Physiol.63:20,1971). The method of spatial facilitation has now been used to determine whether the underlying paths are shared or distinct.

Dorsal root potentials (DRPs) were recorded from caudal most L_6 dorsal root filaments in chloralose-anesthetized cats. 1a afferents from TA-EDL or from GS-PL were selectively stimulated by brief small ($\lesssim$35um) muscle stretches below threshold for 1b afferent activation. 1b afferents were selectively activated by weak electrical stimulation of muscle nerves after 1a afferent thresholds had been increased by prolonged muscle vibration (Coppin et.al, J.Physiol.210:18,1970). 1a afferents of Q and PBSt were selectively activated by weak electrical stimuli ($\lesssim$1.3T). When facilitation occurred the response to simultaneous stimulation of two sets of afferents was greater than the sum of the responses to each alone.

Results showed that shared interneurons are involved in PAD pathways from different 1a afferents, whether from flexors or extensors, and in paths from flexor 1b and flexor or extensor 1a afferents. The convergence undoubtably occurred in paths to 1a afferents. In contrast, there was no convergence in paths from extensor 1b and any source of 1a afferents, although convergence occurred in paths from different extensor 1b afferents. Thus, extensor 1b afferents must use separate paths to depolarize 1a afferents. Latencies of the DRPs depend on co-excitation ranged from 2 to 7ms, indicating that convergence occurred in the shortest (trisynaptic) as well as longer paths. Finally, stimulation of cutaneous, joint or interosseous afferents at $\gtrsim$1.5T depressed 1a-induced DRPs: weaker stimuli had no effects.

The differing patterns of convergence aid identification amongst subgroups of PAD interneurons as well as their distinction from interneurons located in the same region of the spinal cord and involved in other Group I effects, as the 1b(and 1a-like-1b) postsynaptic effects in the motoneurons. Further, the patterns of convergence of segemtal inputs indicate differing control of pre- vs post- synaptic inhibition in spinal motoneurons.

25.17 LUMBOSACRAL LAMINA I CELLS PROJECTING TO MEDIAL AND/OR LATERAL THALAMUS IN THE CAT. A. D. Craig and K.-D. Kniffki*. Physiologisches Institut, Univ. Kiel, D-2300 Kiel, F. R. G.

Relatively little is known about the physiological characteristics of spinothalamic lamina I (STT-lamI) cells, especially those that project to medial thalamus, where a major STT-lamI termination occurs in the n. submedius (Craig and Burton, J. Neurophysiol., 45:443, 1981). The purpose of the present study is to examine the responses of feline STT-lamI cells that project to medial and/or lateral thalamus to inputs from skin and muscle.

Recordings are made from cells in the vicinity of lamina I with tungsten microelectrodes in chloralose-anesthetized cats. Recording sites are verified by small lesions. A linear array of ten bipolar electrodes, inserted at the caudal end of the somatosensory thalamus (AP 7.0) as judged by recording coordinates, is used to activate cells antidromically (standard criteria). Cells are characterized by electrical stimulation of sciatic, tibial, gastrocnemius-soleus (GS), and sural nerves, stimulation of GS group III and IV afferents by close intra-arterial injection of KCl and bradykinin, and natural stimulation of skin and muscle.

To date, 71 STT-lamI cells have been recorded in the lumbosacral spinal cord (L5 - S1) with a mean antidromic latency of 82 ms (range = 25 - 250 ms). Of these, 54% projected only to medial thalamus, 20% only to lateral thalamus, and the remainder to both or to mid-thalamus. A sample of 21 STT-lamI cells has been fully characterized by their response properties to peripheral stimulation and their thalamic projection. Almost all (19) of these cells were activated specifically by noxious stimulation; 14 responded to pinch and/or noxious radiant heat applied to the skin, 3 received convergent noxious skin and deep input, and 2 responded only to noxious deep input. These 19 nociceptive-specific cells project to thalamus as follows: 10 medial, 2 lateral, and 7 medial + lateral. Similarly, almost all the cells (17/19) with a projection to medial thalamus were nociceptive specific. Of the remaining 2 cells, 1 responded only to cooling the skin, and the other was a cutaneous wide dynamic range cell.

These results indicate that lumbosacral STT-lamI cells in the cat are carrying ascending information about noxious stimulation of both skin and muscle. Furthermore, the majority of lumbosacral STT-lamI cells appears to project to medial thalamus (perhaps to the n. submedius) and to be nociceptive specific.

25.18 INTRACELLULAR STAINING OF MULTIRECEPTIVE NEURONS IN CAT LAMINAE III-VII. L.A. Ritz and J.D. Greenspan. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27514.

We have investigated the structure-function relationship of multireceptive neurons in laminae III-VII of the coccygeal cord of the decerebrate cat by intracellularly staining physiologically studied neurons with horseradish peroxidase (HRP).

We studied over 100 units evidencing input from more than one cutaneous receptor type. Among these, 50 units had input from both myelinated and unmyelinated primary afferent fibers and 55 units received input from both thickly and thinly myelinated afferent fibers. A single unit's response properties were first determined by extracellular recording, and, after intracellular penetration and confirmation of response characteristics, we passed iontophoretic current to deposit HRP.

We obtained 12 examples of well stained, single neurons, including 2 with cell bodies in the dorsal nucleus proprius, 7 with cell bodies in lamina V and 3 with cell bodies in lamina VII. Eight of the 12 units had late discharges correlated with the C-wave of a doral root recording. Only one of these 8 had dendrites that reached the superficial dorsal horn. Of the 4 units with no C input, 2 had dorsal dendrites entirely contained within the nucleus proprius and 2 had dorsally passing dendrites with evidence of branching in lamina I.

Six of the 7 lamina V located cell bodies received input from both low and high threshold myelinated mechanoreceptive fibers, while the 7th unit received only high threshold mechanoreceptive input; 4 of these 7 units evidenced input form both A and C fibers, including the one nociceptive-specific unit. The cell body sizes for lamina V neurons ranged from 30 to 73 micrometers in the largest dimension. Each neuron had an extensive dendritic spread in several directions; most noteworthy was the rostrocaudal extension of 800 to 1200 micrometers. Six lamina V neurons had lateral dendrites that reached into the lateral white matter; 2 of these 6 also had medial dendrites in the gray matter over the central canal. Four lamina V neurons gave rise to axons which entered the contralateral ventral white matter; one of these also had an axon collateral with many branches deep in the ipsilateral ventral horn.

There does not appear to be a correlation between the presence or absence of C-fiber input and the dendritic extent or orientation of these multireceptive neurons. The lamina V neurons, all of which received input from cutaneous mechanical nociceptors were large and had extensive dendritic domains.

25.19 THE CELLS OF ORIGIN OF THE MONKEY'S DORSAL COLUMN POSTSYNAPTIC SPINOMEDULLARY (DCPS) SYSTEM. G.W. Lu*, G.J. Bennett, N. Nishikawa* and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, Maryland 20205.

The DCPS system consists of spinal neurons whose axons ascend through the dorsal columns to terminate in the dorsal column nuclei. We have previously reported the location and distribution of the cat's lumbosacral DCPS neurons (Soc. Neurosci. Abstr., 7: 611, 1981) and now report the location and distribution of lumbosacral DCPS neurons in macaque monkeys.

The dorsal columns (DC) of 1 cynomolgus and 3 rhesus monkeys were partially transected in mid or lower thoracic segments. Two monkeys also received bilateral lesions of the dorsolateral funiculi 1-3 cm caudal to their DC transections. A small piece of HRP-containing polyacrylamide gel was inserted into the DC transection, the spinal cord covered with Gelfoam, and the animals allowed to recover. They were sacrificed and perfused 24-68 h later. The retrograde label was developed with TMB.

Dorsolateral funicular lesions had no effect on the frequency or distribution of labeled neurons. Retrogradely labeled cells were concentrated in a broad band in laminae III-IV. Scattered cells were found in laminae V-VII, X, and the dorsolateral white matter. The monkey's distribution is thus different than the cat's where most DCPS cells are concentrated in a narrow band in lamina IV that sweeps down through laminae V-VI along the dorsal horn's medial border.

DCPS neurons were counted in three monkeys. The lumbosacral enlargements (L_4-S_1) contained 682-1,139 cells. Average cell densities ranged from 14.8-41.8 cells in each unilateral millimeter of the enlargement's length. These densities are nearly identical to what we found in cats. Thus in the monkey, as in the cat, DCPS neurons are as numerous as spinocervical neurons but 2-4X less numerous than spinothalamic neurons.

The retrograde label filled the cells' proximal dendritic arbors out to the 2^o and 3^o dendrites. Laminae III-V neurons had dendritic arbors that were relatively narrow mediolaterally and elongated rostrocaudally. Cells found towards the medial borders of laminae V-VII had arbors that fanned-out laterally. Lamina X cells were small and bipolar.

We conclude that, in both the cat and monkey, the DCPS projection is a major source of spinal input to the brain.

25.20 INDIVIDUAL THORACIC SPINAL NEURONS WITH MULTIPLE TERMINATION SITES IN THE RETICULAR FORMATION AND THALAMUS AND THEIR RESPONSES TO INTRACARDIAC INJECTIONS OF BRADYKININ IN THE CAT. R. Neal Weber, Robert W. Blair and Robert D. Foreman, Dept. of Physiol. and Biophys. Univ. of Oklahoma HSC, Okla. City, OK 73190.

Previous studies from our laboratory have shown that noxious stimulation of the heart by bradykinin can alter the activity of spinoreticular neurons in the cat and spinothalamic neurons in the monkey. In these studies the antidromic stimulating electrodes were located bilaterally in the medullary reticular formation (RF) or in the ventral posterior lateral region of the contralateral thalamus of 39 alpha-chloralose anesthetized cats. We recorded from 71 antidromically activated cells found in the T_2-T_4 segments of the left thoracic gray matter. Six different types of rostrally projecting neurons were identified according to the site or sites from which they could be activated: those activated from the 1) contralateral RF (CRF) only, 34 of 71 cells (48%); 2) ipsilateral RF (IRF) only, 12 cells (17%); 3) thalamus only, 9 cells (13%); 4) both CRF and IRF, 8 cells (11%); 5) both CRF and thalamus, 4 cells (6%); and 6) CRF, IRF and thalamus 4 cells (6%). The cell bodies of these neurons were located in laminae I, IV, V, VI, VII, and VIII; the majority were found in V and laminae VII, but no obvious relationship was found between the sites of activation and laminar location. Each of the cells exhibited convergence of sensory input from somatic receptive fields and from sympathetic afferent fibers. Cell activity of 44 spinoreticular and spinothalamic cells was tested for changes following injection of bradykinin (1-2 ug/kg) into the left atrium. Twenty five cells were excited, one cell was inhibited and 32 cells were unaffected following the injection. Average latency from the time of injection of bradykinin to onset of the response was 13s and average response duration was 48s. Average response increased from a control rate of 2 Hz to a peak rate of 16 Hz. Three of 15 cells tested responded to control injections into the descending aorta but with longer latency and less peak activity. Cells were significantly more likely to respond with a greater discharge rate to intracardiac bradykinin injections if they received afferent input from both Aδ and C-fibers than if the input was from Aδ fibers alone. A marked tachyphylaxis to repeated injections of bradykinin developed for 50% of the cells which responded to an initial dose of BK. The six different types of rostrally projecting neurons responded similarly to intracardiac injections of bradykinin. To conclude, since individual spinal neurons projecting to both the reticular formation and thalamus respond to intracardiac BK, both regions receive input when the heart is injured. Supported by National Heart, Lung and Blood Institute Grants HL22732, HL07430 and HL00557.

26.1 DYNORPHIN IMMUNOREACTIVITY IN RAT AND GUINEA PIG NERVOUS SYSTEMS, S.R. Vincent, T. Hökfelt*, I. Christensson*, L. Terenius*, C.-J. Dalsgaard* and M. Schultzberg*. Dept. of Histology and Anatomy, Karolinska Institutet, Stockholm & Dept. of Pharmacology, Uppsala University, Uppsala, Sweden.

Antibodies raised against the endogenous opioid peptide dynorphin-(1-17) (DYN) and specific for the C-terminal region of the peptide were used to examine the distribution of DYN immunoreactivity in the nervous system. The antiserum used (84D) did not cross-react with leucine enkephalin in either radioimmunoassay or immunohistochemistry.

Within the autonomic nervous system, intense networks of DYN-positive nerve fibers were observed in the prevertebral ganglia (inferior mesenteric, coeliac-superior mesenteric), while the paravertebral ganglia (superior cervical, stellate) contained few DYN fibers. DYN-positive fibers were also seen in the myenteric plexi of the duodenum and the proximal and distal colon. SIF cells containing intense DYN immunoreactivity were observed in the superior cervical ganglion and inferior mesenteric ganglion of the guinea pig. The adrenal medulla contained a few DYN-positive nerve fibers, however, chromaffin cells were not DYN-immunoreactive, although they displayed intense enkephalin staining on adjacent sections.

In the spinal cord and medulla DYN cell bodies and fibers were concentrated within the substantia gelatinosa. No DYN-immunoreactivity was observed in the spinal ganglia. DYN fibers and cell bodies were also observed in the nucleus of the solitary tract and in the parabrachial nucleus. The substantia nigra contained an intense network of DYN-positive fibers in the pars reticulata. This network of fibers was very similar to that previously noted for both GABA and substance P in the nigra and showed a similar decrease in the nigra following striatal lesions with ibotenic acid, suggesting the existence of a major striato-nigral DYN pathway. A small group of DYN-postive cells was present just dorso-lateral to the substantia nigra. In the hypothalamus, major DYN cell groups were observed in the ventral premamillary nucleus, the supraoptic and paraventricular nuclei, and especially in the region of the medial forebrain bundle just between the internal capsule and the fornix. DYN cells were also observed in the bed nucleus of the stria terminalis, the central nucleus of the amygdala, and the granule cell layer of the dentate gyrus. The stria terminalis contained many positive nerve fibers. The neocortex contained only single DYN fibers, while the cerebellum did not display DYN-immunoreactivity.

The results provide evidence for an extensive DYN system throughout all levels of the nervous system, distinct from the enkephalin or other opioid systems previously described.

26.2 ENKEPHALINERGIC PATHWAYS IN THE PRENATAL RAT: ORGANIZATION IN SITU AND TRANSPLANTATION IN OCULO. M. Palmer, B. Hoffer*, H. Björklund*†, Å. Seiger*† and L. Olson*†. Univ. Colorado Health Sciences Center, Denver, Colo., and †Karolinska Institute, Stockholm, Sweden.

Immunohistochemical fluorscence techniques were used to determine the presence of endogenous enkephalin-like immunoreactivity (ELI) in the developing central nervous system of the prenatal rat. ELI was first observed in beaded fibers along the midline of ventral pons and cervical spinal cord by postconception day 15. Fluorescence could not be observed in the brains of 14-day-old fetuses, although the adrenal medulla did show ELI at this stage. ELI-positive cell bodies at postconception day 18 were found in most areas in which they have previously been described in adult rats. Many of the cells observed at postconception day 18 were, however, not seen in noncolchicine-treated full-term fetuses with the techniques used here. ELI-positive fibers and terminal fields began to approach adult distributions at postconception day 20-21. Several ELI-positive axon pathways which have not been previously reported in adult or developing brain, for example, pathways in medial neocortex, in fasciculus retroflexus, in tractus mammillothalamicus, between ventral hypothalamus and globus pallidus, and between ventromedial pons and the locus coeruleus area, were observed. Areas of fetal brain and spinal cord tissue, known to contain ELI-positive neurons, were then homologously grafted into the anterior chamber of the eye of adult recipients. These neurons survived well in oculo and elaborated a dense plexus of ELI-positive fibers in the graft. Taken together, these data suggest enkephalinergic pathways develop long before birth in the rat, at an age early enough to permit survival after transplantation to the anterior chamber. (Supported by the Swedish MRC Grants # 14X-03185 and 14P-5867, and NIDA Grant # DA-02702.)

26.3 STUDIES ON THE RELATIVE DISTRIBUTION OF α-NEO-ENDORPHIN/DYNORPHIN AND PROENKEPHALIN NEURONAL SYSTEMS AND THEIR PEPTIDE PRODUCTS. Eckard Weber*, Kevin Roth*, Christopher J. Evans* and Jack D. Barchas. (SPON: W. C. Dement). Nancy Pritzker Laboratory of Behavioral Neurochemistry, Stanford Medical Center, Stanford, CA 94305.

Previous studies have demonstrated that α-Neo-endorphin and dynorphin(1-17) immunoreactivity are colocalized within the same neurons of the rat brain (1,2). Subsequent biochemical analysis of α-Neo-endorphin and dynorphin related peptides in 10 brain regions has shown that the principal dynorphin-related peptide is dynorphin(1-8), which is present in up to 10-fold higher concentrations in brain than dynorphin(1-17) (3). Dynorphin(1-8) but not dynorphin(1-17) is present in equimolar concentrations with α-Neo-endorphin in all brain regions (3). These results imply that dynorphin(1-8) and α-Neo-endorphin are biosynthetically closely related and that dynorphin(1-17) may be a precursor in the formation of dynorphin(1-8). Both our biochemical and immunohistochemical studies suggested that the α-Neo-endorphin/dynorphin neuronal system shows a significant overlap with enkephalin pentapeptide neurons. Most of the enkephalins seem to be derived from the recently characterized pro-enkephalin molecule, which does not contain dynorphin(1-8), dynorphin(1-17) nor α-Neo-endorphin. Therefore, a very important question is whether there are neurons which contain pro-enkephalin products as well as dynorphin and α-Neo-endorphin or whether the α-Neo-endorphin/dynorphin neuronal system is strictly separate from the pro-enkephalin neuronal system. To address this question, we have prepared antibodies specific for pro-enkephalin products (met-enkephalin-Arg^6-Phe^7 and met-enkephalin-Arg^6-Gly^7-Leu^8) and have compared the distribution of these peptides with the distribution of peptides specific to the α-Neo-endorphin/dynorphin system [dynorphin(1-8), -(9-17), α-Neo-endorphin]. The results as of this writing suggest that there is a partial overlap of pro-enkephalin neurons and α-Neo-endorphin/dynorphin neurons.

26.4 CIRCADIAN VARIATION OF BETA ENDORPHIN-LIKE IMMUNOREACTIVITY IN THE ADRENAL GLAND AND SPINAL CORD. K.D. Gipson*, A.D. Okonmoh*, and C.A. Walker, School of Pharmacy, Florida A&M Univ., Tallahassee, FL 32307

A circadian rhythm for beta endorphin-like immunoreactivity in the adrenal gland and spinal cord has been established. Male Sprague-Dawley (200-250g) rats adapted to a 12h light-12h dark programmed illumination cycle and controlled temperature (23 + 1°C) for a minimum of three weeks were used in this study. Animals were sacrificed by decapitation at 4 hr. intervals during the 24 hr. period. The adrenal gland and cervical region of the spinal cord were dissected and extracted with 0.1N HC1. Beta endorphin-like immunoreactivity content was measured by radioimmunoassay. This method employed addition of delayed tracer to improve sensitivity. Phase separation was accomplished by addition of goat anti-rabbit serum in the presence of carrier rabbit serum which is titered to assure mid-zone precipitation. Results of this study show that there is a significant difference between peak and trough levels in both tissues with the peak occurring in the dark phase and the trough during the light phase. These results are in agreement with previous studies conducted in our lab which demonstrated circadian changes in beta-endorphin levels in the hypothalamus and periaqueductal gray-rostal pons regions of the brain. These findings also agree with studies which have demonstrated diurnal changes in responsivity to pain stimuli and morphine induced analgesia. (Supported in part by NASA).

26.5 DEMONSTRATION OF CONTACTS BETWEEN OPIOCORTIN NEURONS IN THE ARCUATE NUCLEUS OF THE RAT HYPOTHALAMUS. G. Pelletier and Y.Y. Chen*. MRC Group in Molecular Endocrinology, CHUL, Québec, Canada G1V4G2.

It has been recently established by immunocytochemistry that peptides derived from proopiocortin, namely ACTH, α-MSH and endorphins, are produced by the same neurons in the rat arcuate nucleus (Watson et al., Nature, 275:66, 1978; Guy et al., Brain Res. 199:135, 1980). These neurons, named opiocortin neurons, are projecting into several brain areas, including several hypothalamic nuclei, septum, thalamus and midbrain. In order to identify target neurons for the opiocortin system, we first investigated the possibility that opiocortin neurons can contact themselves. For this purpose, we extensively studied the localization of immunoreactive ACTH and endorphins in the rat arcuate nucleus. Immunostaining was performed on Vibratome sections using a pre-embedding staining technique described by Pickell et al. (PNAS, 72:658, 1975). In 1.5 μm thick plastic sections, very close contacts between immunostained endings and cell bodies or dendrites were routinely observed. Using serial sections, it was frequently observed that the same positive axon could have contacts with more than one positive cell body. At the ultrastructural level, immunostained neuronal cell bodies, dendrites and endings were routinely detected. All the positive cell bodies and endings contained dense core vesicles of a diameter ranging between 70-120 nm. Twenty-five positive endings making contact with immunostained cell bodies or dendrites were observed. The contacting endings were frequently seen in an area of the cell body or dendrite presenting an invagination in its plasma membrane. No synaptic densities could be observed in the zone of contact between a positive ending and the contacted cell body or dendrite. These observations clearly indicate that neurons producing the same peptides can have contacts between themselves. They provide morphological evidence for autoregulation of neuropeptide systems.

26.6 DIFFERENTIAL IMMUNOCYTOCHEMISTRY OF LEU-ENKEPHALIN AND DYNORPHIN IN THE RAT SPINAL CORD. J.E. Kelsey*, H. Khachaturian, and S.J. Watson (SPON: D. Goodman). Mental Health Res. Inst., Univ. of Mich., Ann Arbor, MI 48109.

Leu-enkephalin has been shown to be distributed throughout the spinal cord gray matter with highest concentrations occurring in the dorsal horn. Dynorphin, which contains Leu-enkephalin at its NH_2 terminus has also been localized to the spinal cord. Due to the possibility of cross-reactivity between antisera generated against these peptides, we have employed antisera directed against the full sequence of each peptide, as well as sequences unique to the dynorphin molecule (i.e. Dynorphin-(7-17); produced in collaboration with D.H. Coy, Tulane Univ.) and to the non-enkephalin portion of BAM-22P (a peptide fragment from the adrenal enkephalin precursor). This has enabled us to differentiate between dynorphin and enkephalin systems. Adult male Sprague-Dawley rats were pretreated with icv colchicine. Animals were perfused with formaldehyde and the spinal cords were processed for PAP immunocytochemistry. Cross-blocking studies demonstrated dynorphin-(1-17) and -(7-17) immunoreactivities to be separable from Leu-enkephalin and BAM-22P immunoreactivities. Comparison of Leu-enkephalin and BAM-22P to dynorphin-(1-17) and -(7-17) immunoreactivities in the spinal cord demonstrated many similarities. The highest density of Leu-enkephalin immunoreactive fibers and terminals occurred in the marginal zone of the dorsal horn and as a group of fibers in the white matter immediately lateral to the marginal zone. Scattered varicosities were also noted in the deeper laminae of the dorsal horn, around the central canal, and to a lesser extent in the ventral horn. Occassional small immunoreactive perikarya were also noted in the deeper laminae of the dorsal horn. Immunoreactive dynorphin fibers and terminals appeared to be present in all of the above areas, but to a lesser extent than Leu-enkephalin immunoreactivity. We were unable to detect dynorphin positive perikarya in the dorsal horn. The distribution of these peptides in the dorsal horn of the spinal cord is consistent with their role in nociception. The similar localization of Leu-enkephalin and dynorphin immunoreactivities in the spinal cord raises the question of their differential post-synaptic effects, and the possibility of enzymatic conversion of some dynorphin to Leu-enkephalin.

26.7 VISUALIZATION OF OPIATE RECEPTORS IN RELATION TO OPIOID PEPTIDE NEURONAL SYSTEMS IN BRAIN AND SPINAL CORD. M.E. Lewis*, H. Khachaturian and S.J. Watson (SPON: E.F. Domino). Mental Health Res. Inst., Univ. of Mich., Ann Arbor, MI 48109.

Immunocytochemical studies of opioid peptide localization and autoradiographic studies of opiate receptor distribution have previously been carried out in different animals, precluding a direct correlation of their loci in brain. To carry out correlative autoradiographic-immunocytochemical studies, we perfused rats with 0.1 M phosphate-buffered 4% formaldehyde (pH 7.4) and obtained 20μm-thick sections of their brains with a cryostat. Opiate receptors$_3$ (μsubtype) were labelled selectively by incubation with 1 nM [^{3}H]naloxone (in 0.05 M Tris HCl, pH 7.4, containing 100 mM NaCl) at 4°C for 1 hr, followed by 5 successive 20 sec rinses in 0.1 M phosphate-buffered saline at 4° C to remove most nonspecific binding. Receptor specificity studies, carried out by liquid scintillation counting of incubated striatal sections, indicated a partial loss of specific [^{3}H]naloxone binding sites due to perfusion, with no apparent change in the pharmacological properties of the remaining sites as indicated by competition binding curves. For the anatomical studies, [^{3}H]naloxone-labelled brain sections from colchicine-treated, perfused rats were fixed with paraformaldehyde vapors at 80°C for 2 hr and processed for liquid emulsion autoradiography (Herkenham and Pert method) and alternate sections were processed for immunocytochemistry using affinity-purified Leu-enkephalin antisera in the PAP procedure (see Khachaturian et al., this meeting). The radiolabelled sections could not be used for immunocytochemistry since the vapor fixation destroyed all enkephalin immunoreactivity. To avoid the necessity of the vapor fixation step, [^{3}H]naloxone-labelled sections were apposed to LKB Ultrofilm or dry, emulsion-coated coverslips (Young and Kuhar method) and later processed for immunocytochemistry. Excellent correlations between the loci of [^{3}H]naloxone binding sites and enkephalin immunoreactivity were observed in a number of areas, including the dorsal horn of the spinal cord, spinal trigeminal nuc., nuc. tractus solitarius, parabrachial nuc., area postrema, interpeduncular nuc., substantia nigra, ventral tegmental nuc., periaqueductal gray, hippocampus, nucleus accumbens and some thalamic, cerebral cortical and olfactory bulb areas. The procedures described here permit, for the first time, direct anatomical correlations between the localization of opiate receptors and opioid peptides. These methods are currently being used for correlative studies visualizing μ, δ and κ opiate receptors in relation to β-endorphin, enkephalin and dynorphin neuronal systems in rat and monkey central nervous system.

26.8 COMPARATIVE BRAIN DISTRIBUTION OF ENKEPHALIN AND AN ENKEPHALIN PRECURSOR FRAGMENT. H. Khachaturian, M.E. Lewis*, V. Hollt[1] and S.J. Watson, Mental Health Research Inst., Univ. of Mich., Ann Arbor, MI 48109; [1]Max Planck Institute for Psychiatry, Munich, West Germany.

The comparative distribution of Leu-enkephalin and an enkephalin precursor fragment, bovine adrenal medullary docosapeptide (BAM-22P), was studied in the rat brain using immunocytochemical procedures. The full amino acid sequence of BAM-22P is as follows: Tyr-Gly-Gly-Phe-Met-Arg-Arg-Val-Gly-Arg-Pro-Glu-Trp-Trp-Met-Asp-Tyr-Gln-Lys-Arg-Tyr-Gly. In this report, we provide evidence for the presence of the enkephalin precursor processing system in the brain. Rats were treated intracerebroventricularly with colchicine (300-400ug) to enhance the visualization of neuronal perikarya. The peroxidase-anti-peroxidase technique of immunocytochemistry was carried out on formaldehyde-fixed, frozen sections, using antisera generated against each peptide. Careful cross-blocking paradigms confirmed the differential antigenicity of each serum.

The use of high doses of colchicine permitted the visualization of widespread enkephalin-containing systems in the brain, some of which have not yet been fully described. Leu-enkephalin immunoreactive perikarya or fibers and terminals were noted in the olfactory bulb, many neocortical and paleocortical regions of the cerebrum, amygdala, hippocampus, basal ganglia, septum, thalamus, hypothalamus, mesencephalic periaqueductal gray, the colliculi, many brain stem reticular formation sites, including some cranial nerve nuclei, and almost all monoamine-containing regions. In most of the above areas, we have also noted at least some BAM-22P immunoreactivity. Furthermore, through serial-section analysis, it has been possible to confirm the close anatomical association between BAM-22P and Leu-enkephalin immunoreactivities; i.e., these immunoreactivies were localized to perikarya and processes in the same region. Studies are in progress to evaluate the possibility of co-localization of these peptides within the same neurons. Nevertheless, the results suggest that brain enkephalin-positive neurons may possess mechanisms for enkephalin biosynthesis similar to those found in adrenal medullary cells.

26.9 DYNORPHIN NEURONAL SYSTEMS: DISTRIBUTION IN BRAIN AND RELATIONSHIP TO OTHER OPIOID PEPTIDES. S.J. Watson, H. Akil, and H. Khachaturian. Mental Health Res. Inst., Univ. of Mich., Ann Arbor, MI 48109.

The opioid peptide dynorphin was extracted and sequenced from nervous tissue. To date this peptide has been biochemically detected throughout the neuroaxis and anatomically localized in a few loci. We previously reported it's visualization in posterior pituitary, and the magnocellular neurosecretory nuclei of hypothalamus in the vasopressin producing cells in normal rats and the magnocellular nuclei of homozygous Brattleboro rats. Because the structure of dynorphin contains leucine-enkephalin we have been concerned that antisera against leucine-enkephalin and dynorphin might cross-react under immunohistochemical conditions, thereby confusing the anatomy of the enkephalin and dynorphin neuronal systems. We have carried out a series of blocking studies using the several opioid peptides across a variety of antisera and can reliably separate the two systems from each other (and from the beta-endorphin system as well).

With the publication of the mRNA structure coding for adrenal proenkephalin it has been possible to eliminate this precursor as a source for dynorphin thereby strongly suggesting a unique dynorphin biosynthetic route. As reported in a separate poster at this meeting (Khachaturian et al) we have used enkephalin and an enkephalin precursor peptide (BAM-22P) antisera to identify enkephalin cells in brain. Dynorphin cells were stained with antisera against dynorphin-(1-13), (1-17) and (7-17).

These two sets of sera (leu-enk, BAM-22P vs. dynorphin-(1-13), (1-17), (7-17)) have allowed consistent separation of these peptide systems in several brain loci.

The dynorphin system in brain is very wide spread including the olfactory bulb, n. accumbens, lateral septal nucleus, globus pallidus, the hypothalamic magnocellular nuclei, the arcuate nucleus, central nucleus of amygdala, several cortical layers, periaqueductal grey, n. parabrachialis, reticular formation, n. gracilus, raphe nuclei, nucleus tractus solitarius, and spinal cord. It composes the third major opioid peptide system in brain.

26.10 IMMUNOHISTOCHEMICAL LOCALIZATION OF ENKEPHALIN-, AND ACTH-RELATED SUBSTANCES IN THE ADENOHYPOPHYSIS OF THE LAMPREY. R. M. Dores, T. E. Finger and M. R. Gold. Depts. of Physiology and Anatomy, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

In the mammalian adenohypophysis, ACTH- and β-endorphin-related polypeptides are synthesized on a common precursor molecule (pro-ACTH/endorphin). Consequently, antisera directed against these peptides react with the same populations of cells. However, the enkephalins, which are not synthesized from β-endorphin, are found only in the neurohypophysis. In this study the distributions of immunoreactive forms of these peptides were assessed in the lamprey. Brains with pituitaries attached were dissected from brook lampreys, Lampetra lamottenii, and fixed with periodate-lysine-paraformaldehyde. The tissue was processed for immunocytochemistry by the indirect peroxidase-anti-peroxidase procedure utilizing a metal intensification of the DAB reaction. The primary antisera were raised in rabbits and were specific for the following: the middle region of ACTH, the NH_2-terminal of ACTH, β-endorphin, γLPH, 16K fragment, met-enkephalin and leu-enkephalin. These antisera were used at dilutions of 1:100 to 1:2000. Blocking experiments involved preabsorption of the antisera with 10 μM of the appropriate peptide. The lamprey adenohypophysis is divisible into three regions: the pro- and meso-adenohypophysis (purported homologs of the pars distalis), and the meta-adenohypophysis (purported homolog of the pars intermedia). In the pro-adenohypophysis a cluster of cells exhibited immunoreactivity with the middle ACTH antiserum and both enkephalin antisera, but did not react with any other antisera. The ACTH reactivity was blocked with ACTH(1-24), and the enkephalin reactivities were blocked with enkephalin but not with β-endorphin(1-31). In the meso-adenohypophysis a small population of cells exhibited immunoreactivity only with the γLPH antiserum. This reactivity was blocked with βLPH but not with β-endorphin(1-31). In the meta-adenohypophysis all cells reacted with the NH_2-terminal ACTH antiserum and both enkephalin antisera; however, these cells did not crossreact with any of the other antisera. The NH_2-terminal ACTH reactivity was blocked with αMSH, and the enkephalin reactivities were blocked with enkephalin but not with β-endorphin(1-31). In the neurohypophysis met- and leu-enkephalin immunoreactive fibers were detected. The absence of βLPH/β-endorphin immunoreactivity coincident with ACTH immunoreactivity, and the immunohistochemical detection of enkephalin in the adenohypophysis are unique to the lamprey. These observations suggest that there have been marked changes during evolution of the ACTH/βLPH family of pituitary hormones.
Supported by NIH Grants AM-06363, AM-18929, AM-19859, NS-09660, NS-06283, NS-15258, and NSF grant BNS 79-12956.

26.11 QUANTITATION AND LIGHT AND ELECTRON MICROSCOPIC STUDIES OF IMMUNOREACTIVE α-NEO-ENDORPHIN/DYNORPHIN RELATED PEPTIDES IN THE RAT SUBSTANTIA NIGRA. Kevin A. Roth*, Eckard Weber* and Jack D. Barchas. (SPON: D. L. Wong) Nancy Pritzker Laboratory of Behavioral Neurochemistry, Stanford Medical Center, Stanford, CA 94305.

In light microscopic studies we have observed an intense granular, terminal-like immunofluorescence in the substantia nigra for immunoreactive dynorphin(1-17) and α-Neo-endorphin (1). Dynorphin(1-8), an aminoterminal fragment of dynorphin (1-17) which is present in rat brain in much higher concentrations than dynorphin(1-17) (2), produces an identical pattern of immunostaining in substantia nigra. No immunoreactive α-Neo-endorphin/dynorphin cell bodies were visualized in the substantia nigra light microscopically. To further these studies, we have examined immunoreactive α-Neo-endorphin, dynorphin(1-8) and dynorphin(1-17) in the substantia nigra electron microscopically by a peroxidase anti-peroxidase pre-embedding staining method.

In preliminary electron microscopic studies, we have failed to observe cell bodies immunoreactive for α-Neo-endorphin/dynorphin in the substantia nigra. Specific α-Neo-endorphin/dynorphin immunoreactivity was seen predominantely in unmyelinated axons, occasional immunoreactive myelinated axons were also seen. More detailed studies are currently in progress.

We have also performed radioimmunoassays on dissected rat substantia nigras to provide quantitative data on the concentrations of α-Neo-endorphin, dynorphin(1-8), and dynorphin(1-17) in this region. This data will also be presented.

26.12 IMMUNOCYTOCHEMICAL LOCALIZATION OF DYNORPHIN IMMUNOREACTIVITY IN RAT CNS. Jacqueline F. McGinty, Lars Terenius*†, and Floyd E. Bloom. The Salk Institute, La Jolla, CA and †Uppsala University, Uppsala, Sweden.

Antisera raised against enkephalin have revealed a widespread pattern of "enkephalinergic"-like immunoreactivity (ir) in the CNS. Several larger molecular weight peptides containing the sequence of either methionine-enkephalin or leucine-enkephalin have been isolated and sequenced. With an antiserum to dynorphin 1-17, an opioid peptide which contains the pentapeptide sequence of leucine-enkephalin at its N-terminus, we have been able to distinguish a specific subdivision of the enkephalinergic network in the rat CNS. Most densely stained fibers are the hippocampal mossy fibers, substantia nigra zona reticulata, and the internal zone of the median eminence. Moderately stained are fibers found within the central amygdaloid nucleus, lateral septum, bed nucleus of stria terminalis (BNST), medial preoptic ara, nucleus accumbens, caudate-putamen, hypothalamic arcuate nucleus, entopeduncular nucleus, periventricular thalamus, midbrain central gyrus, nucleus tractus solitarius, and substantia gelatinosa of trigeminal nerve and dorsal horn. Widely scattered, thick fibers are present in olfactory, limbic and neocortex. Darkly staining cells are present in the central amygdaloid nucleus without colchicine pretreatment. After colchicine treatment, clusters of cells are apparent in prefrontal and cingulate cortex, olfactory peduncle, lateral septum, BNST, hypothalamic paraventricular and supraoptic nuclei, arcuate nucleus, lateral hypothalamus, dentate granule layer, and scattered in the hippocampal CA cellular fields. No dynorphin(ir) was apparent in the lateral perforant path. Dynorphin (ir) was abolished by absorption with 1 μM dynorphin 1-17 but not 1-100 μM dynorphin 1-13, leucine-enkephalin, or α-neo-endorphin. Thus we can distinguish three types of neuronal systems which putatively contain either dynorphin (ir), enkephalin (ir) or both dynorphin/enkephalin (ir) in rat CNS.

26.13 DISTINCT DISTRIBUTION OF IMMUNOREACTIVE DYNORPHIN AND LEUCINE ENKEPHALIN IN VARIOUS POPULATIONS OF ISOLATED ADRENAL CHROMAFFIN CELLS. M. Dumont*, R. Day* and S. Lemaire. Département de Pharmacologie, Centre Hospitalier Universitaire, Sherbrooke, Québec, Canada J1H 5N4.

The distribution of immunoreactive-dynorphin (ir-Dyn) in isolated subpopulations of bovine adrenal chromaffin cells was examined and compared with that of adrenaline (A), noradrenaline (NA) and ir-leucine-enkephalin (ir-Leu-Enk). Using a stepwise bovine serum albumin (BSA) gradient, various populations of catecholamine-storing cells were differentially separated in three layers (I, II and III). Cell layer I was enriched in NA, cell layer II contained both A and NA in equal amounts and cell layer III was enriched in A. Before separation on BSA gradient, the original cell preparation contained 3.5 times more ir-Leu-Enk as ir-Dyn (5.72 and 1.63 pmoles per 10^6 cells, respectively). After separation, ir-Dyn and ir-Leu-Enk were mostly confined to cell layer I and cell layer III, respectively. The secretion of A, NA, ir-Dyn and ir-Leu-Enk by the different cell layers corresponded to their total content: the cell population I mostly secreted NA and ir-Dyn, whereas the cell population III secreted A and ir-Leu-Enk. After subcellular fractionnation of the bovine adrenal medulla, both peptides (ir-Dyn and ir-Leu-Enk) were found in the secretory granules of adrenal chromaffin cells indicating that they are costored and cosecreted with the catecholamines. The levels of [^{3}H]-naloxone and [^{3}H]-Dyn binding to each layer were also compared. [^{3}H]-naloxone and [^{3}H]-Dyn were shown to bind equally and predominantly to cell layer III. These results indicate that bovine adrenal chromaffin cells can be isolated according to their content in specific catecholamines, opioid peptides and opiate binding sites and suggest that Dyn and Leu-Enk have a distinct biosynthetic pathway.

26.14 MET- AND LEU-ENKEPHALIN IN THE GUINEA PIG HIPPOCAMPUS. Douglas W. Hoffman, Richard A. Altschuler and J. Gutierrez*. LNO, Bldg. 36, Rm. 5D32, National Institutes of Health, Bethesda, MD 20205

There are conflicting reports of the localization and molecular form of enkephalin related peptides in the hippocampus. To resolve these points high pressure liquid chromatography (HPLC) and immunochemical techniques were combined to provide unequivocal regional localization, quantitation, and molecular identification of these peptides. Immunocytochemical experiments were performed using antisera raised against enkephalin.

HPLC was performed on whole hippocampal complex from 1 month old female NIH guinea pgs. The tissue was rapidly excised, sonicated in HPLC buffer and centrifuged to pellet particulate matter. Supernatant was injected directly onto a microBondapak octadecylsilane (10 micron) column and isocratically eluted with 0.05% trifluoroacetic acid in 25% acetonitrile. Good separation of enkephalin related peptides was achieved in a short (20 min.) run time. Collected fractions were frozen, lyophilized and reconstituted in a phosphate-BSA buffer for radioimmunoassay (RIA). RIAs were performed with a commercially available met-enkephalin antiserum cross-reactive to leu-enkephalin, allowing detection and quantitation of both these peptides in one chromatographic run and immunoassay. A third fraction of immunoreactivity which was neither leu- nor met-enkephalin was also observed in 7 out of 8 samples, with a retention time (approx. 8 min.) shorter than that of either of them. Present results indicate a higher ratio of leu- to met-enkephalin than has been previously reported for hippocampus.

In subsequent experiments, the whole hippocampus was rapidly dissected on a cooled plastic block into representative subregions. There regions were individually assayed by HPLC-RIA for content of enkephalins, with both met- and leu-enkephalin being found in each region studied. The pattern of immunoreactivity in the hippocampus may be influenced by the 8 min. HPLC peak, which clearly shares immunological characteristics with both met- and leu-enkephalin. The identity of this substance is not known, but it does not appear to be a direct metabolic product of either met- or leu-enkephalin.

26.15 DISTRIBUTION OF TYROSINE HYDROXYLASE (TH)-, LEU^5-ENKEPHALIN (ENK)- AND SUBSTANCE P (SP)-LIKE IMMUNOREACTIVITY IN THE SEPTAL AREA OF THE RAT. C.M. Gall, Dept. of Anatomy, Univ. of Ca., Irvine, Ca. and R.Y. Moore, Dept. of Neurology, S.U.N.Y., Stony Brook, N.Y.

The peroxidase antiperoxidase immunocytochemical technique was used to localize tyrosine hydroxylase-, enkephalin-, and substance P-like immunoreactivity in the septum of adult Sprague Dawley rats.

The pattern of TH-like immunoreactivity within the septum corresponds with previous descriptions of the distribution of catacholaminergic processes obtained with the glyoxylic acid fluorescent method. Thus, TH immunoreactive axonal groups were observed in the central lateral septal nucleus, at the extreme lateral edge of the caudal lateral septal nucleus and at the perimeter of the septofimbrial nucleus. In the former two areas, the varicose TH-positive axons form terminal 'baskets' encapsulating somata and proximal dendrites.

ENK-like immunoreactivity was seen within both perikarya and axons of well delineated fields of the lateral septum. ENK-positive somata were most prevalent in the central lateral septal nucleus (coextensive with the TH axonal field) although a few labeled perikarya were seen in the septofimbrial nucleus and just ventral to the corpus callosum. Lateral to this cell field a dense plexus of varicose ENK immunoreactive axons can be seen to form distinct pericellular baskets around lateral septal neurons.

No SP-positive perikarya were seen. SP-positive axons were seen in all regions of the septum outside the medial septal nucleus/diagonal band complex with marked variation in density. Most notably, only occasional SP fibers were seen in the zone occupied by the principal ENK-positive axonal plexus. A relatively high density of SP-positive axons was found just dorsolateral and ventrolateral to this clear zone. In these more heavily innervated areas the varicose SP axons form pericellular and, more frequently, dense peridendritic terminal arrays.

Although there is irregular overlap between SP and TH axonal fields, it was consistently observed that 1) the pericellular arborizations generated by SP and ENK axons occupy adjacent, non-overlapping fields; 2) TH fibers do not enter the zones of high ENK fiber density; 3) regions containing ENK-positive neurons are innervated by TH positive pericellular baskets; and 4) all immunoreactive axonal types observed in the extreme lateral septum form pericellular and peridendritic terminal arrays. These observations demonstrate a lamination of axonal systems in the lateral septum, an area which lacks well defined cytoarchitectonic subdivisions.

26.16 HISTOCHEMICAL LOCALIZATION OF IMMUNOREACTIVE DYNORPHIN IN THE TOAD BRAIN AND PITUITARY, R. I. Cone. Addiction Research Foundation, Palo Alto, CA 94304.

A biologically-active opioid, immunoreactive with antiserum raised against dynorphin-(1-13), was isolated from the brain of the toad, Bufo marinus.[1] This opioid probably has considerable sequence homology with porcine dynorphin and resembles dynorphin in having very high concentrations in the neurointermediate lobe of the pituitary and low sensitivity to antagonism by naloxone in the guinea pig ileum preparation. It is clearly different from porcine dynorphin in that it has a different retention time on HPLC and a somewhat lower opioid activity relative to its immunoreactivity.

This report concerns the localization of immunoreactive dynorphin staining in slices of toad brain and pituitary using a double antibody immunofluorescence method.[2] Fibers stained with an antiserum raised against a C-terminal fragment of dynorphin[3] were observed in the pars ventralis of the tuber cinereum, the median eminence, medial and lateral forebrain bundles, and along the ventral floor of the hypothalamus in the dorsal chiasmatic region. In sagittal sections, immunostained fibers appeared to extend into the zona externa of the median eminence. In the pituitary, intense staining was observed in the pars nervosa and no staining in the pars distalis. Immunostained cell bodies were observed in the pars ventralis of the tuber cinereum in animals which had been given colchicine (50µg) 48 hr prior to killing. Staining of fibers and cell bodies and staining in the pars nervosa could be prevented by coincubation of the antiserum with dynorphin (20µM) but not with leucine enkephalin (20µM). Additional results were obtained using an antiserum raised against dynorphin.[3] However, staining with this antiserum was not as consistent perhaps because some populations of porcine dynorphin antibodies do not recognize dynorphin in the toad.

Additional studies are in progress to establish further the location and specificity of immunostaining.

26.17 DISTRIBUTION OF ENKEPHALIN-LIKE IMMUNOREACTIVITY IN THE RAT SPINAL CORD: AN IMMUNOHISTOCHEMICAL STUDY. A.S. Moskowitz, S.M. Breedlove, A.P. Arnold & J.C. Liebeskind. Psychology Dept. and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Previous work (Elde et al, Neurosci., 1: 349 - 351, 1976; Simantov et al, Proc. Natl. Acad. Sci. U.S.A., 74: 2167 - 2171, 1977; Watson et al, Life Sci., 21: 733 - 738, 1977) has shown that moderate to dense enkephalin-like immunoreactivity (ELI) is present in laminae I, II, V, VII and X of the rat spinal cord, with lower levels of ELI found in the other laminae. In the present study we investigated the light microscopic distribution of leu-enkephalin-like immunoreactivity (LELI) at cervical, thoracic, lumbar and sacral levels of the rat spinal cord.

Adult male and female Sprague Dawley rats were used. Cryostat sections were cut at 10 μm and processed using the indirect immunohistofluoresence method. Adjacent sections were incubated with preabsorbed primary antiserum in order to ensure staining specificity or were stained with thionin in order to determine anatomical levels.

At all spinal cord levels moderate to high numbers of LELI containing fibers and terminals were seen in laminae I, II and V, whereas low to moderate numbers were noted in laminae VII, VIII and IX. At all levels moderate numbers of LELI containing fibers were found in the dorsolateral funiculus.

Rostrocaudal differences were noted in the density of LELI containing fibers and terminals in lamina X. At the thoracic level a few fibers and terminals were noted dorsal and lateral to the central canal. At the lumbar level many diffusely distributed fibers and terminals were seen dorsal and lateral to the canal, with low to moderate levels of fibers and terminals ventrally. At the sacral level a dense concentration of fibers and terminals was found dorsomedial to the canal, with low to moderate levels of fibers and terminals dorsolaterally, laterally and ventrally.

At the L_5 and L_6 levels moderate numbers of LELI containing fibers and terminals were seen in the sexually dimorphic nucleus of the bulbocavernosus (SNB). The SNB is much larger in adult male than in female rats and consists of motorneurons innervating striated muscles involved in male copulatory behavior (Breedlove & Arnold, Sci., 210: 564 - 566, 1980). No differences in the number or intensity of LELI containing fibers and terminals were seen in males and females.

26.18 REGULATION OF ENDOGENOUS OPIOID PEPTIDE CONTENT IN CULTURED NEURAL CELL LINES. K. M. Braas, S. R. Childers and D. C. U'Prichard. Northwestern Univ. Med. Sch., Chicago, IL 60611, Univ. Florida Coll. of Med. 32610.

Recent reports have demonstrated that numerous neural cell lines contain endogenous opioid peptides. The neuroblastoma x glioma hybrid cell NG108-15 and the neuroblastoma cell N1E-115 have been shown to contain enkephalins (Glaser et al, Eur. J. Pharm. 65:319, 1980; Gilbert, et al, J. Biol. Chem. 257:1274, 1982). We have shown staining of select NG108-15 cells using anti-Met^5-enkephalin (ME) and anti-Leu^5-enkephalin (LE) which is correlated to the state of differentiation induced by dibutyryl cAMP (dBcAMP) treatment. We now describe enkephalin staining in several neural cell lines which possess opiate receptors. The cell lines NG108-15, N1E-115, NCB-20, N4TG-1, N18TG-2 and C6BU-1 were cultured as previously described (Braas et al, J. Histochem. Cytochem. in press, 1982), along with human skin fibroblasts and BHK cells. Two days after plating, some cultures were treated for 5 or 7 days with 1mM dBcAMP. NG108-15 cells grown in serum-supplemented or defined medium were also treated with 1mM 8-bromo-cAMP, 10μM PGE_1 plus 100μM IBMX, or 2mM sodium butyrate (NaB). Further treatment of some cultures with arabinosylcytosine (ARA-C) killed proliferating cells and pure cultures of differentiated cells were obtained. The cells were fixed, processed, and immunocytochemically stained for LM and EM as previously described using anti-ME or anti-LE with the peroxidase anti-peroxidase complex technique. Intense enkephalin-like immunoreactivity was localized throughout the cytoplasm and short processes of select untreated NG108-15, N1E-115, NCB-20 and skin fibroblasts, while C6BU-1 and BHK cells showed little to no staining. Induction of differentiation increased the volume fractions of stained cells. At the EM level, stain was localized to the dense core vesicles found in the cytoplasm and processes of select cells. HPLC analysis and radioreceptor assay demonstrated the presence of 12.6 and 15.1 fmole/10^6 cells of ME and LE in untreated NG108-15 cells grown in serum supplemented medium which approximated the content in cells grown in defined medium. This rose to 30.8 and 33.0 fmole/10^6 cells following dBcAMP treatment. Treatment with ARA-C increased the ME content to 81.0 fmole/10^6 cells, while LE content remained unchanged. Apparently larger increases of enkephalin content was observed for both ME and LE in defined medium cultures treated with NaB. Untreated N1E-115 cells contained 40.7 and 33.5 fmole/10^6 cells of ME and LE respectively. The biochemical analysis for ME and LE correlated well with the immunocytochemical data indicating that the enkephalin content is related to the state of differentiation. Supported by ACS IN-123 (KMB), USPHS grants NS15595 and MH36183 (DCU) and Research Starter Grant from Pharmaceutical Manufacturers Assoc. Found. (SRC).

27.1 BEHAVIORAL EFFECTS OF INDOLE- AND PIPERAZINE-TYPE SEROTONIN RECEPTOR AGONISTS. I. Lucki and A. Frazer. Depts. of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine, and Veterans Administration Hospital, Philadelphia, PA 19104.

The abilities of various indole- and piperazine-type serotonin receptor agonists to alter locomotor activity and to produce the serotonin syndrome were examined in rats.

Locomotor activity of rats was measured in Plexiglas cages, 44x24x20-cm, that employed two photocell detectors to measure a defined ambulatory response of 18 cm along the longitudinal axis of the cage. Intraperitoneal administration of the piperazine-type serotonin agonist, trifluoromethylphenylpiperazine (TFMPP), produced a dose-related decrease in locomotor activity. Activity was reduced significantly by TFMPP at doses of 2.5 mg/kg and higher. The suppression of locomotor activity could be prevented by pretreatment with a number of serotonin receptor antagonists. The potency order for these antagonists for preventing the effects of TFMPP (5 mg/kg) was (most potent to least potent): metergoline mianserin methysergide = cinanserin. Metergoline produced significant blockade of TFMPP's effects at doses as low as 0.3 mg/kg. In contrast, ketanserin and pipamperone, relatively potent and specific antagonists of the serotonin$_2$ receptor, were not capable of preventing TFMPP's effect on locomotor activity at doses as high as 10 mg/kg.

Intraperitoneal administration of indole-type compounds like 5-methoxy-N,N-dimethyltryptamine (5-MeODMT, 3 mg/kg) and d-lysergic acid diethylamide (LSD, 4 mg/kg) to rats produced the serotonin syndrome, a stereotyped behavior frequently used to examine serotonin receptor activation in vivo using rats (B. Jacobs, Life Sci., 1976, 19, 777-786). Pretreatment with metergoline blocked the serotonin syndrome produced by 5-MeODMT. However, TFMPP was not capable of producing the serotonin syndrome at doses up to 36 mg/kg, when toxic effects appeared in the animals.

These results demonstrate differences in the behaviors produced by indole-type and piperazine-type serotonin receptor agonists. It is possible that an interaction of these agonists with different types of serotonin receptors underlies their different behavioral effects.

Supported by research funds from NIMH grants MH36262 and MH29094, and by funds from the Veterans Administration.

27.2 HORMONAL MANIPULATIONS OF THE "SEROTONIN BEHAVIORAL SYNDROME." C.T. Fischette, A. Biegon and B. McEwen . The Rockefeller University, New York, NY 10021.

Sex differences have been found in the stereotypic tryptophan-induced behavioral syndrome (Biegon, A. et al., Psychopharm., 61: 77, 1979), a behavioral pattern which has been correlated with the serotonin$_2$ (5HT-2) receptor (Peroutka et al., Science 212: 827, 1981). In an effort to further characterize the influence of sex hormones upon the serotonergic system, we have used the "serotonin syndrome" as an endpoint to study the effects of hormonal manipulations upon a neurotransmitter system. Pargyline (50mg/kg, i.p.) was administered 1h before l-tryptophan (50mg/kg, i.p.). Animals were observed at 1 and 2h after tryptophan injection and scored for the presence of stereotyped behaviors indicative of 5HT stimulation (Jacobs et al., Life Sci., 19:777, 1976): i.e., resting tremor, head shakes, forepaw treading, hindlimb abduction, salivation, straub tail and hypersensitivity to touch. Results indicate that: 1) a significantly higher number of females exhibit the response as compared to males; 2) ovariectomy has no effect; 3) castration completely abolishes the sex difference; 4) testicular feminized mutants (tfm/y), having a deficit of androgen receptors, respond similarly to females; 5) the sex difference is observed in 18-day old prepubertal as well as adult animals; and 6) this effect is not strain-specific, since it occurs in Sprague-Dawley, King-Holtzman and Wistar rats. The results suggest that androgens, which exert their effects via androgen receptors, reduce the sensitivity of the rat brain to elevated 5HT concentrations. This effect may be mediated by androgen actions on 5HT-2 receptors, although other interpretations are possible. In this connection, we have found that in gonadodectomized male and female rats the pattern of response for 5HT-1 receptor binding in microdissected nuclei differs when animals are given the same hormonal (estrogenic) stimulus (Fischette, C. et al., Fed. Proc., 41(4): 1268, 1982). While further studies on sex differences in the 5HT-2 system are required, current results are consistent with sex differences observed in the occurrence of affective disorders in humans.

27.3 ACUTE AND CHRONIC EFFECTS OF A NEW ANTIDEPRESSANT, TRAZODONE, ON AN ANIMAL MODEL OF DEPRESSION. J.N. Hingtgen*, H.C. Hendrie* and M.H. Aprison. Institute of Psychiatric Research and Depts. of Psychiatry and Biochemistry, Indiana University School of Medicine, Indianapolis, IN 46223.

Previous data from our laboratories have indicated that acute pretreatment with clinical doses of the antidepressive drugs, mianserin, amitriptyline, imipramine and iprindole, results in the blockade of D,L-5-hydroxytryptophan (5-HTP; 50 mg/kg) induced depression in rats working on a food-reinforced operant schedule (Nagayama et al. Pharmacol. Biochem. Behav. 15, 125, 1981). To distinguish between presynaptic and postsynaptic events, these drug effects were compared to those of fluoxetine, a known specific uptake blocker of serotonin (5-HT), which potentiated the 5-HTP induced depression, and to methysergide, a postsynaptic blocker of 5-HT, which almost completely abolished the depressive effect of 5-HTP. Using the same 5-HTP animal model of depression, we are currently studying the effects of a new antidepressive drug, trazodone, a triazolopyridine compound. Rats working for milk reinforcement and exhibiting behavioral depression following administration of 5-HTP (50 mg/kg; I.P.) were pretreated (1 hr. before the 5-HTP injection) with 1, 2, or 4 mg/kg trazodone with resulting blockade of 5-HTP induced depression of 35, 62 and 70%, respectively. Chronic administration of 2 mg/kg trazodone/day also resulted in a significant blockade of the 5-HTP effect (75%). The blockade of 5-HTP induced depression following both acute and chronic treatment with trazodone was similar to that found in our studies with mianserin and amitriptyline. Since fluoxetine potentiates the behavioral effect of a low dose of 5-HTP, we tested for presynaptic effects of trazodone by giving a lower dose of 5-HTP. Neither 2 mg/kg or 4 mg/kg trazodone was found to potentiate the shorter period of depression following 25 mg/kg 5-HTP. Thus, as with other antidepressive drugs used with the 5-HTP animal model of depression, these data suggest an important postsynaptic mechanism associated with trazodone which could be implicated in the therapeutic effectiveness of this drug. These data, as well as CNS binding data for trazodone, provide additional support for the new hypersensitive postsynaptic serotonin receptor theory of depression (Aprison et al., In: Neuropharmacology and Behavior, Plenum Press, N.Y., 1978; Aprison and Hingtgen, In: Serotonin, Plenum Press, N.Y., 1981). (Supported in part by Association for Advancement of Mental Health Research and Education, Inc., Indianapolis (JNH;MHA) and Indiana Department of Mental Health Grant (HCH) 178-679-005.)

27.4 DIFFERENTIAL EFFECTS OF TWO SEROTONIN DEPLETORS ON APOMORPHINE-INDUCED BEHAVIOR IN RATS. H. Chow*, C. H. M. Beck. Dep't. of Psychology, Univ. of Alberta, Edmonton, Alberta, T6G 2E1.

Para-chlorophenylalanine (p-CPA) and para-chloroamphetamine (p-CA) are both serotonin depletors, however, they have different mechanisms of action. The major difference is that p-CPA blocks new synthesis of serotonin while p-CA irreversibly destroys serotonergic neurons. A challenge of p-CPA and p-CA treated animals with apomorphine (Apo) was used in this study to reveal the behavioral correlates of these differential biochemical effects. Sixty male Sprague Dawley rats, randomly assigned to 6 groups, received one of the following injections 3 days before testing: saline (2 ml/kg, .9%, i.p.) or p-CPA (400 mg/kg, i.p.) or p-CPA (250 mg/kg, i.p.) or p-CA (10.4 mg/kg, i.p.) or p-CA (6.4 mg/kg, i.p.). Five minutes before testing, these rats received injections of either saline (2 ml/kg, i.p.) or Apo (5 mg/kg, S.c.). The rats' behavior while in a wooden test box (56x66x64 cm) was recorded continuously by a trained observer during 18 two minute sessions interpolated over 78 minutes. The behavior was recorded using a list of 14 mutually exclusive and 2 non-exclusive behavioral categories. In half of the sessions the rat was alone and in the other half it was paired with a naive, non-drugged rat. Drug-induced behaviors were collapsed into three composite categories, namely, hyperactivity (speed of locomotion), stereotypy (time spent in gnaw, nod, rear-gnaw), hyperreactivity (frequency of jumping). The expression of neither hyperactivity nor stereotypy was affected by the presence of the partner in the test box. Addition of p-CA (10.4 mg/kg or 6.4 mg/kg) to Apo resulted in significantly more hyperactivity and hyperreactivity when compared to both saline-Apo and p-CPA (400 mg/kg) - Apo groups. Addition of p-CPA (400 mg/kg) to Apo resulted in significantly more time spent gnawing on the test floor while saline with Apo resulted in significantly more time spent gnawing on the side of the test box while rearing when compared to all other groups. The proportion of time spent in stereotypy was similar for the saline-Apo and p-CPA (400 mg/kg) - Apo groups. However, the nod component contributed most significantly to the stereotypy for the saline-Apo group whereas the gnaw component accounted for most of the stereotypy in the p-CPA (400 mg/kg) - Apo groups. Thus, the addition of p-CPA (400 mg/kg) to Apo seemed to have altered only the specific form of the Apo stereotypy. In conclusion, it was possible to behaviorally differentiate p-CPA and p-CA with the Apo challenge.

27.5 VOLTAMMETRY IN VIVO: PHARMACOLOGICAL STUDIES IN THE FREELY MOVING RAT WITH MODIFIED ELECTRODES. C.D. Andrews, K. C. Veneziano* and P. J. Knott. Dept. Pharmacology, Marshall Univ. Sch. Med., Huntington, WV 25701, USA.

Voltammetry in the brain of the freely moving rat enables changes in the release of neurotransmitters and their metabolites to be made over extended periods in conjunction with behavioural measurements. We have developed an automated method for voltammetric recording which offers versatility of control with powerful data storage and analytical capabilities. Timing control and electrode selection is provided by an Apple II+ microcomputer which is interfaced to a DCV-5 voltammetry controller (Bioanalytical Systems Inc.). Using this system remote control of chart recorder, voltammetry controller and connection of appropriate electrodes from multiple implants is achieved by a timing program in BASIC. Chemical modification of graphite-nujol paste electrodes by inclusion of stearic acid (Lane, R.F., Soc. for Neurosci., 1981) improves resolution of the dopamine (DA) peak from ascorbic acid (AA) and dihydroxphenylacetic acid DOPAC) by repulsion of acid groups at the electrode surface. We have used stearate modification of silicone-graphite paste electrodes. In vitro studies suggested that inclusion of silicone oil further improved the DA selectivity.

With electrodes chronically implanted in the striatum or nucleus accumbens, linear sweep voltammetry (20mV/sec) in the behaving rat produced peaks at approximately 140mV, 250mV and occasionally at 415mV. Pharmacological studies suggest that the peak at 140mV reflects DA release. Thus this peak increased with amphetamine (2mg/Kg i.p.) and decreased with γ-butyrolactone (250mg/Kg i.p.), returning to preinjection values after several hours. The monoamineoxidase inhibitor pargyline (75mg/Kg i.p.) caused a gradual but prolonged increase in the peak thought to reflect extraneuronal DA and clearly could not represent either DOPAC or HVA as the decline of these metabolites following monamineoxidase inhibition is well established.

(Supported by the N.I.M.H. 1R01-MH35543-01 to P.J.K.)

27.6 MOUSE STRAIN DIFFERENCES IN BEHAVIORAL RESPONSE TO AMPHETAMINE, P. K. Randall* and J. S. Randall*, (SPON: S. S. Erlich) Dept. of Physiology & Biophysics, U. S. C. Sch. of Med., Andrus Gerontology Ctr., Los Angeles, CA 90007.

Neurochemical and neuroanatomical variation between inbred mouse strains are potential model systems for examining brain-behavior relationships. For example, amphetamine- and apomorphine- induced stereotyped behaviors have been used to assess the functional significance of differences in striatal dopaminergic innervation and receptor number between CBA/J and BALB/cJ mice. We have observed that mice, in general, exhibit qualitatively different "stereotyped" behaviors in response to apomorphine and amphetamine, and the strains, in particular, differ qualitatively as well as quantitatively in their responses to each of these drugs. A complete description of the behavioral response to a wide range of amphetamine doses is critical for making quantitative strain comparisons.

CBA/J, BALB/cJ and C57BL6/J mice were observed at intervals of 6 min for 1 hr following IP injections of 2.5, 5.0, 10.0, 20.0 and 40.0 mg/kg d- amphetamine sulfate (n=10/gp). Presence or absence of 28 behavioral categories during each 20 sec observation were recorded. Several behaviors usually contributing to stereotyped behavior rating scales showed striking strain variation.

The dose response curve for locomotor activity and repetitive locomotor behavior suggested an order of sensitivity of BALB/cJ > C57BL6/J > CBA/J. Gnawing and sniffing, however, suggested qualitative strain differences. CBA/J mice increased continuous sniffing as a function of dose through 20 mg/kg. However, neither BALB/cJ nor C57BL6/J mice showed this behavior even at doses as high as 40 mg/kg. Intermittent sniffing decreased with dose in BALB/cJ mice. Gnawing increased with dose in BALB/cJ and C57BL6/J mice but was never observed as a component of the drug response in CBA/J mice. Grooming was only sporadically observed in any strain at 2.5, 5.0, and 10.0 mg/kg. In BALB/cJ mice abortive and self-injurious grooming behavior became the predominant response at 40 mg/kg. This behavior was also observed in CBA/J and C57BL6/J mice at a much lower frequency.

These data are consistent with reports that CBA/J mice are less sensitive to amphetamine than are BALB/cJ mice, but suggest caution in the application of rating scales across these strains.

27.7 ARE BETA 1, BETA 2 OR VASOPRESSIN RECEPTORS INVOLVED INTO DEPRESSION ? B. Delbarre, G. Delbarre, D. Casset-Senon*. Lab. Chir. Exp. Fac. Med., 37032 Tours - France.

Pharmacological and clinical studies suggest that Beta 2 adrenergic stimulant have an antidepressive activity. The mechanism may be explained by release of vasopressin (VP) in blood and C.S.F. (Delbarre et al. Neuroend. lett. 1982 (4) 2). However, a significant decrease in the density of beta adrenergic receptors was observed after antidepressive agents administration (Sulser et al. Biochem. Pharmacol. 1978, 27, 257). In these studies, no distinction has been made between beta 1 and beta 2 receptors. (R.N. Pittman et al. Brain research 1980, 188,357) have shown that beta 1 and beta 2 receptors are differently distributed in C.N.S and appear to be independently regulated. In order to investigate the putative role of these receptors in depression, we have used the antagonism to reserpine induced hypothermia test in mice. Injected in the lateral ventricle (I.C.V.) lysine and arginine VP (0,01 to 0,1 U/mouse), beta 1 selective antagonist agent practolol (20µg/mouse) and intra peritoneal beta 2 stimulant salbuta mol (1 mg/kg) clembuterol (0,5 mg/kg) reverse this hypothermia. But dobutamine (20 µg/mouse) I.C.V, a beta 1 stimulant agent does not reverse hypothermia. As norepinephrine (10 µg/mouse ICV) dobutamine (10 µg/mouse ICV) induces hypothermia. This action is antagonized by DMI (10 mg/kg I.P), practolol (20 µg/mouse ICV) and clembuterol (0,5 mg/Kg IP).

These results suggest that beta 1 and beta 2 receptors independently regulated have also opposite effects on depression and on A.D.H. release.

27.8 MODULATION OF DOPAMINERGIC NIGRO-STRIATAL TRANSMISSION BY PHENCYCLIDINE. H.D. Everist and A. Pert. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205.

There is considerable evidence to suggest that some of the pharmacological effects of phencyclidine (PCP) are mediated through the dopamine system. While PCP has been shown to influence dopaminergic activity, the loci of such actions are unknown. Of interest is the finding that the caudate nucleus as well as the substantia nigra (SN) contain relatively high concentrations of PCP receptors. The purpose of these studies was to ascertain whether the effects of PCP on dopaminergic activity are mediated through either of these structures. In the first series of studies, rats were lesioned unilaterally in the SN with 6-hydroxydopamine. Two to three weeks later the animals were tested in an automated rotometer following i.p. injections of 3, 10 and 20 mg/kg PCP. PCP was found to induce dose-dependent ipsilateral rotational behavior. This effect was attenuated by microinjections of haloperidol (10 µg) into the striatum contralateral to the lesion. In the second series of studies, direct unilateral microinjections of PCP (3, 10 and 25 nmoles) into the SN induced dose-dependent rotational behavior contralateral to the injection. This effect was attenuated by injections of haloperidol into the ipsilateral striatum. Unilateral injections of +PCMP into the SN were five times as effective in eliciting rotational behavior as -PCMP. This corresponds with the efficacy of these two enantiomers in inhibiting PCP binding to brain homogenates. Unilateral injections of PCP (50 nmoles) into the caudate nucleus were without effect on rotational behavior. The findings from these studies suggest that PCP may activate the dopaminergic nigrostriatal pathways through an action in the SN. The precise mechanism of this effect is under study.

27.9 EFFECTS OF CLONIDINE AND NALOXONE ON SELF-STIMULATION RESPONDING BEFORE AND AFTER CHRONIC AMPHETAMINE TREATMENT. Nancy J. Leith, Dept. Pharmacol., Vanderbilt Med. Sch., Nashville, TN 37232

Chronic administration of amphetamine (AMPH) has been shown to produce pharmacodynamic tolerance to the drug's facilitating effects on self-stimulation (SS) responding and a marked post-drug depression of responding reflected in an elevation of the reward threshold (Leith and Barrett, Psychopharmacologia, 46, 1976). The present study was undertaken to provide a first assessment of a possible role for norepinephrine (NE) or opiate systems in the behavioral changes produced by chronic AMPH by examining the effects of clonidine (CLON), an α_2 agonist, and naloxone (NAL), an opiate antagonist, before and after treatment with chronic AMPH.

Animals with electrodes implanted in the MFB were repeatedly tested at 15 current intensities for two successive 15 min sessions. During the first session, baseline responding was assessed. On separate days, subcutaneous injections of AMPH .3 mg/kg, CLON (0.025-.15 mg/kg), NAL (1-4 mg/kg), AMPH + CLON or AMPH + NAL were administered and the second session begin 5 min later. AMPH produced its typical lowering of the reward threshold whereas CLON produced a dose dependent elevation of the threshold with the maximal effect achieved by a dose of 0.1 mg/kg. NAL alone had no effect in the dose range tested. Both CLON and NAL blocked the facilitation produced by AMPH. When acute testing was completed, testing was terminated and increasing doses of AMPH (1-12 mg/kg) were given 3 times daily for 4 days. Two days later the animals were again tested with selected pretreatment doses of the drugs.

The rats developed tolerance to AMPH facilitation of SS responding, which is primarily a reflection of an elevation of the baseline reward threshold. CLON was still able to further elevate the threshold in a dose dependent manner as it had prior to chronic AMPH. Thus, the depressed baseline produced by chronic AMPH is likely unrelated to changes in α_2 receptors.

Testing with NAL, however, did reveal changes after chronic AMPH. Although NAL still had no effect by itself, it no longer blocked AMPH facilitation in chronic AMPH treated rats. When the animals were retested 10 days later and baseline responding had recovered to pretreatment levels, NAL was again able to block the AMPH facilitation. Thus, although AMPH produces a similar relative facilitation of SS responding in acutely and chronically treated rats, the brain mechanisms involved in the two situations must be somewhat different since the facilitation produced acutely is NAL sensitive whereas that obtained in chronically treated animals is not (Supported by MH29217).

27.10 BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF PHENCYCLIDINE AND ITS METABOLITES IN THE CAT. S. Howard-Butcher, M.S. Levine, Dept. of Pharmacology, Mental Retardation Research Center, Brain Research Institute, UCLA, Los Angeles,CA 90024.

We have previously shown that chronic treatment with low doses (1-2 mg/kg) of phencyclidine (PCP) produced marked behavioral effects in the developing kitten (Levine et al., Neuropharmacol. 20: 743, 1981). These effects are age-dependent. Under 21 days the major response consisted of rostrocaudal forelimb movements. After this age the major responses were ataxic locomotion and waxy rigidity. In the present experiment we assessed the behavioral effect of subcutaneous injections of higher doses of PCP, two of its metabolites, phenylcyclohexylamine (PCA) and an alcohol (N-(5-hydroxypentyl)-1-phenylcyclohexylamine) (AL) (Cho et al., Life Sci. 28: 1075, 1981) and one PCP analog (N-N diethylcyclohexylamine (NND)) in kittens between 35-50 days of age. To date we have tested the effects of these substances on 14 kittens from 4 litters. The behavior of the kittens was assessed from 10-15 min pre-injection to up to 7-10 hrs postinjection and rated on a 5 point scale. The most intense response was produced by PCP at both doses and consisted of waxy rigidity (limbs in abnormal postures for extended time periods) with the animal completely immobile. All animals tested displayed waxy rigidity and immobility from 1-2 hrs at 5 mg/kg and for 4-5 hrs at 10 mg/kg. Less intense responses were produced by NND and consisted of locomotor activity with the animal flat on its stomach. PCA was less effective, producing only tremor and staggering followed by loss of hindlimb support. AL was least effective, producing almost no behavioral effect. For all compounds higher doses produced similar behavioral actions as the lower doses but the duration of action was longer.

We have also assessed the capabilities of PCP to release dopamine (DA) in the caudate of 3 adult cats using cyclic voltammetry. Low doses of PCP (1 mg/kg subcutaneous) consistently produced an increase in release of caudate DA (3-5 times control values). The increase in release occurred within 5 min postinjection and continued for at least 3 hrs. Subsequent injections 1 and 2 weeks later did not produce consistent increases in caudate dopamine release suggesting that a rapid tolerance may have developed.

These results indicate that some of the metabolites of PCP, while active, are not as potent as PCP itself. Additionally, our results provide support for a role of caudate DA in the mechanism of action of PCP.

Supported by USPHS Grants HD 05958, HD 05651 and RR 05756. The synthesis of the metabolites of PCP used in this study was supported by USPHS Grant DA 02411 to A.K. Cho.

27.11 AMANTADINE BLOCKS THE EFFECTS OF SEVERAL CENTRAL STIMULANTS, BUT NOT THOSE OF ALCOHOL AND PENTOBARBITONE, IN MICE. M.K. Menon and V.G. Haddox*. Psychopharmacol. Res. Lab. and Alcohol Treatment Unit, V.A. Med. Ctr, Sepulveda, CA 91343 and Dept. Psychiat., UCLA School of Medicine, Los Angeles, CA 90024.

We reported earlier that amantadine blocks the central stimulant effects of d-amphetamine in mice (Menon et al., Eur. J. Pharmacol. 21:311, 1973). This paradoxical effect was confirmed in rats by others (Clark et al., Proc. Soc. Exp. Biol. Med. 151: 434, 1976). Amantadine also reduced the antiparkinsonism effect of l-dopa in humans, but only when given before the latter (Cox et al., J. Neurol. Neurosurg. Psychiat. 36:354, 1973). Experiments were performed to know whether amantadine is able to block the locomotor stimulant effects of drugs other than d-amphetamine.

Male Swiss mice were used and all the drug treatments were made intraperitoneally. The test groups received amantadine HCl (150 mg/kg) 120 min before the stimulant drug. Control mice were treated with distilled water in place of amantadine. One hr after either amantadine or water injection, the mice were placed in individual cages for familiarization and the stimulants were administered after a further 1 hr. A Varimex activity meter was used and the activities were recorded on a printing counter. Differences in the 60 min activity readings between the test and control groups were used for calculating the percent change in their locomotor effects.

Amantadine pretreatment caused a marked reduction (71.5% blockade) in the response to d-amphetamine. This confirmed our earlier findings. Amantadine treatment also was very effective in blocking the responses of mice to other stimulants such as methylphenidate (20 mg/kg, 70.2%), amfonelic acid (1 mg/kg, 91.9%), caffeine (20 mg/kg, 42.9%), 1,3-dimethyl-5-aminoadamantane (D-145, 20 mg/kg, 71.4%), phencyclidine (10 mg/kg, 58.7%), cocaine (50 mg/kg, 69.6%) and d-deprenyl (20 mg/kg, 77.8%). The levorphanol-induced stimulation was not modified by amantadine. Amantadine also did not reduce the duration of the "sleeping-time" caused either by alcohol (5 g/kg) or pentobarbitone (60 mg/kg). The value of amantadine in the management of stimulant abuse needs to be explored. (Supported by the Veterans Administration).

27.12 TL-99 AND 3-PPP, DIFFERENTIAL ACTION IN PRODUCING CONTRAVERSIVE TURNING IN THE 6-OHDA-LESIONED RAT. Gregory E. Martin and R. J. Bendesky*. Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.

TL-99 (Goodale et al., 1980, Science, 210:1141) and 3-PPP (Hjorth et al., 1980, Psychopharm. Bull. 16:85) are two recently reported agents said to be selective for the dopamine autoreceptor. Although TL-99 was thought to qualify as a selective DA autoreceptor agonist due to the fact that it did not produce contraversive turning in the 6-OHDA-lesioned rat (Goodale et al., 1980), a recent report demonstrated TL-99 did produce contraversive turning but the dose-response curve had an inverted U shape (Martin et al., 1981, EJP, 76:15-23). The purpose of the present study was to extend our previous work by quantifying the number of turns produced by each autoreceptor agonist given over a wide dose range. Since TL-99 also possesses potent α_2 activity (Hicks and Cannon, 1980, J.P.P. 32:786), the effect of pretreatment with yohimbine on the TL-99- or 3-PPP-induced turning was also examined. A unilateral 6-OHDA lesion was created in the substantia nigra of 120 female Sprague-Dawley rats using standard stereotaxic procedures. Yohimbine was administered s.c.; all other drugs were given i.p. Turns were recorded in automated rotometers for 1-2 hr following drug administration. TL-99 was given in doses of 1, 1.5, 2, 3, 4 and 6 mg/kg, 3-PPP was given in doses of 1, 3 and 9 mg/kg and apomorphine in doses of 0.1, 0.5 and 1.0 mg/kg. Each dose of each drug was given to 8 rats. Yohimbine (0.5 mg/kg s.c.) was given 1 hour before TL-99 or 3-PPP using a counterbalanced design in which each animal served as its own control. 3-PPP produced a dose-related turning response ($\bar{x} \pm$ S.E.M. = 172 $\pm$ 95 tph after 1 and 564 $\pm$ 128 tph after 9 mg/kg) as did apomorphine (210 $\pm$ 67 tph after 0.1 and 519 $\pm$ 49 tph after 1.0 mg/kg). The turning produced by TL-99 was dose-related up to 3 mg/kg (39 $\pm$ 9 tph after 1 and 220 tph after 3 mg/kg), but the number of turns declined as the dose level was further increased, viz 195 $\pm$ 35 and 122 $\pm$ 31 after 4 and 6 mg/kg, respectively. Pretreatment with yohimbine produced a significant increase (from 130 $\pm$ 15 to 240 $\pm$ 49 and 95 $\pm$ 11 to 218 $\pm$ 45 tph) in TL-99 (4 and 6 mg/kg respectively)-induced turning. Turning produced by 3-PPP (1.0 or 3.0 mg/kg) was not significantly altered by yohimbine pretreatment. Both 3-PPP and TL-99 produce a vigorous contraversive turning response in 6-OHDA-lesioned rats but the sedation produced by the α_2 properties of TL-99 produces a fall in potency of TL-99 at higher dose levels. Hence, 3-PPP appears to be the more selective dopamine agonist. The 6-OHDA-lesioned rat model does not distinguish between post synaptic and DA autoreceptor agonists.

27.13 PHENYLETHYLAMINE DISRUPTS LATENT INHIBITION IN THE GERBIL, Charles J. Hannan, Jr., Robert Patterson*. Clinical Investigation Dept., Eisenhower Army Medical Center, Ft Gordon GA. 30905

The gerbil is used to study attention employing the latent inhibition paradigm. Briefly, the latent inhibition paradigm involves exposing one of two groups of animals to an innocuous stimulus, we used a tone,and then testing both groups in a conditioned avoidance response (CAR) situation using for the conditioned stimulus (CS) the tone previously used, paired with the unconditioned stimulus (US), electric shock. Animals which were exposed to the unpaired CS do not perform as well in the CAR as animals that had never experienced the CS. The explanation for this could be that in the CAR situation the previously meaningless CS had to be unlearned before the meaningfulness of the CS-US relationship could be learned. An animal not exposed or not attending to the CS would only have to learn the CAR and therefore would learn more quickly than its' familiarized counterpart. It was recently reported that amphetamine disrupts latent inhibition; therefore both familiarized and unfamiliarized animals perform at the same level in the CAR (Solomon et al, Biol Psychiat 16:519-537,1981). The same investigators also demonstrated a protective effect of chlorpromazine on the amphetamine disrupted latent inhibition. The authors propose latent inhibition disruption by amphetamine as a model for the attentional defect associated with certain schizophrenias. Phenylethylamine (PEA) has been called an endogenous amphetamine and elevated concentrations have been found in some schizophrenics, so evaluation of its' effects in the latent inhibition model seemed appropirate. The methodology used was similar to that reported in the above reference. PEA was administered for at least 10 days at 50 mg/kg ip each day. Animals were then tested in a BRS/LVE shuttle box.

LATENT INHIBITION MEASURES (MEAN ± SE)

GROUPS (n)	AVOIDS CONTROL/PEA	TRIALS CONTROL/PEA
FAMILIARIZED (5)	30±4 30±12	60±3 11±2
UNFAMILIRIZED (5)	47±2 30±8	27±5 20±10

Saline treated controls exhibit the expected effects of familiarization with the CS: fewer avoids and a greater number of trials to criterian (4 avoids out of 5 trials), relative to the unfamiliarized group. PEA disrupted the latent inhibition effect, as amphetamine was reported to do and may produce a syndrome more consistent with human schizophrenia. Further studies are underway to evaluate the effect of antipsychotic agents in this model.

27.14 POTENTIATION OF THE BEHAVIOURAL EFFECTS OF THE ANTIDEPRESSANT, PHENELZINE, BY DEUTERIUM SUBSTITUTION. K.M. Dewar*, L.E. Dyck*, A.A. Boulton and C.T. Dourish* (Sponsor: J.D. McQueen). Psychiatric Res. Div., University Hospital, Saskatoon, Sask., S7N OXO, Canada.

Recent studies in this laboratory have demonstrated that deuteration of β-phenylethylhydrazine (phenelzine, PLZ) in the α,α,β,β-positions of its side-chain enhances its ability to inhibit MAO after systemic administration. To determine whether the presence of deuterium in these positions affects the behavioural responses to PLZ, we have compared the effects of intraperitoneal PLZ to those of deuterated PLZ (d_4 PLZ).

Male Wistar rats were individually tested in plexiglass cages positioned in an automatic activity recording device which recorded horizontal and vertical movements via a microprocessor and microcomputer system. In addition, the behaviour of each animal was observed and rated during 15 min of each hour for a 12-hour period by a trained observer. The behaviour of rats given 12.5 or 25 mg/kg of PLZ was similar to that of controls. In contrast, these doses of d_4 PLZ elicited wet dog shakes (WDS), forepaw padding, sniffing, repetitive grooming and hyperactivity. A maximum of 10 and 25 WDS (per 15 min) respectively, 6-7 hours post-injection was observed. Maximal stimulation of horizontal activity was observed after 25 mg/kg. PLZ at a dose of 50 mg/kg produced WDS, splayed hindlimbs, sniffing, repetitive grooming and increased horizontal activity. The latency of onset of behavioural stimulation was 2 hours post-injection and peak effects were observed 6-7 hours after drug administration. A maximum of 12 WDS was observed 6-7 h post-injection. After an equivalent dose of d_4 PLZ, however, a maximum of 26 WDS was observed. The intensity of repetitive grooming, horizontal activity, splayed hindlimbs and sniffing was also enhanced. In contrast to PLZ, d_4 PLZ produced forepaw padding.

Behavioural stimulation was increased quantitatively by deuteration though there was little or no effect on the time course of drug action. The present results are compatible with the finding that deuterium substitution of PLZ enhances its MAO inhibitory properties. Since phenelzine is a clinically effective antidepressant, it appears possible that deuterium substitution may have therapeutic value in the treatment of depression.

27.15 ELECTROPHYSIOLOGICAL DEMONSTRATION OF BOTH α_2-AGONIST AND ANTAGONIST PROPERTIES OF RX 781094. J.M. Goldstein, L. C. Knobloch* and J.B. Malick. Pharmacology Department, Stuart Pharmaceuticals, Division of ICI Americas Inc., Wilmington, DE 19897.

The effects of RX 781094 (2-[2-(1,4-Benzodioxanyl)]-2-imidazoline), an agent that has been reported to be a potent and selective α_2-adrenoceptor antagonist (Chapleo et al., Brit. J. Pharmacol. 74:842, 1981) on the firing rate of brain norepinephrine neurons in the locus coeruleus (LC) were studied using extracellular single unit recording techniques. Intravenous injection of low doses of RX 781094 ($\leq$0.25mg/kg) produced an unexpected decrease in LC unit activity similar in magnitude to that observed after clonidine (10 µg/kg, iv). This effect was readily reversed with the α_2-antagonist yohimbine (0.5 mg/kg, iv). Low doses of RX 781094 also antagonized the increase in LC unit activity produced by the α_1-antagonist WB4101 (0.1 mg/kg, iv); clonidine also reversed the increase in LC firing produced by WB4101. The ability of RX 781094 to suppress both spontaneous LC unit activity and the enhancement induced by WB4101, and the ability of yohimbine to reverse these effects suggests that at low doses RX 781094 possesses α_2-agonist properties.

When higher doses of RX 781094 were tested ($\geq$0.5 mg/kg, iv), potent α_2-antagonist properties were clearly demonstrated. RX 781094 produced increases in LC unit activity (comparable to yohimbine at 0.5 mg/kg, iv) and markedly elevated the dose of clonidine needed to suppress LC unit activity (from 10 µg/kg, iv to more than 100 µg/kg, iv). In addition, RX 781094 readily reversed the decrease in LC unit activity produced by clonidine. In fact, in the same rat, it was possible to demonstrate both a decrease in LC unit activity (with low doses of RX 781094) as well as an increase in LC unit activity (with higher doses of RX 781094). In comparison, yohimbine, even at doses clearly below those which enhance LC unit activity, did not produce any significant decreases in firing rates.

On the basis of these results, RX 781094, in addition to its known α_2-antagonist properties, also possesses clonidine-like α_2-agonist activity in this model. Thus, RX 781094 may be a partial agonist at α_2-adrenoceptors in the CNS.

27.16 AMPHETAMINE BUT NOT TRH DISRUPTS PERFORMANCE ON THE RADIAL ARM MAZE. Gregory Lucas Belenky, Lysaida Cardenales*, Lydia E. Robles*, David Arday* and John W. Holaday. Dept. Med. Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20012.

In preliminary studies amphetamine but not thyrotropin releasing hormone (TRH) disrupted performance on the radial eight arm maze. Two groups of 20 Sprague-Dawley rats each were trained to criterion performance on a radial arm maze. To prevent response chaining, the rats were confined for 5 seconds in the center of the maze after completing each run down an arm. One group of rats was tested with amphetamine, and the other group of rats with TRH. For each drug, three doses were compared against a saline control: 0.5, 1.0, and 2.0 mg/kg amphetamine, and 4.0, 8.0, and 16.0 mg/kg TRH. The rats were tested 15 minutes after injection. Our experiment was conducted over four days using a latin square design such that each animal received all four doses of drug during the course of the experiment. Amphetamine increased running time [$F(3,48)=3.09$, $p=.036$] and decreased number of correct responses [$F(3,48)=2.86$, $p=.046$] in a dose dependent manner. In contrast, these doses of TRH had no effect upon either running time or upon number of correct responses. The total number of responses was unaffected by either drug. Work by others indicates that both amphetamine and TRH stimulate locomotor activity, although at the doses which we used amphetamine resulted in greater analepsis than TRH (Vogel, R.A et al, J. Pharmacol. Exp. Ther. 208(1979)161-168). Further experiments with both drugs are being pursued at higher doses and at longer post-injection delays. Our preliminary results suggest that TRH may differ qualitatively from amphetamine in its stimulatory effects.

27.17 CLONIDINE POTENTIATES DRUG INDUCED SELF-INJURIOUS BEHAVIOR IN RATS. K. Mueller. Department of Pediatrics, Univ. Calif. - San Diego, La Jolla, CA, 92093

Self-injurious behavior is a disturbing component of several syndromes and often occurs in the general retarded population. Self-biting (SB) in rats is an unusual behavioral effect of certain central drugs and may provide clues to the proximal mechanism of self-injurious behavior in humans.

Daily administration of caffeine and implantation of continuous release amphetamine pellets produce reliable SB in rats. Although caffeine and amphetamine are structurally dissimilar and produce dissimilar patterns of behavioral changes, the SB produced by both drugs is similar in several respects: latencies to SB are similar, targets of SB are similar, SB occurs in absence of stereotypy, and incidence of SB is potentiated by clonidine, an α noradrenergic agent.

Long Evans hooded rats (N = 14 for each group) were given daily subcutaneous injections of caffeine 30 min after pretreatment with various doses of clonidine, or were implanted subcutaneously with silicone pellets containing 47 mg amphetamine base. Pellet rats were injected with various doses of clonidine twice daily.

As little as 0.025 mg/kg clonidine produced SB when combined with a subthreshold dose of caffeine (for producing SB in these rats); 0.5 mg/kg clonidine increased the incidence of SB to over 50%. Amphetamine pellet rats were less sensitive to this effect of clonidine; only the highest dose (0.5 mg/kg) potentiated SB. The high dose of clonidine (0.5 mg/kg) reduced the general activity of both caffeine and amphetamine pellet rats; that is, clonidine reduced the frequency of such behaviors as locomotions (caffeine and amphetamine), wet dog shakes, and digging/burrowing (caffeine). However, activity generally remained higher than that of undrugged animals.

There was little evidence of opposing behavioral effects of clonidine at doses selected to produce either predominantly presynaptic (0.01 to 0.05 mg/kg) or postsynaptic (0.5 mg/kg) effects. Clonidine is known to reduce caffeine induced behaviors referred to as the quasi-morphine withdrawal syndrome; its concurrent ability to potentiate SB raises questions both about the central effects of clonidine and the central mechanisms of self-injurious behavior.

27.18 ACUTE LOW-LEVEL MICROWAVE IRRADIATION AFFECTS THE ACTIONS OF PSYCHOACTIVE DRUGS. H.Lai*, A.Horita*, C.K. Chou*and A.W.Guy* (SPON: K. Chan). Dept. Pharmacology,Psychiatry & Behavioral Sciences and Rehabilitation Medicine, University of Washington School of Medicine, Seattle, WA 98195.

Male Sprague-Dawley Rats were exposed to circularly polarized 2450 MHz microwave(2 μs, 500 pps) with an averaged power density of 1 mW/cm^2 (SAR = 0.6 W/kg) for 45 minutes. They were then immediately injected with either apomorphine, d-amphetamine, ethanol or morphine, and physiological and behavioral responses were studied. Apomorphine-elicited stereotypic behavior and hypothermia were significantly enhanced by the microwave irradiation when compared with the responses of sham-irradiated control animals. Amphetamine-elicited hyperthermia and ethanol-elicited hypothermia were significantly attenuated by the irradiation. In the case of ethanol, only the initial fall in body temperature was affected. Both morphine-elicited catalepsy and lethality were significantly enhanced by the acute low-level microwave irradiation. A higher percentage of the irradiated animals showed cataleptic response and died after injection of lower dose of morphine. The temperature response curve to morphine was also altered by microwave irradiation.

27.19 SITE SPECIFIC DIFFERENTIATION OF IDENTICAL BEHAVIORS INDUCED BY d-AMPHETAMINE (Amph) AND PHENYLETHYLAMINE (PEA). B.I. Diamond, A. Hitri*, K.S. Rajan and R.L. Borison. Psychiatry Department, Medical College of Georgia and Downtown V.A., Augusta, GA, 30912 and Illinois Institute of Technology Research Institute, Chicago, IL, 60607.

Previously we have shown that Amph and PEA induced behavioral stereotypy, although phenomenologically similar, can be differentiated by dopamine (DA) blockers that affect predominantly limbic areas, from those that affect striatal areas. Moreover, the fact that PEA is an endogenous amine highly concentrated in limbic areas of the brain, supports its role as a mediator in this behavior which serves as an animal paradigm for schizophrenia. Further evidence is presented in the present studies to support the interaction and differentiation of Amph and PEA stereotypy with DA systems. Male Sprague-Dawley rats (200-250 g) were treated daily with either PEA (50 mg/kg) or Amph (3.75 mg/kg) intraperitoneally for three weeks. Stereotyped behavior was quantitated on a weekly basis by using a linearly increasing rating scale to reflect weekly movement changes. Animals were sacrificed at three weeks, brains removed, and the caudate nucleus and nucleus accumbens dissected. Metal levels for Cu, Zn and Mn were measured by atomic absorbtion spectrometry after digestion of tissues with nitric acid. Levels of DA, dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), norepinephrine (NE) and 5-hydroxyindoleacetic acid (5HIAA) were also measured by HPLC using an electrochemical detector. Receptor binding studies using ^{3}H-spiroperidol as the ligand for DA receptors was performed according to the modified method of Fields et al. (1977). Three week treatment with PEA or Amph did not affect striatal Zn levels, whereas striatal Mn levels were elevated by PEA and Cu levels decreased by Amph. Moreover, chronic Amph elevated striatal DA, DOPAC and HVA levels, without affecting their levels in accumbens tissue. Chronic PEA also increased striatal levels of DA, DOPAC and HVA, which in contrast to Amph, also occured in accumbens tissue. Control animals displayed two striatal binding sites, which were differentially affected by Amph. Treatment with Amph decreased the affinity of the high affinity site, while increasing the numbers of low affinity sites, whereas PEA affected only the low affinity site, decreasing the receptor density. These results support the contention that although PEA and Amph produce nearly identical behavior in animals, their underlying mechanisms of action on different dopaminergic systems of the brain can be separated.

27.20 CORTICOSTERONE BINDING IN THE CAUDATE-PUTAMEN: MODULATION OF AMPHETAMINE-INDUCED STEROTYPIC BEHAVIORS BY CORTICOSTERONE INTERVENTION. C. H. DeFiore and B. B. Turner. Depts. of Psych. and Biology, Virginia Tech, Blacksburg, VA 24061.

Although corticosterone (CORT) is selectively bound by discrete areas of the rodent brain, particularly the hippocampus (HC), autoradiographic data indicate no binding of CORT in the caudate-putamen (C-P). However, cats pretreated with glucocorticoids have been reported to show a selective increase in high affinity choline accumulation in the C-P. We wished to evaluate the possibility that this observed increase in choline uptake is mediated by glucocorticoid receptors within the C-P.

We asked whether glucocorticoid receptors in the C-P of adrenalectomized (ADX) rats can be detected by biochemical assay. We determined the amount of specific 3H-CORT binding in C-P cytosols and the ability of C-P nuclei to retain 3H-CORT in vivo. Results indicated that the C-P has 56% of the binding capacity of the HC (205 $\pm$ 11 vs 368 $\pm$ 22 fm/mg protein). The apparent K_d of CORT in the two tissues was similar. No difference in the affinity of any of 8 steroids tested relative to CORT was found between C-P and HC. Nuclei purified from the C-P demonstrated about 40% of the radioactivity present in HC nuclei (1,158 $\pm$ 24 vs 2,988 $\pm$ 320 fm/mg DNA).

We then asked whether the increase in striatal choline uptake induced by glucocorticoids has behavioral significance. Stereotypic behaviors are modulated by the action of amphetamine on striatal dopamine neurons and increased cholinergic function within the striatum antagonizes the stimulation of these behaviors by amphetamine. To test the hypothesis that CORT can modulate striatal acetylcholine function, a 3 x 4 factorial design was used: 4 levels of steroid condition (ADX, intact, ADX + 5 mg/kg and 12.5 mg/kg CORT) and 3 levels of amphetamine condition (0, 1.25, and 2.5 mg/kg). Ambulation, rearing and stereotypy were scored over a 90 min period for each rat (n=8). ANOVA indicated significant CORT X amphetamine X time interaction for all behaviors ($p<.001$). Analysis of group differences showed that, although CORT condition was without effect on the saline group, CORT did affect ambulation, rearing and stereotypy in both amphetamine groups. The effect of amphetamine on stereotypy was facilitated by ADX ($p<.01$, 1.25 mg/kg; $p<.05$, 2.5 mg/kg), and antagonized by high CORT replacement ($p<.01$, 1.25 mg/kg; $p<.01$, 2.5 mg/kg). The stereotypy ratings of the group receiving the lower CORT replacement dose resembled the intact group.

These data provide evidence that 1) functional glucocorticoid receptors exist in the rat C-P and 2) that glucocorticoids can antagonize behaviors mediated by amphetamine, possibly by enhancing cholinergic function within the striatum. (Supported by NIH grant 2-S07-RR-07095-13).

28.2 ACUTE EXPOSURE TO 2.70 GHz PULSED MICROWAVE RADIATION AFFECTS NEITHER PENTYLENETETRAZOL SEIZURES NOR CHLORDIAZEPOXIDE PROTECTION AGAINST SUCH SEIZURES. B. A. Pappas, H. Anisman and R. Ings*. Dept. of Psychology, Carleton University, Ottawa, Ontario K1S 5B6.

One reported psychopharmacological effect of pulsed microwave radiation (PMR) is modulation of behavioral effects of benzodiazepines. These and other findings indicating that PMR affects seizure susceptibility in audiogenic seizure prone rats are consistent with an effect of PMR on brain inhibitory, possibly GABA ergic neurotransmission. We assessed this possibility by examining the effect of brief exposure to PMR upon pentylenetetrazol (PTZ) induced seizures and upon the efficacy of chlordiazepoxide (CDZ) for attenuating such seizures.

In experiment one, relatively unrestrained rats were exposed for 30 min to PMR at power density levels of 0, 5, 10 or 15 mW/cm^2. After exposure they were injected with 0, 20, 40, 60, 70 or 80 mg/kg of PTZ. All three radiation power densities significantly elevated core temperature. PMR did not, however, alter the dose response curve relating seizure parameters and PTZ dose. Exposure to the highest radiation density (i.e. 15 mW/cm^2) very slightly but significantly shortened the latency to seizure onset and also very slightly but significantly increased seizure intensity. Since core temperature elevations were greatest for this PMR exposure group, this effect of PMR on seizures may have been secondary to temperature elevation.

Experiment two assessed the effects of 30 min exposure to these same microwave power densities upon the efficacy of 0, 2.0, 7.5 and 15.0 mg/kg of CDZ for attenuating seizures elicited by 70 mg/kg PTZ. PMR counteracted the hypothermic effects of CDZ in a dose related manner but did not consistently affect the anti-seizure efficacy across all doses of CDZ. There was, however, a suggested enhancement of the anti-seizure effect of only 7.5 mg/kg CDZ by the highest (15 mW/cm^2) radiation power density.

The third experiment aimed to replicate these suggested effects of this (15 mW/cm^2) and higher (20 mW/cm^2), hyperthermia-inducing levels of PMR upon susceptibility to PTZ seizures and the anti-seizure efficacy of CDZ. A more rigorous protocol was employed where the experimenter rating seizures was blind to radiation power density. We failed to repeat the effect of PMR upon either of these phenomena. We conclude that the two isolated, significant effects observed in the first two experiments represented Type II errors (i.e. incorrect rejections of the null hypothesis) which can be expected to occur in large scale experiments. We also concluded from these experiments in which PMR consistently affected neither PTZ nor CDZ action, that a single brief exposure to such radiation has no significant pharmacological effect upon GABA neurotransmission. Supported by Department of National Defence (Canada) contract (B.A.P. and H.A.)

28.3 FURTHER EVIDENCE THAT GABA RECEPTORS MEDIATE THE HYPERKINETIC EFFECT OF INTRARAPHE MUSCIMOL. S. M. Sainati, H. K. Kulmala, and S. A. Lorens. Inst. of Neuropharmacology, Loyola Univ. School of Med., Maywood, IL 60153.

We previously reported (Neurosci. Abstr. 7:925, 1981) that intraraphe microinjections of muscimol (0.44-1.75 nmole in 0.5 µl saline) produced dose-dependent increases in locomotor activity. Intraperitoneal injections of chlordiazepoxide (CDP, 3.8 mg/kg) potentiated, whereas bicuculline (1.1 mg/kg) blocked the muscimol-induced hyperactivity. In order to determine whether these effects of CDP and bicuculline were due to their binding to the same neuronal membranes as muscimol, the following experiments were performed. Cannulae were implanted in the median raphe nucleus (MR) of male albino rats (300-500 g) and the animals adapted to photocell activity chambers. Intra-MR dose-response curves for the water-soluble benzodiazepines, CDP, flurazepam, and midazolam were performed. Drugs were administered in doses of 0.0, 0.22, 0.44, 0.88 and 1.75 nmole in 0.5 µl saline. Both midazolam and flurazepam produced hyperactivity which was most prominent within the first 30 min post-injection. Flurazepam, furthermore, proved twice as potent as midazolam. In contrast, CDP was without effect at any of the doses tested. This observation supports the view that CDP is a "prodrug" which must be demethylated or further modified to form an active metabolite.

In a second experiment, animals received either saline or a sub-effective dose (0.22 nmole) of flurazepam or midazolam into the MR 5 min prior to either a sub-effective dose of muscimol (0.22 nmole) or saline. Only the combinations of a benzodiazepine plus muscimol produced hyperactivity. These combinations, moreover, produced effects as robust as those of a 4-fold higher dose of muscimol alone (0.88 nmole).

Finally, animals received either saline or bicuculline methiodide (0.88 nmole). Bicuculline completely blocked the hyperactivity effects of muscimol. Taken together, these data suggest that the hyperkinetic effects of intra-MR muscimol are due to activation of GABA receptors within the midbrain raphe, rather than at distant sites.

This conclusion is supported by autoradiographic evidence which shows that following intra-raphe injection, 3H-muscimol does not spread appreciably from the target site.

28.4 ACUTE EFFECTS OF GAMMA-HYDROXYBUTYRATE ON TONIC IMMOBILITY IN THE RABBIT.† R. Godbout* and R. T. Pivik, Lab.Neurophysiology, School of Psychology and Department of Psychiatry, Faculty of Health Sciences, University of Ottawa, Ottawa, Ontario K1N 5C8, Canada.

Gamma-Hydroxybutyrate(GHB)is a short-chain fatty acid present in the mammalian brain which is thought to be a metabolite of GABA. Administration of low doses of GHB has been reported to induce sleep and to enhance amounts of paradoxical sleep. At doses exceeding hypnotic levels, GHB has been reported to increase motor activation to the point of inducing seizure activity.

The purpose of the present study was to examine the effects of GHB on the duration, ease of induction and electrographic correlates of tonic immobility (TI), a state variously characterized as a condition of hypnotic sedation and as an innate fear reaction. Previous studies have indicated increased TI duration in conjunction with decreased dopaminergic and cholinergic activity. Since GHB is thought to effect a decrease in neurotransmission based on these neurotransmitters, it was postulated that this compound would facilitate TI.

Five adult New Zealand white male rabbits were chronically implanted (EEG, EMG, EOG) for electrographic recordings, and experimental procedures began after one week of post-operative recovery. TI induced by rapid inversion and placement of the rabbit in the V-shaped trough, was examined under the following conditions: GHB injections at doses of 300, 650 and 1000 mg/kg, a saline injection, and a non-injection (baseline) condition. All injections were administered IV. Sessions were distributed according to a Latin square design and were divided into three time blocks (0, 40 and 120 minutes post-injection). At each time block 5 inductions of TI were attempted. Electrographic recordings were performed periodically.

At the 1000 mg/kg dose level, animals did not exhibit normal characteristics of TI, but instead were extremely flaccid with eyes closed. Accordingly, data from this dosage level were not included in data analyses. For all other conditions, rabbits exhibited normal TI characteristics. No statistical differences were found between conditions for any time blocks for either duration of TI or induction failure rate. However, durations were shown to be longer in GHB sessions vs. non-drug sessions ($p<0.1$).

The present results support previous work indicating that reductions in dopaminergic and cholinergic activities facilitate TI duration.

28.5 DIAZEPAM AND AMINO ACID RELEASE. F. Petty[1,2], A.D. Sherman[1]* and J. Mott[1]*. [1]Neurochemical Research Laboratory, Department of Psychiatry, University of Iowa, Iowa City, IA 52242 and [2]Veterans Administration Medical Center, Iowa City, IA 52242.

The release of endogenous amino acids from slices of frontal cortex was investigated in relation to footshock and to previous experience with footshock. Rats were given 40 minutes of pulsed, intermittant footshock on day 1. On day 2, being placed back into an identical shock box was sufficient to elevate glutamate release by over 50%. Shocking these animals while in the shock box elevated glutamate release only by an additional 10% suggesting that psychological factors were involved in the elevated release. In animals with no previous exposure to shock, being placed in the box or being exposed to mild shock had no effect on glutamate release. Forty minutes of pulsed random footshock produced an increase of over 250%, but this effect had dissipated by 24 hours.

After the initial forty minutes of shock, replacement in the box one, two, or four days later still elevated glutamate release significantly, but replacement at eight days failed to produce the effect. The increased glutamate release could be blocked by diazepam, but not by a sedating dose of haloperidol. In addition, restraint stress sufficient to elevate plasma hydrocortisone levels significantly failed to increase glutamate release.

These data suggest that, in the frontal cortex, glutamate release may be an indicator of anxiety or fear. Since this measure was blocked by diazepam but not haloperidol, it may also be involved in the anxiolytic actions of diazepam.

28.6 EFFECT OF MELATONIN AND Ro 15-1788 ON DIAZEPAM DISCRIMINATION. P. B. Silverman. Neurochem-Neuropharm. Research Section. Texas Res. Inst. Mental Sci., Houston, TX 77030.

Adult male Sprague-Dawley rats were food deprived to about 80% of their free-feeding weight. They were then trained to bar-press for food pellets in a two-lever operant box. Fifteen minutes prior to each daily 20 min. session, rats were injected intraperitoneally (i.p.) with 2.0 mg/kg diazepam or with diazepam vehicle. Following diazepam injection, reinforcement was available for operating one of the levers, while vehicle injection was always paired with reinforcement on the other lever. In either training condition, rats had to emit 20 responses on the appropriate lever in order to obtain a food pellet (FR-20 schedule). Once rats reliably discriminated diazepam from vehicle as indicated by their lever choice for the first twenty responses, the ability of compounds to substitute for (generalize with) diazepam or block the diazepam stimulus was tested. The most interesting results were obtained with melatonin and Ro 15-1788. Melatonin by itself showed no similarity to diazepam at up to 32 mg/kg. It did, however, shift the diazepam dose-response curve appreciably to the left. Initial attempts to train rats to discriminate melatonin from its vehicle have thus far been unsuccessful.

Ro 15-1788 effectively blocked diazepam discrimination. This effect was, however, of limited duration at the doses tested, i.e., Ro 15-1788 was more effective when given as a post-treatment than as a pre-treatment. When tested with pentobarbital, rats responded primarily on the lever paired with diazepam in training. This generalization of pentobarbital with diazepam was not blocked by Ro 15-1788 treatment. Selective antagonists of benzodiazepines such as Ro 15-1788 may prove useful in distinguishing benzodiazepine from non-specific sedative effects of various compounds.

28.7 MECHANISMS OF THE INITIAL TREATMENT PHENOMENON TO DIAZEPAM IN A CONDITIONED SUPPRESSION PARADIGM. D.J. Mokler* and R.H. Rech. Dept. of Pharmacol./Toxicol. and Neuroscience Program, Michigan State Univ., East Lansing, MI 48824.

In drug-naive subjects trained in a conflict procedure, the first doses of diazepam do not show the increase (or release) in punished responding observed with consequent doses. This "initial treatment phenomenon" seems not to depend on pharmacokinetic factors since this effect is seen whether diazepam is given daily or every 5 days. This may correlate with an initial depression in humans after benzodiazepines which tolerates out over two or three doses. The mechanism(s) by which this phenomenon occurs has not been investigated to any great extent. The purpose of the present experiment was to examine these mechanisms.

Female Sprague-Dawley rats (n=20) were water-deprived and trained to drink from a water tube in daily 10-min sessions. After drinking from the tube had stabilized a tone was present for 7 sec on a variable interval 21 sec schedule. During the last 5 sec of the tone drinking from the tube was accompanied by shocks. The number of shocks accepted and water intake were measured. Once behavior had stabilized, rats were divided into three groups. Group I received 3.0 mg/kg diazepam 10 min before and vehicle just after each test session for sessions 1-8; vehicle 10 min before and after the session in sessions 9-14; and 3.0 mg/kg diazepam 10 min before and vehicle after the session in sessions 15 and 16. Group II received vehicle 10 min before and 3.0 mg/kg diazepam after sessions 1-7; and 3.0 mg/kg diazepam 10 min before and vehicle after sessions 8-16. Group III received vehicle both before and after sessions 1-7; and 3.0 mg/kg diazepam 10 min before and vehicle after sessions 8-16. Diazepam was suspended in 0.5% methylcellulose. Drug and vehicle were injected i.p. every 3 or 4 days. Animals were run six days a week.

Group I showed the initial treatment phenomenon with the number of shocks increasing over the first three sessions. Group II and III did not show a significant change from baseline over the first seven sessions. In session 8 (first session that Groups II and III received diazepam pretreatment) Group II showed an increase in shocks which was significantly greater than Group I in session 1, while Group III in session 8 did not show an increase in punished responding significantly different from Group I-session 1. Group II showed an immediate plateau in shocks accepted while Group III showed a continuous increase until session 12. These data suggest that the initial treatment phenomenon relates in part to tolerance to non-specific depressant effects (not behavioral tolerance). Moreover, since Group II showed greater anticonflict activity after the first diazepam pretreatment, compared to Group I, a behavioral tolerance may have limited the peak anticonflict effect attained in Group I. Further evidence to this point as the gradual attrition in anticonflict effects of the drug with later repetitions in Groups II and III. (Supported by 3M Foundation and NRSA grant No. GM-07392).)

28.8 PENTOBARBITAL INHIBITION MEASURED INTRACELLULARLY IN HIPPOCAMPAL CA_3 NEURONS. M. O'Beirne*, N. Gurevich*, P.L. Carlen. Depts. of Physiology and Medicine, Institute of Medical Science, University of Toronto, Addiction Research Foundation Clinical Institute, Playfair Neuroscience Unit, Toronto Western Hospital, Toronto, Canada.

It has previously been reported that barbiturates such as sodium pentobarbital exert their effects by increasing chloride conductance - an augmentation of γ-Aminobutyric acid response. Our data suggests that at lower doses a calcium-mediated potassium conductance may be involved.

Intracellular recording techniques were used to study the effects of sodium pentobarbital on the CA_3 hippocampal cell of the guinea pig. The drug was either perfused or applied by pressure ejection onto the hippocampal slices at concentrations of 10^{-6} or 10^{-5} M. One to 2 minutes after drop application or 3 to 5 minutes after drug perfusion, hyperpolarization of .2 to 8 mV in 5/7 cells occurred. Spontaneous activity when present decreased in 3/4 cells. In most cells the input resistance also decreased. The afterhyperpolarization (AHP) following a train of 2 to 4 spikes elicited by a 100 msec constant current depolarizing pulse was augmented in 4/6 cells. The two cells which did not show an augmentation of the AHP had been dramatically hyperpolarized following pentobarbital application. IPSPs were increased to a variable extent in 5/7 cells. The effects also occurred in 3 cells where K Cl electrodes were used suggesting that chloride channels may not be involved. In 2 CA1 cells, pentobarbital caused hyperpolarization and decreased spontaneous activity.

Alger and Nicoll (1980) have demonstrated that the AHP in CA1 cells is an intrinsic, calcium dependent potassium potential that is initiated by the preceding burst discharge.

These preliminary results suggest that one of the mechanisms of low dose sodium pentobarbital inhibition is by augmentation of calcium mediated potassium conductance similar to that found by Carlen et al using low dose ethanol (Science, Vol. 215, p. 306-309, 1982) and low dose benzodiazepine (Society for Neuroscience, Vol. 7, 1981).

Research supported by NIH grant no. RO1-N516660-02.

28.9 SYSTEMIC ADMINISTRATION OF PUTRESCINE OR MUSCIMOL CAUSES SIMILAR MODIFICATION OF AMPOMORPHINE-INDUCED BEHAVIOR IN RATS. F.D. Feng and B.B. Turner. Depts. of Psych. & Biol., Virginia Polytech. Institute & State Univ., Blacksburg, VA 24061.

Putrescine (PUT) is a diamine having several roles related to cellular metabolism and is also a minor precursor of GABA. We previously reported that oral and i.p. administration of PUT produced behavioral effects resembling those seen after treatment with GABA, GABA agonists, and GABA-transaminase inhibitors. Here we present data which suggest that systemic administration of PUT can modify apomorphine-induced (APO) stereotypic behavior in rats in a manner similar to that of the GABA agonist muscimol (MUS).

Male Sprague-Dawley rats (350-425g) were injected with saline (SAL), PUT (75 mg/kg) or MUS (.75 mg/kg). Fifteen minutes later subjects were given s.c. injections of either SAL or APO (.25 mg/kg). The incidence of locomotor activity and stereotypic behavior was time-sampled over a period of 45 min. Thirteen behavioral categories were scored; data were analysed by ANOVA statistics. Apomorphine per se caused stimulation of locomotor activity and stereotypic behaviors (non-body licking, mastication movements, and discontinuous sniffing). Treatment with MUS/SAL elicited a significant incidence of only mastication stereotypy; PUT/SAL treatment did not induce sterotypy. Neither MUS nor PUT in combination with SAL produced a change in locomotor activity.

Time-dependent drug interactions were found for the incidence of APO induced sniffing stereotypies following PUT or MUS pretreatment: discontinuous sniffing ($F(8,144)=2.49$, $p<.02$) and continuous sniffing ($F(8,144)=2.19$, $p<.05$). An apparent intensity increase, from discontinuous sniffing (DS) to continuous sniffing (CS), resulted from pretreatment with PUT or MUS; these effects lasted less than 60 min posttreatment. The SAL/APO group showed an increase in DS over the first 27 min of the time-sampling period; thereafter DS behavior decreased. The incidence of DS did not increase over time in either the MUS/APO or PUT/APO groups. At 19-27 min in the time-sampling, groups retreated with PUT or MUS were statistically similar and had a level of DS behavior which was significantly lower than that of the SAL group ($p<.05$). An increase in CS behavior was noted in subjects pretreated with PUT as compared with SAL at 10-18 min and 19-27 min of the observation period. During these periods subjects pretreated with MUS did not differ significantly from those pretreated with PUT.

These effects of PUT on APO-induced behavior are similar to those previously reported for MUS. Since PUT modified APO behavior in a manner similar to MUS, the actions of both agents may be expressed in part through common GABAergic mechanisms. (Supported by NIH grant 2-S07-RR-07095-13).

28.PO PRENATAL EXPOSURE TO DIAZEPAM RESULTS IN PERMANENT DEFICITS IN LEARNING AND REWARD-INDUCED EEG ALPHA-LIKE ACTIVITY IN CATS. G. T. Livezey*, L. Isaac, and T.J. Marczynski. Department of Pharmacology, Univ. of Illinois, Chicago, Ill., 60612.

There is much evidence that benzodiazepines act by enhancing GABAergic postsynaptic effects. The emergence of rhythmic synchronized EEG patterns of the alpha type is believed to depend on recurrent and/or feedforward inhibitory (hyperpolarizing) circuits involving GABAergic interneurons. Our previous study (Brain Res.,204:214,1981) showed that the magnitude and duration of the Postreinforcement EEG synchronization (PRS) over the visual cortex in cats trained to press a lever for 1 ml of milk reward are significantly correlated with learning ability .

In the present study we sought to determine whether or not there is a permanent effect of prenatal exposure to diazepam on learning ability, EEG PRS patterns, and the benzodiazepine receptor complement.

The pregnant cats, beginning on day 20 of gestation, were injected daily with diazepam according to the following schedule:

DAY	20 through 23	24-44	45-47	48-50	51-53	54-65
DOSE mg/Kg,i.m.	0.32	0.60	0.45	0.32	0.16	NO DRUG

The dose range did not exceed the human therapeutic doses. Control cats received saline injections. One year old offsprings were trained to press a lever for 1 ml of milk reward on a 1:7 fixed ratio schedule. The 20 min. daily training sessions consisted of standardized "shaping" procedure (Brain Res.204:214,1981) during which the experimenter challenged the animal's ability to eliminate perseveration in ineffectual approaches to the manipulanda. Following training, each cat was implanted with epidural cortical EEG electrodes, and the EEG patterns were monitored and quantified during several lever pressing sessions. Subsequently, the animals were sacrificed, and tissue samples were taken from three cortical areas, olfactory bulb, midline thalamus, caudate nucleus, hippocampus, hypothalamus, and ponse for ^3H Diazepam receptor binding tests.

Although the gross behavior, such as motor skills, playfulness, and eating habits were not apparently different from those of control animals, the drug exposed cats showed significant learning deficits (the time to achieve criterion of bar pressing was more than 5 times greater than that of control cats, and their 'perseveration index' was significantly higher), they showed a total loss of or poorly developed PRS responses (mean PRS index of 1.6 ± 0.2 versus 8.6 ± 1.1 S.D. of control cats), and a 40% reduction in binding of ^3H Diazepam to the fronto-orbital cortex and the hypothalamus. - The loss of PRS is consistent with the evidence that EEG 'spindles' contribute to plasticity of responses (Brain Res.235:51,1982).-Supported by Univ. of Ill. grant 58129.

29.1 DISTRIBUTION OF RADIOIMMUNOASSAYABLE ARGININE VASOPRESSIN (AVP) IN AREAS OF THE CEREBRAL CORTEX AND LIMBIC SYSTEM OF THE RAT BRAIN. M. Benke*, L. Mattiace* and A. Negro-Vilar, (Spon: Marcelle R. Morrison). Dept. of Physiology, Univ. of Texas Health Sci. Ctr., Dallas, TX 75235.

Recent studies on the behavioral effects of AVP and related peptides suggest a role for these compounds in memory consolidation processes. Indeed, the mnemonic process would require the participation of specific neuronal substrates in higher nervous centers. Although several reports have explored the extra-hypothalamic distribution of AVP, few studies have evaluated the presence of AVP in cerebral cortex. The present study was designed to evaluate the distribution of AVP in 15 areas of cerebral cortex as well as in several subcortical limbic structures of the rat brain, taking advantage of a highly specific and sensitive AVP RIA. Young adult male rats of the Holtzman strain were killed by decapitation, their brains removed, frozen on dry ice and 300μ-thick sections were serially cut. The following cortical and limbic structures were punched out: Frontal Polar Cortex (FPC), Pyriform Cortex (PFC, 5 sections, 1 through V rostral to caudal), Frontal Motor Cx (FMC) Cingular Cx (CGC) Entorhinal Cx (ERC, section I and II), Parietal Cx (PC) Insular Cx (IC) Hippocampus (HPC Sections I-III), Septum lateralis (SL), Stria terminalis (ST), Basolateral Amygdala (ABL) and Corticomedial Amygdala (ACO). Tissue punches were homogenized in acetic acid and appropriate aliquots assayed for AVP content, which was expressed per mg of protein. Most cortical areas explored had low but detectable levels of AVP, and could be divided according to AVP levels, in three groups: 1) areas with about 1 pmol AVP/mg protein (PFC-III, PFC-IV and CGC); 2) areas with values around 0.5 pmol/ mg prot. (HPC-I, II, PFC-I, II) and areas with very low (0.3 pmol/ mg prot.) to undetectable values (<0.05 pmol/mg prot.) such as FMC, ERC-I, IPC, PC, IC, PFC5 and ERC-II. Limbic areas had values at or above 1 pmol/mg protein, with the following rank order: ACO>SL>ST>ABL. These results indicate that small but readily detectable levels of AVP are distributed among many cortical areas. Regional differences within the same area also seem to be detected. The results on AVP levels in septum and amygdala confirm previous reports indicating the presence of AVP fibers in those regions. Taken together, our observations indicate that AVP is ubiquituously, albeit sparcely, distributed in many cortical and limbic regions, thus offering an anatomical substrate for the purported behavioral actions of this neural peptide. Supported by a grant from Smith-Kline and French.

29.2 LHRH CELLS: A VARIATION WITH MATURATION. S. Wray and G. E. Hoffman, Dept. of Anatomy, University of Rochester, School of Medicine and Dentistry, Rochester NY 14642.

This study immunocytochemically examined the LHRH system in both male and female rats from early postnatal life through to adulthood. All animals were perfused with a neutral picric acid formalin fixative. The brains were removed and postfixed in this same fixative for 2 - 12 hours. The tissue was then blocked and using a vibrating microtome, sections were cut, at 50 microns. Consecutive sections were taken from the level of the olfactory peduncles caudally through the median eminence. At least one male and one female rat were processed simultaneously to allow comparisons in staining intensities to be made.

The majority of LHRH cell bodies in all ages examined were present within a V-shaped field whose apex lay in the preoptic/ septal area and which extended caudally to the ventrolateral anterior hypothalamus. Although the regional distribution of LHRH did not vary with age in males and females, fluctuations were seen with age in total cell number visualized. For example, a decrease (by approximately one-half) in total cell number visualized occurred just prior to puberty in both sexes. This decrease most likely represents a physiological event rather than cell death due to the fact that total cell number returned to prepubertal levels in both male and female animals at later ages (approximately 1,200 cells).

In the adult, two LHRH cell types were characterized. Cell Type I is a bipolar cell with a large nucleus. Both its soma and dendrite are smooth in contour. Cell Type II is a smaller, irregular cell with many spine-like processes on its dendrite and/or soma. In the prepubertal animal, Type II Cells were present but a predominance of Cell Type I was found. Over development, a striking difference was seen in the ratio of Cell Type I to Cell Type II. In both males and females, the percent of Cell Type I decreased with age and, concomitantly, the percent of Cell Type II increased. The increase in cells with spine-like processes may be indicative of changes in afferent input to the LHRH system.

29.3 RELATIONSHIP OF CATECHOLAMINES, NEUROTENSIN AND SUBSTANCE P TO LHRH CELLS. G. E. Hoffman, S. Wray, G. Pelletier and M. Goldstein. Dept. of Anatomy, University of Rochester School of Med. and Dent., Rochester, NY 14642, Med. Res. Council Grp. in Molec. Endocrinology, Centre Hospitalier de l'Universite, Laval, Quebec, Dept. Psychiatry, New York Medical Center, New York NY 10016.

A wealth of evidence suggests that catecholamines influence gonadotrophin secretion. Neuropeptides such as neurotensin (NT) and substance P (SP) are likewise implicated in the neuroendocrine control of reproduction. To assess whether direct interactions with these neuroeffectors and the LHRH cells were present, co-localization of tyrosine hydroxylase (TH), NT and SP were performed with either a dual immunoperoxidase or immunoperoxidase/ immunofluorescence technique. Adult rats and mice were perfused with a neutral picric acid formalin solution. The brain was removed and sectioned on a vibrating microtome at 20-25 microns. The sections were extensively rinsed in phosphate buffered saline before processing for dual immunocytochemical localization. Both methods produced satisfactory results. Initial experiments indicated that for optimal localization of LHRH and the other substances, the LHRH should be reacted first. No removal of the antibody complexes was necessary to achieve good separation.

A juxtaposition of catecholamine fibers on LHRH cells and their dendrites was noted. Not all the LHRH cells appeared contacted; the cell population close to the borders of the organum vasculosum of the lamina terminalis and adjacent preoptic area regions appeared favored. In addition, LHRH axons were in close apposition to the dopamine cells of the arcuate nucleus and periventricular hypothalamus. Within the median eminence, the anatomical distribution of LHRH and TH was differentially organized with few areas of overlap. These results support a direct action of catecholamines on the LHRH system and suggest that LHRH may influence dopamine function. This latter interaction may modify LH and FSH release through alterations in prolactin secretion.

Both neurotensin and substance P containing axons appeared to contact the LHRH cells. Like the patterns seen for catecholamines, these interactions did not appear to encompass all the LHRH cells and evidence for differential innervation was obtained.

In summary, all of the substances tested appeared to contact some of the LHRH cells. The fact that LHRH axons appeared to contact other LHRH cells may provide a means of integrating this diverse input.

Supported by NIH Grant NS13725 and RCDA NS00321.

29.4 LHRH IMMUNOREACTIVITY AND SEXUAL DIMORPHISM WITHIN THE RAT PREOPTIC AREA. S. E. Hendricks, J. R. Leu, P. Lawson* and M. T. Hagley*. Dept. of Psychology, Univ. of Nebraska at Omaha, Omaha, NE 68182.

A nucleus within the medial preoptic area of the rat has been shown to exhibit a distinctive sexual dimorphism; being several times larger in males than in females (Gorski et al., Brain Res., 148:333, 1978). This Sexually Dimorphic Nucleus (SDN) appears as an intensely staining component of the medial preoptic area. We have attempted to provide a description of the juxtaposition of LHRH containing cells to this nucleus in rats. Male and female rats were perfused with saline followed by Zamboni's fixative and the brains post-fixed in Zamboni's for 48 hr. After 24 hr in 30% sucrose, 50 μ frozen sections were cut in frontal, horizontal, and sagittal planes. Alternate sections were stained with thionin for visualization of the SDN. The sections taken before and after those showing the SDN were immunocytochemically stained for LHRH using the unlabeled antibody (PAP) method of Sternberger. Some animals received daily injections of 100 μg estradiol benzoate for one week prior to sacrifice. Male and female brains were sectioned in each plane. The stained tissues were then described with special attention to the relationship between LHRH-containing cells and the SDN. The major LHRH pathways were not seen to pass through the SDN. However, a few LHRH immunoreactive fibers, but no cell bodies, were observed within and around the SDN.

29.5 CORTICOTROPIN RELEASING FACTOR (CRF): IMMUNOREACTIVE NEURONS AND FIBERS IN RAT AND PRIMATE HYPOTHALAMUS. E.L.F. Battenberg, Floyd E. Bloom, Jean Rivier, and Wylie Vale. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

Corticotropin Releasing Factor (CRF) was one of the first hypophysiotrophic factors to be detected but proved difficult to purify, isolate and characterize chemically. Vale et al., recently isolated, purified and synthetically replicated a 41 residue ovine hypothalamic peptide with potent secretogogic actions on cultured pituitary corticotropes. We report the immunocytochemical detection of CRF-immunoreactive (CRF-ir) neurons in rat and primate hypothalamus, as well as the nerve fibers arising from these neurons. Antisera were raised in rabbits against synthetic ovine CRF or an N-terminal fragment. A series of 12 sera were evaluated, in which the immunogen peptides either coupled to human serum albumin or polymerized, were conjugated to the haptene to emphasize exposure of the N-terminal, or remainder of the CRF sequence. Comparable immunocytochemical results were obtained with all antisera (dilutions 1;500-1;5000) regardless of the antigenic determinants of the immunogen. For immunocytochemical studies, rat and monkey brains were perfused with 4% paraformaldehyde, and processed for indirect immunoperoxidase localization as described by us. A heavy density of CRF-ir nerve fibers was observed in the median eminence. These fibers were found in the internal palisade zone in the anterior regions of the median eminence and moved to the external palisade zone as the tuberal region was approached. A few CRF-ir fibers were traced into the neural stalk. Within the rat hypothalamus, nerve fiber staining was seen in moderate density in the basal arcuate area near the location of corticotropin neurons. A thick thatch-work of fibers was found in the immediate sub-ependymal zone of the third ventricle. CRF-ir perikarya, only detectable in rats pre-treated with intracerebroventricular colchicine, were restricted to the rostral portion of the paraventricular nuclear complex. No positive perikarya were detected within the magnocellular regions of the paraventricular or supraoptic nuclei, although some CRF-ir fibers were detected in the latter nucleus in normal rats. In primate hypothalamus (squirrel monkey) and pituitary (squirrel monkey and human), a rich innervation of the median eminence was prominent, and posterior pituitary fibers were seen. Dispersed CRF-ir neurons were seen with no colchicine pre-treatment, located throughout the anterior periventricular area. These results strongly support the view that ovine CRF may play a major role in regulation of pituitary corticotropin secretion. Supported by USPHS DA 01785, AM 26741, and AA 03504.

29.6 CORTICOTROPIN RELEASING FACTOR (CRF) LOCALIZATION IN THE RAT BRAIN. S. Cummings*, R. Elde, J. Ells and A. Lindall. (SPON: G. Giesler). Univ. of Minnesota, Minneapolis, MN 55455 and ImmunoNuclear Corp., Stillwater, MN 55082.

A 41 amino acid peptide was recently characterized as CRF. To investigate the distribution of CRF throughout the brain, normal and colchicine treated rats were perfused with Zamboni fixative or 4% paraformaldehyde. Primary antiserum directed against CRF was used in both immunofluorescence and immunoperoxidase staining of cryostat and frozen sections, respectively. Specificity of staining was determined by absorption controls.

In the hypothalamus of both normal and colchicine treated rats CRF immunostained fibers were prominent in the external layer of the median eminence, while fewer fibers were found in the internal layer. CRF immunoreactive cell bodies were visible after colchicine treatment as intensely staining aggregations in parvocellular paraventricular nucleus and in the periventricular area, particularly at the caudal level of the optic chiasm. Numerous cell bodies were present throughout the medial preoptic nucleus. Scattered cell bodies were within the lateral and dorsomedial hypothalamic nuclei, premamillary nucleus, lateral mamillary nucleus and supraoptic nucleus as well as dorsal to the latter.

In the forebrain numerous CRF immunoreactive cell bodies were found in the lateral septal nucleus, nucleus accumbens, nucleus interstitialis stria terminalis and central nucleus of the amygdala. Fibers were present in the olfactory tubercle, in nucleus accumbens, stria terminalis and organum vasculosum lamina terminalis.

In the brainstem CRF cell bodies and fibers were present in raphe dorsalis, periaqueductal gray and perihypoglossal nucleus.

CRF immunoreactive neurons were predominately fusiform or multipolar. Immunoreactivity was limited to the cytoplasm of the cell body and proximal dendrites and varied in intensity according to the location of the neuron, suggesting variations in the rate of synthesis of CRF in different regions. Fibers were either coarsely beaded or of a fine diameter according to location.

Results of this investigation indicate a widespread occurrence of CRF immunoreactivity within the rat brain as well as within the hypothalamo-hypophyseal axis. The presence of CRF in neurons outside of the neuroendocrine axis implicates a possible role for this peptide in neurotransmission.

29.7 LOCALIZATION OF CORTICOTROPIN RELEASING FACTOR-LIKE IMMUNOREACTIVITY AND RECEPTOR BINDING ACTIVITY IN OVINE BRAIN. J. Côté*, M. Lavoie*, P. Poyet*, F. Labrie* and N. Barden* (SPON: M. Beaulieu), MRC Group in Molecular Endocrinology, Le Centre Hospitalier de l'Université Laval, Quebec G1V 4G2, Canada.

Corticotropin-releasing factor (CRF) has recently been isolated from ovine hypothalamus and characterized as a 41-amino acid peptide. We have developed and used a sensitive and specific radioimmunoassay for this peptide to demonstrate the presence of CRF-like immunoreactivity in extra-hypothalamic areas of ovine brain. Rabbit anti-CRF serum was produced following repeated injection of synthetic CRF coupled to BSA in Freund's adjuvant. Anti-CRF serum was incubated with ^{125}I-labelled CRF and synthetic CRF standards or brain extracts for 24 h at 4° prior to separation of free and bound tracer by centrifugation after addition of goat-anti-rabbit serum and polyethylene glycol. Synthetic CRF displaced bound tracer at an ED_{50} value of 200 pg and there was no cross reactivity with LHRH, TRH, ACTH, β-endorphin and several other peptides. Discrete regions of ovine brain were homogenized in 20 vol of 2N acetic acid and following centrifugation, the supernatant was lyophylized prior to resuspension in assay buffer. Highest concentrations (3 ng/mg tissue) of CRF-like immunoreactivity were found in the median eminence but appreciable amounts were also noted in hypothalamus, thalamus, amygdala, substantia nigra, septum, habenula and cerebral cortex. Lower concentrations were noted in other brain areas, including the basal ganglia and brain stem. Displacement of bound ^{125}I CRF by brain extracts exhibited curves parallel to synthetic CRF standards. ^{125}I CRF specifically bound to cell membranes prepared from several brain areas, including thalamus, basal ganglia and substantia nigra, but not to membranes prepared from cerebral cortex. Although we do not as yet know either the molecular nature of CRF-like immunoreactivity or its functions, these results indicate, for the first time, the presence of CRF or related molecules and receptor binding activity in widely different regions of ovine brain.

29.8 LOCALIZATION AND CHARACTERIZATION OF THYROTOPIN-RELEASING HORMONE IN THE MEDULLA OBLONGATA OF THE RAT. M.A. Rea, M.J. Kubek, Z.I. Hodes* and M.H. Aprison. Depts. of Psychiatry, Anatomy and Biochemistry, Indiana Univ. Sch. of Medicine, Indianapolis, IN 46223

TRH has been localized throughout the CNS of man and several animal species. Evidence suggests that TRH may act as a neurotransmitter or neuromodulator in the CNS. TRH has been shown also to elicit several neuropharmacological effects. Since some of these effects can be associated with vagal complex functions, we sought to quantitatively measure as well as characterize TRH in specific loci of the caudal medulla oblongata of the rat. Regions containing the dorsal motor nucleus of the vagus (DMN), nucleus tractus solitarius (NTS), hypoglossal nucleus, dorsal column nuclei, descending nucleus V (DNV), nucleus ambiguus (NA), raphe nuclei, dorsomedial and ventromedial reticular formation, and inferior olivary nuclei, were isolated from six 300μm thick frozen sections of medulla (from 900μm caudal through 900μm rostral to the obex) using micropunches constructed of 18 and 20 gauge stainless steel needles. Each region was pooled bilaterally, homogenized in 0.1 N HCl, and vacuum dried. Extracts were assayed for TRH by specific radioimmunoassay (RIA). TRH levels varied 100-fold among medullary nuclei. Highest content (ng/mg protein±SD) were found in DMN (14±4) and NTS (5±2), while lowest levels occurred in the DNV (0.13±0.06). Nearly 65% of the total medullary TRH was localized to nuclei associated with vagal complex (DMN, NTS, NA). Characterization of tissue immunoreactivity (TRHi) in these regions suggests the presence of TRH since: (1) medullary tissue extracts competed with ^{125}I-TRH for antibody binding sites with the same affinity as authentic TRH: (2) TRHi in tissue extracts comigrated with synthetic TRH when subjected to reversed phase high performance liquid chromatography and Sephadex G-10 chromatography; and (3) rat serum TRH peptidases degraded TRHi and authentic TRH at similar rates. Another group of rats were subjected to unilateral (right side) vagotomy. At 33 weeks post-vagotomy, the vagal preganglionic cell population in the ipsilateral DMN was depleted 50-75% while the contralateral side was unaffected. Interestingly, the content of TRH in the ipsilateral (right) DMN remained unchanged (14±4) whereas TRH in the contralateral DMN increased by 50% (21±4; $P<0.05$). The content of TRH in both ipsi- and contralateral NTS was unchanged when compared to sham-operated controls. These results indicate: (1) TRH is present in several specific loci of the medulla, (2) very high levels are found in the vagal complex, and (3) vagotomy may alter TRH in the contralateral DMN. Further studies are in progress in our laboratories to identify the source(s) and function of vagal TRH. (Supported in part by NIH research grants RO1-NS 16205 (MHA) and RO1-AM 28260 (MJK).)

29.9 **TRH IN THE LAMPREY CNS.** L.J. Youngs*, A. Winokur, N.R. Krieger and M.E. Selzer (SPON: D.S. Silberberg). Departments of Neurology, Pharmacology and Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

TRH levels were measured in brains and spinal cords of larval and young adult sea lampreys (P. marinus) and adult river lampreys (I. unicuspis) by radioimmunoassay (RIA). The entire CNS was removed under Tricaine anesthesia. Brains and lengths of spinal cord were weighed, homogenized in PBS pH 7.5, then combined with methanol, and centrifuged at 2,000 RPM. The supernatant was air dried, reconstituted in BSA/PBS, and assayed for TRH content by the RIA procedure of Bassiri and Utiger (Endocrinol. (1972)90: 722). The identity of immunoreactive TRH with authentic TRH was confirmed by HPLC.

In larval P. marinus, brain TRH was 94.2 pg/mg wet wt. ∓21.6 SEM (n=7). Larval cord values were 12.5∓2.4 (n=10). Young adult sea lamprey brain levels were 85.5 pg/mg ∓20.7 (n=5) and mean cord levels were 10.1 (n=2). For adult river lampreys brain TRH was 137.5 pg/mg (n=2) and cord TRH was 10.9 (n=2).

We conclude that: 1) the concentration of TRH in the brain is about 8-12 times that of the spinal cord; 2) there is little difference in CNS TRH levels between large larvae and adult forms; 3) TRH levels are similar in the two genuses studied.

NIH grants NS14837, NS14257, RR05415.

29.10 IMMUNOHISTOCHEMICAL LOCALIZATION OF THYROTROPIN-RELEASING HORMONE (TRH) IN THE RAT BRAIN. R. M. Lechan* and I. M. D. Jackson* (Sponsor: S. Reichlin). Endocrine Division, Tufts-New England Medical Center, Boston, MA 02111.

The perikaryal and fiber distribution of immunoreactive TRH in the rat CNS was demonstrated using the peroxidase-antiperoxidase (PAP) technique after rapid fixation with acrolein.

Six Sprague-Dawley rats (bw 250-350 g) were perfused through the ascending aorta with 5% acrolein (Polyscience Inc.) in a 0.1M phosphate buffer, pH 7.2 for five minutes. Three animals were pretreated with 75 µg of colchicine, stereotaxically injected into the lateral ventricle two days prior to killing. 60 µm sections of the forebrain, brain stem and spinal cord were made on a vibratome and incubated with a well characterized antiserum to TRH at a final dilution of 1:750 containing 0.3% Triton X-100. The reaction product was developed with DAB.

In colchicine treated animals, immunoreactive neuronal cell bodies were found predominantly in the hypothalamus, especially in the parvocellular subdivison of the paraventricular nucleus, suprachiasmatic subdivision of the preoptic nucleus and dorsomedial nucleus. Cells were also present in the posterior magnocellular part of the PVN, perifornical region, lateral hypothalamus, arcuate nucleus, region of the prelateral mammillary nucleus, bed nucleus of the stria terminalis, medial preoptic area and in the diagonal band of Broca. Only rare cells were present in the corticomedial nucleus of the amygdala. In the brain stem, numerous cells were identified in the raphe magnus, pallidus and obscuris. No immunoreactive perikarya were present in the spinal cord.

Immunoreactive neuronal processes were identified in nearly all regions of the hypothalamus but predominantly in the external zone of the median eminence extending into the posterior pituitary, OVLT, parvocellular subdivision of the paraventricular nucleus, periventricular nucleus, perifornical region, dorsomedial nucleus and arcuate nucleus. In other regions of the forebrain, a high density of terminal fields was present in the lateral septal nucleus, bed nucleus of the stria terminalis, corticomedial nucleus of the amygdala, zona incerta and periventricular nucleus of the thalamus. Reaction product was also seen in many regions of the brain stem and was particularly rich in the parabrachial nucleus, trigeminal nucleus, nucleus tractus solitarius, nucleus commissuralis and nucleus intercalatus. In the spinal cord, immunoperoxidase was present in the central grey, intermediolateral cell column and about α-motoneurons in the ventral horn.

These studies demonstrate a wide distribution of TRH throughout many different anatomic regions of the CNS and suggest other roles for TRH as a neurotransmitter and/or neuromodulator independent of its action as hypophysiotropic hormone.

29.11

WITHDRAWN

29.12 IMMUNOCYOCHEMICAL LOCALIZATION OF HISTIDYL-PROLINE DIKETOPIPERAZINE IN INTACT PITUITARY AND PITUITARY MONOLAYER CULTURES. V. May, G. V. Childs* and J. F. Wilber*. Northwestern Univ. Med. Sch., Chicago, IL 60611, Univ. of Texas Med. Branch, Galveston, TX 77550, Louisiana State Univ. Med. Sch., New Orleans, LA 70112

Thyrotropin-releasing hormone (TRH) has been localized immunocytochemically in the secretory granules of pituitary cells in both the intact rat anterior pituitary (Childs et al., J. Histochem. Cytochem. 26:901, 1978) and in pituitary monolayer culture (May et al., J. Histochem. Cytochem. 29:900, 1981). Histidyl-proline diketopiperazine (cyclo his-pro), a cyclic dipeptide formed by pyroglutamate aminopeptidase proteolysis of TRH, has been shown to be biologically active in the central nervous system. Specific antiserum against cyclo his-pro has been developed for use in RIA by Mori et al. (Endocrinol. 108:1955, 1981) that exhibits less than 0.12% crossreactivity with TRH. We now describe its application in immunocytochemical staining of intact pituitary and cell cultures. For intact tissue studies, adult male rat pituitaries were fixed in 1% glutaraldehyde and embedded in Araldite 6005. To determine whether cyclo his-pro could also be found in cells free of external influences, anterior pituitaries were dispersed and grown as monolayer cell cultures for 7-21 days. The cell pellets were then fixed and embedded. Ultrathin sections of intact pituitaries and cultured pituitary cells were stained using anti-cyclo his-pro with the peroxidase anti-peroxidase (PAP) complex technique. A titration curve gave an antiserum working dilution of 1:25,000. Cyclo his-pro immunoreactivity in the intact pituitary was localized in secretory granules with varying intensity in cells that resembled thyrotropes, gonadotropes and corticotropes. An intense staining reaction persisted in pituitary cells maintained in culture which was also localized to the secretory granules. Liquid phase absorptions with 10ng-100ng/ml cyclo his-pro attenuated the staining intensity to below control values. Absorption specificity tests using 1µg/ml LH, FSH, ACTH, TSH, GnRH and TRH failed to alter staining intensity. Solid phase immunoabsorption tests to further demonstrate the specificity and experiments with serially sectioned cells stained for cyclo his-pro, TRH, ACTH, TSH and the gonadotropins for positive identification of the stained cells are presently in progress. These studies demonstrate that the PAP complex technique is capable of detecting cyclo his-pro immunoreactivity in fixed and embedded pituitary tissue and that the cyclo his-pro immunoreactivity persists in pituitary cell cultures. The staining pattern of the cyclo his-pro antiserum is very similar to that for TRH immunoreactivity to suggest a parallelism in their sites of localization. Supported by PHS 5-T32-H07068 (JM) and NIH AM25482 (JFW).

29.13 **IMMUNOCYTOCHEMICAL LOCALIZATION OF TRH IN RAT HYPOTHALAMUS.**

Margaret S. Kreider, Gajanan Nilaver, Earl A. Zimmerman, Andrew Winokur, & Neil R. Krieger
Depts. of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104

The distribution of TRH in the vertebrate CNS has been extensively described by radioimmunological procedures. However, there have been few reports of its immunocytochemical localization. Hökfelt et al (Eur. J. Pharm., 34: 389, 1975) and Choy and Watkins (Cell Tiss. Res., 177: 371, 1977) used indirect immunofluorescence and PAP immunoperoxidase techniques to investigate the in situ localization of TRH in the hypothalamus. We have employed a different immunocytochemical method which utilizes avidin-biotin complexed horseradish peroxidase to examine the distribution of TRH immunoreactive perikarya and processes in the rat hypothalamus.

Male rats (150-200 g) were perfused with phosphate buffered saline followed by lysine periodate fixative 24 hours after pretreatment with colchicine (60 - 120 µg/50 µl 0.9% saline, intracisternal). 50 µ cryostat sections were processed for immunocytochemistry by the ABC method (Vector Laboratories). The sections were incubated with TRH antisera (1:500) overnight at 4° C. The antisera were raised in rabbits against TRH-BDB-BSA as described by Bassiri and Utiger (Endocrinol., 90: 722, 1972). Antisera which had been incubated with 1 X 10^{-4} M TRH-BDB-BSA overnight served as the control sera.

Numerous immunoreactive cell bodies were observed in the periventricular and dorsomedial nuclei of the hypothalamus. A few positive cell bodies were seen in the paraventricular nucleus. The external layer of the median eminence contained the densest network of immunoreactive fibers. The dorsomedial nucleus contained a moderate density of positive fibers. Other hypothalamic areas contained fewer immunoreactive processes. The staining was eliminated by preabsorption of the antiserum with TRH-BDB-BSA but not after incubation with BDB-BSA.

These findings provide further evidence for the cellular localization of TRH in nuclei in the rat hypothalamus. The utility of the avidin-biotin immunoperoxidase method for studies of the cellular localization of TRH in other areas of the CNS is under investigation in our laboratory.

29.14 SOMATOSTATIN AND THE ANTERIOR OLFACTORY NUCLEUS OF THE MOUSE.

C. H. Block, G. E. Hoffman, J. VanLare. Dept. of Anat., University of Rochester Sch. of Med. and Dent., Rochester, NY 14642

The anterior olfactory nucleus (AON), a relay structure of the olfactory system, provides major afferents to the main olfactory bulb (OB). Although somatostatin (SS) cells are present in discrete areas of the AON and scattered throughout the OB, no attempts have been made to examine the axonal distribution of these neurons. The present study was designed to assess the localization of SS in olfactory structures of the murine brain.

Adult male mice were perfused intracardially with Zamboni's fixative and brain sections were cut at 30 microns on a vibrating microtome. The sections were processed using the unlabeled antibody enzyme method or with immunofluorescence techniques. SS cells were found scattered in the rostral extent of AON in pars lateralis and externa. A more dense population of cells surrounded the anterior commissure at the interface with AON, as well as in the pyriform cortex and olfactory tubercle. Sparse fiber networks were observed around AON, and in the external plexiform layer, granule cell layer, and medial periglomerular surfaces of the main OB. A moderately dense SS fiber plexus was found in the superficial layers of taenia tecti and caudal aspects of the olfactory tubercle. Axons were also seen in the superficial layer of prepyriform cortex coursing towards the rhinal fissure, where they ended abruptly.

Because SS fibers are present in OB, we sought to determine if these fibers represented axons of the AON SS neuronal pool. Using immunoperoxidase or immunofluorescence in combination with retrograde tracers injected into OB, we found that less than 3% of SS labeled cells in AON were retrogradely labeled. These results suggest that the SS neurons of AON give rise to axons that are distributed to areas other than OB, perhaps to contralateral AON or prepyriform cortex and that AON represents a heterogeneous neuronal population with a diverse projection field.

Supported by NIH grants NS16107, NS13725, and RCDA NS00321.

29.15 DESCENDING HYPOTHALAMIC OXYTOCIN/MESOTOCIN PROJECTIONS END PREFERENTIALLY ON PULMONARY AND BARORECEPTOR REGIONS OF THE N. SOLITARIUS.

K.T. Keyser*, H.J. Karten and J.B. Cabot. Dept. of Neurobiology & Behavior, SUNY at Stony Brook, New York 11794.

Vagal sensory ganglion neurons innervate cardiovascular, gastrointestinal and pulmonary structures. Their central projections terminate in organotopically specific subnuclei of the nucleus of the Tractus Solitarius (nTS; Katz and Karten '77,'78,'79,'82). The identification of putative neurotransmitters used by vagal sensory afferents, as well as those from central systems which may modify incoming information, is a matter of considerable interest. We have begun investigations of the organization of nTS in the pigeon with antisera directed against a number of peptide and non-peptide antigens, including oxytocin and neurophysin.

There is a specific distribution of oxytocin-like imunoreactivity (OLI) in the nTS. A region of dense immunoreactive terminals is found predominately within the nucleus sulcalis dorsalis and in the nucleus parasolitarius lateralis (Katz and Karten, in press). These subnuclei receive their vagal inputs from baroreceptor and pulmonary targets, respectively (Katz and Karten, 1979). The pattern of neurophysin-like immunoreactivity (NLI) is identical to that of OLI. A sparse scattering of OLI- and NLI-containing axons were found surrounding the entire nTS complex. The neurophysin antiserum consisted of the IgG fraction of an antiserum which recognizes all three neurophysins. Preincubation of the oxytocin antiserum with synthetic peptides (10µM) indicated no cross-reactivity at the immunohistochemical level with arginine vasopressin, arginine vasotocin (the avian equivalent of arginine vasopressin) or the neurophysins. Preincubation of the oxytocin antiserum with mesotocin (1µM), the avian equivalent of oxytocin, abolished staining as did 1µM oxytocin controls.

Various pathway tracing techniques have shown that the medial preoptic area, the anteromedial hypothalamus and the nucleus periventricularis magnocellularis (PVM) project to brainstem (Finkelstein and Berk, 1980; Berk and Butler, 1981). Furthermore, neurons in these areas exhibit oxytocin-like, vasotocin-like and neurophysin-like immunoreactivity. We have, therefore, begun studies to determine which diencephalic nuclei give rise to the projection to nTS. Preliminary results from our HRP injections indicate that, among other areas, a restricted subdivision of the PVM may be a source of the OLI- and NLI-containing projection to the nTS. Autoradiographic studies of descending projections of PVM are consistent with these results although the exact trajectory of this pathway remains to be clarified. Supported by NS12078 to H.J.K. and HL24103 to J.B.C.

29.16 **COMPARISON BETWEEN NEURONS DEMONSTRATING SOMATOSTATIN-LIKE IMMUNOREACTIVITY AND THOSE CONTAINING ACETYLCHOLINESTERASE IN THE RAT FOREBRAIN**

Nancy J. Woolf, Susan R. McGurk*, and Larry L. Butcher. Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, California, 90024.

In order to demonstrate whether or not somatostatin-like immunoreactive (SLI) neurons of the forebrain also stained for acetylcholinesterase (AChE, E.C. 3.1.1.7), we processed brain tissue for fluorescent immunohistochemistry, and, following microscopic examination, counterstained the same tissue sections for AChE according to the pharmacohistochemical regimen (Butcher, L.L., & Bilezikjian, L., Eur. J. Pharmacol. 34:115, 1975).

SLI neurons were found in the frontal, cingulate, parietal, insular, and pyriform cortices, but not in the limbic cortex. Most cortical cells were weakly reactive for AChE, and no SLI cells in the cortex contained appreciable amounts of AChE. Other SLI cells were found in the caudate-putamen complex, nucleus accumbens, olfactory tubercle, nucleus of the diagonal band, lateral preoptic area, anterior amygdalar area, periventricular hypothalamus, and the central, lateral, and basolateral nuclei of the amygdala. Although intensely AChE-stained neurons were found in the caudate-putamen, nucleus accumbens, olfactory tubercle, nucleus of the diagonal band, and the lateral preoptic area, and moderately to intensely AChE-stained neurons were found in the periventricular hypothalamus, the more intensely AChE-stained cell population did not overlap with the SLI neuronal population.

In the caudate-putamen the SLI neurons had maximal soma extents ranging 14-25 µm, whereas intensely AChE-staining neurons in the caudate-putamen measured 20-44 µm. The SLI cells of the striatum had the following distribution of soma shapes: oval, 49%; fusiform, 36%; triangular, 9%; and round, 6%.

29.17 SOMATOSTATIN-IMMUNOREACTIVITY IN THE BRAINSTEM: A COMPARISON OF METHODS. B. J. Morley and J. I. Koenig*, Res. Div., Boys Town Inst., Omaha, NE 68131 and Dept. Physiology, Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

Somatotrophin release inhibiting factor (somatostatin; SRIF) has been demonstrated in several non-hypothalamic areas of rat brain, including the brainstem (Krisch, B., Cell Tiss. Res., 217: 531, 1981; Takatsuki et al., Brain Res., 213: 211, 1981; Finley et al., Neurosci., 6: 2173, 1981). There are discrepancies among these reports with respect to the appearance of SRIF-immunoreactivity in adult animals and whether immunoreactivity is found in both cell bodies and terminals, or only in terminals. Since the concentration of somatostatin in the brainstem is lower than in hypothalamic areas, its visualization is likely to be more easily affected by variations in procedure.

We have systematically investigated several variables which might affect SRIF-immunoreactivity, including the source of the primary antibody, type of fixation, method of sectioning, colchicine-treatment, and the addition of agents promoting the penetration of antibodies into the tissue. We also compared the unlabeled peroxidase (PAP) and the avidin-biotin complex procedures.

Most of these variables affected the intensity of SRIF staining and some combinations of these variables resulted in the absence of staining. In our hands, the most significant single variable was penetration of the primary antibody. By varying fixation and optimizing penetration, we obtained heavy SRIF staining in both cell bodies and terminals, even without the use of colchicine treatment or pronase. Under optimal conditions we have noted no difference in the distribution of anti-somatostatin prepared by us and commercially available anti-somatostatin.

In comparison with previous research, our results are similar to those recently reported by Finley et al. (Neurosci., 6: 2173, 1981), in which pronase treatment was used to enhance the labeling of SRIF-immunoreactivity. Our results confirm the presence of SRIF-immunoreactivity in the brainstem and also suggest that the absence of SRIF-immunocytochemical labeling must be interpreted cautiously when more than one procedure is not investigated. (This research was supported in part by Biomedical Research Development Grant 1-S08-RR09003).

29.18 EFFECTS OF CYSTEAMINE ON BRAIN SOMATOSTATIN-14, SOMATOSTATIN-28 LI AND SOMATOSTATIN-28(1-12) LI. C. Bakhit, R. Benoit, and F.E. Bloom. The Salk Institute, La Jolla, CA 92037.

Three peptidic fragments related to somatostatin have been identified in rat brain. The original peptide somatostatin-14 (SS14) corresponds to the C-terminus of somatostatin-28 (SS28) whose N-terminus is somatostatin-28(1-12) [SS28(1-12)]. We have recently characterized the distribution of these somatostatin related peptides in selected rat brain regions using three specific radioimmunoassays: antiserum S310 recognizes only SS14, antiserum S329 reads the middle region of SS28 but not SS14 nor SS28(1-12) and antiserum S320 reads SS28 (1-12) but not SS14 and not SS28. The highest tissue concentration of the three peptides was found in hypothalamus and lowest in cerebellum. SS28(1-12)-like immunoreactivity (LI) was either equal to or more abundant than SS14. [Benoit et al. Endocrinol. 110, Abs. #913 1982).]

We report here the effects of cysteamine on the levels of the three somatostatin related peptides in selected regions of rat brain. Male Sprague-Dawley 200 g rats were injected intracerebroventricularly (ICV) with a 20 µl solution containing either saline or cysteamine. Rats were killed 2 1/2 hours later and the following brain regions dissected: cerebral cortex (CC), hippocampus (H), neostriatum (NS), hypothalamus (HY), and pons-medulla (PM). Tissues were collected, boiled, and extracted with 2M acetic acid and the extract analyzed by RIA.

Cysteamine (1400 µg/rat) produced a marked depletion of SS14 in all regions tested (% depletion: CC 37, H 48, NS 31, HY 45, PM 37). SS 28 LI was not significantly altered in all regions except H where there was a 22% depression. SS28(1-12) LI was not significantly altered in all regions except PM in which a 21% depression was observed. The above ICV dose of cysteamine produced in rats various behaviors which included: running fits, tonic-clonic seizures, barrel rotation, piloerection and frozen stares. A lower ICV dose of cysteamine (500 µg/rat) also produced a marked depletion of SS14 but did not alter the other two peptides. None of the behavioral effects described above were observed with the 500 µg ICV dose of cysteamine. Subcutaneous injection of cysteamine (90 mg/kg) also produced a selective depletion of SS14 but no obvious behavioral effects. The decrease of SS14 content was in agreement with recent studies by Sagar, S.M. et al. J. Neurosci. 2: 325, 1982 and Szabo, S. and Reichlin, S. Endocrinol. 109: 2255, 1981.

This study demonstrates that cysteamine selectively depletes SS14 in all brain regions tested and only marginally affects SS28 LI and SS28(1-12) LI in certain regions. This research is supported by NIAAA 07273 and AM 26741.

29.19 CHOLECYSTOKININ: RADIOIMMUNOASSAY, IMMUNOHISTOCHEMISTRY, RECEPTOR BINDING AND PHYSIOLOGICAL ACTIONS IN SPINAL CORD CULTURES. S.E. Hays*, M.A. Rogawski, M.C. Beinfeld*, L.R. Skirboll, T. Hökfelt* and G. Norell*. SRI International, Menlo Park, CA 94025; Lab. of Neurophysiology, NINCDS, Bethesda, MD 20205; Dept. of Pharmacology, St. Louis Univ. Med. Sch., St. Louis, MO 63104; Neuroscience Branch and Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

The spinal cord is richly innervated by cholecystokinin (CCK)-containing fibers. Although a major fraction of these may be derived from sensory ganglia and supraspinal descending systems, recent studies have demonstrated the existence of CCK-immunoreactive neuronal perikaria within the spinal cord. In this report, we give evidence that CCK-containing neurons are maintained in dissociated culture and present physiological data suggesting their functional role.

Spinal cords with some adherent sensory ganglia were cultured from 12 to 14 day old C57BL/6 mouse embryos. Following 4 to 6 weeks in vitro, the cells were harvested and extracted with methanol for radioimmunoassay (Beinfeld et al., Brain Res. 212: 51, 1981). The cultures contained levels of immunoreactive CCK-8 comparable to that found in adult spinal cord (0.97 ± 0.23 ng/mg protein). In contrast, pure cultures of dissociated spinal ganglia demonstrated less immunoreactivity (0.24 ± 0.03 ng/mg protein). Immunofluorescence staining of spinal cord cultures grown on glass coverslips revealed occasional islands containing dense networks of immunoreactive fibers with numerous brightly fluorescent varicosities that formed rosettes around the soma and processes of spinal cord neurons.

To determine if receptor sites for CCK are present on cultured neurons, radioligand binding was carried out using [^{125}I]CCK-33 (0.4 nM). Crude synaptosomal membranes prepared from frozen tissue demonstrated specific high affinity binding sites similar to those found in brain membranes. Binding was displaced by CCK-8 with an IC_{50} of 5 nM whereas desulfated CCK-8 had five-fold lower affinity for the CCK receptor. The functional role of CCK-8 was explored by applying the peptide to spinal neurons during intracellular recording. In a subpopulation of cells, CCK-8 (0.2-100 µM) produced a long lasting (20-200 sec) enhancement of action potential generation in response to stimulation with intracellular depolarizing current while desulfated CCK-8 had little or no such activity. In many cases, these effects on excitability were accompanied by a small membrane depolarization (0.5-4 mV) and a decrease in membrane conductance (5-19%). These studies demonstrate that spinal CCK-containing neurons can survive in cell culture. The existence of functionally active CCK-receptors on some spinal neurons supports the idea that the peptide serves as a neurotransmitter whose function may be to tonically modulate the excitability of target neurons within the cord.

30.1 REGIONAL DISTRIBUTION OF CATECHOLAMINES IN THE BRAINSTEM AND SPINAL CORD OF THE DOG. K.B. Brosnihan, R.C. Speth, P. Bridle*, C.L. Chernicky and C.M. Ferrario. Cleveland Clinic Research Division, Cleveland, OH 44106.

Little work has been done on the distribution of catecholamines in the dog's brainstem. The localization of catecholaminergic cell bodies and varicosities in the medulla of the dog was was first determined in preliminary studies with glyoxylic acid-induced fluorescence (unpublished results); the localization of the locus coerulus (LC) and A5 nucleus in the pontine tegmentum of the dog was based upon the study of Ishikawa et al. (Brain Res. 86: 1, 1975). Six male adult dogs (10-20 kg) were anesthetized with sodium pentobarbital. The brains were removed within 4 minutes of administration of an overdose of pentobarbital and were frozen immediately on dry ice. A block of brainstem tissue beginning 6 mm caudal to the obex and terminating at the level of the inferior colliculus was sliced in 2 mm sections. The spinal cord was removed from C7 to T3. Micropunches (13 or 15 ga) from the regions of the lateral reticular nucleus (A1), the dorsal motor nucleus of the vagus and nucleus tractus solitarius (A2), A5, LC, area postrema (AP), hypoglossal nucleus (HN), pyramidal tract (PT) and intermediolateral cell column (IML) were assayed for catecholamines radioenzymatically, and values expressed per mg protein. Norepinephrine (NE), epinephrine (EPI) and dopamine (DA) were measured on combined punches from these regions. Following dissection of the nuclei the remaining tissue in each slice was assayed for catecholamines.

	NE	EPI	DA
LC	19.76 ± 3.96	1.05 ± 0.14	1.63 ± 0.25
A2	14.60 ± 1.96	1.03 ± 0.15	1.48 ± 0.24
HN	10.10 ± 2.05	0.50 ± 0.13	0.77 ± 0.16
A5	8.56 ± 0.86	0.61 ± 0.11	0.60 ± 0.08
IML	8.04 ± 1.56	0.13 ± 0.04	0.39 ± 0.10
A1	6.36 ± 1.03	0.31 ± 0.03	0.50 ± 0.08
AP	5.32 ± 1.26	0.70 ± 0.22	1.33 ± 0.25
PT	1.30 ± 0.40	0.08 ± 0.02	0.14 ± 0.04

$\bar{X}$ ± S.E. (ng/mg protein) (n = 6)

Highest levels of NE were found in the LC and A2 regions. All regions punched except the PT possessed substantially higher levels of catecholamines than found in remaining tissue. The results indicate that the distribution of catecholamines in the dog brainstem and spinal cord is similar to that reported for other species. (Supported by an NHLBI grant [HL-6835]).

30.2 ESTIMATION OF DOPAMINE TURNOVER IN STRIATAL, LIMBIC AND FRONTAL CORTICAL AREAS OF HUMAN BRAIN. P.J. Langlais* F.X. Walsh* T.J. Stevens* and E.D. Bird*. (SPON: A. Pope). Brain Tissue Resource Center, McLean Hosp., Belmont, MA 02178

Recent studies in rat brain have shown that the rates of dopamine (DA) synthesis and release are several fold greater in prefrontal cortex than in striatum, limbic areas or olfactory tubercle (Bannon et al., Brain Res. 218:376-382, 1981). This same mesocortical DA projection system has received considerable attention since its response to chronic neuroleptic treatment also differs from that observed in other DA systems (Bacopoulos, N.G. et al., Brain Res., 157:396-401, 1978) and has been implicated in behavioral disturbances both in animals and in man. In the present study, the levels of DA and homovanillic acid (HVA), the major DA metabolite in human brain, were measured in the caudate, n. accumbens, frontal cortex (Brodmann A10), cingulate gyrus (A24) and paraolfactory gyrus (A25) of human post-mortem brain. Brain tissue was obtained and stored at -70°C from 12 patients who were free from neurological disease and any psychoactive drug therapy. The concentrations of DA and HVA, determined by reversed-phase, high performance liquid chromatography coupled with electrochemical detection, were found to be much higher in the caudate and accumbens than in any of the three frontal areas. The concentration of DA in two of the frontal cortical areas, A10 (.0025 ng/mg) and A24 (.005 ng/mg) were quite similar but was significantly higher in A25 (.680 ng/mg, $p<.001$). The concentration of HVA was also significantly higher in A25 (1.949 ng/mg, $p<.001$) than in A10 (.133 ng/mg) or A24 (.254 ng/mg). When the turnover of DA was estimated by calculating HVA/DA ratios, DA turnover was found to be significantly higher in A10 (86.1, $p<.001$), A24 (73.2, $p<.001$) and A25 (5.9, $p<.01$) when compared to caudate (1.8). Interestingly, the turnover of DA in A25 was significantly different from that of A10 and A24 but not significantly different from that of n. accumbens. These findings suggest that the synthesis and release of DA within terminals innervating frontal cortex differ significantly from striatal and limbic structures of human brain. These findings may indicate that frontal DA terminals may lack autoreceptors as has been proposed in rat frontal cortex.

30.3 ASYMMETRIES IN HUMAN BRAIN DOPAMINE RECEPTOR BINDING: RELATIONSHIP TO MIDBRAIN DOPAMINE CELL NUMBER. D.C. German, D.S. Schlusselberg*, B.A. McMillen, K. McDermott*, W.K. Smith*, and D.J. Woodward. Depts. of Physiol., Psychiat., Cell Biol., and Pharmacol., Univ. of Texas Health Sci. Cntr, Dallas, TX. 75235.

Midbrain dopamine (DA)-containing neurons decrease in number with aging and are abnormally sparse in Parkinson's disease. In mice, there is a positive correlation between the number of nigral DA neurons and the number of striatal ^{3}H-spiperone binding sites (putative DA D2 receptor sites). The present experiment was undertaken to determine whether the number of midbrain DA neurons is correlated with the number of ^{3}H-spiperone binding sites in the human brain.

Fresh human brains were obtained 12-14 hours postmortem. The left and right nucleus accumbens (NA), caudate nucleus (CAU), and putamen (PUT) were dissected out. For each brain area we measured the receptor number and affinity for ^{3}H-spiperone binding (Scatchard analysis), the level of DA, and its metabolite, DOPAC. The most obvious differences in the six brains examined (17-51 years of age) was a 21-26% difference in the number of binding sites on the two sides of the brain: for the NA, 3 brains were right predominant and 2 were left predominant; for the CAU 2 were right predominant; and for the PUT 5 brains were right predominant. In one brain there was a marked and general right predominance such that there were more binding sites on the right NA (44%), CAU (37%) and PUT (48%) vs. the left.

A system built around a Data General Eclipse (S/130) minicomputer and Ikonas Color Graphics system was used to map the location of the midbrain DA neurons. Cells containing neuromelanin pigment in 50 µm thick Nissl stained sections were identified as catecholamine-containing neurons. Sections were analyzed from the rostral pons to the level of the caudal mammillary bodies (12-14 mm). This system allows one to count and reconstruct the 3-dimensional topography of the midbrain DA neurons. In 3 brains reconstructed so far, there were differences in the number of DA cells on the two sides of the brain.

The anatomical reconstruction technique will allow examination of laterality effects, aging effects, areas of cell loss relative to specific parkinsonian symptomatology, and possible abnormalities in DA cell number in schizophrenics.

This research supported by Grants MH-33513, MH-30546, DA-2338, AA-0390, and the Biological Humanics Foundation.

30.4 EVIDENCE FOR THE SEGREGATION OF CATECHOLAMINES IN THE RAT CAROTID BODY. D. S. Christie* and J.T. Hansen. Department of Anatomy, The University of Texas Health Science Center, San Antonio, TX 78284.

Central to our understanding of arterial chemoreceptor transduction is the hypothesis that subtypes of glomus cells exist which selectively release either dopamine (DA) or norepinephrine (NE) as neuromodulators during chemoreceptor stimulation. However, evidence for the segregation of DA and NE to specific subtypes of glomus cells is indirect, based largely on total catecholamine (CA) content of the carotid body and on the morphology of the CA-containing dense-core vesicles. Therefore, to determine if there is a segregation of glomus cell CAs, we employed a pharmacologic paradigm used by Hess (Neurosci. 3:413, 1978) which depletes all carotid body CAs and then selectively regenerates DA while keeping NE levels significantly lowered. Reserpine (5mg/kg ip) significantly ($P < 0.01$) depleted CA levels and then, 24 hrs later, administration of L-dopa (100mg/kg ip) selectively regenerated DA to original control levels while NE remained significantly ($P < 0.01$) depleted. Analysis of carotid body CAs by HPLC 90 min after L-dopa administration validated this approach. However, ultrastructural stereology failed to demonstrate any significant difference in the concentration of glomus cell dense-core vesicles. Subsequently, we performed potassium dichromate cytochemical staining in an effort to distinguish those vesicles which still contained appreciable amounts of CA, presumably DA. Our preliminary results demonstrate that not all glomus cells are positively stained, suggesting that DA and NE may be segregated to subtypes of glomus cells. However, incubation of tissue for 24 hours in potassium dichromate at low pH (4.1) caused oxidation and poor morphological preservation. We currently are repeating our cytochemistry at higher pH (6.5), which should improve tissue morphology and enable us to more reliably identify which glomus cell subtype contains the presumptive DA staining. (Supported by USPHS Grants R01 HL25508 and RCDA K04-HL00680 to J.T.H.)

30.5 THE VENTRAL TEGMENTAL AREA OF THE MONKEY MESENCEPHALON. D.L. Felten and J.R. Sladek, Jr. (SPON: J.A. Clemens). Depts. of Anat., Indiana Univ. Sch. of Med., Indianapolis, IN 46223 and Univ. of Roch. Sch. of Med., Rochester, NY 14642.

The ventral tegmental area (VTA) of the rhesus monkey and squirrel monkey mesencephalon was examined with histofluorescence, Golgi-Cox, cresyl violet, and transmission and X-ray analytical E.M. to localize dopaminergic cell bodies, dendrites, and axons, to examine dendritic cytoarchitecture, and to localize synapses impinging upon dendrites and somas. Several zones of dopaminergic neurons were present in the VTA. In the ventral portion, medium-sized (20-35 um dia.) neurons were found within and dorsal to the interpeduncular nucleus. A few clusters of small neurons were noted near the midline. These ventral neurons were multipolar, with dendrites coursing in scattered directions. Fluorescent neurons were also abundant in the lateral region of the VTA, between the fascicles of the III nerve coursing through the ventromedial tegmentum medial to substantia nigra. The lateral VTA neurons were multipolar or bipolar, with many dendrites oriented vertically, in parallel with the III nerve fascicles. These dendrites were fluorescent; Golgi-Cox impregnation revealed small vertical clusters or bundles of dendrites. Axons of the ventral VTA neurons ran rostrally in a paramedian position in the ventral mesencephalic tegmentum, moved laterally to run just dorsal to the medial portion of substantia nigra, and then coursed through the lateral hypothalamus towards the basal forebrain. Both smooth and varicose axonal profiles were noted. A dorsal region of VTA neurons was also present in the midline. A narrow longitudinal wedge of cells extended upward from the base of the central gray between the paired columns of somatic oculomotor neurons. These small neurons (less than 20 um diameter), were present among a dense bed of catecholamine (CA) varicosities. Their dendrites were usually not fluorescent and did not form bundles. Their axons could only be traced for a short distance rostrally, and some appeared to head caudally. The neurons of the lateral VTA were examined with TEM for the topography of afferent synapses. The presence of CA in the VTA neurons was confirmed with the X-ray analytical technique of Wood (chromium tagging of glutaraldehyde-condensed CA). Numerous axo-dendritic synapses were identified (clear round and flat or pleomorphic, but very few dense core), and some dendro-dendritic appositions were present. Few axo-somatic synapses were found. The dendrites clustered into bundles, with dense afferent synaptic contacts, while the somas were relatively isolated from afferent synapses. These relationships may contribute to the regulation of these dopaminergic neurons which influence limbic and cortical functions. Supported by NIH grant RO1NS15677.

31.1 CO-OCCURRENCE OF SUBSTANCE P-LIKE AND CHOLECYSTOKININ-8-LIKE IMMUNOREACTIVITIES IN AN INTRINSIC FIBER SYSTEM OF THE CORTEX IN TURTLE. Anton Reiner and William D. Eldred. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

The pallium of the turtle telencephalon, from the septal area to the rhinal fissure, is arranged in a three-layered cortex: 1) a broad superficial molecular layer, 2) a thin cellular layer and 3) a thin subcellular layer. Three subdivisions of the cortex are generally recognized, a medial (cm), a dorsomedial (cdm) and a dorsal (cd). A lateral, noncortical extension of cd (termed the pallial thickening, PT) is often included as part of the cortical formation of turtle.

We have utilized LM and EM immunohistochemical techniques to characterize the distribution of substance P-like immunoreactivity (SPLI)(antibody obtained from Sera Labs, England) and cholecystokinin-8-like immunoreactivity (CCKLI)(antiserum obtained from M. Beinfeld) within the cortex and PT of turtle. With a simultaneous immunofluorescent labeling procedure (Erichsen et al., Nature, '82), we have found that both SPLI and CCKLI are present within an extensive fiber network of the cellular layer of the entire cortex and PT. The vast majority, if not all, of the fibers and terminals of this system contained both SPLI and CCKLI. Numerous SPLI-containing and CCKLI-containing neurons were observed in the molecular and cellular layers of cdm and cm. Cortical transection between cdm and cd resulted in the loss of both SPLI and CCKLI from cd and PT but not from cdm and cm. Thus, the intrinsic SP/CCK fiber system appears to originate largely from neurons of more medial portions of the cortex.

At the ultrastructural level, terminals containing SPLI show an identical labeling pattern to those containing CCKLI. In each, labeled terminals were filled with a diffuse cytoplasmic DAB reaction product and contained large labeled dense core vesicles (1300Å) and a few unlabeled large dense core vesicles (1300Å). Terminals containing SPLI and terminals containing CCKLI made conventional chemical synapses onto cell bodies in the cellular layer. Within labeled terminals, numerous small unlabeled vesicles (600Å) were clustered at synapses. The similarity in size of the SPLI-containing and the CCKLI-containing vesicles, as well as the small number of unlabeled large dense core vesicles, is consistent with the possibility that SPLI and CCKLI are present in the same vesicles.

The function of this intrinsic fiber system of turtle cortex is unclear. The present results, however, suggest that synaptic communication between this system and the cortical neurons may be complex and involve two neuroactive peptides and the additional unidentified substance(s) contained in the small unlabeled vesicles. This research was supported by NS-16857 to A.R. and EY-03801 to W.D.E.

31.2 RELATIONSHIP OF DOPAMINE AND CHOLECYSTOKININ IN MESOLIMBIC PROJECTIONS OF THE SUBSTANTIA NIGRA-VENTRAL TEGMENTAL COMPLEX. M. J. Iadarola, H.-Y.T. Yang and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Immunocytochemical studies have suggested the co-existence of dopamine (DA) and cholecystokinin (CCK) in neurons of the substantia nigra (SN)-ventral tegmental (VTA) complex, projecting to nucleus accumbens (NA) and olfactory tubercle (OT). We have studied this association with biochemical techniques in rats with unilateral 6-hydroxydopamine (6OHDA) infusion or mechanical hemitransection of the meso-limbic DA system. The OT, NA and caudate-putamen (CP) were assayed for CCK content (by radioimmunoassay) and tyrosine hydroxylase (TH) activity.

Ten to twenty days after hemitransection, the maximal loss of CCK was approximately 60% for both OT and NA. The CCK content of the CP remained unchanged even though TH activity was decreased 85-97% by the lesion.

The effect of 6OHDA lesions appeared to be highly dependent upon both the location and extent of the lesion. The maximal loss of CCK after 6OHDA lesions of the VTA was approximately 50% for both the OT and NA and was associated with nearly complete destruction of DA projections (>80% loss). The ratio of percent decrease in CCK to the percent decrease in TH was approximately 1:2 in both the OT and NA. Thus, almost 50% of the CCK content of OT and NA does not appear to be dependent upon the integrity of a DA projection.

Following 6OHDA lesions placed in SN, as much as a 50% loss of TH activity was obtained in the OT and NA; no change in CCK content was associated with these lesions. This suggests that although the more laterally placed DA cells in the vicinity of the SN send projections to the OT and NA, these projections contribute little or no CCK to these nuclei. As was observed with the hemitransections, no reduction of the CCK content of CP was obtained despite losses of TH of >85%.

In summary, our data suggest that 1) about 50% of the CCK content of NA and OT is not associated with mesolimbic DA neurons; 2) There is a small but significant contribution (to NA and OT) of cells lateral to VTA that contain DA but no CCK; 3) Nearly 70% of the DA innervation of the OT and NA may contain CCK; 4) The striatal content of CCK appears to be largely independent of the DA projections to this nucleus (in agreement with a report by Meyer et al., Science, 1982).

31.3 FACILITATION OF SPINAL MOTONEURON EXCITABILITY BY SEROTONIN AND SUBSTANCE P APPLIED AT THE SAME SITES WITHIN THE VENTRAL HORN. S. R. White. Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland A1B 3V6.

Serotonin (5HT) and substance P (SP) coexist in some neuronal cell bodies located in the medulla oblongata of the rat (Chan Palay, et al. Proc. natn. Acad. Sci. USA 75 1978, 1582; Hokfelt, et al. Neuroscience 3 1978, 517). Axons project from these somata to the spinal cord and form terminals in the ventral horn which also appear to contain both 5HT and SP (Gilbert, et al. Neuroscience 7 1982, 69). 5HT, applied iontophoretically, markedly enhances glutamate (GLU) excitation of spinal motoneurons (White & Neuman, Brain Research 188 1980, 119). Similarly, motoneuron responsiveness to dorsal root stimulation is enhanced by iontophoretically applied SP at some dose levels (Krivoy, et al. Brain Research 202 1980, 365). In the present study, the effects on motoneuron excitability of SP and 5HT applied at the same sites within the ventral horn were examined.

Multibarrel micropipettes were used for iontophoretic drug application and to record extracellular spikes from single alpha-motoneurons at L_4 or L_5 in rats. Automatic current balance was employed. Motoneuron spikes were evoked by cycling brief periods of GLU application. Stable responses to GLU were established and the effects of SP, 5HT and the acetic acid vehicle for SP were examined.

SP (25-50 nA, 60 sec) had qualitatively similar effects to 5HT (15-20 nA, 60 sec) on approximately 70% of the neurons tested. A brief period of inhibition of GLU-evoked activity was followed by a prolonged period of facilitation which outlasted current application by at least two minutes. Neither SP nor 5HT directly excited the motoneurons. For the remaining neurons, SP produced only facilitation of responsiveness to GLU with no inhibition. Preliminary results suggest that the facilitatory effects of SP and 5HT are additive. Acetic acid vehicle, alone, (30-50 nA, 60 sec) inhibited motoneuron firing during application, with recovery but no facilitation afterward. The effects of methysergide and putative SP antagonists are currently being examined.

31.4 INCREASED EXCITATORY RESPONSIVENESS OF SPINAL NEURONS TO SUBSTANCE P AND 5-HYDROXYTRYPTAMINE IN p-CHLOROPHENYLALANINE-PRETREATED CATS. C. D. Raspantini*, S. Jeftinija*, T. L. Yaksh, V. L. W. Go*, A. A. Larson, and M. Randić (SPON: J. D. Blaustein). Dept. of Vet. Physiol. Pharmacol., Iowa State Univ., Ames, IA 50011; Dept. of Neurosurg. and Gastroent., Mayo Fnd., Rochester, MN 55905, and Dept. of Vet. Biol. Univ. of Minnesota, St. Paul, MN 55108.

The co-existence of 5-hydroxytryptamine (5-HT) and substance P (SP) in the same neurons of the brain stem raphé system and in its descending projections to the spinal cord has been demonstrated. Since the physiological significance of the presence of SP and 5-HT within the same spinal cord nerve endings is unclear, we have examined whether depletion of central 5-HT stores with p-chlorophenylalanine (pCPA) modifies responsiveness of spinal neurons to SP and 5-HT.

Thirty adult cats were pretreated with DL-p-chlorophenylalanine (350 mg/kg, i.p.) 72 hrs prior to the experiment. The activity of neurons in laminae I-VII of the lumbosacral and caudal spinal cord was recorded extracellularly. Microiontophoresis was used to study the effects of SP (3.7mM in 20mM acetic acid, pH 5.5, Beckman), 5-HT creatinine sulfate or HCl (50mM, pH 4-5), and norepinephrine bitartrate or HCl (0.2M, pH 3.8-4.7) on the spontaneous and evoked firing of the functionally identified neurons. The spinal cord concentrations of 5-HT and several neuroactive peptides (SP, neurotensin, cholecystokinin and vasoactive intestinal polypeptide) were also determined in control and p-CPA-pretreated cats.

Our results are based on data obtained from 189 neurons. Of these 92 were studied in the intact cats and 97 in the animals pretreated with p-CPA. SP(20-200nA for 2 min) caused excitation of 31% of the class 1 units (activated by sensitive mechanoreceptors) and about 70% of the class 2 (activated by nociceptors and sensitive mechanoreceptors) and class 3 units (activated by nociceptors only) in the intact cat spinal cord. However, in the cats pretreated with pCPA the number of units excited by SP was significantly increased, irrespective of the type of their sensory input. In addition, the proportion of nociceptive neurons depressed by 5-HT was decreased, as compared to controls. Units excited by 5-HT exhibited long-lasting and sustained responses. Three days following pCPA treatment, the 5-HT content of the dorsal and ventral halves of the spinal cord was reduced to 15.4% (0.11 ± 0.02µg/g fresh tissue) and 18.7% (0.13 ± 0.01µg/g) of control values, respectively. However, spinal levels of the peptides were not convincingly modified by the p-CPA treatment.

In conclusion, it appears that the 5-HT depletion increases excitatory responsiveness of all categories of cutaneous spinal neurons to SP and 5-HT.

31.5 DESTRUCTION OF SUBSTANCE P AND SEROTONERGIC NEURONS BY EARLY POSTNATAL ADMINISTRATION OF 5,7 DHT. A. C. Towle,* R. A. Mueller, G. Breese, and J. Lauder. Biol. Sci. Res. Center and Depts. of Anesthesiology and Anatomy, UNC School of Med., Chapel Hill, NC 27514.

Substance P and serotonin are putative neurotransmitters which have been proposed to co-exist in some central neurons, particularly those in the ventral medulla which project into the spinal cord. In this study we have determined the effect of 5,7 DHT on the biochemical content and immunocytochemical localization of substance P and serotonin. Three-day-old rat pups were injected initially with DMI (20 mg/kg i.p.) then 1/2 hour later with 5,7 DHT (75µg intracisternal). Animals for immunocytochemistry were treated with colchicine 24 hours prior to perfusion with 4% paraformaldehyde 100 mM Borate pH 10.5 and processed for paraffin embedding. The antisera were localized using a bridge of biotinylated second antibody-avidin-biotinylated HRP. The serotonin antisera was raised in a rabbit immunized with a serotonin-hemocyanin conjugate and the monoclonal substance P antibody was purchased from Pel Freeze.

Early postnatal administration of 5,7 DHT results in a dramatic and irreversible loss of brain serotonin content when measured by reverse phase HPLC 2 weeks to 2 months later. Immunocytochemical evidence demonstrates the loss of most (80-90%) serotonergic cell bodies and terminals throughout the brain. This is in contrast with the many previous studies which have reported that following 5,7 DHT administration to adult rats the serotonergic neurons are "pruned" yet the cell bodies remain intact.

Interestingly, we have also observed that virtually all of the medullary neurons which contain both substance P and serotonin are destroyed by the 5,7 DHT treatment, yet neurons and terminals that appear to contain only substance P are not affected at all. In view of the large depletion of serotonin content and medullary substance P immunostaining it is somewhat surprising that substance P content is not similarly reduced in the spinal cord, medulla or midbrain when measured by radioimmunoassay. The 5,7 DHT treatment does reduce TRH content in the spinal cord by 50% indicating the destruction of TRH-serotonin neurons.

The observation that the substance P content remains constant, even with the complete and permanent destruction of the substance P-serotonergic neurons, suggests that either these neurons contribute relatively little to the total substance P content or that reinnervation occurs to take the place of the missing terminals.

31.6 THE FORMATION OF CHOLINERGIC AND ELECTRICAL SYNAPSES BY RAT SYMPATHETIC NEURONS IN VITRO. D. Higgins*, L. Iacovitti+, T.H. Joh+ and H. Burton. Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110. +Lab. Neurobiol. Cornell Univ. Med. Coll., New York, NY 10021.

We have reported (Higgins & Burton, Neuroscience, in press) that sympathetic neurons from 21 day rat fetuses form electrotonic synapses when they are maintained in dissociated cell culture in a serum-free, chemically-defined medium (N_2, Bottenstein & Sato, PNAS 76:514-517, 1979). In these earlier experiments, the neurons received no exposure or a minimal exposure (< 2 hr) to a serum-containing medium (SM) (25% human placental serum, 10% chick embryo extract). We have now examined the effect of varying the length of exposure to SM on the properties of these neurons. Four groups of cultures of dissociated sympathetic neurons were established; group I was plated in N_2 supplemented with trypsin inhibitor (0.25%, 2 hrs) and then was maintained in N_2; group II was exposed to SM for 2 hrs and then was maintained in N_2; group III was exposed to SM for 48 hrs and then maintained in N_2; group IV was plated and maintained in SM. Fluorodeoxyuridine (10 µm) was used to kill non-neuronal cells. Choline acetyltransferase (CAT) activity ($\bar{X}$ ± SEM) was measured in monolayer cultures. Electrophysiological experiments and immunocytochemical staining for tyrosine hydroxylase were done during the 3rd and 4th weeks in vitro on neurons maintained on micro-islands of collagen (to enhance the detection of synapses).

In groups I & II only electrotonic synapses were observed; no CAT activity was detected (< .05 pmoles acetylcholine formed/neuron/hr) at either 3 or 6 weeks in vitro in group II. In group IV only chemical, cholinergic synapses were observed; the CAT activities were 2.2 ± 0.4 (3 weeks) and 9.0 ± 2.2 pmoles/neuron/hr (6 weeks). In group III both electrical and chemical, cholinergic synapses were observed; the CAT activities were 0.36 ± .02 (3 weeks) and 0.50 ± .07 pmoles/neuron/hr (6 weeks). In all 4 groups, more than 95% of the neurons were found to contain tyrosine hydroxylase molecules within their perikarya. Furthermore, in group III some of the neurons which contained tyrosine hydroxylase communicated with other neurons by means of both electrical and cholinergic synapses. We conclude: 1) that some neurons in vitro can simultaneously express parts of three different synaptic communication systems (cholinergic, catecholaminergic, electrical); 2) that even a brief exposure (48 hrs) to a cholinergic inducing medium is capable of causing a very long-lasting (6 wk) change in the properties of sympathetic neurons maintained in N_2. (Supported by NIH Research Grants NS 14416 and NS 09809 and a Fellowship from the Missouri Heart Association.)

32.1 COLOCALIZATION OF SUBSTANCE P, ACETYLCHOLINESTERASE, MUSCARINIC RECEPTORS AND ALPHA-BUNGAROTOXIN BINDING SITES IN THE RAT INTERPEDUNCULAR NUCLEUS. A. Rotter and D.M. Jacobowitz. Dept. of Pharmacology, Univ. of Calif., Irvine 92717 and Lab. of Clinical Science, NIMH, Bethesda MD 20205.

The interpeduncular nucleus (IPN) is a midline structure which receives a major, bilateral axonal input arising from the habenulae and passing through the fasciculi retroflexi. The evidence now available indicates that the neurons which make up this pathway contain acetylcholine (ACh) and substance P (sP). The presence of both neurotransmitters in the IPN raises the possibility of an interaction between the converging cholinergic and sP-containing systems. In order to clarify the spatial relationship between the two systems we have localized acetylcholinesterase (AChE) by acetylthiocholine histochemistry, sP by immunofluorescence methods and cholinergic receptors by autoradiography of receptor-bound tritiated quinuclidinyl benzilate or iodinated alpha-bungarotoxin (α-BuTX). The results have revealed considerable complexity in the spatial organization of the various neurochemically defined systems.

We have used the localization of AChE to define several zones of intense staining. In the rostral part of the IPN there is moderately high staining distributed uniformly throughout the nucleus. Further caudally, dense bands of staining are present as lateral zones (LZ) of the IPN which border on the medial lemniscus. The LZ is separated from a moderately stained median zone (MZ) by a lightly stained perivascular zone (PZ) which coincides with the previously described area containing crest synapses. Capping the MZ is a well demarcated region of densely stained neuropil extending to, but not continuous with the dorsal tips of the LZ. At the caudal end of the IPN intense AChE is found only in a narrow layer at the ventral margin of the nucleus. sP is present in high concentrations in the LZ and it's distribution is identical to that of AChE. The distribution pattern of muscarinic receptors and α-BuTX binding sites within the IPN correspond closely to that of AChE. High concentrations of both receptors are found in the LZ, MZ and the dorsal cap whereas the PZ is unlabeled. In addition, islands of high density labeling are found immediately lateral to the dorsal tip of the LZ. The receptors are localized postsynaptically since bilateral destruction of the habenulae does not diminish receptor density or change their pattern of distribution.

The results provide a morphological basis for an interaction between ACh and sP-containing axon terminal within the IPN, raise the possibility of nicotinic acetylcholine receptor function being modulated by sP and support the hypothesis that sP activity is terminated by AChE mediated hydrolysis.

32.2 INTERRELATIONSHIP BETWEEN SEROTONINERGIC AND SUBSTANCE Pergic SYSTEM IN RAT BRAIN. P. Savard*, Y. Mérand*, P. Bédard, J.H. Dussault* and A. Dupont, Département d'Endocrinologie Moléculaire, CHUL and Département de Neurobiology, Hôpital de l'Enfant Jésus, Québec, Canada.

Thyroid hormone deficiency at birth is known to cause irreversible marked impairment of brain differentiation and lead to cretinism. Cell differentiation and synapse formation have been shown to be retarted in the hypothyroid state and accelerated by hyperthyroidism. Neonatal hypothyroidism led to a marked increase of substance P content mainly in nuclei known to be involved in brain substance Pergic system. Such enhancement was completely reversed by thyroxin treatment. Recently we also demonstrated that serotonin (5-HT) content was increased by postnatal thyroidectomy. On the other hand, coexistence of 2 putatives neurotransmitters, the biogenic amine 5-HT, and the polypeptide substance P (SP) has been demonstrated in some neurons of the CNS of the rat by immunofluorescence and various histochemical techniques. The aim of the present experiments was to investigate if the increased effect of neonatal thyroid deficiency on substance P was related to the high serotonin content in brain nuclei. Rats were made hypothyroid by injection of 125 μCi of carrier-free ^{131}I on the first day after birth. Half of this group of animals were subsequently treated with thyroxine (T_4). A third group of littermates were permitted to mature normally. For study the relationship of SP and 5-HT, we decreased the 5-HT metabolism with parachlorophenylalanine (PCPA) (i.p. 300 mg/kg) 48 and 24 hours before the sacrifice at day 45. Subsequently, SP content was measured by radioimmunoassay. The PCPA treatment increase the substance P content in nucleus dorsalis raphes and nucleus medialis raphes, the brain regions containing the cells bodies of 5-HT. Moreover, this treatment blocked completely the increased effect of neonatal thyroid deficiency on substance P content of brain nuclei, mainly substantia nigra, pars reticulata and nucleus interpeduncularis; both structures are involved in the better defined striatonigral and habenulo-interpeduncular tracts. The increase of substance P content of brain nuclei in postnatal thyroidectomy seems to be serotonin-dependent. This is the first demonstration of a pathophysiological interaction between substance P and serotonin at the brain level.

32.3 MODULATION OF SUBSTANCE P CONTENT OF RAT BRAIN NUCLEI FOLLOWING PHARMACOLOGICAL MANIPULATION OF SEROTONINERGIC SYSTEMS. Nicholas Barden*, Michel Daigle*, Vallier Picard* and Thérèse Di Paolo. (Spon. P. Leung). MRC Group in Moleculcar Endocrinology, Le Centre Hospitalier de l'Université Laval, Québec, G1V 4G2

Since substance P (SP) has been demonstrated to be co-localized with serotonin (5-HT) in the descending raphe system we have studied the effects of alterations of 5-HT metabolism in this and other brain areas. Brain nuclei were punched from frozen 300μm slices of rat brain and extracted with 0.1M $HCLO_4$ or 2M-acetic acid prior to assay, respectively, of 5-HT content by HPLC with electrochemical detection or SP content by specific radioimmunoassay. Ten days after injection of rats with the 5-HT neurotoxin, p-Cl-amphetamine (PCA, 10 mg/kg B.W., i.p.) or 3 days after 5-HT synthesis blockade with p-Cl-phenylalanine (PCPA, 300 mg/kg B.W., i.p.), the 5-HT content of all brain nuclei studied was reduced by a mean of respectively 50% and 81%. In PCA treated animals, no significant changes in SP content were noted, whilst following PCPA administration, the SP content of nucleus interpeduncularis was increased by 84% and that of substantia nigra pars reticulata was increased by 88% when compared to normal animals. Blockade of 5-HT receptors by methysergide (15 mg/kg for 5 days) did not significantly change 5-HT levels or turnover but resulted in 50-200% increases in the SP content of 10 of the 28 brain nuclei studied. Significant decreases in the SP content of numerous areas were seen following treatments (pargyline 30 mg/kg, 5-HTP 50 mg/kg or a combination of the two) which simultaneously increased 5-HT levels. These results ilustrate the modulation of distinct SP-containing systems of the rat brain by pertubation of central serotoninergic pathways and indicate a reciprocal relationship between the SP and 5-HT concentrations of numerous brain nuclei.

32.4 MOTOR EFFECTS OF INTRATHECAL INJECTIONS OF SUBSTANCE P AND 5-HT IN CHRONIC SPINAL RATS. L. Tremblay*, R. Maheux*, P. Bédard and M. Filion. Laboratoire de Neurobiologie, Hôpital de l'Enfant-Jésus, 1401, 18e Rue, Québec, Qué. G1J 1Z4.

Substance P (SP) was administered intrathecally (in the spinal subarachnoid space) to rats hypersensitive to intrathecal 5-HT and to intraperitoneal 5-HTP 15 days following complete spinalization or neurotoxic destruction of 5-HT pathways by 5-7-DHT. Large doses of SP (0.1 to 1.0 mg) depressed the spontaneous EMG activity of the paralyzed hindlimbs, blocked or prevented the large increase of EMG activity produced by 5-HT (or 5-HTP), and depressed or abolished nociceptive reflexes. These effects lasted at least 24 hours and up to several days after a single large dose. Smaller doses (below 0.1 mg) greatly increased the EMG activity. The increased activity was sometimes abruptly interrupted by a period of extinction lasting minutes. Thereafter it returned slowly to normal. During this time and for more than 24 hours after the administration of SP the responses to intrathecal 5-HT were greatly reduced; nociceptive reflexes, however, were not abolished. A depolarization block very likely explains the depressant action of large doses of SP. Indeed smaller doses induce a strong excitatory effect which sometimes leads to a block of short duration. However the depressant action of SP on the excitability of spinal neurons by 5-HT cannot always be explained by depolarization blocks since it is present when the EMG activity has returned to normal, 24 hours following the administration of SP. In conclusion SP has long term effects on the excitability of spinal neuron by 5-HT.

32.5 SYNAPTIC RELATIONS BETWEEN CORTICAL AND DOPAMINERGIC AFFERENTS AND ENKEPHALIN-CONTAINING NEURONS IN THE NEOSTRIATUM. J.J. Bouyer*, V.M. Pickel, T.H. Joh, R.J. Miller and D.J. Reis (SPON: B. Judd). Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 and Dept. of Pharmacology and Physiological Sciences, Univ. of Chicago, Chicago, IL 60637

Pharmacological studies have shown that L-glutamate, the presumed neurotransmitter of cortical afferents to the neostriatum, may presynaptically release dopamine from nigrostriatal axons and also potentiate apomorphine-induced stereotypies (Scatton et al., Br. Res. 232:331, '82). By combining anterograde degeneration with electron microscopic immunocytochemistry, we sought to determine the neuroanatomical relation between cortical afferents, tyrosine hydroxylase (TH)-labeled dopaminergic terminals, and intrinsic neurons containing the morphine-like pentapeptide, Met^5-enkephalin in the neostriatum. Specific antisera to TH and to Met^5-enkephalin were localized by the peroxidase-antiperoxidase method in the neostriatum of adult rats 1-4 days following unilateral removal of the cerebral cortex. By light microcopy, varicose processes showing TH immunoreactivity had a similar intensity and distribution in the neostriatum homolateral and contralateral to the cortical ablation. In contrast, enkephalin-like immunoreactivity (ELI) appeared significantly more intense in perikarya and processes in the cortically deafferented versus intact neostriatum. By electron microscopy, about 35% of the total degenerating terminals showed an apposition of plasma membranes with terminals containing TH immunoreactivity. However, in most cases, specialized densities were not detected between the degenerating and TH-labeled axon terminals. Both the degenerating and TH-labeled terminals also formed asymmetric and symmetric contacts with unlabeled dendrites and dendritic spines. Electron microscopic analysis of degenerating boutons in relation to profiles showing ELI, indicated that enkephalin-containing dendrites received cortical afferents. The degenerating and enkephalin-labeled terminals were frequently in close proximity, but formed synapses predominately with unlabeled dendrites. These studies are consistent with a presynaptic interaction between cortical afferents and dopaminergic terminals, and further suggest that the enkephalinergic neurons may be stimulated by cortical afferents.

32.6 FUNCIONAL INTERACTIONS BETWEEN CHOLECYSTOKININ AND DOPAMINE: A PHARMACOLOGICAL APPROACH. S.Govoni, E.Faccini*, G.Pasinetti*, C.Missale*, A.Rossi*, P.F. Spano*, M.Trabucchi. Dept. of Pharmacology and Pharmacognosy, University of Milan, Italy.

Recent immunocyto-chemical and electrophysiological studies indicate the existence of a functional relationship between cholecystokinin (CCK) and dopaminergic transmission. In order to gain more information on the interaction between CCK and dopaminergic neurons we measured the concentrations of Cholecystokinin immunoreactive material (CCK-IR) in structures of the nigro-striatal and of the mesolimbic dopaminergic system after pharmacological manipulation of dopamine synthesis and storage. In the same brain structures dihydroxyphenylacetic acid (DOPAC) concentrations were also measured after s.c. injection of Caerulein, a peptide having structure and biological activities similar to those of CCK, but more resistant to enzymatic cleavage.

Our results show that a treatment depleting Dopamine decreases the CCK-IR content in striatum and n.accumbens. The content of CCK-IR is decreased by 37% in rat striatum 24 hrs. after reserpine injection (6 mg/Kg s.c.). This decrease fails to occur in n.accumbens. The intravenous injection of α-methyl-para-tyrosin (α-MPT) decreases CCK-IR both in striatum and n.accumbens. On the other hand the subcutaneous injection of small doses of caerulein (20-50 ug/Kg) causes an almost complete reduction of the spontaneous motor activity and slightly reduces DOPAC content in striatum and n.accumbens. However at variance with the hypomotility induced by low doses of apomorphine, the decreased motor activity following caerulein injection (20 ug/Kg s.c.) is not antagonized by haloperidol pretreatment (50 ug/Kg s.c.).

Our results support the existence of a pharmacologically and, perhaps, physiologically relevant interaction between CCK and dopaminergic neurons. Nevertheless the difference between caerulein and apomorphine induced hypomotility indicate the need for further investigations of the neuronal mechanisms mediating caerulein actions after peripheral injection. It is tempting to speculate that the potent behavioural effects of CCK and CCK related peptides may be of some clinical relevance.

32.7 EFFECTS OF A LONG-TERM CHLORDIAZEPOXIDE ADMINISTRATION ON BIOGENIC AMINES CONTENT AND GAD ACTIVITY IN CAT BRAIN. A.G. Roberge, L. Vachon*, and N. Tremblay*. Dép. de Nutrition humaine (FSAA), et Dép. de Biochimie (Médecine), Université Laval, Ste-Foy, Québec, Canada, G1K 7P4.

In an attempt to precise the central neurochemical effects of chlordiazepoxide hydrochloride (CDP) on a neuroanatomical basis, cats underwent a 7 consecutive days treatment with CDP at doses of 0.4, 10.0, and 20.0 mg/kg/day, per os, and were killed 18 hr after the last administration. The serotonin (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), noradrenaline (NA), and dopamine (DA) endogenous levels were measured in 12 brain areas. Moreover, the enzymatic activity of glutamic acid decarboxylase (GAD) was assayed in some brain areas.

Few effects on the 5-HT, 5-HIAA, and NA contents were observed with a 0.4 mg/kg CDP treatment. These changes were found in the piriform lobe (amygdala), hippocampus, mesencephalon, and mesencephalon raphe nuclei. Moreover, the DA concentration was not affected in any structure assayed. On the other hand, the changes induced by the 10 and 20 mg/kg CDP doses were extended to many more structures. The effects observed after the two doses generally included an increased 5-HT content, a decreased 5-HIAA level, a high 5-HT:5-HIAA ratio, and a rised NA and DA concentrations. However, in some structures, after CDP administration, the NA level was found lowered, whereas the 5-HIAA content was enhanced.

GAD activity was reduced with a 0.4 mg/kg CDP treatment in the ventral mesencephalon, whereas the highest CDP dose 20 mg/kg induced an increased enzyme activity in this brain area. Moreover, the enzymatic activity was enhanced after both the 10 and 20 mg/kg CDP treatments in the hypothalamus.

These results show that a long-term CDP administration in cats induces localized changes in the endogenous content of biogenic amines at low doses, but much more extended effects were observed at high doses. They also reaveal that GAD activity is selectively affected by CDP treatment. Moreover, these findings are in agreement with a reducing action of benzodiazepines on the turnover and release of biogenic amines in the CNS, but also suggest that certain discrete areas are more involved by these changes, thus dissociating them from the rest of brain.

Finally, the variation observed in GAD activity also suggest an interaction between two types of neurotransmitters: biogenic amines and γ-aminobutyric acid (GABA) following a CDP treatment (Supported by a Grant (MA-6590) of the Medical Research Council of Canada. L. Vachon is holder of a studentship from the Fonds de la Recherche en Santé du Québec).

32.8 MECHANISM OF BENZODIAZEPINE ACTION ON RETINAL DOPAMINE NEURONS. C. W. Kamp and W. W. Morgan, Dept. of Anatomy, The Univ. of Texas Health Sci. Ctr. at San Antonio, Texas 78284.

Intraocular flurazepam (FLU, 0.5 or 1.0 μmole/eyeball), a water soluble benzodiazepine (BZ), caused a highly reproducible, dose-dependent inhibiton of the light-evoked enhancement of retinal dopamine (DA) synthesis (Kamp and Morgan, Eur. J. Pharmacol. 77: 343, 1982). The barbiturates, another group of CNS depressants, were shown previously to reduce retinal DA activity by potentiating a well-characterized, inhibitory GABAergic input to the dopaminergic cells. Since the BZ act in other areas of the CNS by enhancing GABAergic transmission, we proposed that the BZ reduced retinal DA activity by potentiating the GABAergic input to these cells. The results of studies to test this hypothesis are presented here.

Intraocular injections of the selective GABA antagonists, picrotoxinin or bicuculline methiodide were unable to reverse the actions of FLU even though the dosages proved potent enough to block the ability of the GABA agonist, muscimol (MU, 1.5 nmole/ eyeball), to suppress light-enhanced DA synthesis. A submaximal dosage of FLU was unable to enhance the inhibitory effects of a dosage of MU which could be readily potentiated by the barbiturates. Finally, the BZ antagonist, RO 15-1788 (4 μg/eyeball or 3.0 mg/kg, i.v.) could not block the FLU-mediated inhibition of DA sythesis.

Taken together these results imply that the effects of the BZ on retinal DA function may not be mediated by the classical GABA-linked BZ receptor found in other areas of the CNS or by a BZ receptor at all. (This project was supported by a PMA Foundation Grant to CWK and DA-00755 and NS14855 to WWM.)

32.9 DIFFERENT ADAPTIVE CHANGES OCCURRING IN CEREBRAL NORADRENERGIC AND SEROTONERGIC NEURONS AFTER PROLONGED STIMULATION OF GABA RECEPTORS. B. Scatton, B. Zivkovic*, L. Rouquier*, J. Dedek* and G.Bartholini*
Synthélabo-LERS, Research Dept. Paris, France.

Acute administration of the specific GABA receptor agonist progabide (100-1200 mg/kg ip) enhanced DOPEG-SO_4 and MOPEG-SO_4 levels and the rate of α-methyl-p-tyrosine-induced disappearance of norepinephrine (NE)-an effect antagonized by picrotoxin- in the hypothalamus, septal areas and olfactory tubercle but not in other NE-rich brain areas. Similar changes were observed in the hypothalamus after acute administration of other GABA agonists e.g. muscimol, depamide, THIP, kojicamine but not baclofen suggesting the involvement of a GABA-A type receptor. The GABA mediated enhancement of NE turnover does not appear to be connected to a direct effect of GABA on NE cell bodies as infusion of muscimol (0.1-1 µg) into the locus coeruleus failed to affect NE turnover ; it is most probably mediated indirectly via GABAergic synapses involved in the local circuits regulating noradrenergic neuron activity.

Enhancement of GABA synaptic activity decreases striatal serotonergic transmission. Thus, acute administration of progabide (200-600 mg/kg ip) decreases 1) the α-propyldopacetamide-induced disappearance of serotonin (5HT), 2) the amine accumulation caused by pargyline, 3) the accumulation of 5HTP following NSD-1015 in the rat striatum but not in other 5HT-rich brain areas.

After repeated treatment for 14 days with progabide (400 mg/kg, ip, bid), the initial increase in hypothalamic and septal NE utilization and DOPEG-SO_4 levels was no longer observed (tolerance). In contrast, repeated progabide treatment decreased striatal 5HTP accumulation more effectively than the acute treatment (reverse tolerance). Moreover, while the acute treatment failed to affect 5HT synthesis in cerebral cortex, repeated treatment with progabide decreased it. Tolerance with respect to increase in NE turnover is not connected to induction of drug-metabolizing enzymes or development of GABA receptor subsensitivity as 1) the progabide effects on 5HTergic transmission are preserved or even enhanced during repeated treatment, 2) no-cross tolerance between progabide and THIP or muscimol was observed. This tolerance is more likely related to adaptive changes of the mechanisms regulating NE release. In this respect however, the failure of repeated progabide treatment to affect the ability of clonidine to decrease hypothalamic or septal NE turnover excludes the occurence of a subsensitivity of α_2 adrenoceptors.

In conclusion, the present results indicate that cerebral NEergic and 5HTergic systems undergo opposite adaptive changes after prolonged stimulation of GABA synaptic activity. These differential adaptive changes may be connected to the different nature of the neuronal circuits involved in the regulation of NE and 5HT neuronal activity.

32.10 ACETYLCHOLINE INHIBITS DOPAMINE-SENSITIVE ADENYLATE CYCLASE OF RAT STRIATUM. M. Olianas*, P. Onali, N. H. Neff and E. Costa. (SPON: J.C. Byrd). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

We have recently shown that striatal muscarinic receptors are coupled in an inhibitory manner to adenylate cyclase (a.c.) and have suggested that occupancy of these receptors by endogenous effectors may modulate the sensitivity of this enzyme system to stimulatory inputs. In order to verify this possibility, we investigated the effect of acetylcholine (ACh) on the dopamine (DA)-sensitive a.c. assayed in a lysed synaptosomal preparation of rat striatum. In the presence of 20 µM GTP and 0.5 mM MgATP, DA stimulated the enzyme activity in a dose-dependent manner, with an apparent EC50 of 3-4 µM with a maximal effect (two fold increase) at a concentration of approximately 50 µM. When ACh was included in the reaction mixture, the stimulation of a.c. by DA was attenuated. Dose-response curves of a.c. activity to DA (1-100 µM), carried out in the absence and in the presence of 100 µM ACh, showed that ACh inhibited the net stimulation of a.c. by approximately 30-40% at all the concentrations of DA tested. Double reciprocal plots of the enzyme activity revealed that ACh decreased the Vmax of the DA-stimulated enzyme without significantly changing the Ka for DA. The inhibitory effect of ACh was completely antagonized by 2 µM atropine, which failed to affect the stimulation of a.c. by DA. Dose-response curve of a.c. to ACh (0.05-500 µM), carried out in the absence and in the presence of 3 µM DA, showed that the inhibitory effect of ACh on the DA stimulated activity was dose-dependent with an apparent EC50 of approximately 0.5 µM and reached a maximum at a concentration of 10 µM. ACh (100 µM) did not inhibit the stimulation of striatal a.c. by L-phenylisopropyladenosine (0.5 to 200 µM). These results indicate that occupancy of striatal muscarinic receptors by ACh inhibits the activation of a.c. by DA in a non-competitive manner. The opposite effects exerted by these neurotransmitters on the striatal a.c. system may be a part of the functional balance between the dopaminergic and the cholinergic inputs at the level of the basal ganglia.

32.11 ENHANCEMENT OF THE HALOPERIDOL-INDUCED SUPPRESSION OF FOOD-REINFORCED LEVER-PRESSING BEHAVIOR BY INTERACTION WITH α_2-ADRENORECEPTORS. J. A. Engel, K. Johannessen*, S. Liljequist* and M. Goldstein. Department of Pharmacology, University of Göteborg, Box 33031, S-400 33 Göteborg, Sweden, and Department of Psychiatry, New York University Medical Center, New York, N.Y. 10016.

Recent evidence indicates that the noradrenergic neuronal inputs regulate the activity of the dopaminergic neuronal systems. We have recently found that drugs affecting the α_2-adrenoreceptors alter the synthesis and turnover rate of the nigrostriatal dopamine-system. Thus the α_2-receptor antagonists SKF 64139 (7,8-dichloro-1,2,3,4-tetrahydroisoquinoline) and SKF 72223 (5,8-dimethoxy-1,2,3,4-tetrahydroisoquinoline) increased the accumulation of DOPA and decreased the disappearance of dopamine following inhibition of its synthesis. The significance of these biochemical findings was further tested in behavioral experiments.

Inhibition of catecholamine synthesis with α-methylparatyrosine (α-MPT) was previously shown to potentiate the behavioral suppression caused by dopamine-receptor antagonists, in all probability due to inhibition of the compensatory increase in dopamine turnover induced by these drugs. In the present study we investigated the effects of SKF 72223 and the α_2-adrenoreceptor agonist clonidine on the haloperidol-induced suppression of food-reinforced lever-pressing behavior (fixed ratio 40:1) in rats. Small, behaviorally inactive, doses of both SKF 72223 and clonidine were found, in analogy with α-MPT, to enhance the haloperidol-induced behavioral effects. These results indicate that α_2-adrenoreceptor mechanisms may be involved in the regulation of dopaminergic activity. It is also suggested that the TIQ derivative SKF 72223 and clonidine may exert their effects on α_2-adrenoreceptors associated with different norepinephrine systems.

32.12 ON-LINE DETECTION OF EXOCYTOSIS FROM ADRENAL CHROMAFFIN CELLS. B.G. Livett, P. Boksa* and †T.D. White, Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Québec, and †Dept. Pharmacology, Dalhousie University, Halifax, N.S. Canada.

The release of neurotransmitters and hormones from neuronal and endocrine cells is conventionally measured by sequential assays of the released transmitter or hormone by chemical, radiochemical or immunoassay techniques, following stimulation of the cells. The exocytotic release of catecholamines and opiates from adrenal chromaffin cells presents few problems when the cells are maintained as monolayer cultures firmly attached to a collagen substrate (Livett et al, Nature, 289:317-319, 1981) but is more difficult with cells in suspension culture which require centrifugation or filtration to separate the cells from the medium. These separation procedures are unsatisfactory in that they often result in high basal release values, take considerable time (2-3 min), and may damage and/or activate the cells. Chromaffin vesicles contain in addition to catecholamines (CA) large amounts of ATP which may be used as a sensitive marker for exocytosis. Adult bovine adrenal chromaffin cells prepared by collagenase digestion and Percoll fractionation (Livett et al, Nature, 278:256-257, 1979)were suspended in DMEM + 10% fetal calf serum and assayed in this medium for release of ATP, either immediately or after maintenance in suspension culture for 24h, by a modified firefly-tail luciferin-luciferase luminescence technique (White, J. Neurochem., 30: 329-336, 1978). Light output (maximum peak height) was proportional to ATP concentration over the range (10^{-9}-10^{-7}M). With this technique we were able to observe the initial time course of release of ATP during (rather than following) stimulation with various agonists, and its modification by a variety of antagonists and neuromodulators. Release of ATP induced by ACh, nicotine, K^+ and veratridine was Ca^{++}-dependent. The release of ATP paralleled that of CA and both showed desensitization at high agonist concentrations. SP produced an immediate and longlasting inhibition (IC_{50} 10^{-6}M) of nicotine- and ACh-evoked ATP secretion while having no effect on veratridine or K^+ evoked release. In contrast, Met-enkephalin and a number of opioid peptides were 100-1000 fold less potent than SP. Neither SP nor the opioids had any effect on basal release of ATP. The most potent opioid peptide was the endogenous "big" Met-enkephalin, the docosapeptide (BAM-22P) (Mizuno et al, BBRC, 97: 1283-1290, 1980). BAM-22P produced an enhanced and prolonged (20 min) basal release of ATP and also inhibited nicotine stimulated release of ATP by 42% at a concentration ($5x10^{-5}$M) where Met-enkephalin had no significant effect. This technique now provides a convenient inexpensive and rapid means of assessing the on-going interaction of drugs and endogenous neuropeptides with the process of secretion.

32.13 FAILURE OF ADENOSINE ANALOGUES TO PRODUCE BENZODIAZEPINE-LIKE SPECIFIC BEHAVIORAL EFFECTS. T. Gherezghiher*, D. Spencer, Jr., F. Elmesallamy, and H. Lal (SPON: I.M. Korr). Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, Texas 76107.

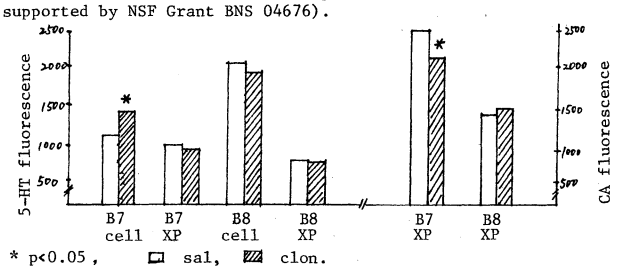
The purines, inosine and hypoxanthine, have been hypothesized to be endogenous ligands for the benzodiazepine receptor (Skolnick, et.al., Fed. Proc., 39: 3050, 1980). Adenosine has also recently been hypothesized to mediate the behavioral effects of benzodiazepines, since benzodiazepines inhibit adenosine uptake into cortical synaptosomes (Phillis, et.al., Gen. Pharmac., 12: 67, 1981) and adenosine-stimulated cAMP accumulation in-vitro (Traversa and Newman, Bioch. Pharm., 28: 2363, 1979). However, in-vivo evaluation of these ligands in terms of their similarity of behavioral effect to the benzodiazepines has not yet been carefully studied.

Blockade of the interoceptive discriminable stimuli produced by pentyletetrazol (PTZ) is a sensitive behavioral assay for the anxiolytic action of benzodiazepine activity (Lal, H. and Shearman, G., Ann. Rep. Med. Chem., 15: 15, 1980). We employed this assay to determine in-vivo interaction of adenosines with diazepam. Male hooded rats were trained in the drug discrimination procedure on an FR 10 food reinforcement schedule to press one lever when injected with PTZ (20 mg/kg) and another lever when injected with saline. After a reliable PTZ-saline discrimination was learned, prior injection of diazepam reliably blocked IDS produced by PTZ and the subjects chose the saline lever. When the adenosine analog 2-chloro-adenosine (2CA) and L-phenylisopropyl adenosine (L-PIA) were tested for benzodiazepine-like activity on this test, neither L-PIA (0.04 - 0.16 mg/kg) nor 2CA (0.16 - 0.32 mg/kg) blocked drug lever selection in the PTZ-injected rats in doses up to those producing profound sedation. These results indicate that activation of the adenosine A_1 receptor (Daly, et.al., Life Sci., 28: 2083, 1981) which leads to inhibition of adenylate cyclase and a fall in intracellular cAMP levels, does not produce benzodiazepine-like behavioral effects. It is therefore unlikely that inhibition of adenosine uptake and of adenosine-stimulated cAMP accumulation mediate the therapeutic efficacy of benzodiazepines in treating anxiety.

32.14 EFFECTS OF CLONIDINE ON MIDBRAIN RAPHE NEURONS IN RATS. E.H.Y. Lee* and M.A. Geyer, Dept. of Neurosciences and Psychiatry, Univ. of California, San Diego, School of Medicine, La Jolla, CA 92093.

By using our quantitative cytofluorimetry technique, we have previously reported that the dopaminergic agonist apomorphine selectively increased the intracellular level of serotonin (5-HT) in the dorsal raphe (B7) without affecting the median raphe (B8) (Lee, E.H.Y. & M.A. Geyer, Brain Res. Bull., In Press). In order to assess the influence of noradrenergic inputs to serotonergic neurons, we examined the effects of the alpha-adrenergic agonist clonidine on these raphe nuclei. Briefly, a measure of fluorescence fading using a computerized microspectrofluorimeter enables us to discriminate changes in 5-HT from changes in catecholamines and to discriminate intracellular from extracellular amines (Geyer et al., J. Pharm. Expl. Ther. 207:650-667, 1978). Forty-five minutes after intraperitoneal injections of saline or clonidine (50 µg/kg), male Sprague Dawley rats (225-250 g) were sacrificed, the midbrain raphe area was removed, freeze-dried, treated with formaldehyde, and embedded in paraffin. Microscopic measures were made in both the dorsal and median raphe nuclei in 8 micron sections. The results showed that as with apomorphine, clonidine elevated the intracellular 5-HT content in B7 significantly with no appreciable effect on serotonergic cells in B8. Conversely, clonidine significantly decreased extraperikaryal (XP) CA levels in B7, suggesting some alteration in CA release and/or turnover rate in this nucleus while CA levels in B8 were not affected.

The possible relevance of the ventral noradrenergic projections from locus coeruleus to B7 to the effects of clonidine is considered. Further studies including both clonidine and the noradrenergic antagonist piperoxane are in progress to determine the anatomical pathway and mechanism responsible for the effects of clonidine on dorsal raphe neurons. (This work was supported by NSF Grant BNS 04676).



32.15 NALOXONE-AMPHETAMINE INTERACTIONS: BIOCHEMICAL EFFECTS IN DOPAMINE TERMINAL REGIONS. Craig D. Applegate*, Ronald Kuczenski and Nancy J. Leith. (SPON: D. Schmidt). Dept. Pharmacology, Vanderbilt University School of Med., Nashville, TN 37232.

The ability of naloxone to antagonize the locomotor stimulant effects of low doses of amphetamine (AMPH) is well documented (Neuro. Sci. Abs., 6, 37, 1980). However, biochemical correlates for this pharmacological interaction have not been well defined. As the locomotor stimulant effects of AMPH have been shown to be dependent on the integrity of the mesolimbicocortical dopamine system (Brain Res., 201, 107, 1980), and as opiate agonists and antagonists have been shown to affect monoamine synthesis and release (J. Pharm. Pharmac., 30, 613, 1978) we have explored the biochemical consequences of naloxone-AMPH interactions in the mesolimbicocortical and nigrostriatal dopamine systems in an attempt to establish biochemical correlates for the behavioral interaction of these compounds.

Male Sprague-Dawley rats (N = 36) were administered saline or naloxone (1.0 mg/kg) immediately followed by saline or AMPH (1.0 mg/kg). Thirty minutes following drug administration, animals were sacrificed. The corpus striatum, substantia nigra, prefrontal cortex and nucleus accumbens were subjected to HPLC (electrochemical detection) analysis using a modification of the methods of Magnusson et al., J. Chromatog., 221, 1980. Using this technique we were able to determine the utilization of dopamine and serotonin in the brain areas examined.

Administration of 1.0 mg/kg of AMPH resulted in a characteristic increase in dopamine levels and decrease in the levels of its metabolites in the striatum and n. accumbens. Naloxone alone was not observed to affect any measure of dopamine biochemistry in these regions nor did naloxone alter the effects of AMPH on serotonergic function. However, combined injections of naloxone and AMPH resulted in a reversal of the AMPH induced decline in HVA levels in the n. accumbens (p = .019). This reversal of AMPH's effects by naloxone was not observed in any other brain region examined. The selective reversal in aspects of dopamine biochemistry in the n. accumbens following injections of naloxone and AMPH suggests this brain region may serve as the neural substrate for the behavioral effects of combined injections of these compounds.

32.16 THE EFFECTS OF CHRONIC OPIATE TREATMENT ON α_2-ADRENERGIC RECEPTOR SYSTEMS. L. M. Vicentini, R. J. Miller* and M. J. Robertson*. Dept. of Pharmacological and Physiological Sciences, Univ. of Chicago, Chicago, IL 60637.

A growing body of literature suggests that opiate and α_2-adrenergic systems interact. For example, α_2 and opiate receptors appear to be colocalized in certain brain areas. Moreover clonidine, an α_2-agonist, has been shown to suppress some symptoms associated with opiate withdrawal in dependent subjects. Finally, a recent study (1) employing ^{3}H-clonidine (^{3}H-Clo) has indicated an increase in the number of α_2-receptors in the cerebral cortex of morphine addicted rats. We further investigated the effect of chronic opiate treatment on α_2-receptors by examining the binding of ^{3}H-yohimbine (^{3}H-YOH), an α_2-antagonist, to the cerebral cortex and whole kidney of morphine-addicted rats. In addition, we studied ^{3}H-YOH binding to NCB-20 neuroblastoma x glioma cells after chronic opiate treatment. This cell line possesses opiate receptors. Male Sprague-Dawley rats (250-300g) were implanted with 3 morphine pellets (75 mg base/pellet) and were sacrificed 72 hr later. The cerebral cortex and kidney were processed following the method of Perry and U'Prichard (2). NCB-20 cells were incubated with 1 µM etorphine or D-Ala^2, D-Leu^5-enkephalin or 10 µM morphine for 24-48 hr and binding of ^{3}H-YOH was determined by the method of Kahn et al. (3).

TABLE 1

^{3}H-Yohimbine

		Control		Addicted	
	n	K_D	B_{max}(fmol/mgpro)	K_D	B_{max}(fmol/mgpro)
Rat cortex	11	3.69 ± 0.72	66.6 ± 11.30	3.82 ± 0.56	67.22 ± 8.70
Rat kidney	5	2.35 ± 0.17	48.99± 7.37	2.44 ± 0.14	53.82 ±10.50
NCB-20	5	4.50 ± 0.49	73.66± 10.26	4.68 ± 0.69	62.03 ±11.03

Binding determinations using ^{3}H-Clo yielded essentially similar results as those obtained with ^{3}H-YOH. These data indicate that 1) α_2-adrenergic receptors exist on NCB-20 cells and 2) no significant alterations in either α_2-receptor affinity (K_D) or number (B_{max}) after chronic opiate exposure were apparent in any of the systems examined.

32.17 TRANSMITTER INTERACTIONS IN THE CEREBELLUM OF THE RAT. R.S. Flint* and W.J. McBride. Depts. of Psychiatry & Biochemistry, Inst.Psych. Res., Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

Examination of the depolarization-induced release of endogenous amino acids has indicated transmitter roles for GABA, glutamate (Glu) and aspartate (Asp) in the cerebellum of the rat (Flint et al., J. Neurochem. 37: 1425, 1978). Other investigations have implied that acetylcholine (Kan et al., Brain Res. 146: 221, 1978) and norepinephrine (NE) (Bloom et al., Brain Res. 25: 501, 1971) may participate in the process of neurotransmission within this region as well. In order to study the interactions among these putative transmitter systems, we examined the changes in the K^+-stimulated, Ca^{2+}-dependent release of endogenous NE, GABA, Glu, and Asp in response to exogenously added NE, GABA, Glu, Asp, and the cholinergic agonist, carbachol. The cerebella from two adult Wistar rats were removed and sliced longitudinally into 300 x 300 µm sections. These slices were combined and then suspended in Sephadex in polypropylene columns for superfusion. Initially, the K^+ concentration was varied to determine what level would yield a submaximal stimulated release, thus, providing a sufficient range for the detection of either inhibitory or excitatory effects. A K^+ concentration of 30-35 mM was found to be adequate for this purpose. The indicated transmitter candidates were administered individually at a concentration of 100 µM in the superfusion media containing the elevated level of K^+ in both the absence and presence of Ca^{2+}. The stimulated release of NE was significantly potentiated by GABA (130% of control; $p<0.05$); carbachol tended to slightly increase the release of NE (113%) as did Asp (119%; N= 3), while Glu had no effect. However, addition of NE caused a small decrease in the release of Asp (84% of control; N=3) while GABA potentiated its release (290%; $p<0.05$); carbachol had no effect on the release of Asp. GABA also increased the K^+-stimulated release of Glu (150% of control; $p<0.05$). NE and carbachol did not alter Glu release, nor did they effect the stimulated release of GABA. All observed changes were dependent on the presence of Ca^{2+}. The effects on the release of NE by carbachol, GABA, and Asp are presumably mediated through a direct interaction with presynaptic receptors on the terminals of the noradrenergic projection into the cerebellum. However, these data do not rule out interneuronal involvement. The stimulatory effect of GABA, although discordant with electrophysiological studies, is consistent with a previous study in this area of the CNS (Gallo et al., Brain Res. 205: 431, 1981). These results suggest that the transmitter interactions and neural circuitry within the cerebellum may be more complex than previous studies have so far indicated. (Supported by MH 00203 and The Indiana Public Health Trust).

32.18 ACETYLCHOLINE-MEDIATED INHIBITION OF BASAL AND VASOACTIVE INTESTINAL PEPTIDE-STIMULATED ADENYLATE CYCLASE IN RAT GH3 PITUITARY CELLS. J.P. Schwartz, M. Olianas* and P.L. Onali. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

The rat GH3 pituitary cell line has been used as a model system to study the biochemical events required for regulation of prolactin secretion. Many of the agents known to regulate prolactin secretion from anterior pituitary in vivo, including thyroliberin (TRH) and vasoactive intestinal peptide (VIP), also affect prolactin release in this cell line. VIP and TRH have been shown to stimulate adenylate cyclase in both GH3 and anterior pituitary cells: however, the role of the resultant increase of cyclic AMP in the secretion of prolactin has not yet been clearly elucidated. Acetylcholine (ACh) has been reported to inhibit prolactin secretion from GH3 cells and thus offered the possibility to examine further the relationship between adenylate cyclase activation and prolactin secretion. We now report that ACh can inhibit both basal and VIP-stimulated cyclase in GH3 cells, thus supporting the concept that cellular cyclic AMP levels correlate with prolactin secretion rates. VIP stimulated the adenylate cyclase of GH3 cells 11-14 fold, with a K_a of $\sim 2 \times 10^{-8}$M. The inclusion of 100 µM ACh depressed the VIP stimulation of cyclase by 60% in a non-competitive manner: the K_a for VIP in the presence of ACh was 2.5×10^{-8}M. ACh also inhibited basal adenylate cyclase activity, with a maximal inhibition of 35-40%. The K_i for ACh inhibition of basal adenylate cyclase was 3×10^{-7}M and a comparable K_i was determined for the ACh inhibition of VIP-stimulated cyclase. These effects of ACh were blocked by 1 µM atropine, suggesting that ACh is acting through a muscarinic receptor. These results provide support for the concept that activation and/or inhibition of the adenylate cyclase of mammotrophs by neurotransmitters or neuromodulators is directly related to the effects of these agents on prolactin secretion.

32.19 SEROTONERGIC TERMINALS IN THE NUCLEUS TRACTUS SOLITARIUS: ULTRASTRUCTURE AND SYNAPTIC ASSOCIATIONS WITH CATECHOLAMINERGIC NEURONS. V.M. Pickel, J. Chan*, T.H. Joh and A. Beaudet. Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 and Montreal Neurological Inst., McGill Univ., Montreal, Canada.

Fluorescence histochemistry and immunocytochemistry have shown that terminals containing serotonin, 5-hydroxytryptamine (5-HT) are localized within the nucleus tractus solitarius (NTS), including the catecholaminergic neurons of the A2 region. In this study, immunocytochemistry and radioautography are combined in order to determine: (1) the ultrastructural morphology of 5-HT terminals in the NTS and (2) whether the 5-HT terminals form synapses with catecholaminergic neurons in the A2 region. Adult rats were pretreated with a monoamine oxidase inhibitor and subjected to a 2 h intraventricular infusion of 50 nM ^{3}H-5HT. The brains were fixed by intraaortic arch infusion of a mixture of 4% paraformaldehyde and 0.5% glutaraldehyde. Twenty micron vibratome sections were collected throughout the rostrocaudal NTS, then immunocytochemically labeled with specific antiserum to serotonin (Immunonuclear Corp.) or tyrosine hydroxylase (TH), an enzymatic marker for catecholamines. Alternate immunocytochemically-labeled sections were processed for light or electronmicroscopic radioautography. By light microscopy, punctate clusters of reduced silver grains indicating uptake of ^{3}H-5-HT were distributed throughout the medial and commissural portions of the NTS. The distribution of radioautographically labeled varicosities generally paralleled the distribution of peroxidase labeling for serotonin and superimposed certain dendrites immunocytochemically labeled for TH. By electron microscopy, the serotonergic terminals identified either by radioautography or immunocytochemistry exhibited a dark cytoplasmic matrix and contained numerous, small, clear and a few large, dense vesicles. These terminals generally formed either asymmetric or symmetric axodendritic synapses. However, a few of the serotonergic terminals formed symmetric junctions with perikarya or failed to show membrane specializations in four or more serial sections. In favorable longitudinal planes of section, many of the apparently "non-synaptic" terminals were " boutons en passant" which formed symmetric axodendritic contacts at some point along their length. The perikarya and proximal dendrites receiving the serotonergic terminals usually did not have TH immunoreactivity. However, more distal dendrites and dendritic spines of the catecholaminergic neurons labeled with TH directly received terminals which incorporated ^{3}H-5-HT. These studies demonstrate an extensive network of serotonergic terminals which predominately contact the soma and proximal dendrites of non-catecholaminergic neurons and the more distal dendrites of catecholaminergic (A2) neurons within the NTS.

Suppported by grants from NIH (HL 18974) and MRC (MA 7366).

32.20 GABA TURNOVER IN RAT STRIATUM: EFFECTS OF GLUTAMATE AND KAINIC ACID. O. Giorgi*, J. L. Meek, and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington D.C. 20032.

Previous work from this laboratory has demonstrated that the increases in GABA content after local injection of the irreversible GABA-T inhibitor gabaculine provides an estimate of GABA turnover that can be useful for comparative purposes (Forchetti and Meek, J. Neurochem. 38:1336-1341, 1982). As part of a study on the interactions of neurotransmitters and GABA in the striatum, we have further characterized this technique, and examined the effects of two excitatory aminoacids (kainic acid and glutamate) on GABA accumulation elicited by local injections of gabaculine. GABA content in the striatum was measured by HPLC. GABA-T activity was assayed in striatal homogenates using saturating concentrations of GABA, alpha-ketoglutarate and pyridoxal phosphate. The rate of formation of product (glutamate) was measured by HPLC. Drugs were injected stereotaxically into the striatum of ether anesthetized rats in a total volume of 2 µl over 3.5 min.

A dose of gabaculine (20 µg) which induced a maximal accumulation of GABA caused only a 50% inhibition of GABA-T 60 min after injection. With a 100 µg dose of gabaculine, GABA-T inhibition was 93% at 60 min. We used this dose subsequently to prevent possible artifacts due to incomplete inhibition. Under these conditions, GABA accumulation (25 nmol/mg prot /hr) was linear with time for at least 60 min.

One week after injection of kainic acid (1 µg) to destroy intrinsic striatal neurons, the GABA content was descreased by 55%. The accumulation of GABA after gabaculine was decreased by 60%. The results indicate that the majority of the GABA which accumulates arises from neurons sensitive to kainic acid.

A major neuronal afferent to the striatum is from the cortex. This excitatory pathway may be glutamatergic. We examined the acute effect on GABA accumulation of glutamate and of kainic acid, an excitatory, non-metabolizable, non-accumulated amino acid. When gabaculine was injected simultaneously with kainic acid (4.7 nmol) the accumulation of GABA was linear with time, and significantly greater than controls (42 vs 30 nmol/mg prot/hr). Glutamate itself was able to significantly increase GABA accumulation after gabaculine. A dose of 1 µmol glutamate caused an accumulation that was 59% greater than in animals receiving only gabaculine. The increase in the turnover rate of GABA most probably reflects the increase in neuronal activity induced by these excitatory aminoacids.

33.1 IDENTIFICATION AND PHARMACOLOGICAL SENSITIVITY OF A TRANSIENT OUTWARD CURRENT IN THE SOMATA OF CULTURED MAMMALIAN CENTRAL NEURONS. Jeffery L. Barker and Michael A. Rogawski (SPON: T.G. Smith). Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20205.

Molluscan neuron somata possess an outward current species, I_A, which becomes activated upon depolarization from potentials more negative than resting potential and which displays rapid time-dependent inactivation (J.A. Conner and C.F. Stevens, J. Physiol. 213: 21, 1971; E. Neher, J. gen. Physiol. 50: 36, 1971). It has been suggested that I_A serves to regulate the frequency of repetitive spike firing during sustained depolarization by retarding the decay to threshold of the hyperpolarizing afterpotential following a spike. In the present study, we identified a similar outward current in mammalian cultured neurons that seems to have a comparable functional role. Membrane currents were recorded under voltage clamp from cultured mouse spinal cord neurons using separate voltage-sensing and current-passing microelectrodes. The cells were bathed at 21° C in Hank's balanced salt solution containing tetrodotoxin (TTX; 1-3 μM) to block the voltage-sensitive Na^+ current. Cationic salts and drugs were applied extracellularly by pressure ejection from blunt micropipettes. Voltage steps to -50 mV or above from holding potentials of -60 mV or less elicited a transient outward current which peaked within 5-15 msec and decayed with a time constant of ~25 msec. Hyperpolarizing conditioning steps to -70 mV of as short as 10 msec could remove inactivation produced by holding at -50 mV. Inversion of the current relaxation following a brief depolarizing command occurred at -60 to -70 mV, suggesting that K^+ is the charge carrier of the current. As is the case in molluscan somata (S.H. Thompson, J. Physiol. 265: 465, 1977), high concentrations of 4-aminopyridine (4-AP; 2-10 mM) blocked the transient current in a dose-dependent fashion whereas tetraethylammonium ion (TEA; 25 mM) or Co^{2+} (20 mM) were without effect. In contrast to I_A, the delayed K^+ conductance (I_K) was unaffected by 4-AP, although it was highly sensitive to TEA. Consequently, spike broadening was observed with TEA but not 4-AP. To examine the functional role of I_A, 4-AP (10 mM) was applied to spinal neurons in TTX-free medium during the passage of a long depolarizing current step at rheobase. The drug induced the cells to generate repetitive action potentials by facilitating the rise of the electrotonic potential between spikes. These results indicate that mammalian central neurons possess a transient outward current qualitatively similar to that of molluscan neurons. Interference with I_A should lead to abnormal neuronal discharge, and this might, in part, contribute to the convulsant activity of 4-AP. Moreover, physiological modulation of I_A could be an important factor in the regulation of neuronal firing in the mammalian central nervous system.

33.2 4-AMINOPYRIDINE ENHANCES VOLTAGE-SENSITIVE CALCIUM ENTRY IN CULTURED MAMMALIAN CENTRAL NEURONS. Michael A. Rogawski and Jeffery L. Barker. Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20205.

4-Aminopyridine (4-AP) produces a powerful enhancement of quantal neurotransmitter release at the neuromuscular junction and at central and peripheral synapses. This effect has been attributed to presynaptic spike broadening resulting from a blockade of voltage-sensitive K^+ channels. However, the effects of 4-AP on transmitter release occur at concentrations below those which interfere with K^+ conductances. Therefore, the alternative hypothesis that 4-AP promotes the influx of Ca^{2+} through voltage-sensitive channels has been proposed, although no direct supporting evidence has as yet been obtained. To distinguish between these two alternatives, we carried out intracellular recordings from the somata of mouse spinal neurons in dissociated culture. Current recordings were obtained under voltage clamp with separate voltage-sensing and current-passing microelectrodes. Low concentrations of 4-AP (0.04-1 mM) applied by pressure ejection from micropipettes markedly enhanced the frequency and amplitude of synaptic potentials recorded in these cells. At these concentrations, 4-AP had no effects on spike duration or on the delayed outward current (I_K). When the cells were bathed in medium containing tetrodotoxin (3 μM) to block I_{Na} and tetraethylammonium ion (25 mM) to block I_K, a highly voltage-dependent, slowly inactivating inward current was revealed. This current became activated upon voltage clamp steps to -30 mV from holding potentials more negative than -50 mV. The following evidence indicates that the charge carrier of this inward current is Ca^{2+}: (1) the current is absent in Ca^{2+}-free medium but is expressed upon pressure ejection of Ca^{2+} (10 mM), (2) the current is blocked by Co^{2+} (10-20 mM), Mn^{2+} (15 mM) and Ni^{2+} (15 mM), (3) the current is present when the cells are bathed in medium containing Ba^{2+} (2 mM) instead of Ca^{2+}, and (4) the tail of the current diminishes in amplitude upon repolarization to more depolarized potentials but does not invert. In 2 mM Ca^{2+}-containing medium, pressure ejection of 4-AP (0.1-10 mM) markedly enhanced the amplitude and slowed the decay of the Ca^{2+} current, whereas in Ca^{2+}-free medium or in the presence of Co^{2+} there was no detectable effect on the voltage-current characteristics. These results demonstrate that 4-AP can facilitate a voltage-dependent Ca^{2+} current at concentrations more than 10-fold lower than required to block K^+ currents (see companion abstract). If similar effects occur at the nerve terminal, this could account for the facilitatory effect of 4-AP on quantal release.

33.3 CHARACTERISTICS OF A PERSISTENT MUSCARINE-SENSITIVE POTASSIUM CURRENT IN CULTURED RAT SYMPATHETIC NEURONS. J. E. Freschi. Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814.

I previously described the membrane currents seen under two-electrode voltage clamp of neurons in primary cultures of rat superior cervical ganglia (SCG) (Freschi, J. E., Soc. Neurosci. Abstr. 7:901, 1981). I describe here further properties of a persistent muscarine-sensitive potassium current (M-current, Brown and Adams, Nature 283:673, 1980).

Depolarizing steps from the resting potential activated an outward current that exponentially deviated from the leakage current at potentials negative to those expected for classical outward rectification. The outward current activated in this range was better studied with hyperpolarizing step commands from holding potentials between -30 and -60 mV. Such commands caused a small inward relaxation with a time constant (τ) of 50-100 msec (37°). Repolarization then evoked an outward current with a τ always larger than that of the tail current. The inward relaxations became faster and smaller with increasing hyperpolarizing commands and became outward at potentials more negative than -80 mV. This reversal potential for M-current tails was dependent on external potassium concentration. The ohmic current jump at the end of voltage steps was smaller than that at the beginning, suggesting that hyperpolarization moves the cell to a lower conductance state. In fact, M-conductance reached a minimum at about -70 mV from a maximum value of 50 nS at about -20 mV. This conductance activation curve could be fitted by an exponential equation using constants that suggest that a single tetravalent gating particle controls the M-channel conductance state. The M-current was abolished by muscarine (1 μM) and reduced by TEA (30 mM). Cobalt had no consistent effect on M-currents.

These data agree with M-current analyses previously done with bullfrog sympathetic neurons and with isolated adult rat SCG neurons studied with single-electrode voltage clamp (Constanti, A. and Brown, D. A., Neurosci. Lett. 24:289, 1981). Minor differences between these studies will be discussed.

33.4 I_h: AN INWARD CURRENT UNDERLYING ANOMALOUS RECTIFICATION IN MOUSE SENSORY NEURONS. G.Westbrook*and M.Mayer.* Lab.Devel.Neurobiol., NIH, Bethesda,Md.20205(SPON: M.H. Whitnall)

Anomalous rectification occurs in many neurons and is observed with voltage recording as a membrane resistance decrease on hyperpolarization, or as a membrane resistance increase on depolarization. Recent evidence suggests that in some neurons membrane depolarization activates a persistant inward current producing an apparent membrane resistance increase under current clamp, but this was not seen in DRGs. However, anomalous rectification was prominent during membrane hyperpolarization.

We have investigated the mechanism of anomalous rectification evoked by membrane hyperpolarization in tissue cultured mouse DRG neurons with a two electrode voltage clamp. Hyperpolarizing commands from the resting potential(-50 to -60mV) evoked slow inward current relaxations. The activation variable of this current(I_h) is close to zero at -60mV and one at -100mV. The time constant of the I_h relaxations and their envelopes was strongly voltage dependent. Ih appears to be a mixed Na^+-K^+ current since inward current relaxations evoked from a holding potential of -50 or -60 mV in 4.5,14.5, or 25mM K^+ were strongly suppressed in Na^+-free solution, and the inward tail currents were abolished; or in 4.5mM K^+ reversed.

Cs^+(0.2-10mM) reversibly blocked I_h and prevented the time dependent sag seen in hyperpolarizing electrotonic potentials(i.e. anomalous rectification). I_h was not blocked by TTX, Mn^{++}, or Ba^{++} and is thus a distinct current from that generating "anomalous rectification" during membrane depolarization. It is, however, strikingly similar to the cardiac current, I_f or I_{K2}. Adams and Halliwell(J.Physiol.,324:62P,1982) have also described inward relaxations in hippocampal neurons, activated over a similar voltage range, and distinct from the M current. The original descriptions of anomalous rectification in neurons suggested that a membrane resistance drop occurred on hyperpolarization. In DRGs under voltage clamp, measurement of the membrane chord conductance indicates that a genuine conductance increase does occur on hyperpolarization, due to the activation of I_h, confirming earlier speculation.

At present it is unclear how the time and voltage dependent current I_h relates to the mechanism generating anomalous rectification in muscle, where the channels carrying inward K^+ current show strong rectification in the inward direction. (MLM is a Harkness Fellow.)

33.5 PROPERTIES OF DELAYED RECTIFIER K CHANNELS IN NEUROBLASTOMA CELLS. Fred N. Quandt and Toshio Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., 303 E. Chicago Ave., Chicago, IL 60611.

Presently, there are few reported studies concerning the properties of single delayed-rectifier K channels. We have measured currents through individual K channels of this type from membranes of N1E-115 neuroblastoma cells.

Recordings of currents using the gigaohm-seal, patch clamp technique were made from intact or excised membranes. Outward currents due to the opening of voltage-dependent channels occur in response to depolarizations to potentials less negative than -20 mV. This potential is at the foot of the conductance-voltage curve for the delayed-rectifier K currents recorded from the whole cell ($g_K/\bar{g}_K$=0.02). In outside-out patches, these currents were blocked by the addition of 15 mM tetraethylammonium to the external perfusate, a procedure which blocks the delayed-rectifier K channels in these cells. These channels did not appear to require the presence of internal Ca, since they were recorded from outside-out patches using a K glutamate internal solution to which 20 mM EGTA had been added; or from inside-out patches using a 150 mM KF, 0 mM Ca internal solution.

The conductance of the open state of these channels was 16 pS in one typical case (10°C). The conducting state of the channel usually exhibited multiple, short-duration transitions toward the closed conductance level, similar to those reported for K channels in squid axons (Conti and Neher, Nature 285, 140, 1980). A typical mean open time (-10 mV, 6°C) was 43 msec. K currents recorded from the whole cell inactivate over a period of seconds. Prolonged depolarizations applied to membrane patches indicated that the probability of a K channel opening declined over a similar period of time. Inactivation can be explained by the reduced probability.

A second type of outward current due to channel opening, which was smaller in amplitude, was frequently observed during depolarizations. Both types of conducting states were observed in the same recording, and occur in either cell-attached membranes or excised, inside-out membranes. Both populations of conducting states were reversibly blocked by replacing internal K with Cs in inside-out membrane patches, indicating that K is the normal current carrier for each. The conductance ratio for the two populations is estimated to be 0.3, assuming the same reversal potential for each. This second population is often observed, although not exclusively, after inactivation of the larger amplitude conducting state. The two populations could represent separate open states for a single type of channel, or separate types of delayed rectifier K channels. Supported by NIH grant NS14144.

33.6 DECAY OF CALCIUM CURRENTS IN RAT SKELETAL MUSCLES P. Lynn Donaldson and Kurt G. Beam* Department of Physiology and Biophysics University of Iowa Iowa City, IA 52242

Currents were measured in rat omohyoid muscles using the three microelectrode voltage clamp technique (Adrian, et al., J. Physiol. 208:645, 1970). When the larger and faster ionic currents carried by sodium and potassium in rat omohyoid muscles were blocked, a slow inward Ca current remained. (External solutions contained (mM): TEABr (146), CsBr (5), $CaAc_2$ (2-10), $MgAc_2$ (1), HEPES (10), sucrose (400), TTX (1 uM), and 3,4-diaminopyridine (5).) Ca currents were strongly affected by temperature, being barely detectable at temperatures less than 15° C and often regenerative at temperatures above 30° C. Most currents were recorded at temperatures of 24-27° C. Inward Ca currents decayed during a maintained depolarization and were sometimes succeeded by a late outward current of variable magnitude. In some muscle fibers, the inward Ca current was blocked by cadmium (0.2-0.5 mM) and the outward current was reduced. In other fibers, the late outward current of control records was nearly the same as the outward current which remained after the inward current was blocked. It, therefore, appeared that the decay of inward currents is a consequence of Ca channel inactivation, activation of a Ca-independent outward current, and, in some fibers, a Ca-dependent K current. The addition of nickel or manganese (5 mM) altered the inward current in a time-dependent manner. Bathing muscles in solutions containing these cations and Ca, initially reduced the rate of inward current decay and the apparent steady-state level of the late outward current with little effect on the peak current. Currents recorded after a longer exposure to Ni or Mn had reduced inward peak amplitudes. The time-dependence of these effects suggests two spatially separate sites of action. The early effect of Mn and Ni may be to decrease either Ca-dependent or Ca-independent late outward current. At later times, these cations block inward Ca current. Barium, substituted for Ca, slowed the decay and reduced the amplitude of the inward current. When Ca was returned to the bath, the inward currents were larger than the currents prior to Ba.

33.7 USE OF AEQUORIN TO DETERMINE CHANGES IN INTRACELLULAR FREE Ca^{++} IN MURINE NEUROBLASTOMA CLONE N1E-115 CELLS. R. Michael Snider, Elliott Richelson and John Blinks. Departments of Pharmacology and Psychiatry, Mayo Foundation, Rochester, MN 55905.

A rise in intracellular free calcium ion concentration [Ca^{++}] is implicated in a variety of neurobiological processes, including neurotransmitter release and receptor-mediated cyclic GMP formation. One of the most satisfactory tools for monitoring changes in [Ca^{++}] is the bioluminescent protein aequorin, which changes the intensity of its light emission in response to variations in [Ca^{++}] within the physiological range. Aequorin can be microinjected into small cells only with great difficulty, however, and to date the only neuronal cells which have been studied with aequorin are the giant nerve cells of invertebrates (see Blinks, Techniques in Cellular Physiology-Part II, P126:1-38, 1982).

Murine neuroblastoma clone N1E-115 cells are well suited for studying intracellular [Ca^{++}] and relating the results obtained to neuronal physiology. These cells are thought to have both voltage-sensitive (Study et al., Proc. Natl. Acad. Sci. 75:6295-6299, 1978) and voltage-insensitive (Richelson and El-Fakahany, Biochem. Pharmacol. 30:2887-2891, 1981) Ca^{++} channels. Moreover, activation of guanylate cyclase is hypothesized to result directly from a rise in intracellular [Ca^{++}].

Aequorin was loaded into cells by making them reversibly hyperpermeable (Winegrad, J. Gen. Physiol. 58:71-93, 1971) with the EGTA method of Sutherland et al. (Proc. Aust. Phys. Pharm. Soc. 11:160P, 1980) as modified by Morgan and Morgan (Fed. Proc. 41:1522, 1982). Cells loaded in this way adhere normally to culture flasks and appear normal under the microscope. They luminesce detectably in physiological salt solution and can be shown by ionophore (X537A) treatment or detergent lysis to contain large amounts of active aequorin for at least 18 hours after loading. Cells made reversibly hyperpermeable (without aequorin loading), then returned to physiological salt solution, synthesized cyclic GMP in response to agonists or Ca^{++} ionophores in an apparently normal manner (83-112% of control cells).

Experiments are in progress to examine the role of Ca^{++} in receptor-, depolarization-, and ionophore-mediated cyclic GMP formation in neuroblastoma cells. (Support: Mayo Foundation, MH27692, HL07111 and HL12186).

33.8 CALCIUM-DEPENDENT ACTION POTENTIALS OF RAT SPINAL DORSAL HORN NEURONS IN VITRO. K. Murase* and M. Randić (SPON: M.-F. Cheng). Dept. of Vet. Physiol. Pharmacol., Iowa State University, Ames, IA 50011.

The neurons of the superficial parts of the spinal dorsal horn have long resisted electrophysiological analysis due to the small size of the cells and the technical difficulties in obtaining stable intracellular recordings in vivo. We have therefore developed an in vitro rat spinal cord slice preparation in order to analyze the biophysical properties of these cells. Our initial studies have demonstrated the viability of this preparation (Miletić and Randić, Pharmacologist, 22:204, 1980) and that satisfactory intracellular recordings could be maintained for several hours (Murase and Randić, Neurosci. Abstr., 7:529, 1981).

Rats 9 to 18 days-old were used. After lumbosacral laminectomy, 300 μm thick horizontal superficial dorsal horn slice was maintained in an oxygenated Ringer solution according to the described technique (Murase et al., Brain Res., 234:170-176, 1982).

Intracellular recordings from dorsal horn neurons show that direct or orthodromic stimulation generates spike potentials followed by a brief after-hyperpolarization. Synaptic potentials were elicited by the activation of primary afferent fibers in the dorsal root. Input resistance for dorsal horn neurons ranged from 48 to 267 MΩ, and membrane time constant was in the range of 3 to 10 msec.

Dorsal horn neurons perfused with tetrodotoxin (TTX) and tetraethylammonium (TEA) frequently exhibit a slow regenerative depolarizing potential followed by a slow after-hyperpolarization in response to strong depolarizing currents. This potential is probably produced by an influx of Ca^{++}, because it is blocked by low [Ca^{++}], Co^{++} or Mn^{++}, and enhanced by high levels of extracellular Ca^{++}. A low-threshold Ca^{++} conductance is, in addition, observed in dorsal horn neurons. This conductance appears to be activated at membrane potentials more negative than -65 mV, and reaches saturation at membrane levels about -85 mV. Addition of Ba^{++} or TEA to the perfusing medium provides a suggestive evidence for the presence of inactivation of the low-threshold Ca^{++} conductance and the lack of inactivation for the high-threshold Ca^{++} potential. Certain neuroactive peptides appear to modulate calcium-dependent action potentials in dorsal horn neurons.

These results indicate that action potentials in dorsal horn neurons are generated by voltage-dependent conductance increases to sodium and calcium ions, and in particular that two distinct types of calcium spikes are probably present in these cells. The presence of voltage-dependent Ca^{++} channels may be an important mechanism for regulating the firing behavior of dorsal horn cells.

33.9 EXCITABILITY OF GROWTH CONES OF MULTINUCLEATE PC-12 CELLS. S.L. Huttner* and P.H. O'Lague. Biology Dept., Univ. of Calif., Los Angeles, CA 90024.

Multinucleate cells (up to 250 μm in diameter) produced by polyethylene glycol fusion of cells from the clone PC-12 have been used as a model system for studying various aspects of neuronal development, particularly those of sympathetic neurons. These large cells, similar to their parent cells, respond to nerve growth factor (NGF) by growing neurite-like processes and by expressing Na-dependent action potential mechanisms; they also exhibit Ca-dependent action potential mechanisms as well as several K-dependent mechanisms (O'Lague, PH, and Huttner, SL, PNAS 77:1701-1705). The neurite-like processes of the large cells end in growing tips which resemble the growth cones of neurons in culture and which frequently are large enough to permit stable intracellular recordings. Electrophysiological recordings from these tips have been made using a single intracellular microelectrode to pass current and to record membrane voltage responses. The cells were grown with NGF (7s, 100 ng/ml) for 5 days. In every case tested (n=25) the growth cones had resting potentials of -50 to -65 mV and depolarizing current pulses elicited only passive voltage responses. However, the presence of an excitable mechanism was demonstrated by locally blocking delayed rectification by applying TEA from the tip of a micropipette (1-10 μm in diameter). Only when the pipette tip was positioned within approximately 10 μm of the growth cone were action potentials elicited. Positioning the tip over the process or the cell body failed to give action potentials when current pulses were applied in the growth cone. The action potentials were unaffected by TTX (3 μM) or by reduced external Na (15 mM) but were reversibly diminished by lowering external Ca (0.1 mM) or by applying Cd (0.75 mM). The action potential was followed by a long-lasting afterhyperpolarization (300 msec to 1 sec in duration) which resembled the Ca-dependent K-conductance found in the soma membranes of these cells (see ref. above).

This work was supported by NIH Grant NS-12901 and by a Center Grant from MDA. Dr. S.L.H. was supported by a postdoctoral fellowship from MDA and by NRSA Training Grant NS-07101.

33.10 DEVELOPMENTAL CHANGES IN ELECTRICAL EXCITABILITIY OF CULTURED XENOPUS MUSCLE CELLS. P. DeCino and Y. Kidokoro. The Salk Institute, Molecular Neurobiology Lab, San Diego, CA 92138.

Cultured muscle cells from embryos of Xenopus laevis have been studied electrophysiologically to determine what ionic channels are responsible for action potential (AP) generation during development and how the addition of neural tube cells to the cultures influence these channels. Since these are small muscle cells the maximum rate of rise of the AP (V_{max}) was considered to be proportional to the ionic current density flowing during the upstroke of the AP. Comparisons between sister cultures of different ages in culture showed that V_{max} increased with time. In seven experiments in which the muscle was cultured prior to in vivo innervation V_{max} increased an average of 8 fold between days 1-2 and days 6-8 in culture. This increase was also observed in cultured muscle from later staged (post-synaptogenesis) embryos. The resting potential (average -92 to -96 mV), specific membrane resistance (~10 KΩcm^2) and capacitance (~2 μF/cm^2) did not change throughout the observation period.

In some excitable cells the ionic component responsible for the AP upstroke often shifts from Ca^{++} to Na^+ (or vice versa) during development. However, in Xenopus muscle cells under the culture conditions used here no such shift was detected. The AP rising phase always was Na-dependent and tetrotoxin (TTX) sensitive. The sensitivity to TTX ($K_{0.5}$ 9nM) did not shift with time in culture. In muscle cells cultured alone, then the developmental change was an increase in Na current density reflecting an increase in channel density and/or a change in channel kinetics.

Addition of neural tube cells often had the effect of further increasing V_{max} (2.9 fold). This effect was was independent of actual nerve contact with the muscle cell and seemed to increase when greater amounts of neural tube cells were added to the cultures. This result suggests the involvement of a diffusable substance from neural tube cells. Whatever the factor it did not seem to work by activating acetylcholine receptors found on these muscle cells since blockage with α-bungarotoxin did not alter the effect.

33.11 THE DEVELOPMENT OF SODIUM CHANNELS DURING DIFFERENTIATION OF CHICK SKELETAL MUSCLE IN CULTURE. J. Baumgold, J. B. Parent* and I. Spector*. Lab. of Neurobiol., NIMH, Bethesda, MD 20205, Howard Univ. Cancer Ctr., Washington, DC 20060, Lab. of Biochem. Genetics NIH, Bethesda, MD 20205.

The development of sodium channels during differentiation of chick skeletal muscle in culture was followed at three different levels of cellular organization: 1) ^{3}H-saxitoxin (^{3}H-STX) and ^{125}I-scorpion toxin (^{125}I-ScTX) binding were used to monitor the appearance and elaboration of two different binding sites on the sodium channel; 2) ^{22}Na-uptake studies were performed in order to assess the capacity of these developing channels to function in mediating ^{22}Na-uptake when stimulated with various toxins, and 3) the electrophysiological responses of these cultures were recorded in order to assess the functionality of these channels. When the development of the sodium channel was assayed using binding studies, we found that, whereas ^{3}H-STX binding developed gradually after cell fusion and reached a maximal value (58 fmol/mg protein) after 8 days in culture, the ^{125}I-ScTX binding developed rapidly during and after cell fusion to reach a maximal value by 4 days in culture. Two different rates of development were also found with the ^{22}Na-uptake studies. When ^{22}Na-uptake was stimulated using batrachotoxin (200 nM), the initial rates of ^{22}Na-uptake increased gradually after fusion to reach a maximal value of 12 nmoles of Na/min/culture by 8 days in culture. When the ^{22}Na-uptake was stimulated by both scorpion toxin (300 nM) and batrachotoxin (200 nM), however, the cultures exhibited a rapid increase in their initial rate of ^{22}Na-uptake after fusion. Sodium dependent action potentials could first be detected in 4 day old cultures. However, sodium dependent action potentials could be induced in 3 day old cultures within minutes after addition of 200 nM ScTX. In the presence of ScTX the rate of rise and amplitude of the sodium action potential develops earlier and reaches a higher maximal value than in the absence of this toxin.

Based on this data, we propose the following model for the development of sodium channels. We hypothesize that this intrinsic membrane protein gets incorporated into the membrane in an immature form, capably of binding ^{125}I-ScTX but not ^{3}H-STX. This immature channel is electrophysiologically non-functional. In the course of maturation, we predict that this protein undergoes a post-translational modification or aggregation which renders it electrophysiologically functional and capable of also binding ^{3}H-STX. We further predict that this maturation process can be mimicked, on a more rapid time scale, by the addition of ScTX. Thus, the addition of ScTX to immature cells induces the post-translational modification or aggregation to occur in minutes, rather than in days.

33.12 EFFECT OF COCULTURE AND in vitro (RE)INNERVATION ON THE ELECTRICAL MEMBRANE PROPERTIES OF RAT MYOTUBES. B.A. Suarez-Isla*, J.M. Thompson and S.I. Rapoport (Spon: Anne E. Schaffner) Laboratory of Neurosciences, NIA, NIH, Baltimore, Maryland 21224.

Intracellular recording techniques have shown that neurons dissociated from 8-day chick embryo neural retina form transient synapses with rat muscle cells in culture that begin to be suppressed within 48 h of coculture (Ruffolo et al., PNAS, 75, 2281, 1978). On the contrary, dissociated spinal cord neurons (SCN) from the same source form stable synapses that generate spontaneous m.e.p.p.s. even after 2 weeks in coculture. We report here the effects elicited by 24 to 72 h coculture with chick embryo neurons on the electrical membrane properties of cultured muscle cells. All differences reported refer to paired sets of control(C) and coculture(CC) dishes in which 8 to 10 unbranched, spindle-shape myotubes (6 to 14 days old) were tested (values given as mean + S.D.). We found that only neurons that form stable synapses (SCN) induced a significant decrease ($P<0.01$) in the incidence of slow hyperpolarizing after potentials (slow HAPs; τ=90-200 ms at 37°C; RMP>-45 mV) following an overshooting action potential evoked by anode break excitation. The percentage of cells showing a distinct slow HAP decreased from 86.9 + 12.8 (C; 87/100 cells) to 52.2 + 20.4 (CC; 42/79 cells). This result was obtained from 17 matched pairs of dishes coming from 6 primary dissociations. Comparison of frequency distribution histograms of specific membrane resistance (R_m; bin size=200Ω.cm^2) of cells from all dishes with slow HAPs and cells without them, indicated a significant shift towards lower R_m values ($P<0.01$; Kolmogorov-Smirnov test) in cells devoid of HAPs (mean cells with HAPs=918Ω.cm^2; N=98; without HAPs=608Ω.cm^2; N=86). When C and CC dishes were separately analyzed the shift to lower R_m was also evident, the cells without HAPs in the CC dishes being responsible for most of the shift. However, no significant differences in HAP incidence or R_m distribution were found among CC cells with or without spontaneous synaptic activity. A small but significant ($P<0.001$) decrease in RMP occurred 72 h after coculture (C: -51.0+8.2 mV; N=167. CC: -45.1 +9.7 mV; N and subsequent to a significant decrease in slow HAP incidence (24 h). All these effects could be induced by SCN conditioned medium. However, similar periods of coculture with neurons from chick retina elicited none of these changes.

The slow HAP and its associated Ca^{2+}-dependent K^+-conductance (Barrett et al., Dev. Biol., 82, 258, 1981) seem to be responsible in part for maintaining spontaneous contractile activity before innervation in vivo. This mechanism is partially suppressed during (re)innervation in vitro by neurons that form stable synapses but not by those that form only transient synaptic contacts. These findings support the view that the processes of synapse selection and stabilization in vitro are contemporary to the induction of specific changes in the electrical membrane properties of cultures muscle cells.

33.13 THE IONIC BASIS OF THE ACTION POTENTIAL IN NERVE TERMINALS OF A MOTOR NEURON NERVE NET. Peter A. V. Anderson and Walter E. Schwab*, Whitney Marine Lab and Dept. of Physiology, University of Florida, Gainesville, FL 32611 and Dept. of Biology, Virginia Polytechnic Institute and State University, Blacksburgh, VA 24061.

The motor neuron nerve net of the jellyfish Cyanea capillata is a diffuse network of small (cell body diameters 10-20 μm, axon diameter 5 μm) bipolar neurons. Electronmicroscopy has shown that these neurons are connected by symmetrical chemical synapses; that is, each terminal contains an active zone and an accumulation of vesicles with the active zones of the two terminals directly apposing one another. This organization implies that transmission across the synapse is non-polarized and chemical and this has been confirmed physiologically.

The dimensions of the cells are such that we estimate that a given cell body is within a fraction of a space constant of a synapse. Consequently, an electrode in the soma will accurately monitor events in the pre- or post-synaptic terminals of nearby synapses, thereby allowing the physiology of the synapses to be examined in detail.

The neurons have a negative resting potential (-58mV) and produce very complex and variable positive-going spikes. However, when Cd^{++} and Ni^{++} are added to the sea water, or if cells are bathed in high Mg^{++}, low Ca^{++} artificial sea water, the complexity and variability is lost, leaving a clean, fast, overshooting action potential. At the same time, synaptic transmission is blocked. Somewhat similar action potentials can be recorded in sea water when neurons are stimulated extracellularly with paired stimuli at intervals less than the relative refractory period of the cells. The conclusion from these observations is that the complexity and variability of the spike is the result of the superimposition of synaptic potentials and a single small calcium dependent event on the action potential. The action potential itself is sodium dependent but TTX insensitive, and repolarization is the result of two pharmacologically distinct mechanisms. A delayed, Ca^{++} activated K^+ efflux which produces an after-hyperpolarization and a tetraethylammonium and 4-aminopyridine sensitive, presumably voltage activated, early potassium efflux.

These various properties of the neurons are very conventional despite the phylogenetic primitiveness of the animal. Therefore, since it is possible to impale the pre- and post-synaptic terminals of the synapses, we have a preparation with which to examine the physiology of excitatory chemical synapses in both the pre- and post-synaptic terminals.

33.14 **ORIGIN OF THE DEPOLARIZING AFTER-POTENTIAL IN APLYSIA CELL R15.** **William B. Adams and Irwin B. Levitan. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.**

In Aplysia cell R15, and in many other spontaneously active cells, individual action potentials are followed by a depolarizing after-potential (DAP). In those cells that can display either beating or bursting activity, it is the presence or absence of the DAP that determines the form of activity; bursting cells have a DAP, beating cells do not. When R15 is voltage clamped, brief (10 msec) depolarizing pulses activate a tail current that consists of three components: a rapidly decaying current from the Na^+, Ca^{++}, and K^+ channels that are activated during the pulse; a slower inward current with kinetics matching those of the DAP; a very slow hyperpolarizing current.

Several lines of evidence suggest that the inward current that produces the DAP arises from passive spread of current back into the soma from an action potential that is propagating down the axon away from the soma: (1) Activation occurs over a very narrow range of depolarizing pulse potentials. (2) Under normal conditions, activation of the inward current requires both Na^+ and Ca^{++} in the bathing medium, reflecting the mixed Na^+/Ca^{++} action potential in R15. If K^+ channels are blocked by Cs^+, 4-AP, and TEA, either Na^+ or Ca^{++} suffices. (3) With K^+ channels blocked, it is possible to prevent activation of the inward current by following the depolarizing pulse with a brief hyperpolarizing pulse. The necessary amplitude of the hyperpolarizing pulse depends linearly on the amplitude of the depolarizing pulse and not on the amount of activation of the inward current. (4) DAPs are not found in R15s in which the axons have been ligated.

33.15 SLOW ACTION POTENTIAL IN THE GIANT MOTONEURON OF CRAYFISH : CONDITIONS FOR TRIGGERING, IONIC MECHANISM AND LOCALIZATION. G. Czternasty*, R.T. Kado* and J. Bruner, Lab. de Neurobiologie, Université de Picardie, 80039 Amiens and Lab. de Neurobiologie cellulaire, C.N.R.S., 91190 Gif-sur-Yvette, France.

The slow action potential (SAP) in the giant motoneuron (MoG) somata, described previously (Czternasty & Bruner, Neurosci. Lett., suppl. 7, S.379, 1981) was further studied in the present work under current and voltage clamp. The SAP (threshold at -19 mV ± 2, N = 4) is voltage and time dependent on conditioning depolarization of several seconds (to -50 mV). The constant outward conditioning current produces a slowly increasing depolarization which reaches a plateau. Hyperpolarizing test current pulses during the conditioning depolarization show that the input resistance increases 2 to 3 times. Depolarizing test pulses show a decrementing depolarization. This decrement disappears with conditioning time and the depolarizing pulse produces a SAP going to about +10 mV. Under voltage clamp from holding at -70 mV to holding -50 mV the outward current diminishes with time to about a third of its initial value. I-V curves obtained before, during and after the conditioning period show markedly decreased slopes after conditioning. A slow inward current ($I_{in.s.}$) also appears after conditioning. The SAP and $I_{in.s.}$ persist in Na-free or TTX (10^{-6} M) solution, are blocked in Co^{++} (10 mM) or Mn^{++} (2,5 mM) solution and cannot be triggered in zero Ca^{++}. On the other hand $I_{in.s.}$ become progressively larger with increasing $[Ca^{++}]$ out. Finally, net $I_{in.s.}$ did not reverse for depolarizations as high as +80 mV. Simultaneous recording of the local membrane current of the soma with a pair of extracellular electrodes indicates a somatic localization for these currents.

These results indicate that the SAP is due to somatic, voltage dependent calcium channels. The channels can produce a SAP or $I_{in.s.}$ in voltage clamp from -70 mV if the cell is injected with TEA. In non injected cells the conditioning depolarization is necessary to produce the same effects. A tentative interpretation of these results would be that a voltage dependent inactivation of the delayed rectification channels exists in the MoG membrane.

33.16 MAMMALIAN CEREBRAL AXONS: DIFFERENTIAL EFFECTS OF 4-AMINOPYRIDINE ON SLOW AND FAST FIBERS. R. J. Preston*, S. G. Waxman and E. C. Lampley*. Dept. of Neurology, Stanford Sch. of Med. and VA Med. Ctr., Palo Alto, CA 94304.

Studies of mammalian peripheral and spinal myelinated axons suggest that they exhibit a relatively small response to potassium conductance (g_k) blocking agents that readily alter action potentials in nonmyelinated fibers. We have investigated the effects of the g_k blocker 4-aminopyridine (4-AP) on conduction in mammalian cerebral axons.

Wistar rats (250-300 gm) were anesthetized with Ketamine plus Xylazine to allow recording of the compound action potential (CAP) in the anterior corpus callosum at distances of 1 to 3 mm from stimulation electrodes. Prior to 4-AP application the callosal CAP was characterized by two closely apposed short duration (0.5-1.5 msec) negative waves. These had onset latencies suggesting near maximal conduction velocities of 8.0 and 2.2 m/sec respectively, for two discrete groups of constituent fibers. The application of 4-AP typically caused reversible increase in the duration of the late wave without marked effect on the early negativity. This result was achieved with either of two procedures. In one, recording and stimulation electrodes were stereotaxically positioned and the tip (30-50 μm) of an injection pipette was positioned along the fiber path between them and within 200-800 μm of the recording electrode. From 0.1 to 0.3 μl of 0.2-0.5 mM 4-AP was ejected over a period of 60 sec. In the other procedure, cortical tissue was removed by suction to permit placement of stimulating and recording electrodes under visual control and to allow superfusion of callosal fibers with normal or 4-AP solutions warmed to 37° C.

We interpret these experiments as indicating that the potassium conductance blocking action of 4-AP rapidly alters action potential mechanisms of slowly conducting, presumably non-myelinated callosal axons, but does not affect the action potential of more rapidly conducting myelinated fibers. These results suggest that the finding that peripheral and spinal myelinated axons may lack significant nodal potassium conductance may be extended to mammalian cerebral myelinated axons.

34 SYMPOSIUM. THE ASSEMBLY OF SOMATOTOPIC MAPS IN THE CENTRAL NERVOUS SYSTEM: A CARTOGRAPHER'S DELIGHT. R.K. Murphey, SUNY Albany, NY (Co-chairman) and H.P. Killackey, U.C. Irvine (Co-chairman); M. Constantine-Paton, Princeton; E. Macagno, Columbia.

The existence of highly ordered afferent projections has been a topic of interest to neuroscientists and developmental biologists since the turn of the century. Numerous hypotheses have been put forward to account for the precision of this mapping. Most hypotheses assume that the information necessary for the assembly of such maps exists as cues for the growth and maintenance of neural processes. Most of these hypothetical cues can be grouped under one of three headings: spatiotemporal cues, chemoaffinity cues and competitive interactions. The participants have each focussed their attention on a sensory system in a different species. Dr. Macagno will discuss aspects of the development of the compound eye of Daphnia and other invertebrates, Dr. Killackey the vibrissal system of the rat, Dr. Constantine-Paton the retino-tectal system of the frog and Dr. Murphey the cercal afferent system of the cricket. Results from each of these species will be discussed in the context of possible mechanisms for the assembly of somatotopic maps. We will highlight similarities and differences among the various species and attempt to assess the likely role of previously proposed cues in guiding neurons to their proper targets.

There is considerable controversy in the field and the various biases of the participants represent most of the possible positions which could be adopted on this topic. As a result we expect some lively exchanges among the participants and the audience.

35 SYMPOSIUM. SYMPATHETIC GANGLIA AS MODELS FOR SYNAPTIC TRANSMITTER ACTIONS. B. Libet, Univ. of California, San Francisco (Chairman); J.H. Ashe, Univ. of California, Riverside; L. Jan, Univ. of California, San Francisco; S. Konishi*, Tokyo Medical and Dental University.

Views of synaptic transmitter actions in sympathetic ganglia have progressed from that of a cholinergic-nicotinic one, related to that at neuromuscular junctions, to include a variety of novel actions mediated by ACh, catecholamines and peptides. Since these actions are analyzable in relatively simple and definable synaptic pathways they provide models for as yet unspecified synaptic actions in related transmitter systems in the brain.

Various lines of evidence have indicated that a second transmitter (a catecholamine), released by an intraganglionic interneuronal structure, is the direct mediator for the slow IPSP's. John Ashe will discuss this proposition and the more recent evidence on it.

The slow EPSP is a direct muscarinic response to ACh. Ben Libet will discuss the potential contributions to it of a cyclic GMP-mediated component with no change in membrane conductance, and one due to muscarinic closure of the "M"(K^+) channels with a decrease in conductance.

The long-term potentiation by one transmitter (dopamine, DA), of the s-EPSP responses to another transmitter (ACh), provides a unique model for a heterosynaptic modulatory interaction. Libet will discuss features of this action and evidence specifying the modulatory DA receptor as one coupled to adenylate cyclase.

An even later s-EPSP, with durations of many minutes and mediated non-cholinergically, has also been demonstrated in frog and more recently in mammalian ganglia. Lily Jan will discuss the identification of the peptide LH-RH as the probable transmitter in frog ganglia, features of release and postsynaptic action of LH-RH, and possible roles of other peptides.

Enkephalin is one of a number of peptides found in mammalian ganglia. Shiro Konishi will discuss evidence indicating that presynaptic inhibition can be produced in these ganglia by orthodromic (preganglionic) input, and that intraganglionic enkephalin appears to be the mediating transmitter acting on the presynaptic terminals.

36.1 MONOCLONAL ANTIBODIES THAT RECOGNIZE SPECIFIC RETINA CELL TYPES, AFFECT SYNAPTIC FUNCTION, OR INHIBIT CELL ADHESION. Gerald B. Grunwald, G. David Trisler*, Haruhiro Higashida*, Paul Darveniza* and Marshall Nirenberg. Laboratory of Biochemical Genetics, NHLBI, NIH, Bethesda, MD 20205.

We are using embryonic chick neural retina as a model system for studies on synapse formation and neuron differentiation. Monoclonal antibodies were generated by fusing P3X63 Ag8 myeloma cells with spleen cells from mice immunized with 14 day chick embryo retina cells or mouse or rat embryo retina-neuroblastoma hybrid cells.

Antigen distribution in retina was determined with frozen sections of retina and fluorescein-conjugated IgG or peroxidase-conjugated IgG directed against mouse immunoglobulin. Four antibodies were found that bind to photoreceptor outer segments but not to other cells in retina, three bind to photoreceptor soma, three bind to antigens in the outer synaptic layer of retina, two bind to antigens restricted to cell soma in the inner nuclear layer, one binds to an antigen localized in discrete clusters in the inner synaptic layer, two bind to antigens associated with ganglion neuron soma, and six bind to Muller cells. Other patterns of antigen distribution were detected with 22 other antibodies. For example, 7 antibodies bind to the outer limiting membrane of retina, the outer synaptic layer, and localized clusters of antigen associated with amacrine and ganglion neuron soma.

Four patterns of antibody binding were observed with 7 day chick embryo retina: antibodies bind to cells located at the outer margin of retina, the inner margin, the inner and outer margins, or to cells uniformly distributed in retina. These patterns of antibody binding change between the 7th and 14th day of development. Many antigens that were not detected in 7 day embryo retina were expressed by the 14th day of development.

Preliminary data indicate that six of the antibodies to chick retina inhibit intercellular adhesion. The frequency of myotube miniature end plate potentials between NBr10-A neuroblastoma hybrid cells and striated muscle cells was increased 200-400% by four antibodies, and decreased greater than 50% by two antibodies directed against retina-neuroblastoma hybrid cells. Thus, monoclonal antibodies were obtained that recognize specific cell types in the retina, affect transynaptic communication or inhibit intercellular adhesion.

36.2 A TRYPSIN SENSITIVE ACETYLCHOLINE SECRETION REACTION IN CHICK EMBRYO RETINA CELLS - POSSIBLE REQUIREMENT FOR SYNAPSE FORMATION. R. Ray, J.M. Thompson, and M. Nirenberg. Lab. Biochem. Genetics, NHLBI, NIH, Bethesda, MD 20205.

Some neurons dissociated from chick embryo retina with trypsin formed synapses with cultured striated muscle cells after incubation with muscle cells for >75 min; whereas, few synapses were formed during the initial 75 min of incubation (Puro, D. G., et al. (1977) Proc. Natl. Acad. Sci. USA, 74, 4977). To see whether dissociation of cells with trypsin decreases the ability of the cells to secrete acetylcholine (ACh), we determined the effect of trypsin on ACh secretion by 12 day chick embryo retina cells perfused in vitro with medium containing 5.4 or 81 mM K^+. Retina cells were incubated with [^{3}H]-choline, washed, and [^{3}H]-ACh secreted into the medium was determined. Trypsin had no effect on the basal rate of [^{3}H]-ACh secretion in medium containing 5.4 mM K^+, but [^{3}H]-ACh secretion due to depolarization by 81 mM K^+ was decreased approximately 50%. Stimulus-dependent ACh secretion is known to require Ca^{2+} ions; however, no effect of trypsin was detected on $^{45}Ca^{2+}$ uptake by retina cells at 5.4 or 80 mM K^+. However, the increase in $^{45}Ca^{2+}$ uptake by NBr10-A neuroblastoma-buffalo rat liver hybrid cells due to 80 mM K^+ was inhibited approximately 50% by trypsin. NBr10-A cells possess voltage-sensitive Ca^{2+} channels, secrete ACh, and form synapses with striated muscle cells. The apparent insensitivity of voltage-dependent Ca^{2+} channels of chick embryo retina cells to trypsin under the conditions tested does not preclude the possibility that these Ca^{2+} channels may be sensitive to trypsin under other conditions. The demonstration that trypsin inhibits K^+-dependent ACh secretion, but not $^{45}Ca^{2+}$ uptake by chick embryo retina cells suggests that a component or components required for ACh secretion other than voltage-sensitive Ca^{2+} channels may be sensitive to trypsin and may be required for synapse formation.

36.3 FUNCTIONAL AND BIOCHEMICAL DIFFERENTIATION OF MOTOR NERVE TERMINALS FORMED IN THE ABSENCE OF MUSCLE FIBERS. M.A. Glicksman* and J.R. Sanes. (SPON: M. Willard) Department of Physiology Washington University School of Medicine, St. Louis, MO 63110

During reinnervation of adult vertebrate skeletal muscle, axons regenerate and form new, functional nerve terminals at original synaptic sites on denervated muscle fibers. When muscle is damaged as well as denervated, myofibers degenerate but their sheaths of basal lamina (BL) persist. Axons regenerate to contact original synaptic sites on the BL sheaths and there acquire morphological characteristics of nerve terminals such as synaptic vesicles and active zones; BL regulates this differentiation (J. Cell Biol. 78:176,1978). We show here that these nerve terminals, formed in the absence of the postsynaptic cell, also differentiate physiologically and biochemically.

Both cutaneous pectoris muscles of the frog were denervated and damaged, to obtain nerve- and muscle-free BL sheaths. Frogs were x-irradiated to prevent myofiber regeneration. Muscles were examined 3 weeks later, when reinnervation was maximal. To study the functional capacity of nerve terminals, paired muscles were bathed in horseradish peroxidase (HRP) while the nerve on one side was stimulated (10 Hz for 1h with 30 sec rest every 5 min), then reacted for HRP and prepared for electron microscopy. The appearance of HRP in vesicles indicates endocytosis and, by implication, vesicle recycling (J. Cell Biol. 54:30,1972; 57:315,1973). 76±14% (SE,n=4 muscles) of the terminals on the stimulated side contained >1 labeled vesicle compared to only 9±5% on the unstimulated side. Biochemical differentiation was assayed immunocytochemically with an antiserum to Torpedo electroplax synaptic vesicles that selectively stains nerve terminals in adult muscle (Nature 280: 403, 1979). Cryostat sections were incubated with antiserum and fluorescein-conjugated second antibody; synaptic sites were identified with a histochemical stain for acetylcholinesterase (which is in BL and survives muscle damage). Antibody-stained structures were present at (although not confined to) synaptic sites. We conclude that axons can acquire morphological, immunochemical and physiological properties of normal nerve terminals in the absence of the postsynaptic cell, and that BL triggers some step(s) in this process. (Supported by MDA and NSF.)

36.4 DIFFERENTIATION OF BASAL LAMINA IS AN EARLY EVENT IN THE DEVELOPMENT OF THE NEUROMUSCULAR JUNCTION IN VIVO. A.Y. Chiu and J.R. Sanes, Department of Physiology, Washington University School of Medicine, St. Louis, MO 63110

Muscle fiber basal lamina (BL) survives injury to nerve and muscle, and regulates differentiation of both pre- and postsynaptic elements when neuromuscular junctions reform (J. Cell Biol. 78:176,1978; 82:412,1979; Glicksman and Sanes, this vol.). If BL plays comparable roles during development, its differentiation and that of nerve and muscle must be interdependent. As a first step in understanding these interactions, we have begun to correlate appearance of individual BL components with known events in synaptogenesis. In the rat, acetylcholine receptors (AChRs) and acetylcholinesterase become concentrated at synaptic sites on embryonic day 16 (E16; birth = E22), whereas other steps in neuromuscular maturation, such as elimination of polyneuronal innervation and formation of junctional folds, occur postnatally. We show here that differentiation of muscle fiber BL into immunocytochemically distinct synaptic and extrasynaptic regions begins by E16.

Antisera distinguish three classes of components associated with BL -- those concentrated at synapses, a second class concentrated extrasynaptically and a third shared by synaptic and extrasynaptic BL (J. Cell Biol. 83:357,1979; 93:442,1982). We used one antiserum of each class and also generated a monoclonal antibody that recognizes a synaptic antigen previously defined with serum. Cryostat sections of embryonic rat intercostal muscles were incubated with anti-BL and fluorescein-second antibody; rhodamine-α-bungarotoxin, which binds to AChRs, was added to identify synaptic sites. Shared and extrasynaptic antigens are present over parts of the myotube surface by E15. On E16, when bungarotoxin first identifies synaptic sites, the synaptic antigen is concentrated at some of them. By E17 the synaptic antigen is concentrated at and the extrasynaptic antigen excluded from many synapses; shared antigens are present both synaptically and extrasynaptically. The small set of antisera used so far does not reveal (but certainly does not rule out) qualitative changes in BL during later stages of development. Synapse-specific staining of embryos and adults with the monoclonal antibody shows that the synaptic antigen present in embryos is closely related to that in adults. Our results show that the BL is already divided into chemically distinguishable synaptic and extrasynaptic domains at an early stage in neuromuscular development in vivo and thus could, in principle, be involved in regulating later events. (Supported by MDA and NSF.)

36.5 ACTIVITY AND NEURAL EXTRACT REGULATE ACCUMULATION OF BASAL LAMINA BY CULTURED MYOTUBES. J.R. Sanes, D.H. Feldman and J.C. Lawrence, Jr.*, Depts. of Physiology and Pharmacology, Washington University School of Medicine, St. Louis, MO 63110

Skeletal muscle fibers are ensheathed by a basal lamina (BL), which extends through the synaptic cleft and plays important roles in neuromuscular regeneration and function (J. Cell Biol. 78:176,1978; 82:412,1979). Antigens associated with BL are differentially distributed: some ("synaptic") are concentrated at synapses, some ("extrasynaptic") are excluded from synapses, and some ("shared") are present in both synaptic and extrasynaptic BL (J. Cell Biol. 83:357,1979; 93:442,1982). It is likely that nerve and muscle interact during development to produce this pattern. Two ways in which nerves can influence muscle fibers are by causing muscle activity and by releasing soluble factors. We used myotubes cultured from 19d rat embryos to study the effects of activity and a neural extract on accumulation of BL. Tetrodotoxin (TTX) or lidocaine were used to paralyze the normally spontaneously active myotubes. A saline extract of adult rat brain was the source of soluble neural factors. BL was studied by LM and EM immunocytochemistry and by ^{125}I-antibody binding, using antisera to "synaptic" and "shared" BL components.

Spontaneously active myotubes accumulate BL over much of their surface. Shared antigens are present throughout the BL while synaptic antigens are concentrated in small patches, often associated with clusters of acetylcholine receptors (AChRs; visualized with rhodamine-α-bungarotoxin). Paralyzed myotubes accumulate less shared antigen-rich BL than active myotubes. New BL forms if TTX is removed from cultures, and BL is lost if active myotubes are paralyzed. However, synaptic antigen-rich patches are not lost, but actually increase in number when myotubes are paralyzed. Thus, activity stimulates BL accumulation overall, by a selective effect on shared antigens.

Application of brain extract also enhances BL accumulation. However extract, unlike activity, greatly increases the number of synaptic antigen-rich patches. Extract also increases the number of AChRs and of AChR-rich clusters; new synaptic BL- and AChR-rich patches generally coincide. Thus, activity and neural factors both increase BL accumulation, but in different ways. Our results suggest that nerves could regulate accumulation of BL by myotubes in two ways--shared components being stimulated primarily by nerve-evoked activity, and synaptic components by soluble factors released from the nerve. (Supported by MDA and NSF.)

36.6 THE INVOLVEMENT OF CALCIUM IN THE FORMATION OF ACH RECEPTOR CLUSTERS. H. Benjamin Peng* (SPON: C. Anderson). Dept. of Anatomy, Univ. of Illinois College of Medicine, Chicago, Illinois 60612.

Recently we have shown that the clustering of acetylcholine receptors (AChRs) can be induced in cultured Xenopus muscle cells by polypeptide-coated latex beads (Nature 292:831). A complete set of structural specializations characteristic of the postsynaptic membrane also develops at the bead-muscle contacts. Thus the bead-muscle coculture can be used as a model for understanding the cellular processes involved in the formation of AChR clusters during innervation.

The induction of AChR clustering by the latex beads can occur in a medium consisting only of inorganic ions. We hypothesize that the beads may cause a local change in the permeability to certain ion(s), thus triggering the machinery for the AChR clustering. In particular, the involvement of calcium was tested through the use of calcium antagonists. The formation of the clusters was induced by polyornithine-coated latex beads and the clusters were assayed by labeling the cells with tetramethyl rhodamine-conjugated α-bungarotoxin followed by fluorescence and phase microscopy after a 2 hr to overnight bead-muscle coculture. The mean percentage of beads which were associated with AChR clusters was used as an index. In calcium-free medium containing 0.4mM EGTA, the formation of clusters was inhibited. The beads also failed to induce clustering in the presence of 5mM $CoCl_2$, 5mM $NiCl_2$, 0.3mM verapamil or 0.3mM D-600. In the control, 60-90% of the beads would induce clusters, whereas in the presence of these calcium antagonists only less than 10% of the beads were associated with clusters. This suppression is reversible - if the antagonists were removed following a 2 hr incubation, the formation of clusters returned to 70-100% of the control level. Existent clusters were much less affected by the antagonists-if the clusters were first induced by the beads followed by the addition of antagonists, the association of clusters with the beads was still seen. Two other agents, 5mM $MnCl_2$ and 0.5mM nifedipine, were found to be ineffective in suppressing the clustering.

The effect of these agents in interfering with the entry of calcium into the cells is well known. Our results thus suggest that the induction of AChR clustering by the latex beads is mediated by a Ca^{2+}- regulated process. Since the clusters at the bead-muscle contacts are highly localized, this process must likewise be activated in a highly localized manner. Thus we propose that a local rise in intracellular calcium concentration may trigger the formation of AChR clusters. (Supported by NIH grant NS 16259 and MDA)

36.7 CHARACTERIZATION OF IDENTIFIED MOTONEURONS IN VITRO. R.J. O'Brien*, L.W. Role and G.D. Fischbach. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Using a technique similar to that of Okun and McPheeters (Soc. Neurosci. 6:733) we have identified living motoneurons amidst a heterogeneous population of chick spinal cord cells in culture. A high concentration of both Lucifer Yellow V.S. and Wheat Germ Agglutinin-Lucifer Yellow was injected into the legs of 5-day chick embryos. After 16 hrs of retrograde transport cells were dissociated and plated on glass coverslips. Frozen sections of chick spinal cord showed that the label was confined to the anterior horn. Cell counts on the stage of a microscope equipped with inverted fluorescence optics showed that 60% of the total lumbar motor column can be identified with this technique. This figure amounts to about 3% of the total cells in our culture.

Up to 7 days in culture the number of fluorescently labeled motoneurons decreased with a half life of 2 days when grown in media containing 5% chick embryo extract (CEE) on collagen or on lysed fibroblasts. Growth in 0% CEE on lysed fibroblasts was indistinguishable from that in 5%; these neurons had extensive processes and appeared quite healthy at 7 days in vitro. Motoneurons grown on collagen with 0% CEE showed nearly a 4-fold decrease in number at 3 days and an 8-fold decrease by 5 days in culture when compared to the three other growth conditions. Comparison with other cell types indicates that the survival effect of lysed fibroblasts in 0% CEE may be specific for motoneurons.

This system presents an opportunity for studying whether cells of similar origin (i.e., spinal cord) have an equal capacity to induce clusters of acetylcholine receptors on myotubes. Using Lucifer Yellow CH injection and rhodamine α-bungarotoxin staining we found that 95% of the motoneurons had neurites associated with rhodamine patches, as compared to 19% for the nonmotoneurons. When expressed in terms of the number of receptor clusters per area of nerve-muscle contact, motoneurons had 16 times more neurite-associated receptor clusters than nonmotoneurons (1.1/100 μ vs. .067/100 μ).

Intracellular microelectrode and patch clamp recordings show that identified motoneurons are electrically excitable and that they can form chemical synpases with muscle. Dye-coupling was investigated by intracellular injection of Lucifer Yellow. Between days 1 and 3 in vitro 24% of the motoneurons were dye-coupled to another neuron as opposed to 5% of the nonmotoneurons. By 6 days in vitro only 6% of the motoneurons were coupled to other neurons. We have also observed 3 examples of dye-coupling between motoneurons and flat cells, and one example of dye-coupling between a motoneuron and a myotube. Chemosensitivity and interneuron synaptic studies are underway.

36.8 TRANSMITTER RELEASE AND RECEPTOR AGGREGATION AT CILIARY NEURON-MUSCLE SYNAPSES. L.W. Role, R.I. Hume and G.D. Fischbach. Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

The chick ciliary ganglion contains cholinergic neurons which innervate muscle in vivo. In culture ~70% of the ciliary neurons form functional synapses on muscle by 1-2 weeks (Nishi & Berg PNAS 74:5171, 1977). We have exploited this high degree of connectivity to examine the early events in synaptic transmission and the distribution of acetylcholine receptor (AChR) clusters along the full extent of the neurite arborization.

At 12-24 hr after plating, intracellular stimulation and recording demonstrated short latency (2-5 msec) rapidly rising (2.5-10 msec time to peak) postsynaptic potentials (psp) in 60% of the nerve-muscle pairs tested (n=66). Amplitude histograms obtained on 14 of 16 pairs tested are consistent with a quantal release mechanism at these early synapses.

The earliest contacts rapidly fatigue so that long series of psp's could not be evoked. However, it is clear that synapses can form within 2 h. Between 1-12 h after plating 28 of 97 nerve muscle pairs tested were synaptically connected. Most of the psp's were rapidly rising discrete responses. However, on occasion long latency (20-50 msec), very slow rising (50 msec time to peak), long duration (>100 msec) nonfluctuating responses were recorded. Out of 182 nerve-muscle pairs tested with intracellular recording, 2 examples of electrical coupling were observed. In one of these cases injection of Lucifer Yellow revealed that the cells were also dye-coupled.

The relationship between the neuronal arborization and distribution of AChR clusters in neuron muscle cocultures was studied by injecting neurons with Lucifer Yellow and labeling receptors with rhodamine α-bungarotoxin (RBTX). Within 24-36 h an individual neuron can induce as many as 30 nerve-associated RBTX patches; as many as 10 RBTX patches may be associated with a given neurite on the same muscle. There were 2.3±0.3 RBTX patches/100 μ nerve muscle contact (24-36 h). This is similar to the value obtained when identified spinal motoneurons are studied in the same manner (see O'Brien et al., this volume). Twenty-five percent of the neurite endings, most with typical growth cone morphology, have associated RBTX patches (12-36 h).

We have observed rapid rise psp's in the absence of subneural RBTX patches. We have also observed quantal psp fluctuations with only 1 subneural RBTX patch. Thus, fluctuations in amplitude of the psp's do not necessarily correlate with the number of synapses as indicated by AChR clusters. The precise distribution of subneural AChR clusters and parameters of transmitter release is being investigated further.

36.9 RISE TIMES OF SYNAPTIC CURRENTS AT THE DEVELOPING NEUROMUSCULAR JUNCTION. R. W. Kullberg and H. Kasprzak*. Biology Dept., Univ. Alaska, Anchorage, AK 99508.

The rise times of miniature endplate currents (MEPCs) decrease from about 2 msec to less than .5 msec during development of the myotomal neuromuscular junction of Xenopus laevis (Kullberg, R.W., Mikelberg, F.S. & Cohen, M.W., Develop. Biol., 75:255, 1980). This change appears to be due to two developmental processes: an increase in acetylcholinesterase (AChE) activity and a decrease in acetylcholine receptor (AChR) channel open time. At the newly formed synapse, little or no AChE activity can be detected, whereas at the mature synapse, application of anticholinesterase prolongs synaptic currents and Karnovsky stain shows abundant esterase at the synaptic regions (Kullberg et al, ibid.). During the same period of time that AChE activity is increasing, the open time of AChR channels decreases from an average of 3.0 msec to 0.7 msec (Kullberg, R.W., Brehm, P. & Steinbach, J.H., Nature, 289:411, 1981; Kullberg, R.W. & Steinbach, J.H., unpublished). The effects of these two processes on the rise times of synaptic currents were examined by blocking AChE activity at the mature synapse and substituting embryonic AChR channels in place of mature ones by a mathematical procedure. Under control conditions, the mean rise time of externally recorded MEPCs at the mature myotomal synapse was 0.4 $\pm$ 0.1 msec (mean $\pm$ s.d., n = 26 recording sites). Application of 3 mM methanesulfonyl fluoride abolished AChE activity and lengthened rise times to 0.7 $\pm$ 0.2 msec (n = 17 sites). Embryonic channels were then mathematically substituted in place of mature ones, and the MEPC rise times were further prolonged to embryonic values. Channel substitution was done by treating each MEPC as a convolution between a driving function, Y(t), representing the frequency of channel opening, and an exponential function, exp(-t/tau), describing the rate of channel closing (tau = mean channel open time). The shape of Y(t) was calculated from single MEPCs according to the equation: $Y(t) = C(dV(t)/dt + V(t)/tau)$, where V(t) = MEPC voltage, tau = 0.7 msec and C = arbitrary constant with units of channels/mV. The calculated Y(t) from each mature MEPC was then convolved with exp(-t/3msec) to produce a corresponding theoretical embryonic MEPC. This procedure was carried out on 390 MEPCs sampled at 17 recording sites. The mean rise time was 2.2 $\pm$ 0.6 msec, which compares closely to the value previously obtained from the newly formed synapse, 2.3 $\pm$ 0.6 msec (Kullberg et al, Develop. Biol., ibid.). These results indicate that the developmental decrease in MEPC rise time is solely due to increased AChE activity and decreased AChR channel open time. Developmental changes in AChR density, diffusion distance, release kinetics or other factors presumably do not contribute to the change in rise time.

36.10 THE EFFECTS OF DC CURRENT INJECTION ON IN SITU AXONAL GUIDANCE AND SYNAPTOGENESIS. G.Q.Fox, D.Kötting* and G.P.Richardson* Dept. Neurochemistry, Max-Planck-Inst. für biophysikalische Chemie, 3400 Göttingen, FRD.

Embryonic and neonatal Torpedo marmorata were used to study the effects of DC current injection on axonal guidance and synaptogenesis within their electric organs. The electric organ is so structured that current can be directed in a parallel axis to synaptic terminal formation and perpendicular to axonal growth. In vitro studies have shown that neurites will preferentially guide towards the cathode when grown within an electric field. Data are also available that show that growth cones generate ionic currents and that such currents appear to be a prelude to the establishment of a variety of developmental growth patterns. In our system, therefore, current injection would be postulated to effect synaptic terminal formation but not ingrowth of axons, which occurs at right angles to current flow.

Cationic probe studies with ruthenium red, alcian blue/lanthanum and lysozyme demonstrate that the ventral electrocyte surface including the basal lamina has relatively more anionic sites than the dorsal surface. As this surface is the exclusive post-synaptic locale, its cathodal nature is consistent with the hypothesis.

Estimated current densities of 1-100$\mu A/cm^2$ were injected in a ventral-dorsal(top $\ominus$) and dorsal-ventral (top $\oplus$) direction. Samples of electric organ were then evaluated quantitatively at the electron microscopic level for percent neuritic coverage of postsynaptic membrane. Top $\ominus$ currents, predicted to retard percent coverage, did so in an apparent strength-duration manner with a current density of $10\mu A/cm^2$ applied for 2 weeks being the minimum necessary to evoke a statistically significant response. Top $\oplus$ injections, predicted to enhance percent coverage, appear to do so only under maximal tolerable current densities for extended periods of time(e.g. $50\mu A/cm^2$ for 4 weeks). No evidence was obtained to suggest that the ingrowth of axons was in anyway effected by the currents in either direction.

In conclusion, the results support a hypothesis of synaptogenesis which must take into consideration galvanotropic effects.

36.11 APPEARANCE AND DEVELOPMENT OF CHEMOSENSITIVITY OF EMBRYONIC AMPHIBIAN SPINAL NEURONS IN VITRO. Nicholas C. Spitzer & John L. Bixby, Biology Dept., UCSD, La Jolla, CA 92093

The development of excitable membrane properties has been investigated in the Rohon-Beard neurons of the Xenopus spinal cord. Cultures prepared from neural plate stage embryos contain a population of neurons that is likely to include Rohon-Beard cells and motoneurons, on the basis of their early birthdate and profiles of sensitivity to neurotransmitters. The differentiation of the action potential of these neurons parallels the development of the impulse in Rohon-Beard neurons in vivo. We have examined the development of chemosensitivity of these cells isolated in culture. Low density cultures are prepared by dissociating the spinal region of the neural plate in Ca^{++}/Mg^{++}-free saline, and cells are grown in a defined medium without exogenous organic components. Neurons can be recognized by their morphology as early as six hr. in vitro, and impaled with intracellular microelectrodes.

Neurons are initially insensitive to bath application of GABA, but are depolarized in association with a conductance increase as early as 8½ hr in culture, corresponding to Nieuwkoop & Faber stage 24 for intact siblings from the same clutch of eggs. This time of onset is indistinguishable from that reported for the Rohon-Beard neurons in vivo (Bixby & Spitzer, J. Physiol., in press). As in vivo, a fraction of these cells are also depolarized by glycine. Furthermore, cells that are hyperpolarized by GABA and glycine become sensitive at about the same time. This is the chemosensitivity profile described for adult frog motoneurons.

The sensitivity of the cells was examined by iontophoretic application of GABA to the soma during the first 24 hr in culture; sensitivities as high as 180 mV/nC have been observed, which are comparable to those observed for Rohon-Beard neurons in vivo at this stage of development. The reversal potentials of these iontophoretic responses were determined by injecting current to shift the membrane potential to different levels; voltage dependent conductances were suppressed pharmacologically. Neurons have reversal potentials of either -35 or -60 mV, which are similar to the values reported for Rohon-Beard neurons and motoneurons in vivo, respectively. The latter class of neuron can functionally innervate skeletal muscle cells in these cultures. The depolarizing response to GABA is reduced or blocked by 10 µM picrotoxin or curare, like that of Rohon-Beard neurons in the spinal cord, as is the hyperpolarizing response of the other cells. Thus the development of sensitivity to neurotransmitters of some of these neurons in dissociated cell culture parallels the development of Rohon-Beard neurons in vivo, with respect to the time of onset, degree of sensitivity, reversal potential and pharmacology of the responses to GABA. In addition, putative motoneurons developing in these cultures become sensitive to neurotransmitters at roughly the same stage as the Rohon-Beard neurons.

36.12 DEVELOPMENT OF A HIGH AFFINITY GABA UPTAKE SYSTEM IN EMBRYONIC AMPHIBIAN SPINAL NEURONS IN CULTURE. Janet E. Lamborghini and Amanda Iles.* Biology Dept. B-022, UCSD, La Jolla, CA 92093

The differentiation of several neuronal membrane properties has been studied in Rohon-Beard neurons developing in vivo. The onset and development of electrical excitability and chemosensitivity have been described for these amphibian spinal neurons, as well as the electrical uncoupling of these cells. The development of a heterogenous population of spinal neurons which include the Rohon-Beard neurons has been examined in dissociated cell culture. The development of the action potential under these conditions parallels its development in vivo. These cultures thus appear to be a useful model system for the study of the mechanisms underlying neuronal differentiation. A high affinity uptake system for neurotransmitter precursors is another characteristic neuronal membrane property. Here we describe the evaluation of a high affinity uptake system for GABA and its development in neurons in vitro.

Cultures were prepared from Xenopus neurulae. Uptake was assayed by exposing the cells to (^{3}H)-GABA for one hour and processing the cultures for autoradiography. Uptake by 24 hour old cultures occurred by a high affinity mechanism because 1) 35% of neurons were labeled by exposure to 10^{-7} M (^{3}H)-GABA, 2) the percentage of neurons labeled was greatly reduced by treatment with 10^{-5}M ouabain, 3) labeling was blocked by replacement of the Na^+ in the medium with Li^+, and 4) labeling was blocked by incubation at 0°C.

The development of this high affinity uptake system for GABA was studied by assaying its presence at different times after the cultures were prepared. Fewer than 6% of neurons showed labeling at 6 and 12 hrs in culture. The percentage of cells accumulating GABA rose steeply between 12 and 18 hrs to 35% and remained at that value through 24 hrs. This suggests that the ability to accumulate GABA by a high affinity uptake system develops in this population of cultured neurons between 12 and 18 hours in culture. This period is several hours later than that in which cultured neurons are becoming sensitive to GABA (see Spitzer & Bixby, this volume).

Experiments in vivo demonstrate that Rohon-Beard neurons have the ability to take up GABA, while primary motor neurons do not. Results of previous studies (Spitzer & Lamborghini, 1976) indicate that the majority of neurons in these cultures is composed of Rohon-Beard neurons and primary motor neurons. These facts together suggest that at least some of the neurons which accumulate GABA in our cultures are Rohon-Beard neurons.

The presence of a high affinity GABA uptake system in neurons developing in culture raises the possibility that the neurons use this compound as a neurotransmitter.

Supported by grants from the NIH and the ONR.

37.1 SELECTIVE STAINING OF CELLS IN TREE SHREW AND GRAY SQUIRREL RETINAE FOLLOWING INTRAVITREAL INJECTION OF PROCION YELLOW DYE. Heywood M. Petry, Dept. of Psychology, Vanderbilt University, Nashville, TN, 37240

The tree shrew (Tupia glis) and eastern gray squirrel (Sciurus carolinensis) are diurnal mammals which occupy similar ecological niches. Both have cone dominated retinae and exhibit dichromatic color vision. The visual system of these species differs, however, in at least three important respects. First, tree shrew color vision resembles that of human deuteranopes, while that of the gray squirrel is similar to human protanopes. Second, rods account for less than 4% of the receptors in the tree shrew retina, whereas 35-40% of squirrel receptors are rods. Third, while receptors are arranged in a single retinal layer in the tree shrew, gray squirrel receptors are organized into two tiers: rods being located in the inner, more vitreal tier, and cones being located in the outer tier (West & Dowling, J. comp. Neurol., 1975, 159, 439). The overall similarities in the size and lifestyle of these animals, coupled with the differences in their retinal organization and color vision prompted this study of a feature common to the visual systems of both species: the short-wavelength sensitive cone system.

To anatomically identify the short-wavelength sensitive cones, 10-15 μl of Procion Yellow M4RF (7% in deionized water) was injected into the vitreous humor of anesthesized tree shrews and gray squirrels. A similar procedure has been shown to selectively and completely stain short-wavelength sensitive cones in the monkey retina (de Monasterio et al., Science, 1981, 213, 1278). After a 20-25 hour period, the tree shrews and squirrels were perfused with formalin, and retinal pieces were dehydrated, defatted, and embedded in EPON. Sections were cut at a thickness of 10 microns in either the radial or tangential plane and observed under episcopic fluorescence. In both species, cone outer segments were stained routinely. In addition, a small, regularly spaced population of receptors, as well as horizontal, bipolar, and ganglion cells, were completely stained by the dye. Completely stained cells were more common in central retina, although they regularly occurred in peripheral regions as well. In the tree shrew all stained receptors appeared to be cones. However, in the squirrel retina, completely stained receptors were located in the inner "rod" tier. This presents two intriguing possibilities. Either Procion Yellow is taken up by rods in this species, or there is a population of presumably short-wavelength sensitive cones located in the squirrel's "rod" tier. Regardless, the results suggest that although both species are diurnal dichromats occupying a similar niche, the organization of their cone and rod systems is very different. (Supported by EY-04239 to H.M. Petry and EY-01778 to V.A. Casagrande)

37.2 EXCITATORY AMINO ACIDS SUBSERVE PHOTORECEPTOR AND ON BIPOLAR NEUROTRANSMISSION. M. M. Slaughter* and R. F. Miller (SPON: A. I. Cohen). Dept. of Ophthal., Physiol. and Biophys., Washington Univ. Sch. of Med., St. Louis, Mo. 63110.

The effects of ± cis 2,3 piperidine dicarboxylic acid (PDA), a putative excitatory amino acid antagonist, were examined in the superfused retina-eyecup preparation of the mudpuppy using intracellular recording techniques. We found that PDA was a general excitatory amino acid antagonist that opposed the depolarizations evoked by aspartate, glutamate, kainic acid, and N methyl aspartate. In horizontal cells, PDA blocked the kainic acid induced depolarization but not the GABA induced depolarization, indicating a selective action of PDA. In the outer retina, PDA essentially blocked the light response of horizontal cells and OFF bipolars. This was associated with a hyperpolarization similar to that caused by the use of cobalt to block photoreceptor transmitter release. The center response of the ON bipolar was unaffected by PDA while the antagonistic surround was blocked, as would be expected from PDA's action on horizontal cells. In the inner retina, both ON and OFF light responses were diminished by PDA. The block of the OFF responses could be explained by PDA's effect on the OFF bipolar. But, since the ON bipolar functions normally, PDA must block the ON bipolar neurotransmitter. Conductance measurements indicate that the block of the light responses was not due to a shunting action by PDA.

Several selective aspartate antagonists (D α amino adipate, D α amino subrate, and D γ glutamyl-glycine) were used in an attempt to identify synaptic pathways that utilize this excitatory amino acid neurotransmitter. These agents did not block photoreceptor or bipolar cell transmission. We conclude that photoreceptors release an excitatory amino acid, probably glutamate, that interacts with two general types of post-synaptic receptors: one on the ON bipolar and the other on the horizontal cell and the OFF bipolar. In addition, the ON bipolar releases an excitatory amino acid neurotransmitter. The OFF bipolar may utilize the same neurotransmitter as the ON bipolar, but this cannot be evaluated with this protocol.

Supported by NIH Grant No. EY03868 and EY03014

37.3 LIGHT AND DARK-DEPENDENT RELEASE OF GLUTAMATE AND ASPARTATE IN THE ISOLATED RETINA OF THE MUDPUPPY. R.F. Miller, M.M. Slaughter* and S.C. Massey* Departments of Ophthalmology, Physiology and Biophysics, Washington University School of Medicine, St. Louis Mo 63110.

We have analyzed the amino acid content of perfusate fluid collected from the isolated retina of the mudpuppy. Reverse-phase high pressure liquid chromatography was used for separation and identification of amino acids using an O-phthalaldehyde derivitization procedure and flurometric detection. An isolated mudpuppy retina was moved between 100uL wells containing a Ringer's solution combined with various pharmacological agents. The use of DL-2-amino-4-phosphonobutyrate(APB) and cis 2,3 piperidine dicarboxylate (PDA) provides a preparation in which light modulated neuronal activity is restricted to the photoreceptors. When the retina is bathed in APB and PDA containing Ringer's, glutamate and aspartate release are readily detected. Continuous dark release of glutamate and aspartate is significantly reduced in cobalt or low Ca++, high Mg++ Ringer. A strong bleaching light causes modest changes in glutamate release:A light evoked increase and decrease have been seen. A striking increase in glutamate release is observed during dark adaptation following the bleaching light. The enhanced glutamate release is blocked by low Ca++, high Mg++(20mM). Aspartate release is comparatively unaffected by the light vs dark cycle. These observations are discussed in view of neuropharmacological evidence from this laboratory which favors glutamate as a photoreceptor transmitter.

37.4 THE ACTIONS OF ASPARTATE, GLUTAMATE, AND THEIR ANALOGS ON RETINAL NEURONS OF THE RABBIT, Stewart A. Bloomfield* and John E. Dowling. The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Previous investigations in lower vertebrate retinas have suggested that the acidic amino acids aspartate (L-Asp) and glutamate (L-Glut) are neurotransmitters released by the photoreceptors. We have initiated a study of the actions of these agents and their analogs on the retinal neurons of a mammal. The effects of these drugs were evaluated according to their modulation of the intracellularly-recorded responses of neurons in the superfused, isolated retina-eyecup of the rabbit (Dacheux et al., Fed. Proc.:32, 1973).

Horizontal cells (HCs) displayed equal sensitivity to L-Asp and L-Glut. At concentrations of 2.5 mM and greater, these agents caused a depolarization of the dark membrane potential and an attenuation of the light-evoked responses; actions consistent with that expected of the endogenous photoreceptor transmitter. Kainic acid (KA), a structural analog of glutamate, had a similar effect on HCs but at concentrations as low as 50 μM. HCs were less sensitive to N-methyl-DL-aspartate (NMDLA), a structural analog of aspartate; depolarizing effects could be elicited only with applied concentrations of 100 μM or more. When exposed to low concentrations of NMDLA (50 μM), about 65% of the HCs hyperpolarized. This effect could not be reversed with the simultaneous addition of 50 μM KA to the perfusate, suggesting that low concentrations of NMDLA antagonized the effect of KA.

Preliminary results show that ON-bipolar cells are hyperpolarized by 50 μM KA and are insensitive to 50 μM NMDLA. OFF-bipolars are strongly depolarized by 50 μM KA and are hyperpolarized by 50 μM NMDLA. As was the case for HCs, this hyperpolarizing action of low concentrations of NMDLA could not be reversed by the simultaneous application of KA.

In the inner retina, amacrine and ganglion cells were considerably more sensitive to KA than NMDLA. Following the application of 50 μM KA or 100 μM NMDLA many cells displayed an initial increased spontaneous spike activity followed by a large depolarization of the dark membrane potential which abolished both spiking and the light-evoked responses.

37.5 EFFECTS OF AMINO ACID DRUGS ON RESPONSE PROPERTIES OF FISH HORIZONTAL CELLS. S. C. Mangel*, M. Ariel* and J. E. Dowling. (SPON: E. M. Lasater). The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Response properties of fish horizontal cells were investigated before and after the application of glutamate and aspartate agonists and antagonists. Drugs were applied to the isolated carp retina while recording intracellularly from horizontal cells. As reported previously, glutamate and aspartate depolarize the membrane potential of all types of dark-adapted horizontal cells, an action which is consistent with that of the endogenous photoreceptor transmitter. However, N-methyl-DL-aspartate (NMDLA), a structural analogue of aspartate that acts as an aspartate agonist on spinal cord motorneurons (Watkins et al., 1981), hyperpolarizes the membrane potential of dark-adapted horizontal cells and decreases the amplitude of their light-evoked responses. These effects of NMDLA are not expected of a photoreceptor transmitter agonist, but rather suggest that NMDLA is an antagonist of the photoreceptor transmitter(s).

The effects of NMDLA are indistinguishable from those of alpha methyl glutamic acid, a glutamate antagonist, and alpha amino adipic acid, an aspartate antagonist. Furthermore, during the hyperpolarization of L-type cone horizontal cells produced by NMDLA and the two antagonists, an increase in the response to diffuse blue light occurs, as well as a decrease in the response to diffuse red light. Because application of Co^{++} produces a hyperpolarization with no concomitant spectral difference, the blocking action of these antagonists may reveal that red cones release a different transmitter than blue cones. The blue response increase that occurs following application of acidic amino acid antagonists does not occur when small spot stimuli are used. Therefore, these antagonists may reveal the presence of a surround feedback from L-type (H1) horizontal cells which is wavelength dependent. Possible synaptic pathways will be discussed.

37.6 DOPAMINE (DA) AND DRUGS THAT INCREASE INTRACELLULAR CYCLIC AMP DECREASE JUNCTIONAL COMMUNICATION BETWEEN L-HORIZONTAL CELLS. J. Neyton*, M. Piccolino* and H. M. Gerschenfeld* (SPON: ENA) Lab. Neurobiol., Ecole Normale Supérieure, 75005 Paris, France and Istituto Neurofisiologia, C.N.R., 56100 Pisa, Italy.

The axon terminals of L-horizontal cells of the Pseudemys turtle retina, which correspond to the large field horizontal cell (L1HC) of Simon, are coupled by gap-junctions and thus form an extensive network. We have reported (Piccolino et al.,PNAS, June '82) that micromolar concentrations of bicuculline and picrotoxin evoke a narrowing of the receptive field profile of the L1HC. This effect is accompanied by a marked decrease in the diffusion of the Lucifer yellow dye in the L1HC network and is rapidly reversed by GABA. When GABA was applied alone at 0.5-1 mM it increased the peripheral contribution to the L1HC responses. We interpreted the effects of the GABA antagonists as resulting from a decrease in the conductance of the gap-junctions of the L1HC network.

DA (0.2-10 µM) as well as its agonists epinine (1-10 µM), apomorphine (20-40 µM) and ADTN (1 µM) also evoke a narrowing of the receptive field profile of the L1HC. The DA-antagonists cis-Z-flupenthixol (50 µM) and piflutixol (50 µM) when applied previous to the amine treatment, prevent the effects of DA (10 µM).

Since DA was shown to increase cyclic AMP concentration of isolated horizontal cells of fish retina (van Buskirk and Dowling PNAS 78,825,1981), we investigated the effects of other drugs that increase intracellular cyclic AMP concentration. Forskolin (5 µM), a stimulator of adenylate cyclase (Seamon et al.,PNAS 78, 3367,1981) and isobutylmethylxanthine (IBMX, 20-50 µM), an inhibitor of phosphodiesterases, both also evoke the shrinking of the L1HC receptive field profile. However, IBMX may also cause an increase of sensitivity and a slowing down of the L1HC responses. Moreover, both DA and forskolin induce a remarkable restriction of the diffusion of Lucifer yellow in the L1HC network.

Our experiments suggest that both the receptive field narrowing and the restriction of Lucifer yellow diffusion evoked by DA and its agonists are probably due to a decrease in the conductance of the gap-junctions in the L1HC network in which cyclic AMP may be involved as a second messenger. A possible antagonistic interplay between a GABAergic and a dopaminergic system intervening in the regulation of the permeability of the gap-junctions between L1HC and thus in their receptive field properties is being investigated.

37.7 EFFECTS OF 6-HYDROXYDOPAMINE ON THE SPATIAL PROPERTIES OF CARP HORIZONTAL CELLS. J.L. Cohen and J.E. Dowling. Dept. of Ophthal., New York Univ. Med. Ctr., New York, NY 10016 and Bio. Labs, Harvard Univ., Cambridge, MA 02138.

The perikarya of the interplexiform cell lies in the inner nuclear layer amongst the amacrine cells. In teleost fishes it makes connections presynaptically to horizontal and bipolar cells in the outer plexiform layer, while in the inner plexiform layer it makes both pre- and postsynaptic contacts with amacrine cells. The interplexiform cell has been shown to contain the neurotransmitter dopamine. Very little information exists as to its physiological role. Recent evidence (Negishi & Drujan, 1979) suggests that dopamine may influence the spatial properties of the horizontal cells. We therefore wanted to determine what effect the removal of dopamine had on the spatial properties of the horizontal cells as well as to elucidate any possible mechanisms of action.

Carp were injected in one eye with 10 µl of 1 mg/ml 6-OHDA in 0.9% NaCl with 1 mg/ml ascorbate added as an antioxidant. Injections were made on two consecutive days. Intracellular recordings from the horizontal cells were made on day seven. Receptive field diameters were determined by recording the response of the horizontal cells to spots of light of increasing diameter. Control retinas responded linearly to spots of increasing size up to about 2.5 mm in diameter. Stimulation with larger diameter spots had no effect on response amplitude. Retinas treated with 6-OHDA responded linearly throughout the range of stimuli sizes used. We therefore conclude that depletion of dopamine in the carp retina increases the diameter over which a test stimulus will elicit a response from the horizontal cell.

To try to determine the mechanism of action of dopamine on the spatial properties of the carp horizontal cells we tested the effects of dopamine and 8-bromoadenosine 3'5' monophosphate (8-bromocAMP) on the horizontal cells. Horizontal cell responses to spots and annuli were made equal with neutral density filters. Dopamine (10-100 mM) and 8-bromocAMP (0.25-25 mM) were sprayed on the retina by means of an atomizer. Responses to spot stimuli increased in amplitude, while surround responses decreased in some cells. The change in receptive field size in these cells was not accompanied by a consistent membrane potential change. These preliminary results therefore suggest that dopamine exerts its effects on receptive field size indirectly, i.e., via cAMP.

37.8 DEVELOPMENT AND CONNECTIVITY OF PUTATIVE CHOLINERGIC AMACRINE CELLS IN RABBIT RETINA. Edward V. Famiglietti, Jr. Dept. of Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201

Litters of pigmented rabbits were born in a conventional animal care facility, and time of birth was established to within 8-16 hrs. Animals were sacrificed at timed intervals; their retinas were flat-mounted and taken through a Golgi-Kopsch impregnation procedure. At 5 days of age, starburst (Sb) amacrine cells, the putative cholinergic amacrine cells of mammalian retina, were recognizable by the radial symmetry and regular branching of their stellate dendritic trees. They were very different from adult Sb amacrines, however, in having sinuous dendrites of conventional (gradual) taper, virtually no proximal-distal differentiation in dendritic contour, and numerous irregular spinous processes 1-8 um in length along the course of the dendrites. At this stage, ganglion cells exhibit a similar degree of immaturity, and cannot be readily classified by criteria developed for adults. Bipolar cells have dendritic terminals in the outer plexiform layer and bushy axon terminals in the inner plexiform layer (IPL), even though synaptic ribbons have not been seen in the IPL at this stage (McArdle, C.B., J.E. Dowling, and R.H. Masland, J. Comp. Neur., 175:253, 1977).

At 8 days of age, Sb amacrines have assumed features of adult cells; in particular, a beginning of the tripartite annular organization of the dendritic tree is evident, i.e. a proximal zone of conventionally tapering dendrites, an intermediate zone of slender, smooth dendrites, and a distal zone of beaded dendrites with boutons en passant and boutons terminaux (Famiglietti, E.V., Invest. Ophthalmol. Suppl., 20:204, 1981).

At 10 days, Sb amacrines are virtually indistinguishable from adult cells, and adult types of ganglion cells are easily recognized by their branching patterns. Nevertheless, the ganglion cells retain immature dendritic spinous appendages seen at earlier stages. Despite the presence of immature spines and contours of their axon terminals, rod bipolars and more than one type of cone bipolar can be distinguished at this stage.

Golgi-impregnated Sb amacrine cells have been examined by electron microscopy in adult rabbits; they receive bipolar input in the proximal and intermediate dendritic zones, while their distal zone of boutons delivers extensive output to ganglion cell dendrites. These distal dendrites are involved to a small degree in amacrine-to-amacrine interactions as well. This simple polarization of synaptic connectivity in Sb amacrines, odd though it seems in adult cells with their very slender (0.2 to 0.3 um) intermediate dendritic segments, may be established at an early developmental stage in which the dendritic tree has a more conventional appearance, resembling that of ganglion cells.

37.9 PSEUDOCHOLINESTERASE AND ACETYLCHOLINESTERASE STAINING IN CAT AND MONKEY RETINA. R.-B.Illing* and A.M. Graybiel, Dept. of Psychology and Brain Science, Mass. Inst. Technology, Cambridge, MA 02139.

Twenty-two cat and 7 monkey retinae were reacted for either pseudocholinesterase (BuChE, using butyrylthiocholine iodide as substrate) or acetylcholinesterase (AChE) in the presence, respectively, of the inhibitor of the other enzyme.

In the cat retina, AChE activity was found in all categories of cells in the ganglion cell layer (GCL), including all types of ganglion cells, displaced amacrine cells and microglia. In whole mounts, the radial pattern formed by ganglion cell fibers could be seen up to the optic nerve head. In cross-sections, 3 sublaminae of the inner plexiform layer (IPL) could be distinguished, the middle band being pale. No AChE activity appeared in other layers. BuChE histochemistry allowed us to distinguish distinct types of retinal cells. Three of these appear to be amacrine cells(B1-B3). B1 cells had soma diameters of 13-15μm, were situated at the inner border of the inner nuclear layer (INL), and had dendritic trees that were sparsely branched in the outer IPL and stained for up to a diameter of 400μm. B2 cell bodies lay in the same plane of focus as the B1 cells, but had smaller diameters (11μm) and richly branched dendritic trees (>200μm dia). There were hints that other cell types in the INL might also be BuChE-positive. B3 cell bodies lay in the GCL but they appeared to be amacrine cells because they were not peroxidase-positive after massive HRP injections into the lateral geniculate, superior colliculus and pretectum. They had spherical 10-12μm somas, no nuclear fold and branched dendritic arbors of 300μm. As with AChE, BuChE staining clearly showed the ganglion cell fiber pattern in whole mounts. Unlike AChE preparations, BuChE stained only a few ganglion cells strongly; these had β and γ cell profiles. In sections, the IPL was diffusely stained, most heavily near the INL. The outer nuclear layer (ONL), receptor inner segments and outer limiting membrane were also stained. Müller cells were BuChE-positive and their inner endfeet formed a gridwork in the axon layer.

In monkey, AChE stained all cells in the GCL, as in cat; split the IPL into 5 bands; and stained the inner part of the outer plexiform layer (OPL). BuChE stained at least B1 cells and B3 cells. Of cells in the GCL, those with the largest profiles were apparently not stained. IPL staining was split into 5 bands, OPL staining into 3 bands.

We conclude that BuChE as well as AChE is a differential marker for retinal sublayers and that BuChE activity in particular marks at least 3 populations of amacrine cells and probably ganglion cell types in the small and medium size range as well.

Supported by the Deutsche Forschungsgemeinschaft (RBI), NIH 5P30 EY02621 and NIH 5R01 EY02866.

37.10 MORPHOLOGICAL, PHARMACOLOGICAL, AND PHYSIOLOGICAL CHARACTERIZATION OF AMACRINE CELLS IN THE MUDPUPPY RETINA. P. A. Coleman* and T. E. Frumkes. Dept. Psychology, Queens College of CUNY, Flushing, New York 11367.

Current models of the vertebrate retina maintain that ganglion cells receive an excitatory input from the depolarizing bipolar cells at light on and from the hyperpolarizing bipolar cell at light off. In addition, an inhibitory on-off input from amacrine cells has been shown to modify ganglion cell discharge. In the mudpuppy, this characterization has been made on the basis of pharmacological and physiological evidence alone.

In the present study, intracellular responses were obtained from neurons of the superfused mudpuppy retina with electrodes fashioned out of triangular glass and filled with Horseradish Peroxidase. These electrodes provide a combination of technical advantages including easy filling, relatively low impedance (facilitating extrinsic current injection and yielding superior physiological recordings), and the ability to characterize cells anatomically. The physiological and pharmacological characteristics of on-off amacrine cells prove similar to those described earlier: accordingly, these neurons rarely spike to maintained illumination, have high sensitivity to exogenously applied GABA and glycine but show no signs of on-off inhibition, and have large receptive field with no obvious signs of center-surround antagonism. The dendrites of these neurons arborize diffusely throughout the inner plexiform layer (IPL) and cover an extremely large expanse ($\gg$500 mμ). On amacrine cells also rarely spike to maintained illumination and are sensitive to exogenously applied GABA and glycine but in other respects differ from on-off amacrines. Specifically, On amacrines have small ($<$300 mμ) receptive fields and depolarizing current injection reveals transient inhibition at the onset and offset of photic stimulation. The dendritic field of these neurons (80-200 m diameter) is restricted to a narrow ($<$5 mμ) plane of the IPL very close to the ganglion cell bodies. Our results suggest that On amacrines are inhibited by GABA and/or glycine releasing on-off amacrines and in turn provide On inhibitory input to postsynaptic neurons. Results are compared with data from other types of identified amacrine cells in mudpuppy and with the synaptic structure of the IPL in other species.

(Supported by NIH Grant EY01802)

37.11 COMPARISON OF EFFECTS OF KAINIC ACID ON SOMATOSTATIN, SUBSTANCE P AND DOPAMINE IN THE RABBIT RETINA. S.M. Sagar, L. Weinstein* and J.B. Martin. Neurology Service, Massachusetts General Hospital, Boston, MA 02114.

We have previously documented the presence of somatostatin-like immunoreactive material (SLI) in the rabbit retina. In this study we report an unexpected failure of the neurotoxin kainic acid (KA) to deplete the rabbit retina of more than 50% of its content of SLI. Groups of adult, male Dutch belted rabbits were sedated with pentobarbital, 20 mg/kg IV, and received injections of varying doses of KA (30-240 nmol) intravitreally into one eye and saline vehicle into the other. One week later the rabbits were killed and their retinas removed. A segment of each retina was removed for histological examination and the remainder was extracted and assayed for SLI and substance P-like immunoreactivity (SP) by radioimmunoassay, dopamine (DA) by HPLC with electrochemical detection and protein. Histologically, KA produced destruction of the inner layers of the retina in a dose-related manner, with preservation of the photoreceptors, and with a dose-related depletion of retinal protein content. At KA doses of 60-240 nmol, both SP and DA content were reduced to 3-21% of control values. The dose-response curve for SLI depletion was approximately parallel to those of SP and DA, but the greatest mean depletion of SLI observed was 50%. This failure to reduce retinal SLI content by more than 50% at doses of KA which produce severe histologic damage to the neural retina and dramatic depletions of SP and DA content demonstrates that the SLI-containing structures of the rabbit retina, presumably a subclass of amacrine cells, are partially resistent to the neurotoxic action of KA. This result is in marked contrast to results reported in rat and chick. We hypothesize that SLI in the rabbit retina is contained in two pharmacologic types of cells in about equal abundance; one type is sensitive to and one type insenstive to KA. This hypothesis, if verified, would have importance in investigating the mechanism of action of KA and the pharmacology of somatostatin-containing neurons of the retina.

Supported by NIH Grant AM 26252. S.M.S. was a postdoctoral fellow supported by the National Eye Institute.

37.12 MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED RABBIT RETINAL GANGLION CELLS. F. R. Amthor, C. W. Oyster, and E. S. Takahashi. Dept. of Physiological Optics, University of Alabama in Birmingham, Birmingham, Alabama 35294.

Intracellular recordings and iontophoretic HRP injections were made in rabbit retinal ganglion cells in a superfused eyecup preparation. The morphologies of these cells were analyzed in flat mount preparations. Inner plexiform layer (IPL) ramification of the cell's dendrites were determined with the aid of three dimensional computer reconstruction.

We report a variety of cells with concentrically organized receptive fields as well as several more complex types. ON and OFF center concentric cells were found with at least two and possibly three distinct morphologies corresponding to previously identified anatomical classes. At least one anatomical class (radial dendritic morphology), which has subgroups whose dendrites branch in either sublamina a or b, can now be associated with a physiological class (concentric cells) which are either OFF center (dendrites in sublamina a) or ON center (dendrites in sublamina b), respectively. All concentric cells found so far appear to obey this a/b (OFF/ON) sublamination scheme.

An ON-OFF cell having attributes of the local-edge-detector physiological class has been found to have a dense and intricate branching pattern which is globally bistratified and possibly tristratified. The morphology of this cell may be distinct from morphological types we have previously reported, but is similar to an ON-OFF cell reported by Bloomfield & Miller, (1981).

38.1 IN VITRO LABELING RECEPTOR AUTORADIOGRAPHY: LOSS OF LIGAND DURING PREPARATION. M.J. Kuhar and J.R. Unnerstall. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205

In vitro labeling autoradiography involves 1) incubating slide mounted tissue sections with ligands (LIG) to label receptors with a high degree of specificity, and 2) generating autoradiograms by a procedure which does not allow a significant loss of, or diffusion of, ligand from receptor. Young and Kuhar (Brain Res. 179:255, 1979) dealt with the second point by avoiding contact with aqueous or organic media and by directly apposing labeled, slide-mounted tissue sections (LASEC) to dry, emulsion-coated coverslips. Subsequently, others suggested modifications of this which involved fixation of the LASECs with hot aldehyde vapors, dehydration and defatting of the LASECs in ethanols and xylene, and direct dipping of the LASECs into hot, molten emulsion. It was implied that at least some LIGs were fixed to the receptors by the aldehyde treatment. In this study, we have tested for the loss of several reversible receptor labeling LIGs from formaldehyde vapor fixed LASECs in ethanol solutions.

LASECs were made by routine procedures. They were fixed in a heated, closed vessel containing paraformaldehyde. After various treatments, the tissue sections were scraped from the slides for determination of specific binding.

Fixed LASECs were soaked for various times in 70% ethanol. Every LIG examined was lost from the section in significant quantities. ^{3}H-Naloxone and ^{3}H-muscimol showed the least loss which was 30-40%. ^{3}H-Dihydromorphine, ^{3}H-para-aminoclonidine, ^{3}H-prazosin and ^{3}H-spiperone showed 70-80% loss. ^{3}H-n-Methylscopolamine (NMS) was totally lost. Changes in fixation conditions could reduce but not prevent the loss of some LIGs. The bulk of the loss occurred by one minute after which it was more variable and slower.

Several experiments were carried out with NMS in attempt to prevent total loss of ligand from LASECs. Other reagents were used as fixatives, and LASECs labeled with NMS were dipped directly into molten emulsion (Kodak NTB-3) without any exposure to ethanol or xylene; there was still a total loss of label within 60 seconds.

Thus, the introduction of dehydration, defatting and wet emulsion application into in vitro labeling procedures is not without problems, even in fixed tissues. The loss of ligand, which varied widely depending on the ligand used, indicated the possibility that diffusion of ligand will occur in the section to the extent that anatomical resolution will be reduced. Even if this latter were not a possibility, longer exposure times will be necessary. The total loss of at least one LIG indicates that these procedures are not generally applicable.

38.2 LOCALIZATION OF SEROTONIN-LIKE IMMUNOREACTIVITY IN THE LOBSTER HOMARUS AMERICANUS. B.S. Beltz and E.A. Kravitz. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

The amine serotonin (5HT) is found in lobsters both in central ganglia and in association with the neurosecretory neurons and pericardial organs (PCOs) of a diffuse peripheral neurohormonal network. This peripheral network, which is found along the second nerve roots of thoracic and subesophageal ganglia, releases at least three physiologically important compounds (5HT, octopamine, and the peptide proctolin) into the haemolymph. Among its many peripheral actions, circulating 5HT induces a contracture and enhances the strength of nerve-evoked contractions in lobster exoskeletal muscles. In addition, we believe that 5HT released from central synaptic sites can cause a rigid flexion of the legs and abdomen, similar to the posture seen when 5HT is injected at high concentrations into freely moving lobsters (see Kravitz et al. (1981) in Serotonin Neurotransmission and Behavior, eds. Jacobs and Gelperin, pp. 190-210).

To explore the peripheral and central actions of 5HT at a cellular level, we require a detailed knowledge of the locations of serotonergic cell bodies and release sites. To this end, we have used immunohistochemical techniques in wholemount preparations to explore the distribution of 5HT-like immunoreactivity in the lobster nervous system. The specificity of our antibody (obtained from Immunonuclear Corp.) was demonstrated by showing that immunoreactivity was lost: (1) when antibody solution was pre-absorbed with a 5HT-albumin conjugate (the original antigen) or with 5HT and (2) when 5HT was depleted from tissues by treatment with the neurotoxin 5,7-dihydroxytryptamine.

With this method we found over 100 cell bodies that contain 5HT-like immunoreactivity. A few of these are located peripherally near PCOs, but the vast majority are located in central ganglia. Every ganglion tested contains at least one immunoreactive cell body. Approximate cell body counts per ganglion are: 34-brain; 1 per circumesophageal ganglion; 26-subesophageal ganglion; 2 per thoracic ganglion; 3-5 per abdominal ganglion. Pairs of cell bodies in the 5th thoracic and 1st abdominal ganglia send processes out the thoracic second roots to form part of a dense plexus of fine fibers and varicosities that surrounds the roots and PCOs. The neurosecretory neurons located at the bifurcations of the second roots do not show any immunoreactive staining.

With the wholemount preparations, we have been able to trace the projections of many of the immunoreactive neurons, and have constructed a map of this system of cell bodies, fibers and endings in Homarus. We are using this map to locate the same cells in living preparations in order to examine their relationships to the peripheral neurohormonal network and the generation of particular postures. (Supported by NIH).

38.3 IMMUNO-REACTIVE MYELINATED 5-HT AXONS IN THE MEDIAL FOREBRAIN BUNDLE OF MONKEY AND RAT. Efrain C. Azmitia and Patrick J. Gannon, Dept. of Anatomy, Mt. Sinai Sch. Med. N.Y., N.Y. 10029

Ascending monoaminergic fibers, classically described as unmyelinated (Dahlstrom and Fuxe ,Acta physiol. scand. 62, 1, 1964; Beaudet and Descarries, J. physiol. Paris, 77, 193, 1981) use the MFB as their major route. We here report the presence of myelinated axons immuno-reactive to an antibody raised against 5HT-hemocyanin (gift of J. Lauder).

Monkeys and rats were pretreated with pargyline (50 and 200 mg/Kg, respectively) and L-tryptophan (50 and 200 mg/Kg respectively) before intracardial perfusion with 4% paraformaldehyde, 0.2% glutataldehyde and 0.1% $MgSO_4$ in 0.1M phosphate buffer (20°C). After post fixation in the same fix without glutaraldehyde, 20 um vibratome sections were cut through the hypothalamus and processed by the immuno-peroxidase method. All antibodies were prepared in 0.1M Tris buffered saline) containing 1% normal sheep serum and 0.1% Triton X-100. Sections were pre-incubated in 0.05% 3,3-diaminobenzidine containing 0.2% nickel ammonium sulfate for 10 min at 20°C before the addition of 0.003% hydrogen peroxide. The sections were subsequently post-fixed for 1 hr at 20°C in 2% osmium tetroxide in 0.1M phosphate buffer (pH 7.2) and then block stained in 0.5% uranyl acetate at 5°C for 30 min. No further heavy metal staining was required.

In the monkey 25% and in the rat 1% of the total number of immuno-reactive fibers were myelinated. These fibers ranged between 1.0 - 2.1 um in diameter. Specific labeling was seen in small clear vesicles, the outer mitochondrial membrane , and in patches along the inner axonal membrane. Descending myelinated axons labeled by exogenous ^{3}H-5-HT have been previously reported (Chan-Palay, J. Neurocytol. 7, 419, 1978; Ruda and Gobel, Brain Res. 184, 57, 1980).

38.4 CO-LOCALIZATION OF CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE IN MAMMALIAN FOREBRAIN. A.I. Levey[1], E.J. Mufson, M-M. Mesulam, and B.H. Wainer.[1] University of Chicago,[1] Chicago, IL 60637, and Harvard University, Boston, MA 02215.

Acetylcholinesterase (AChE) has been employed as a histochemical marker for cholinergic neurons despite questionable specificity. We developed monoclonal antibodies against the more specific marker, choline acetyltransferase (ChAT). We now report a comparison of AChE and ChAT localization in the mammalian forebrain. Sections from animals (5 rats, 1 monkey) pretreated with diisopropylfluorophosphate (DFP) were stained either for ChAT by immunoperoxidase, or AChE with silver nitrate intensification, or co-stained for ChAT and AChE in the same section. ChAT was visualized as a diffuse brown reaction product, and AChE as black granules. The procedures were tested in the oculomotor nucleus in the rat and showed that 97% of the cells stained for both markers. In the adjacent serotonergic dorsal raphe nucleus, all the cells were AChE-positive and ChAT-negative.

Major cholinergic projections to mammalian neocortex are believed to arise from a magnocellular system in the basal forebrain that includes the nucleus of the diagonal band of Broca (NDBB) and the nucleus basalis of Meynert (NBM). Double-stained sections of these areas showed that virtually all ChAT-positive cells were AChE-positive; however, these neurons were admixed with significant numbers of ChAT-negative and AChE-positive cells.

Some investigators believe that intensely AChE-stained cells are likely to be cholinergic. The double-labelled cells in the present study exhibited a wide range of AChE-staining intensity; however, intensely-stained cells always co-localized with ChAT. Since the intensity of the AChE stain might be perturbed in the co-localization procedure, cells counts were performed on adjacent sections stained for either ChAT or AChE alone. In the NDBB, there were 62% more ChAT-positive than AChE-rich cells ($P<0.01$), and in the NBM there were 54% more ChAT-positive cells ($P<0.01$). These results suggest that although AChE-rich cells are probably cholinergic, many cholinergic neurons in the basal forebrain do not stain intensely for AChE following DFP treatment. Strikingly different results were obtained in the neostriatum where there was virtually a 100% correspondence between the large AChE-rich cells and ChAT-positive cells. Similar results were obtained in the one monkey forebrain examined. Thus, the use of specific anti-ChAT antibodies to localize cholinergic neurons is likely to be more reliable than AChE histochemistry.

38.5 CHOLINERGIC PROJECTIONS FROM THE MESENCEPHALIC TEGMENTUM TO NEOCORTEX IN RHESUS MONKEY. E.J. Mufson, A. Levey, B. Wainer and M-M. Mesulam. Harvard Sch. of Med., Boston, Ma. and Univ. of Chicago, Chicago, Ill.

The nucleus basalis of Meynert is a major source of cholinergic input to the neocortex of the rhesus monkey. There are other non-thalamic subcortical projections into cortex. For example, many neocortical regions receive direct projections from the brainstem Raphe nuclei and from the nucleus locus ceruleus. These nuclei are sources of serotonergic and noradrenergic innervation for neocortex. The present study was undertaken to determine whether the brainstem was also a source of cholinergic input to neocortex.

Peroxidase anti-peroxidase (PAP) immunohistochemical staining with monoclonal antibodies shown to be specific to choline acetyltransferase (ChAT) revealed intensely positive neurons in the deep tegmental grey of the monkey mesencephalon. The region containing these neurons corresponds mostly to the nucleus cuneiformis and probably also overlapped with the nucleus tegmenti pedunculopontinus. The ChAT positive neurons were arranged into a compact lateral and a diffuse medial subdivision. ChAT positive neurons were seen to penetrate into adjacent fiber bundles.

Animals were injected with DFP. Tissue subsequently processed for AChE showed an intense reaction in these deep tegmental neurons. This contrasts sharply with the weak AChE positivity in other non-cholinergic but AChE containing nuclei such as the substantia nigra. We found that in the cuneiformis nucleus, all ChAT-positive neurons were also AChE-rich and that there were no AChE-rich neurons that lacked ChAT.

In order to demonstrate that neurons of this nucleus project to cortex, we examined the brainstem of several monkeys which had received cortical HRP injections (i.e. cingulate, insula, areas 5 and 8). Retrogradely labeled neurons were observed in the same nuclear region that contained the ChAT and AChE rich neurons. In tissue processed for the concurrent demonstration of AChE and HRP, HRP labeled neurons in this nucleus were also AChE-rich. On the basis of tissue processed for the concurrent demonstration of ChAT and AChE, we concluded that these HRP labeled, AChE-rich neurons are also ChAT positive. Therefore, our findings demonstrated the presence of a cholinergic projection from the deep tegmental grey to many cortical regions. Compared to the cholinergic input from the nucleus basalis, this appears to be a rather minor projection. For example, in five cases with cortical HRP injections a semiquantitative analysis revealed a mean of 100 HRP-labeled neurons per case in this cholinergic nucleus of the tegmentum as compared to a mean of 2200 neurons per case in the nucleus basalis. However, the number of cell bodies that give rise to projections give little indication as to the number of cortical terminations. These findings indicate that the deep tegmental grey contributes an additional cholinergic input to neocortex. Supported by NIH grants NS 17661, 09211, and the Essel , the Whitehall and the Francis Ledder Foundations.

38.6 LOCALIZATION OF BOMBESIN-LIKE IMMUNOREACTIVITY IN THE SPINAL CORD AND SENSORY GANGLIA: IMMUNOHISTOCHEMICAL EVIDENCE FOR DUAL ORIGIN OF THE PEPTIDE IN THE SPINAL CORD. P. Panula*, M. Hadjiconstantinou*, H.-Y.T. Yang and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Indirect immunofluorescence and peroxidase/antiperoxidase methods were used to study the localization of bombesin-like immunoreactivity (BN-LI) in the spinal cord and sensory ganglia of the rat. Rhizotomies were carried out at lower lumbar and sacral level to study the possible contribution of sensory fibres in the BN-LI of the spinal cord. Transection of the spinal cord at midthoracic level was performed to find out the extent of immunoreactive fibres originating from higher level of the CNS. Fresh 8 or 15 μm thick cryostat sections of formalin fixed spinal cords and spinal sensory ganglia were used for immunohistochemistry. The specific bombesin antiserum produced in rabbits was diluted 1:1000 and incubation was carried out for 48 hours at 4°C. The swine anti-rabbit antiserum and the PAP complex were diluted 1:50 and incubations were carried out at room temperature for 30 min. When immunofluorescence was used the sections were incubated with rhodamine-conjugated swine anti-rabbit antiserum, diluted 1:40 for one hour. Consecutive sections were incubated with bombesin antiserum preabsorbed with different amounts of bombesin or substance P. Bombesin was found to block the staining whereas substance P had no effect. In radioimmunoassay procedure our bombesin antiserum cross reacted with substance P less than 0.1%. In normal spinal cord, BN-LI was found in superficial layers of the posterior horn, around the motoneurones of the anterior horn and around the central canal in varicose fibres and terminal-like structures. After rhizotomy, the staining in the posterior horn diminished considerably whereas the staining of the anterior horn was unchanged. Transection of the spinal cord left the staining in the posterior horn unchanged and the terminals in the anterior horn were seen as well. Bombesin-like immunoreactivity was found in spinal ganglion cells but the number of immunoreactive cells was lower than the number of substance P-immunoreactive cells as revealed by a specific substance P antiserum. When consecutive sections were stained with the two antisera different cells were stained. We conclude that a bombesin-like peptide is present in the spinal ganglion cells which project to the posterior horn of the spinal cord. The rest of the BN-LI in the spinal cord may be derived from spinal interneurones or enter the spinal cord from the sensory ganglia between the transection and rhizotomy levels. It appears that the sensory ganglion cells that contain BN-LI are different from those that store substance P.

38.7 IMMUNOCYTOCHEMICAL LOCALIZATION OF MONOAMINE OXIDASE-B IN ADULT RAT BRAIN AND EARLY QUAIL EMBRYOS. P. Levitt[1], J.E. Pintar[2], G.D. Maxwell[3] and X.O. Breakfield[4]. [1]Sect. Neuroanatomy & Dept. Human Genetics, Yale Univ. Sch. Med., New Haven, CT 06510. [2]Dept. Anat. & Med., Mt. Sinai Sch. Med., New York, NY 10029. [3]Dept. Anatomy, UConn Health Ctr. Farmington, CT 06032

The mitochondrial enzyme monoamine oxidase (MAO) is responsible for deamination of many biogenic amines. Two types of MAO activity (MAO-A and MAO-B) can be distinguished on the basis of substrate affinities and drug sensitivities, and are mediated by two distinct enzymes. Pharmacological analysis has revealed differential distribution of MAO-A and MAO-B activities in the adult rat central nervous system (CNS). In addition, developmental analysis in whole quail embryos has demonstrated the presence of both MAO-A and MAO-B activities. In general, these approaches have not been useful in elucidating the specific cellular distribution of the two enzymes. Using an antiserum raised against pure bovine MAO-B (enzyme from Dr. James Salach), we have performed immunocytochemical analysis to localize MAO-B specifically in the adult rat CNS and in quail embryos at different developmental stages.

MAO-B immunoreactivity is present in two major CNS cell classes in the rat: astrocytes and serotonin-containing neurons. This localization was confirmed in double immunofluorescence experiments using antisera to glial fibrillary acidic protein or serotonin. Both protoplasmic and fibrillary astrocytes are immunoreactive throughout the brain, whereas oligodendrocytes are MAO-B negative. In addition, cells in regions lacking a blood-brain barrier, such as the circumventricular organs, are MAO-B positive. Ependymal cells lining the ventricles also stain for MAO-B. Catecholamine-containing neurons, such as those in the substantia nigra and locus coeruleus are MAO-B negative, although astrocytes in these regions are heavily stained. The presence of MAO-B in certain cell types may be related to the regulation of biogenic amine entry into the CNS and control of amine levels.

Quail embryos at 2-5 days of development contain MAO-B immunoreactive cells in the truck regions previously shown to contain or accumulate biogenic amines (including serotonin). These structures include the yolk sac, notochord, ventral neural tube and bilaterally symmetric cell populations near the dorsal aorta (likely the primary sympathetic chains). In addition, immunoreactivity is observed at the junction of the dermatome and myotome and within scattered cells throughout the embryo that may be neural crest derived. These results, combined with previous embryonic MAO activity measurements suggest that MAO-B may help to regulate amine levels in specific cell populations during early embryonic development.

Supported by NS18031 (PL), NS12105 and NS17083 (XOB), NS16115 (GDM), Basil O'Connor Starter Grants 5-326 (PL) and 5-289 (GDM) from the March of Dimes and the Hazen Foundation (JEP).

38.8 LOCALIZATION OF AROMATIC L-AMINO ACID DECARBOXYLASE IN NON-MONOAMINERGIC NEURONS OF THE RAT SPINAL CORD. C.B. Jaeger, G. Teitelman, V.R. Albert*, D.H. Park, T.H. Joh and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

In the central nervous system (CNS), the enzyme aromatic L-amino-acid decarboxylase (AADC) is believed to be contained only in these systems of neurons which synthesize and store serotonin (5HT), and the catecholamines. In the periphery, however, AADC has been found in some endocrine cells (e.g. pancreatic islet, Teitelman et al., Proc. Natl. Acad. Sci. USA 78:5225, 1981) that do not synthesize monoamines. We sought to determine whether non-monoaminergic neurons which contain AADC exist in the CNS.

Immunocytochemical staining using highly speicific antibodies against AADC, tyrosine hydroxylase (TH), phenylethanolamine-N-methyltransferase (PNMT), and 5HT revealed the presence of cells containing AADC in the spinal cord of neonatal and adult rats. In contrast, TH, PNMT, and 5HT could not be localized in perikarya similar to AADC positive cells. Cells containing AADC were found primarily in area X of Rexed surrounding the central canal. They had a variable distribution at different levels of the spinal cord. Most AADC positive cells were juxtaposed to the ependymal cells of the central canal. They had small round to oval cell bodies and several short processes. Electron microscopic examination of AADC cells stained by preembedding immunocytochemistry showed that AADC containing cells had features common to neurons: typical asymmetric synapses were found between dendrites of AADC cells and small axonal boutons. Axon terminals containing pleomorphic vesicles abutted the soma of AADC positive cells. With few exceptions, AADC containing neurons of the spinal cord extended at least one of their processes into the lumen of the central canal.

This is the first demonstration of a population of AADC containing neurons in the CNS which do not synthesize monoamines. The observations raise the question of transmitter identity in these neurons. Moreover, their morphology make the spinal AADC cells good candidates for "spinal cerebrospinal fluid (CSF) contacting neurons" that are present in numerous vertebrates including mammals (Vigh and Vigh-Teichman, Int. Rev. Cytol. 35:189, 1973). Conceivably, like spinal CSF contacting neurons, the spinal AADC neurons possess a pathway of communication via the CSF to other areas of the central nervous system.
(Supported by NIH HL-07379).

38.9 ANALYSIS OF SYNAPTIC INPUT TO VASOPRESSIN (VP) NEURONS IN THE PARAVENTRICULAR NUCLEUS (PVN). A.J. Silverman and A. Hou-Yu*. Depts. of Anat./Cell Biol. and Neurol., Columbia Univ., P&S, New York, N.Y. 10032.

The PVN is recognized as a regulatory center of autonomic function. Although information has been obtained in the last few years on the cytoarchitectonic organization of the PVN and its efferent projections, relatively little is known about the synaptic input to the various cell types. We now report our observations on the synaptology of immunocytochemically identified VP neurons using ultrastructural immunocytochemistry alone or in combination with 3H-norepinephrine (NE) radioautography. A monoclonal antibody to vasopressin (MAVP) (Clone III D-7) that does not cross-react with either oxytocin or arginine vasotocin was produced (Hou-Yu et al., J. Histochem. Cytochem., in press). This antibody was used to identify the VP cells. Adult rats were perfused with either lysine periodate paraformaldehyde, 2% glutaraldehyde or 2% glutaraldehyde, 1% paraformaldehyde with 0.002% $CaCl_2$ and 3% sucrose. Vibratome sections were cut, treated with 0.2% Triton X 100 for 20 min and then exposed to the MAVP for 48hrs. Sections were next incubated in a second antibody conjugated to HRP followed by DAB and H_2O_2. These sections were dehydrated and embedded EPON 812 for EM. Reaction product was present in the cytoplasm of the somata, dendrites and axons. A major synaptic input is observed on all portions of the VP cell. For dendrites and somata, synapses occur on spinous processes as well as on non-spinous regions of the plasma membrane. Both symmetrical and asymmetrical membrane specializations were observed and the presynaptic element contained either clear spherical, elongate or pleomorphic vesicles. Occasionally terminals with dense core vesicles and without apparent membrane specializations were seen. On axons in the median eminence the majority of synapses were asymetrical with clear, round vesicles. To determine if any of these terminals contained norepinephrine, we infused 100 uCi of 3H-NE into the ateral ventricle or 10 uCi directly into the tissue. At approriate times thereafter the animals were perfused with fixative nd tissue processed for EM immunocytochemistry as above. Thin ections were coated with Ilford nuclear emulsion according to he method of Kopriwa and exposed for up to 3 mos. Silver grains ver axon profiles and immunocytochemical reaction product were bserved in the same thin sections demonstrating that the techniues are compatible. This approach makes possible the qualitaive and quantitative analysis of the NE input to VP neurons. upported by AM 20337, a grant from the Whitehall Fnd (AJS) and n MDA fellowship (AH-Y).

38.10 IMMUNOCYTOCHEMISTRY OF OLFACTORY TUBERCLE AND OLFACTORY CORTEX. R.A.E. Bakay*, L.E. Westrum, A. Hendrickson (SPON: J.S. Lockard). Depts. Neurological Surgery, Biological Structure, and Opthalmology, Univ. of Washington, Seattle, WA 98195, and J.Y. Wu, Dept. Cell Biology, Baylor College of Medicine, Houston, TX 77030

The olfactory tubercle has been shown to have a very strong reactivity to certain transmitter enzymes, especially glutamic acid decarboxylase (GAD) but less is known of the pattern in the adjacent and interconnected olfactory cortex. Also since recent receptor-binding studies in these areas implicate opiate receptor binding here, the comparative examination of this region for enkephalin reactivity would be particularly useful. Olfactory tubercle (OT) and the adjacent prepyriform cortex (PYR) are being studied immunocytochemically with a variety of specific antibodies to transmitters enzymes. Included are commercially obtained antisera to met-enkephalin and GAD antisera prepared according to the protocol of J.Y. Wu. With light microscopy, GAD reactivity in OT was seen predominantly in deeper layers, including layer III and with especially positive accumulations adjacent to the Islets of Calleja and protruding into the scallops of layer II cells. Somewhat less distinct reactivity, granules and fibers were seen in layer I, especially near the pia. A few large cells deep in layer III show slight reactivity in colchicine injected material. The PYR shows definite reactive fibers and terminals throughout layer I but somewhat concentrated immediately under the lateral olfactory tract and deep layer I nearer the cell bodies. No reactive cells were seen in colchicine material. Enkephalin reactivity was striking in OT but complementary to GAD with a heavy distribution throughout layers I, II and upper III, avoiding to a great extend the GAD positive deeper areas. Islet of Calleja and their GAD positive cores were not enkephalin reactive. PYR had reactive fiber and terminals in upper layer I, and deeper in layer III. Reactive cells were rare in colchicine injected material. The results show a GAD and enkephalin-related reactivity which is complementary but with some areas of overlap.

39.1 EFFECTS OF HYPOTHALAMIC PERIVENTRICULAR AND AMYGDALAR LESIONS ON EPISODIC GROWTH HORMONE AND THYROTROPIN SECRETION AND SOMATOSTATIN. L. C. Terry, W. R. Crowley, C. Lynch*, C. Longserre*, R. Free* and N. Petersen*. Depts. of Neurol. & Physiol., U. of Michigan and VA Hosp., Ann Arbor, MI 48105 and Dept. of Pharmacol, U. of Tennessee, Memphis, TN 38163.

Somatostatin (SRIF) inhibits growth hormone (GH) and thyrotropin (TSH) secretion in the rat, and passive immunization with SRIF antiserum elevates plasma GH & TSH. Earlier studies (W.R. Crowley & L.C. Terry, Brain Res. 200:283, 1980) have shown that lesions of the hypothalamic periventricular nuclei (HPV) and medial-basal amygdaloid nuclei (AMYG), which contain high concentrations of SRIF neurons, deplete SRIF in the median eminence (ME). The present study assessed the involvement of these SRIF systems in the regulation of basal episodic GH and TSH secretion by placing discrete lesions in the HPV and AMYG.

Two experiments were performed using freely-behaving, chronically cannulated, male albino rats (300-400g) kept on a constant light-dark cycle (12-12h, lights on at 600h) with food and water ad lib. In one experiment, bilateral electrolytic anodal lesions (2mA x 10sec) were placed in the HPV at the level of the paraventricular nucleus. In a second experiment, bilateral thermocoagulation lesions (55°C x 1min) were placed in the AMYG. Blood samples were removed from animals every 15min for 5.5h (beginning at 1000h) 2 weeks postoperatively. Animals were then decapitated and their brains were removed rapidly and frozen. Individual brain nuclei were microdissected and assayed for SRIF (radioimmunoassay) and protein content (Lowry method). Plasma concentrations of GH and TSH were determined by a double antibody radioimmunoassay. Only animals bearing correctly placed lesions were evaluated.

HPV lesions significantly reduced SRIF levels in the ME (227.8 ± 48.1 vs 557.3 ± 22.7 pg/ug protein) and arcuate (18.9 ± 5.9 vs 42.4 ± 8.7) and anterior HPV nuclei (6.6 ± 1.1 vs 31.4 ± 10.5). AMYG lesions caused a smaller but significant reduction in ME SRIF (554.2 ± 56.3 vs 750.1 ± 81.7). Neither the total amount of GH secreted (area under curve, trapezoidal method) nor plasma GH peaks, troughs or interpeak intervals were altered significantly by HPV or AMYG lesions. However, AMYG lesions caused a significant elevation in the total amount of TSH secreted (195,897 ± 7192 vs 152,087 ± 11,650 ng/ml x min) and mean plasma TSH levels (508 ± 16 vs 380 ± 18 ng/ml). HPV lesions did not significantly alter plasma TSH levels.

These results suggest that (1) SRIF neurons in the HPV and AMYG do not have a significant function in regulation of basal episodic GH secretion, and (2) AMYG but not HPV SRIF perikarya are involved in regulation of basal TSH secretion.

Supported by grants from the Veterans Administration and NIH.

39.2 GROWTH-INDUCING HIPPOCAMPAL TRANSECTIONS AFFECT LIMBIC AND GASTROINTESTINAL SOMATOSTATIN AND LIMBIC CHOLINE ACETYLTRANSFERASE CONCENTRATIONS IN HAMSTERS. K.T.Borer,S.Segal*,A.I.Vinik*&B.Shapiro*. Departments of Physical Education and Internal Medicine,University of Michigan,Ann Arbor,MI 48109.

Growth-inducing transections of dorsal hippocampus are associated with significant depletions of serotonin and norepinephrine from hippocampus and cerebral cortex (Borer,K.T. et al Brain Res.Bulletin 4:239,1979).To characterize further the neurochemical and peptidergic circuits responsible for suppression of somatic growth in adult hamsters, we transected bilaterally dorsal hippocampus in 18 adult female hamsters (Borer,K.T. et al.,Neuroendocrinology 29:22,1979),sham-operated 17 controls, and measured somatostatin and choline acetyltransferase concentrations in cerebral cortex,hippocampus,septum,median eminence,gastric fundus, antrum, and pancreas on day 14 of the experiment. To verify that cuts were effective in facilitating somatic growth, animals were weighed daily, and a blood sample was collected on day 14 for determination of hamster growth hormone by a homologous radioimmunoassay. After an initial weight loss, hippocampal cuts induced a significant ($p < 0.05$) increase in ponderal growth rate, and were associated with significantly higher concentrations of growth hormone in the serum (54.2 ± 7.9 vs 7.8 ± 1.6 ng/ml, $p < 0.01$). Other significant ($p < 0.05$) differences were as follows:

	SOMATOSTATIN (pg/mg)		CHOLINE ACETYLTRANSFERASE (pM/mg)	
	Hippocamp.cuts	Controls	Hippocamp.cuts	Controls
Hippocampus	198.7±18.1	299.5±42.1	522.9± 76.8	3105.8± 100.5
Septum	178.8± 9.8	167.5±13.5	5086.6±191.6	4651.5± 192.3
Antrum	52.4±10.0	29.4± 3.2		
Pancreas	98.0±17.4	184.3±22.0		

Significant depletion of somatostatin and choline acetyltransferase from hippocampus, and an apparent accumulation of both substances in the septum, suggest that hippocampal transection may be damaging somatostatinergic and cholinergic projections from septum to hippocampus.Significant shifts in gastroenteropancreatic somatostatin concentrations suggest a possible involvement of this peptide in the control of nutrient entry during lesion-induced acceleration of growth in adult hamsters.

39.3 HIGH AFFINITY ALDOSTERONE RECEPTOR OF RAT BRAIN BINDS GLUCOCORTICOIDS AS WELL AS MINERALOCORTICOIDS. K. Beaumont and D.D. Fanestil*. Dept. of Medicine, Univ. of California, San Diego, La Jolla, CA 92037

We have investigated the steroid specificity and regional distribution of the high affinity cytoplasmic aldosterone (ALDO) receptor recently identified in rat brain (Anderson and Fanestil, 1976). ^{3}H-ALDO binding to adrenalectomized rat brain cytosols was measured by the dextran-coated charcoal method at concentrations varying from 0.2 to 50 nM. Biphasic Scatchard plots of saturation data were obtained. At 4°C, in the presence of Mo^{++} to stabilize receptors, affinities of the two sites for ^{3}H-ALDO were 0.28 ± 0.23 nM and 18.0 ± 2.5 nM, with densities of 33.0 ± 4.4 fmole/mg pro and 221 ± 29 fmole/mg pro, respectively (mean ± SEM, n=6). At these concentrations, ^{3}H-ALDO did not bind detectably to corticosteroid binding globulin (CBG) of adrenalectomized rat serum. However, ^{3}H-corticosterone (B) did bind to CBG under these assay conditions with an extrapolated affinity of 0.3 nM at infinite protein dilution. Therefore, prior to specificity studies, CBG was eliminated from cytosol preparations of perfused rat brain by selective precipitation of cytosol receptors with 36% NH_4SO_4. Less than 2% of ^{3}H-B binding to NH_4SO_4 precipitates of perfused brain cytosols was to CBG. The specific glucocorticoid RU 26988 (Mogiulewsky and Raynaud, 1980) was used to block low affinity ^{3}H-ALDO binding. Specificity of steroids for displacing ^{3}H-ALDO from the high affinity receptor under these conditions is DOC > 9αfluoroF > B > ALDO > Cortisol > spironolactone > Dex > TRIAM. Addition of 0.6% dialyzed serum to cytosol, an amount similar to that contaminating unperfused brain homogenates, altered the apparent specificity of this site by sequestering unlabeled DOC and B. The specificity in the presence of CBG was ALDO > DOC >> B, similar to the mineralocorticoid receptor of kidney. Specificity of the low affinity ^{3}H-ALDO binding site was similar to that of the glucocorticoid Type II steroid receptor. Regional distribution of the two receptors was determined in presence of 10^{-8}M RU 26988 to block low affinity binding or 10^{-8}M spironolactone to block high affinity receptors. Both receptors are at highest density in hippocampus and least dense in hypothalamus. Outside of these areas, the regional distribution of the two receptors is not correlated. The high affinity receptor is most concentrated in limbic areas (amygdala, septum, temporal cortex, striatum) while the low affinity receptor is at high density in cerebellum and cortex. These studies indicate that the high affinity aldosterone receptor of rat brain may bind either corticosterone or aldosterone under conditions used for autoradiographic and in vitro experiments. Which endogenous steroid activates this receptor under physiological conditions is not known.

39.4 OPIATE RECEPTOR MECHANISMS OF PROLACTIN AND GROWTH HORMONE RELEASE IN THE RAT. K. Spiegel, I.A. Kourides* and G.W. Pasternak. Dept. of Neurology, Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021.

Serum prolactin and growth hormone levels are markedly increased by opiates and opioid peptides. The subpopulation(s) of opiate binding sites which mediates this release has not been well established. Recent work suggests the existence of sites which selectively bind morphine-like drugs, termed mu_2 sites, and other sites which preferentially bind enkephalins, called delta sites. Recent studies also suggest an additional, higher affinity site, termed mu_1, which binds both opiates and enkephalins very potently. Naloxazone is an opiate antagonist which selectively blocks mu_1 sites irreversibly.

Rats had chronic intravenous cannulae placed. Dose response studies demonstrated that maximal prolactin release required lower doses of morphine than those needed for the maximal growth hormone response. Groups of rats (n=6) were treated with either naloxone or naloxazone (50 mg/kg,iv). After waiting 24 hours to permit elimination of naloxone and nonirreversibly bound naloxazone, baseline levels were drawn, all animals given morphine sulfate (10 mg/kg,iv), and additional samples taken at 15, 30, and 45 minutes. Peak prolactin levels in the naloxone group, seen at 15 min., were 152 + 32 ng/ml, quite similar to untreated controls (119 + 13 ng/ml; n=4). Blockade of mu_1 sites by naloxazone treatment dramatically lowered the peak prolactin levels, also seen at 15 min., to 29 + 8ng/ml ($p<0.003$). In contrast, peak growth hormone values in naloxazone treated animals (648 + 161 ng/ml) were increased 250% relative to the naloxone treated group (260 + 89 ng/ml; $p<0.10$). These results suggest different receptor mechanisms for the opiate modulation of the two hormones. Mu_1 sites appear to mediate the morphine-induced release of prolactin but not growth hormone.

39.5 STUDIES ON THE INHIBITORY ROLE OF MORPHINE ON THE RELEASE OF DOPAMINE INTO THE HYPOPHYSIAL PORTAL VASCULATURE AND ON THE SYNTHESIS OF DOPAMINE BY TUBEROINFUNDIBULAR NEURONS. M.J. Reymond* and J.C. Porter (SPON: M. Stewart). Cecil H. and Ida Green Center for Reproductive Biology Sciences, Depts. of Obstetrics and Gynecology and Physiology, Univ. of Texas Health Sci. Center at Dallas, Dallas, TX 75235.

A consequence of treatment of rats as well as humans with morphine is hyperprolactinemia due to the release of prolactin from the anterior pituitary gland. This effect of morphine treatment appears to be due, at least in part, to an inhibitory action of morphine on the tuberoinfundibular dopaminergic neurons of the hypothalamus. In the present investigation, we evaluated the efficacy of morphine, administered intracerebroventricularly to ovariectomized adult rats, on the release of hypothalamic dopamine into the hypophysial portal vasculature. In addition, we sought to ascertain the extent to which the suppression of the release of hypothalamic dopamine was due to the inhibition of the synthesis of dopamine in the tuberoinfundibular neurons, as evaluated by the accumulation of dihydroxyphenylalanine (DOPA) in the median eminence of rats given 3-hydroxybenzylhydrazine (NSD 1015), a centrally acting inhibitor of the activity of aromatic L-amino acid decarboxylase. During the 60 min following the intracerebroventricular administration of 60 ng of morphine sulfate, a 90% reduction in the rate of release of hypothalamic dopamine into hypophysial portal blood occurred. A dose-related decrease in the rate of release of dopamine into the portal vasculature was observed between 1 ng and 60 ng of morphine sulfate. Regardless of the quantity of morphine sulfate (1 ng to 500 ng) given to the animals, the concentrations of norepinephrine and epinephrine in hypophysial portal plasma and femoral arterial plasma remained unchanged, and no evidence was obtained for hypothalamic release of norepinephrine or epinephrine. The efficacy of morphine on the release of dopamine into the hypophysial portal blood was not associated with an equal efficacy of the drug on the synthesis of dopamine in tuberoinfundibular neurons. No effect of morphine was observed on DOPA accumulation in the median eminence of NSD-treated rats that had received 50 ng of morphine sulfate intracerebroventricularly, and only a 50% reduction was observed in the accumulation of DOPA in the median eminence of rats given 500 ng of morphine sulfate. These findings are illustrative of a discordance in the effect of morphine on the amplitudes of the release and the synthesis of hypothalamic dopamine, and they may be suggestive of a direct influence of morphine on the mechanisms of release of dopamine from the tuberoinfundibular neurons into the hypophysial portal vasculature.

39.6 ELEVATED GLUCOSE UTILIZATION IN NEUROHYPOPHYSIS AND SUBFORNICAL ORGAN OF BRATTLEBORO RATS LACKING VASOPRESSIN. M. Kadekaro, P.M. Gross, H.H. Holcomb§, L. Sokoloff and J.M. Saavedra§§. Laboratory of Cerebral Metabolism, Biological Psychiatry Branch§, and Laboratory of Clinical Science§§, National Institute of Mental Health, Bethesda, Maryland 20205.

Brattleboro rats with hereditary diabetes insipidus (DI) are characterized by an abnormally high water intake and correspondingly high output of hypo-osmolar urine. Despite the fact that these animals cannot elaborate vasopressin, the hypothalamo-neurohypophysial system is hypertrophied and presents morphological characteristics compatible with enhanced metabolism.

In an attempt to characterize the functional significance of these morphological alterations we have employed the 2-[^{14}C]deoxyglucose quantitative autoradiographic technique in the conscious Brattleboro rat. Long-Evans (LE) rats were used as controls. Results were obtained from 3-6 month old male rats fed normal rat chow and tap water ad libitum. Water intake was monitored in the individually caged animals. DI rats (n=6) consumed 92±4 ml/100 g body weight/24 h. LE rats (n=6) drank 11±0.3 ml/100 g body weight /24 h. The table below shows that glucose utilization was selectively increased in the subfornical organ and in the neurohypophysis of DI rats. The hypothalamic nuclei responsible for the secretion of vasopressin in normal animals were not metabolically different in Brattleboro rats. Values for glucose utilization (in µmoles/100 g/min) of structures listed are expressed as means ± SEM of 6 rats.

	LE	DI	
Subfornical organ	51 ± 3	73 ± 3	* $p < 0.001$
Paraventricular n.	62 ± 4	58 ± 4	
Supraoptic n.	60 ± 2	62 ± 4	
Suprachiasmatic n.	66 ± 4	61 ± 5	
Neurohypophysis	44 ± 3	88 ± 8	* $p < 0.001$

The finding that the glucose metabolic rate is elevated in the subfornical organ is interesting inasmuch as this structure mediates drinking in response to high plasma levels of angiotensin II. DI rats are known to have increased plasma concentrations of sodium and angiotensin II. The mechanisms and significance of the elevated glucose utilization in the neurohypophysis are not known.

39.7 GENETIC DIFFERENCES IN CNS ANDROGEN AND ESTROGEN RECEPTORS IN MICE. Neal G. Simon* and Richard E. Whalen (SPON: M. J. Weiss). Long Island Research Institute, Health Sciences Center T-10, SUNY, Stony Brook, NY 11794.

Evidence for a relationship between genotype and hormone binding macromolecules in the CNS has been provided through studies of androgen-insensitive (Tfm) male rats, mice and humans. With this mutation an 85-95% reduction in androgen receptor (AR) levels is seen in comparison to unaffected males. Whether there are genetically determined differences in CNS cytosol receptor proteins for androgens and estrogens among non-mutant males, however, remains to be determined. We addressed this question by examining diethylstiboestrol (DES) and dihydrotestosterone (DHT) binding in hypothalamic-preoptic-septal sections from orchiectomized CD-1, CF-1, and CFW outbred mice.

A modification of the Chamness, et al. (Brain Res., 1979) hydroxylapatit assay was used for 6-point saturation analyses. Cytosols were incubated for 3 or 4 hr with varying concentrations of ^{3}HDES (.04-1.84 nM) or ^{3}HDHT (.078-6.28 nM) at 0-4° C with or without a 100-fold excess of the appropriate unlabeled hormone.

Scatchard analyses of the data revealed that for both hormones there were differences among the strains either in the number of binding sites (B_{max}) and/or in the avidity of the binding (K_d). In the ER assays, CFW males had the highest B_{max} (12.81 fmol/mg protein), followed by CD-1 (9.22 fmol) and CF-1 (6.8 fmoles)males. The apparent K_d in CF-1 males (.14 x 10^{-10}M) was lower than that observed in the other strains (both .32 x 10^{-10}M). AR levels were again greatest in CFW males (B_{max} = 10.36 fmol), followed by CF-1 (9.68 fmol) and CD-1 (8.13 fmol) males. The apparent K_d values for DHT binding to AR were 1.04 x 10^{-10}M (CFW), 2.89 x 10^{-10}M (CF-1), and 2.36 x 10^{-10}M (CD-1).

The results are in reasonable accord with other studies of AR and ER in mice. The detection of differences among genotypes in apparent K_d and B_{max} values suggest that these factors may contribute to strain differences in hormonal sensitivity

39.8 EFFECTS OF POSTERIOR HYPOTHALAMIC LESIONS ON THE ONSET OF MENARCHE AND TIME OF THE FIRST OVULATION IN THE FEMALE RHESUS MONKEY. Ei Terasawa, Michael D. Loose*, John J. Noonan* and Thomas E. Nass*, Wisconsin Regional Primate Research Center, Neuroscience Training Program, University of Wisconsin, Madison, Wisconsin 53715-1299.

The effect of experimental lesions in the posterior hypothalamus on the onset of menarche and on the time of first ovulation was examined in a non-human primate. Bilateral lesions were made through a thermister electrode in the posterior hypothalamus with the aid of X-ray ventriculography in female rhesus monkeys (n=7) at 18 months of age. Electrode tip diameter and tip exposure were 0.7 mm and 1.0mm, respectively, and an electrode tip temperature of 73°C was maintained for 1 min. A total of eight animals of a similar age served as controls and sham controls. All animals were caged individually and examined daily for vaginal bleeding and sex-skin color changes. In addition to the weekly blood drawing for monitoring the changes in hormonal parameters, body weight and nipple size measurements were obtained periodically. The time of the first ovulation was determined by laparoscopic observation of the newly formed corpus luteum and by the values of circulating progesterone. After confirmation of the 2nd ovulation, animals were autopsied and the location and extent of lesions were histologically determined. The bilateral lesions were approximately 2-3 mm in diameter and overlapped the center line of the hypothalamus. In all animals lesions included the premammillary area and the posterior nucleus, while the arcuate nucleus was entirely spared. In most cases lesions encroached upon the ventromedial nucleus and the dorsomedial nucleus rostrally, or the mammillary nucleus caudally or both.

Posterior hypothalamic lesions advanced the age at menarche (22.2±1.3 months, p=0.014, Mann-Whitney U test) and the first ovulation (40.7±2.7 months, p=0.047) when compared to those of control animals (menarche 30.3±3.1; the first ovulation 51.6±4.2 months). The body weight at menarche of lesioned animals (2.6±0.1 kg) was smaller (p=0.047) than that of controls (3.1±0.2kg), but the body weight at the first ovulation of lesioned animals (4.4± 0.3kg) was not different from that of controls (4.3±0.2kg). Hormonal and physical changes during maturation in lesioned animals occurred earlier than those in controls; i.e., an increase in circulating estradiol and growth in nipple size prior to menarche and the first ovulation, and the growth spurt prior to the first ovulation in lesioned animals not only began earlier, but also attained mature levels several months earlier than control animals.

Therefore, lesions in the posterior hypothalamus induced true precocious puberty in the female rhesus monkey. (Supported by NIH grants RR-00167, HD11355, HD15433.)

39.9 NEURAL PATHWAYS MEDIATING LUTEINIZING HORMONE SECRETION IN MALE MICE. Arthur Coquelin and Roger A. Gorski. Department of Anatomy and Laboratory of Neuroendocrinology of the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

As in most mammals, male mice release luteinizing hormone (LH) in abrupt, intermittent episodes. These dramatic, all-or-nothing elevations of circulating LH occur spontaneously or as a reflexive response to the presence of a female (Coquelin and Bronson, Endocrinology 106: 1224, 1980). Is there a single system of neurons that underlies both the intrinsic and reflexive patterns of episodic LH release in mice? As an initial approach to this question we examined LH secretion in mice after hypothalamic deafferentation. We expected that the spontaneous episodes of LH release would not be affected by either anterior (retrochiasmatic) or complete deafferentation of the basal hypothalamus, but that LH responses to social stimuli might be blocked by such surgery. Sexually inexperienced, individually housed, adult CF-1 males received either anterior deafferentation (n=10), complete deafferentation (n=9), or sham surgery (n=6) using a 28 ga Halasz-type stereotaxic knife. All males were implanted with intra-atrial cannulas one week later. Sequential blood samples (30 µl) were withdrawn at 5 min intervals beginning 5-6 days after cannulation; plasma LH was measured by radioimmunoassay. Blood was collected over the 6 hr period before through 1 hr after placing an ovariectomized female into the males' cages. All the control males and 8 of 10 anteriorly deafferented males exhibited 1-2 spontaneous episodes of LH release. Following exposure to females the anteriorly deafferented group demonstrated rapid rises in plasma levels of LH that were indistinguishable from those of the control group. Among the males that responded (6/10 anterior deafferentation vs. 4/6 sham; $X^2 = 0.37$, $p>0.50$), comparable peak values of plasma LH were attained ($\bar{x} \pm$ S.E., anterior deafferentation = 221 ± 49 ng/ml, sham = 248 ± 39 ng/ml; $F(1,8) = 0.16$, $p>0.70$). Neither spontaneous pulses nor hormonal responses to females typical of normal males were obvious in the completely deafferented group. Instead, irregular yet prominent fluctuations of basal LH occurred at approximately 30 min intervals and masked potential individual elevations of hormone following exposure to females. Analysis of variance with repeated measures revealed no overall increase of plasma LH after the social stimulus ($F(1,8) = 0.01$, $p>0.90$). Our results suggest that one neural input mediates the intrinsic as well as the reflexive pattern of LH release in male mice and that it originates outside the medial basal hypothalamus. These afferents may converge upon the median eminence along a rostral-to-caudal, lateral-to-medial projection. Supported by NRSA HD06160 to A.C. and NIH HD00182 to R.A.G.

39.10 COMPARISON OF UPTAKE AND RAPID RELEASE OF DOPAMINE (DA) FROM MEDIAN EMINENCE (ME) AND STRIATAL (S) SYNAPTOSOMES. Karen A. Gregerson*, Pierre Drapeau*, and Michael Selmanoff (SPON: Bruce K. Krueger). Department of Physiology, University of Maryland School of Medicine, Baltimore, Maryland 21201.

Release of preaccumulated ^{3}H-DA from crude synaptosomal preparations (P_2 fraction) from rat ME and S was examined using a rapid filtration technique. Synaptosomes were prepared from comparable masses of tissue (10-15 mg) and run in conjunction for comparison between the tuberoinfundibular and nigrostriatal DA neurons. Synaptosomes were preloaded by incubation in 0.1µM ^{3}H-DA for 30 minutes at 30°C. At this concentration, uptake of ^{3}H-DA was about 2-fold greater into S than into ME synaptosomes, consistent with the differences in uptake kinetics between ME and S reported by Anunziato and coworkers (Neuroendo. 31:316, 1980). Addition of 5×10^{-7}M desipramine, a norepinephrine (NE) reuptake blocker, to the incubation medium, resulted in 20% inhibition of ^{3}H-DA uptake into ME synaptosomes, which may be accounted for by the percentage of NE terminals in the catecholamine population of the ME. Desipramine had no effect on ^{3}H-DA uptake into S synaptosomes, a comparatively NE-poor tissue. ^{3}H-DA release over short time intervals (1-10 seconds) was measured in 2-3 samples/mg tissue with a rapid filtration method using solutions containing 0.1% BSA, which we found to be necessary for stabilizing the synaptosomes. High K^+-induced release of ^{3}H-DA from ME synaptosomes was Ca^{++}-dependent and occurred in two phases. A "fast" phase of release occurred during the initial second of depolarization [rate constant of release (k_{rel}) = 0.012 sec^{-1}] and was followed by a leveling-off of release during the next 9 seconds. The k_{rel} during the fast phase was 2-3 orders of magnitude greater than that previously observed for ^{3}H-DA release from ME utilizing superfusion techniques. The k_{rel} for the fast phase in S synaptosomes (see also Drapeau and Blaustein, Neurosci.Abstr.7:441, 1981) was much greater than that for ME synaptosomes, suggesting that the kinetics of DA release, as well as those for uptake, are markedly different between the ME and S. We are currently using this highly sensitive technique to examine the effects of prolactin, β-endorphin and NE on the release of ^{3}H-DA from ME and S synaptosomes.

39.11 MONOCLONAL ANTIBODIES TO TYROSINE HYDROXYLASE FROM THE CORPUS STRIATUM OF THE RAT. J.F. Sissom* and J.C. Porter. Cecil H. and Ida Green Center for Reproductive Biology Sciences, Depts. of Obstetrics and Gynecology and Physiology, Univ. of Texas Health Sci. Center at Dallas, Dallas, TX 75235.

Tyrosine hydroxylase was purified from the corpus striatum of the rat brain according to the procedure of Vulliet et al. (Proc. Natl. Acad. Sci. U.S.A. 77: 92-96, 1980). This procedure involved precipitation with ammonium sulfate, column chromatography employing DEAE and hydroxylapatite, and sucrose density centrifugation. The specific activity of tyrosine hydroxylase, assayed according to the method of Foreman and Porter (J. Neurochem. 34: 1175-1183, 1980), was increased 100- to 200-fold by this purification procedure. Homogeneity of the final product was confirmed by disc gel electrophoresis using SDS-PAGE. The molecular weight of the purified enzyme was approximately 60,000, a value similar to that reported by Joh et al. (Proc. Natl. Acad. Sci. U.S.A. 75: 4744-4748, 1978) for tyrosine hydroxylase in the rat brain. The purified enzyme was used in the immunization of mice of the BALB/c strain. When the presence of antibodies in the serum of the mice was detected, the spleens of the animals were removed, and the spleen cells were fused with mouse myeloma cells (NS-1 cell line). The procedure of Kennett et al. (Monoclonal Antibodies. Hybridomas: A New Dimension in Biological Analyses, Plenum Press, New York, 1980, pp. 368-369) was followed in the hybridization. An ELISA technique was used to identify hybridomas that secreted antibodies to tyrosine hydroxylase. Clones, identified as TH-1 and TH-6, of two antibody-secreting hybridomas were isolated in soft agar and propagated in cell culture. Clonally derived cells were injected intraperitoneally into mice, and monoclonal antibodies were harvested from the ascites fluid. To evaluate the specificity of TH-6 antibodies, 10 mg of immunoglobulins isolated from ascites fluid was covalently conjugated to 1 g of Sepharose 4B gel. A homogenate of rat corpus striatum tissue was prepared, and aliquots of the homogenate were subjected to affinity chromatography using TH-6 immunoglobulin-Sepharose 4B or glycine-Sepharose 4B, which served as the control. After chromatography on a TH-6 immunoglobulin-Sepharose 4B affinity column, the total activity of tyrosine hydroxylase in the homogenate was reduced 98% compared to the control. These results are supportive of the view that TH-6 antibodies are directed against tyrosine hydroxylase. On the basis of results obtained using assays specific for subclasses of mouse immunoglobulins, it would appear that these monoclonal antibodies are of the IgM class.

39.12 SLOW WAVE FIELD POTENTIALS IN THE RAT BRAIN DURING PUBERTY AND THE ESTROUS CYCLE. J. F. Masken and R. J. Morgan. Dept. of Physiology and Biophysics, Colorado State University, Fort Collins, CO 80523.

Chronic stainless steel electrodes were implanted in the amygdala (AMY), medial preoptic area (POA), and arcuate nucleus (ARC) of both prepubertal and adult normal female Sprague-Dawley rats. Slow wave field potentials were recorded daily from these areas simultaneously for the first 10 min of each half-hr from 7:30 h until 14:10 h throughout the onset of puberty and during the course of the estrous cycle. Recorded analog data was analyzed by cross-correlation analysis for the amount of correlation and direction of signal flow between pairs of electrodes (i.e. AMY-POA, AMY-ARC, POA-ARC), and for conduction times between pairs of sites.

The correlation of slow wave activity for AMY-POA in both prepubertal and adult rats was higher than that of AMY-ARC and POA-ARC with AMY-ARC being the lowest. The correlation for all three combinations, i.e. AMY-POA, AMY-ARC, and POA-ARC was lower in the prepubertal animal. The change in the level of correlation appeared gradually and prior to vaginal opening in the case of AMY-ARC and POA-ARC, but the correlation for AMY-POA increased rather abruptly and right at first estrus. The correlation for all three combinations in adult cycling rats was lowest during proestrus. Also, signal traffic from AMY to the POA lasts longer and takes longer en route during the "critical period" on the day of proestrus than at other times of the cycle, implying a change in signal pathway at this time. Other changes seen in the direction of signal flow (in which area does the signal originate) could be of significance with respect to daily fluctuation in GnRH and LH release.

40.1 EPENDYMAL NEUROGENESIS IN ADULT FEMALE CANARIES. Steven A. Goldman* and Fernando Nottebohm (SPON: D.R. Griffin). The Rockefeller University, New York, N.Y. 10021.

Previous reports have demonstrated the neuroplasticity of the songbird vocal control nucleus HVc. In male canaries this nucleus varies in volume seasonally, in concordance with seasonal song acquisition. The adult female's HVc expands in response to systemic testosterone administration; new dendritic outgrowth may comprise some of this observed increase in size, as has been previously shown for the vocal control nucleus RA. We became interested in the possibility of neuronal proliferation in the adult HVc, as a possible basis for both the gonadally-induced changes in gross HVc volume and the seasonal learning of song.

Sixteen intact adult female canaries were injected i.m. with ^{3}H-thymidine, 50 μCi every 8 hr over a 2 day period. Some birds were given testosterone implants, at varying times (0-18 days) before thymidine treatment, while others were given cholesterol implants before thymidine. The birds were killed 5 weeks after hormone implantation and their brains processed for autoradiography. All birds showed considerable numbers of labelled neurons, glia, endothelia and ependymal cells in and around HVc; little labelling was found elsewhere. Cholesterol and testosterone treated birds had similar neuronal labelling indices, which ranged from 1.8-4.0 % in HVc. Since all of these females had intact ovaries, we have not excluded a gonadal influence on neuronal recruitment, S-phase or survivability. In fact, four gonadectomized adult female canaries, subsequently treated with ^{3}H-thymidine, showed labelling indices that were depressed with respect to those of the intact females.

In order to better identify labelled HVc cells, two thymidine treated birds were prepared for electron microscopic analysis, and processed for combined light autoradiography and ultrastructural analysis of adjacent ultrathin sections. Cells tentatively identified as neurons in 1μm sections were confirmed as such ultrastructurally. We also determined the origin of the thymidine incorporating neurons, by sacrificing two thymidine treated females within 24 hr after their thymidine injections, thereby precluding significant migration of the newly born labelled cells. Analysis of these brains revealed no cells of neuronal morphology present in HVc, but a very heavily labelled ependyma overlying HVc. We tentatively conclude that neuronal precursors exist in the HVc ependyma, which incorporate tritiated thymidine during the S-phase preceding their mitosis; after division, these cells migrate into (and to some extent beyond) HVc. This ependymal neurogenesis occurs in the absence of exogenous testosterone and seems to be a normally occurring phenomenon in intact untreated adult females.

This research was supported by PHS grants 5R01MH18343 and S07 RR07065.

40.2 CONNECTIVITY AND KINETICS OF NEURONS BORN IN ADULTHOOD. Fernando Nottebohm and Steven A. Goldman*. The Rockefeller University, New York, N.Y. 10021.

We have noted in the preceding abstract the existence of ependymal neurogenesis in the adult female canary HVc. In an effort to more precisely elucidate the functional significance of the new HVc neurons, we have studied (1) the patterns of connectivity of these new neurons, (2) the extrapolated turnover of HVc with time, based on the kinetics of HVc neuronal recruitment, and (3) the relative pattern of neurogenesis in adult male canaries.

In a study of the connectivity of the new HVc neurons, two testosterone-implanted adult female canaries were pretreated with 60 μCi injections of ^{3}H-thymidine, twice daily for one week; after a one month hiatus these birds were given iontophoretic injections of the retrograde tracer HRP into two HVc projection nuclei, area X and RA. These nuclei each receive projections from HVc, thereby allowing the HRP to label those subclasses of HVc neurons projecting to each nucleus. The birds were sacrificed 24 hr later and their brains processed for combined HRP histochemistry and thymidine autoradiography. Preliminary data suggest that thymidine incorporating, newly born neurons may not retrogradely label with HRP, indicating that the new HVc neurons probably do not project to either of HVc's two principal targets, RA or area X. It is possible that the new cells project to another, as yet undescribed, target nucleus, but we believe it more likely that they serve as local interneurons within HVc.

We have determined that neurons are added to the adult female's HVc at the rate of approximately 1% per day of the total HVc neuronal pool. However, if the new cells do not include projection neurons, as our HRP data would seem to suggest, then a subclass of interneurons within HVc would account for all of the new neurons, indicating a recruitment much greater than 1% per day within this restricted subpopulation.

In a separate study we examined the possibility that the normal adult male canary might show HVc neurogenesis. Twelve one-year-old male canaries were injected for a two week period with ^{3}H-thymidine (30 μCi i.m., b.i.d. x 14 days) and sacrificed at varying intervals afterwards. Their brains were removed and processed for autoradiography. Analysis of these brains showed a considerable number of labelled, neuron-like cells in HVc; ultrastructural analysis of these cells is now being performed. We tentatively conclude that the adult male canary exhibits neurogenesis, presumably similar in nature to that of the adult female.

40.3 RECRUITMENT OF ADDITIONAL SYNAPSES INTO A BRAIN NETWORK TAKES EXTRA BRAIN SPACE. Timothy J. DeVoogd, Barbara Nixdorf* and Fernando Nottebohm. The Rockefeller University, New York 10021

Adult female canaries treated with testosterone (T) develop male-like song. This hormone treatment also induces an enlargement of telencephalic nuclei involved in song control. An earlier study showed that at least part of this enlargement was due to growth of dendrites. It was inferred at that time that this growth added to the network space controlling song. For this to be true, extra dendritic length would have to correspond to a net gain in number of synapses. In the present study, we test this hypothesis.

Six adult female canaries were given Silastic implants of crystalline testosterone following the fall molt. All began singing about two weeks later and gradually improved to the level of sustained, stereotyped song previously observed in T-treated females. Four treated females and five untreated control females were perfused for electron microscopy six weeks after hormone treatment. The brains were sectioned at 100u. Each slice was lightly counterstained and photographed. Slices containing nucleus robustus archistriatalis (RA) were alternately processed either with osmium tetroxide for conventional electron microscopy or with ethanolic phosphotungstic acid (EPTA) for selective staining of synapses. RA was then disected out of the slices and embedded in Epon. One T-treated female proved inadequately fixed and is not considered further. Synapses in EPTA-stained tissue were counted in medial, central and lateral regions of RA in sections 0.2u thick using dark field light microscopy (from G. Vrensen, personal communication). Since synaptic density did not vary between the regions sampled, these counts were pooled for later analyses. Ultrathin sections of the conventionally prepared tissue were stained with lead citrate and uranyl acetate. Synapses were counted in nine micrographs (32,400X) taken from the central region of each RA.

As shown in the table RA is more than 80% larger in the T-treated than in the control females. The density of synapses as measured by either technique, varies only slightly between treatment groups. This study is currently being replicated. We conclude from the present sample that T-induced song requires a substantially larger synaptic network than that of a non-singing female--obtained by extending RA.

	T-treated	Control
N	3	5
Synapses per $100u^2 \times .06u$	15.3	15.5
Synapses per $100u^2 \times .2u$	58.0	63.2
RA size x mm^3	.137	.074

40.4 RETINAL AND TECTAL GROWTH IN THE TELEOST FISH, HAPLOCHROMIS BURTONI. R. D. Fernald and J. Presson, Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

Teleost fish grow throughout their lifetime and consequently the nervous system adds cells and generates new synaptic connections during adulthood. For example, in the teleost H. burtoni, a 50% increase in body length is associated with a 33% increase in lens diameter (eye size) and a 100% increase in brain weight. H. burtoni offers significant advantages for analysis of the consequences of this post-embryonic growth of the nervous system. First, H. burtoni relies heavily upon its well developed visual system for behavioral interactions which are crucial to its survival. Second, growth of males in this species depends critically upon social interactions. Thus male growth can be controlled so that animals of any desired size and growth rate can be made available.

Previous studies of growth in lower vertebrates (Xenopus, goldfish) have suggested that retino-tectal synaptic partners must change to allow the growing retina to be mapped onto the growing tectum without disturbing the regularity of the retino-tectal map. This suggestion stems from the fact that the retina grows by adding annular rings of cells but the tectum grows in a "U" shaped pattern, adding few cells to the rostral pole while adding many cells to the caudal pole. Since cells are being added to the temporal retina but not to its tectal projection site, the rostral tectum, changing retino-tectal connections seems necessary.

To analyze retinal and tectal growth patterns in H. burtoni, 3-H thymidine was injected intraperitoneally to label the DNA of actively dividing cells. All types of retinal cells were labeled in a ring around the perimeter of the retina, and rod nuclei were labeled across the retina as reported previously. Although the temporal retina has a higher cell density than other regions at all ages, cells appeared to be added uniformly around the retina. This represents an additional constraint on retino-tectal growth in H. burtoni, since maintenance of the region of high density must be achieved without differential cell addition. Cell addition in the tectum of H. burtoni appears to be "U" shaped. Few labeled cells are found in the rostral tectum but the caudal tectum is heavily labeled. Analysis of growth after varying survival times will allow a comparison of the temporal and spatial dynamics of tectal cell addition with those of retinal cell addition. Supported by a grant from the Whitehall Foundation.

40.5 IMMUNOLOGICAL PRIVILEGE IN THE BRAIN WITH RESPECT TO FUNCTIONAL BRAIN GRAFTS. W.J. Freed,* H. E. Spoor, D. Sachs and R.J. Wyatt.* Adult Psychiatry Branch, NIMH, St. Eliz. Hosp., Wash. D.C. 20032; Immunology Branch, National Cancer Institute, NIH, Bethesda, Maryland 20205

Partial restoration of function following damage to certain brain nuclei in animals has recently been accomplished through transplantation of brain tissue. For example, fetal substantia nigra (SN) or adult adrenal medulla transplanted to the brain lateral ventricles partially restores dopaminergic function in the caudate nucleus following SN lesions. Much of this work has employed random-bred rat strains, such as Sprague-Dawley, in which homograft rejection would be expected to occur. These grafts may therefore survive because of the "privileged" status of the brain as a site for transplantation. To rule out the possibility that matching at the major histocompatibility complex (MHC) was responsible for this graft acceptance, we have studied survival and rejection of brain grafts in genetically-defined rat strains.

Rats of the inbred Fisher 344 (F344) strain were used as graft recipients. Donors were either syngeneic F344 rats or Brown Norway (BN) rats, having an MHC difference. Intraventricular SN allografts from BN donors were, in most animals, found to survive for at least four months and in some cases reduced lesion-induced rotational behavior. There was no unusual degree of macrophage infiltration, and the grafts produced catecholaminergic fibers which penetrated into the host (F344) brain.

Several months subsequent to the implantation of BN or F344 grafts, skin patches derived from the tails of either F344 or BN donors were grafted to the skin of the F344 recipients. Syngeneic F344 skin grafts were not rejected, while BN skin grafts were rejected in a mean of 12 $\pm$ 1.6 (mean $\pm$ SEM) days in animals with BN brain grafts, and 14 $\pm$ 1.6 days in animals with F344 brain grafts. This difference was not statistically significant ($T_{(13)}=0.8$, $p=0.44$). However, rejection of BN skin grafts was associated with disappearance of the BN brain grafts. No surviving BN brain graft tissue was found in any of the eight animals that had rejected a BN skin graft, while F344 skin grafts did not adversely affect BN brain grafts.

These findings, in keeping with the original observations of Medawar (Br. J. Exp. Pathol., 29:58, 1948), suggest that the privileged status of the brain as a site for transplantation can be abrogated by sensitization through another route. This is consistent with aberrant central processing of the immune stimulus (Kaplan, H.J. and Stevens, T.R., Transplantation, 19:302, 1975) or with an interruption in the afferent arm of the immune system. Thus brain grafts can survive and function across MHC differences, but fail when the host is sensitized by extracerebral antigenic stimulation.

40.6 RESPONSE PROPERTIES AND SOMATOTOPIC ORGANIZATION OF DORSAL HORN NEURONS FOLLOWING NERVE LESIONS IN THE CAT. L. M. Pubols. Dept. of Anatomy. The Medical College of Pennsylvania, Philadelphia, PA 19129.

It has been reported (Devor & Wall, J. Comp. Neurol. 199:277, 1981) that chronic sciatic and saphenous nerve lesions lead to striking alterations in dorsal horn somatotopic organization. It was the purpose of the present study to identify the population(s) of neurons responsible for this change by examining the receptive field properties of single neurons in chronically deafferented dorsal horns. Seven adult cats with lesions of the right sciatic and saphenous nerves were studied at survival times of 6-12 hr (1), 14 days (2), and 45-67 days (4). Responsiveness ipsilateral to acute (6-12 hr) deafferentation was greatly diminished. Results from chronic lesion animals, which were similar at all survival times, have, therefore, been compared with data from intact dorsal horns of 10 other animals. The right L6 dorsal horn was mapped mediolaterally in transverse rows of dorsoventral electrode penetrations spaced 200μm apart. The most medial penetration containing any responsive neurons was marked in each row by ejection of horseradish peroxidase from the electrode tip, and by using the same electrode as a marker 200μm lateral to this penetration. All receptive fields ipsilateral to the lesions were proximal to the ankle. The median location of the most medial active penetration in 18 rows of penetrations in chronic lesion animals was 71% of the distance from the medial to the lateral boundaries of the dorsal horn, vs. 86.5% of that distance for the most medial penetration with RF's proximal to the ankle in intact dorsal horns ($p < .02$, Mann-Whitney U; ranges = 25-95% vs. 68-98%). Some clearly aberrant somatotopy was observed. However, a silent zone in the medial dorsal horn was always found in the lesion group. A high proportion of single neurons ipsilateral to the lesions (71%, n = 21) showed convergence of input from both hair and high threshold mechanoreceptors, and many had large receptive fields. For 52% of single neurons the region of skin responding to hair movement was surrounded by a larger area responding only to skin compression. The response properties of neurons in the present study are similar to those of some classes of spino-cervical tract and postsynaptic dorsal column neurons (Brown & Franz, Exp. Brain Res. 7:231, 1969; Fyffe et al. Neurosci. Abstr. 7:611, 1981). Data from the present study provide only partial confirmation of the results of Devor and Wall, who found: (1) proximal receptive fields across the entire width of the dorsal horn within 28 days of sciatic and saphenous nerve lesions; and (2) uniform mechanical thresholds throughout the receptive fields of neurons ipsilateral to deafferentation.

40.7 THE AREA 3b REPRESENTATION OF THE HAND IN OWL MONKEYS REORGANIZES AFTER INDUCTION OF RESTRICTED CORTICAL LESIONS. W. A. Jenkins, M. M. Merzenich, J. M. Zook, B. C. Fowler and M. P. Stryker. Coleman Laboratory, Depts. of Physiol. and Otolaryngol., UCSF, San Francisco, CA 94143.

In earlier studies, we demonstrated that transection of the median nerve or amputation of fingers results in a progressive reoccupation of the deafferented cortical zone representing these skin surfaces in Areas 3b and 1 in adult owl and squirrel monkeys. The nature of this reorganization led to the conclusion that representational changes of the same kind should also occur following restricted central somatosensory system lesions.

To test that hypothesis, a restricted cortical lesion was effected by microcauterization of surface vessels within a limited sector of the hand representation in Area 3b in adult owl monkeys. Following induction of the lesion, the representation of the hand was immediately mapped in detail, to functionally delineate the boundaries of the lesion and to precisely define the skin sector whose representation was lost consequent from it. One monkey was again mapped six days later; the boundaries of the lesion and the surviving overt representation were very similar to those defined immediately after making the lesion. By contrast, monkeys remapped 1 1/2 to 4 months later were found to have profoundly reorganized hand representations, with a re-emergence of topographic representations of skin surfaces formerly represented in the territory of the lesion. The locations and topographics of the representations of skin surfaces previously mapped over the cortical region surrounding the lesion were also significantly (sometimes dramatically) altered. The observed reorganizational changes: 1) Probably occurred at the thalamocortical or cortical level; 2) indicate that reorganization occurs with detection of the limits of the damaged cortex through the recovery process; and 3) probably underlie the relatively rapid functional recovery seen after limited cortical damage in this region in man. They further underscore the fact that cortical map structure is dynamically maintained in adult primates.

Further studies are being directed toward determination of the distances over which such reorganizational changes occur, and to determine whether this reorganization process constitutes the principal basis for recovery from stroke. (Supported by NIH Grant NS-10414 and Hearing Research Inc.)

40.8 ISOLATION VERSUS GROUPED HOUSING IN RATS: DIFFERENTIAL EFFECTS OF LOW DOSES OF HEROIN IN THE PLACE PREFERENCE PARADIGM. T. Hunt*, S. Schenk*, L. Colle*.(SPON:L.Switzman)Centre for Research on Drug Dependence, Montreal, Quebec, Canada.

Male long Evans rats were reared from weaning (21-23 days) either in isolation or in groups of four for 40 days. Animals were then individually introduced to a testing apparatus consisting of two distinct chambers. A modified place preference paradigm was used consisting of 3 phases: (1) An habituation phase (4 days) during which rats were allowed free access to the entire test apparatus for 15 min. periods daily; (2) A conditioning phase (4 days) during which rats were confined to their non-preferred side for 15 minutes each day immediately following subcutaneous injection of heroin HCl; (3) Test phase (1 day) during which rats were again allowed free access to the testing chamber following injection of vehicle. The difference in time spent on the conditioned side during habituation and test periods was determined. The group-reared rats showed maximal effects at the lowest dose of heroin whereas the same magnitude of drug effect was attained only at the highest dose used in the isolated rats. This differential sensitively to heroin in the place preference paradigm is discussed in terms of the modification of behavioral effects of opiates by environmental influences.

40.9 PERIPHERAL NERVE STIMULATION ENHANCES RECOVERY OF FUNCTION FROM NEUROLOGICAL DEFICITS IN HUMANS.

J. B. Walker, Walker Pain Inst., Los Angeles, Ca. 90024

Electrical subcutaneous nerve stimulation (SCNS) of radial, median, and saphenous nerves abolished clonus temporarily in subjects with spasticity according to a double-blind study (Science, 216, 203 (1982). Unilateral stimulation suppressed clonus on the contralateral side, and stimulation of the nerves in the wrist suppressed ankle clonus indicating the mechanism mediating the effect must be centrifugal inhibition. After repeated administration of SCNS, subjects can be free of clonus for months.

SCNS also produced improvement of intention tremor in subjects with cerebellar damage. Unilateral SCNS produced ipsilateral improvement. These results, taken together, indicate that SCNS exerts its effect centrally and raises the intriguing possibility that SCNS produces long-lasting changes in neuronal circuitry.

41.1 ADRENAL GLANDS PARTICIPATE IN THE REDUCED FEAR RESPONSE IN SPONTANEOUSLY HYPERTENSIVE RATS. J.E. LeDoux, A. Sakaguchi and D.J. Reis, Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

The behavorial response to aversive stimulation is reduced in spontaneously hypertensive rats (SHRs) when compared with strain-matched Wistar-Kyoto controls (WKYs) in nocioceptive tests and in tests of conditioned fear (LeDoux et al., Fed. Proc. 41: 1364, 1982; Hypertension, in press). That endogenous opiate systems might play a role in these strain differences is indicated by the observation of increased opiate receptor binding in the SHR brain (Martucci and Hahn, Endo. Res. Commo., 6: 291, 1979) and by the fact that treatment of SHRs with the opiate antagonist naloxone enhances both the hypoalgesia and the reduced fear response (LeDoux et al., Fed. Proc., 41: 1364, 1982). The adrenal glands have long been implicated in fear responses (Weiss et al., Science, 163: 197, 1969; Moyer, J. Genetic Psychol., 92: 17, 1958) and adrenal medullary cells contain enkephalin (Wilson et al., PNAS, 77: 4364, 1980). If the adrenal glands contribute to the reduced fear response in SHRs, adrenalectomy should enhance the response; if adrenal opiates are involved, naloxone should have no effect in adrenalectomized SHRs. Classical conditioning (30 trials) was used to establish fear reactions to environmental stimuli. The unconditional stimulus (US), an electric footshock (0.5 sec, 1.5 mA), was delivered at the termination of the conditional stimulus (CS), a pure tone (10 sec, 800 Hz, 80 db). Conditioned fear behavior was assessed the next day by measuring the duration of immobilization ("freezing") during a 300 sec presentation of the CS. Freezing was assessed in: (a) untreated SHRs (n = 10) and WKYs (n = 10); (b) SHRs subjected to bilateral removal of the adrenal glands (n = 6) or sham operation (n = 6); (c) adrenalectomized SHRs treated with saline (2 ml/kg, ip; n = 5) or naloxone (10 mg/ml/kg; n = 5). The duration of freezing (in sec) was less ($p<.01$) in SHRs (171 ± 12) than in WKYs (275 ± 12), thus confirming the strain difference in fear behavior (LeDoux et al., Fed. Proc., 41: 1364, 1982). Freezing in adrenalectomized SHRs (261 ± 12) was greater ($p<.01$) than in sham operates (174 ± 15), indicating that the adrenal glands might play a role in the reduced fear response. Treatment of adrenalectomized SHRs with naloxone reduced ($p<.01$) the duration of freezing (153 ± 18) relative to adrenalectomized SHRs treated with saline (255 ± 15), indicating opiate stimulation rather than blockade. These data demonstrate that adrenalectomy in SHRs eliminates the strain difference in conditioned fear and that treatment with naloxone reverses the effects of adrenalectomy. We conclude: (a) the adrenal glands play a role in the reduced fear response in SHRs; (b) adrenalectomy may alter the effects of naloxone at opiate receptors.

41.2 Rapid Development of Tolerance to Exogenous Cholecystokinin on Satiety-Related Behaviors

J. N. Crawley, Neurobiology Program CR & D
E. I. DuPont de Nemours & Co., Glenolden PA 19036

Cholecystokinin octapeptide (CCK_8) reduces food intake in fasted rats, mice, sheep, pigs, monkeys, and humans.[1] CCK reduces exploratory and social behaviors, initiating the behavioral sequence associated with satiety.[2,3] The present study investigated the ability of chronic CCK_8 administration to produce long lasting changes in body weight and satiety-related behaviors. Alzet osmotic minipumps containing CCK_8 1.0 µg/kg/hr, 0.1 µg/kg/hr, caerulein 1.0 µg/kg/hr, 0.1 µg/kg/hr, or saline were intraperitoneally implanted. Daily food intake and body weight were recorded over the two week infusion. Behavioral responses to a challenge dose of CCK_8 were evaluated during chronic infusion and after removal of the minipump. No significant change in body weight was detectable with any treatment at any time point. Time course of the exploratory behavioral responsiveness to the CCK_8 challenge indicated a rapid development of tolerance to chronic CCK within the first day of infusion. Exogenously administered CCK_8 appears to induce satiety more effectively by acute administration than by chronic infusion.

41.3 Hypothalamic(HYP), Pituitary and Plasma Levels of Pro-opiomelanocortin-Derived(POMC) Peptides During Feeding Stimulated by 2-deoxy-D-glucose(2DG) and Insulin(INS) Administration in Rats. J. Mark Davis*, Marie J. Gibson, and Dorothy T. Krieger, Div. of Endocrinology, Mount Sinai Medical Center, New York, NY 10029

In order to further investigate the possible relationship between β-endorphin(β-ep) and feeding stimulated by 2DG (400mg/kg) and INS(10 U/kg) injections(sc), we measured several POMC-derived peptides in the HYP, pituitary lobes, and plasma in 5 groups(n=8) of male rats studied 60 min post-SAL,-2DG, or -INS injection, or 150 min post-SAL or -INS injection. At 60 min food intake in INS was 3-fold higher, and in 2DG 10-fold higher, than in SAL group. Food intake in INS at 150 min was 4-fold higher than SAL, but equivalent to 2DG at 60 min.

Table 1: Plasma immunoreactive(IR)-peptides and corticosterone(B)

	IR-β-ep+		IR-ACTH+		B++	
	60′	150′	60′	150′	60′	150′

	INS	.30±0.2	.36±0.5	-	-	.13±0.1*	.20±.03
	SAL	.09±.01	.09±.01	.14±.04	.19±0.3	-	-
AP+	2DG	.10±.01	-	.09±.01	-	-	-
	INS	.11±.01	.18±.05	.18±.05	.08±.01*	-	-
	SAL	.98±.21	1.19±.23	-	-	.87±.30	.51±.05
NIL§	2DG	1.06±.20	-	-	-	.62±.11	-
	INS	1.12±.10	1.19±.23	-	-	.66±.23	.84±.23

+ ng/mg wet wt.; § µg/mg wet wt.; *$p<0.05$ vs. saline

Increases in plasma IR-ACTH and B were greater following 2DG than INS. Only 2DG was associated with increases in plasma IR-β-ep. Both stimuli were associated with similar decreases in HYP α-MSH levels. No changes were seen in HYP IR-β-ep levels. The only change in pituitary IR-peptide levels was a decrease in IR-ACTH in the AP at 150 min following INS.

Further characterization of other forms of these peptides is in progress. These preliminary findings suggest that both 2DG and INS produce similar alterations in POMC-derived peptides in HYP, but quite different responses in plasma. The significance of these changes relative to reported differential naloxone effects on 2DG and INS feeding remain to be determined.

41.4 MODULATION OF CNS INSULIN RECEPTORS BY STREPTOZOTOCIN-INDUCED DIABETES: EVIDENCE FOR INDEPENDENT INSULIN RECEPTOR SYSTEMS IN THE CNS. R. J. Waldbillig*, D. J. Steel*, and M. S. Kappy* (SPON: T. Schoenfeld). Depts. of Psychology and Pediatrics, University of Florida, Gainesville, Florida 32611

Recent evidence indicates that the brain contains an insulin-insulin receptor system. Published reports have shown that neither CNS insulin levels nor insulin receptor binding in brain tissue are affected by diabetes or systemic hyperinsulinemia However, these analyses were performed on whole brain homogenates, and it is entirely possible that an analysis employing greater anatomical selectivity might reveal regional differences. This is most likely to occur in circumventricular areas such as the hypothalamus and area postrema, where it has previously been shown that blood-borne (pancreatic) insulin is capable of binding to neural tissue (Van Houten and Posner, Diabetologia, 20: 255, 1981) The purpose of the present work was to determine the effect of streptozotocin-induced diabetes on insulin receptors in the olfactory bulb, medial and lateral hypothalami, area postrema and liver.

Three weeks following intravenous streptozotocin (65 mg/kg) treatment, twenty male Long-Evans rats were decapitated,and the above mentioned areas assayed for insulin receptor binding by the method of Havrankova et al. (J. Clin. Invest. 64: 636, 1979).

The results of this work indicate that compared to non-streptozotocin treated controls, diabetic rats exhibited an increased insulin receptor binding in the medial and lateral hypothalamus, area postrema and liver. The extent of the hypothalamic "up-regulation" seems to be greater in the medial area than in the lateral. In contrast to its effects in the hypothalamus and area postrema, diabetes produces a "down-regulation" of insulin receptors in the olfactory bulb. These data are taken to indicate that unlike the olfactory bulb, circumventricular areas are exposed to pancreatic insulin and are "up-regulated" in its absence. The insulin receptors in the olfactory bulb may instead reflect levels of activity in an endogenous insulin system.

41.5 EVIDENCE FOR AN INSULIN-SENSITIVE HYPOTHALAMIC CIRCUIT CONTROLLING HEPATIC GLUCOSE PRODUCTION. G. E. Weider*, and R. J. Waldbillig* (SPON: G. M. Hope) Department of Psychology, University of Florida, Gainesville, Florida 32611

Recently evidence has been presented indicating that the brain contains an insulin and insulin receptor system that is independent of pancreatic insulin (Havrankova and Roth, Diabetologia 20: 268, 1981). However, there is also evidence that blood-borne insulin binds to neurons in the medial hypothalamus (Van Houten and Posner, Diabetologia 20: 255, 1981). The studies presented here examined the role of insulin receptors in hypothalamic function by investigating the relationship between the level of hypothalamic insulinization and plasma glucose levels.

The results of this work indicate that in non-diabetic free-moving rats 1.0 ul infusions of regular insulin (50-200 uU) into the ventromedial nucleus (VMN) produce a short latency, long-lasting and dose-dependent reduction in plasma glucose. Studies infusing ^{125}I-insulin indicate that this hypoglycemic effect is not the result of insulin "leaking" into the vasculature. Preliminary evidence also indicates that the hypoglycemic effect is not secondary to an increased pancreatic insulin release because an enhanced hypoglycemic effect can be produced in diabetic (streptozotocin treated) rats. More recent studies have revealed that blood samples drawn from the hepatic vein show a greater hypoglycemic effect than those drawn from the vena cava. This is interpreted as indicating that VMN insulin infusions produce a reduction in hepatic glucose output. Current work is using hepatic vagotomys to investigate the role of the autonomic nervous system in VMN-insulin induced hypoglycemia.

41.6 CHOLECYSTOKININ (CCK-8) SPECIFICALLY ANTAGONIZES OPIATE-MEDIATED ANALGESIAS. P.L. Faris*, B.R. Komisaruk, L.R. Watkins, and D.J. Mayer. Inst. Animal Behavior, Rutgers Univ., Newark, NJ 07102 and Dept. Physiol., Med. Coll. VA, Richmond 23298.

Since the effects of CCK are opposite those of opiates on feeding behavior and catecholaminergic activity, and CCK and opiates coexist anatomically, CCK may function as an endogenous opiate antagonist. We therefore examined the effects of CCK on opiate-mediated analgesia produced by environmental stimuli or morphine. Watkins, et al. (Pain (1981) suppl. 1: S263) have shown that hind paw (HP) and front paw (FP) shock produce non-opiate and opiate analgesia, respectively, on the tail flick test. Opiate analgesia was also produced using a classical conditioning paradigm (CCA) (FP shock: UCS; non-electrified grid: CS). Using these paradigms to elicit opiate-mediated analgesias, we found that CCK-8 (3 µg/kg IP) attenuated both FP shock-induced analgesia (FSIA) and CCA ($p<0.0001$). Morphine analgesia (10 mg/kg IP) was also attenuated by CCK-8 (5 µg/kg IP). Desulfated CCK-8 (des CCK) failed to antagonize FP FSIA and CCA. Additionally, the antagonistic effects of CCK-8 are specific to opiate analgesias, since HP (non-opiate) FSIA was not attenuated by CCK-8 in either intact or T2 spinalized animals. To determine the effective dose range and also the anatomical localization of CCK-8 action, we administered intrathecally (IT) 3.6, 20, 36, 200 and 360 ng of CCK-8 immediately prior to FP shock. Both FP FSIA and CCA were attenuated by 3.6 and 360 ng CCK-8 ($p< 0.0001$); the other doses were ineffective. Since 3.6 ng of des CCK did not affect FP FSIA ($p=0.17$) or CCA, but 360 ng des CCK did produce antagonism, only the effect of 3.6 ng CCK-8 appears to be specific to the sulfated form of CCK. At the 360 ng dose, the effect is apparently due to the gastrin-like properties of the sulfated and unsulfated forms of CCK-8, because an equimolar dose of secretin, which belongs to a different family of GI peptides, failed to antagonize FP FSIA. The effect of CCK-8 can not be explained by a hyperalgesic effect independent of an opiate interaction since 3.6, 36 and 360 ng IT CCK-8 did not affect baseline levels of pain responsiveness. These findings suggest that blockage of CCK-8 action may be effective in treating chronic pain, and an increase in CCK-8 action may mediate morphine tolerance. In addition, the satiation-producing effects of CCK-8 may be mediated through its anti-opiate properties. Supported by NSF Grant BNS78-24504 (BRK) and PHS DA00576 (DJM).

41.7 BEHAVIORAL EFFECTS OF CORTICOTROPIN-RELEASING FACTOR (CRF) AND RELATED PEPTIDES. D. R. Britton, [1]K. Lederis*, D. Hoffman*, [2]W. Vale and [2]J. Rivier*. Dept. Physiol., Sch. Med. Univ. New Mexico, Albuquerque, N.M., 87131, [1]Dept. Pharmacol., Univ. Calgary, Calgary. ALTA, CAN., [2]Peptide Biol. Lab., Salk Inst., La Jolla, CA.

In 1981, a 41 amino acid residue peptide of ovine hypothalamic origin was purified and synthesized (Vale et al., 1981). This peptide (referred to as CRF) is a potent stimulus to the release of ACTH and beta-endorphin from the anterior pituitary, both in vitro and in vivo. In addition, intracerebral ventricular (icv) administration of CRF produces activation of the sympathetic nervous system (Brown et al., 1982) and peripheral administration causes vasodilitation. Many of these effects are shared by the structurally related peptides, sauvagine (SA) and urotensin I (UT). Because of the potentially important role of CRF in mediating some of the endocrine responses to stress, we were interested in studying its behavioral effects. We hypothesized that CRF might produce behavioral expressions of the stress response just as it appeared capable of producing endocrine and sympathetic nervous system expressions of stress responding. We have previously shown (Britton et al., 1982) that icv CRF does produce behavior which mimics, in many ways, that observed in response to the stress of exposure to a novel environment. Specifically, fasted rats were given access to a single food pellet secured in the center of a novel open field and observed for 15 min. During this time, CRF treated rats (1.5 to 150 pmol/rat, icv) showed increased grooming, decreased food consumption, decreased duration of eating episodes as measured by the mean amount eaten per approach to the food pedistal, decreased rearing and decreased number of approaches to the food. The present data indicate that many of these behaviors are still observed in animals which have been habituated to the modified open field by several days of repeated exposure. Similar effects are seem upon icv administration of the related peptides SA and UT. These data indicate that the ability of CRF or related peptides to produce behavioral expressions of stress are not dependent upon the presence of external environmental stressful stimuli.

41.8 CONTRAVERSIVE ROTATION FOLLOWING B-ENDORPHIN, BUT IPSIVERSIVE ROTATION FOLLOWING MORPHINE MICROINJECTION IN RAT MIDBRAIN RETICULAR FORMATION. Y.F. Jacquet. Center for Neurochemistry, Rockland Research Institute, Ward's Island, New York City, 10035.

A unilateral microinjection of B-endorphin (2.9×10^{-9} mols) in the rat caudal midbrain reticular formation resulted in a late-onset episode of rotation consistently contraversive to the side of microinjection. A similar microinjection of morphine (2.6×10^{-8} mols) also resulted in a late-onset episode of rotation that was consistently ipsiversive to the side of microinjection. Met-enkephalin (1.7×10^{-8} mols), similar to B-endorphin, resulted in contraversive rotation (that was of immediate onset, but of short duration -- approximately 15 min). We previously reported (Jacquet, et al, Science, 1977) that the unnatural enantiomer of morphine, (+)-morphine, resulted in ipsiversive rotation at this site, indicating that the ipsiversive rotation was a non-stereospecific action of morphine. The present findings of opposing actions of B-endorphin and morphine in vivo parallel the in vitro findings previously reported (Jacquet, Science, 1980) in which morphine stimulated, but B-endorphin inhibited, the electrically-stimulated contractions of the rat vas deferens. In the present paradigm, ipsior contra-versive rotation may differentiate between the excitatory or inhibitory actions of opiates and opiate peptides. The former is non-stereospecific and not blocked by naloxone, while the latter is stereospecific and blocked by naloxone.

41.9 CORTICOTROPIN RELEASING FACTOR PRODUCES BEHAVIORAL ACTIVATION AND IMPROVES LEARNING IN RATS, G.F. Koob, M. Le Moal, F.E. Bloom, R.E. Sutton*, J. Rivier* and W. Vale. A.V. Davis CTR Behavioral Neurobiology and Peptide Biology Labs, Salk Inst. San Diego, Ca. 92138 and Lab. Neurobiologie des Comportements, Université de Bordeaux II, Bordeaux, France.

A 41 Amino acid peptide, with the ability to stimulate the secretion of corticotropin and β-endorphin, corticotropin releasing factor (CRF), has been examined for its ability to produce behavioral action. Male, albino Wistar rats were each equipped with a chronic cannula aimed above the lateral ventricle to allow acute intra-cerebroventricular (i.c.v.) injection of CRF. Rats were then well habituated to photocell activity cages (20 x 25 x 36 cm each with two horizontal infrared photocell beams across the long axis 2 cm above the floor). Several days later, the rats were rehabituated to the photocell cages for 90 min and then injected i.c.v. with 0.015, 0.15 and 1.5 nmoles of CRF corresponding to 0.1, 1.0 and 10.0 micrograms, respectively. CRF produced a dose-dependent increase in activity that was significant at the 0.15 and 1.5 nmole doses. Whereas saline injected rats rapidly went to sleep, CRF injected rats had high activity counts for a period lasting over five hours at the highest dose. Behavioral observation revealed a set of behaviors which appeared to reflect a general behavioral activation including elevated walking, grooming, rearing, and even climbing up and down the two mesh sides of the photocell cages. Behavior at the highest dose was characterized by more bizarre forepaw treading and repetitive locomotion. In contrast to these results, CRF injected i.c.v. at similar doses produced a dose-dependent decrease in activity in a novel open-field test. A dose of 0.15 nmoles of CRF, injected one hour before the test, significantly decreased outer square crossings and rearings and virtually eliminated inner square activity. Peripheral, subcutaneous injection of CRF did not produce any of these effects. CRF, injected in a dose of 0.15 nmoles (one hour prior to testing, for each of six days) significantly facilitated the learning of a visual discrimination in a Y maze. Here, rats were well habituated to the maze, and CRF injections began only after formal acquisition testing was begun. These results suggest that CRF can produce behavioral activation in rats that is dependent on the stressfulness of the situation, and that this activation can facilitate learning.

41.10 PHARMACOLOGICAL INDUCTION AND BLOCKADE OF LONG AXIS ROTATION IN RATS SUGGEST INVOLVEMENT OF NEUROPEPTIDES IN MINIMAL BRAIN DYSFUNCTION. A.K. Dua*, R. Bose* and C. Pinsky* (SPON: L.M. Wilson). Department of Pharmacology and Therapeutics, Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada R3E 0W3.

The phenomenon of rotation in animals and human beings around their longitudinal axis is a rare one. Recently this phenomenon has been described in rats ("barrel rolling") after intracerebroventricular (ICV) infusion of vasopressin, luteinizing hormone releasing hormone, substance P, dynorphin, somatostatin and bradykinin. We observed this phenomenon unexpectedly in rats after ICV administration of bacitracin 200 µg. Rats (180-200 g) were prepared with indwelling cannulae implanted stereotaxically in right lateral ventricle. Just before or at the end of infusion most rats displayed long-axis rotation (LAR) in their cages. On a flat surface the rotation was propulsive, carrying the animal for distances of up to 70 cm. The rat is typically quiet at the start of rolling, then turns its head upwards halfway and extends the contralateral forelimb upward; LAR begins at this point. Rolling is initiated actively in the upper half of the body and is soon followed by hind limb involvement. This twisting motion thus leads to LAR in the entire body. During all stages of LAR the eyes are fixed and there is no nystagmus. The LAR response to ICV bacitracin is blocked by naloxone 5.0 mg kg^{-1} and amphetamine 7.5 mg kg^{-1}, given twenty min prior to bacitracin. Diazepam 5.0 mg kg^{-1}, i.p. blocks the response when given after the onset of LAR, as does phenytoin 1.0 µg ICV.

There is no known common structural moiety among those neuropeptides which produce LAR, and no common site of action has become evident. It is possible that excess release of neuropeptides, in patients displaying the LAR syndrome, somehow interacts with a number of different central mechanisms to produce the phenomenon of LAR. Since naloxone blocks bacitracin-induced LAR (this study) and atropine blocks somatostatin-induced LAR (Cohn and Cohn, 1975) the syndrome might represent a dyskinetic expression of generalized malfunction in multiple neurotransmitter pathways. Amphetamine blockade of LAR has several interesting clinical implications. The rolling could be an expression of hyperkinesia in animals, and this model may prove useful in exploring the juvenile hyperkinetic syndrome in minimal brain dysfunction, for which no good model had been described.

41.11 EFFECT OF THE PEPTIDE CYCLO(LEU-GLY) ON OPIATE-INDUCED DOPAMINERGIC SUPERSENSITIVITY. J.M. Lee*, R.F. Ritzmann, K.A. Steece*, and J.Z. Fields. Dept. of Physio. Biophys., Univ. of Illinois Med. Ctr., Chicago, Ill. 60612. and Dept. of Pharmacol., The Chicago Med. Sch., North Chicago, Ill. 60064.

Recent reports from our laboratories have indicated that the peptide, cyclo(Leu-Gly) (cLG), an analog of MIF(Pro-Leu-Gly-NH_2), administered prior to chronic exposure to opiates, prevents the development of both analgesic tolerance and some signs of physical dependence. The same peptide treatment also prevented the development of morphine-induced increases in certain physiological respones to the dopamine agonist apomorphine (APO). The present study investigated behavioral and physiological responses (stereotypy and hypothermia) to APO in an attempt to correlate these phenomena with neurochemical changes-specific (3H)-spiroperidol binding to dopamine receptors (DA-R)-occurring in the rat striatal and hypothalamic DA systems, respectively.

The experiments were performed following chronic opiate treatment with and without prior cLG administration. Changes in the parameters for binding of antagonists to DA-R have been documented (Ritzmann, et. al., Life Sci. 30:1573-80 (1982). With regard to interaction of agonist with the DA-R, the IC-50 curves for displacement of (3H)-spiroperidol by DA appeared to fit a biphasic, two site model in both striatal and hypothalamic control tissues. Pseudo-Hill coefficients were less than unity (0.7 and 0.5, repectively). The high affinity component of the DA inhibition curve, comprising about 20% of the total specific binding, had and IC-50 value of 1 x 10^{-7} M. Chronic opiate treatment led to a 10-fold decrease in the IC-50 value for the high affinity site (indicating an increase in affinity of DA for the DA-R) in both striatal and hypothalamic tissue. This increase in affinity was blocked by prior peptide administration. In parallel, cLG prevented the increase in APO-induced stereotypy and hypothermia which was observed in chronic opiate treated rats.

These data suggest that the ability of the peptide to block the development of some signs of physical dependence induced by opiates may involve the ability of the peptide to interfere with the opiate-induced changes in DA systems, particularly, with the DA receptor sites that recognize the agonist, dopamine.

41.12 BOMBESIN EFFECTS ON THE MESOLIMBIC DOPAMINE SYSTEM OF THE RAT. D.W. Schulz*, P.W. Kalivas*, C.B. Nemeroff and A.J. Prange, Jr. (SPON: P. Morell). Neurobiology Program, Department of Psychiatry and Biological Sciences Research Center, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

Exploratory locomotor behavior in rats has been reported to be dependent upon intact dopaminergic mesolimbic pathways. Neurotensin, an endogenous neuropeptide, injected directly into the ventral tegmental area (VTA) produces an increase in exploratory behavior which is correlated with increased dopamine turnover in the nucleus accumbens and blocked by intracerebroventricular (icv) administration of haloperidol, a neuroleptic drug. Bombesin, a tetradecapeptide with neurotensin-like properties has recently been reported to increase spontaneous locomotor activity in rats when administered icv. The purpose of the present study was to determine whether bombesin increases locomotor activity by an action on this mesolimbic dopamine system.

Adult male Sprague-Dawley rats were stereotaxically implanted with injection cannulae whose tips were localized to the A_{10} nucleus of the VTA or the lateral ventricles. Photocell cages were used to assess locomotor and rearing behavior, and local concentrations of dopamine and dopamine metabolites (3,4-dihydroxyphenylacetic acid and homovanillic acid) were analyzed by high performance liquid chromatography. Bombesin doses ranged from 0.05 to 1.5 µg.

Intra-A_{10} injection of bombesin produced a prolonged dose-dependent significant increase in locomotor activity and a marked suppression of rearing behavior. However, these effects were not reversed by icv haloperidol, and no significant changes in dopamine turnover (as measured by DOPAC/DA ratios) were noted in terminal mesolimbic regions. Furthermore, icv bombesin was equipotent with intra-VTA bombesin in inducing these behavioral effects.

Peripheral pretreatment with the histamine or acetylcholine antagonists diphenhydramine or atropine (10 mg/kg) respectively, did not alter bombesin-induced locomotor activity.

These data support the view that bombesin can modulate spontaneous locomotor behavior in rats, but that its primary site of action is probably not on mesolimbic dopamine neurons.

42.1 Learned Change in the Spinal Stretch Reflex (SSR): Persistence and Reversal. J. R. Wolpaw and R. F. Seegal., Center for Laboratories and Research, NY State Dept. Health and Depts. of Neurology and Anatomy, Albany Medical College, Albany, NY 12201.

Monkeys can change the amplitude of the spinal stretch reflex (SSR) without change in initial muscle length or background EMG activity (Wolpaw et al., NS Absts 7:249 (1981)). Change is evident in 5-10 days and continues over several weeks. To better define the features of this learned change in primate CNS function, we studied its persistence and reversibility.

Five monkeys were trained to keep elbow angle at 90° (±1.5°) against steady extension force. If this angle was held for a randomly selected 1-2s period, and if the average absolute value of biceps EMG (from chronic i.m. electrodes) for the final 0.2s was within a given range, a brief force pulse extended the elbow 3-4°. SSR amplitude (amp) was measured as the average absolute value of biceps EMG 12.5-21.5ms after pulse onset minus background EMG amp. Under the Control condition, reward was given 100ms after pulse onset. Under the SSR↑ or SSR↓ condition, reward was given only if SSR was greater (SSR↑) or less (SSR↓) than a criterion value. Data were obtained from each monkey for up to 1 year. Electrodes, background EMG, steady extension force, and the first 40ms of pulse-induced movement were stable throughout.

Control condition data were obtained from each animal for 10-50 days. SSR amplitude was stable throughout this period. Next, each animal was exposed to the SSR↑ or SSR↓ condition. SSR amplitude changed appropriately over 10-20 days and stabilized at a new level. Then each animal was exposed to one or more of the following four manipulations on one or more occasions (each occasion preceded by restabilization of SSR amp).

1) When the same condition was maintained, SSR amp remained stable (followed up to 50 days).

2) When the same condition was maintained but the criterion made harder, SSR amp changed appropriately by an additional increment with a time course similar to the initial change.

3) When the animal was removed from the task for a period of 4-30 days, SSR amp on task resumption was similar to that at task cessation; that is, learned change was preserved.

4) When the condition was reversed (SSR↑ to SSR↓ or visa versa), SSR amp changed appropriately with the usual time course.

These observations, that SSR change persists without continued performance and that further change or reversal of previous change occurs as slowly as initial change, suggest that SSR change may prove a technically approachable system for studying the neuronal and synaptic bases of a learned change in primate CNS function.

42.2 IS LONG-TERM POTENTIATION IN THE DENTATE GYRUS DEPENDENT ON AN ALTERATION IN THE PRESYNAPTIC TERMINAL ACTIVITY? B. R. Sastry, S. S. Chirwa*, J. W. Goh* and H. Maretic*. Neuroscience Research Laboratory, Department of Pharmacology, The University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

Potentiation of the hippocampal response that occurs after a tetanic stimulation of the inputs is long-lasting and has been implicated in processes such as learning and memory. The present investigations were undertaken to examine whether a presynaptic mechanism could account for this long-term potentiation (LTP). In vivo expts. were carried out on rats anaesthetized with a mixture of methoxyflurane, N_2O and O_2. Stimulating and recording electrodes were placed in dentate gyrus (DG) and in the ipsilateral entorhinal cortex (EC). In some expts., an extra stimulating electrode was placed in the non-terminal regions (NTR) of perforant path (PP). The field potential (FP) in the DG produced by a stimulation in EC and the antidromic field potential (AFP) in EC caused by a stimulation in DG or the NTR of PP were evoked at 0.2 H_z. In some rats, a seven-barrelled micropipette was positioned in the DG to antidromically activate EC neurones and to iontophoretically apply drugs. Tetanic stimulations (20 H_z, 30 sec), caused a post-tetanic reduction (by 30-80%) in the size of the AFP in EC produced by a stimulation in DG (24 of 26 expts.), but not by stimulation at NTR of PP (8 expts.). The FP in DG was facilitated (by 30-60%, 17 of 17 expts.). The time course of the increase in the FP in DG paralleled that of the decrease in the AFP in EC. The threshold for antidromic activation in DG, but not at the NTR of PP of 12 single EC neurones was increased by 30-60% during the post-tetanic period. Mn^{++} (50-200 nA) and Co^{++} (50-200 nA), when iontophoretically applied in DG, counteracted the post-tetanic reduction of the AFP in EC (Mn^{++}: 6 of 7; Co^{++}: 5 of 6 expts.). Calcium antagonists are known to interfere with the development of LTP. In vitro studies were conducted on transversely sectioned hippocampal slices of rats. In these expts. the PP was stimulated (0.2 H_z) to evoke a FP in DG. Glutamic acid diethylester, when applied to the slice preparation during the tetanic stimulation (100 H_z, 5 sec) in amounts that could completely block the evoked FP in DG (8-12 mM), did not prevent the onset of LTP (7 of 9 slices).

These results indicate that LTP in DG is associated with a Ca^{++}-dependent reduction in the excitability of presynaptic terminals and that LTP could be elicited even if the subsynaptic receptors were blocked during the tetanic stimulation of the input. It is, therefore, possible that LTP is caused by an enhancement in the presynaptic efficacy.

(Supported by The University of British Columbia.)

42.3 DIFFERENTIAL FUNCTIONAL RESPONSE CORRELATES OF HIPPOCAMPAL CELL TYPES IN THE BEHAVING RAT. E.P. Christian*, M.O. West and S.A. Deadwyler* (SPON: P.B. Smith). Dept. of Physiol. and Pharmacol., Bowman Gray Sch. of Med., Winston-Salem, NC 27101

Numerous studies have correlated discharge patterns of hippocampal neurons with either the spatial features of an animal's environment, or alternatively to the performance of specific conditioned behaviors. We attempted to determine whether these two seemingly disparate functional roles are subserved by a common or by possibly different hippocampal neuronal subpopulations.

Seven Sprague Dawley rats were chronically prepared with a detachable microdrive system positioned above the dorsal hippocampal formation, allowing isolation of single units in the CA1 and CA3 subfields. Electrode position was verified by stimulation of the perforant path and commissural afferent fiber systems. Cells were further classified on the basis of spontaneous and evoked firing characteristics described by Fox and Ranck (Exp. Br. Res., 41: 399, 1981). Activity of each isolated unit was recorded in the following situations: 1) during performance of an auditory tone discrimination task (Deadwyler et al., Science 211: 1181, 1981) and 2) during traversal to find water at specific locations on a 61 x 61 cm square elevated platform.

The results are summarized in the table below:

	Correlates of Unit Firing	
	Spatial	Conditioning
Theta Cells	0/15	14/15
Complex Spike Cells	11/16	2/16

Complex spike cell firing was correlated with the animal's presence in a specific spatial location on the open platform, but not to the tone stimulus during conditioning. Theta cells, in contrast, showed a marked propensity to increase firing rate at the onset of the auditory conditioned stimulus, but showed no correlated discharge to distinct spatial aspects of the open platform. Firing activity of theta cells increased when the animal moved to any location on the platform.

This result is compatible with the hypothesis that there are two functionally distinct neuronal systems within the hippocampus. The fact that theta cell firing during conditioning resembled the discharge pattern previously reported for dentate granule cells in the same situation (West et al., Exp. Br. Res., 44: 287, 1981) suggests the possibility of a functional linkage between granule cells of the dentate gyrus and theta cells of the hippocampus proper. (Supported by NS 18288).

42.4 HIPPOCAMPAL PYRAMIDAL CELL ACTIVITY DURING TWO-TONE DISCRIMINATION AND REVERSAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE RESPONSE. T.W. Berger. Psychobiology Program, Departments of Psychology and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

Previous work has demonstrated that hippocampal pyramidal cells exhibit a learning-dependent increase in firing frequency during one-tone (i.e., sensory discrimination) conditioning of the rabbit nictitating membrane (NM) response (Berger, T.W. and Thompson, R.F., Proc. Nat. Acad. Sci., 75, 1978). Despite this fact, a consistent finding has been that bilateral hippocampectomy does not retard behavioral learning in such a paradigm (e.g., Solomon, P.R. and Moore, J. W., JCPP, 89, 1975). Recently, we have shown that bilateral hippocampectomy does prevent or severely impair reversal of two-tone discrimination learning of the rabbit NM response, (Orr, W.B. and Berger, T.W., Neurosci. Abstr., 7, 1981) a finding which is consistent with previous work using other behavioral paradigms (see Hirsh, R., Behav. Biol., 12, 1974). The present study, therefore, examined the electrophysiological activity of antidromically identified hippocampal neurons during two-tone discrimination and reversal learning of the rabbit NM response.

Under halothane anesthesia, all animals were prepared for single unit recording with implantation of microdrives overlying the dorsal hippocampus and bipolar stimulation electrodes into the fornix. Following two weeks of recovery, animals were trained in a two-tone discrimination task using either a 1K or 10K HZ tone as the CS+, a 1K or 10K HZ tone as the CS- (counterbalanced) and a corneal airpuff as the UCS. Single unit electrodes were lowered into the CA3 region of the hippocampus for extracellular recording of isolated neuronal activity during behavioral conditioning. A cell was identified as a pyramidal neuron if: i) a spontaneously occurring action potential could be successfully collided using fornix shock or ii) the spontaneous firing characteristics of the neuron matched those of cells that were collided. Results showed that during asymptotic discrimination performance, hippocampal pyramidal neurons exhibit a significantly higher frequency of discharge to the CS+ than to the CS-. In addition, as described in previous studies (Berger, T.W. et al., Brain Res., 193, 1980), the distribution of action potentials within conditioning trials correlates highly with the topography of the behavioral response.

Supported by The McKnight Foundation, NSF grant BNS80-21395 and NIMH grant MH00343.

42.5 A NEURAL LOCUS WHERE A CONDITIONED STIMULUS ALTERS BEHAVIOR (ACOUSTIC STARTLE): SELECTIVE EFFECTS OF STIMULATION SITE AND DIAZEPAM. W.K. Berg* and M. Davis, Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508. SPON: M. SHEARD.

When a startle response is elicited in the presence of a stimulus previously associated with an aversive shock, startle magnitude will be increased. To determine the neural locus at which a conditioned stimulus alters this behavior, "startle" responses were elicited by electrical stimulation at specific points along the acoustic startle circuit to assess the extent of the circuit needed to mediate the conditioned effect.

Separate groups of male albino rats were implanted with chronic, bilateral electrodes in the ventral cochlear nucleus (VCN, n= 13), the nuclei of the lateral lemniscus (LL, n=8) or the nucleus reticularis pontis caudalis (RPC, n = 10). Following recovery animals received two daily training sessions with 10 light shock pairings in each session (1.1 sec light, 0.5 sec, 0.5 mA shock, 0.6 light-shock interval). During testing (1 to 3 days later) startle was elicited with either an acoustic (50 msec white noise burst) or an electrical (single, 1 msec cathodal pulse - 12-100 uA) "startle" stimulus. For half of each of the trial types, a light preceded the startle stimulus by 0.6 sec.

Consistent with previous studies in unoperated animals, the light increased acoustically elicited startle by 109%. The light also increased startle when elicited electrically in the VCN by 137% ($t(12) = 5.5$, $p < .01$). Moreover, within rats, there was a high correlation between the degree of potentiation of acoustic and VCN-elicited startle ($r(11) = .84$, $p < .01$). In contrast, potentiation did not occur when the response was elicited in the LL or RPC, suggesting that the conditioned stimulus modulates transmission at the VCN or LL, but not in the RPC or spinal cord. To distinguish between the former two sites, 7 rats were implanted with electrodes near the ventral acoustic stria, the fibers that connect the VCN to the LL. Each of these rats showed potentiated startle indicating that the sites beyond the VCN (e.g., the LL) must be involved. Diazepam (.625, 1.25 or 2.5 mg/kg) selectively decreased potentiation of VCN-elicited startle in the presence of the light in a dose-related manner without altering baseline startle amplitudes.

These results strongly suggest that the light modulates startle at the LL and demonstrate, perhaps for the first time in the vertebrate, a specific neural site at which a learned stimulus association alters a behavioral response. The LL may also be the site where diazepam acts to attenuate fear since this nucleus has one of the highest densities of benzodiazepine receptors in brain.

42.6 ORIENTING REACTION HABITUATION IN PATIENTS WITH EPILEPTOGENIC CEREBRAL TUMORS. R. Rogozea and V. Florea-Ciocoiu+. Inst. Neurol. Psychiat., Bucharest, ROMANIA.

An electrographic study on the resistance to habituation of the somatic (EMG), autonomic (finger plethismogram, galvanic skin reaction, respiration, pulse) and EEG (acoustic evoked potential, EEG-blocking reaction) components of the orienting reaction elicited by a repetitive auditory stimulus was performed in 41 patients with epileptogenic cerebral tumors and in 128 matched subjects in three control groups.

The study evidenced a significant higher resistance to habituation of the orienting reaction components in patients with epileptogenic cerebral tumors than in control subjects. Thus, in these patients, the somatic autonomic and EEG components of the orienting reaction necessiteted a significantly larger number of repetitive applications of auditory stimulus to become habituated.

The degree of habituation disturbances depended on the seizure frequency and preoperative history, on the features of interictal EEG tracings as well as on the tumor surgical removal. The most important increases in the resistance to habituation of the orienting reaction components were found in patients with frequent (daily) seizures, in cases with an over three-year preoperative seizure history, in patients with fast EEG rhythms or diffuse or focal irritative-type EEG abnormalities as well as in those with a shorter time elapsed from the tumor surgical removal.

The above-mentioned habituation disturbances of the orienting reaction components noted in patients with epileptogenic cerebral tumors should be related to the effects induced by the pathologic impulses arising from the nervous tissue surrounding the cerebral tumor on the neural structures and pathways involved in the regulation of nervous excitability and, implicitly, in the control and integration of repetitive sensory messages.

42.7 SEPARATE NEURAL MEDIATION OF DIFFERENT COMPONENTS OF ATTENTION. MaryLou Cheal. Neuropsychology Laboratory, Ralph Lowell Laboratories, Mailman Research Center, McLean Hospital and Harvard Medical School, Belmont, MA 02178.

Attention is not a unitary process either as expressed behaviorally or as mediated neurally. Behaviorally, different components of attention can be demonstrated, such as awareness of a stimulus, selective attention necessary for memory of a stimulus, maintenance of attention to a stimulus, and the shift of attention from one stimulus to another. Additionally, separate neural mediation of these different components of attention is inferred from psychopharmacolgical data. Previously, it was reported that scopolamine, the acetylcholine receptor blocker, disrupted maintenance of attention in gerbils (Neuroscience Abstracts, 1981, 7, 524). On the other hand, apomorphine, the dopamine (DA) receptor agonist, disrupted selective attention (Neuroscience Abstracts, 1979, 5, 644). In fact, even drugs with very similar neurochemical functions have different effects on different components of attention, and the same drug at different doses may have qualitatively different behavioral effects. Four different DA agonists have now been studied: amphetamine, apomorphine, L-DOPA, and piribedil (ET 495). Piribedil (10-300 mg/kg), like amphetamine, did not affect selective attention, whereas, L-DOPA (100 mg/kg) acted like apomorphine in disrupting selective attention. During the peak period of drug activity following this same dose of L-DOPA, the gerbils were able to respond to the stimulus and appeared to be aware of it. In distinction to the high dose effect of L-DOPA, a low dose of L-DOPA (10 mg/kg) or piribedil (30 mg/kg) caused a perseveration of responding to the stimulus, suggesting an inability to shift attention normally. Differential effects of these DA agonists on norepinephrine mechanisms may explain the difference in behavioral effects. An interaction of the NE receptor agonist, clonidine , and apomorphine was shown previously in these behaviors (Neuroscience Abstracts, 1980, 6, 813).

42.8 MEMORY RETENTION: EFFECT OF PROLONGED CHOLINERGIC STIMULATION IN MICE. James F. Flood*, Gary E. Smith* and Arthur Cherkin. GRECC, VA Medical Center, Sepulveda, CA 91343.

Many studies report improved memory retention following administration of acetylcholine precursors or of drugs which activate cholinergic receptors. A basic assumption is that an increased level or duration of cholinergic receptor activity will improve memory processing. We tested the duration hypothesis by prolonging the action of a cholinergic agonist, arecoline hydrobromide (ARE), by making two or three successive intraventricular injections, the first within 3 min after training, the second 90 min later, and the third after another 90 min. Memory, tested one week after training, was scored as the percent of mice (N=20/group) which met the criteria for memory retention in our T-maze active avoidance paradigm (Brain Res. 215, 77-185, 1981). Each injection of ARE was fixed at 50 ng/mouse, a dose which did not improve retention significantly when injected once (see Table, Groups 1-2).

The retention score for one ARE injection (35%) or two ARE injections (45%) did not differ significantly from the score for saline controls (25%), whereas three ARE injections caused marked improvement (95%; $p<0.01$, Dunnett's t-test). Delaying a single injection for 183 min after training gave a score of 30% for a dose of 50ng, and a score of 20% for a dose of 150ng, indicating that the effect of three spaced injections of 50ng each was not due simply to greater effectiveness at the 183-min delay, nor to the cumulative ARE dose (150ng) resulting from 3 injections. Also, three spaced saline injections gave a score of 25%, ruling out a non-specific enhancing effect of repeated injections. Our results support the hypothesis that prolonging the duration of cholinergic stimulation improves memory processing.

	INJECTION AT STATED INTERVAL POST-TRAINING (min)			RETENTION SCORE	
GROUP	3	93	183	(%)	REMARKS
1	ARE*	-	-	35	No sig. diff. from Gp. 2.
2	SAL	-	-	25	
3	ARE	SAL	SAL	20	Result of Gp. 6 is not due to multiple injections per se.
4	ARE	ARE	-	45	No sig. diff. from Gp. 2 or 9.
5	ARE	ARE	SAL	35	
6	ARE	ARE	ARE	95	Differs from Gp. 9 ($p<0.01$).
7	SAL	SAL	ARE	30	183-min interval is not critical for result of Gp. 6.
8	SAL	SAL	3xARE*	20	183-min interval is not critical for result of Gp. 6.
9	SAL	SAL	SAL	25	No diff. from Gp. 2.

*Each ARE injection is 50ng/mouse. The total Gp. 8 dose is 150ng.

42.9 FACILITATION OF RETENTION FOR PASSIVE AVOIDANCE CONDITIONING PRODUCED BY OPIATE ANTAGONISTS. Michela Gallagher. Dept. of Psychology, Univ. of North Carolina, Chapel Hill, NC 27514.

A number of studies, including our own, have reported that administration of naloxone, an opiate antagonist, facilitates time-dependent memory processes. This finding may indicate that naloxone enhances memory processes by blocking endogenous activation of opiate receptors. In support of this interpretation several of these previous studies have also reported that post-training opiate agonist administration impairs memory processes, an effect opposite to that produced by naloxone. However, naloxone possesses pharmacological activity which is not mediated by its opiate antagonist properties (Dingledine et al. Europ. J. Pharmacol. 47: 19, 1978; Baldino and Beckman. Brain Res. 232: 247, 1982). Therefore, the present study was undertaken to determine whether the effect of naloxone on memory processes is 1)shared by other opiate antagonists, and 2)exhibits stereospecificity.

Sprague-Dawley rats received one-trial step-through passive avoidance conditioning using the procedure described by Gallagher et al. (Science. 198: 423, 1977). Intraperitoneal injections were administered immediately after the training trial, and retention testing was conducted 24 hrs later. In addition to an uninjected control group and a vehicle-injected control group, opiate antagonist-injected groups received either naloxone (0.5, 1.0, or 2.0 mg/kg), diprenorphine (0.25, 0.5 or 1.0 mg/kg), or levallorphan (2.5, 5.0 or 10.0 mg/kg). A group receiving post-training administration of dextrallorphan (10.0 mg/kg), the inactive enantiomer of levallorphan, was also included.

Statistical analysis of retention test step-through latencies revealed that each of the three opiate antagonists significantly increased retention when compared to the control groups. For each opiate antagonist, the two higher doses were effective while the lowest dose did not significantly alter retention. In addition, the increased retention produced by levallorphan exhibited stereospecificity. Whereas levallorphan increased retention, a comparable dose of dextrallorphan did not produce a significant effect.

This experiment provides strong support for the interpretation that naloxone facilitates retention of passive avoidance conditioning as a function of its opiate antagonist properties. This effect of naloxone was shared by other opiate antagonists and was not observed following administration of the inactive enantiomer of one of these antagonists, levallorphan. These results suggest that memory processes may be, at least in part, controlled by endogenous opioid peptides which regulate opiate receptor activity.

Supported by NIMH grant MH-35554

42.10 NALOXONE-INDUCED FACILITATION OF LATENT INHIBITION IN RABBITS. Elizabeth Bostock and Michela Gallagher. Neurobiology Program and Dept. of Psych., Univ. of N. Carolina, Chapel Hill, NC 27514.

A number of investigations have reported that administration of the opiate antagonist naloxone produces facilitation of time-dependent memory processes. Although the majority of these studies have used avoidance conditioning procedures, the effect of naloxone on memory processes does not appear to be restricted to tasks which employ aversive stimuli. In addition to retention of passive and active avoidance conditioning, naloxone has been observed to facilitate retention of habituation in rats. The present investigation was undertaken to investigate further the effects of post-training naloxone administration on retention of exposure to a non-aversive stimulus by using a latent inhibition procedure.

New Zealand albino rabbits in the latent inhibition groups received 15 tone (1 KHz, 82 dB, 5 sec) presentations per day for 3 consecutive days. On Day 4 all rabbits received a standard Pavlovian heart rate conditioning session in which 15 tone alone presentations were followed by 40 trials in which the tone was paired with an unconditioned stimulus consisting of eyelid shock (1.2 mA, 500 msec). The latent inhibition effect of tone pre-exposure is normally a decrement in subsequent conditioning. A normal conditioning group (Day 4 only), an uninjected latent inhibition group (Days 1-4), and three latent inhibition groups which received intraperitoneal injections on Days 1-3 immediately following the 15 tone presentations were included. These latter groups included a vehicle-injected group, a group receiving a 1.0 mg/kg injection of naloxone, and a group receiving two 0.5 mg/kg injections of naloxone spaced 30 min apart.

Statistical analyses revealed that compared to the normal conditioning group, the uninjected latent inhibition group exhibited a significant decrement in conditioned heart rate responding. A comparison of the uninjected and vehicle-injected latent inhibition groups revealed no significant differences in conditioned heart rate responding between these control groups. However, compared to the latent inhibition control groups, both of the groups which received naloxone administration exhibited a significantly greater latent inhibition effect.

The facilitation of latent inhibition produced by naloxone administration following the pre-exposure sessions is consistent with other reports that naloxone enhances time-dependent memory processes in rats. The present investigation appears to indicate that this finding generalizes to another laboratory species, the rabbit. Furthermore, these results provide additional evidence that the effect of naloxone on memory processes is not limited to retention of aversive experiences.

Supported by NIMH grant MH-35554

42.11 OPPOSITE EFFECTS OF LEU-ENKEPHALIN AND METHYLNALOXONE ON AVOIDANCE CONDITIONING: POSSIBLE INVOLVEMENT OF PERIPHERAL OPIOID RECEPTORS. J.L. Martinez, Jr., K. Olson*, C. Hilsten*, and J. de Graaf*. Psychobiology Department, School of Biological Sciences, University of California, Irvine, CA, USA, and CNS Pharmacology Department, Organon, Oss, The Netherlands.

Previously, Martinez and Rigter (Neurosci. Abs., 1980, 6, 319) reported that the impairing actions of Met- and Leu-enkephalin on acquisition of a one-way active avoidance response in rats were altered by removal of the adrenal medulla. Adrenal medullectomy abolished the actions of Met-enkephalin and shifted the effective dose of Leu-enkephalin to higher doses, suggesting that enkephalin effects on conditioning may be related to peripheral mechanisms.

The present study was undertaken to determine whether methylnaloxone, an opioid antagonist, which has a limited ability to cross the blood brain barrier, would affect avoidance conditioning in a manner similar to naloxone, which crosses freely into the brain. Further, it was expected that the naloxones would affect conditioning in a manner opposite to Leu-enkephalin, an opioid agonist. Male Swiss-Webster mice (25-30 g) were trained in a discriminated Y-maze avoidance task. On trial 1 the door was opened, and the shock was turned on (1.0 mA). The shock was terminated when the mouse reached either the right or left goal arm. Following a 30-sec intertrial interval, the mouse was replaced in the start box. On trial 2 and all remaining trials (up to a total of 8), the mouse had 10 sec to enter the safe arm before the shock came on, and was trained to the side opposite its initial choice. An error was recorded if on trials 3-8, the mouse first entered the wrong goal arm or re-entered the start box.

Five minutes before training, the mice were injected i.p. with either Leu-enkephalin (Sal, 100 or 200 µg/kg), naloxone (Sal, 1 or 10 mg/kg), or one of two forms of methylnaloxone (Sal, 1 or 10 mg/kg): (1) methylnaloxone HCl, (2) methylnaloxone HBr. It was found that Leu-enkephalin (100 µg/kg, $p<.01$) impaired acquisition of the response, as these animals made more errors than their saline control group. Naloxone (1 and 10 mg/kg, $p<.02$), methylnaloxone HCl (10.0 mg/kg, $p<.05$), and methylnaloxone HBr (1 mg/kg, $p<.05$) all facilitated acquisition, as these animals made fewer errors than their saline control groups.

It is likely that Leu-enkephalin and the naloxones affected conditioning by acting on opioid receptors, since they had opposite actions. Further, since the methylnaloxones do not readily cross into the brain, and they affect conditioning at comparable doses to naloxone, it is likely that their actions are mediated through peripheral opioid receptors.

42.12 EFFECTS OF PERIPHERAL EPINEPHRINE ADMINISTRATION ON THE EXTINCTION OF LEARNED FEAR. M.A. Downen* and R.A. Jensen. Department of Psychology, Southern Illinois University, Carbondale, IL 62901.

Previous research indicates that peripheral administration of catecholamines modulates acquisition and retention of learned responses. Epinephrine (E) administration reliably results in the enhanced acquisition and retention of avoidance responses. Of particular interest is the possibility that the behavioral effects of E are due to peripheral autonomic arousal. Thus, we investigated the effects of peripheral E administration on the extinction of a learned fear.

Earlier findings from our laboratory indicated that E retards the extinction of a step-up avoidance response in young rats. With mature rats, differential effects were seen according to the duration of footshock received on training day. With long footshock, E facilitated extinction as compared to saline control animals. However, extinction was retarded in animals receiving E and a short duration footshock compared to saline controls.

In the present experiments, animals were trained to a criterion of two consecutive step-up active avoidance responses with a 1.25 mA footshock. Extinction was achieved by placing the animals in the training apparatus with no shock for 6 min on the day after avoidance training. On testing day, there was a difference in the latency-to-step-up measure between the animals that were injected with saline that received an extinction trial (S-E) and those that were in the saline-no-extinction (S-NE) group. The 0.5 and 1.0 mg/kg doses of E decreased latency to step onto the shelf compared to the S-E group. The total time spent on the shelf was low for the S-E animals as compared to the S-NE animals. Again, 0.5 and 1.0 mg/kg E impaired extinction. These results using an active avoidance task generally indicate that the increased peripheral arousal induced by E impaired the acquisition of extinction of fear.

To assess the generality of the effect of E on extinction, an inhibitory avoidance task with low intensity footshock was used. The difference in step-through latency between S-E and S-NE rats was large with S-E animals showing more extinction. In this task administration of 0.5 mg/kg E prior to the extinction trial significantly enhanced extinction measured on the test day. Thus, the findings with an inhibitory avoidance task with low intensity footshock indicate that the increased arousal induced by E administration enhances the acquisition of extinction.

These differential drug effects on extinction might be due to the differing amount of footshock administered on training day in these two tasks. The effects seen fit an inverted U-shaped function for arousal induced by either shock intensity or dose of E and indicate that the degree of peripheral arousal modulates the degree of extinction of a learned fear.

43.1 TIME VARYING PULSATILE SEQUENCES FOR ELECTRICAL STIMULATION OF THE AUDITORY NERVE DERIVED FROM THE NEURAL ACTIVITY RECORDED IN RESPONSE TO COMPLEX SOUNDS. K. M. Mudry. Dept. of Electrical Engineering, Univ. of Akron, Akron, OH 44325.

VIIIth nerve auditory activity was examined in bullfrogs (*Rana catesbeiana*) to determine whether there are several basic sequences of action potential patterns occurring in response to simple and complex sounds.

Responses to single tones and combinations of two and three tones with various rise-fall times and intensities were analyzed. The combination tones were either phase-locked and phase-triggered or of random phase and unlocked frequencies.

The time of occurrence of the action potentials for each stimulus was stored in a mini-computer. For various driving signals, spike patterns were compared for fibers with similar and different best frequencies, thresholds and spontaneous activity levels. These comparisons between spike patterns were made through the use of post-stimulus, inter-spike-interval, and difference histograms, dot displays, power spectral analyses, and cross-correlation analyses.

To convey maximum information to the central auditory system through electrical stimulation of the VIIIth nerve with one electrode, a single pulsatile sequence must be used. Several suggestions for an appropriate pulsatile stimulation pattern will be presented. An ensemble of time varying pulsatile sequences chosen to maximize the information sent to the central auditory system via a two or three channel stimulation system implanted to drive certain populations of auditory fibers in the VIIIth nerve [either populations from the amphibian papilla and basilar papilla or populations tuned to low (75<BF<400 Hz), mid (400<BF<1000 Hz) and high (1000<BF<1800 Hz) frequencies] will be suggested.

Based on these studies the benefits of increasing the number of channels in an auditory prosthesis will be examined and the consequences of misplacement of electrodes on the information transmitted to the central nervous system will be discussed.

43.2 ORIGIN OF EFFERENT ACOUSTIC AND EFFERENT VESTIBULAR NEURONS IN VERTEBRATES. A COMPARATIVE STUDY. J. Strutz* (SPON: B. Fischer).Dept. Oto-Rhino-Laryngol. Unit f. Morph. Brain Res., Univ. Freiburg, West-Germany

Representatives of all classes of vertebrates (goldfish, tree frog, turtle, caiman, chicken, guinea pig) were investigated to determine the origin of centrifugal fibers to the inner ear. The anesthetized specimen received injections of a 50% aqueous solution of HRP (volume: 0.2 ul) either into the cochlear duct (to determine efferent acoustic neurons, exception:fish) or into the ampulla of the horizontal semicircular canal (to determine efferent vestibular neurons).For histochemistry we used Mesulam's TMB technique.

In the goldfish (Carassius auratus) labeled efferent labyrinthine neurons are restricted to the ipsilateral nucleus motorius tegmenti of the brain stem reticular formation, close to the midline and just lateral to the fasciculus longitudinalis medialis. In amphibians (frog, Hyla cinerea) parent cells are found more laterally in the ipsilateral reticular formation (Nucleus reticularis medius,Rm). In a primitive reptile (turtle, Terrapene ornata) efferent acoustic and efferent vestibular neurons appear bilaterally in the Rm, with a dorso-ventral extension from the abducens nucleus to the superior olive (OS). In contrast,in a highly developed reptile (Caiman crocodilus),efferent vestibular neurons remain bilaterally in the Rm, while efferent acoustic neurons form a separate population close to the OS. This resembles highly the situation found in avians (Gallus domesticus). The process of the spatial separation of the acoustic from the vestibular efferent cells is even more pronounced in mammals (guinea pig) where efferent vestibular neurons appear bilaterally in the phylogenetically old position in the Rm, and more dorsal in a position lateral to the genu of the facial nerve. The efferent acoustic neurons shift more ventrally and are found bilaterally in the superior olivary complex. In addition, neurons of the guinea pig's ventral nucleus of the lateral lemniscus participate in the efferent cochlear innervation.

In all species investigated, the primary vestibular and acoustic nuclei, respectively, are labeled by anterograde HRP transport. However, no labeled efferent cells are found in these nuclei.

Supported by grant of the DFG, SFB 70.

43.3 COLLATERALS OF LABYRINTHINE EFFERENT AXONS. J.C. Adams. Dept. of Otolaryngology and Anatomy, Medical University of S.C., Charleston, SC 29425.

Retrograde marking techniques were used to demonstrate that axons projecting to the labyrinth of the cat send collaterals to at least one other target. Following filling of the cochlea on one side with HRP, the labelled efferent bundle can be traced into the eighth nerve on the contralateral side. In such experiments a few labelled axons have been seen entering the contralateral cochlear nucleus. Application of fluorescent retrograde markers reveals patterns of the collateral innervation of the efferent systems. Application of retrograde markers in both cochleas results in double labelled vestibular efferent cells as well as double labelled large and small olivocochlear cells. Double labelled olivocochlear cells are also seen when one label is applied to a cochlea and another label injected into the ipsilateral or contralateral ventral cochlear nucleus. Double labelled cells were not seen when the second label was placed into either dorsal cochlear nucleus. These findings were supplemented by acetylcholinesterase staining in young animals. Labyrinthine efferent cell bodies and their axons stain darkly in the newborn and collaterals can be seen entering the ventral cochlear nucleus. Esterase staining in the superficial granular layer of the ventral nucleus and in the molecular/granular region of the dorsal nucleus is conspicuous by its absence in young animals. These results support the work of others who have evidence showing that esterase activity in superficial granule cell regions of the cochlear nucleus may not be due to terminals of olivocochlear collaterals. If vestibular efferent fibers have central collaterals the esterase staining indicates that they are in the interstitial nucleus of the vestibular nerve.

Supported in part by NSF grant BNS 81-10222 and by a South Carolina Biomedical Research Grant.

43.4 INTRACELLULAR RESPONSES OF CELLS IN MOUSE COCHLEAR NUCLEUS TO ELECTRICAL STIMULATION OF THE AUDITORY NERVE IN VITRO. D. Oertel. Dept of Neurophysiology, Univ. of Wisconsin, Madison, WI 53706.

Intracellular recordings have been made from brain slices of cochlear nuclei of mice 2 to 4 weeks old. The slices consisted of the most lateral parasagittal section of the cochlear nucleus, 250 μm thick. They contained the stump of the auditory nerve, a large part of the anteroventral and parts of the posteroventral and dorsal cochlear nucleus. They were continually superfused with saline whose composition was changed during intracellular recordings. Cells were impaled under visual control and responses were recorded to electrical stimulation of the auditory nerve. Responses of 7 cells fall into 2 categories.

Two cells, about 0.5 mm anterior to the point of entry of the auditory nerve into the cochlear nucleus, responded to nerve stimulation with large (30 mV), brief (2 msec) depolarizations. The depolarizations were graded with stimulus strength and they were abolished reversibly when Mg^{2+} was substituted for Ca^{2+} in the saline. These cells had small (20 mV) action potentials whose shapes were not altered by the removal of extracellular Ca^{2+}.

Four cells, lying anterior or just dorsal to the point of entry of the auditory nerve, responded to nerve stimulation with an excitatory postsynaptic potential (about 10 mV, 5 msec) followed by a longer inhibitory postsynaptic potential (reversed at resting potential, -60 mV, 10 msec). A fifth cell responded with only an inhibitory postsynaptic potential. These cells had large (>40 mV) action potentials. One cell had action potentials which were not affected by the removal of extracellular Ca^{2+} while two others had action potentials whose undershoots were Ca^{2+} dependent.

None of 9 excitatory responses to auditory nerve stimulation recorded intra- and extracellularly, which were abolished by the removal of extracellular Ca^{2+}, was blocked by 5 x 10^{-5}M D-∝-aminoadipate (Martin, M.R. and Adams, J.C., Neuroscience 4:1097, 1979). None of 5 cells with Ca^{2+} dependent responses to auditory nerve stimulation was sensitive to 10^{-4}M l-glutamate superfused in the bath; none of 5 cells was sensitive to 10^{-4}M l-aspartate (Wenthold, R.J., Brain Res. 143:544, 1978).

Supported by a grant from NIH, NS 17590.

43.5 A PATHWAY CONNECTING THE RIGHT AND LEFT COCHLEAR NUCLEI IN THE CAT. Nell B. Cant and Karen C. Gaston*. Department of Anatomy, Duke University Medical Center, Durham, NC 27710.

Connections between the right and left cochlear nuclear complexes were studied with retrograde and anterograde axonal transport techniques. Very large multipolar neurons in the anterior and posterior divisions of the anteroventral cochlear nucleus and in the posteroventral cochlear nucleus project to the ventral and dorsal cochlear nuclei on the opposite side. In addition, giant cells in the deep layers of the dorsal cochlear nucleus project to the contralateral posteroventral cochlear nucleus and possibly also to the contralateral dorsal cochlear nucleus. The pattern of terminal distribution of the crossed connections was determined using anterograde axonal transport of horseradish peroxidase-labelled wheat germ lectin. Although no part of the cochlear nuclear complex is completely free of anterograde label, the densest labelling is found in the anterior division of the anteroventral cochlear nucleus, throughout the posteroventral cochlear nucleus, where it is closely associated with cell bodies, and in the fusiform and superficial layers of the dorsal cochlear nucleus.

These direct synaptic connections from one cochlear nucleus to the other might play a role in processes such as sound localization that depend on binaural interactions within the central nervous system.

Supported by NIH grant NS14655.

43.6 THE NUCLEI OF THE OWL'S AUDITORY BRAINSTEM ARE CHARACTERIZED BY UNIQUE MODES OF BINAURAL INTERACTION. A. Moiseff and M. Konishi. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

A neurophysiological correlate to sound localization has been described in the midbrain auditory nucleus of the barn owl, Tyto alba (Knudsen and Konishi, Science 200:795-797, 1978). Owls determine the location of a sound source from cues derived from ongoing-time disparities ("OTD", which in the case of tonal stimuli is equivalent to interaural-phase disparity) and interaural intensity differences ("ID") (Knudsen and Konishi, J. Comp. Physiol., 133: 1-11, 1979; Moiseff and Konishi, J. Neurosci., 1: 40-48, 1981). In preparation for an in-depth investigation of the neural mechanisms responsible for extracting the location of a sound source from these binaural cues, we have been characterizing the binaural interactions present in the nuclei of the auditory brainstem and midbrain.

The nuclei studied thus far are: olivaris superior (Os), the nuclei of the lateral lemniscus (Lemnisci lateralis, pars ventralis = LLv; ventralis lemnisci lateralis = VLV) and mesencephalicus lateralis, pars dorsalis (MLD, the avian homologue of the mammalian inferior colliculus). Units within these nuclei were tested for their monaural response to stimulation of the contralateral and ipsilateral ears as well as their response to the binaural parameters of OTD and ID. The responses to monaural stimuli were classified according to the unit's response relative to its spontaneous activity (excitation, inhibition, or no effect). Sensitivity to binaural stimuli were classified as "+" if the unit was sensitive or "-" if it was not.

The following table summarizes the responses found within the binaural areas of the specified nuclei to monaural and binaural stimulation:

	MONAURAL		BINAURAL	
NUCLEUS	CONTRALATERAL	IPSILATERAL	OTD	ID
Os	Excitation	Excitation	-	-
VLVp	Excitation	Excitation	+	-
VLVa	Excitation	Inhibition	-	-
LLv	Excitation	Inhibition	+	-
MLD*	Inhibition	Inhibition	+	+

(*area within MLD with restricted auditory receptive fields.)

Our results suggest that these nuclei are organized as functionally homogeneous groups of cells and can be classified according to their "physiological signatures." (Supported by a Helen Hay Whitney post-doctoral fellowship to A. M., and an NIH grant to M. K.)

43.7 FREQUENCY SELECTIVITY IN THE ROSTRAL MIDBRAIN/POSTERIOR THALAMUS OF THE LEOPARD FROG (RANA P. PIPIENS). Z.M. Fuzessery and A.S. Feng, Dept. of Biophysics and Physiol., Univ. of Illinois, Urbana, IL 61801.

A single unit study of frequency selectivity of auditory neurons in the anterior midbrain and posterior thalamus indicates that large percentage of these cells are either facilitated (threshold is decreased) by appropriate multiple tone stimuli, or require multiple tones for excitation. Such neurons were recorded in the rostrolateral torus semicircularis, tectum, pretectal gray, and the posterolateral and posterocentral thalamic nuclei. As a class, these neurons appear to be selective for low (100-600 Hz) and high (1200-2500 Hz) frequencies in the species receptor response range. Facilitated neurons responded to single low frequency tones, but typically only at high intensities (>90 dB SPL). This response threshold could be dropped as much as 40 dB if a single high frequency tone was added to the stimulus. Mid frequencies were either inhibitory, non-excitatory or excitatory only at low intensities (< 70 dB SPL) and becoming inhibitory at higher intensities. Neurons responding only to multiple tones were also selective for combinations of low and high frequency tones, and were either inhibited or not excited by mid frequencies.

Other neurons responded well to single tones, and were typically broadly tuned. In some cases, they displayed distinct bimodal or trimodal tuning curves. Some bimodally tuned neurons had two discrete excitatory areas, with best frequencies in the low and high frequency ranges. Single tone responders were often inhibited by mid frequencies at higher intensities, and in this respect were similar to the multiple tone responders.

The trend which emerges from this study is a gradation in selectivity for low and high frequency tones. At one extreme, neurons are broadly tuned to all frequencies, progressing to neurons responding to low or high frequencies, and finally to neurons which respond only to low and high frequencies.

The mating call of this species has a bimodal distribution of spectral energy, with energy peaks in the low and high frequency ranges. Therefore, some of these neurons have a frequency selectivity which appears to be suspiciously well tuned for the selective detection of this call.

43.8 PERIODICITY ANALYSIS IN THE TIME DOMAIN BY COUPLED NEURONAL OSCILLATIONS IN THE AUDITORY MIDBRAIN OF THE GUINEA FOWL. G. Langner*(SPON: H. Scheich). Zool. Inst. der TH-Darmstadt, Schnittspahnstr. 3, 61 Darmstadt, BRD.

Periodic amplitude fluctuations with periodicities below 2 kHz are typical for many acoustic communication signals, e.g. human vowels and voiced consonants. In consequence analysis of such periodicities which in this case are amplitude modulated sine waves (AM) should be highly important for auditory systems. In the auditory midbrain nucleus (MLD) of 7 awake Guinea fowls (Numida meleagris) 420 units were recorded. About 20% of the analyzed units showed preferences for various combinations of the modulation frequency f_m and the carrier frequency f_c of AM-signals. For a given response maximum the relationship of the period $\tau_m = 1/f_m$ and the period $\tau_c = 1/f_c$ may be described by an empirical equation, the periodicity equation:

$$m \cdot \tau_m + n \cdot \tau_c = l \cdot \tau_1,$$

where m, n and l are little integers typical for a unit. τ_1 is a time constant of 0.4 ms, possibly the delay of a synaptic transmission in the auditory system. The temporal patterns of the neuronal responses support this interpretation. Amplitude fluctuations like stimulus onsets or the waves of the envelopes of the AM-signals elicit spike trains oscillating with periods which are multiples of $\tau_1 = 0.4$ ms. These oscillations may be coupled strongly to a certain f_m as a function of f_c. Variation of f_m or f_c shifts the mean delay of the phase coupled activity proportional to $m \cdot \tau_m$ or $n \cdot \tau_c$, respectively. These effects are explained with input activity phase coupled to f_c which coincides at the level of the recorded units with oscillating input coupled to f_m. The coincidence condition is described by the periodicity equation given above.

Psychophysical pitch matching experiments were performed by presenting AM-signals to 5 human subjects. The pitch was measured by matching it to the pitch $P = 1/\tau_p$ of a pure tone. The results indicate that the postulated mechanisms and the periodicity equation are adequate for the explanation of periodicity pitch in humans. Hence the period τ_p of the perceived pitch may be described by the equation:

$$\tau_p = n \cdot \tau_c - l \cdot \tau_1,$$

where n and l are integers and $\tau_1 = 0.4$ ms. Furthermore plots of τ_p as a function of τ_c reveal steps at 0.4 ms intervals indicating that the neuronal time constant is the same in the bird and the human (Langner, G., Exp.Brain Res., 44:450-454,1981).

(Supported by Deutsche Forschungsgemeinschaft SFB 45)

43.9 ORGANIZATION OF MEDIAL SUPERIOR OLIVARY PROJECTIONS TO THE INFERIOR COLLICULUS IN THE CAT: REGIONAL SEGREGATION WITHIN THE CENTRAL NUCLEUS. Craig K. Henkel and Kevin M. Spangler*, Department of Anatomy, Wake Forest University, Bowman Gray School of Medicine, Winston-Salem, North Carolina 27103.

Recent studies based on retrograde transport of HRP suggest that the projection of the medial superior olivary (MSO) nucleus to the inferior colliculus is both tonotopic and regionally segregated. In the present investigation autoradiographic experiments in the cat were correlated with HRP studies in order to reexamine the scheme of midbrain projections from MSO. In five cats HRP injections involved parts of the inferior colliculus. Throughout MSO on the side of large HRP injections, a large proportion of cells were labeled; in contrast, on the contralateral side, labeling was confined mainly to a few cells in the ventral pole of MSO. Consistently, laterally placed HRP injections in the central nucleus resulted in labeling of a larger number of neurons in MSO than in medially placed injections. Injection sites restricted to either the dorsomedial region or caudal section of the central nucleus labeled no MSO neurons. The distribution of MSO fibers in the midbrain was mapped in seven experiments with tritiated leucine injections in the superior olivary complex. Projections to the inferior colliculus in each case were distributed to the ventrolateral division of the central nucleus and always spared a section of the nucleus caudal to the commissure of the inferior colliculus. The most ventrally placed injections in MSO, corresponding in position to its highest frequency representation, labeled fibers ending within an obliquely oriented zone typical of the laminae described in the central nucleus of the inferior colliculus. Dorsomedially the labeled district approached a vertical mid-collicular line but did not appear to end within the dorsomedial division of the central nucleus. As isotopic injections involved more dorsal parts of MSO, labeled fibers ended in a more vertical array in the central nucleus and even more laterally. Autoradiographic results together with HRP experiments support previously described features of a scheme, though somewhat more restricted, for MSO projections to the inferior colliculus. Since the lateral projection field of MSO in the inferior colliculus appears to overlap with the projection of another binaurally responsive structure, the dorsal nucleus of the lateral lemniscus, it may reveal a pattern for functionally partitioning the ventrolateral subdivision.

43.10 HORSERADISH PEROXIDASE DEMONSTRATION OF AFFERENT AND EFFERENT CONNECTIONS OF THE INFERIOR COLLICULUS C. J. Jones-Mumby*, C.O. Trouth, E. J. Moore*, J. A. Holloway, and M. Odek-Ogunde*, Laboratory of Neurophysiology, Howard University College of Medicine, Washington, D. C. 20059.

Following electrophysiological identification of units responding to acoustic clicks and/or electrical stimulation of the contralateral cochlear nucleus (CN), horseradish peroxidase (Sigma VI, 30-50% solution) was iontophoresed into the ventral, dorsal, and medial portions of the central nucleus of the inferior colliculus (ICC) of 20 cats. The results revealed:

I. Retrograde connections with: A. ventral ICC: Ipsilaterally-from medial (MSO) and lateral (LSO) superior olives; periolivary nuclei (PON); and in pairs of clusters from ventral nucleus of lateral lemniscus (VNLL). Contralaterally-from the fusiform cell layer of dorsal portion of dorsal cochlear nucleus (DCN); central postero-(PVCN) ventral and dorsal antero-(AVCN) ventral cochlear nuclei; nucleus paragigantocellularis lateralis (NPL); reticular division of substantia nigra (SNR). Bilaterally from the dorsal nucleus of lateral lemniscus (DNLL). B. dorsal ICC: Ispilaterally from LSO and MSO, VNLL (in pairs of clusters); and scattered throughout CN and PON; Contralaterally from the superficial to middle fusiform and molecular cell layers of the ventral DCN; ventral PVCN and AVCN. Bilaterally from DNLL. C. medial ICC: from Ipsilateral LSO and MSO.

II. Anterograde connections with ventral, dorsal, and medial ICC: Ipsilaterally - brachium (BIC) and nucleus (NBIC) of brachium of inferior colliculus; medial geniculate body (MGB). These anterograde findings were verified by the identification of retrograde labelling in the ICC following injections into corresponding regions of the dorsal, medial, and ventral MGB.

Following injections into the dorsal (low frequency region) and ventral (high frequency region) ICC, reaction-product was observed in the ventral (low frequency region) and dorsal (high frequency region) DCN respectively. These data confirm the existence of tonotopicity between ICC and CN nuclei, perhaps involving frequency specific cell forms. Further, the findings suggest that the output of the ICC is tonotopically organized. This is inferred from the identification of labelling in the lateral region of the ventral (low frequency region) MGB subsequent to injections in the dorsal ICC.

43.11 CRITICAL PERIOD FOR CENTRAL AUDITORY DEVELOPMENT IN CBA/J MICE. D. B. WEBSTER. Kresge Hearing Research Lab., Dept. of Otorhinolaryngology, LSU Med. Cntr., New Orleans, LA 70119.

In order to determine the time period when a conductive hearing loss affects the size of cochlear nucleus neurons, 9 groups (7 mice per group) of CBA/J mice had their left external auditory meatus removed at varied days after birth (DAB) and were sacrificed for anatomical analyses following different survival periods. All brains were serially sectioned, stained with cresyl violet, and the cross-sectional areas of 30 globular cells of the ventral cochlear nucleus were measured from both right and left side of each brain. Blind procedures were used to avoid observer bias. In mice operated on at 4 DAB and sacrificed at 12 DAB, there was no significant size difference between right and left sides ($p>.05$) and the neurons were of adult size. In mice operated on at 4 DAB and sacrificed at 18 DAB, the globular cells were 9% smaller on the left than on the right ($p<.01$). For those mice operated on at 4 DAB and sacrificed at 24, 45, and 90 DAB the globular cells were 21%, 16%, and 16% smaller on the left side than on the right (all $p<.01$). Left meatal removal at 12 DAB and sacrifice at 24 DAB resulted in neurons 19% smaller on the left ($p<.01$). Meatus removal at 12 DAB and sacrifice at 18 DAB resulted in neurons 14% smaller on the left ($p<.01$), while removal at 18 DAB and sacrifice at 24 DAB resulted in neurons 10% smaller on the left than on the right ($p<.01$). Left meatal removal at 45 DAB and sacrifice at 90 DAB resulted in only a 1% difference in globular cell size between sides ($p>.05$). In all the mice analyzed, the globular cells on the right (normal) side were of adult size. I am currently preparing mice whose left meatus is removed at 24 DAB and sacrificed at 45 DAB. Unilateral meatal removal causes an approximately 19% reduction of globular cell somata size between 12 and 24 DAB. Meatal removal does not affect globular cell cross-sectional area before 12 DAB and removal after 45 DAB also does not affect globular cell size. There is, therefore, a critical period in mouse development when a conductive loss causes a significant shrinkage of globular cell somata.

44.1 SELECTIVE SPINAL CORD AMINO ACID ABNORMALITIES IN FRIEDREICH'S ATAXIA. Roger F. Butterworth and Jean-François Giguère*. Lab. of Neurochemistry, Clinical Research Inst. of Montreal (University of Montreal), 110 Pine Ave. w., Montreal Québec Canada H2W 1R7.

Spinal cord lesions in Friedreich's Ataxia invariably include loss of fibres in the gracile funiculi and in the pyramidal and dorsal spinocerebellar tracts. The present study was initiated to examine the possibility that loss of these specific neuronal tracts in Friedreich's Ataxia might be accompanied by changes in the distribution of certain cerebral amino acids suggested to be involved in spinal cord neurotransmission. Spinal cord samples from cervical, thoracic and lumbar levels, obtained at necropsy from four cases of Friedreich's Ataxia and ten controls were dissected into the following regions; spinal grey matter, dorsal columns, dorsal white matter and ventral white matter. The amino acids glutamate, glutamine, glycine and aspartate were measured in these regions by a sensitive double isotope dansyl microassay as previously described (Butterworth et al., J. Neurochem., 38, (1982). Glutamate and glutamine concentrations were found to be decreased by up to 70% in grey matter of Friedreich's lumbar cord. Glutamine levels were reduced to a similar extent in affected dorsal columns. No differences were observed at higher (cervical and thoracic) levels. These findings are consistent with a loss of nerve terminals and axons of affected primary sensory neurons and of descending corticospinal tracts, both of which have been suggested by previous experiments to utilise glutamate as neurotransmitter. A third group of fibres affected in Friedreich's Ataxia, namely those of the dorsal spinocerebellar tract originate in the Clarkes Nuclei and terminate in the cerebellar vermis as the putatively glutamatergic mossy fibres. Glutamate concentrations were recently found to be significantly reduced in cerebellar vermis of two Friedreich's patients (Huxtable et al., Can. J. Neurol. Sci., 6, 255, 1979). The findings from the present study when taken in conjunction with those of this earlier study afford evidence for selective degeneration of long, large diameter glutamatergic nerve fibres in Friedreich's Ataxia.

44.2 DEPRESSED NOREPINEPHRINE UPTAKE BY SYNAPTOSOMES ISOLATED FROM HYPOTHALAMUS AND BRAIN STEM OF HYPERTENSIVE RATS. K. Hough*, J. Rho, B. Newman and N. Alexander (Spon: D.F. Lindsley). Depts. of Medicine and Anatomy, University of Southern California Schools of Medicine and Pharmacy, Los Angeles, CA 90033.

In order to study a possible alteration of the transmembrane norepinephrine (NE) uptake system in spontaneously hypertensive rats (SHR), we have studied the uptake processes directly in the synaptosomes isolated from the hypothalamus and brain stem of SHR. The synaptosome-enriched subfraction was prepared by flotation, employing our modification of a discontinuous Ficoll-sucrose gradient (Booth and Clark, Biochem. J. 176:365, 1978). The synaptosomes obtained by our procedure are morphologically relatively pure with more intact synaptosomes than previous preparation, and demonstrate that NE uptake is highly sodium-dependent (80%) and ouabain sensitive (70%). The initial ^{3}H-NE uptake by the hypothalamic synaptosomal fraction of SHR during the first 10 minute incubation period averages 1.065 ± 0.32 p moles per mg protein while that of Wistar Kyoto (WKY) control was 1.545 ± 0.36 p moles per mg protein. Thus, the ^{3}H-NE uptake by SHR samples in the initial 10 minute incubation period was considerably lower than that of WKY (31.1%) and the difference was statistically significant ($p<0.01$). Synaptosomes were also prepared from brain stem regions, in parallel with hypothalamic synaptosomes, from the same animals. In four comparative studies between SHR and WKY, in which two SHR stems and two WKY stems were combined per experiment, WKY also had greater uptake in each experiment averaging 36% higher uptake of NE per mg protein during the first 10 minute incubation period. These findings may together indicate an alteration of a membrane transport mechanism in genetic hypertension.

44.3 GLUTAMIC ACID BINDING IN FIBROBLASTS FROM PATIENTS WITH HUNTINGTON'S DISEASE. P.T.-H. Wong, V. K. Singh and E. G. McGeer. Kinsmen Laboratory of Neurological Research, University of British Columbia and Division of Immunology, Children's Hospital, Vancouver, B. C., Canada.

It was recently reported that fibroblasts from Huntington's disease (HD) patients exhibit hypersensitivity to glutamate toxicity and degenerate at a rapid rate when challenged with glutamic acid.[1] We therefore attempted to confirm these findings and to investigate whether the binding of glutamate to HD fibroblast membrane is significantly altered when compared to controls.

Fibroblasts from clinically unaffected subjects were found to be 88% viable in normal medium as determined by the trypan blue exclusion method. HD fibroblasts, however, were only 66% viable. This conflicted with the observations of Gray et al.[1] that cultures from both sources were more than 98% viable. They further reported that glutamate at 30 mM concentration was toxic to only HD fibroblasts, reducing cell viability to 6%. In contrast, we observed reductions of cell viability by glutamate to 39% and 8% with control and HD fibroblasts, respectively. In other words, glutamate decreased cell viability of control cultures by 55% (from 88% to 39% viability) but by 88% (from 66% to 8% viability) with HD cultures. Although differing in detail from those of Gray et al., the present results substantiate the conclusion that HD fibroblasts are more susceptible than control fibroblasts to glutamate toxicity.

Specific binding of [^{3}H]glutamate was obtained by measuring binding at concentrations ranging from 30-1000 nM in the presence and absence of 100 µM unlabelled glutamate. On linear regression analysis of the Scatchard plots, both HD and control fibroblast membranes showed single straight lines ($r = 0.99$) with K_D of 295 nM and B_{max} of 88 pmol/mg protein for HD fibroblasts and 462 nM and 175 pmol/mg protein, respectively, for control fibroblasts. Hill plots also showed straight lines ($r = 1$) with slopes of 1.

44.4 NEUROTENSIN SYSTEMS IN HUMAN SUBSTANTIA NIGRA: NORMAL/PARKINSON'S DISEASE. G. R. Uhl, P. J. Whitehouse*, C. L. White III*, J. C. Hedreen, R. E. Carraway*, D. L. Price*, and M. J. Kuhar. Departments of Neuroscience, Neurology, and Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205. Department of Biology, University of Massachusetts, Worcester, MA 01605.

Several lines of evidence indicate that neurotensin systems are present in the substantia nigra (SN) of the rat. Immunocytochemical studies show neurotensin fiber and terminal pathways of moderate density, and in vitro labeling with [^{3}H] neurotensin followed by autoradiography demonstrates dense neurotensin receptors in this region. Moreover, lesions produced by injection of 6-hydroxydopamine suggest that these receptors are associated with the dopaminergic neurons of the SN (Palacios, J.M. and Kuhar, M.J., Nature 294:587-589, 1981). Finally, when iontophoresed into the SN, neurotensin causes excitation.

With this as background, we examined the distribution of pre- and postsynaptic neurotensin markers in brains from human controls and a patient with Parkinson's disease (PD), a disorder associated with loss of pigmented dopaminergic neurons in the SN. Using rabbit antineurotensin serum and a conjugated peroxidase reagent, we have visualized immunoreactive fibers and terminals in low-to-moderate density in the pars compacta and reticulata of the SN. Fibers are not demonstrated when the antiserum is preincubated with neurotensin (10^{-5} M). Using in vitro labeling with [^{3}H] neurotensin, autoradiography discloses high densities of label in the SN and much lower grain densities over the adjacent cerebral peduncle. Grains cluster around pigmented perikarya of compact neurons. As predicted (Uhl G.R., Prange, N., and Nimeroff, A.J., N.Y. Acad. Sci., in press), the SN in PD shows a substantial loss of neurotensin receptors (to 30% of control values in preliminary quantitative studies).

The demonstration of neurotensin afferents in the SN and the finding that neurotensin receptors are expressed by pars compacta cells in the human SN suggest a role for this peptide in nonpyramidal motor control systems. In PD, loss of SN cells is associated with loss of receptors for this peptide, and changes in this system may have a role in the clinical expression of PD. Information concerning the anatomy and functional properties of this neurotensin system may have implications for therapy of PD and other movement disorders. 44.5 AMYOTROPHIC LATERAL SCLEROSIS: ALTERATIONS IN NEUROTRANSMITTER RECEPTORS. P.J. Whitehouse*, J.K. Wamsley, M.A. Zarbin*, D.L. Price, W.W. Tourtellotte*, L. Davis* and M.J. Kuhar (SPON: W.S. Young, III). Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Amyotrophic lateral sclerosis (ALS) is a degenerative neurological disease characterized by selective loss of upper and lower motor neurons. At autopsy, ALS spinal cords show loss of motor neurons, although it is now believed that the affected nerve cells do not die suddenly but exhibit a variety of structural/functional changes which antedate cell death. Expression of neurotransmitter receptors is one of the principle functional properties of nerve cells and might be expected to be altered early in the disease process. Knowledge of the receptor populations at risk in ALS would provide information concerning normal transmitter - specific circuitry as well as the consequences of diseases on these systems.

In the present study, muscarinic cholinergic, glycinergic, benzodiazepine, GABAergic and adrenergic receptors have been examined in normal and ALS tissue by an in vitro labeling autoradiographic method (Young and Kuhar, Brain Res. 179:255, 1979). Tissues from cervical, thoracic, and lumbar spinal cords, obtained from six patients with ALS and six controls (matched for age, sex and postmortem delay in autopsy) were labeled with [^{3}H] drugs by standard methods and autoradiographs prepared by using emulsion-coated coverslips or tritium-sensitive film (Palacios et al., Neurosci. Lett. 25:101, 1981).

In normal cords receptors were heavily concentrated in Rexed layers II-III and particularly with cholinergic and glycinergic in layer IX. The results are the first quantitative analysis of the distribution and density of these receptors in normal human spinal cord, and documents, at the light microscopic level, the severe loss of muscarinic cholinergic (particularly high affinity), benzodiazepine and glycine receptors in association with degeneration of motor neurons in ALS.

Loss of neurons appears to be the most obvious cause of loss of receptor binding in ALS. Other mechanisms such as alterations in affinity for ligand or blockade by exogenous or endogenous agents seem unlikely. Examination of animal models of ALS in which studies of the evolution of the disease are possible may provide further insight into disease mechanisms. Since receptors are neuronal markers, indicators of connectivity, and sites of drug action, the use of receptor mapping in neurological disorders may facilitate our understanding of pathophysiology and direct attempts at drug therapy.

44.6 ALTERATIONS IN REGIONAL BRAIN LEVELS OF NEUROTENSIN, THYROTROPIN-RELEASING HORMONE AND SOMATOSTATIN IN SCHIZOPHRENIA AND HUNTINGTON'S CHOREA. C.B. Nemeroff, P.J. Manberg*, W.W. Youngblood*, A.J. Prange, Jr. and J.S. Kizer*, Biological Sciences Research Center, University of North Carolina School of Medicine, Chapel Hill, N.C. 27514

A variety of peptides have recently been isolated and characterized in brain tissue. Several of these may be neurotransmitters. The present study was designed to determine whether alterations in regional brain levels of three endogenous peptides, thyrotropin-releasing hormone (TRH), somatostatin (SRIF) and neurotensin (NT), occur in patients with schizophrenia or Huntington's chorea. Human brain tissue was collected and dissected at the MRC Brain Bank in Cambridge, England using previously described methods (Brain 102:333-346, 1979) and kindly provided by Dr. Martin Rossor. We examined brain samples from 50 patients without psychiatric or neurological disease (mean age 71 years, range 27-103 years), 46 schizophrenics (mean age 58 years, range 20-86 years) and 24 Huntington's choreics (mean age 54 years, range 26-78 years). The frozen brain samples were weighed, homogenized in 20 volumes (w/v) of 1N HCl, centrifuged at 12,000g for 30 min and the clear supernatants lyophilized. Radioimmunoassay procedures previously described were utilized to determine the regional brain concentrations of NT-like (J. Neurochem., in press), TRH-like (J. Neurosci. Meth. 4:305-314, 1981), and SRIF-like immunoreactivity (Endocrinol. 101:613-622, 1977). The concentrations of all three peptides were significantly increased in the caudate nucleus of the Huntington's patients, but not of the schizophrenic patients. No significant group-related alterations in the levels of any of the peptides studied were observed in the hypothalamus. However, there was a three-fold rise in SRIF-like immunoreactivity in the nucleus accumbens tissue of the Huntington's patients. In addition the Huntington's patients had significantly higher levels of TRH-like immunoreactivity in the amygdala. Brodmann's area (BA) 24 (cingulate cortex) showed no alterations in the concentration of any of the three peptides in samples from schizophrenic patients when compared to controls. However in schizophrenics, levels of TRH-like immunoreactivity were significantly decreased in two areas of frontal cortex (BA 12 and 32). Levels of SRIF-like immunoreactivity were significantly reduced in BA 12, and levels of NT-like immunoreactivity were significantly increased in BA 32. Whether these alterations in peptide levels in the CNS of patients with schizophrenia and Huntington's chorea are involved in the pathogenesis or behavioral aspects of these diseases is unknown.

44.7 SELECTIVE SENSITIVITY OF DOPAMINE NERVE TERMINALS IN CEREBRAL ISCHEMIA - EVALUATION OF THE POTENTIAL PROTECTIVE EFFECT OF PARGYLINE. J. Weinberger* and G. Cohen. Dept. of Neurology, The Mount Sinai Sch. of Med., New York, N.Y. 10029

The study of energy-dependent, high affinity uptake of radiolabelled transmitters has been employed as a paradigm of neuronal membrane function in ischemia. Previous studies (Weinberger, J., Cohen, G., J. Neurochem., 38: 963, 1982) have shown a significantly greater reduction in dopamine uptake relative to glutamate after 16 hours of unilateral cerebral ischemia in the Mongolian gerbil. We investigated whether the monoamine oxidase (MAO) inhibitor pargyline could prevent the selective destruction of dopamine nerve terminals by preventing the formation of hydrogen peroxide and/or derived oxygen radicals.

Unilateral cerebral ischemia was induced in the Mongolian gerbil by left carotid ligation. Pargyline 75 mg/kg was administered i.p. 2 hours prior to ligation. 9/34 (26.5%) of pargyline treated animals and 8/32 (25.0%) of the untreated animals developed stroke. There were 2 deaths in each group. Seven treated and 8 untreated animals exhibited milder circling behavior.

Synaptosomes were prepared by differential centrifugation in 0.32M sucrose. Uptake was carried out in Krebs Ringer phosphate buffer pH 7.4, at concentrations of 5×10^{-9}M for dopamine and 8×10^{-6}M for glutamate. Synaptosomes were separated from the incubation medium by filtration through 0.65 micron Millipore filters for subsequent scintillation counting of ^{3}H-dopamine and ^{14}C-glutamate within the synaptosomes. The uptake into the ischemic (left) and control (right) hemispheres was expressed as the L/R ratio. The extent of reduction of uptake at 16 hours in animals with stroke is shown in the following table (mean ± SEM):

	Dopamine	Glutamate
Pargyline Treated	0.214 ± .043*	0.369 ± .033
Untreated	0.147 ± .024**	0.316 ± .012

The greater reduction in uptake of dopamine compared to glutamate was significant in treated and untreated animals (*$p < .02$, **$p < .001$).

Although uptake of dopamine was improved by 45% in pargyline treated animals, the data did not achieve statistical significance in this limited series. A greater protective effect may have been precluded if increased levels of endogenous vasoactive monoamines resulted in a more severe circulatory disturbance in the pargyline treated animals.

44.8 RECEPTOR BINDING CHANGES IN ZINC AND COPPER DEFICIENT RATS. J.D. Geiger*, J.C. Wallwork*, P.K. Seth*, L.M. Klevay*, H.H. Sandstead*, and S.S. Parmar. Departments of Physiology and Surgery, University of North Dakota School of Medicine and USDA, ARS, Human Nutrition Research Center, Grand Forks, ND 58202.

Trace metal nutriture has been shown to affect brain neurotransmitters which may lead to alterations in receptor binding and function. The effects of zinc and copper deficiency on receptor binding were investigated. Male Long-Evans weanling rats were divided into 3 groups for the zinc study; zinc deficient (ZD), pair fed (PF) and ad libitum-fed (ALZ). Zinc deficiency was produced by a standard method (Wallwork et al., Br. J. Nutr. 45: 127, 1981). Zinc deficiency was verified by a decrease in femur zinc levels by atomic absorption spectrometry. The zinc levels of 286 ± 24, 292 ± 39 and 93 ± 7 µg/g ($P < 0.0001$) were found in ALZ, PF and ZD rats, respectively. Weanling male Sprague-Dawley rats were rendered copper deficient using a standard method (Klevay, Am. J. Clin. Nutr. 26: 1060, 1973). Two groups of animals were used for the copper study; copper deficient (CD) and ad libitum-fed (ALC). Copper deficiency was verified by a decrease in hematocrit of 31% ($P < 0.001$). Brain regions from control and deficient animals were isolated and crude synaptic membranes were prepared for binding studies (Seth et al., Toxicol. Appl. Pharmacol. 59: 262, 1981).

In general, no significant changes between PF and ZD animals were observed in binding affinity for ^{3}H-diazepam (benzodiazepine), ^{3}H-muscimol (GABA), ^{3}H-spiroperidol (dopamine), ^{3}H-5HT (serotonin), and ^{3}H-QNB (muscarinic) receptors in brain preparations. However, significant changes were observed between ALZ and PF animals as evidenced by an increase in ^{3}H-QNB binding to cerebellar membranes from 17 ± 3 to 35 ± 7 pmol/g protein ($P < 0.01$). The K_D values for ^{3}H-spiroperidol binding to striatal membranes were 0.86 (ZD), 0.43 (PF) and 0.48 (ALZ). The B_{max} values for ZD, PF and ALZ rats were 757, 638 and 599 fmol/mg protein, respectively. The binding of ^{3}H-QNB to striatal and cerebellar membranes from ALC and CD rats increased from 595 ± 66 to 704 ± 82 ($P < 0.02$) and 19 ± 4 to 28 ± 7 ($P < 0.01$) pmol/g protein, respectively. ^{3}H-muscimol binding also increased in cerebellar membranes from 39 ± 12 to 53 ± 9 ($P < 0.02$) pmol/g protein. ^{3}H-Diazepam binding in brain preparations from CD rats decreased from 92 ± 18 to 75 ± 14 ($P < 0.02$) pmol/g protein.

Copper deficiency had no significant effect on ^{3}H-spiroperidol (striatum) and ^{3}H-5HT (frontal cortex) binding. Copper deficiency appears to affect receptor binding more profoundly than does zinc deficiency, although nonspecific starvation influences can not be discounted. These results may explain some of the manifestations of trace metal deficiency in animals. (Supported in part by the Dakota State Aerie Fraternal Order of Eagles)

44.9 DOPAMINERGIC REGULATION IN ANOREXIA NERVOSA. W.P. Owen, K.A. Halmi, E. Lesley* and P. Stokes., NY Hospital, White Plains, NY 10605.

Hypothalamic anatomical structures regulating feeding, sexual behavior and menstrual activity, all of which are disturbed in anorexia nervosa, are strongly influenced by dopaminergic activity. Lack of response of growth hormone (GH) to L-DOPA in weight restored anorectics indicate that dopaminergic regulation of GH secretion is impaired in anorexia nervosa. Since prolactin (PRL) secretion is also influenced by dopamine (DA), another indirect assessment of dopaminergic activity is the measurement of PRL response to a DA antagonist such as chlorpromazine (CPZ). Failure of anorectics to respond to clomiphene adequately and to establish a mid-cycle peak of leuteinizing hormone (LH) secretion is a phenomen that is seen in hyperprolactinemia. However, a survey of the literature reveals less than 10% of anorectic women have elevated basal prolactin levels. Could a central decrease in dopaminergic activity which should increase PRL secretion be masked by increased cortisol secretion which suppresses PRL? In order to access dopaminergic regulation of PRL secretion in anorexia nervosa, we measured PRL response to CPZ while concommitently assessing cortisol secretion.

Method - Six female recently treated normal weight anorexia nervosa patients had GH, PRL, and cortisol levels measured at AM fasting, 2 and 8 hours after 50 mg CPZ on testing days 1 and 2. At 11 PM on day 1 the patient received 1 mg dexamethasone (DX).

Results - Two of the six patients had a negligible PRL response to CPZ (21 ng/ml to 27 ng/ml and 14 ng/ml to 23 ng/ml). Another two patients had a minimal response (24 ng/ml to 35 ng/ml and 15 ng/ml to 27 ng/ml). Two patients had an adequate response (34 ng/ml to 62 ng/ml and 27 ng/ml to 100 ng/ml). Clearly dopaminergic regulation of PRL secretion is impaired in two patients and could be considered less than optimal in two other patients. Since anorectics have an impaired response of GH to L-DOPA, as well as an impaired response to a dopamine antagonist, one may hypothesize anorectics have a deficiency of the dopamine post-synaptic receptor sites. Two patients did not suppress to DX. One of these had a normal PRL response to CPZ and the other had a negligible response. Dopaminergic regulation of prolactin seems to be independent of the endogenous hypothalamic mechanisms which determine response to DX in anorexia nervosa. More patients need to be studied in order to access the relationship of resistance to DX to dopaminergic regulation of GH and PRL.

44.10 GLUTAMATE EXCITOTOXICITY IN LOCUST MUSCLE: A POTENTIAL MODEL SYSTEM FOR AMINO ACID CYTOTOXICITY IN VERTEBRATE CNS Ian R. Duce*, P. Lynn Donaldson+, and Peter N.R. Usherwood*. +Dept. of Physiology & Biophysics, Univ. of Iowa, Iowa City, Ia. 52242, and *Dept. of Zoology, Univ. of Nottingham, Nottingham, England (SPON: by R. Hahin).

Kainic acid (KA), an amino acid analogue of glutamate, injected into vertebrate central nervous systems causes selective degeneration of neurons in various loci of the CNS (e.g., the striatum, cerebellum, and hippocampus). One hypothesis for the selective neuronal degeneration in specific regions is that KA is excitotoxic to neurons with glutamate receptors. We examined this hypothesis in locust muscles, which have well characterized glutamate receptors. Locust retractor unguis muscles were dissected and isolated in small petri dishes. Some muscles were exposed to Concanavalin-A (1 uM) which blocks desensitization of glutamate receptors. Bath application of 1 mM L-glutamate caused degeneration of the muscle fibers which was first observed as an increased opacity in the muscle after 30 min. The ultrastructure of these muscles was marked by vacuolation of the terminal cisternae of the sarcoplasmic reticulum. Muscles not pretreated with Con-A but exposed to glutamate for the same time period did not degenerate. Longer exposures (up to six hours) produced more extensive damage. Analogues of glutamate were effective in initiating muscle damage in the same order as their pharmacological potency, e.g. L-quisqualate >L-glutamate >L-cysteine sulphonate >L-aspartate and L-kainate. Low Ca saline slowed the development of degeneration by glutamate, while high Ca saline accelerated the degeneration. 100mM K saline did not promote muscle fiber damage. Denervation, which induces supersensitivity in locust muscles, enhanced the degeneration initiated by glutamate. One possible mechanism for the cytotoxicity of glutamate was tested by measuring the increase in ^{45}Ca in the muscles. Intracellular Ca increased in muscles treated with Con-A and glutamate, an increase which was 10 times greater than in muscles treated with only glutamate. A similar increase in intracellular Ca, initiated by KA, could be partially responsible for the selective degeneration of vertebrate neurons with glutamate receptors.

44.11 THE RELEASE AND NEOSYNTHESIS OF GLU ARE INCREASED IN EXPERIMENTAL MODELS OF HEPATIC ENCEPHALOPATHY. F.Moroni,G.Lombardi*,D.Pellegrini*,C.Paparozzi*,C.Cortesini*.Dept.of Pharmacology and Dept.of Surgery University of Firenze.Firenze ITALIA.

In order to invenstigate the role of aminoacid mediated neurotransmission in the pathogenesis of hepatic encephalopathy,we studied the content,synthesis and release of Glutamate (GLU), GABA and Glutamine (GLN) in rats with a surgically constructed porto-caval anasthomosis (PCA) or after ammonium acetate administration (7 mmoles/Kg).

The synthesis of GLU and GABA was studied by infusing to the animals ^{13}C-glucose and by measuring the amount of endogenous and $^{13}C_2$-labelled aminoacids with mass-fragmentography.(Moroni et al. J.P.E.T.270,870-877,1978).The release of Glutamate and GABA was monitored by applying cortical cups and by measuring aminoacid output as previously described.(Moroni et al.Naunyn-Schmiedeberg Arch.Pharmacol.316,235-239,1981).

Four weeks after PCA,the content and the synthesis of GABA were not modified in the striatum,wile in the cortex and hippocampus of the same animals the incorporation of $^{13}C_2$ derived from ^{13}C-glucose into GLU was approximately doubled.In these animals the concentration of GLN in the blood and in the brain increased by 90% and by 300% respectively.

Ammonium acetate (7 mmoles/Kg; i.p.; 30 min) doubled the incorporation of $^{13}C_2$ into the molecule of GLU and increased by 90% the release of the aminoacid from the parietal cortex.

Taken together the results suggest an increased availability of GLU at the receptor level in the two experimental models of hepatic encephalopathy studied. Since an increased function of GLU releasing neurons may cause convulsions, spreading depression and eventually gliosis and neuronal degeneration, it is possible that the increased activity of the glutamatergic system play a role in the pathogenesis of hepatic encephalopaty.

44.12 CATECHOLAMINES (CA) IN BLOOD OF RATS WITH PHEOCHROMOCYTOMA (PHEO) N. Alexander, S. Yoneda* and N. Vlachakis* Univ. of So. Cal. Sch. of Med. Los Angeles, CA 90033

We reported that human and rat red blood cells (RBC) contain CA and CA metabolites (Life Sci. 29:477, 1981). We now report that rats with chronically elevated norepinephrine (NE) and dopamine (DA) also have high concentrations of CA in RBC. The New England Deaconess Hospital (NEDH) rat develops a PHEO after scapular implant of tumor fragment. Groups (n=9) of adult, female NEDH rats, with and without tumor implant, were used for weekly measurements of tail blood pressures and tail vein CA. The first rise in pressure and plasma NE occurred 3 weeks after tumor implant, viz., +9 mm Hg ($p<0.01$) and +1.1 ng/ml (<0.05), respectively. Controls (sham implant) showed an insignificant change of +4 mm Hg and no change in NE. Tail pressure and plasma NE continued to rise in PHEO rats and, in those still living 6 weeks after implant, mean increases were 20 mm Hg (<0.001) and 2.5 ng/ml (<0.01) respectively. Plasma DA also rose significantly (1.0 ng/ml) and in parallel with plasma NE in PHEO rats whereas plasma epinephrine did not change. RBC NE and DA concentrations were increased simultaneously and to the same extent as those of plasma in PHEO rats. Thus from 3 to 6 weeks after tumor implant RBC NE and DA were significantly higher than in controls. Starting 3 weeks post implant, 2 major metabolites, normetanephrine and dihydroxyphenylethyleneglycol, also rose continuously in plasma of PHEO rats. In some rats, 4 to 6 weeks after implant, an indwelling aortic catheter was used to measure mean arterial pressure (MAP) and to sample blood at 3 intervals, AM, noon and PM, over a period of 12 hours in free moving rats (n=10). In PHEO rats plasma NE declined 1.2±.5 ng/ml between AM and noon (<0.05). Their RBC NE showed a parallel but insignificant decline, 0.80±.4 ng/ml (NS) indicating a slower loss of NE from RBC than from plasma. Plasma and RBC NE and DA were significantly higher in PHEO than in control rats at each time interval yet PHEO MAP was consistently only 8-9 mm Hg higher (NS). Thus unrestrained, undisturbed PHEO females did not have a significant MAP elevation. Summary: The NEDH PHEO rat is uniquely suited for studies of chronically elevated circulating CA and CA metabolites and this study showed that RBC as well as plasma of female PHEO rats contain high concentrations of both NE and DA within 3 weeks of tumor implant. Restrained, but not free moving, PHEO rats had elevated arterial pressure. A decline in PHEO RBC NE lagged behind that of plasma NE.

45.1 THE FROGMOUTH AND THE EAGLE: A COMPARISON OF OCULOMOTOR STRATEGIES. Josh Wallman and John D. Pettigrew. National Vision Research Institute, 386 Cardigan St., Carlton, 3053 Victoria, Australia; City College, City Univ. of N.Y., New York, NY 10031.

Among birds, the location of the eyes and the geometry of the foveae probably represent a variety of compromises between the need for frontal, binocular, vision and the need for lateral, panoramic, vision. As a start in understanding the implications of these different compromises, we have compared two predatory birds which both use binocular vision for hunting, but which differ in their use of panoramic vision. The Little Eagle (Hieraaetus morphroides) is a diurnal predator whose retina contains two foveae: a binocular fovea looking frontally which subserves stereopsis and a monocular fovea used in lateral vision. The Tawny Frogmouth (Podargus strigoides) is a nocturnal predator, whose eyes contain a single, frontally directed, binocular fovea. It hunts from close to the ground, so prey may appear anywhere within a large part of its visual field; when threatened it adopts a camouflage posture. Both of these situations seem to favor lateral vision. We report here differences in oculomotor behavior, specifically in the position of primary gaze and in the yoking of saccades, consistent with the different habits of the two birds.

Scleral search coils were implanted under the conjunctiva near the limbus. The coils were calibrated with reference to retinal landmarks seen through an ophthalmoscope; these were compared to more complete retinal maps made on anesthetized animals.

The frogmouth showed a pattern of eye movements consistent with the competing demands of lateral and frontal vision; most of the time the eyes remained near the lateral extreme of the oculomotor range observed, thereby maximizing the field of vision. In this position the region of binocular overlap was eliminated. Saccades were infrequent and usually disjunctive. Large convergent saccades (up to 24 deg) brought the visual axes into alignment, presumably to permit binocular vision.

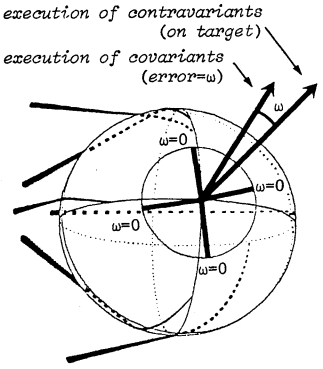
In contrast, the eagle tended to keep its eyes closer to the medial edge of its oculomotor range. In the primary position of gaze, its the binocular foveae were 24 deg divergent (exactly straddling the region of binocular overlap), so that the foveae were within the binocular field, but just barely so. Saccades were very frequent and most were approximately conjugate, although unequal saccades in the two eyes often caused the gaze to be directed more laterally in one eye at a time.

Our data indicate that there is a spectrum along which species vary in the degree of saccadic yoking. The frogmouth, in which conjugate saccades are rare, lies near one end, while the eagle lies somewhere near the middle; primates, to whom Hering's Law applies much more strictly, represent the other extreme.

45.2 TENSOR NETWORK THEORY APPLIED TO THE OCULOMOTOR SYSTEM. CNS ACTIVITY EXPRESSED WITH NATURAL, NON-ORTHOGONAL COORDINATES. G. Ostriker, A. Pellionisz and R. Llinas. Dept. Physiology and Biophysics, New York Univ. Med. Ctr., 550 First Ave., NY 10016.

Nature often provides inherently oblique systems of coordinates, where Cartesian conventions are not valid. The extra-ocular motor system is an example of a geometry in which the intrinsic frame of reference is clearly non-orthogonal. Previous models (Robinson, Boeder) have defined the positional parameters of the extra-ocular muscles. It is apparent that a general approach to coordinate systems, such as tensor analysis, is needed. Expressing the above models with this method, applicable to any coordinate system, the implications of non-orthogonality and an overcomplete number of axes can be revealed naturally.

While an eye movement is a physical invariant, we describe it vectorially in "oculomotor hyperspace" by either covariant or contravariant components. By definition, movement arises through the physical summation of contravariant vector components. However, if the CNS were to relay intention (covariant) vectors directly to the extraocular muscles, the degree of accuracy in the production of intended movements would be a measure of the orthogonality of the system. For saccadic eye movements we work with two coordinate systems, one based upon the actual length changes of the six extraocular muscles and their axes of rotation, and another which is a projection of the first system onto a tangent plane. We characterize saccadic eye movements (from primary, secondary, and tertiary positions) by both covariant and contravariant components. Allowing covariant vectors to be relayed to the muscles (as if they were contravariants), this movement will differ from the original direction by an "error" angle ω, as shown.



Orthogonality would result in eigenvectors (defined by ω=0) in all directions. Our results show that the execution of covariants leads to an error in every direction except for the four eigenvectors of the system. Supported by Grant NS13742.

45.3 ACTIVITY OF ABDUCENS AND OCULOMOTOR NEURONS DURING SYMMETRICAL VERGENCE EYE MOVEMENTS. Lawrence E. Mays and John D. Porter, Departments of Physiological Optics, Physiology & Biophysics and the Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294

There is substantial evidence that the control systems for conjugate and vergence eye movements are relatively independent. Some neurons in the midbrain near the oculomotor nucleus have a pure vergence signal (Mays, Neurosci. Abstr. 7, 1981) while other cells in the pons carry a horizontal conjugate signal only (Mays, ARVO, 1982). Experiments by Keller (Vision Res. 13, 1973) indicate that horizontal rectus motoneurons combine conjugate and vergence signals. Nonetheless, the activity of neurons in the oculomotor and abducens nucleus was re-examined because of: 1) the discovery of abducens internuclear neurons which should carry a conjugate signal only, 2) the existence of oculomotor internuclear neurons, and 3) the fact that earlier experiments used asymmetrical vergence movements which appear to have both conjugate and vergence components.

Extracellular unit recordings were made in three rhesus monkeys trained to look at visual targets for a liquid reward. The horizontal and vertical positions of both eyes were measured using the search coil technique. Symmetrical vergence movements were elicited by changing binocular disparity using a mirror stereoscope or by changing both disparity and accommodation with far and near targets.

In agreement with earlier work by Keller, most abducens neurons appear to carry both conjugate and vergence eye movement signals. A small proportion of abducens units has the purely conjugate signal expected of abducens internuclear neurons. Some abducens units have conjugate and vergence signals which would not be expected of either internuclear or lateral rectus motoneurons. Most oculomotor neurons which have an on-direction appropriate for the medial rectus muscle combine the conjugate and vergence signals. A small proportion clearly has a conjugate signal but no vergence signal.

45.4 LOCALIZATION OF NEURONS PROVIDING AFFERENT AND EFFERENT INNERVATION OF MONKEY EXTRAOCULAR MUSCLES. J.D. Porter, B.L. Guthrie*, & D.L. Sparks, Dept. of Physiology & Biophysics/Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

Recent studies (Buttner-Ennever and Akert, J. Comp. Neurol. 197, '81; Spencer and Porter, J. Comp. Neurol. 198, '81) concerned with the localization of motoneurons innervating primate extraocular muscles (EOM) have made it clear that the classical scheme of organization is incomplete and, in some cases, incorrect. Moreover, the proprioceptive innervation of monkey EOM's remains uncharted. As a prelude to our physiological studies of the EOM proprioceptive system, retrograde horseradish peroxidase (HRP) techniques were used to identify and localize muscle afferent and efferent cell somata. Individual EOM's of adult rhesus monkeys were isolated and injected with 30-50 µl of a 10% HRP solution. Following 24 hour survival and paraformaldehyde/glutaraldehyde fixation, sections were cut and processed for the histochemical demonstration of HRP. Examination of all brainstem motor nuclei served as the control for our injections.

Our data extend the findings of recent HRP studies to include all muscles having an action upon the globe. Motoneurons lying within the oculomotor nucleus exhibited a more complex organization than that described by Warwick (J. Comp. Neurol. 98, '53). Medial (MR) and inferior rectus (IR) representations were in accordance with the contemporary HRP data. Superior rectus (SR) motoneurons were distributed along the medial aspect of the contralateral nucleus, with the predominate representation at caudal to mid-nuclear levels. SR motoneurons were also clustered among the small MR and IR motoneurons in the dorsomedial portion of the nucleus. Inferior oblique motoneurons filled the gap lateral to the SR group and ventral to MR and IR at their respective levels. Superior oblique motoneurons were confined to the trochlear nucleus contralateral to the injection site. Motoneurons innervating the lateral rectus muscle were found in the abducens nucleus proper and in the ventral abducens nucleus, as noted by Spencer and Porter ('81). Consistent with data in the cat (Porter and Spencer, J. Comp. Neurol. 204, '82), neurons subserving sensory innervation of the extraocular muscles were confined to the semilunar ganglion. Section of the ophthalmic division of the Vth nerve prior to HRP placement selectively disrupts ganglion labeling while motor innervation remains intact. Thus EOM afferent fibers course centrally along a path distinct from the motor supply. The separation of fiber types allows chronic deafferentation of the EOM's to be performed in order to assess the role of muscle proprioception in the control of eye movements (Guthrie et al., Soc. Neurosci. Abstr., '82).

45.5 ROLE OF EXTRAOCULAR MUSCLE PROPRIOCEPTION IN EYE MOVEMENTS STUDIED BY CHRONIC DEAFFERENTATION OF INTRA-ORBITAL STRUCTURES. B.L. Guthrie*, J.D. Porter and D.L. Sparks (SPON: J. Smythies). Dept. of Physiology & Biophysics/Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294

The extraocular muscles (EOM) of monkeys contain well-developed proprioceptors but their contribution to eye movement remains a mystery. Our anatomic studies show that, in monkey, centrally directed fibers from these receptors pass through the first division of the trigeminal nerve (Porter et al., Soc. Neurosci. Abstr. 1982) and at this location are isolated from motor fibers to EOMs. Taking advantage of this fact, an intracranial procedure was used to chronically deafferent the EOMs by sectioning the ophthalmic nerve bilaterally.

Conjugate and disjunctive eye movements were studied before and after surgery to delineate the role of proprioception. A major goal was to determine whether or not eye position information exists as a central 'corollary discharge' in the absence of proprioception.

Following deafferentation spontaneous saccades in the dark and light were similar to control movements. Saccadic eye movements to continuously present and remembered targets were normal. In the stimulate-compensate paradigm of Mays and Sparks (Science 208, 1980) deafferented monkeys made compensatory saccades to remembered targets. This indicates that EOM proprioception is not essential for spatial localization of visual targets.

After surgery binocular fixation of visual targets was interrupted by slow adduction of the non-dominant eye while the dominant eye remained on target. Monocular fixation of a visual target was accompanied by slow adduction of the nonviewing eye while the viewing eye (right or left eye) remained on target.

No fundamental deficits in smooth pursuit were identified except that the above mentioned monocular 'drift' was superimposed on pursuit movements.

Deafferented monkeys performed vergence tasks poorly. Although an appropriate initial vergence response was made to stimuli with crossed or uncrossed disparity, the resultant vergence angle was not maintained due to the medial 'drift' of the non-dominant eye.

In the absence of proprioception: a) a central 'corollary discharge' is used for spatial localization of targets; b) conjugate eye movement signals are normal; and c) maintenance of binocular alignment during binocular or monocular target fixation is impaired. The hypothesis that EOM proprioception is a feedback signal used to stabilize binocular alignment after disparity or accommodative vergence eye movements is being investigated.

45.6 THE FINE STRUCTURE OF OCULOMOTOR MOTONEURON ACTIVITY DURING SACCADES. H. P. Goldstein* and D. A. Robinson. Wilmer Institute, The Johns Hopkins University, Baltimore, MD.

The waveform of the firing rate of oculomotor motoneurons during saccades has been grossly described as a per-saccadic, high frequency burst of firing (the pulse) abruptly falling to a post-saccadic, tonic firing rate (the step). However, details of the per-saccadic discharge rate and the per- to post-saccadic transition were not known. Knowledge of these details is required to test models of the oculomotor plant during saccades. Specifically, hysteresis has been a controversial issue: Does the steady-state firing rate at a given position depend on the path the eye took in getting to that position? Claims have been made for and against hysteresis. It was possible that hysteresis was confused with slow changes in the post-saccadic rate arising from compensation of long time constant plant elements. We believe we have resolved this issue.

Single units were recorded in the abducens nucleus of monkeys (Macaca mulatta) trained to follow a visual target. Eye position was measured by the search coil technique. Behavior was averaged over many, nearly identical saccades. We had the monkeys make repeated saccades from an eccentric position (+20 or -20 deg) to primary position. The eccentric gaze was held for three seconds giving adequate time for long time constant viscous plant elements to reach steady state. Because of the possible reflection of these long time constants in the neural signal, we acquired data for three seconds after the target stepped. The per- to post-saccadic transition (from the pulse to the step) was not abrupt as previously held, but instead reached the final tonic rate with an exponential time course: an initial exponential with a short time constant followed by a variable exponential tail with a longer time constant. Typically the initial exponential had a time constant of 90 milliseconds and accounted for 16% of the per- to post-saccadic transition. For the saccades ending at identical positions but coming from different directions, the final firing rates were also identical thus showing no signs of hysteresis.

45.7 STRUCTURE FUNCTION CORRELATION OF ABDUCENS MOTOR AND INTERNUCLEAR NEURONS IN RELATION TO EYE MOVEMENTS: AN INTRACELLULAR HRP STUDY IN THE ALERT SQUIRREL MONKEY. A. Strassman*[1], R.A. McCrea[2] and S.M. Highstein[1]. Albert Einstein College of Medicine[1], Bronx, New York 10461 and University of Chicago, Chicago, Illinois 60637

Male squirrel monkeys (600-800gms) were implanted with scleral search coils to measure eye movements with the magnetic field technique. A modified bolt was cemented to the skull for head stabilization and animals were seated in a primate chair. A recording chamber was implanted over the cerebellum and horseradish peroxidase (HRP) loaded glass microelectrodes advanced into the brain stem. Eye movements were either spontaneous, pursuit or rotation induced nystagmus. The usual recording and injection sites were intra-axonal. After characterization and recording of physiological activity (spike frequency) in relation to gaze, twelve abducens internuclear and four abducens motoneurons were injected with HRP. After 24-30 hour survivals, a modified diaminobenzidine-cobalt intensified protocol was used to develop the HRP reaction product.

Discharge patterns of both classes of neuron were burst-tonic or tonic with an ipsilateral on-direction. Rate-position plots yielded k values of motoneurons ranging from 10-14.5. K values of internuclear neurons ranged from 7-24. Both classes of cells usually burst for on-direction and paused for off-direction saccades or quick phases of nystagmus. Complete soma-dendritic plus axonal fills were not uncommon. Neuronal soma size and location was overlapping but the smaller internuclear neurons tended to have a caudal collateral. Dendritic fields of both classes of cells were completely overlapping and confined within the cellular borders of the nucleus. Dendrites of motoneurons, in contrast to internuclear neurons, were more numerous, thinner, more highly tapered and more branched, as in the cat (Highstein et al., J.C.N., in press). There were no axon collaterals of either class of neuron within the abducens nucleus but one motoneuron had an axon collateral which terminated in the abducens nerve below the nucleus. Internuclear neurons terminated in the medial rectus subgroup A of the IIIrd nucleus. Approximately one third also terminated in and around the median longitudinal fasciculus both in front of and behind the abducens nucleus; one third lacked the caudal collateral and terminated in front of the abducens; and the remaining third traveled to the oculomotor nucleus without collaterals.

These studies support the role of abducens moto- and internuclear neurons in the production of conjugate horizontal gaze.

Supported by NIH EY 01670

45.8 THE LOCATION AND PROJECTIONS OF SQUIRREL MONKEY VESTIBULAR NEURONS WITH HORIZONTAL EYE POSITION SENSITIVITY. S.M. Highstein, R.A. McCrea and A. Strassman* (SPON: J.M. Goldberg). Dept. Neuroscience, Albert Einstein Coll. Med., Bronx, NY 10461; and Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637.

The purpose of the present study was to identify the location and axonal projections of vestibular neurons in the alert squirrel monkey whose activity was related to eye movements in the horizontal plane. Squirrel monkeys were prepared for recording by implanting a chamber over the cerebellum so that microelectrodes filled with a solution of HRP could be inserted into the brainstem. During the experiment, the monkey's head was restrained by fixing a chronically implanted bolt to a primate chair positioned on a vestibular turntable. Eye movements were measured with the magnetic search coil technique. In a few experiments, stimulating electrodes were chronically positioned on the oval and round windows for electrical stimulation of the vestibular nerve.

A total of 17 vestibular axons whose physiological activity was related to horiontal eye position were injected and recovered. Three of these neurons were also activated at monosynaptic latencies (<1.1 msec) following electrical stimulation of the vestibular nerve. In addition to horizontal eye position, the firing rate of the injected vestibular axons was also related to eye velocity during smooth eye movements. Most of the axons paused during saccades in all directions, except for saccades with a horizontal component in the on direction. Eight of the injected cells had axons coursing rostrally in the ascending tract of Deiters (ATD), and were located in the ipsilateral ventral lateral vestibular nucleus (VLVN) or the lateral part of the medial vestibular nucleus (MVN). Most of the ATD axons projected to the oculomotor nucleus without giving rise to collaterals to other areas. However, two axons gave rise to collaterals which terminated ventromedial to the ipsilateral abducens nucleus, and one gave rise to a collateral which terminated in the reticular formation rostral to the abducens. Six of the injected axons originated from cells in the MVN or the VLVN, crossed the midline, and terminated in the contralateral abducens nucleus and MVN. In addition, these axons had collaterals which ascended and descended in the contralateral MLF. The descending collaterals terminated in the prepositus nucleus, the medullary reticular formation, and the midline raphe nuclei. The ascending collaterals terminated in the dorsal pontine reticular formation, and could be followed to the oculomotor nucleus. The results of these experiments demonstrate that many of the primate vestibular neurons with horizontal tonic eye position sensitivity project to medial or lateral rectus motor nuclei, and that some of these neurons receive direct inputs from the vestibular nerve. The collateral projections of these neurons suggest that the prepositus, the dorsal pontine reticular formation, and the medullary raphe may play an important role in horizontal vestibuloocular reflexes.

(Supported by NIH grant EY-01670.)

45.9 THE LOCATION AND COLLATERAL PROJECTIONS OF SQUIRREL MONKEY VESTIBULAR NEURONS WITH VERTICAL EYE POSITION SENSITIVITY. R.A. McCrea, A. Strassman* and S.M. Highstein. Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637; Dept. Neuroscience, Albert Einstein Coll. Med., Bronx, NY 10461.

The location and axonal projections of vestibular neurons whose activity was related to vertical or oblique eye movements was studied by injections of HRP into the axons of 25 vestibular neurons which had been physiologically characterized in the alert squirrel monkey. In a few experiments, stimulating electrodes were chronically implanted on the oval and round windows for electrical stimulation of the vestibular nerve; and five of the injected vertical eye movement related axons were activated at monosynaptic latencies following stimulation of the vestibular nerve. The firing rate of all of the injected axons was related to eye position, and most tended to pause during saccades. Three major groups of cells were injected.

One group of axons (N=8) which responded maximally during downward oblique eye positions arose from cells in the lateral part of the medial vestibular nucleus (MVN) and the medioventral lateral vestibular nucleus (VLVN). These axons ascended in the MLF and terminated in the contralateral trochlear nucleus (IV) and lateral aspect of the oculomotor nucleus (III). In addition, some axons had collaterals which terminated in the dorsal raphe nucleus (DR) the interstitial n of Cajal (IC), and in the region of the MLF. One neuron gave rise to a collateral which terminated in the contralateral abducens nucleus (Abd). Caudal branches of these axons terminated primarily in the region of Roller's nucleus (RN) and the caudal medullary raphe.

A second group (N=3) arose from cells in the caudal superior vestibular nucleus, and responded maximally during upward oblique eye positions. The axons of these cells ascended and terminated in ipsilateral IV, the lateral part of III, and IC. Two cells gave rise to collaterals which terminated in the ipsilateral pontine and medullary reticular formation, and one cell had a collateral which terminated in the ipsilateral Abd.

The third group of axons (N=14) arose from cells in the VLVN and the lateral aspect of the MVN, and responded maximally during upward eye positions. These axons ascended in the contralateral MLF and terminated in the medial aspect of the contralateral III and in the IC. One cell terminated bilaterally in III. Caudal branches of these axons terminated in the medullary reticular formation, RN and in the medullary raphe nuclei.

The results of this experiment demonstrate that many primate vestibular neurons with vertical eye position sensitivity receive direct inputs from the vestibular nerve, and project to extraocular motor nuclei. The collateral projections of these cells suggest that the medullary raphe nuclei and RN may play an important role in vertical vestibuloocular reflexes, and that the abducens nucleus receives inputs from some vertical vestibular neurons.

(Supported by NIH grant EY-01670.)

45.10 MESENCEPHALIC NEURONS THAT DISCHARGE FOR TARGET MOVEMENTS, SACCADES AND EYE POSITION. C.R.S. Kaneko and A.F. Fuchs. Regional Primate Research Center and Dept. Physiol. & Biophys., Univ. of Wash., Seattle, Washington 98195

Our preliminary injections of horseradish peroxidase into the omnipause neuron region of the cat revealed a large afferent input from a restricted midline mesencephalic area. Since omnipause neurons are thought to be an essential link in the production of saccades, we wanted to ascertain whether this mesencephalic region contained neurons whose discharge might convey appropriate oculomotor signals. During the course of single unit recordings from this area in alert, trained animals, we discovered a group of neurons that discharge in relation to both eye and target movement.

In two cats, a region rostral to the oculomotor nucleus and medial to the retroflex bundle contained neurons that discharged with a sporadic tonic rate that was related to vertical eye position in about one-half of the population. Slopes of the rate/position relation ranged from 0.5 to 2.1 spikes/deg. All neurons also showed a tonic or phasic increase or decrease in discharge for vertical saccades in a preferred direction although some sensitivity to pure horizontal movements was seen. The preferred direction for saccades could be in the same or opposite direction to the eye position preferred direction. In contrast, target movements in the preferred direction for saccades elicited an increase in firing rate. This increase was maintained until the saccade-related discharge, after which the firing rate returned to that appropriate for the newly obtained eye position. The saccade-related discharge was independent of target movement since it occurred during spontaneous saccades. Target-related discharge was independent of eye movement since it occurred when the target was moved and the animal did not track the target. Since these neurons continued to discharge while a retinal error was present following a target step, we have tentatively termed them error cells.

We have recorded similar neurons in the mesencephalon of a single monkey. These neurons displayed a wider variety in their discharge characteristics: although nearly all had eye position sensitivity (range 0.9-4.0 spikes/deg) a few showed none; and while most had high tonic rates of discharge, some had none. The discharge in response to target movements and saccades was less reliable but usually synergistic. In addition some neurons discharged most vigorously for oblique target/eye movements.

45.11 PROBABLE INHIBITORY BURST NEURONS IN THE MONKEY. C. A. Scudder, T. P. Langer*, and A. F. Fuchs. Regional Primate Center and Dept. of Physiol.& Biophys., Univ. of Wash. Seattle, WA 98195.

In the cat, Hikosaka and his collegues have identified a group of neurons immediately caudal to the abducens nucleus which discharge a burst of spikes for ipsilateral saccades and make monosynaptic inhibitory connections with the contralateral abducens nucleus. They have been appropriately named Inhibitory Burst Neurons (IBNs). In the monkey, we have recorded burst neurons in a location comparable to that of cat IBNs. Three lines of evidence suggest that these are IBNs in the monkey. (1) Horseradish Peroxidase (HRP) injected into one abducens nucleus retrogradely labeled cells just ventrocaudal and slightly medial to the contralateral abducens nucleus. We verified that this was the location where burst neurons were recorded by placing electrolytic lesions at appropriate recording sites, injecting HRP in the same monkey, and comparing adjacent Nissl and HRP-processed tissue sections. (2) Microstimulation (10 μA) near putative IBNs yielded eye movements and EMG responses appropriate for a crossed inhibitory connection. During fixation, stimulation caused the eyes to move ipsilaterally. Moreover, responses from EMG electrodes in the contralateral lateral rectus muscle were of opposite sign, and of 0.5 ms longer latency, than responses elicited by contralateral abducens nucleus microstimulation. (3) As in the cat, cells discharged a burst of spikes for ipsilateral saccades and little or no burst for contralateral saccades. That is, for a cell with a crossed inhibitory connection, the burst was functionally appropriate.

A quantitative analysis of 17 neurons revealed that the onset of discharge in monkey IBNs filled the range from short-lead to long-lead. Only about one-fourth were classical short-lead burst neurons (5.1-10 msec latencies), for which the number of spikes was strongly correlated with saccade size, as was burst duration with saccade duration. The discharge of the remaining burst neurons (10-200 ms latency) included a compact burst ($\geq$ 300/sec) whose onset immediately preceeded the saccade. For this portion, burst parameters were also correlated with saccade parameters but more weakly than for short-lead burst neurons.

45.12 HORIZONTAL OR GLOBAL GAZE PALSY INDUCED BY KAINIC ACID LESIONS IN THE PONS OF THE MONKEY. V. Henn*, W. Lang*, K. Hepp* and H. Reisine (SPON: M. B. Bender). Depts. of Neurology and Pathology, Univ. Hosp., Dept. of Physics, ETH; Zürich, Switzerland.

Rhesus monkeys were prepared for chronic single unit recordings in the paramedian pontine reticular formation (PPRF). Single unit activity in this area has been related to rapid eye movements. Long lead burst signals have been located in the more rostral parts in contrast to the short and medium lead as well as burst-tonic (i.e. signals related to eye position also) activity found in more caudal parts. Small injections of kainaic acid were placed selectively into rostral or caudal areas to observe their differential effects. Such injections lead to preferential loss of cells leaving fiber systems mostly unaffected. Histology shows a rather sharply limited area around the injection site with complete loss of neurons and invasion of microglia.

Unilateral PPRF injections lead to neurological deficits which are identical to those after electrolytic lesions with loss of all rapid eye movements towards the ipsilateral side (Bender and Shanzer, The Oculomotor System, N.Y., 1964).

Bilateral rostral PPRF lesions lead to a complete loss of rapid eye movements in the horizontal plane only, leaving vertical saccades intact.

Bilateral caudal PPRF lesions lead to a total loss of rapid eye movements in all directions.

In all cases of unilateral or bilateral lesions slow eye movements induced by vestibular stimulation were intact in all directions. With bilateral lesions, pursuit movements could be elicited, and the eyes could be held in eccentric positions of gaze. The experiments support the hypothesis that on a premotor level the generation of rapid and slow eye movements are independent from each other; that the velocity-to-position integrator necessary to hold the eyes in eccentric gaze positions is located outside of the PPRF; that the caudal PPRF plays an important role in coordinating and controlling the occurrence of rapid eye movements in all directions although the immediate premotor apparatus for generating rapid vertical eye movements is located in the rostral mesencephalon.

45.13 SINGLE UNIT RECORDING WITH FREELY MOVING HEAD: A NEW MICRODRIVE PRINCIPLE. B. Merker* and J.D. Schlag. Dept. of Anatomy and B.R.I., U.C.L.A., Los Angeles, CA 90024.

In the past the technique of single unit recording in behaving animals achieved precision in electrode control at the price of highly restrictive behavioral conditions. The size, weight, and mode of advancement of conventional microdrives prevent them from being mounted on the unrestrained head of animals. This limitation has been overcome in a new microdrive system which allows electrodes to be moved with micron accuracy and full compliance on the unrestrained head without impeding any of its movements.

A mechanical transducer of novel design, weighing 8g and measuring 8x10x41mm, converts one full turn of rotary input motion to 1.09μm of linear output motion over a range of 20mm of continuous fine travel (unlimited gross travel). Mounted on a conventional chronic well, its low input torque requirements allow it to be driven remotely by a fine and flexible stainless steel wire, suspended from a mount at a convenient distance. From there the wire, in turn, can be rotated either by mechanical means or via an electric motor. The system currently in use on cat and monkey permits the animal to move its head with complete freedom during single unit recording, its trunk alone being restrained.

The low mass of the head-mounted transducer means that even rapid and violent head movements transmit no significant force to the electrode. Single unit records are therefore stable, well isolated units with a signal-to-noise ratio of 3:1 or better being held through bouts of struggling, head shaking, and experimenter manipulations such as alternately fixing and freeing the head.

The system works to best advantage in combination with a search-coil system for monitoring movement: the same inducing magnetic fields that yield a gaze signal from a scleral search coil yield a head position signal from an equivalent coil permanently attached to the head. In addition, wire loops fastened to ear or limb may be used to obtain information on ear position and the timing of limb movements.

The performance of the system will be demonstrated on film, and via single unit and behavioral records obtained in the course of microelectrode exploration of the subthalamic region (zona incerta, fields of Forel, and prerubral field) in relation to the behavior of eyes, head, and paws.

Supported by USPHS research grant NS-04955.

46.1 SINGLE-UNIT RECORDINGS FROM A VOCAL CONTROL NUCLEUS OF THE SINGING MOCKINGBIRD. J. S. McCasland and M. Konishi. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

We have developed a new technique for recording from single neurons in song system nuclei of the freely-behaving, singing mockingbird. The method employs an X-Y microdrive designed by our machinist Herb Adams. This device of approximately two grams is constructed so as to allow multiple electrode tracks over a 4 x 4 mm area, thus allowing a nucleus to be mapped for single unit properties during song. This confers a special advantage in the song system because its nuclei are anatomically discrete, with boundaries which can be physiologically defined. Thus, in principle such mapping can be done over long periods of time without the need for sacrificing birds to verify track locations. The chronically implanted microdrive is sufficiently stable so that units can be isolated and held for periods up to several hours.

Our preliminary data show that many cells exhibit premotor activity for all mockingbird song elements, and do not respond to those same song elements presented as auditory stimuli. Some of these cells have relatively constant pre-sound latencies for the various elements, while others show long-latency "anticipatory" activity at the initiation of song and between elements of a long song bout.

A few cells show more selective premotor activity, producing highly stereotyped bursts of spikes for only a few song elements. Thus far we have not found examples of such cells which are also responsive to playback of the sounds for which they produce motor activity. At least some of the cells which are responsive to playback are inhibited during singing, as predicted from our multiple-unit data.

Interaction between motor output and auditory feedback is known from behavioral experiments to be necessary for the motor phase of song learning. The ability to examine this interaction at the cellular level should enable us to assess the neurophysiological correlates of song learning in the various nuclei of the vocal control system.

46.2 PATTERN GENERATION BY DELAYED EXCITATION IN PARALLEL WITH RECIPROCAL INHIBITION. P.A. Getting. Dept. of Physiol. Biophys., Univ. of Iowa, Iowa City, IA. 52242.

The central pattern generator (CPG) network underlying escape swimming of the mollusc Tritonia diomedea consists of four premotor interneuron pools termed cerebral cell 2 (C2), dorsal swim interneurons (DSI), and two subgroups of ventral swim interneurons (VSI-A & VSI-B). During a swim, bursts in DSI alternate with coactive bursts in both VSI-A and VSI-B. Mapping of the monosynaptic connectivity among the four CPG interneuron types revealed that the synaptic basis for pattern generation by this network was reciprocal inhibition between DSI and VSI paralleled by delayed synaptic excitation from DSI to C2 to VSI. Delayed excitation of the VSI group was mediated by two distinct mechanisms. For VSI-A, delayed excitation resulted from the integrative properties of the multicomponent inhibitory-excitatory synapse from C2 to VSI-A. The initial action of this dual action synapse was inhibition, but after a delay of 1-1.5 sec, this synapse converted to excitation resulting in the delayed burst in VSI-A. The mechanism of delayed excitation in VSI-B was distinctly different and relied upon the interaction of synaptic excitation with tha activation of a transient outward potassium current (A-current). The VSI-B had a deep resting potential (-60 mV) which removed inactivation of A-current. The VSI-B responded to injected depolarizing currents with a long delay of 0.4-4.0 sec to the first spike. Once repetitive firing started, the spike frequency accelerated to a steady state level proportional to the injected current. Voltage clamp of VSI-B revealed that both the long delay and the acceleration in spike frequency could be accounted for by the activation and subsequent inactivation of A-current upon depolarization. The VSI-B received only synaptic excitation from C2, thus the delay in the onset of VSI-B bursts during a swim resulted from the interaction of synaptic excitation with the kinetic properties of A-current intrinsic to the VSI-B. Reciprocal inhibitory networks will produce repetitive bursts only if some additional properties are included. Previously proposed mechanisms include post-inhibitory rebound, synaptic fatique, and accumulative refractoriness. The reciprocal inhibitory network of the Tritonia swim system uses a new mechanism of delayed, synaptically mediated excitation.

46.3 THREE FORMS OF THE TURTLE SCRATCH REFLEX. Lawrence I. Mortin, Joyce Keifer* and Paul S.G. Stein. Dept. of Biology, Washington University, St. Louis, MO 63130.

The red-eared turtle Pseudemys scripta elegans, when low-spinal, displays three different forms of the scratch reflex behavior in response to gentle mechanical stimulation. Biomechanical constraints on the hindlimb and body compel the turtle to use different strategies of limb movements to scratch separate parts of its body. Stroboscopic videotape studies of hindlimb movements and electromyographic recordings were used to analyze the different aspects of each scratch form. The rostral scratch reflex (previously called the turtle scratch reflex; J. Comp. Physiol. 140:287, 1980, 145:477, 1982 and 146:401, 1982) is initiated by stimulation of the shell bridge region. Hip protraction moves the hindlimb rostrally. With the hip held protracted, the knee extends and the dorsum of the foot performs the rub. Knee extensor muscle (FT-KE; femorotibialis) activity occurs during the latter half of hip protractor muscle (VP-HP; ventral puboischiofemoralis internus) activity in the rostral scratch. The pocket scratch reflex is initiated by stimulation of the skin or shell of the pocket region, located between the shell bridge and the hindlimb. The hip is protracted and the knee flexed to bring the limb into the pocket. Then knee extension and hip retraction occur simultaneously as the knee performs the rub. FT-KE activity occurs after VP-HP activity and during hip retractor muscle (HR-KF; flexor cruris, pars flexor tibialis internus) activity in the pocket scratch. The caudal scratch reflex is initiated by stimulation of the shell or skin caudal to the hindlimb. Hip retraction moves the limb caudally. With the hip held retracted, the knee is extended and the heel or side of the foot performs the rub. FT-KE activity occurs after HR-KF activity and before VP-HP activity in the caudal scratch.

A transition zone (TZ) exists at the boundary between two adjacent scratch reflex receptive fields. Within a TZ the turtle's limb has the mechanical ability to use either of the two bordering scratch reflex forms to rub against the stimulated site. Stimulation within a TZ can elicit (1) a pure form of the scratch, indistinguishable from a scratch initiated within the receptive field rostral or caudal to the TZ, (2) a switching scratch behavior, a multicycle scratch in which one cycle of a pure form of scratch is followed by a subsequent cycle of a second pure form of scratch, or (3) a hybrid scratch reflex, such that within a single cycle of scratch there are characteristics typical of two different scratch forms. The smooth and uninterrupted nature of the hindlimb movements during a TZ scratch imply some form of convergence in the controlling elements for the different scratch reflex motor programs. Supported by NIH Grant NS-15049 to PSGS and NIH Training Grant in Neurobiology NS-07071 to LIM.

46.4 CENTRAL PROGRAMS FOR THREE FORMS OF THE TURTLE SCRATCH REFLEX. Gail A. Robertson, Joyce Keifer* and Paul S.G. Stein. Dept. of Biology, Washington University, St. Louis, MO 63130.

Three distinct forms of the scratch reflex are centrally programmed in the turtle spinal cord. The motor program underlying each scratch form has been described for the freely moving limb using electromyography (EMG). Each motor program is elicited by stimulation in a specific receptive field (Mortin et al., this vol.). In the immobilized, low-spinal turtle, identified scratch programs can be recorded from peripheral nerves innervating the hip protractor (HP) muscle VP-HP, the knee extensor (KE) muscle FT-KE, and the hip retractor (HR) muscle HR-KF. For each scratch form, sequences of activation of hip and knee motor neuron pools exhibited in the peripheral nerve recordings (ENGs) are similar to the patterns of muscle coordination observed with EMGs in the moving limb. The receptive field mapped for each central program in the immobilized turtle is identical to that mapped for the corresponding program in the preparation with limb movement. Transition zones exist between adjacent receptive fields in the immobilized turtle, and stimulation in these regions elicits a variety of responses exhibiting many similarities to the transition motor patterns evoked in the preparation with a moving limb.

Intracellular recordings indicate that motor neurons (MNs) of a given pool receive phasic excitatory and inhibitory synaptic drive correlated with the activation of other motor pools. For example, each HP MN receives a Cl-mediated inhibition during the HR phase of a scratch, independent of the receptive field stimullated. The associated antiphasic relationship between HP and HR ENGs is basic to all scratch programs. A feature that differentiates the three scratch forms is the relative timing of the KE activity in the HP activity cycle. In the rostral scratch, KE activity begins late in the HP burst. Both HP and KE activity are terminated at the onset of the HR burst and remain quiescent for its duration. Each HP MN initially exhibits a slow ramp of depolarization and a low frequency discharge. At the onset of KE activity, a marked increase in excitatory drive is reflected in a more rapid membrane potential trajectory and a higher frequency discharge. A single phase of Cl-mediated inhibition is correlated with the subsequent HR burst. In the pocket scratch, KE activity begins after the termination of the HP burst, and is co-active with the first part of the HR burst. Each HP MN receives a single phase of excitatory activation, followed by a Cl-mediated inhibition during the KE phase of the cycle. A second phase of inhibition is correlated with the remainder of the HR burst. These observations show that HP MNs receive timing information linked to the activation patterns of HR and KE MNs characteristic of each scratch form. Supported by NIH Grant NS-15049 to PSGS and NIH Training Grant in Neurobiology NS-07071 to GAR.

46.5 A SIMPLIFIED CIRCUITRY SCHEME FOR THE GASTRIC MILL NETWORK IN LOBSTER TESTED BY PHOTOINACTIVATION OF CELLS. M. Wadepuhl* and A. I. Selverston. Dept. of Biol., Univ. of Calif. San Diego, La Jolla, CA 92093.

One approach to the understanding of complicated networks is to reduce them to a set of basic connections. Predictions made on the basis of such a reduced circuit can then be tested experimentally.

We have reduced the 11 celled gastric mill network in the stomatogastric ganglion to a system of 5 cell groups. We reduced the number of 22 synapses to 6, selecting those, which we and others have determined to be the most important (Russell, D.F.and Hartline, D.K., Science 200:453, 1978; Thompson, R.S., Biol. Cybern 43: 71, 1982; Selverston A.I. et al., Prog. Neurobiol. 7:215, 1976). We have tested this scheme by photoinactivation of groups of cells (Miller, J.P. and Selverston, A.I., Science, 206: 702,1979). The crucial connection appears to be a reciprocal inhibition between Int 1 and the LG/MG-complex. These cells fire alternately and periodically inhibit GM and LPG, which can be viewed as follower cells. Int 1 also excites the DG/AM complex and inhibits the GM. In addition DG exhibits not only plateau potentials (Russell, D.F. and Hartline, D.K., Science, 200:453, 1978), but can be caused to burst in the presence of Octopamine (Wadepuhl, M. and Selverston, A.I., in prep.).

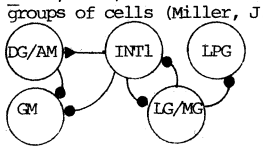

Fig.1 Reduced circuitry Scheme

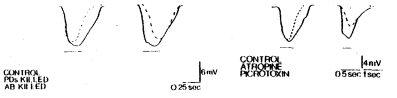
In non-bursting preparations the LPG, GM and Int 1 fire tonically while DG, AM, LG, MG are silent. This allows us to make several predictions:

1) Inactivation of LPG and GM should not alter the pattern.
2) Killing of DG and AM should only reduce the modulation of GM.
3) Inactivation of LG and MG should not effect DG and AM but should cause LPG to go tonic.
4) Killing Int 1 should abolish all patterned activity, except for DG/AM which may continue to burst if there is enough excitory input from outside the ganglion present.
5) Finally the minimal circuit for alternating burst generation should be the Int 1 and LG/MG groups.

We are able to show remarkable coincidence between our experimental results and the predictions. Deviations from our expectations point towards some functional significance of the synapses neglected in the above scheme.

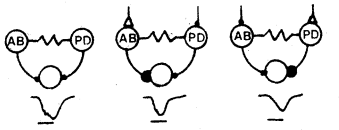
46.6 ELECTRICALLY COUPLED NEURONS RELEASE DIFFERENT TRANSMITTERS RESULTING IN A VARIABLE TIME COURSE SYNAPSE. E. Marder and J.S. Eisen. Biology Dept., Brandeis University, Waltham, MA 02254

The lobster stomatogastric ganglion (STG) contains an ensemble of electrically coupled neurons composed of the 2 PD motor neurons and the single AB interneuron. The PD neurons 1) make cholinergic neuromuscular connections, 2) contain choline acetyltransferase (CAT; E.C.2.3.1.6.; 17.7 ± 1.5 pmole/cell/hr; n=31; activity in 31/33 cells) and 3) evoke increases in G_{K^+} which are blocked by atropine, scopolamine, QNB and TEA but insensitive to picrotoxin. The AB neuron 1) contains no detectable CAT (<1/30 of the activity of a PD neuron; n=9) and 2) evokes rapid increases in G_{Cl^-} plus G_{K^+} which are blocked by picrotoxin but insensitive to atropine, scopolamine, QNB and TEA. The combined AB plus PD-evoked inhibition in postsynaptic neurons can be dissected into its component parts either pharmacologically or using the Lucifer yellow photoinactivation technique as shown by the superimposed tracings below.



bar indicates firing time of presynaptic neuron(s) here and below

The electrically coupled AB & PD neurons act as the pacemaker for the pyloric rhythm of the STG by inhibiting the other pyloric neurons. The functional consequences of the different time courses of AB-evoked and PD-evoked IPSPs are seen below:



resistor-electrical synapse
filled circle-chemical IPSP
triangle-excitatory input
size of filled circle is proportional to amount of transmitter released by that neuron.

Any excitatory or inhibitory input onto either the PD or AB neurons but not both (asymmetric input) will alter the ratio of PD-released to AB-released transmitter and therefore, will alter the ratio of PD-evoked to AB-evoked inhibition in a postsynaptic neuron. Because of the different time courses of PD-evoked and AB-evoked inhibition, this should alter the phase relationships between the AB/PD and postsynaptic neurons.

J.S. Eisen was a Gillette Fellow at Brandeis University. Research support by NIH NS17813 and a Sloan Fellowship to E. Marder.

46.7 ACTIVATION OF ASYMMETRIC INPUTS ONTO ELECTRICALLY COUPLED NEURONS GENERATING A VARIABLE TIME COURSE SYNAPSE: A MECHANISM FOR CHANGING PHASE RELATIONSHIPS BETWEEN NEURONS. J.S. Eisen and E. Marder. Biology Department, Brandeis University, Waltham, MA 02254

The electrically coupled cholinergic PD and glutamatergic AB neurons jointly inhibit the PY neurons of the lobster STG. The following predictions can be made about the phase relationships of the firing times of AB, PD and PY neurons based on the model presented in the previous abstract (Marder & Eisen, above): 1) an increased ratio of PD-released to AB-released transmitter will result in an increase in PD-evoked inhibition. Because the PD neurons evoke the late portion of the combined IPSP (see Marder & Eisen, above), this should prolong the late portion of the IPSP and thus the PY neuron should begin to fire later following a synchronous AB/PD burst than it would under control conditions and 2) a decreased ratio of PD-released to AB-released transmitter should decrease the amount of PD-evoked inhibition and thus, the PY neuron should begin to fire earlier following an AB/PD burst than it would under control conditions.

In order to test this model we activated selectively two different asymmetric inputs into the STG. Dopamine (DA) decreases the ratio of the amplitudes of PD/AB slow wave depolarizations. Therefore, the model would predict that the PY neuron should begin to fire earlier in the presence of DA than under control conditions. This prediction was confirmed in experiments in which the phase relationships between PY and AB/PD neurons were compared under control conditions and in the presence of DA. Stimulation of the IVN through fibers increases the ratio of the amplitudes of PD/AB slow wave depolarizations. The model would predict that the PY neuron should begin to fire later following IVN stimulation than under control conditions. Again, this prediction was borne out in experiments in which the phase relationships between PY and PD/AB neurons were examined prior to and following IVN stimulation.

These results strongly suggest that asymmetric inputs onto electrically coupled neurons which evoke different responses in a postsynaptic neuron can modulate the phase relationships among these neurons.

46.8 THE COUPLING OF SEGMENTAL OSCILLATORS CONTROLLING ABDOMINAL PUMPING IN THE LOCUST. Simon F. Giszter* (SPON: R. Lane). Lab. of Dr. G. Hoyle, Inst. of Neuroscience, Dept. of Biology, Univ. of Oregon, Eugene, Oregon.

Many kinds of repetitive animal behaviours appear to be driven by the activity of coupled oscillators. The object of this study is to determine the method of coupling of segmental oscillators driving ventilation in the locust, and how coupling strength varies over a range of cycle periods.

Simultaneous pumping by abdominal segments 2-7 drives a unidirectional airflow through the tracheal system. For efficient airflow segmental movements must be tightly phaselocked. Segmental abdominal ganglia produce appropriately phased antagonistic motoneuron activity in isolation. Hence these ganglia contain a set of coupled oscillators suitable for such analysis.

I have examined segmental interactions in the restrained, resting locust by myographically monitoring specific muscle activity. Sets of records of 250 consecutive pumping cycles were collected for 2 adjacent segments using an on-line PDP11/44 computer. Absolute time of onset, burst duration, interburst duration, and number of spikes per burst were measured and then analysed as time series.

Two parallel pathways transferring information in opposing directions were detected and seem strong enough to account for phaselocking of the segments in the resting animal. Firstly, information moves posteriorly from the metathoracic ganglion to all unfused abdominal ganglia, controlling the onset of inspiration and turning off expiratory activity in all segments. By contrast information controlling the start of expiration travels anteriorly: the intersegmental lag of the expiratory bursts is related to the onset of the next expiratory burst in the more anterior segment by a negative feedforward process. Several neuronal pathways may be contributing to each one of these couplings. Descending interneurons which might be the principle elements in the first coupling have been described (Lewis, Miller & Mill, 1973; Pearson, 1980).

The descending pathway switches expiration to inspiration in all segments, while local control is the more important in phaselocking pairs of oscillators.

Supported by an SRC overseas award and a Morgenroth scholarship to S. Giszter, and NSF Research Grant BNS 82-41884 to Dr. G. Hoyle.

46.9 MOTOR NEURONS AS FUNCTIONAL ELEMENTS OF THE VENTILATORY OSCILLATOR IN THE CRAB. R. A. DiCaprio* and C. R. Fourtner. Dept. of Biological Sciences, SUNY Buffalo, Buffalo, Ny 14260.

In Crustacea, motor neurons as well as interneurons have been shown to play a role in the pattern generator for two sterotyped behaviors, a centrally generated locomotor activity (crayfish swimmeret beating, Heitler, W. J., Nature, 275:231, 1978) and a peripherally generated rhythmic behavior (stomatogastric ganglion, Selverston, A. I., IN Identified Neurons and Behavior in Arthropods, 1977). Simmers and Bush (Brain Res., 197:247, 1980) and DiCaprio and Fourtner (Soc. Neurosci. Abst. 7; 744, 1981) have shown that a number of non-spiking interneurons are elements of the central pattern generator responsible for ventilation in the crab, Carcinus maenas. We report here a more detailed study of the motor neurons associated with the ventilatory system.

Ventilation is the result of rhythmic dorsal/ventral movements of the gill bailer produced by two loosely grouped sets of muscles, the levators and depressors (Young, R. E., J. Comp. Physiol, 101:1, 1975). The motor pattern consists of alternating bursts of the motor neurons to these muscles. Within each of these groups are motor neurons which are active during the initial, middle, and final phases of each burst. Intracellular recordings obtained from motor neurons active in different phases of each group demonstrate that all of these neurons interact with the central pattern generator. Injection of intracellular current pulses into ten ventilatory motor neurons reset the motor pattern, however, the current pulse is only effective when the motor neuron membrane potential is in the depolarizing phase of its oscillation. This resetting effect is not dependent upon spiking activity in the motor neurons, because a current pulse can effectively reset the rhythm when the neuron is held hyperpolarized below its spike threshold. In addition, the injection of constant hyperpolarizing current into motor neurons slows the ventilatory rhythm and in two instances, completely stops the rhythm. Therefore, the motor neurons to the levator and depressor muscles of the gill bailer contribute to the neural circuit responsible for ventilation and this interaction appears to be non-spiking in nature. (Supported by grants 1F32NS06277 to R.A.D.)

46.10 ELECTRICAL COUPLING AND UNCOUPLING OF LEECH SWIM OSCILLATOR NEURONS VIA RECTIFYING ELECTRICAL SYNAPSES. W. Otto Friesen. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Four pairs of segmentally repeated interneurons which serve to generate the leech swimming rhythm have been described previously (Friesen, W.O., Poon, M. and Stent, G.S. J. Exp. Biol. 75: 25-43, 1978). It now appears that this quartet of interneurons is a subset of the complete circuit, for we have discovered four more neuron pairs which also must be considered candidate neurons of the swim oscillator. These additional neurons became evident after we began desheathing the segmental ganglia prior to intracellular recording. The desheathing procedure, which appears not to disturb neuronal function, greatly increases visibility of small neuronal somata and greatly facilitates intracellular recording. We here describe the dual interactions between one of these newly identified interneuron pairs, cells 60, and cell 208, an unpaired oscillator candidate interneuron identified by Weeks (Doctoral dissertation, Univ. of Calif., 1980; Neurosci. Abstr. 7: 137, 1981).

The swim oscillations of the cell 60 pair and cell 208 are antiphasic as a result of the inhibitory synaptic input cell 208 receives from cells 60. This input appears to be direct because: 1) the inhibition is strong, up to 22 mV hyperpolarization per 1.0 nA of current injected into cell 60; 2) the synaptic delay is less than 10 ms and 3) the inhibitory effects persist in Na^+-free Ringers (Tris HCl substituted for NaCl). The inhibitory synapse is effective since hyperpolarization of one cell 60 during swimming activity reduces the hyperpolarizing phase of cell 208 oscillations by about 50%. In quiescent preparations, cells 60 and cell 208 are also coupled via a powerful rectifying electrical connection (coupling strength in the forward direction, cell 60 to cell 208, is about 0.4). The diode connection, if effective during swimming, would act to counter the synaptic inhibition and tend to synchronize cells 60 and cell 208 activities. This antagonistic effect is prevented during swimming activity because cell 208 oscillations, unlike those of cells 60, are superimposed onto a depolarized plateau of about 10 mV, producing a reverse bias across the coupling diode. Thus during swimming activity the current cannot pass through the diode connection, leaving only the synaptic inhibition to set the phase of cell 208. A possible role for the diode interaction could be to synchronize non-swimming activities of cells 60 and cell 208. While such synchronization could also be accomplished via a non-rectifying electrical coupling, the diode connection provides a mechanism for uncoupling these cells during swim activity. Supported by NIH grant NS14965 and NSF grant BNS81-0243.

46.11 THE SWIM-INITIATING ABILITY OF INTERSEGMENTAL SEROTONIN-CONTAINING LEECH INTERNEURONS. M.P. Nusbaum and W.B. Kristan, Jr. Dept. of Biology, UCSD, La Jolla, CA. 92093

Two of the bilaterally-paired serotonin-containing interneurons, designated cell 61 and cell 21, can initiate and maintain the swim motor program in the leech Macrobdella decora. These cells share this swim-initiating ability with cell 204 (Weeks and Kristan, J. exp. Biol. 77: 71-88, 1978) and the serotonin-containing Retzius cells (Willard, J. Neurosci. 1(9): 936-944, 1981). In most respects, this ability is more like that of cell 204 than the Retzius cells in that swim initiation occurs within seconds rather than minutes from the onset of stimulation, and swim initiation by these cells can be effected in large volumes of saline.

Two aspects of the swim-initiating ability of a single cell 61 are different from those of both cell 204 and the Retzius cells. First, the cycle periods it produces are often longer than during swims initiated by cell 204 or the Retzius cells. Second, stimulation of a single cell 61 can sustain the swim motor pattern either in all of the ganglia of a chain, or sometimes exclusively in its own and near neighboring ganglia. Swims initiated by any other means do not result in such a localized generation of the swim motor pattern. However, simultaneous stimulation of two cells 61 causes a swim motor pattern similar to that initiated by these other means.

Cell 61 activity has an excitatory effect on some identified cells in the swim circuit, including: cell 204; the central pattern generating interneuron cell 208; and the dorsal and ventral longitudinal motor neurons. Furthermore, depolarizing cell 204 strongly excites cell 61. During swims initiated by some other means, cell 61 receives rhythmic bouts of excitatory input so that it fires impulses in phase with impulse bursts in cell 208.

Mechanosensory stimulation sufficient to initiate swimming has a strong excitatory effect on cell 61. This activation of T (touch), P (pressure) and/or N (nociceptive) sensory neurons polysynaptically excites cell 61, primarily via the multimodal giant fiber (S cell) system, with which cell 61 has an electrical rectifying connection.

The Retzius cells and cells 61 appear to influence the swimming pattern generator by different mechanisms. The Retzius cells are neurosecretory cells, exerting their effects on the nervous system by increasing the level of serotonin in the blood, whereas the properties of cell 61 suggest that it initiates swimming via discrete synaptic contacts within the ganglion.

This work was supported by PHS Grant GM07313.

46.12 NEURONS MODULATING HEARTBEAT IN THE LEECH: CENTRAL CONNECTIONS AND PERIPHERAL EFFECTS. R.L. Calabrese and A.R. Maranto (Spon: L.P. Tolbert). The Biological Laboratories, Harvard University, Cambridge, MA 01238.

An elaborate and well-characterized central pattern generator programs the rhythmic beating of the paired hearts in the leech, Hirudo medicinalis. The pattern generator itself comprises a set of segmental heart interneurons. These interneurons rhythmically inhibit a set of segmental heart motor neurons, which time and coordinate the constrictions of the hearts.

We have recently discovered a new class of efferent neurons that receive rhythmic inhibition from the heartbeat central pattern generator. A bilateral pair of these neurons is located in the corresponding position in each of the fifth and sixth segmental ganglia. We have named these cells HA or heart accessory neurons. The HA cells of the fifth ganglion have axons projecting out the contralateral roots of the fifth and more anterior ganglia, while the HA cells of the sixth ganglion have axons projecting out the contralateral roots of the sixth and more posterior ganglia. These peripheral axons extend out to the heart muscle.

Tonic activity in the HA neurons increases the tension produced by the heart muscle in response to heart motor neuron discharge and induces autonomous rhythmic beating of the hearts when heart motor neuron activity is experimentally suppressed.

Experiments are now in progress to determine the electrical effects of the HA neurons on the heart muscle cells.

Supported by NSF grant BNS-8121551 and an Alfred P. Sloan fellowship to RLC.

46.13 ACTIONS OF ACETYLCHOLINE ON THE RHYTHMIC BURST ACTIVITY OF CARDIAC GANGLION. R. E. Sullivan and M. W. Miller. Bekesy Laboratory of Neurobiology, University of Hawaii, Honolulu, Hawaii 96822.

The cardiac ganglion of Homarus americanus was examined as a possible locus of cholinergic cardioexcitation. Spontaneously bursting isolated ganglia responded to bath application of acetylcholine (10^{-5} - 10^{-3} M) with increases in burst frequency, impulses per burst, and burst duration. Both the motorneurons and premotor cells are excited by acetylcholine. Intracellular recordings from motorneurons revealed 1-5 mV depolarizations which appear to be due to an increase in apparent membrane resistance. Moreover, there was a marked enhancement in the rate of rise of the interburst pacemaker potential.

In the presence of TTX ($3X10^{-7}$ M) bath application of acetylcholine resulted in a concentration-dependent depolarization (K_d = 10^{-4} M) of motorneurons which was effectively antagonized by atropine ($1X10^{-4}$ M). At high concentrations of acetylcholine (10^{-4} - 10^{-3} M) the depolarization was accompanied by repetitive driver potentials. Preliminary manual voltage clamp experiments on isolated motorneurons bathed in TTX saline containing cadmium ($4X10^{-4}$ M) indicated that the depolarization is produced by a net inward current. Similarities between this cholinergic effect and those previously reported for the pentapeptide proctolin (J. Neurobiol. 12, 629, 1981) suggest that isolated cardiac ganglion motorneurons may be a useful preparation for studying the cellular mechanisms underlying peptidergic/muscarinic responses which enhance or induce spontaneity. 46.14 DOPAMINE NEURONS IN THE BUCCAL GANGLIA OF HELISOMA TRIVOLVIS. D. L. Trimble and D. L. Barker. Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242.

Using the Falck-Hillarp and glyoxylic acid methods, we have located catecholamine-containing neurons on the ventral side of the buccal ganglia of Helisoma. Three populations of catecholamine-containing cells were identified based on cell size and position. Extensive fluorescence was also visible in the peripheral nerve trunks of the buccal ganglia. ^{3}H-Dopamine, but not ^{3}H-norepinephrine, was synthesized from ^{3}H-tyrosine in buccal ganglia. Dopamine synthesis studies of the nerve trunks of the buccal ganglia indicated they all contain dopamine except for the cerebral-buccal connectives, which are the only connections between the buccal ganglia and the rest of the animal's central ganglia. These observations suggest that a dopaminergic system is intrinsic to the buccal ganglia.

The buccal ganglia produce a patterned-motor output (PMO) consisting of alternating bursts of action potentials in retractor and protractor motoneurons. In an attempt to mimick some of the effects that dopamine neurons might have on the PMO, we investigated the effect of bath-applied dopamine on isolated buccal ganglia. Dopamine initiated and/or maintained the PMO of the buccal ganglia, effects similar to those of bath applied 5-HT (Granzow and Kater, Neurosci., 2, 1977). However, the effects of dopamine were more consistent and did not show any tendency to desensitize. The threshold for effects of bath-applied dopamine is about 10^{-7}M, and maximal activation occurs at 10^{-5}M.

In order to demonstrate that the response to dopamine is distinct from the response to 5-HT, haloperidol was used to specifically block the dopamine receptors. Application of 10^{-5}M haloperidol totally blocked the effects of bath-applied dopamine but did not affect the ability of 5-HT to stimulate motor output.

Treatment of the buccal ganglia with haloperidol alone, thereby blocking any spontaneous functioning of dopamine in the system, had several effects on the ongoing PMO of the ganglia. There was an overall reduction in spontaneous activity and there was also a qualitative change in the pattern of the motor output. This is consistent with the hypothesis that at least some of the dopamine neurons in the buccal ganglia normally contribute to the generation of patterned motor output.

47.1 LOCOMOTION IN THE ADULT CHRONIC SPINAL CAT. S. Rossignol, H. Barbeau and J. Provencher* (SPON: J. Montplaisir). Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.

The recovery of locomotor capacities was investigated in four male adult cats (3.9 to 4.4 kg) spinalised at Th 13 under Nembutal anesthesia. The bladder was expressed once a day. The evaluation of treadmill locomotion was started as early as 24 hours after the operation and repeated at least twice a week. Up to now one animal has been tested for 2 weeks, 2 for 3 weeks and 1 for 9 months. In each session, electromyograms (EMGs) were recorded with a pair of copper wires bilaterally inserted into Vastus Lateralis (VL), Semitendinosus (ST) and lumbar Multifidus (Mf). The movements of the animals were simultaneously recorded on videotape.

All cats were capable, within 24 to 48 hours, of small alternate stepping movements at the hip and knee joints although only with perineal stimulation. Thereafter, stepping movements of increasing amplitude were elicited without such stimulation when the dorsum of the feet rubbed against the treadmill belt. Treadmill speeds of up to 1.0 $m.s^{-1}$ could be followed with perineal stimulation but without foot placement or weight support. In one cat bilateral foot placement appeared at the 27^{th} day, at which stage the animal could then, without stimulation, follow speeds of up to 1.4 $m.s^{-1}$. At 8 weeks, this animal could stand on its hindlimbs for more than 3 minutes, with concomitant EMG activity in both VLs. The animal could also walk with complete weight support of the hindquarters for more than 3 minutes at speeds ranging from 0.1 to 0.6 $m.s^{-1}$. These episodes were accompanied by an increase in amplitude of VL activity and the appearance of two bursts per step cycle in each Mf which is typical of axial muscles. The major change occurring thereafter, up to 3 months, was a progressive lengthening of the step duration for the same treadmill speeds. For example, at a speed of 0.2 $m.s^{-1}$, the step cycle duration, measured from consecutive onsets at ST, was 662 ms ± S.D. 87.3 (N=34) at day #12 and 1091 ms ± S.D. 82.4 (N=10) at day #164. This lengthening of the step cycle duration was attributed mainly to an increase in duration of extensor activity but also in part to a longer delay between the end of ST and the onset of VL.

These preliminary results indicate that adult cats progressively recover locomotion capacities after spinalisation, with foot placement and adequate weight support of the hindquarters. (Supported by a Group grant of the Canadian MRC. H.B. received a postdoctoral fellowship from the FRSQ).

47.2 GAIN CHANGES IN CUTANEOUS REFLEXES DURING LOCOMOTION IN THE ADULT CHRONIC SPINAL CAT. C. Julien, H. Barbeau and S. Rossignol. Centre de recherche en sciences neurologiques, Dép. de physiologie, Université de Montréal, Montréal, Québec, Canada H3C 3J7.

In 8 experimental sessions, stimulation of the skin was applied to the dorsum of the foot during treadmill locomotion (0.3 $m.s^{-1}$) of one adult chronic spinal cat (Th 13). Electromyograms (EMGs) were recorded with a pair of percutaneously inserted copper wires, or with chronically implanted stainless steel wires, from ipsilateral (I/L) and contralateral (C/L) Vastus Lateralis (VL), Semitendinosus (ST), Tibialis Anterior (TA) and Gastrocnemius Lateralis (GL). Mechanical stimulation of the skin was given by contacting the foot with a rod equipped with an electrical switch. Electrical stimulation of the skin (single 5 ms pulse or trains of 10 pulses, 1 msec at 100 Hz, 1-3 mA) was delivered through wires chronically implanted subcutaneously at the dorsum of one foot. Mechanical stimulation during the swing phase induced a short latency (10 to 14 ms) and short duration augmentation of activity of I/L flexors (TA and ST) and the C/L extensor, VL. During stance the same stimulation increased the activity in I/L extensors (VL and GL) as well as in the C/L flexor ST.

Weak electrical stimulation which did not evoke any detectable EMG response during quiet standing was very effective in eliciting large excitatory responses during walking. In 7 experimental sessions, electrical stimuli were given at various phases of the step cycle (defined to start and end at the onset of successive ST bursts). For each muscle, the area of the integrated EMG was measured at a fixed latency (10-12 ms) and a fixed duration (10-20 ms) after the stimulus and an equivalent control period preceding the stimulus was subtracted. During the I/L swing phase, large excitatory responses in I/L ST and TA and C/L VL were found. In the early part of the I/L stance, mainly C/L ST responses were found. For the remainder of the stance phase I/L VL responses were predominant.

After injection of Clonidine, a noradrenergic agonist, the animal walked with longer steps and there was a large increase in the threshold for eliciting the responses, which were, however, essentially similar to those obtained during the control period of walking. Trains of stimuli during standing did not evoke long latency and long duration discharges. It is concluded that during locomotion in the adult chronic spinal cat, there are important tonic and phasic gain changes in the transmission of cutaneous reflexes. Although the threshold for evoking short latency responses may be increased by Clonidine, late discharges generally seen in acute spinal cats injected with noradrenergic drugs have not been seen in the adult chronic spinal cat. (Supported by a Group grant from the Canadian MRC. C.J. supported by an MRC fellowship and H.B. by an FRSQ fellowship).

47.3 MODULATION OF THE LOCOMOTOR PATTERN BY NORADRENERGIC, SEROTONERGIC AND DOPAMINERGIC AGONISTS IN THE ADULT CHRONIC SPINAL CAT. H. Barbeau and S. Rossignol. Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.

After complete spinalisation at Th13, adult chronic spinal cats are capable of walking on a treadmill with foot placement of the hindlimbs and weight support of the hindquarters. In the present study, we investigated the effects of monoamine agonists on the locomotion of a cat chronically spinalised for more than 60 days and in which all descending monoaminergic terminals are presumed to be degenerated. In 7 experimental sessions, the electromyographic (EMG) activity of Vastus Lateralis (VL) and Semitendinosus (ST) was recorded bilaterally through percutaneously implanted copper wires. The movements of the animal were also simultaneously video-recorded before and after the injection of drugs.

Clonidine (150 µg/kg), a noradrenergic agonist, markedly modified the locomotor pattern, especially at low speeds (0.05-0.6 $m.s^{-1}$). There was an increase in the step length, a better foot placement, an elevation of the hip indicating a better weight support and a pronounced abduction of the hindlimbs. For example, at a speed of 0.2 $m.s^{-1}$, the control cycle duration was 959 ± 32 ms (N= 13) while it increased to 1984 ± 69 ms (N= 10) after Clonidine. The ST and VL bursts were at least twice as long while the amplitude remained similar to those of the control period. With Quipazine (1 mg/kg), a serotonergic agonist, there was an increase of extensor tonus at rest. During walking, the hips were markedly raised and the hindlimbs tended to adduct. The cycle was also prolonged at 0.2 $m.s^{-1}$ from 910 ms ± 67 ms to 1412 ms ± 77 ms (N= 7). The ST bursts duration remained unchanged. The VL bursts only slightly increased in duration but at least doubled their amplitude. Apomorphine (0.5 mg/kg), a dopaminergic agonist, produced a marked tendency for a sustained flexion of the hindlimbs which could disrupt the locomotor pattern. The amplitude of ST bursts was increased and that of VL was decreased. The cycle length was virtually the same at 0.2 $m.s^{-1}$ as that of control.

Previous observations indicated that a well developed locomotion is possible in adult chronic spinal cats in the absence of bulbo-spinal monoaminergic endings. However, the present results show that the stimulation of aminergic receptors modifies locomotion significantly, suggesting that the activation of these receptors may normally serve to modulate the overall expression of the spinal locomotor pattern generator by changing, for instance, the duration or the amplitude of the EMG activity. (Supported by a Group grant from the Canadian MRC. H.B. received a postdoctoral fellowship from the FRSQ).

47.4 MICROSTIMULATION OF THE MEDULLARY RETICULAR FORMATION AT REST AND DURING WALKING IN THALAMIC AND INTACT CATS. T. Drew*, R. Dubuc and S. Rossignol. Centre de recherche en Sciences Neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.

Stimulation of the medullary reticular formation (MRF) during locomotion in high decerebrate and thalamic cats was reported to augment flexor burst activity and to diminish the extensor burst in the ipsilateral (I/L) hindlimb depending on the time of occurrence of the stimulation in the step cycle (Orlovsky, G.N., 1972, Brain Res. 40: 359). Experiments were designed to study the responses to MRF stimulation (11 pulses, 0.2 msecs, 330 Hz, $\leq$35 µA) in thalamic and chronically prepared cats (7 and 2 animals respectively) at rest and during walking on a moving belt.

Glass-coated tungsten microelectrodes (2-5 MΩ) were stereotaxically inserted into the MRF at coordinates in the range of AP -6 to -12, L 0.5 - 2.5. Stimuli were delivered throughout tracks where field potentials as well as single unit firing could be antidromically evoked by stimuli delivered to the spinal cord (L_1) by implanted microwires. Electromyograms (EMGs) from up to 14 muscles were recorded in the neck, all four limbs and the back. The results from both preparations were essentially similar and will be presented together.

At rest the predominant response in the forelimbs was an I/L elbow flexion and a contralateral (C/L) elbow extension although bilateral elbow extension was also seen at some stereotaxic coordinates of the MRF. It should also be noted that EMG was often evoked in the antagonist muscles to those causing movements. In the neck, bilaterally evoked responses were most common although head movement was always to the I/L side. The largest forelimb responses were normally from the location at which the maximal antidromic field potential was evoked and at this position activity was also normally evoked both in the I/L Quadriceps group and bilaterally in the back muscles. Latencies of the earliest effects in the forelimbs were of the range 9-15 msecs and for the neck 6-10 msecs.

During locomotion the patterns of muscular activity evoked by the MRF stimulation depended critically on the phase of the step cycle during which the stimulation was applied. Stimulation applied during the I/L forelimb stance period often evoked strong activity in both I/L forelimb and hindlimb extensors with concomitant flexion of the C/L flexor muscles. Stimuli given during the swing phase of the I/L forelimb caused hyperflexion of I/L fore- and hindlimbs with extensor responses on the C/L side. It is concluded that the MRF is capable of effecting changes in the pattern of activity in flexors and extensors of all four limbs. (Supported by a Group Grant of the Canadian MRC; T. Drew supported by a Canadian MRC Postdoctoral Fellowship).

47.5 TESTING THE ROLE OF RENSHAW CELL RHYTHMICITY DURING FICTIVE LOCOMOTION. J. Jamal*, B. Noga*, S.J. Shefchyk* and L.M. Jordan (SPON: R.M. Jell), Department of Physiology, University of Manitoba, Winnipeg, Canada.

Renshaw cells (RCs) are known to be excited by motor axon collaterals and to produce inhibition of several types of spinal cord neurons, including alpha and gamma motoneurons and Ia inhibitory interneurons, suggesting a role for RCs in the shaping of motor output. Although RCs have been demonstrated to be rhythmically active during locomotion (McCrea et al., J. Neurophys., 44:475, 1981), their contribution to this motor activity is unclear. It has been demonstrated that the excitation of RCs is due in part to the action of acetylcholine at nicotinic receptors (Curtis and Ryall, Exp. Brain Res., 2:66, 1966). Furthermore, the intravenous administration of the nicotinic antagonist mecamylamine (MEC) has been shown to effectively antagonize the excitation of RCs produced by antidromic stimulation of motoneuron axons (Ueki et al., Exp. Neurol., 3:141, 1961). The present research examines the effect of MEC on RC and motoneuron activity during fictive locomotion.

Locomotion was induced by stimulation of the mesencephalic locomotor region in mesencephalic preparations (as described by Jordan et al., Brain Res., 177:204, 1979). The animals were paralyzed using gallamine triethiodide, which has no effect on RC discharge (Brooks and Wilson, J. Physiol., 146:380, 1959).

RC spiking and recurrent IPSPs in motoneurons produced by electrical stimulation of a cut ventral root were greatly diminished following i.v. doses of 1-3 mg/kg MEC. While all of the RCs examined displayed rhythmic activity linked to the locomotor cycle prior to drug administration, RC rhythmic activity during fictive locomotion was completely abolished by the drug. At the same time, the pattern of fictive locomotion monitored from peripheral motoneuron axons was unchanged. The rhythmic bursting activity of motoneurons was altered only to the extent that the number of spikes per burst was increased. No significant changes in the rhythmic membrane potential oscillations of motoneurons recorded intracellularly were observed, but previously undetected EPSPs were revealed during the depolarized phase of the step cycle.

These results show that RC rhythmicity during locomotion is determined by excitatory drive from motor axon collaterals. RCs appear to limit motoneuron spiking and to control excitatory input to motoneurons, but they do not contribute significantly to the factors determining the membrane potential oscillations in motoneurons during fictive locomotion.

Supported by a grant from the Medical Research Council of Canada (MRC) to LMJ. SJS is a predoctoral student of the MRC.

47.6 *TEMPORAL COORDINATION OF TWO COINCIDENT MOTOR PROGRAMS: LOCOMOTION AND HINDLIMB PAW SHAKE.* *M.C. Carter*, C.A. Giuliani* and J.L. Smith (SPON: C.M. Harris) Dept. of Kinesiology and Brain Research Institute, UCLA, CA 90024.*

It has been hypothesized that locomotion (Grillner, et al. Exp. Brain Res. 34:1979) and the paw shake response (Smith, et al. Neurosc. Abst. 1980) are rhythmical behaviors organized primarily by central pattern generators in the spinal cord. However, these centrally programmed movements differ with respect to their patterns of motoneuron recruitment and cycle times. Thus, production of locomotion and paw shaking concurrently may provide insight as to how the CNS coordinates two distinct motor programs.

Two normal cats were chronically implanted with bipolar electrode wires in the right and left lateral triceps brachii (RLT, LLT) and soleus (RSO, LSO) as well as the right tibialis anterior (RTA) and lateral gastrocnemius (RLG). EMG records obtained during normal locomotion at 0.7 m/s were compared with records from walking and concurrent shaking at the same treadmill speed. Paw shaking was induced by applying tape to the plantar surface of the right hindpaw. Cycle time (CT, measured from successive LSO burst onsets), burst durations and onset latencies normalized to percent of CT, were obtained from the EMG records.

The cats did not shake the taped hindpaw during each step cycle, rather the response was intermittent and confined to the swing phase. Analyses were limited to cycles in which the cat locomoted at a relatively fixed point on the treadmill. During normal locomotion average CT was 638ms ± 40. The SO and LT muscle pairs were active on average 50% of the cycle, while the RTA was active for 20%. Activity of the RLG was more variable and ranged from 30-40% of the cycle. Onset latencies for all muscles were very consistent: RSO and RLG occurred at 50% into the cycle (50% ± 4 and 55% ± 3), while the RTA and RLT onsets were within the first 20% (20% ± 2 and 19% ± 6). Onset of the LLT occurred later in the cycle and averaged 73% ± 5. Comparisons between normal locomotion and cycles where the shake occurred revealed the step cycle was modified in one of two ways. In some instances CT increased 150ms on the average, yet normalized burst durations and onset latencies remained constant. Thus, the entire cycle lengthened proportionally. On other trials CT did not change, but LSO and RTA burst durations increased as RSO decreased, indicating the stance phase of the taped hindlimb shortened while the swing phase increased as the paw completed 2-3 shake cycles. Forelimb coordination appears unaffected by paw shaking.

Our data suggests that the two motor programs are temporally coordinated such that there is efficient time-sharing of the motoneuronal pools. Muscular phasing is modulated in such a way as to accommodate brief hindpaw shaking while maintaining continued locomotion. Supported by NIH Grant, NS 16333.

47.7 *AIRSTEPPING IN THE CHRONIC CORDOTOMIZED CAT.* *C.A. Giuliani*, C. Sabin* and J.L. Smith (SPON: E.E. Decima). Dept. Kinesiology and Brain Research Institute, UCLA, CA 90024.*

Airstepping has been identified as rhythmic alternating movements of the hindlimbs that commonly occurs in chronically cordotomized cats when they are suspended vertically with hindlimbs pendant (Sherrington, J. Physiol. 40:28, 1910). Evidence from Grillner's lab (Brain Res. 43:24, 1979) supports the concept of a spinal central pattern generator capable of producing locomotor-like rhythms which may resemble airstepping (ASTP). The present study attempted to identify the temporal characteristics of ASTP recorded in chronic cordotomized cats as compared with the characteristics observed in treadmill and fictive locomotion.

Data were obtained from 4 cats: 2 were cordotomized at 8 mos of age, 1 each at 2 wks and 3 mos of age. ASTP was evaluated at 1-3 mos after cordotomy. The soleus (SO), lateral gastrocnemius (LG), tibialis anterior (TA) and vastus lateralis (VL) of left hindlimbs were chronically implanted with bipolar electrode wires. EMG recordings were synchronized with videotaped movements of spontaneous ASTP as well as ASTP during gentle pinching at the base of the tail (TP). EMG parameters analyzed included: cycle time (CT, defined as the interval between SO burst onsets), latency of burst onset normalized to percent of CT for evaluation of intralimb coordination, and burst duration.

A total of 87 cycles of spontaneous ASTP were analyzed. The average CT, 533 ±107 ms was much shorter than CT recorded during weight-supported treadmill locomotion that ranged on average from 1.25s at 0.2m/s to 600ms at 1.2m/s in cordotomized cats (Smith, J.L., Exp. Neurol., 1982, in press). Intralimb coordination during ASTP was similar to that seen during treadmill locomotion of both cordotomized and intact cats. In 90% of the cycles studied, burst onset of the extensor synergists, SO/LG and SO/VL, occurred within the first 10% of the cycle, while the TA burst onset averaged 78% ±8 into the cycle. Of 121 cycles analyzed, TP altered ASTP in each cat. Variability of CT increased, while the average CT was unchanged in 3 cats and markedly increased in 1 cat. During TP, intralimb coordination of the extensors was unaffected, although an increased variability of TA onset latency was observed. The influence of TP on SO and TA burst duration varied in each animal and overall burst duration was more affected by TP than was CT.

Our data suggest that the intralimb coordination during ASTP is similar to that seen in treadmill locomotion of chronic cordotomized or intact cats, as well as to the rhythms seen during fictive locomotion. Thus, ASTP may provide a good behavioral model in which to examine activity produced by the central pattern generators in the lumbosacral cord.
Supported by NIH grant NS 16333.

47.8 RECOVERY, RECEPTIVITY, AND PERTURBATION OF PAW SHAKING IN CHRONIC SPINALIZED CATS. C. Sabin*, C.A. Giuliani* and J.L. Smith. Dept. of Kinesiology and Brain Research Institute, UCLA, CA., 90024.

Previous studies have indicated that paw shaking responses (PSR), rapid alternating flexion and extension of the hindlimb to a cutaneous stimulus, can be elicited in spinalized cats, with temporal characteristics resembling those of intact cats (Smith, Neurosci. Abst., 1980). The purpose of the present study is to describe the recovery of PSR following cordotomy as well as to determine the receptivity of the PSR to a wide range of stimuli. In addition, PSR was studied with afferent perturbations imposed by immobilization.

Five female cats were cordotomized at T_{12} as young adults (8 mos or older) and bipolar fine wire electrodes were surgically implanted into the lateral gastrocnemius (LG). PSR was elicited by applying masking tape to the hindpaw at the level of the central plantar pad. To determine the temporal characteristics of PSR, cycle times (CT), defined as the time between two consecutive LG burst onsets, were measured. Recovery of PSR was evaluated from EMG recordings taken 2x weekly for 40 days after cordotomy. Receptivity of PSR to a range of cutaneous stimuli was evaluated using water (25°C), ice, hot (50-70°C), and cold (0-15°C) stimuli in addition to tape. Hot and cold stimuli were applied using a metal plate, affixed to a force transducer, which could be heated or cooled. In some cats PSR was tested subsequent to immobilization of the ankle (110° flexion) and knee (115° flexion) in a plaster cast.

Paw shaking responses were observed as early as 48 hours after cordotomy. From days 2-10 after cordotomy, CT ranged from 105 to 109 ms. From days 11-20, the CT decreased to normal values of 80-94 ms and was stable throughout the remaining testing period (21-40 days). Receptivity to varying stimuli was evaluated according to consistency of PSR elicitation with each stimulus as well as by counting the number of cycles within a PSR. Tape and water were the most effective stimuli, eliciting PSR in 76% of the trials. Ice, hot, and cold stimuli tended to elicit flexion withdrawl in a majority of the trials. In addition, tape elicited PSR averaged 5 cycles longer than responses elicited by other cutaneous stimuli. Immobilization produced an increase in CT from an average of 96 ms to 134 ms and on 16% of the trials, the LG exhibited abnormal, lower amplitude EMG bursts that occurred between the normally fast-rising, short-duration PSR bursts.

Our results suggest that paw shaking is an automatic movement triggered by a variety of cutaneous cues that is coordinated by central pattern generators in the lumbosacral cord. Lack of normal phasic feedback does not disrupt the coordination, but lengthens the CT.

Supported by NIH grant NS 16333.

47.9 LOCOMOTION INDUCED BY INTRATHECAL DRUG ADMINISTRATION IN SPINAL CATS. D.J. Omeniuk* and L.M. Jordan (SPON: K.W. Cheng), Dept. of Physiology, Univ. of Manitoba, Winnipeg, Canada.

Available evidence suggests that locomotion is patterned at the level of the spinal cord, and that signals from the brainstem are normally required for the activation of the central pattern generator for locomotion. Norepinephrine (NE) and dopamine (DA) have been implicated as transmitters in pathways descending from the brainstem to the spinal cord, and L-DOPA and clonidine (an agonist of NE) can induce locomotion in spinal animals (see Grillner, Physiol. Rev. 55:247, 1976). In contrast, locomotion induced by brainstem stimulation is not abolished by depletion of spinal and brainstem NE (Steeves et al., Brain Res. 185:349, 1980). Commissiong has suggested DA as the mediator of L-DOPA effects in the spinal cord (Fed. Proc. 40:2771, 1981). This study was conducted in order to assess NE and DA as possible transmitters involved in the initiation of locomotion, and to determine the feasibility of intrathecal drug injection as a means for initiation of locomotion in spinal animals.

Cats (n=18) were spinalized in the lower thoracic region by cutting the cord with scissors (n=11) or by crushing the cord with forceps (n=7). A cannula was inserted into the subarachnoid space so that the tip reached the lumbosacral enlargement. The animals were rated on the basis of their ability for weight bearing (WB) and generation of rhythmic locomotor movement (RM). The cats were also filmed as they walked on a moving treadmill belt, and the kinematics of the gait were analysed. Drugs used were NE and glutamic acid (Glu), which were dissolved in Elliots Solution A, and DA dissolved in saline with ascorbic acid (10 mg ascorbate/50 ml saline). Control injections were done with the vehicle solutions.

NE elicited increased WB and/or RM in 13 of 14 cats. Concentrations of 10^{-4}M or greater were effective. The quality of RM and WB obtained were sufficient to propel the cats along a treadmill or overground with a support for lateral stability. Once locomotion was induced by NE, subsequent doses were more effective. DA was considerable less effective than NE in evoking locomotion, especially when administered after a time period long enough for degeneration of noradrenergic terminals (7 to 9 days post-transection). Glu could induce RM but not WB.

This study establishes the feasibility of locomotor induction in spinal animals by intrathecal drug administration, and it demonstrates that walking with weight support can be achieved in adult spinal animals. The fact that DA effects were comparatively slight suggests that DA plays little role in the production of spinal locomotion by L-DOPA. The results with Glu show that the NE effects are not likely to be due simply to global excitation.

Supported by the MRC and the Canadian Paraplegic Association.

47.10 MESENCEPHALIC LOCOMOTOR REGION (MLR) UNIT ACTIVITY DURING LOCOMOTION. E. Garcia-Rill, R. D. Skinner and J. A. Fitzgerald*. Dept. Anatomy, Univ. Arkansas for Med. Sciences, Little Rock, AR 72205.

The MLR is an area of the cat posterior mesencephalon which when stimulated induces locomotion as long as (a) a precollicular-postmamillary transection has been performed and (b) the animal's weight is supported by a hammock. Stimulation of the MLR is not necessary, however, if a precollicular-premamillary transection is performed, since there is spontaneous locomotion. The activity of single neurons in the area of the MLR was studied in the spontaneous locomotion preparation. Under short-acting barbiturate anesthesia the transection was performed and a recording well implanted over the MLR following suction ablation of the overlying cortex and extirpation of the tentorium. Glass micropipettes were advanced by a miniature microdrive supported by the well and the location of recorded neurons was marked by deposition of Fast Green dye. EMG's were recorded from flexors and extensors of each limb.

The spontaneous locomotion preparation is characterized by episodes of four-, two- and one-limb walking mixed with periods of no activity. This allowed assessment of the relationship between unit activity and EMG(s). A total of 55 units which were localized within the MLR were studied from 5-45 min. These cells were located in the cuneiform nucleus and in the nucleus tegmenti pedunculopontinus, which is embedded in the brachium conjunctivum. Close to 30% of these units fired rhythmically in relation to the alternating EMG patterns. Analysis of firing patterns determined that six units fired in advance of contralateral forelimb flexor EMG. A similar number of units fired in relation to the EMG from both forelimbs or both hindlimbs. Other units fired in relation to a complete two- or four-limb step cycle.

In addition, a total of eleven single cells were studied in the Interstitial nucleus of Cajal (INC). Four of these units were found to fire in relation to two-limb or four-limb EMG patterns. Projections of the INC are described elsewhere at this meeting.

Our results suggest that neurons in the MLR and, perhaps, the INC may ultimately influence the firing of locomotion oscillators at the level of the spinal cord.

Supported by USPHS grants NS 15359, NS 16143 and ISP 8011447.

47.11 EFFECTS OF COMPLETE UNILATERAL HINDLIMB DEAFFERENTATION ON LOCOMOTION IN CATS. C. S. Lewis*, L. C. Maxwell* and E.Eidelberg Research Program, Veterans Administration Hospital, and U. of Texas Center for the Health Sciences, San Antonio, TX. 78284

Cats (2-4k_g) were trained to walk on a moving treadmill at speeds of 0.4 to 0.6 meters/second. Then the left hindlimb was deafferented by intradural section of dorsal roots L_1 to S_1. The extent of the deafferentation was verified by serial histological sections, which also served to look for inadvertent damage to the spinal cord. The findings described below were obtained in cats where the deafferentation was complete and there was no histologically significant cord injury.

The pattern of locomotor activity of the deafferented hindlimb was studied by conventional kinematic methods from movie films taken prior to the surgery and serially after it for 6 weeks. Muscle samples were taken from extensor digitorum longus, soleus and vastus lateralis, quick frozen and subjected to routine histochemical analysis. Fiber type distribution and fiber cross-sectional areas were examined in the deafferented limb, the intact contralateral limb and in both limbs of sham-operated controls.

Severe and persistent deficits in stepping were found. Some recovery was observed within the first two weeks and stabilization had become clearly apparent by 4 weeks. The deficits included altered rhythmicity, loss of coordination, and reduced amplitude of the hip flexion. The knee and ankle joints were hyperextended and their movements paralleled those of the hip. This pattern differs significantly from that previously described by others. We conclude that sensory feedback is essential for normal locomotor function.

47.12 HOW IS THE MONOSYNAPTIC REFLEX MODULATED DURING THE STEP CYCLE? S. J. Shefchyk, R. B. Stein and L. M. Jordan, Depts. of Physiology, University of Manitoba, Winnipeg, Canada, and University of Alberta, Edmonton, Canada.

If brief stretches are applied to a muscle of a high decerebrate cat which is induced to walk by stimulation of the mesencephalic locomotor region, a pronounced modulation of the monosynaptic reflex response is observed during each step cycle (Aldridge et al. Soc. Neurosci. Abstr. 7:560, 1981). Electrical stimulation of nerves at a strength which excites only the largest afferent fibers produces a similar modulation of the H-reflex. This modulation could be produced either by cyclic variations in the monosynaptic EPSP evoked by homonymous motoneurons or by cyclic variations in the membrane potential (Em) which would vary the probability of the EPSP's producing nerve impulses.

To examine these issues, intracellular recordings from identified motoneurons were made during fictive locomotion in the mesencephalic preparation (as described by Jordan et al. Brain Res., 177:204, 1979). Data were obtained for the following motoneuron types: triceps surae, tibialis anterior, semitendinosus and posterior biceps. Conductance was measured using current injections of short hyperpolarizing pulses through the recording microelectrode (as described by Shefchyk et al. Soc. Neurosci. Abstr. 7:687, 1981). No significant changes in motoneuronal conductance were observed during the step cycle. Therefore, conductance changes could not account for any changes observed in the monosynaptic EPSPs. In some motoneurons (47% of cells sampled) the monosynaptic EPSP displayed small cyclic variations with the maximum amplitude occurring during the depolarized phase of Em oscillations during the step cycle ("in phase" modulation), as suggested by Schomburg and Behrends (Brain Res., 143:533, 1978). In other motoneurons the peak EPSP amplitude occurred during the Em hyperpolarization (12%) or displayed no modulation at all (41%). For the entire population examined, no significant trend was observed, although there was a tendency for "in phase" modulation to occur in those cells with the greatest variation of the Em during the step cycle. Thus, the previously observed modulation of the monosynaptic reflex during locomotion appears to occur mainly by Em variation, although some motoneurons also show EPSP modulation.

47.13 THEORY OF LATERAL LINE SYSTEM FUNCTION IN TWO DIMENSIONS
Richard S. Babb. Iona College, New Rochelle, New York, 10801.

A simple theory of lateral line system function is proposed, based on the known anatomy and physiology of this system in the shark. The lateral line receptors are found bilaterally within the dermis, running the length of the body. Individual lateral line receptors are very sensitive to low frequency vibrations in the surrounding water, and are able to provide a neural signal in the lateral line branches of the cranial nerves after transducing this mechanical disturbance. Phase differences in contralateral lateral line nerves would thus correspond to the phase difference in the wave detected by the contralateral lateral line detectors (Schuijf,1981). This phase information is fed via the lateral line nerves to granual cell clusters and hence the parallel fibers which run transversely across the lateral line lobe (Larsell,1967). If, as has already been suggested (Braitenberg,1967), the slowly conducting parallel fibers of the cerebellum act as timing devices, then the phase differences between the wave fronts at contralateral lateral line receptors can be measured in terms of the distance the neural signal can travel from the midline before meeting its counterpart traveling in the opposite direction along an adjacent parallel fiber towards the midline. Intersection of activity on one side rather than the other would represent a lag in the phase of the wave activating the lateral line receptors on that side. The parallel fiber region in which the two signals meet would provide a maximum of activation of the Purkinje cells in that region. Such activation could be used to modify the direction of swimming.

Such unbalanced activity in the lateral line lobe could account for the ability of the shark to home in on the source of vibration. Purkinje cells with dendrites intersecting the parallel fibers in a region of maximum excitation would be activated and would then inhibit motor neuron activity on the same side. Reduction in motor neuron activity on one side would produce a lessened contraction of the trunk swimming wave on that side, so as to produce a turn in the swimming. The turn would continue until the neural activity , and hence muscular activity, is balanced, in which case the shark would be heading directly towards the source.

Since two lateral lines run one above the other on each side of the head region, phase determinations are in principle possible in the yaw-axis allowing interception in three-dimensions. Further since the vestibular apparatus is thought to have evolved from the lateral line detectors, the vestibular cerebellum of all vertebrates including that of humans, may function in a similar way.

47.14 EFFECT OF CHRONIC SOMATOSENSORY DEAFFERENTATION AND DARKNESS ON SELF-DIRECTED BEHAVIORS AND THEIR RELATION TO SELF-INJURY IN MONKEYS.
G. Yakalis* and E. Taub. Inst. for Behavioral Research, 2429 Linden Lane, Silver Spring, MD 20910

The behavior of seven monkeys (Macaca fascicularis) with chronic, unilateral forelimb deafferentation (4-5 years postoperative) and four normal monkeys were recorded on videotape. The frequency of several categories of self-directed behaviors to different parts of the body was tabulated. 1. The incidence of self-grooming acts was no different for the deafferented limb than for the contralateral, intact limb or the corresponding limb in normal animals. Thus, the stimulus for the control of grooming may not be somatosensory in nature. 2. Scratching to the deafferented limb was greatly reduced, but was not abolished. The scratching that persisted was directed predominantly to the deafferented shoulder, which bordered intact portions of the body. Scratching to the intact, contralateral forelimb in deafferented animals was elevated. 3. More nibbling and licking was directed toward the deafferented arm than to the intact arm. This difference was completely accounted for by animals with lesions on their arms. 4. Mouth capture, defined as taking a part of the body between the teeth without breaking the skin, was observed much more frequently in deafferented than in normal limbs, usually directed toward the area of a lesion. This behavior was essentially passive in nature; it was never observed to have an aggressive character. 5. Biting, defined as an act in which the skin was penetrated, was not observed either to intact or deafferented limbs.

In order to test whether self-grooming is under the control of vision, five of the monkeys were kept continuously in total darkness. The monkeys exhibited a greatly reduced amount of self-directed behaviors, most markedly grooming (reduced to 4%), but also licking (14%), nibbling (27%) and scratching (58%). This result cannot be explained by a reduction in the general activity level in the dark; it suggests that in monkeys the performance of these self-directed behaviors, especially grooming, is under visual control.

Results suggest that maintenance and enlargement of lesions in chronically deafferented monkeys are due to an elevation in behaviors that are passive in character (licking, nibbling), and not to aggressive or other acts (scratching, biting) that might occur in response to dysesthesias. Moreover, darkness which should not affect dysesthesias, reduced all self-directed behaviors. The absence of dysesthesias is consistent with the human deafferentation literature. The question of whether dysesthesias are present in some animals, including monkeys, for an initial period following dorsal rhizotomy still requires resolution.

47.15 THE EFFECTS OF REEFFERENT AND REAFFERENT FEEDBACK ON MOVEMENTS OPPOSING ELASTIC FORCES.
D.E. Teoduru, T.A. Tran* and A.J. Berman. Dept. of Neurosurgery, VA Medical Center, Bronx, NY 10468.

Reefferent loops (collateral discharge) provide a "sense of effort" (McClosky, 1981) while reafferent loops (proprioceptive feedback) provide information on the status of muscles and joints (Evarts, 1981). This study sought to examine the effects of reefferent and reafferent inputs on limb movements exerted against an elastic force. In a trace-avoidance conditioning paradigm, at the sound of a click, intact, unilateral (uDR) and bilateral (bDR) dorsal rhizotomized (C_2 to T_3) monkeys were required to exert a criterion force (CF), flexing an unseen forelimb to stretch a spring a required distance (each 1/2 in. = 1 lb. of force). The first peak (PF), the first peak to reach criterion (PC) and the highest peak (PH) were recorded in lbs. of force on all trials.

Intact monkeys exhibited an ascending saw-tooth shaped response where PF<PC<PH; thus PC was generally within a wide envelope formed by PF and PH. uDR monkeys showed a narrower PF-PH envelope where PC was closer to CF than the PC of intact and uDR monkeys. Whenever a monkey avoided shock, on 80% of the trials on two consecutive days, CF was increased by 1/2 lb. increments. uDR and bDR monkeys were able to change their movements so as to overcome the spacial restraints imposed on the limb by the apparatus. An appropriate response seemed to be systematically hunted for and when found was performed with the DR limb in a stereotype manner, suggesting that new motor programs can be developed in open loop fashion.

These results suggest that reefferent feedback is adequate to guide open loop extensions of force. Intact monkeys perform rapid unopposed limb movements in open loop fashion (Fromm and Evarts, 1978) as ascending afferents are blocked by corticofugal motor collaterals (Felix and Weisendanger, 1971). However, when large forces oppose movements, reafferent inputs may overwhelm these inhibitory systems, interferring with open loop execution of the movement and making it discontinuous (Brooks, 1979). In uDR monkeys, reafferents from the intact side may have a smaller but similar effect on movements of the DR limb. Since PH of intact monkeys exceeded CF much more than the PH of DR monkeys, we conclude that reafferent inputs interfere with reefferent readouts of effort.

47.16 PHYSOSTIGMINE: ANTAGONISM OF ANTIMUSCARINIC INDUCED DISRUPTION OF EQUILIBRIUM PERFORMANCE IN MACAQUES,
C. T. Bennett, D. N. Farrer*, and N. L. Lof*. School of Aerospace Medicine, Brooks Air Force Base Texas 78235.

Nine macaques were trained to perform a compensatory tracking task that required them, while in a restraining chair, to maintain a relatively vertical position. Adjusted root mean square (ARMS) of the platform movement was the primary dependent variable. In the first of three studies, the monkeys were injected with saline or 0.05, 0.10, or 0.15 mg/kg (IM) of physostigmine. A significant disruption in equilibrium performance was observed to occur within 15 minutes. The animals behavior returned to within normal limits in 90 minutes. In the second study, animals were injected with 0.25 mg/kg (IM) of atropine, then, 90 minutes later with saline or 0.05, 0.10, or 0.15 mg/kg (IM) of physostigmine. The latter injection was timed to coincide with the maximum affect of atropine. Significant antagonism of the antimuscarinic affect on equilibrium was observed to occur within 15 minutes. In the third study, the same series of doses were used, but injections were administered at the same time. Not only did we observe an antagonism of the early affects of physostigmine, which occur prior to the behavioral actions of atropine, but, also, reversal of the antimuscarinic affects, which occur after the behavioral affects of physostigmine have subsided.

47.17 PROJECTIONS OF THE INTERSTITIAL NUCLEUS OF CAJAL (INC) TO THE AREA OF PROBST'S TRACT. 1. ANATOMY. S. Griffin*, R. Nelson*, R. D. Skinner and E. Garcia-Rill (SPON: T. Sims). Dept. Anatomy, Univ. Arkansas for Med. Sciences, Little Rock, AR 72205.

The Mesencephalic Locomotor Region (MLR) of the cat is known to send downstream projections in the area of Probst's tract (Anat. Rec. 199, 90A, 1981). Injections of fluorescent dye into the area of Probst's tract retrogradely label cells in the MLR. Elsewhere at this meeting we report that the activity of some MLR neurons is related to the EMG pattern produced by locomotion. In addition, a small number of INC cells showed similar characteristics. Since stimulation of the area of Probst's tract (Pontobulbar Locomotor Strip) is known to induce locomotion, it became important to determine if descending projections of the INC travel in the area of Probst's tract.

Under barbiturate anesthesia, fluorescent dyes (DAPI or Bisbenzimide) were injected (0.05 µl) into the area of Probst's tract, or the medial longitudinal fasciculus (MLF). Following appropriate survival times, the animals were anesthetized and perfused transcardially with buffered formalin. The brains were treated according to standard procedures for fluorescence microscopy. Following injections of dyes into the MLF, retrogradely labeled cells were observed bilaterally in the INC, although in greater numbers ipsilaterally. Following injections of dyes into the area of Probst's tract, many retrogradely labeled cells were seen in the contralateral INC, and only a few cells ipsilaterally. In cases in which dye injections spread into the medial vestibular nucleus, a greater number of ipsilateral INC cells were labeled without contralateral INC labeling.

In addition to contralateral INC labeling, injections in the area of Probst's tract induced retrograde labeling in the mesencephalic trigeminal root, cuneiform nucleus, nucleus tegmenti pedunculopontinus, and medial central gray. Very sparse labeling was observed in the substantia nigra, subthalamic and entopeduncular nuclei.

Our results suggest that, in addition to the known descending projections of the INC to the ipsilateral medial vestibular nucleus and ipsilateral MLF, a primarily contralateral projection descending in the area of Probst's tract is present. Coupled with evidence showing rhythmic activity in INC during locomotion and induced locomotion following stimulation of the area of Probst's tract, these data suggest INC may also be involved in the modulation of locomotion oscillators at the spinal cord level.

Supported by USPHS grants NS 15359, NS 16143 and ISP 8011447.

47.18 PROJECTIONS OF THE INTERSTITIAL NUCLEUS OF CAJAL (INC) TO THE AREA OF PROBST'S TRACT. 2. ELECTROPHYSIOLOGY. R. D. Skinner, J. A. Fitzgerald* and E. Garcia-Rill. Dept. Anatomy, Univ. Arkansas for Med. Sciences, Little Rock, AR 72205.

Injections of fluorescent dyes into the area of the medial longitudinal fasciculus (MLF) in the cat produce retrograde labeling primarily in the ipsilateral INC, whereas injections into the area of Probst's tract produce labeling in the contralateral INC (see accompanying presentation). Electrophysiological experiments were undertaken to confirm these anatomical observations. Extracellular recordings using glass micropipettes were made in the INC. Responses were studied following stimulation through comb electrodes spanning the medulla from the MLF medially to the area of Probst's tract dorsolaterally. Surgical procedures were carried out under barbiturate anesthesia and recordings under locally anesthetized, paralyzed conditions. Fast Green dye was deposited at various recording sites. A total of 131 neurons were identified within the boundaries of the INC. Forty-seven could be antidromically activated from the medulla (or from comb electrodes at C1). Close to 50% of these INC neurons responded antidromically to MLF stimulation. About 20% responded antidromically to contralateral Probst's tract stimulation, and an additional 20% responded antidromically to both MLF and contralateral Probst's stimulation. Close to 10% were activated antidromically from the MLF and ipsilateral Probst's tract stimulation. The latency for antidromic responses following MLF stimulation at medullary levels was 1.0 ± 0.5 S.E. mean msec, and 1.4 ± 0.7 S.E. mean msec following MLF stimulation at C1 levels. The mean latency for antidromic responses following Probst's tract stimulation at medullary levels was 1.2 ± 0.5 S.E. mean msec.

Orthodromic responses were observed in 13 of the antidromically responsive neurons and in 21 otherwise non-responsive units at latencies ranging from 2-30 msec.

Our results confirm the presence of a significant descending projection from the INC to the contralateral Probst's tract region, in addition to the known ipsilateral descending projections to MLF and medial vestibular nucleus.

47.19 AFFERENT CONNECTIONS OF THE VENTRAL TEGMENTAL NUCLEUS OF GUDDEN IN THE CAT AS REVEALED BY HORSERADISH PEROXIDASE GEL IMPLANTS AND TETRAMETHYLBENZIDINE NEUROHISTOCHEMISTRY, S.M. Carlton*, Y. Katayama*, G.R. Leichnetz, D.P. Becker and R.L. Hayes. Depts. of Neurosurgery and Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298.

Following mechanical brain injury, changes in the level of neural activity occur in regions responsible for some of the pathophysiological sequelae of concussion. Studies of regional rates of glucose metabolism employing (^{14}C) deoxyglucose indicate that the ventral tegmental nucleus (VTN) demonstrates a notable increased level of glucose metabolism following low grade mechanical brain injury in the cat. In addition, microinjection of cholinergic agonists into VTN in the cat results in postural atonia, a behavioral state typically seen following concussive injury (Hayes et al, Soc. for Neurosci. Abstr. 8 In press). In the light of these observations, a study of the afferents of VTN was undertaken to identify those sites which could mediate the increased rate of glucose utilization seen in this nucleus after concussive injury.

Four adult cats were stereotaxically implanted with a solid pellet of horseradish peroxidase (HRP) polyacrylamide gel in the VTN and adjacent areas through a previously implanted stainless steel cannula to avoid contamination along the implantation tract. Following a 48 hr. survival period, the animals were perfused with mixed aldehydes (1% paraformaldehyde, 1.25% glutaraldehyde) in 0.1M phosphate buffer, frozen sectioned at 40µ and reacted according to the tetramethylbenzidine protocol of Mesulam ('78).

An abundance of retrogradely labelled cells were observed in the ipsilateral medial and lateral mammillary nuclei (MN), contralateral dorsal tegmental nucleus, and bilaterally in the lateral habenular (Hb) and interpeduncular nuclei. A moderate amount of labelling was seen in the hypothalamus, ipsilateral prerubral fields, ventral periaqueductal gray, interstitial nucleus of Cajal (INC), nucleus of the posterior commissure, trochlear and vestibular nuclei, contralateral deep superior colliculus (dSC), and bilateral medial Hb. A small number of heavily labelled cells were observed in the ipsilateral rostral mesencephalic reticular formation. An occasional labelled cell was present in the ipsilateral oculomotor nucleus. Contamination of the medial longitudinal fasciculus, dorsomedial to the VTN, could account for some of the retrograde labelling in the INC, oculomotor, trochlear and vestibular nuclei, while interruption of tectospinal fibers might explain the scattered labelling in the dSC. The large numbers of heavy labelled neurons in the medial and lateral MN, suggests that they represent the primary source of afferents to VTN.

Supported by NIH Grant NS-12587.

47.20 ACTIVATION OF PONTINE CHOLINERGIC SITES IN THE CAT IMPLICATED IN COMA PRODUCED BY MECHANICAL BRAIN INJURY: BEHAVIORAL AND PHYSIOLOGICAL STUDIES. R. L. Hayes, Y. Katayama*, S. M. Carlton* and D. P. Becker. Div. of Neurosurgery, Virginia Commonwealth University, Richmond, VA 23298.

Low levels of mechanical brain injury in the cat produce increased glucose metabolism in the vicinity of the cholinergic pontine ventral tegmental nuclei (Hayes R. L. et al., Neurosci., 11:376, 1981). Other data have suggested that cholinergic activation of this region may produce profound behavioral suppression resembling coma (e.g. Mitler, M. M. and Dement, W. C., Brain Res., 68:335, 1974). Thus we investigated the behavioral, anatomical and pharmacological features of carbachol microinjection in the cat pons. Two guide tubes (26 g) were chronically implanted bilaterally through the cerebellum of 35 cats. After recovery from surgery, awake, unanesthetized cats were loosely restrained in canvas bags. Carbachol was microinjected (0.4-0.6 ug/0.2-0.3 ul, bilaterally) at 4 day intervals through cannulae (33 g) into various pontine loci. Systematic behavioral assessments of motor functions (M) included examinations of EMG, locomotion, flexion and stretch reflexes, resting muscle tone, righting and placing reflexes and pupillary reflexes. Changes in arousal (A) were inferred by studying eye lid, nictitating membrane and pupillary responses to intense stimuli, eye tracking movements, eye blink to visual stimuli and EEG changes. 150 sites were studied. Carbachol microinjection produced maximal M suppression in dorsomedial pontine sites extending from the vicinity of the ventral tegmental (VTN) area caudally to an area slightly ventromedial to locus coeruleus (VM-LC). Within VM-LC, carbachol microinjection produced far greater suppression of M than A. Other sites were associated with equivalent M and A suppression. Microinjection in the gigantocellular tegmental field produced relatively little suppression of M and A. No behavioral effects resulted from microinjection into locus coeruleus. Atropine, either microinjected (0.4-1.2 ug, bilaterally) or systematically administered (0.5-1.0 mg/kg,i.v.), significantly antagonized behavioral effects produced by prior carbachol microinjection. Microinjection of mecamylamine (0.4-1.2 ug, bilaterally), did not antagonized carbachol produced behavioral suppression. These data suggest that activation of muscarinic cholinergic pontine sites in the region of VTN may mediate some components of behavioral suppression seen after mechanical brain injury in the cat. Supported by NIH Grant #NS12587.

48.1 CORTICOSTRIATE PROJECTIONS FROM THE POSTERIOR PARIETAL CORTEX IN RHESUS MONKEYS. E.H. Yeterian and B.A. Leonard*. Department of Psychology, Colby College, Waterville, ME 04901.

Recent autoradiographic investigations have demonstrated that certain regions of the frontal and temporal lobes have more extensive projections to the striatum than had been observed with ablation-degeneration methods. The present study considered the possibility that autoradiography might reveal posterior parietal areas to have more widespread corticostriate projections than previously described, that is, projections to rostral and caudal as well as middle regions of the striatum. In 14 monkeys, tritiated amino acids were injected into various architectonic subdivisions of the posterior parietal cortex as delineated by Pandya and Seltzer (1982). The rostral inferior parietal lobule (IPL), area PE, projects to the lateral head of the caudate nucleus, and to central and ventral portions of the body. In the rostral putamen, projections are strongest ventrolaterally, with some dorsolateral and central extent. More caudally in the putamen, a band of projections extends diagonally from a ventrolateral to a dorsomedial location. The projections of the mid-ventral IPL, areas PG and PGop, were similar to those of area PF, except that none were evident in the lateral putamen. The caudal portion of the dorsal IPL, areas PG and Opt, projects heavily to dorsolateral and ventral regions of the head and body of the caudate nucleus, and to the medial portion of the tail. Projections to the putamen are sparse. The caudalmost IPL, area Opt, projects only to the caudate nucleus, dorsally in the head, dorsally to ventrally in the body, and medially in the caudal bend of the nucleus.

The superior parietal lobule (SPL) has a different distribution of corticostriate projections. The rostral SPL, area PE, projects laterally in the rostral putamen, and dorsally at more caudal levels. Projections to the caudate nucleus are sparse, in lateral regions of the body. The SPL along and within the middle third of the intraparietal sulcus, areas PE and PEa, has similar projections to the putamen, and also a projection to the head of the caudate nucleus laterally. The caudal SPL, area PEc, projects to dorsolateral regions of the head of the caudate nucleus, and along the dorsal and lateral borders of the putamen. Finally, the medial parietal cortex, areas PGm and PEm, has projections to the dorsolateral head and body of the caudate nucleus, and to the adjoining dorsomedial putamen.

These results reveal that posterior parietal projections are distributed broadly throughout the rostral-caudal extent of the striatum. Rostral areas of both the IPL and the SPL project more extensively to the putamen, while caudal areas project more extensively to the caudate nucleus. Inferior parietal projections are, overall, more widespread than those from superior or medial areas.

(Supported by Colby College Social Science Grant A22097.)

48.2 COLLATERAL AXON SYSTEMS WHICH PROJECT UPON THE CAUDATE NUCLEUS, AS STUDIED IN THE CAT WITH THE FLUORESCENT DOUBLE LABELING METHOD. G. James Royce, Dept. of Anatomy, University of Wisconsin, Madison, WI 53706

The retrograde fluorescence technique was used to label single neurons within both subcortical and cortical regions which, in addition to projecting to the caudate nucleus, also project to other structures. After experimentation with many other pairs of fluorescent tracers, Evans Blue (EB) and Fast Blue (FB) were chosen as the best combination for studying the systems involved. The tissue sections were examined with a Nikon Fluophot microscope which is electrically coupled to an X-Y plotter.

Following injections of EB into the caudate nucleus and FB into the rostral cortex (gyrus proreus) doubly labeled neurons are present within several thalamic nuclei which include the ventral anterior, ventral lateral and mediodorsal nuclei. Doubly labeled cells are also present in most members of the intralaminar group, including the central medial, paracentral, central lateral and parafascicular nuclei. Although the centromedian nucleus contains large numbers of singly labeled EB cells which project to the caudate nucleus, and a few FB cells which project to the cortex, doubly labeled neurons are absent from this posterior intralaminar nucleus, in this series of experiments.

In a separate series of experiments, EB was injected into the caudate nucleus and FB was injected into the centromedian and parafascicular nuclear complex. Following such injections, doubly labeled neurons are present within the cerebral cortex, where they are confined to layers V and VI. These doubly labeled cells are medium-sized pyramidal neurons, which are found within areas 4 and 6, in the anterior limbic area, in the cingulate and anterior sylvian gyri, and within the buried cortex of the presylvian sulcus.

This study was supported by NIH grant NS13453.

48.3 ISOLATION OF THE MONOSYNAPTIC THALAMO-STRIATAL EPSP IN SPINY PROJECTION NEURONS OF RAT CAUDATE-PUTAMEN. K. D. Phelan*, C. J. Wilson, H. T. Chang and S. T. Kitai. (SPON: Sharleen Sakai). Department of Anatomy, Michigan State University, East Lansing, MI 48824.

Stimulation of thalamic intralaminar nuclei or structures along the intrathalamic trajectory of thalamo-striatal axons evoked complex EPSPs and subsequent hyperpolarization in rat neostriatal spiny neurons identified by intracellular injection of horseradish peroxidase. The initial EPSP portion of the response, which could be as much as 75 ms in duration, was seen to consist of several components. In intact urethane and ketamine anaesthetized rats, latency variations suggestive of a polysynaptic origin could often be demonstrated even for early (2-10 ms) EPSP components. Individual components of the excitatory response could not be clearly distinguished in most neurons however, and the earliest excitatory component usually appeared to be monosynaptic.

After large acute aspiration lesions of ipsilateral cerebral cortex, early polysynaptic EPSP components of thalamic-evoked EPSPs were absent or greatly attenuated. This suggested that most or all of the short latency polysynaptic EPSP components arose via a thalamo-cortico-striatal route. A short latency (1.6-4.0 msec) monosynaptic EPSP and a second excitatory component with a more variable latency (8-28 ms) remained intact after acute decortication. These were not dependent upon intact cortico-thalamic or cortico-striatal axons, since they were both still present in experiments performed as long as 4 days following ipsilateral hemidecortication. The longer latency excitatory response was shown to be polysynaptic by its latency variation with changes in stimulus intensity and frequency. This component of the response was abolished after acute thalamic hemitransections separating thalamo-striatal neurons from their axons. In these experiments, stimulation of thalamo-striatal axons rostral to the transection continued to evoke monosynaptic EPSPs in striatal spiny neurons. These EPSPs ranged from 1.8-3.0 ms in latency, had peak amplitudes at latencies of from 7-12 ms, were 20-37 ms in duration and attained peak amplitudes up to 11 mV. This EPSP is interpreted as representing the sole monosynaptic effect of thalamo-striatal afferents to spiny projection neurons. [Supported by NIH Grants NS 17294 (to C.J.W.) and NS 14866 (to S.T.K.)].

48.4 A GOLGI-ELECTRON MICROSCOPIC STUDY OF TWO TYPES OF LARGE NEURONS IN THE MONKEY NEOSTRIATUM. J. Carey* and M. DiFiglia. Dept. of Neurology, Mass. General Hospital, Boston, MA 02114

Golgi studies in the monkey neostriatum (DiFiglia et al, Brain Res., 114, 1976) have shown that at least two types of large neurons are present. Aspiny type 11 neurons have been identified by their large (30-40 μm) round or ovoid somata and numerous smooth surfaced varicose dendrites which curve around the cell body and extend up to 250 μm away. The spiny type 11 neuron has an elongated soma (30-40 μm in length) and few thick sparsely branching spiny dendrites which extend long distances (up to 600 μm).

In the present study neurons belonging to the aspiny type 11 (N=4) and spiny type 11 (N=1) categories were selected from Golgi impregnated monkey (M. fascicularis; N=2) caudate tissue which had been gold-toned according to the protocol of Fairen et al (J. Neurocytol., 5, 1977) and embedded in Epon for ultrastructural study. Results showed that aspiny type 11 neurons had a round, eccentrically positioned nucleus, which at most levels exhibited numerous shallow indentations along its inner face. The cytoplasm at all levels was rich in organelles and contained many single strands and some large stacks of rough endoplasmic reticulum (RER). Primary dendrites had abundant microtubules arranged in parallel arrays and the varicosities present in distal branches contained numerous mitochondria. Synaptic contacts were infrequent on the cell body and proximal dendrites and more numerous on distal branches where they appeared mostly on varicosities. Up to four boutons could be seen contacting the same varicosity. The most numerous were about 1 μm in size, contained pleomorphic vesicles and formed symmetric synapses. Boutons with round or pleomorphic vesicles formed asymmetric synapses and also contacted nearby dendritic spines. The spiny type 11 neuron had an elongated, centrally located nucleus. At some levels the nucleus showed no indentations and in other locations exhibited a few shallow and deep enfoldings. The cytoplasm was rich in organelles and contained small stacks of RER and a well developed Golgi apparatus which rimmed various portions of the nucleus. Synapses were observed relatively frequently on the cell body and dendritic shafts and were formed by axon terminals of different types which made either symmetric or asymmetric contacts. Dendritic spines always appeared postsynaptic and were contacted by boutons with round or pleomorphic vesicles which made asymmetric synapses. The axon initial segment also received many synaptic inputs. The present electron microscopic results support Golgi studies that distinguish two classes of large neostriatal neurons in the monkey and demonstrate differences in the pattern of distribution of synaptic inputs to these cells. (Supported by NIH grant NS 16367).

48.5 NEURONAL ACTIVITY IN THE VENTRAL STRIATUM OF THE BEHAVING MONKEY. E.T.Rolls, J.Ashton*, G.Williams*, S.J.Thorpe*, G.J.Mogenson, F.Colpaert*, and A.G.Phillips. University of Oxford, Department of Experimental Psychology, Oxford, England.

The ventral striatum of the primate receiyes projections from structures such as the amygdala, hippocampus and inferior temporal visual cortex (ITC). To analyse the functions of the ventral striatum, the activity of more than 400 single neurons was recorded in a region which included the nucleus accumbens and olfactory tubercle in 4 macaque monkeys in test situations in which lesions of the amygdala, hippocampus and ITC produce deficits. The following types of neuronal response have so far been identified. First, there are neurons which respond to novel visual stimuli. Different neurons in this category show pattern-specific habituation over 1-10 trials, and show retention of this habituation over 1-14 intervening trials. A small number of neurons respond to familiar rather than to novel visual stimuli. Second, other neurons respond to visual stimuli of emotional significance. Many of these neurons respond to faces and some other aversive stimuli, some respond to certain rewarding stimuli, for example to some foods, some respond to both rewarding and aversive visual stimuli, and other neurons respond with opposite changes of firing rate to aversive and rewarding visual stimuli. These neurons do not respond simply in relation to arousal, produced by inputs from different modalities. Third, other neurons respond differentially in a visual discrimination task, either to the stimulus associated with punishment or to that associated with reward. Fourth, other neurons respond in relation to somatosensory stimuli or movement. Fifth, other neurons respond, as in the head of the caudate nucleus (Rolls et al, 1979), to cues such as a 0.5 sec tone which the monkey uses to prepare for the performance of the visual discrimination task. Sixth, other neurons responded in relation to arousal, however this was produced. A number of neurons responded in more than one category, responding maximally for example to relatively novel aversive stimuli. These findings are consistent with the hypothesis that the ventral striatum is involved in certain behavioral responses to novel and emotion-provoking visual stimuli, which influence it through its inputs from limbic structures.

48.6 DENDRO-DENDRITIC SYNAPSES IN SUBSTANTIA NIGRA: QUANTITATIVE DESCRIPTIONS BASED ON SERIAL ELECTRON MICROGRAPHS. J.C. Linder*, S.J. Young* and P.M. Groves (SPON: D.S. Segal). Dept. of Psychiatry, Univ. Calif. San Diego, La Jolla, CA 92093.

Recent evidence has established that dopaminergic neurons of the substantia nigra release dopamine from their dendrites, presumably regulating dopaminergic neuronal activity and the release of neurotransmitters from afferent and efferent pathways. An important unresolved question, however, has been the mode of release of dopamine from these dendrites. This study has analyzed dendro-dendritic synapses in serial sections of substantia nigra from rats whose catecholaminergic synapses had been labeled with intraventricular 5-hydroxydopamine.

Distinct dendro-dendritic synapses, all labeled by 5-hydroxydopamine, were found only in pars compacta, but were rare even in that region of substantia nigra. Quantitative descriptions were based on 29 dendro-dendritic synapses made by 15 serially-sectioned (14-52 sections/series) presynaptic dendrites. These synapses were all very small, having a mean junctional length of 322±23nm and appearing in only 2-23 adjacent 80nm sections. The synaptic clefts averaged 15±0.8nm in width and were bordered by delicate symmetrical membrane specializations. A small number (mean=32±5) of labeled pleomorphic synaptic vesicles (30.7±0.7nm in diameter) were clustered against the junctional membrane. No reciprocal or serial synapses were found.

The morphology of several dendro-dendritic synapses has been visualized by computer-assisted three-dimensional reconstruction and compared to reconstructions of axo-dendritic synapses in the substantia nigra. Presynaptic dendrites had diameters of 0.23-1.9µm and did not change calibre at the site of the synapse, in contrast to axons which had terminal enlargements. Presynaptic dendrites did not receive other synapses near the dendro-dendritic junctions. They frequently made several dendro-dendritic synapses onto different postsynaptic dendrites within a short distance, but then remained closely apposed to the adjacent dendrite for several micrometers with no further synaptic junctions. The postsynaptic elements of these dendro-dendritic synapses closely resembled the presynaptic dendrites. They were of similar diameter and also received very few axo-dendritic synapses. In 4 instances, it was possible to show that the postsynaptic dendrites were also labeled by 5-hydroxydopamine, indicating that some dendro-dendritic synapses exist between dopaminergic neurons. The results of this ultrastructural study suggest that these dendro-dendritic synapses contribute to the dendritic release of dopamine in the substantia nigra.

48.7 EFFERENT CONNECTIONS OF THE VENTRAL PALLIDUM IN THE RAT. S.N. Haber, H.J. Groenewegen* and W.J.H. Nauta, Dept. of Psychology and Brain Science, Mass. Inst. of Technology, Cambridge, MA 02139 and Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Recent findings suggest a subdivision of the striatum into a. a ventromedial region (including the nucleus accumbens and olfactory tubercle) receiving partially overlapping projections from hippocampus, amygdala, ventral tegmental area, mesencephalic dorsal raphe nucleus, and prefrontal cortex (Kelley et al., Neuroscience 7, 615-630), and b. a dorsolateral region that receives a massive projection from the somatosensory cortex but is either avoided or only sparsely innervated by the afferents from the limbic-associated structures enumerated above. The proposed subdivision thus contrasts a limbic-innervated with a somatic cortex-innervated district of the striatum. Hitherto unpublished observations in this laboratory indicate that the striatopallidal projection from the limbic-afferented region of the striatum involves almost exclusively the pallidal compartment called the ventral pallidum (vp), while that from the non-limbic region exclusively involves the main body of the pallidum or dorsal pallidum (dp). We here report an autoradiographic study of the projections from the subcommissural portion of the vp as demonstrated by anterograde transport of tritiated amino acids, with control experiments involving surrounding structures such as the bed nucleus of the stria terminalis, lateral preoptic area, nucleus of the diagonal band and adjoining striatum. Preliminary findings indicate that the subcommissural vp projects not only to the most medial part of the subthalamic nucleus and to the substantia nigra, but also to the amygdaloid complex (mainly nucleus basalis lateralis), the mediodorsal nucleus of the thalamus, and the lateral habenular nucleus. Less unambiguous evidence suggests possible further vp projections to the peribrachial region, lateral hypothalamus, reticular and ventral anterior nuclei of the thalamus, nucleus accumbens and prefrontal cortex. Considered together, these findings indicate a conduction line leading from the limbic-afferented striatal subdivision via the ventral pallidum both into somatic motor circuitry (subthalamic nucleus), as well as back into the circuitry of the limbic system.

48.8 FLUORESCENT RETROGRADE STUDY OF THE PALLIDOINTRALAMINAR AND PALLIDONIGRAL PATHWAYS IN PRIMATE. L. De Bellefeuille* and A. Parent. Lab. of Neurobiology, Fac. Med., Laval Univ., Québec, Canada, G1K 7P4.

In regard to its thalamic, habenular and midbrain efferents, the primate internal pallidal segment (GPi) was shown to be organized according to a complex pattern consisting of 3 concentric zones: (1) a large central 'motor' zone where most neurons send axonal branches to both thalamus and midbrain, (2) a small peripheral 'limbic' zone which encroaches largely upon the lateral hypothalamus and whose neurons project only to habenula, and (3) a peripallidal 'reticular' zone composed of large acetylcholinesterase-containing cells related to nucleus basalis and projecting diffusely to neocortex and to a lesser extent to brain stem (Parent and De Bellefeuille, Brain Res. 1982).

In an attempt to further our knowledge of the organization of GPi, Evans blue (EB) was injected into the VA/VL thalamic nuclei and DAPI-primuline mixture (DP) in centre-médian/parafascicular intralaminar complex (CM/Pf) in 4 squirrel monkeys (Saimiri sciureus). In a second series of experiments 7 squirrel monkeys received EB injections in VA/VL and DP injections in the substantia nigra (SN).

In the first series of experiments most of the CM/Pf-projecting cells were found to be clustered in the dorsolateral and central portion of ipsilateral GPi, whereas the VA/VL-projecting cells were much more abundant and more diffusely distributed in the same structure. About 65% of all the fluorescent pallidal cells were double-labelled, 25% were labelled only with EB (VA/VL-projecting cells), and 10% only with DP (CM/Pf-projecting cells). A few scattered CM/Pf-projecting cells were also found in contralateral GPi. In addition, a significant number of retrogradely-labelled cells was found in the ipsilateral superior colliculus (stratum griseum medium), in the nucleus tegmenti pedunculopontinus pars compacta and diffusa, bilaterally, and in ipislateral nucleus reticularis thalami and zona incerta, after CM/Pf injections. In the second series of experiments, VA/VL injections resulted in a profuse retrograde labelling of GPi cells, as in the monkeys of the first experimental group. In contrast, the GPi appears devoid of DP-labelled cells even after rather massive SN injections. However, a significant number of SN-projecting cells was found in the dorsolateral portion of the external pallidal segment (GPe).

In conclusion, our findings suggest that the pallidointralaminar and pallidothalamic pathways arise mostly from the same neurons in the lateral part of GPi, whereas the pallidonigral projection seems to originate exclusively from the GPe.

48.9 PICROTOXIN IN THE STRIATUM INCREASES FIRING RATE IN THE VENTROMEDIAL NUCLEUS OF THE THALAMUS (VMT).
P. Patino* and M. Garcia-Munoz. (SPON: J. Garcia-Ramos) Dept. of Neuroscience, Cellular Physiology Research Center, National University of Mexico, 04510 Mexico,D.F.

Recent studies propose that activation of a GABAergic system which projects from substantia nigra may be involved as an output system for nigro-striatal responses. Studies on turning behaviour induced by substantia nigra pars compacta lesion, indicate that VMT is among the structures involved in this behavioural expression after dopamine receptor activation.

We have investigated the extracellular activity of cells in VMT of control and 6-OHDA lesioned rats. The mean firing rate of control cells is 0.9+0.01 spikes/sec. After amphetamine 0.1 mg/kg i.v. it increases to 8.1+0.04 spikes/sec. However this effect is not observed after intrastriatal injection of amphetamine (20 ng/0.5 µl) or apomorphine (20-200 ng/1 µl). Nevertheless picrotoxin (200 ng/1 µl) or glutamate (200 ng/1 µl) locally injected into the striatum does increase VMT firing rate.

This study provides further evidence for a possible relationship between the striatum, and VMT, which could be mediated through the substantia nigra or the globus pallidus.

48.10 BEHAVIOURAL CHANGES INDUCED BY ALTERING GABA TRANSMISSION IN THE THALAMUS.
M. Garcia-Munoz, A. Zainos* and L. Chavez*. Dept. of Neuroscience, Cellular Physiology Research Center, National University of Mexico, 04510 Mexico, D.F.

It has been suggested that the striato-nigral pathway and the substantia nigra reticulata efferents are important for the influence of striatal dopamine receptors on behaviour. GABA seems to be the major neurotransmitter of this output system.

We have investigated the effect of manipulating GABA transmission in the ventromedial (VM) and parafascicular (PF) nucleus of the thalamus which receive a gabaergic input from the substantia nigra reticulata. Muscimol (250 ng/0.5 µl) locally injected in VM or PF induces catalepsy. Picrotoxin (250 ng/0.5 µl) in VM or PF impairs the animal's orienting response towards an electrically stimulated site in the skin (1-5mA / 60 sec). Picrotoxin in VM alone induces $\bar{X}$=74±30 contralateral turns/30 min and stereotyped upward sniffing. If picrotoxin is injected in PF, the turning is ipsilateral and faster $\bar{X}$=74±30 turns/30 min. The blockade of GABA receptors in the parafascicular nucleus also produces a new motor expression consisting of an ipsilateral barrel rolling $\bar{X}$=318±40 turns/30 min.

This study provides evidence for two possible components of the motor output, one involved in the locomotion in circles and the other in the maintenance of balance and posture.

48.11 SOURCES OF INFORMATION CONVERGING WITH BASAL GANGLIA OR CEREBELLAR INPUT TO THE THALAMUS.
M.E. Anderson and J.L. DeVito. Depts of Rehab. Med., Physiol. and Biophys., and Biol. Struct. and Regional Primate Res. Cent., Univ. of Wash., Seattle, WA 98195.

There is considerable evidence to suggest that output from the basal ganglia (BG) and cerebellum (CB) remains separated at the thalamus. To identify potential sources of information converging with BG or CB output at the thalamus, we have made small injections of horseradish peroxidase into different areas of the ventroanterior and ventrolateral thalamus in cats and quantitatively assessed the relative retrograde labeling of neurons in the basal ganglia and deep cerebellar nuclei. We then compared the locations of cortical and subcortical neurons labeled when HRP was injected into relatively "cerebellar" or "basal ganglia" thalamus.

When HRP was injected into the most rostral portions of VA, the ratio of BG:CB cells labeled was high, and in the cerebral cortex, HRP labeled cells were restricted to ventral portions of gyrus proreus, the prefrontal regions. Outside of ENTO and SN, no labeled neurons were found in the brainstem, including the superior colliculus (SC) or pedunculopontine region (PPN). When HRP was injected more caudally into VL (A 11.0), the ratio of BG:CB neurons labeled depended on the ventromedial to dorsolateral position of the injection. With ventromedial injections, which labeled more BG than CB, neurons labeled in the cortex were located in the ventral prefrontal areas and in area 6, but there was little label in area 4. Labeled neurons also were found in SC and PPN. As the injections progressed dorsolaterally, more CB cells were labeled and, in the cortex, fewer cells were labeled in the prefrontal regions and more in area 4. In the brainstem, labeled neurons were in the pretectum, with only a few in PPN and SC.

When injections were located even more caudally in VL, sometimes extending into prominent portions of the ventrobasal complex the number of BG cells labeled dropped markedly, and, in the cortex, most labeled cells were in area 4. In the brainstem, few labeled cells were present in SC, a few were present in the red nucleus, but none were seen in PPN.

These data show that sources of input converging with basal ganglia information at the thalamus are cortical areas 6 and the gyrus proreus, the superior colliculus or pretectal areas, and the PPN region. Thalamic areas receiving input from cerebellar nuclei receive information from cortical area 4 and perhaps 6 and the red nucleus, but probably not from the superior colliculus or PPN. There also may be a further suborganization of corticothalamic relationships or convergence of BG and CB input to restricted areas of the thalamus.

48.12 ELECTRON MICROSCOPIC AUTORADIOGRAPHY OF PALLIDOTHALAMIC TERMINALS IN THE CAT.
K. Kultas-Ilinsky, I. A. Ilinsky and K. R. Smith. Depts. of Anatomy and Surgery, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

The entopeduncular nucleus (EPN), - feline homologue of the primate medial segment of the globus pallidus, is the main source of pallidothalamic projections. The precise thalamic area receiving projections from the EPN was reported in a previous light microscopic autoradiography study (Ilinsky et al., 1982). In the present investigation, we used electron microscopic autoradiography for the ultrastructural identification of pallidal terminals in the thalamus to determine their synaptic sites. The animals received 0.1-0.3 uL injections of 2,3,4,5[^{3}H]-leucine (70 uCi/ul) in the EPN and after 4-5 days survival they were perfused for electron microscopy. Tissue samples were removed from the ventral medial and ventral anterior thalamic nuclei and processed for electron microscopic autoradiography as described earlier (Kultas-Ilinsky et al., 1980).

The majority of labelled pallidal boutons were of medium size (2.0-5.0 um in length along the postsynaptic membrane and 1.0-1.5 um in height). In a number of instances favorable section planes revealed the en passant nature of pallidal boutons. Profiles of labelled terminals contained large numbers of uniformly distributed small clear vesicles of variable shape, as well as variable amounts (1-10) of large dense core vesicles. The average mean diameter of clear synaptic vesicles was 36 nm and the average ellipticity index (Dl/Ds) was 1.6. Pallidal boutons in all instances formed symmetrical type synaptic contacts. Multiple synaptic junctions between an individual bouton and postsynaptic structure were very frequent. Synapses were invariably on dendritic shafts and never on spines. Quantitative analysis of the distribution of synaptic sites showed that 40% of pallidal synapses were on somata and primary dendritic branches of thalamocortical projection neurons, 36% on secondary dendrites, 13% on tertiary dendrites. Eight percent of labelled boutons formed synapses on vesicle-containing dendrites of local circuit neurons. An interesting feature of the distribution of pallidal terminals was their tendency to be located at bifurcation sites of the dendrites of thalamocortical projection neurons. For example, 37% of all the terminals on primary dendrites were located at the branching points. Our data indicate that pallidal activity reaches both types of cells in the thalamus: thalamocortical projection neurons and local circuit neurons, though in different proportions. On the thalamocortical projection neurons pallidal terminals occupy a strategically important positions which would enable them to control the activity arriving at the thalamus via other afferent systems. (Supported by NINCDS grant #IROI NS17388 -01 and a grant from the American Parkinson Disease Association.)

48.13 THALAMO-SUBTHALAMIC PROJECTION: AN AUTORADIOGRAPHIC STUDY. T. Sugimoto*, N. Mizuno and T. Hattori. Dept. Anat., Fac. Med., Univ. Toronto, Med. Sci. Bldg, Toronto, Ont. M5S 1A8 Canada and Dept. Anat., Fac. Med., Kyoto Univ., Kyoto 606 Japan.

In the course of studies on thalamic projections in the rat and cat using anterograde fiber tracing methods, a substantial, yet previously unreported projection from the centre median-parafascicular nuclei (CM-Pf) to the subthalamic nucleus (STN) was observed. Small injections of 3H-leucine were made stereotaxically into the CM-Pf complex in rats. In cats, a mixture of 3H-leucine and 3H-proline was injected into the CM-Pf. Control injections were made intentionally at several neighboring thalamic nuclei including the ventral, medial or intralaminar nucleus. Tissue from all animals was processed using standard autoradiographic procedures. In all animals which were injected with isotope into the CM-Pf complex, the ipsilateral STN was heavily labeled over its rostral one-fourth. Thus, label was most concentrated within the rostral pole of the STN, became more sparse caudally, and disappeared over the caudal half of the STN. The rostral pole of the rat STN was quite diffusely labeled. In the cat, however, radiolabel was distributed mainly in the ventral or ventromedial portions of the STN, especially the portion intermingled with labeled fibers of passage bordering the ventral aspect of the STN. These clearly identified labeled fibers of passage consisted of several groups of fiber bundles which appeared to run in the cerebral peduncle and approached the ventral aspect of the STN. At the middle levels of the STN heavily labeled fibers of passage were seen along the ventral and dorsal boundaries of the STN, encircling the convex-shaped, sparsely labeled nucleus. In control experiments, in which isotope was injected into the ventral, medial or intralaminar thalamic nuclei, no prominent accumulation of silver grains occurred within the STN. Thus, the CM-Pf fibers projecting to the STN were not distributed to the middle nor caudal levels of the STN. The restricted rostral distribution pattern of label in the STN may be the reason why previous HRP studies (Rinvik et al., '79, in cat and monkey; Carpenter et al., '81, in monkey) failed to reveal any thalamic afferents to the STN. The CM-Pf complex has widespread projections to the striatum as well as the projection described here to a restricted region of the STN. The CM-Pf is thus in a position to exercise control over divergent portions of the basal ganglia. (Supported by the grants from the Medical Research Council of Canada).

48.14 A GOLGI STUDY OF THE NEURONS IN THE CENTROMEDIAN-PARAFASCICULAR COMPLEX IN THE LESSER BUSHBABY (GALAGO). J. C. Pearson*, C. H. Phelps, and J. R. Norris* (SPON: G. Crampton). Dept. of Anat., Wright State Univ. Sch. of Med., Dayton, OH 45435

In the present study the morphology of neurons in the centromedian-parafascicular (CM-PF) complex of three adult lesser bushbabies (Galago senegalensis) was examined using the zinc chromate modification of the Golgi method. All forebrains were cut in a transverse plane oriented approximately perpendicular to the longitudinal axis of the brainstem. Nuclear configuration of the CM-PF complex was confirmed by comparison of Golgi stained sections with transverse forebrain sections processed according to cell body and fiber stains. Two basic cell types were identified in the centromedian nucleus, and designated as principal neurons or interneurons (Golgi type II neurons). Somata of principal neurons were round to oval in shape, and from 15-22μm in diameter. Each cell gave rise to 2-5 primary dendrites which were of unequal thickness, infrequently branched, and appeared to diverge from the cell body in a radiate type of branch pattern similar to that previously described for reticular formation neurons. Some dendritic processes extended long distances from the somata (more than 200μm) and were oriented in a ventromedial to dorsolateral plane parallel to the direction of the fibers in the interal medullary lamina. The dendrites contained a moderate amount of spines which consisted of small bulbous spheres (less than 1μm diam.) supported by short (approx. 2μm) slender stalks. The spines appeared to be arranged in serial order with no apparent clustering. Axons appeared as short partially impregnated structures (approx. 20-40μm long) which often arose from the proximal portions of primary dendrites. Golgi type II neurons in the centromedian had rounded cell bodies approximately 11-14μm in diameter. Each cell gave rise to 2-4 dendrites which were relatively long (approx. 150-200μm) and infrequently branched. The dendrites supported appendages which were often long (30μm) and intricately branched into many independent lobules or swellings which resembled multilobulated appendages described in previous Golgi studies of many regions of the CNS. Some dendritic branches did not support bulbous appendages, but rather, contained evenly spaced swellings which gave the presumed dendritic process an axon-like appearance. In the parafascicular nucleus several principal neurons with somatic spines were observed. Dendrites of these cells supported spines which were similar in morphology to those observed on dendrites of principal cells in the centromedian. Axons appeared partially impregnated and frequently arose from primary dendritic processes. (Supported by RI-RD funds awarded by the WSU Research Council.)

48.15 A GOLGI STUDY OF THE NEURONS IN THE SUBTHALAMIC NUCLEUS IN A PROSIMIAN (GALAGO). C. H. Phelps, J. C. Pearson*, and J. R. Norris*. Dept. of Anat., Wright State Univ. Sch. of Med., Dayton, OH 45435

The morphology of neurons in the subthalamic nucleus of three adult prosimian primates (Galago senegalensis) was studied using the zinc chromate modification of the Golgi method. Impregnated sections were cut in a transverse plane oriented approximately perpendicular to the long axis of the brainstem. The location of impregnated neurons in the subthalamic nucleus was confirmed by comparison of Golgi stained sections with cell-body and fiber stained brain series. The present results indicate two kinds of principal neurons, and small cells considered to be interneurons in Galago subthalamic nucleus. Because of several points of similarity with principal neurons previously described in the subthalamic nucleus of Macaca mulatta (Rafols and Fox, JCN,168: 75-112, 1976), the principal neurons in Galago were accordingly designated as "radiating neurons" or "elongated fusiform neurons." Radiating neurons had ovoid somata (15-25μm diam.) which supported many fine somatic spines 2-4μm in length. Each somata gave rise to 4-7 primary dendrites which branched infrequently and supported a variable number of spines. Most spines consisted of small bulbous spheres supported by short stalks and were concentrated along the proximal dendritic regions. The dendrites also gave rise to many beaded axon-like processes which extended for distances of up to 80μm from their dendritic origin. The dendrites extended for long distances (approx. 400μm) from the cell bodies and demonstrated a radiate type branch pattern. Some dendritic processes extended into the overlying lenticular fasciculus, and many were conspicuous in their considerable extension (greater than 200μm) into the ventrally located crus cerebri. Elongated fusiform neurons were less frequently found than radiating neurons, and were often located along the dorsal aspect of the nucleus or immediately adjacent to the crus cerebri. Their somata were fusiform in shape, free of spines and gave rise to from two to five primary dendrites. The dendrites supported fewer spines than did those of the radiating neurons, and they often extend greater distances from the somata. Axons of both principal cell types were impregnated only in what appeared to be the initial segments. Presumed interneurons had small, round cell bodies (10-15μm diam.) and few infrequently branched and extrememly sinuous dendrites. These dendrites gave rise to many elaborately branched appendages and supported many beaded, axon-like processes. (Supported by research development funds awarded by the WSU Research Council.)

48.16 A GOLGI STUDY OF RAT SUBTHALAMIC NUCLEUS. Salman Afsharpour*, H. Imai and S. T. Kitai. Department of Anatomy, Michigan State University, East Lansing, MI 48824.

The morphology of the subthalamic nucleus (STH) of Sprague-Dawley rats was studied by the Golgi techniques (Ramon-Moliner's modification, 1957; Valverdé, 1970; Gobel, 1978). Sections were cut either in sagittal or coronal planes. Golgi impregnated neurons were analyzed under a light microscope and were drawn with the aid of a drawing tube. Some representative neurons were also photographed. The cross-sectional areas of the soma (SA) were measured with the aid of a graphic analyzer attached to a PDP-11 computer.

The soma shape varied between elongated fusiform, polygonal and round. The SA varied between 140-440 μm^2. Some of the cells had a few somatic spines. Two to six proximal dendrites gave rise to tapering dendrites which extended up to 500 μm in length. These dendrites were sparsely covered with spines.

Neurons located in the central portion of STH had oval dendritic fields whose long axis was parallel to the long axis of the nucleus in either frontal or sagittal planes. Some of these neurons had one or two dendrites which crossed the borders of STH into the zona incerta, the lateral part of the hypothalamus or the cerebral peduncle (CP). Most neurons located at the borders of STH in general had their dendritic fields extended parallel to the border and were confined within the nucleus except those cells adjacent to CP which had some of their dendrites extending into CP.

Two types of afferent fibers were observed to terminate within STH. One type of fibers were axon-collaterals arising from CP, and the other were fibers that crossed the internal capsule and entered STH rostrally. There were many fibers passing through STH without giving rise to any axon-collaterals.

These results suggest that contrary to the other species (i.e. man, monkey, cat) the rat STH is an open nucleus and that STH may consist of varieties of only Golgi type I neurons. (Supported by USPHS Grant 14866 to S.T.K.)

48.17 SUBTHALAMIC NUCLEUS OF THE RAT: AN ELECTRON MICROSCOPIC STUDY. H. T. Chang, H. Kita and S. T. Kitai. Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

As a part of parallel physiological and anatomical studies of the subthalamic nucleus (STH) in our laboratory, we report here the study of the normal ultrastructural morphology of the rat STH. Adult male albino and hooded rats under deep anaesthesia were perfused with saline and followed by 1% formaldehyde and 2% glutaraldehyde in phosphate or bicarbonate buffer. Brains were cut with Vibratome and STH was prepared for EM analysis.

The overall appearance of STH was dominated by large numbers of myelinated fibers (diameters, D, ranged from 0.3 to 1.5 μm) in the neuropil within which were dispersed tightly packed cell bodies. The neuronal somata were often closely apposed to each other without any intervening glial membranes. Membrane appositions were also found between somata and dendrites as well as dendrites and dendrites. Although puncta adherence junctional complexes were observed, no gap junctions were found on any of these membrane appositions.

The STH cell bodies (D between 10 and 25 μm) were characterized by abundant organelles. Some cells had cilia. The nuclei had deeply invaginated membrane and pale nucleoplasm with little heterochromatin. Filamentous nuclear rods were often observed. In the neuropil, the dendrites were mostly thin (D between 0.5 to 1 μm) with an occasional stubby spine. Both Gray's type I and type II axon terminals were found in STH: The type I terminals formed asymmetrical synapses mainly with thin dendrites and spines. These terminals (D ranged from 0.2 to 1 μm) contained medium-sized round vesicles (D up to 45 nm) and often formed synapses with two postsynaptic targets. The type II terminals formed symmetrical synapses mainly with somata and large dendrites, including the spines on both of these structures. These terminals were often large (D up to 5 μm) and contained large pleomorphic vesicles (largest D up to 50 nm). Frequently these terminals formed adherence junctions with the postsynaptic membrane in addition to the synaptic junctional complexes. Some type II terminals arose directly from myelinated axons, indicating a fast conduction of signals from this afferent source. A third group of terminals included morphological characteristics intermediate between the above two types of terminals, and may represent tangentially sectioned terminals of both types as well as terminals from either intrinsic collaterals of STH cells or other afferent sources.

It is likely that the cortical excitatory inputs and the pallidal inhibitory inputs to STH observed in our physiological studies were mediated by the type I and II terminals respectively.

(This study was supported by National Research Service Award 1F32NS06951-01 to H.T.C. and NIH Grant 14866 to S.T.K.)

48.18 LIGHT MICROSCOPIC OBSERVATION OF RAT SUBTHALAMIC INTRACELLULARLY-STAINED NEURONS. H. Kita, H. T. Chang and S. T. Kitai. Department of Anatomy, Michigan State University, East Lansing, MI 48824

Neurons in the subthalamic nucleus (STH) were intracellularly recorded using HRP-filled microelectrode. After the completion of electrophysiological analysis (which will be presented in a separate paper), some neurons were intracellularly-labeled with HRP. At the end of an experiment, animals were fixed with a mixture of 1% formaldehyde and 2% glutaraldehyde. The brains were cut into 50 μm serial sagittal sections and reacted with the diaminobenzidine.

Light microscopic analysis of HRP-stained STH neurons revealed that: 1) The axons of all analyzed neurons were traced beyond the borders of STH, indicating that they were projection neurons. 2) The somata were polygonal or oval in shape and usually three or four primary dendrites arose from the soma. Occasionally a few spines were seen on the soma. Dendritic trunks tapered slightly and divided into long thin sparsely spined branches. 3) The neurons could be divided into two groups based on their axonal morphology; one with intranuclear axon collaterals and the other without. Differences were also observed in the ratio of their dendritic branching pattern between these two groups: neurons with intranuclear collaterals had higher dendritic tip/stem ratio than the neurons without intranuclear collaterals. 4) Reconstruction of the dendritic field was made in three different planes. In either sagittal or frontal planes, the dendritic field was usually oval in shape and the long axis was parallel to the main axis of STH. In the horizontal plane, the dendritic field of all the neurons were polygonal in shape. 5) All the parent axons originated from the soma ran dorsolaterally and bifurcated at least once. After bifurcation, one axon ran rostrolaterally within the cerebral peduncle and terminated in the globus pallidus. The other collateral coursed caudally or mediocaudally and terminated in the substantia nigra. 6) Some of the globus pallidus-bound axons emitted fine axon collaterals within the entopeduncular nucleus. 7) The terminal arborizations observed in all places (i.e. globus pallidus, entopeduncular nucleus, STH and substantia nigra) were formed with varicose collateral branches which also gave rise to short filaments with beaded endings.

These observations indicated that rat STH comprises of at least two groups of projection neurons with distinguishable axonal and dendritic morphology. The information from single STH neurons could be sent to the globus pallidus, the substantia nigra, and in some neurons, to the entopeduncular nucleus as well as STH itself.

48.19 IMMUNOCYTOCHEMICAL STUDY TO IDENTIFY NEOSTRIATAL PROJECTION NEURONS AND THEIR PUTATIVE NEUROTRANSMITTERS, SUBSTANCE P AND METHIONINE ENKEPHALIN. Ronald H. Bradley and S. T. Kitai. Department of Anatomy, College of Osteopathic Medicine, Michigan State University, East Lansing, MI 48824.

Morphology of the neostriatal projection neurons has been previously identified by Golgi gold toning, HRP retrograde labeling, or intracellular labeling with HRP. In this study we intend to identify the neostriatal projection neurons and their putative neurotransmitters by immunocytochemical methods in the rat brain.

In order to retrogradely label the neostriatal projection neurons, n-acetyl-WGA was stereotaxically injected into substantia nigra or globus pallidus. After 48 hours post-injection period, animals were again injected stereotaxically with colchicine (10 μg/ml) in the lateral ventricle contralateral to the substantia nigra or globus pallidus previously injected with WGA. After a 48 hour post-injection time, animals were perfused via the left ventricle of the heart with 1% paraformaldehyde, 1% glutaraldehyde in a microtubule stabilizing buffer. The brains were removed, blocked into hemi-brains and embedded in glycol methacrylate (GM). Sections were cut on a Sorvall JB-4 microtome (4 microns) and used for immunocytochemical localizations. Projection neurons were identified by incubating GM sections with antiserum to n-acetyl-WGA and visualized by our modified PAP technique. Alternate GM sections were then reacted for either substance P or methionine enkephalin. These sections were viewed stained as well as unstained to check for specificity of the PAP staining.

In order to better identify neurotransmitter and neostriatal projection neurons, alternate sections were examined by a double labeling of either projection neuron-substance P or projection neurons - methionine enkephalin. Substance P or methionine enkephalin antiserum were incubated with the GM section and identified with goat-anti-rabbit conjugated fluorescence; the sections were then re-incubated with antiserum to WGA and visualized with goat-anti-rabbit conjugated to rhodamine.

Results showed that some neostriatal projection neurons contained either substance P or methionine enkephalin. However, not all neurons that labeled as projection neurons contain substance P or methionine enkephalin as well as not all neurons labeled with substance P or methionine enkephalin were projection neurons. These data indicate that at least some neostriatal projection neurons may utilize substance P or methionine enkephalin as neurotransmitters.

48.20 RESPONSES OF SUBTHALAMIC NEURONS TO INTRACELLULAR ACTIVATION, ORTHODROMIC AND ANTIDROMIC STIMULATION. S. T. Kitai, H. Kita and H. T. Chang. Department of Anatomy, Michigan State University, East Lansing, MI 48824.

Stimulation of globus pallidus (GP) has been previously shown to suppress the spontaneous firing of extracellularly recorded subthalamic (STH) units. It was also reported that this stimulation sometimes resulted in firing of STH neurons. In order to study more precise synaptic events underlying these phenomena, intracellular recording of the responses of STH neurons to GP stimulation was performed in male Sprague-Dawley rats anaesthetized with urethane (1.0-1.5 g/kg) or Ketamine (100 mg/kg). Unilateral decortication of the frontal cortex was performed in all animals in order to eliminate corticosubthalamic fibers passing through GP in which the stimulating electrodes were placed. Stimulation electrodes were also placed in the substantia nigra (SN) to study by antidromic activation and a collision technique whether single STH neurons project to both GP and SN. Square current pulses of 0.05-1.0 msec duration were used for stimulation. Bevelled glass micropipettes containing 4% horseradish peroxidase (HRP) in Tris buffer (pH 7.6) and .5 M potassium methylsulfate or 1.0 M potassium chloride were used for intracellular recording. Recorded neurons were labeled by iontophoretic application of HRP through the recording electrode.

GP and SN stimulation evoked antidromic spikes in single STH neurons with mean latency of 1.2 and 1.1 msec respectively. The mean conduction velocity of the axons of STH neurons projecting toward GP was estimated to be 2.5 m/sec and toward SN 1.4 m/sec. These differences in conduction velocities of bifurcating axons made it possible for a simultaneous arrival of STH signals in GP and SN. All STH neurons responded to stimulation of GP with short latency (mean 1.3 msec) monosynaptic IPSPs with a duration of 5-24 msec and followed by depolarizing potentials. Input resistance determined from plateau values of membrane responses to hyper- and depolarizing stimuli ranged from 9-28 MΩ (mean = 18; S.D. = 6, n = 7). Membrane time constants estimated from 1/e point of the membrane potential changes produced by weak current pulses ranged 4-9 msec (mean = 6, S.D. = 2, n = 7). Repetitive spike discharge up to 500 Hz in STH neurons was evoked by suprathreshold direct depolarizing stimuli delivered through recording electrode. Morphology of the labeled neurons indicated that all the recorded neurons were Golgi Type I neurons. Some of the axons were traced to both GP and SN. We conclude that suppression of spontaneous STH neuronal activities by GP stimulation is achieved by monosynaptic IPSPs. Excitation reported previously is most likely due to inadvertent activation of corticosubthalamic fibers coursing through GP. (Supported by NIH Grants NS 14866 to S.T.K. and NRSA 1F32NS06951 to H.T.C.)

48.21 CELLULAR COMPARTMENTS AND MOSAICS OF OPIATE RECEPTORS, AFFERENT FIBER TERMINATIONS, AND CHOLINESTERASE LEVELS IN THE NUCLEUS ACCUMBENS OF THE RAT. Sandra Moon Edley and Miles Herkenham. Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

The striatum of the rat is characterized by a mosaic fit of opiate receptors, acetylcholinesterase (AChE) levels and thalamic parafascicular nucleus projections (Herkenham and Pert, Nature, 291: 415, 1981). Using adjacent cryostat-cut sections from the same brain, we extended that analysis to the nucleus accumbens and compared cytoarchitecture, AChE enzyme histochemistry, mu-opiate receptors and the terminal distributions of thalamic or mesolimbic afferent sources.

A thionin stain of the nucleus accumbens reveals two forms of cellular compartmentalization; cell clusters consisting of 20-200 closely-packed neurons per 25 um-thick section and cell islands made visible by a thin, cell-poor rim. Sections stained for AChE reveal great enzyme heterogeneity throughout the nucleus. The medial half of the accumbens is AChE-dense while the dorsal and dorsolateral portions are AChE-poor. In addition, most of the cell clusters have low AChE levels, though some clusters are associated with very dense AChE staining. The cell islands are also characterized by low AChE levels, but both the cytoarchitectonic and AChE borders are indistinct.

Opiate receptors marked by [^{3}H]naloxone are densely and heterogeneously distributed throughout the accumbens. Dense receptor spots are in register with the cell clusters and either the AChE-poor or dense patches. The relationship between opiate receptors and AChE elsewhere is more complex. For example, in the medial accumbens, high AChE levels span a wider zone than the narrow receptor-dense stripe along the medial edge.

Injections of [^{3}H]amino acids were placed into the thalamic paratenial (Pt) nucleus or the ventral tegmental area (VTA). Strikingly heterogeneous terminal distributions were found in the nucleus accumbens. The Pt termination is punctuated by vacancies; some of these have sharp edges and correspond to boundaries of cell clusters. Another form of heterogeneity is less dramatic: larger, less-sharply defined zones of reduced terminations are in register with cell islands and AChE-poor zones. Many of these areas are also opiate-receptor dense. The terminations of VTA fibers share this latter pattern, that is, areas of low VTA termination density correspond to cell islands, low AChE levels and high opiate receptor density. Exceptions to this can be found, however.

In summary, the type of mosaic that characterizes tract terminations, opiate receptors and AChE levels in the caudate-putamen seems also to apply to the nucleus accumbens. In the accumbens, however, it is easier to find a morphological correlate of the mosaics, namely the cell clusters and islands.

48.22 CELL CLUSTERS IN THE CYTOARCHITECTONIC ORGANIZATION OF THE NUCLEUS ACCUMBENS IN THE RAT. V.B. Domesick. (SPON: C. Marotta). Mailman Research Center, McLean Hospital, Belmont, MA 02178 and Dept. of Anatomy, Harvard Medical School, Boston, MA 02115.

At present, various cytoarchitectonic, histochemical, or connectional criteria are not useful to delimit the nucleus accumbens from the remaining striatum dorsally (the caudatoputamen) and ventrally (the olfactory tubercle). In fact, the homogenous appearance of their cytoarchitecture has served to emphasize the continuity between these three striatal regions. Our purpose in studying the cytoarchitecture of the nucleus accumbens was to identify subregions that might be correlated with specific categories of afferents. Conventional histological techniques were used to prepare albino rats for light or electron microscopy. Series of sections 25 or 50 microns were stained for Nissl with cresylechtviolet. Serial semithin plastic sections were stained with toluidine blue. Ultrathin sections were en bloc stained with uranyl acetate, contrasted with lead citrate and viewed in a Siemens-Elmiskop 1A electron microscope.

In Nissl stained sections the nucleus accumbens could be characterized by an array of heterogeneous cell clusters. Varying numbers of cells were distributed in unique arrangements forming round, crescent, eliptical or strip-like shapes. Each cluster was also distinguished by the density of its cell packing. Semithin plastic sections revealed that all of the clusters were composed of subunits of two to six closely apposed cells. At the electron microscopic level the cytoplasmic membranes of diadic and triadic cell groups often showed an intervening gap of 5-10 nm. The appearance of the resulting apposition of cell membranes suggests some type of functional cell junction. The pattern of cell clustering may serve to define distinct subregions of the nucleus accumbens which may be distinguished from each other as well as from those in the remaining striatum. Cell clusters also characterize the caudatoputamen and olfactory tubercle. The entire striatum may be organized in zones defined by unique patterns of cell clusters. The possible correspondence of cell clusters to various inputs will also be explored. This work was supported by NIMH grant PO1 MH31154.

48.23 EVIDENCE FOR A PROJECTION FROM THE LATERAL PREOPTIC AREA AND SUBSTANTIA INNOMINATA TO THE MESENCEPHALIC LOCOMOTOR REGION. L.W. Swanson, G.J. Mogenson and M. Wu. The Salk Institute, La Jolla, CA 92037, and Dept. Physiol. Univ. Western Ontario, London, Ontario.

We have undertaken a series of combined neuroanatomical-electrophysiological studies to clarify the organization of neural mechanisms that mediate adaptive, goal-oriented behavioral responses commonly associated with the hypothalamus. One of the most important components of such responses must involve an interaction between the hypothalamus and somatomotor control systems for locomotion, and for head and eye movements during foraging behavior. Considerable evidence (Brain Res. Rev. 3:1, 1981) suggests that locomotor activity can be modulated by a multisynaptic pathway that first involves projections from the hypothalamus to the ventral tegmental area, and second involves projections from the latter to the nucleus accumbens.

In a previous study, we (Mogenson, Swanson and Wu; J. Neurosci., in press) described the topographical organization of projections from the nucleus accumbens to the ventral globus pallidus and a subpallidal region that includes parts of the substantia innominata, lateral preoptic area and lateral hypothalamic area, and showed that electrical stimulation of the nucleus accumbens changes the spontaneous discharge rate of many neurons in the ventral pallidium and subpallidal region.

The present series of experiments was designed to determine whether cells in the subpallidal region of the rat project directly to dorsal parts of the midbrain reticular formation that Shik and Grillner have called "the mesencephalic locomotor region", which is centered in the pedunculo-pontine (PPN) and cuneiform nuclei in the cat. First, a series of anatomical studies with axonally transported markers was carried out. Autoradiographic experiments with injections of ^{3}H-amino acids confined to the subpallidal region demonstrated a pathway to the PPN and adjacent parts of the central gray, and retrograde tracer experiments with injections of true blue in the PPN confirmed that many cells in the substantia innominata, lateral preoptic area, and lateral hypothalamic area (as well as some cells in the n. accumbens itself) project to the PPN. And second, a series of electrophysiological experiments was carried out to determine whether the spontaneous discharge rate of individual neurons in and around the PPN of urethane anesthetized rats was influenced by single-pulse stimulation of the substantia innominata and lateral preoptic area. It was found that the spontaneous discharge rate of 42 out of 47 neurons tested was changed, that the most frequent response was suppression of the discharge rate, and that the onset latency of most responses was between 2.5-5 msec.

These results suggest that some cells in the substantia innominata and lateral preoptic area may be directly involved in the modulation of locomotor responses, although further work is needed to determine the role of the dorsal midbrain tegmentum in somatomotor control mechanisms.

49.1 CATECHOLAMINE AND INDOLEAMINE CONCENTRATIONS IN THE DEVELOPING RAT HYPOTHALAMUS. A.G. Watts* and H.F. Stanley* (SPON: G. Fink). MRC Brain Metabolism Unit, Department of Pharmacology, 1 George Square, Edinburgh, U.K.

The effect of sexual differentiation of the brain upon central neurotransmitter systems is far from clear. Here we report the changes in concentrations of catecholamines and indoleamines throughout development in neuronal areas which have been shown to have sex dependent morphological differences. The concentrations of dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), serotonin (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA) were simultaneously determined (using HPLC with electrochemical detection) in the preoptic area and hypothalamus of male and female rats at 36 hr and 4, 12, 20, 40 and 80 days of age. No detectable differences in the concentrations of any of the four compounds were found between the sexes at any age. Concentrations of each compound increased slowly over the first 12 d after birth; however, between day 12 and day 20 a rapid increase in the concentration of all compounds was found. At day 20, 5-HT and DOPAC had reached the concentrations found in adults while 5-HIAA was at its greatest concentration. DA concentrations increased steadily throughout development, maximum concentrations being reached in adults. The molar ratio of 5-HIAA to 5-HT is thought to be an indicator of the turnover rate of 5-HT (Tozer, T.N., Neff, N.H. and Brodie, B.B., J. Pharm. & Exp. Ther. 153, 177, 1966). In the present study the ratio reached a maximum at 4 d of age with lowest values being found in adults. No significant differences between the sexes were found during development; however, small but significant differences were found at 40 d (males 0.72 $\pm$ 0.02, females 0.67 $\pm$ 0.01; $p < 0.05$) and adults (males 0.43 $\pm$ 0.01, females 0.49 $\pm$ 0.01; $p < 0.001$). Currently, experiments are being carried out with the aid of the tryptophan decarboxylase inhibitor, m-hydroxybenxylhydrazine, to determine whether the ratio differences found between animals at 4 d and adults were due to either differences in turnover, differences in MAO activity or the mechanisms of acid metabolite excretion.

These results show that any sexually dependent differences in dopaminergic or serotonergic systems are not reflected by differences in total content. However, the results do suggest that the rates of development of dopaminergic and serotonergic systems differ from one another.

49.2 CARBOHYDRATE COMPONENTS DURING CEREBELLAR DEVELOPMENT OF NORMAL AND MUTANT MICE IN VIVO IN VITRO, AND IN OCULO. W. Wille*, Institute for Genetics, University of Cologne, Fed. Rep. Germany (SPON: E. Trenkner)

De novo synthesis, changes in composition, and degradation of carbohydrate (CHO)-containing molecules are developmentally dependent events in the cerebellum. Some of the involved glycosidases express age-dependent differences in specific activity during postnatal development of the cerebellum and differ significantly in the corresponding tissue of the neurological mutant staggerer (sg)(Wille & Trenkner, J. Neurochem., 37:443, 1981; Wille et al.,in press). Indirect evidence for differences in cerebellar surface CHO depending on age and genome has been described earlier (Hatten & Messer, Nature, 276:504, 1978; Trenkner, Nature, 277:566, 1979).

One phenotype of the staggerer (sg/sg) mutation (degeneration of cerebellar internal granule cells) is also expressed in transplants of embryonic sg/sg-cerebellum "anlage" grafted, grown, and differentiated in eyes of +/+ recipient mice (Wille et al., submitted). This proves the intrinsic quality of the cerebellar mutation in staggerer. Besides the cerebellum in vivo and the microwell cell cultures (Trenkner & Sidman, J.Cell Biol., 75:915, 1977) the transplants provide an excellent model system of intermediate complexity for neuronal histogenesis offering the opportunity of manipulating the CHO-metabolism. Effects of exogenous interference in defined steps of development-dependent CHO-pathways can be analyzed histologically, histochemically, and biochemically.

Cerebellum transplants (grafted at embryonic day 11 from wildtype donors) differentiate in oculo into cerebellum-like tissues containing the requisite neuronal and glial cell types (Hoffer et al., Brain Res. 79:165, 1974). Inhibition of glycoprotein synthesis with tunicamycin applied to the grafts by intraocular injection 8 to 15 days after grafting ("P0 - P7") cause selective granule cell death as analyzed in 45 days old transplants. Injections at "P10" or later do not affect the survival of cerebellar granule cells.

Experiments with specific inhibitors of the CHO-metabolism and their effects on histogenesis and the composition of glycoproteins and gangliosides during cerebellar development in vivo, in vitro, and in oculo are presented.

49.3 IN VITRO TRANSLATION OF NEURON-SPECIFIC PHOSPHOPROTEINS: DEVELOPMENTAL STUDIES AND MESSENGER RNA PURIFICATION. S. Kanazir*, R.M. Lewis*, W.C. Wallace*, L.J. DeGennaro*† and P. Greengard. Dept. Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510, U.S.A. and †Max Planck Institute for Psychiatry, Dept. Neurochemistry, 8033 Martinsried, Federal Republic of Germany

In an effort to correlate synaptogenesis with the appearance of specific neuronal phosphoproteins, we have developed an in vitro translation assay of brain polypeptides. Protein I, a synaptic vesicle-associated protein which is localized specifically in presynaptic nerve terminals, is phosphorylated by Ca^{2+}/calmodulin-dependent and cAMP-dependent protein kinases. Protein III, also found in nerve terminals, is phosphorylated by cAMP-dependent protein kinase. We have now studied the relative levels of synthesis of Protein I and Protein III in developing postnatal rats. Polysomes were isolated from rat brain at various ages and translated in a rabbit reticulocyte lysate. The newly-synthesized proteins were immunoprecipitated with specific antibodies and measured. The relative level of synthesis of Protein I increased from birth (0.05% of total ^{35}S-methionine incorporated into protein) to a maximum level at day 14 (0.33%), then decreased to an adult level of 0.15%. The changes in the synthesis of Protein III were similar to those observed for Protein I. We have also studied the synthesis of G-substrate, a Purkinje cell-specific protein phosphorylated by cGMP-dependent protein kinase. This protein was detected as early as day 8 in postnatal rat cerebella.

Messenger RNA's (mRNA) for Protein I and Protein III were partially purified by specific immunoprecipitation of polysomes followed by oligodT-cellulose affinity chromatography (suggesting that both mRNA's are polyadenylated). We have also partially purified the mRNA for a cytosolic protein (32K) phosphorylated by a cAMP-dependent protein kinase in dopaminoceptive neurons. We are continuing studies of neuronal biosynthesis in relation to synaptogenesis using recombinant DNA techniques.

49.4 DEVELOPMENT OF GABAergic NEURONS IN PRIMARY CULTURES OF RAT RETINA. I. Pech* and P.V. Sarthy. Depts. of Ophthalmology, Physiology and Biophysics, University of Washington, School of Medicine, Seattle WA 98195.

We are interested in the development of neurotransmitter systems and synapse formation in the vertebrate retina. In order to study these problems in vitro, we have developed conditions for maintaining rat retinal neurons in culture. Retinas were dissected from 16 day old rat fetuses and dissociated after trypsinization. The resulting cell suspension was plated onto polyornithine coated plates in Leibovitz's L-15 medium supplemented with 10% horse serum and maintained in an air atmosphere. Under these conditions, monolayer cultures of retinal neurons could be maintained for up to one month. That these cells were neurons was confirmed by the presence of tetanus toxin receptors on their surface. Two distinguishing features of these cultures were: (i) few non-neuronal (flat) cells were present, and (ii) the neurons did not aggregate but remained as individual cells so that their survival and process formation could be readily assayed by cell counting.

In order to establish the presence of GABAergic neurons, the synthesis, release and uptake of GABA were studied in these cultures. GABA synthesis was demonstrated by incubating cells with ^{3}H-glutamate and measuring the formation of ^{3}H-GABA. The presence of glutamic acid decarboxylase (GAD), an enzyme involved in GABA synthesis, was also confirmed by a radiometric assay. Cultures preloaded with ^{3}H-GABA were shown to release ^{3}H-GABA upon depolarization with 48 mM K^+. Further, this release was suppressed in the presence of 5 mM Co^{2+}. GABA uptake was established by two different methods. Light microscopic autoradiography indicated that virtually all cells took up ^{3}H-GABA and that this uptake was almost completely blocked by 1 mM GABA, DABA and Nipecotic acid, and only partially by β-alanine. Biochemical uptake studies showed the existence of a high affinity GABA uptake system in these cells.

Development of the above parameters was studied in cultures up to 3 weeks. ^{3}H-GABA synthesis was first detected at 4 days in vitro (d.i.v.) and increased thereafter, up to 2 weeks in culture. GAD activity showed a parallel increase with time. A small amount of GABA release was noted as early as 2 d.i.v.. GABA was taken up by a small fraction of the cells as early as 1 d.i.v.. With longer time periods in culture, an increasing number of cells took up ^{3}H-GABA, and the intensity of labeling was also enhanced.

Supported by Grants EY-03664 and EY-01730.

49.5 MECHANISMS REGULATING THE BIOCHEMICAL DEVELOPMENT OF THE LOCUS COERULEUS (L.C.) IN CULTURE. C.F. Dreyfus, K.A. Markey, M. Goldstein and I.B. Black. Div. of Developmental Neurology, Cornell Med. Coll., 515 E. 71st St. New York, N.Y. 10021 & Dept. of Psychiatry, New York University Medical Center, New York, N.Y. 10016.

In previous work we have found that a number of catecholaminergic phenotypic characters develop during growth of the embryonic mouse l.c. in explant culture. In the present studies we have examined underlying ontogenetic mechanisms.

Explantation of the l.c. on embryonic day 12 (E-12), prior to normal expression of tyrosine hydroxylase (T-OH) or dopamine-β-hydroxylase(DBH), noradrenergic biosynthetic enzymes, results in the de novo expression of these phenotypic characters after 7 days. Moreover, explantation of the E-18 l.c., after early expression of noradrenergic traits has occurred in vivo, results in a marked quantitative increase in T-OH activity, to levels greater than that attained in E-12 cultures.

To define mechanisms of development in vitro, we focused on the E-18 cultures. Immunotitration studies with a specific antiserum revealed that the increase in T-OH activity in these cultures was entirely attributable to accumulation of increased enzyme molecules. Further, the increase in T-OH activity was inhibited by cycloheximide, camptothecin and actinomycin D, suggesting that protein- and RNA-synthesis are required for the elevation of T-OH in vitro. Finally, immunotitration revealed that the higher levels of T-OH activity seen in E-18 cultures when they are compared to E-12 cultures was due to increased numbers of enzyme molecules. Morphometric studies indicated that this difference in T-OH protein was not attributable to differences in l.c. neuron numbers in the E-12 and E-18 cultures.

We conclude that development in the brain in situ is not necessary for initial phenotypic expression or for subsequent increases in T-OH and DBH. Our studies suggest that l.c. neurons are capable of actively elaborating T-OH molecules in the tissue culture setting in the absence of normal afferent and efferent connections. (Supported by NSF Grant BNS 8024081).

49.6 DEVELOPMENT OF CATECHOLAMINES AND ADRENERGIC RECEPTORS IN THE RAT SPINAL CORD. Leonard L. Ross, Arlene Pylypiw*, and Walter Chmelewski.* Dept. of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

The sympathetic preganglion neurons in the spinal cord receive a substantial descending catecholaminergic (CA) input from supraspinal levels. In the chick, we have reported that the descending developing axons contain catecholamines and that they establish their first synaptic contacts with spinal cord preganglionic neurons at 10-12 days in ovo. Adrenergic receptors appear 4 days later. The present study was undertaken in order to characterize the CA development sequence in the rat and relate it to parallel studies of peripheral innervation.

α- and β-adrenergic receptors were measured in homogenates of thoracolumbar spinal cord by the specific binding of ^{3}H-prazocine or ^{3}H dihydroalprenolol (DHA), respectively. Receptor density (B max) and the apparent dissociation constant (Kd) for ligand binding were calculated by Scatchard analysis. Levels of adrenaline (A) noradrenaline (NA) and dopamine (DA) were determined using high performance liquid chromatography with electrochemical detection.

The presence of α-receptors was first noted at E16 (B max = 9 fmoles/mg protein). From E16 to E22 the number of receptors increases to 116 fmoles/mg protein. At birth, receptor density falls to 80 fmoles/mg protein, rises over the next 2 weeks to the highest prenatal level and gradually falls to the adult level of 50 fmoles/mg protein. β-adrenergic receptors are not detectable until E18. They increase in density slowly pre- and postnatally to a peak of 120 fmoles/mg protein at age 15 days. This is followed by an abrupt fall to the adult level of 70 fmoles/mg protein. The affinities of both receptors did not change during development.

NA is first detectable at E16 at a concentration of 60 pg/mg. The concentration rises gradually to a peak of 410 pg/mg at 20 days postnatally and falls to an adult level of 210 pg/mg. DA is not detected until 1 day postnatally at a level of 15 pg/mg. It follows the same time course, rising to 110 pg/mg at 20 days and then falling to the adult level of 50 pg/mg. A is not detectable at any age.

Of interest are the presence of NA 2 days before the appearance of β-adrenergic receptor and the dramatic increase in both transmitter and receptor during the first 2 weeks of postnatal life. This time is also the period of the most intense peripheral autonomic synapse formation. The relationship between these two events is under investigation.

49.7 ONTOGENY OF SUBSTANCE P-LIKE AND ACETYLCHOLINESTERASE STAINING IN THE DEVELOPING AVIAN CILIARY GANGLION. J.T. Erichsen, B.M. Davis and H.J. Karten. Dept. of Neurobiology & Behavior, SUNY at Stony Brook, New York 11794.

Substance P-like immunoreactivity (SPLI) and enkephalin-like immunoreactivity (ELI) are found in the preganglionic terminal endings of the avian ciliary ganglion (Erichsen et al., J. Neurosci., in press). The present report describes the ontogeny of SPLI and acetylcholinesterase (AChE) staining in the chick ciliary ganglion and the relationship between the immunoreactive endings and presumptive cholinergic neurons during development.

SPLI first appears in the ciliary ganglion at Stage 26 (St 26). From St 26 to St 35, SPLI staining is diffuse and weblike in appearance and shows no obvious morphological specializations around individual neurons. At St 37, pale fluorescent SPLI rings can be found around a small number of neurons. At St 40, there are many more pale immunoreactive endings, as well as several intensely labeled SPLI endings. At hatching, the intensity of SPLI is greater in an increasing number of preganglionic endings, a trend that continues through 7 days post-hatching. Although consistently less intense than ELI in the same endings, SPLI appears to increase in intensity as ELI decreases. Recent RIA studies by White et al. (Neurosci. Abs., 1982) have confirmed this apparent developmental trend in the intensity of SPLI.

AChE histochemistry revealed that most, if not all, postganglionic neurons in the ciliary ganglion contain AChE at St 30 and continue to show intense staining throughout subsequent development. Using combined immunohistochemical and AChE staining techniques, SPLI (as well as ELI) was demonstrated in terminals on these presumptive cholinergic cells.

SPLI usually co-occurs with ELI in terminal endings in both the chick and pigeon (Erichsen et al., Nature, 1982) ciliary ganglion. Yet the ontogeny of SPLI is notably different from that of ELI: SPLI is minimal until St 37 and then increases progressively until after hatching; ELI reaches a maximum at St 37 and then declines slightly. Both SPLI and ELI are present in preganglionic endings before synapses in the ciliary ganglion begin to function (Landmesser & Pilar, 1972). Therefore, in addition to their putative role in neurotransmission, substance P and enkephalin may also be involved in the regulation of synaptogenesis. Supported by EY07039 to J.T.E. and EY02146 to H.J.K.

49.8 THE FUNCTIONAL ONTOGENY OF DOPAMINE AUTORECEPTORS IN THE NUCLEUS ACCUMBENS, OLFACTORY TUBERCLES AND STRIATUM IN THE RAT. F. Scalzo* and L.P. Spear, Dept. of Psychology, SUNY-Binghamton, Binghamton, NY 13901.

The regulation of dopamine (DA) synthesis and release in nigrostriatal and mesolimbic brain regions is thought to be partially mediated by presynaptic DA autoreceptors. The interruption of impulse flow along DA afferents by lesion or pharmacological blockade with drugs such as gamma-butyrolactone (GBL) leads to an activation of tyrosine hydroxylase activity and a subsequent increase in DA in the terminal regions of these pathways. This effect is attenuated by pretreatment with a DA agonist such as apomorphine.

Shalaby and Spear (1981), on the basis of psychopharmacological studies with apomorphine, have suggested that DA presynaptic receptors mature relatively late in ontogeny when compared with dopamine postsynaptic receptors. In a subsequent neuropharmacological investigation, Shalaby, Dendel and Spear (1981) refined this hypothesis to suggest that autoreceptors in the nigrostriatal and mesolimbic DA systems may mature at different ages. They found a consistent apomorphine attenuation of a GBL-induced increase in DA by day 14 in the striatum, but not until 35 days postnatally in the olfactory tubercles (OT).

In the present report, the development of presynaptic DA autoreceptors was neuropharmacologically investigated in the striatum, OT and nucleus accumbens (NAC). One-hundred forty-eight Sprague-Dawley albino rats were used. Animals 14, 21, 28, 35 and 49 days postnatally were injected with 750 mg/kg GBL alone, 1 mg/kg apomorphine alone, a combination of apomorphine and GBL, or 1% ascorbate and .9% saline. Forty minutes later, animals were sacrificed, their brains removed and striata, OT and NAC dissected and assayed for DA, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). In addition, determinations were made in the striatum of 7-day old animals under all drug conditions.

GBL significantly increased DA levels in the striatum at 21, 28, 35 and 49 days of age. This increase was consistently attenuated by apomorphine pretreatment beginning at 28 days. In the olfactory tubercles, while GBL significantly increased DA levels at 28, 35 and 49 days, this increase was attenuated only at 35 days. In NAC, GBL had no effect on DA levels. Measurement of dopamine metabolites (DOPAC and HVA) revealed an apparent alteration in DA utilization with age in striatum. These results suggest that DA presynaptic autoreceptors mature later in OT than in striatum while, in the NAC, presynaptic DA receptors appear to be less sensitive to the effects of GBL.

49.9 QUANTITATION OF THE DEVELOPMENTAL SENSITIVITY OF NEONATAL RAT EEG TO THE CONVULSIVE EFFECTS OF GAMMA-HYDROXYBUTYRIC ACID. L.J. Bearden, O.C. Snead and H.I. Stephens*. Dept. of Pediatrics and Neurosciences Program, Univ. Alabama in Birmingham, Birmingham, AL 35294.

The gamma-hydroxybutyric acid (GHB) model of petit mal seizures has several intriguing characteristics. Perhaps the most salient of these is that GHB produces electrical and behavioral effects which are very much like those seen during absence seizures. Moreover, these electrical and behavioral effects of GHB are blocked by the anticonvulsants which are used successfully for the clinical management of petit mal epilepsy. There also appear to be developmentally related aspects of the endogenous supply of GHB. For example it has recently been observed that the concentration of GHB in rat brain decreases slowly from 14 days prenatal to 13 days postnatal, then falls dramatically between 13 and 20 days postnatal (Snead and Morley, Dev. Brain Res. 1:579-589, 1981). The relation between this decrease in GHB concentration and the development of the brain is not known.

The developmental aspects of the EEG are well characterized in primates. However, the manner in which the EEG changes with age in many laboratory animals is not well defined (Epstein, Developmental Psychobiology 13:629-631, 1980). Such information is of obvious importance to experimental work. But a clear understanding of these changes is essential for laboratory animal studies of age related disorders such as petit mal epilepsy. Recent experiments in our laboratory have focused on quantitating the sensitivity of the developing rat brain to the convulsive electrical effects of GHB.

Male Sprague-Dawley rats (age 24 hrs-4 wks) from our own breeding colony were used in these experiments. Animals were implanted with epoxylite insulated tungsten macroelectrodes in the cortex, hippocampus, caudate and amygdala under halothane anesthesia and allowed to recover from surgery. Rats were given various doses of sodium gamma-hydroxybutyrate i.p. Bipolar EEG was recorded from each electrode on a polygraph (Grass, Model 78) and on FM tape (Ampex, FR 1300). The EEG was analyzed visually and by means of a Fast Fourier Transform algorithm which was coded in Fortran to run on a minicomputer (Data General, Nova 2). Power spectral density plots of the results of this type analysis were generated as a compressed spectral array on a plotter (Cal Comp 1039) under computer control (Honeywell/Xerox 560). The sensitivity of rats to the electrical effects of GHB increased with increasing age. It was also observed that at the onset of the electrical effects of GHB, the convulsive activity appeared discretely in neonatal animals as compared to the gradual appearance seen in adult animals. These results indicate a developmental sensitivity of the rat brain to the convulsive electrical effects of GHB.

49.10 MULTIPLE IMMUNOREACTIVE FORMS OF MET- AND LEU-ENKEPHALIN IN FETAL AND NEONATAL RAT BRAIN AND IN RAT GUT. Barbara L. Silva*, June L. Dahl, Miles L. Epstein† and Iris Lindberg*†† (SPON: Hanna Sobkowicz). Departments of Pharmacology and †Anatomy, University of Wisconsin Medical School, Madison, WI 53706, and ††Laboratory of Preclinical Pharmacology, NIMH, St. Elizabeth's Hospital, Washington, D.C. 20032.

We have used carboxyl-specific antisera to study the development of met- and leu-enkephalin in rat brain and gut. Although both peptides were detected early in ontogeny (at 13-16 days of gestation), the radioimmunoassay data showed different developmental profiles for the two peptides and an apparent 4-fold increase in the ratio of met- to leu-enkephalin from fetal life to adulthood. However, fractionation of HCl extracts of fetal and neonatal brain tissue by HPLC revealed the presence of immunoreactive forms other than met- and leu-enkephalin. For example, in extracts of 16-day fetal and 1-day neonatal brain, there were two peaks of leu-enkephalin immunoreactivity. One emerged at the position of leu-enkephalin, the other eluted with about one-third the retention time. There were four peaks of met-enkephalin immunoreactivity in extracts of fetal brain, one with the retention time characteristic of met-enkephalin, the others with shorter retention times. In contrast, all of the met-immunoreactivity in adult brain eluted with the retention time characteristic of authentic met-enkephalin and all of the leu-enkephalin immunoreactivity eluted in the position of authentic leu-enkephalin. Multiple immunoreactive forms of met- and leu-enkephalin were found in extracts of both fetal and adult gut tissues. Characterization of these various immunoreactive forms is in progress. Preliminary results suggest that the leu-enkephalin-like peptide present in embryonic brain and in gut is a low molecular weight, hydrophilic molecule which is converted to leu-enkephalin in the presence of TFA. We speculate that it may be a phosphorylated or sulfated form of leu-enkephalin. It is interesting in this regard tha an O-sulfated leu-enkephalin has very recently been reported to be present in rat brain [Unsworth et al. (1982) Nature 295, 519]. Supported in part by funds provided by the Medical School Research Committee (JLD) and by NIH grant NS16280 (MLE).

49.11 CULTURED EMBRYONIC CEREBELLAR CELLS ACCUMULATE ^{3}H GABA. S. Roffler-Tarlov and M. E. Hatten, Dept. of Neurology, Tufts University School of Medicine, Boston, MA 02111 and Dept. of Pharmacology, New York University Medical Center, New York, NY 10016.

The autoradiographic localization of ^{3}H GABA captured by high affinity uptake systems present in gamma amino butyric acid (GABA) utilizing neurons has been a useful technique for identifying GABA neurons in mature brain. We have applied the technique for study of the development and interaction of cells disassociated from developing mouse cerebellum on embryonic day (E) 13. At E 13 the mouse cerebellum consists of proliferating young neurons from subventricular and ventricular zones, post mitotic neurons which have begun to migrate in the intermediate zone, proliferating young granule neurons from the emerging external granular layer and immature glia. The major types of neuronal precursors are those of granule cells, Golgi II cells, Purkinje cells and deep cerebellar neurons. Several lines of evidence point to GABA as the transmitter for both Golgi II cells and Purkinje cells but not of granule cells or the deep nuclear cells. Examination of autoradiograms of E 13 cerebellar cells exposed to ^{3}H GABA (5.8×10^{-7} M) for 30 min, after one day in monolayer culture showed that approximately 30% of the cell bodies accumulated ^{3}H GABA. After 3-5 days in vitro heavy accumulation was also observed in the processes of these cells. The cells are able to accumulate ^{3}H GABA nearly a week before synapses are made in culture.

Two lines of evidence suggest that the majority of cells which accumulate ^{3}H GABA are neurons. First, total uptake of ^{3}H GABA was reduced 47% by 100 µM diamino butyric acid (DABA) an antagonist of the neuronal uptake of GABA and 10% by the glial uptake blocker beta alanine (100 µM). The effect of DABA on uptake could be visualized in autoradiograms. Second, double labeling of cultures with glial filament antibody and ^{3}H GABA showed that the majority of cells which accumulate GABA are neurons.

These experiments show that a specific neurotransmitter characteristic distinguishes between groups of cerebellar neurons before migration and the establishment of synapses has taken place.

49.12 DEVELOPMENTAL CHANGES IN THE LEVELS OF N,N-DIMETHYLTRYPTAMINE AND RELATED INDOLEALKYLAMINES IN RAT BRAIN. J.M. Beaton and P.E. Morris*. Neurosciences Program and Dept. of Psychiatry, Univ. of Ala. in Birmingham, Univ. Station, Birmingham, Al 35294.

In the last decade the hallucinogen N,N-dimethyltryptamine (DMT) has been identified as a normal constituent of human urine, blood and cerebrospinal fluid. It has subsequently been characterized as a putative neurotransmitter or neuromodulatory substance in rat brain. Using an isotopic dilution gas chromatographic/mass spectrometric assay for the simultaneous quantification of tryptamine (T), DMT, O-methyl-bufotenin (OMB), tetrahydro-beta-carboline (THBC) and 6-methoxy-tetrahydro-beta-carboline (6-MeOTHBC), the brain levels of these compounds were measured in rats of various ages (1-60 days old). The subjects were mixed sex, Sprague-Dawley rats bred in our animal facilities. The time of birth of each litter was noted (within a 3 hour time range). Groups of rat pups were then sacrificed by decapitation at age 24 hours, 72 hours and 7, 10, 14, 17, 21, 24, 28, 31, 35, 40, and 60 days. For each analysis sample approximately 2 g of brain tissue was used, necessitating the pooling of several brains for the younger animals. Five samples were analyzed for each age tested. All subjects were group-housed in a 12 hour light/dark cycle. After sacrifice the brains were frozen in liquid nitrogen and stored at -70^0 for later analysis. The analyses were carried out using deuterated internal standards as previously reported (Biochem. Pharmacol. 29, 1049, 1980) and the compounds were derivatized with heptafluorobutyryl imidazole. The endogenous compounds were quantified against the internal deuterated standard.

Varying levels of all compounds were identified at most age ranges tested. As has been previously reported the levels of the compounds were very low in the older rats (35 days and above), however, the levels of DMT and OMB were relatively high in the younger rats, peaking at age 22 days. The median values for DMT ranged from 1.3 ng/g wet weight in 35 day old rats (it was not detected in 60 day old rats), to 11.7 ng/g wet weight in 22 day old rats. The corresponding values for OMB, THBC and 6-MeOTHBC were 3.4 to 31.4, 5.3 to 14.2 and 9.6 to 25.3 ng/g wet weight, respectively. There was considerable variation between samples, which may have been due to a male-female sex difference. (Currently, the levels of these compounds are being measured separately in male and female rats at several ages.) Although the roles for DMT and the other compounds in brain has not been determined, it is of interest to note that the levels of these compounds does vary in the developing rat brain.

49.13 PLASMINOGEN ACTIVATOR PRODUCTION AND GLIAL CELL DIVISION: PARALLEL EVENTS IN THE DEVELOPING CHICK SPINAL CORD. N. Kalderon. The Rockefeller University, New York, NY 10021.

The pair of proteases, plasminogen activator and its reaction product plasmin, has been implicated in several tissue remodelling processes. It was previously reported (Kalderon, PNAS 1979. 76, 5992-5996) that chick embryonic spinal cord cells produce plasminogen activator, and that this plasmin-generating system is essential for the tissue morphogenesis to assume a normal pattern in vitro. In the present study, the production of plasminogen activator by embryonic spinal cord tissue as a function of spinal cord development was determined on chick embryonic spinal cords, starting from day 4 of incubation until hatching. Spinal cords were collected from each embryonic day (4-20) and solubilized in 0.2% Triton X-100. The lysates were assayed on [^{125}I]fibrin-coated plates supplemented with purified plasminogen. It was found that the developing spinal cord produces plasminogen activator. This production is markedly enhanced during three stages: on days 8, 11, and 14-16. The fact that the level of production of plasminogen activator varies during the different stages of development implies that the production of this enzyme is switched on and off during the differentiation process. Several gross tissue remodelling processes are taking place within the chick embryonic spinal cord, e.g., cell death of motoneurons (massive degeneration between days 6-9; Chu-Wang & Oppenheim 1978. J. Comp. Neur. 177, 59-86), glial cell division (starting from day 8 on; Fujita 1965. J. Comp. Neur. 124, 51-60). In an attempt to correlate the peaks of plasminogen activator production with these tissue remodelling processes the content of DNA per protein of the developing spinal cord was determined, on each day, starting from day five until day seventeen of incubation. The ratio of DNA/protein peaks during several stages of development, specifically on days 5, 8, 11 and 14. These peaks on days 8, 11, and 14 indicate bursts of cell division which are probably due to glial cell division since the neuroblasts only divide during days 3-8. It seems that glial cell division and the production of plasminogen activator occur at the same time. The two events are probably closely related as plasminogen was found to be mitogenic for glial cells in vitro. (Supported by grants from NIH NS17169 and Muscular Dystrophy Association)

49.14 PHARMACOLOGIC ONTOGENY OF SEROTONERGIC AND DOPAMINERGIC NEURONS IN THE RAT. W.H. Lyness. Department of Pharmacology and Therapeutics, Texas Tech University Health Sciences Center, Lubbock, Texas 79430.

Neonatal rats administered amphetamine-analogs or neuroleptics, it is known, behave comparably to their adult counterparts, i.e., hyperactivity-stereotypy or sedation. This study examined tissue punches of striatum, nucleus accumbens (NAS), frontal cortex (FC), and the olfactory tubercles for the neurochemical responses to dopamine (DA) agonists and antagonists in rats 5 days to 180 days old. The DA concentrations of 5 day old rats were lower in all areas and increased with age. The NAS appeared the most mature in regard to DA content and levels of the two DA metabolites DOPAC and HVA. Extensive dose response curves with haloperidol and clozapine show less sensitivity to drug-induced DOPAC and HVA increases in 5 day old rats. The magnitude of drug-induced metabolite increases approaches the adult response by 15 days old. Conversely, DA agonists apomorphine and bromocriptine, which characteristically lower DOPAC-HVA concentrations, did so comparably in all brain regions except FC of 5 day olds. These results might suggest a maximal DA synthesis and release which cannnot be enhanced easily by DA-antagonists but can be attentuated by DA agonists. Studies using γ-butyrolactone (GBL) show increases in DA content of all brain areas except FC as early as 5 days old suggesting DA presynaptic autoreceptors are functional.

Studies of neonatal cortical 5-HT neuronal systems indicates a lower (20% of adult values) absolute level of 5-HT but near adult levels of its metabolite 5-HIAA (80% of adult values). Brain levels of tryptophan (TRY) were 3 times those of adults at 2 days old and rapidly declined with age. TRY loading (50 mg/kg i.p.) increased brain TRY in rats of all ages but failed to increase 5-HT concentrations in 2 and 5 day old rats. Treatment of animals with NSD-1015 results in linear accumulations of 5-hydroxytryptophan with time in rats of all ages but indicated higher rates of 5-HT synthesis in neonatal rats. While TRY loading produced further increases in brain TRY in 2 and 5 day old rats over untreated animals, the failure to increase 5-HT content might be due to the already maximal synthesis rate in neonatal rats. Increased synthesis of neurotransmitter in neonates appears to be a common factor in both the DA and 5-HT neuronal systems although the responsible mechanisms may be different.

49.15 DEVELOPMENT OF CENTRAL GABA MECHANISMS: NEUROCHEMICAL AND FUNCTIONAL ASPECTS. T. Hedner*, J. Hedner*, K. Iversen*, J.Jonason* and P. Lundborg*. (SPON. N. Bass) Dept of Pharmacology, Univ. of Göteborg, and Dept of Clinical Pharmacology and Pediatrics, Sahlgren´s and East Hospitals, Göteborg, Sweden.

Previous ontogenetic studies have indicated that GABA mechanisms may be relatively mature during early stages of development. In order to further study these mechanisms we have investigated 1) the postnatal regional development of GABA levels as well as accumulation after GABA-T inhibition, 2) effects of experimental asphyxia on GABA levels and accumulation in 4 days old rats, 3) CSF GABA concentrations in human neonates, 4) respiratory effects after GABA administration to preterm rabbits.

Rats of various postnatal ages (1-60 days) were used in the experimental studies.

3-mercaptopropionic acid was given immediately before sacrifice and brain dissection to all animals. In the human, CSF samples were collected on ice and immediately deepfrozen (-70°C) until analysis. GABA was assayed by a fluorimetric method. Respiratory studies were performed on anesthetized (halothane in O_2) preterm (29 days gestation) rabbits in a whole body plethysmograph after intraperitonal injections of GABA, 750 mg/kg.

During the immediate postnatal period in the rat regional GABA levels were relatively high. Until 7 days of age a general decrease was seen in most regions (striatum, midbrain, brainstem, cerebellum, upper and lower spinal cord). Increases were then seen in all regions except for the spinal cord where GABA levels continuously decreased until adult age. GABA accumulation after aminooxyacetic acid (AOAA) was more marked at older ages. In 4 days old rats 60 min of 6% hypoxia induced an increase in GABA levels during and shortly after the hypoxic insult. CSF GABA concentrations in the human infants ranged between 8-45 nmoles/ml which is approximately 20-100 times the concentrations found in adults. Infants with perinatal asphyxia demonstrated increased CSF GABA concentrations compared to respective controls. GABA administration to preterm rabbits depressed both basal respiration and CO_2 induced respiratory stimulation. The decrease in basal pulmonary ventilation was mainly due to a decrease in tidal volume, as respiratory frequency was not significantly altered.

From the present studies we conclude that central GABA mechanisms are relatively biochemically as well as functionally mature during early postnatal age. Neonatal asphyxia causes an increase in central GABA activity which may be an etiological factor for the respiratory depression seen in this and several other neonatal disorders.

49.16 COMPARISON OF CSF MONOAMINE METABOLITE AND PRECURSOR MEASUREMENTS IN THE RAT PUP AND IN HUMAN CHILDREN. B.A. Shaywitz, G.M. Anderson*, J.G. Young and D.J. Cohen*. Labs. Devel. Psychobiol. & Neurochem., Yale Univ. Sch. of Med., New Haven, CT 06510.

The monoamine metabolites homovanillic acid (HVA), 5-hydroxyindoleacetic acid (5-HIAA) and 3-methoxy-5-hydroxyphenylethyleneglycol (MHPG) have been extensively measured in human cerebrospinal fluid (CSF) in an attempt to estimate central turnover of the parent amines (dopamine DA, serotonin 5-HT, and norepinephrine NE respectively). Although correlations have been observed between brain and CSF metabolite levels in both humans and rats it is not clear to what extent changes in turnover and metabolite levels in different brain areas will be reflected in CSF levels. The measurements made in CSF from children are further confounded by developmental aspects. We have previously reported preliminary studies centered around measurements made in CSF obtained from the developing rat pup. We have now further characterized the ontogeny of the compounds, their interrelationships, and the effects of alterations in brain neurochemistry on CSF levels. We are particularly interested in the effects of pharmacological agents which might be used to treat neuropsychiatric disorders of childhood. Thus, we have examined the effects of methylphenidate, amphetamine, and fenfluramine on precursor (tryptophan and tyrosine) neurotransmitters (5-HT, NE, DA) and metabolite levels (5-HIAA, HVA, and indoleacetic acid) in whole brain, brain areas and cisternal CSF of the developing rat pup. The age dependence of the alterations will be presented and the results compared to our and others' findings in children.

49.17 SUBCELLULAR DISTRIBUTION OF POLYAMINE ACETYLATION IN THE DEVELOPING MOUSE BRAIN. J.G. Ortiz and E. Giacobini. Lab. of Neuropsychopharmacology, Dept. of Biobehav. Sci., Univ. of Conn., Storrs, CT 06268.

Acetylpolyamines are considered to be important intermediates in polyamine metabolism. In the vertebrate brain the putrescine to GABA pathway proceeds via acetylputrescine. There is also evidence for an active contribution of putrescine to GABA levels in developing nerve tissue (Seiler, N., Neurochem. Intl., 3:95, 1981). The acetylation of polyamines was examined in the following fractions of the developing and maturing mouse brain, whole homogenate, crude nuclei (P1), crude mitochondria (P2), microsomes and cytosol.

During the perinatal period (day 20 of gestation to day 4 after birth, a.b.), polyamine acetylation in whole homogenate was found to be high. Following a peak at day 5, the activity declined towards adult values.

In P1 and microsomal fractions acetylation of spermidine was high at day 1 and then declined rapidly to nearly adult values by day 10. Putrescine acetylation exhibited an additional peak at day 4.

In contrast to the adult animal (90 days), putrescine and spermidine acetylation was present in the P2 and soluble fractions. Acetylation of spermidine in the P2 fraction is highest at day 1, while putrescine acetylation is highest at day 3. Acetylation of both substrates is barely detectable at day 42 a.b.

Putrescine and spermidine acetylation in the soluble fraction showed the highest activity at day 5 a.b. after which there was a fast decline towards adult values.

These results suggest that polyamine acetylation may play an important role in polyamine metabolism in the developing mouse brain. The activity found in the P2 and soluble fractions strongly suggests that putrescine, via acetylputrescine, contributes significantly to the GABA levels during development.

(Supported by U.S. Public Health Service grants NS 11430 and NS 14086 to E.G.).

49.18 ENHANCEMENT OF RESPONDING FOR ELECTRICAL STIMULATION OF BRAIN BY COCAINE IN 10 DAY OLD RAT PUPS. Gordon A. Barr*, Leo Maniachi*, and Ted Lithgow* (SPON: W. H. Bridger). Dept. of Psychiatry, Albert Einstein College of Medicine and the Biopsychology Program, Hunter College, CUNY, New York, New York 10461.

In adult rats, stimulant drugs lower threshold and increase responding for brain stimulation reward (BSR). It has been proposed that these drugs may act through enhancement of catecholamine function. Recently, it has been shown that rat pups as young as 3 days of age will also work for BSR. Moreover, although many neurochemical systems, including the catecholamines, are not fully developed in preweanling rats, we have shown enhancement of responding for brain stimulation following amphetamine treatment in 10 day old rat pups. In the present study, we tested a second stimulant, cocaine, on BSR in this age pup.

Using stereotaxic methods developed for immature rats, 150 μ bipolar electrodes were aimed at the medial forebrain bundle. About 16-18 hours postoperatively, pups were placed in a small heated chamber (13 X 12 cm) with two omni-directional poles protruding from the floor. Nudging one pole produced a 280 msec pulse train (2.0 V, 125 Hz), while nudging the second pole had no consequence. Responses were recorded hourly. After the fifth hour, pups were injected i.p. with either cocaine (10 or 30 mg/kg) or saline and responses recorded for an additional five hours. Increased responding on both poles indicated increased activation; differentially enhanced responding on the active pole indicated enhancement of the stimulation.

The highest dose of cocaine enhanced responding differentially. The number of responses on the positive pole increased six-fold in the hour following injection while responding on the neutral pole only increased slightly. At the lower dose, responding on both poles increased from two to three-fold. Responding did not change on either pole following saline injection.

These results demonstrate that cocaine, like amphetamine, can enhance BSR in 10 day old rat pups. Cocaine differs from amphetamine only in having a shorter duration of action in these studies. For both drugs, higher doses were required in pups than typically used in adults to increase responding for stimulation. The neurochemical systems mediating the actions of the two stimulants on BSR are functional in this particular as early as 10 days of age.

49.19 NALOXONE INCREASES PREFERENCE FOR STRESS-RELATED ODORS IN RAT PUPS. C.A. Cornwell-Jones, Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

According to the affiliative need hypothesis, naloxone increases perceived stress by blocking opiate receptors, and developing animals seek out conspecifics in an effort to relieve the stress (cf. Panksepp et al., Neurosci. Biobehav. Rev., 4, 1978). This hypothesis suggests that naloxone should increase pups' preference for odors associated with the home-cage, but not other odors.

Experiments 1 and 2 examined the effects of naloxone injection on preference for home-cage vs. other odors. Sprague-Dawley rat pups 10-12 days old were injected with 0.1 ml of 1 μg/g naloxone HCl or saline and replaced in their home cages. Control pups were uninjected. In Expt. 1, home cages contained pine shavings, and in Expt. 2, cages contained cedar shavings. Seven min after injection, pups were tested in an apparatus with a screen floor which allowed pups to smell but not touch or taste shavings in 2 compartments below. One compartment contained fresh pine shavings. The other contained either fresh cedar shavings or soiled pine shavings from the nest of a strange litter. Each pup was tested on both odor choices.

Naloxone affected preference for home-cage, but not non-home-cage odor in both experiments. Pine-reared controls and naloxone treated pups preferred pine-nest to pine odor, while saline-injected pups were indifferent. Cedar-housed control and naloxone-treated pups preferred cedar to pine odor, while saline-injected pups showed no preference. Thus, naloxone did not increase preference for home-cage odors over control levels, but prevented the injection procedure from reducing that preference.

A final experiment examined naloxone effects on preferences for non-home odors encountered under stressful vs. non-stressful conditions. Following saline or naloxone injection, pine-reared pups were either placed in pine shavings under a heating pad, placed in lemon-scented shavings in a heated jar, or placed in lemon-scented shavings in a refrigerated jar. Animals were returned to their home cages after 30 min. and tested 24 hrs later on cedar vs. pine and lemon vs. pine.

All groups preferred pine to lemon-scented shavings except the group injected with naloxone and exposed to refrigerated lemon shavings 24 hrs earlier. This group showed no preference on the lemon vs. pine test, and averaged significantly more time over lemon odor than cold-exposed saline-injected pups or unexposed naloxone-injected pups.

The combined data suggest that naloxone increases pups' preference for odors encountered under stressful conditions. These results are consistent with the idea that naloxone acts as a false opiate in immature rats.

49.20 DEVELOPMENT OF BENZODIAZEPINE BINDING SITES IN DIFFERENT REGIONS OF THE FETAL RAT BRAIN. M. Schlumpf, J.G. Richards, W. Lichtensteiger and H. Moehler*. Inst. of Pharmacology, Univ. of Zurich, Zurich, and F. Hoffmann-La Roche, Basle, Switzerland.

Benzodiazepines (BDZ) are known to readily cross the placental barrier when administered to pregnant rats. Administration of BDZ during pregnancy results in subtle changes in the behavior of offspring. The availability of novel BDZ ligands with different pharmacological profiles, in particular the specific BDZ antagonist Ro 15-1788, provides an opportunity to investigate the ontogeny of pharmacologically relevant BDZ binding sites (receptors) in fetal rat brains.

Zivic Miller-Sprague Dawley rats were mated for 1½ hr at the onset of the dark period (embryonic day (ED) 1 is 24 hr after mating). An in vitro autoradiographic method (Young and Kuhar, Brain Res. 179, 255 (1979)) was used to visualize the binding sites of ^{3}H-flunitrazepam and ^{3}H-Ro 15-1788 in cryostat sections from fetal brain. The specificity of radioligand binding was checked by co-incubating sections with an excess of the non-radioactive antagonist or clonazepam respectively.

Specific BDZ agonist and antagonist binding was detected on ED 14 in the spinal cord and lower brain stem. Between ED 14 and 15 labelling spread throughout the lower brainstem, the mesencephalon and parts of the diencephalon. On ED 16 binding was present in the developing caudate putamen, olfactory bulb and the frontolateral parts of the neocortex. In neocortex only the most superficial cortical layer appeared labelled at this stage of development. During the later stages of prenatal development the density of BDZ binding in the di- and telencephalon increased and developed into an adult-like pattern. In the neocortex, layer I appeared as a distinctly labelled band, while very little or no labelling was seen below the cortical plate. In general, a caudo-rostral gradient was observed in the development of BDZ binding sites in fetal rat brain.

The capacity of the fetal brain to specifically bind BDZ may be related to the functional deficiencies described in the offspring of BDZ-treated mothers. Our observations suggest that different brain structures may become sensitive to the action of BDZ at different times in prenatal development.

50.1 ALTERED CENTRAL AND SOMATIC DEVELOPMENT IN MALNOURISHED ARTIFICIALLY REARED RAT PUPS. J. Diaz, E. Moore*, C. Stamper, F. Petracca*. Dept. of Psychology, University of Washington, Seattle, WA 98195.

The procedure of rearing rat pups away from their mother and siblings exclusively by intragastric feedings provides a means for direct examination of nutritional requirements for normal development. This technique allows separation of malnutrition from undernutrition which is not possible using litter size or maternal diet manipulations. Rat pups artificially reared days 4 through 18 have been found to differ significantly from their normally reared siblings on day 18 in specific organ weights despite similar whole body growth. The purpose of this study was to examine the development of these differences.

Four-day old female Long Evans hooded rat pups were assigned by weight to either a normally reared group (NR) or an artificially reared group (AR). Both groups were further subdivided according to the age at which they were to be sacrificed : day 5,6,8,12, or 18. Animals assigned to the AR group were reared using a formula accepted as a substitute for mother's milk, according to a procedure previously described (Diaz, et. al, J. Nutr., 1982). On the day of sacrifice, each animal's brain, liver, kidney, and spleen were removed and weighed. The brain was dissected and the cerebellum weighed.

The following table summarizes the organ weight data for the AR group compared to the NR group :

	DAY 5	DAY 6	DAY 8	DAY 12	DAY 18
WHOLE BRAIN	-9%	-8% *	-11% **	-11% **	-8% **

The malnutrition in the AR group was so severe that significant deficits in brain weight could be observed after 48 hours of gastric infusions. The subsequent brain growth of the AR animals showed its largest deficit during the time of fastest brain growth. The decreased deficits seen on day 18 in the AR group suggest that these animals may experience a recovery period of enhanced brain growth. The specific nature of the malnutrition responsible for such a brain weight deficit remains unclear. However, the accelerated liver growth in these animals suggests the presence of a toxin or an inappropriate component in the formula.

Recent experiments in our laboratory examining different formulas suggest that the pattern of reduced brain growth and accelerated liver growth reported in the present study is not a necessary consequence of artificial rearing.

50.2 THE EFFECTS OF PRENATAL AND POSTNATAL MALNUTRITION ON BRAIN LIPIDS. Paula K. Lundberg, C. Robert Almli, Richard W. Florman* and Peter J. Morgane. Washington Univ. Sch. of Med., St. Louis, MO 63110 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545

Pre- and postnatal (PN) malnutrition has been shown to be associated with a variety of deficits in rats. Typically, the brains of rats that have been malnourished postnatally show reductions in the total amount of cholesterol (CHOL) and phospholipids (PHOS) as well as reductions in the concentrations of these lipids. With the exception of the "large litter" technique, these results occur regardless of the method used to effect malnourishment. Since we have been interested in developing an animal model of the small-for-gestation-age infant utilizing a 6% protein diet, determination of the diet's effects on brain lipid levels is important for the explanation of its behavioral consequences. The total lipid content in the brain can be considered an index of general growth, while the concentrations of brain CHOL and brain cerebroside and sulfatide can be considered an index of myelination. Thus, the purpose of the present study was to determine the effects of pre-and PN exposure to a 6% protein diet on offspring lipid levels.

Prior to breeding, during gestation and lactation dams were maintained on normal (N) (25% casein) or low-protein (LP) (6% casein) isocaloric (4.3 kcal/g) diets. After weaning, offspring were maintained on their respective diets. Pups were sacrificed on PN days 21 or 35, their brains were removed, dissected into four parts and frozen for lipid analysis. CHOL was analyzed using a Biodynamics Kit. PHOS was analyzed using the method of Fiske and Subbarow. Analyses of cerebroside and sulfatide as well as analysis of the other brain regions are currently in progress.

The weights of the telencephalon were reduced in both the day 21 (t=13.58, df=22, p .001) and day 35 (t=10.03, df= 30, p .001) LP rats. Telencephalon CHOL concentrations (mg/g brain) in the day 21 LP rats were not different from those of the N rats, but total CHOL content (mg) was lower in the LP rats (t= 4.80, df=21, p .001). In the day 35, LP rats, however, both the concentrations of CHOL (t=3.63, df=29, p .01) and total brain CHOL (t=7.33, df=29, p .001) were less than those of the normals. Total PHOS levels (mg) in the telencephalon were reduced in the day 21 LP rats only (t= 2.34, df=16, p .05).

These data suggest that exposure to a 6% protein diet results in impaired brain growth since brain weight, brain CHOL and PHOS levels are lower at weaning. Moreover, exposure until day 35 results not only in reductions in brain weight and total CHOL, but also CHOL concentration implying that myelination is also reduced. (Supported by BSRG grant SO7RR05389, NICHD grant HDO6364 and NHLBI grant HL07456-01.)

50.3 ALTERATIONS IN NEURONAL DISCHARGE RATES IN DEVELOPMENTALLY PROTEIN MALNOURISHED RATS. W. C. Stern, A. Johnson*, O. Resnick and P. J. Morgane. Neuropharmacology Lab., D. Dix Hosp., Raleigh, N.C. and Worcester Fndn. Exp. Biol., Worcester, MA.

There has been little electrophysiological evaluation at the single unit level of changes in the CNS in rats reared under conditions of protein malnutrition. The present study examined in normal adult rats fed a 25% casein diet and developmentally protein malnourished rats fed an 8% casein diet: (a) the spontaneous discharge rates (and inter spike intervals) of neurons in the parietal cortex and medial thalamus and (b) the effects of electrical stimulation of the locus coeruleus (LC) and raphe dorsalis (RD) inputs to these neurons. The isocaloric diet regimens were initiated prior to conception and continued throughout the gestation, lactation and post-weaning periods until testing in adulthood. Neuronal activity was recorded extracellularly in urethane anesthetized rats using glass micropipette electrodes. Following recording of baseline activity, stimulation (10 Hz, 0.1-1.0 mA, trains of biphasic pulses) of 10-30 sec was applied to the LC or DR.

The results were: (a) The spontaneous discharge rates of populations of cortical and thalamic units were substantially different in protein malnourished rats compared to the normal controls. The protein malnourished group had a virtual absence (5-7% of all units) of fast-firing cells (>20 spikes/sec) compared to the normal controls (31-42% of units). Consequently, there was a 30-50% decrease in average discharge rates in the malnourished group. (b) Activation of the aminergic pathways by electrical stimulation of the LC or DR produced comparable patterns of changes in neuronal firing rates of the cortical and thalamic units in normal and protein malnourished rats.

The most important aspect of the present findings was the very substantial reductions in the proportion of forebrain units with a fast spontaneous firing rate (>20/sec) in the protein malnourished rats. The basis of this effect is not known, but could be related to the enhanced levels of norepinephrine and serotonin previously reported to occur in these animals. Alternatively, the malnourished rats may have a deficiency in an excitatory neurotransmitter. The extent of the present changes in spontaneous discharge rates in other brain regions and the underlying physiological abnormality responsible for these differences remains to be determined.

50.4 MALNUTRITION AND THE DEVELOPMENT OF THE BRAIN: A TIMETABLE FOR REHABILITATION. A. G. Angulo-Colmenares, L. Briceño-Mayz* and J. L. Colmenares. Servicios de Anatomía Patológica y Endocrinología, Hospital Militar "Dr. Carlos Arvelo", Caracas, Venezuela.

Previous work has shown that, when proper nutrition is provided, rats malnourished during lactation reach normal body weight and attain a normal size to their cerebral hemispheres by 70 days of age and have normal values of cerebral cortex thickness by 40 days (Angulo-Colmenares, A. G., J. W. Hinds and D. W. Vaughan, Brain Res. 169:121-138, 1979). We now report on our attempt to rehabilitate rats malnourished perinatally until 30 and 40 days of age.

Pregnant Sprague-Dawley rats were given either a 24% (control) or 8% (experimental) protein diet starting at day 10 of gestation and continuing until 30 (R30) or 40 (R40) days after birth. At this time rehabilitation was induced by feeding the animals a 24% diet. In addition, the R30 group, which was still lactating at 30 days, was left with their pups until day 40 and the litter was reduced from 8 to 4 pups. Throughout the experiment a group of animals was kept malnourished by feeding them the 8% diet. Observations were made on tissue from animals 40, 70 and 90 days old fixed by vascular perfusion of aldehydes and embedded in Araldite.

Our results indicate that while a substantial recovery is made in terms of body weight, neither group achieves normal values by 90 days of age. Three dimensions of the cerebral hemispheres were measured: length, width and height. At 40 days all three dimensions are significantly reduced in the malnourished animals. These differences have disappeared in the R30 group at 70 days of age. In the R40 group the length and height are no longer different at 70 days but the width is still significantly reduced in the 90 day animals. Preliminary results suggest recovery of cerebral cortex thickness in the R30 animals by 70 days while the R40 group apparently did not recover by 90 days.

We conclude that in this particular model of perinatal malnutrition, the manipulations that induce rehabilitation in the brain are no longer effective after 40 days of age. The question remains if the stimulation of growth by pharmacological manipulations and/or hyperalimentation may further increase the possibilities of rehabilitation. 50.5 THE EFFECTS OF PRENATAL PROTEIN DEFICIENCY ON THE DEVELOPMENT OF THE CORPUS CALLOSUM IN THE BALB/C LABORATORY MOUSE. P. Wainwright* R. Stefanescu* (SPON: R. Marteniuk). Dept. of Health Studies, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

The study compared the effects of an 8% vs 27% casein diet during gestation on forebrain fibre tract development in the laboratory mouse. The Balb/c strain was used because it is prone to having a defective or absent corpus callosum. Females were assigned to the experimental diets either two weeks prior to mating (chronic) or on the seventh day of gestation (acute). Fetal brain development was assessed at 18.5 days after conception. The data indicated that protein deficiency increased the number of animals who did not have a corpus callosum present in a midsagital section (chronic 14.7%, acute 23.9%, control 7.4%; $\chi^2_{(2)} = 5.35$, $p = .05$). In addition, in those animals in whom the structure was present, it was evident that the cross sectional area was smaller in the chronically deprived animals than in the controls. Covariance analysis indicated that this effect was independent of effects on other variables such as brain weight and area of the anterior commissure. This suggested that the smaller cross sectional area was not merely evidence of growth retardation but was an effect specific to the corpus callosum.

50.6 EFFECT OF PRENATAL PROTEIN MALNUTRITION UPON THE CORTICAL AND HIPPOCAMPAL EEG IN THE DEVELOPING RAT. J.D. Bronzino, M. Kelly,* K. Austin,* C. Cordova,* C. Siok,* O. Resnick and P.J. Morgane Worcester Foundation For Experimental Biology, Shrewsbury, MA 01545.

Although many studies have shown that dietary protein deficiencies during the period of most rapid brain growth causes significant and often irreversible alterations in the structure, chemical composition and function of the brain, the effects of protein malnutrition on ontogenesis of electrical activity in specific neuronal formations is not well understood. Since developmental processes undergo definite ontogenetic sequences, electrographic measures in normal animals can serve as baseline indicators against which those obtained during various insults to the brain can be compared. Recently, we have demonstrated (Brain Res. Bull. 5:51-60, 1980) the effects of prenatal protein malnutrition upon the frequency characteristics of the EEG as the developing rat matures from early post-weaning to adulthood. In the present studies we undertook a quantitative study of the developing EEG in normal (25% casein diet) and protein malnourished (8% casein diet) rats during the preweaning stage of development. Specifically we utilized power spectral techniques to quantify EEG patterns in several vigilance states as the animal matured from 14 to 22 days of age. Although changes in the frequency characteristics, especially at lower frequencies (0.5 - 3 Hz), were observed in the cortical EEG, the most significant findings of this study involved the theta rhythm (4 - 11 Hz) in the hippocampal EEG. In normal development, the power in the 4 - 7 Hz band gradually increases while power in the 7.5 - 11 Hz band gradually decreases and the frequency at which the peak power value occurs continually shifts to higher values (i.e., from 5 to 6.5 Hz) in this preweaning period. The protein malnourished animals had significantly less power in the theta band of frequencies at 14, 18 and 22 days of age. In addition, the gradual shift in the frequency of the peak power for the protein malnourished animals lagged behind those of the animals reared on the 25% casein diet until 22 days of age when the frequencies were observed to be approximately equal between the two diet groups. These results indicate that the electrographic activity recorded from the hippocampus in animals reared on a protein deficient diet are electrographically "immature" during preweaning, i.e., at 14, 18 and 22 days of age, and demonstrate that prenatal protein malnutrition can significantly alter specific electrographic measures related to theta activity. (Supported by NIH Grant NICHHD HD06364.)

50.7 ALTERATION OF REM EPISODES IN THE DEVELOPING RAT PRODUCED BY PRENATAL PROTEIN MALNUTRITION K. Austin,* J.D. Bronzino, M. Kelly,* C. Cordova,* C. Siok,* O. Resnick and P.J. Morgane (SPON: R. Volle) Worcester Foundation For Experimental Biology, Shrewsbury, Massachusetts 01545.

In order to for understand the functional implications of organic effects of protein malnutrition on the developing brain, we have studied sleep behavior in normal and malnourished rats at various times of life. We have previously reported the effects of prenatal protein malnutrition upon the sleep profiles of adult rats (Expl. Neurol. 57:440-450, 1977). In the present study we examined the sleep profile in rats reared on a normal (25% casein) diet and a protein deficient (8% casein) diet during the preweaning stage of development, particularly 14 to 22 days of age. Chronic indwelling bipolar recording electrodes were implanted in frontal cortex and hippocampus under ether anesthesia at 14, 18 and 22 days of age. Following surgery the animals were placed into a sleep chamber, and after recovery from anesthesia they were recorded for 6 hours to establish the sleep profile for each animal. The most significant finding of this study involved REM sleep. At 14 and 18 days of age, protein malnourished rats spent significantly less time in REM sleep, but by 22 days of age had approximately the same REM sleep percentage displayed by those animals reared on the 25% casein diet. Although less time was spent in REM sleep in animals 14 and 18 days of age, these protein malnourished animals had a significantly higher number of REM episodes when compared to normals, i.e., the animals exposed to prenatal protein malnutrition experienced more frequent REM bouts but spent much less time in REM sleep than those animals reared on a normal diet. These results demonstrate effects of dietary prenatal protein restriction on the REM sleep state and the overall sleep-waking process. The effects are restricted to the REM sleep state and do not involve slow-wave sleep. Since prenatal protein malnutrition alters the sleep-waking characteristics of the rat during preweaning, i.e., at 14 and 18 days of age, derangements in those neuronal structures involved in the REM sleep control system, may be caused by prenatal protein malnutrition. (Supported by NIH Grant NICHHD HD06364)

50.8 THE EFFECT OF PROTEIN MALNUTRITION ON THE COPULATORY BEHAVIOR OF THE MALE RAT. R.D. Hall, B.J. Feldman* and J. Flemming*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

In this laboratory Forbes and Svare (in preparation) found that developmental protein malnutrition led to abnormally high levels of plasma testosterone (T) in rats 240 days of age. At that age and at 120 days testes and seminal vesicles were also relatively heavier in protein deprived rats than they were in well-nourished ones, but plasma T levels were not elevated in the younger animals. The purpose of this study was to determine whether the morphological and hormonal differences between the protein malnourished and well-nourished rats had behavioral correlates and, if so, whether they were age related.

In three experiments rats were reared under four dietary conditions: Half of the rats were born to dams fed a low protein (8% casein) diet from 5 weeks before mating until their pups were weaned at 21 days of age. The other half was reared by dams fed a 25% casein diet. At weaning half of the pups in each group were switched to the other diet.

In the first experiment 32 males were given a single test of copulatory behavior at each of two ages, 165 and 325 days. In the second experiment 46 males were given as many as four tests to achieve ejaculation at 170, 215 and 305 days of age. In the final experiment 40 males were allowed three tests beginning at 95 days of age.

In all three experiments rats subjected to the protein deprivation in both preweaning and postweaning periods, or in one or the other only, were more effective copulators than well-nourished rats. This was evident in several measures of intromission responses: the number of intromissions, interintromission intervals, and the proportion of copulatory attempts that achieved intromission. The greater success of the protein malnourished rats in achieving intromission also resulted in more ejaculations at the older test ages. The diminished capacity for intromitting associated with the high protein diet also occurred with increasing age. In neither case did other measures of the copulatory behavior suggest that sexual arousal was decreased. These data suggest that penile reflexes may be enhanced by elevated T levels in protein malnourished rats, although other factors may also be involved. The more vigorous copulatory behavior of malnourished 95-day-old males, which presumably have normal plasma T levels, suggests that other factors are important.

This research was supported by NIH grant HD06364.

50.9 DIETARY OBESITY IN WEANLING RATS WITH AND WITHOUT DORSOMEDIAL HYPOTHALAMIC LESIONS (DMNL). Lee L. Bernardis and Larry L. Bellinger. VA Med. Ctr. Buffalo and SUNY at Buffalo, NY 14215 and Dept. Physiol. Baylor Coll. of Dent., Dallas TX 75246.

Recent studies by others have shown that, although post-weaning intact rats fed cafeteria diets eat 50% more calories (CAL) than chow-fed rats they gain only slightly more weight (BW). Their feeding efficiency (EFU) is reduced and their brown adipose tissue (BAT) weight is increased; their capacity for dietary-induced thermogenesis (DIT) appears as great as that of mature rats. Weanling male rats received DMNL and sham operations (CON) and were fed lab chow for 15 days post-operatively (POP). During this time they showed the previously reported hypophagia and BW and length retardation. Following this, they were fed a high-fat diet, sucrose as drinking fluid, cookies and assorted "junk food" for various periods until the 185th POP day. In most parameters, our findings are in contrast to those in slightly older (5 d) rats. Thus, CON ate the same CAL or less than chow-fed CON. DMNL rats and their chow-fed counterparts ate comparable CAL. EFU was greater in both CON and DMNL rats fed "junk food" compared with CON and DMNL fed chow. However, CON and DMNL rats under each dietary treatment had comparable EFUs. BW as such was consistently reduced in DMNL compared to CON. Except during the "junk food" period, CON weighed less than chow-fed CON. However, DMNL rats fed the special diets in whatever combination weighed consistently less than chow-fed DMNL rats. Change in BW, i.e. ΔBW, was greatly increased in the two "junk"-fed groups; this was paralleled by increased plasma levels of glucose, glycerol and free fatty acids at sacrifice. BAT weight was increased in the CON fed the special diets compared to chow-fed CON, but was similar in the two DMNL groups. BAT weight of DMNL on the special diets was also reduced compared to special diet-fed CON but there was no difference in BAT weight between chow-fed DMNL and CON. BAT lipid content was comparable in the special diet-fed groups and in turn was greater in these two groups than in their chow-fed counterparts. Epididymal fat pads weighed more in the special diet-fed groups than in the chow-fed groups but, as with BAT, the special diet-fed DMNL rats showed lower epididymal pad weights than their CON. The epididymal pads in the chow-fed groups were comparable in DMNL and CON. Linear growth was retarded in both DMNL groups compared with their CON but, most remarkably, was dramatically reduced in both special diet-fed groups compared with their chow-fed counterparts. Manifestations of dietary obesity and DIT differ in weanling rats from slightly older and mature rats. DMNL bring about additional differential responses that point to yet to be identified deficits in DIT.

Supported by VA Funds.

50.10 PRENATAL PROTEIN MALNUTRITION IN RATS: INFLUENCES ON BRAIN NOREPINEPHRINE SYNTHESIS. Oscar Resnick, Rachelle Hasson* and Maravene Miller. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

We have reported significant elevations in regional brain norepinephrine (NE) levels from birth through adulthood in rats whose dams ingested a low protein diet (8% casein) starting 5 weeks prior to conception as compared to progeny from dams fed a normal diet (25% casein). These alterations appeared to be correlated with increases in phenylalanine (Phe) availability to the brain rather than with elevations in brain or plasma tyrosine (Tyr) levels (Miller et al., Exp. Neurol., in press, 1982). To determine which of the brain and peripheral changes were due to prenatal protein deficits and which were caused by lactational deficiencies, rats born to dams fed the 8% or 25% diets were cross-fostered at birth to dams of the opposite diet, i.e., pups from 8% dams were fostered on 25% dams (8/25 rats); 25% pups were fostered on 8% dams (25/8 rats). At weaning (day 21), these rats were compared to unswitched pups of each diet (8/8 or 25/25 rats). The results (table below) show that while some constituents can be induced as a sequela of lactational deficits, many were not rehabilitated by a sufficient diet during lactation. Accordingly, adequate nutrition instituted at birth was ineffectual in reversing the prenatal-determined alterations in brain NE synthesis. While the mechanism(s) responsible for these changes are unknown, these data demonstrate that prenatal protein malnutrition alone can importantly influence brain catecholamine metabolism in the postnatal period.

50.11 TRYPTOPHAN AVAILABILITY: ALTERATIONS IN BRAIN INDOLEAMINE METABOLISM IN RATS AS SEQUELAE OF INTERGENERATIONAL PROTEIN MALNUTRITION. Maravene Miller, Rachelle Hasson* and Oscar Resnick. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The second filial (F_2) generation of protein deprived rats, whose dams were exposed to an 8% casein diet from their own conception (8-F_1 rats), showed a small-for-gestational-age syndrome at birth (>30% decreases in body weight) as a response to their dams' poor nutritional status. This severe in utero malnutrition caused the 8-F_2 pups to show significant elevations in brain serotonin (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), and tryptophan (TRP) at birth (Table below) compared to 25-F_2 rats whose dams were exposed to an adequate diet (25% casein) from their conception. After birth, the poor milk production of the 8-F_1 dams caused their pups to display the failure-to-thrive symptoms (>60% decreases in body weight) of infantile marasmus by day 11 of lactation. Also, these lactational deficits were responsible for the 16-190% increases in brain indoleamine metabolism of the 8-F_2 pups versus the 25-F_2 rats during lactation (days 5-21). Interestingly, both groups of F_2 pups had significantly higher values for their brain 5-HT, 5-HIAA, and TRP values at birth and other ages compared to F_1 rats (Exp. Neurol. 57: 142, 1977). These increases were 29-495% for the 8-F_2 vs 8-F_1 pups and 9-142% for the 25-F_2 vs 25-F_1 rats. These data indicate that the availability of TRP to the developing brains of F_2 offspring can be increased under conditions of either chronic lack or super abundance of protein in the F_1 maternal diet.

50.12 GANGLIOSIDES IN BRAIN REGIONS FROM THE DEVELOPING OFFSPRING OF CONTROL AND ETHANOL PUPS. M.J. Druse-Manteuffel, A.B. Noronha* B.G. Oden* and R.G. Haas* (SPON. J.H. Hofteig). Department of Biochemistry, Loyola University Medical School, Maywood, IL 60153.

The present study examined gangliosides (GA) in 6 brain regions - cerebral cortex (CX), cerebellum (CB), hippocampus (HIP), hypothalamus (HT), brain stem (BS) and corpus striatum (CS) - from the 10 to 24 d. offspring of control (C) and ethanol (E)-treated female rats. Female rats were pair-fed, using C or 6.6% (v/v) E liquid diets which contained 21% protein (Sub. Alc. Abuse/Misuse 2: 359, 1981), either on a chronic basis (prior to and during gestation) or on a short-term basis (3rd trimester of gestation). Offspring of 'chronic' mothers were given an intracerebral injection of [^{3}H]- or [^{14}C]-N-acetylmannosamine 16 h prior to sacrifice . GA were extracted (Life Sci. 3: 1227, 1964) and separated by thin layer chromatography (TLC) (Lipids 15: 1055, 1980). GA were quantitated by scanning resorcinol-treated TLC plates (BBA 24: 604, 1975). The relative distribution of radioactivity among brain region GA was determined by liquid scintillation counting.

We noted developmental changes in C rats in the proportion of several GA. 1) GQ_{1b} decreased in the BS & HIP. 2) GT_{1b} decreased and GM_1 increased in the CX. 3) GD_{1b} increased in the BS. Although GD_{1a} & GT_{1b} were major GA in each brain region examined, $GD_{1a}/GT_{1b} > 1$ in the CX, HIP & CS, while the ratio was ~ 1 in the HT, BS & CB.

In comparison to C pups, the offspring of chronic 'alcoholic' rats demonstrated several significant differences in the relative distribution of GA and associated radioactivity in the different brain regions. The most notable differences were the increased proportion of GT_{1b} in the CS & HIP and the decreased proportion of this GA in the CX of 10 d E pups. In addition, developing E pups demonstrated a consistent decrease in the proportion of GD_{1b} in the CS and a transient decrease of GD_{1a} in the HT. The relative synthesis of GD_{1b} was decreased in the HIP, CS and CB in 10 d E pups, whereas that of GT_{1b} was transiently increased in the HT, BS, CS & CB. Although all brain regions demonstrated GA abnormalities in the E pups, the greatest differences were found in the HIP & CS.

In contrast to the offspring of chronic 'alcoholic' rats, there were no differences in the distribution of brain region GA in the offspring of rats that were treated with E on a short-term basis. However, the latter group of animals demonstrated an increased concentration of total GA in the BS & HIP at 10 d.

This research was supported by grants from the USPHS - AA 03490- & The Schweppe Foundation. M.J. D.- M. is the recipient of a Schweppe Foundation Career Development Award.

50.13 GANGLIOSIDES IN AXOLEMMA FROM DEVELOPING CONTROL AND ETHANOL PUPS. J.M. Gnaedinger* and M.J. Druse-Manteuffel. Department of Biochemistry, Loyola Univ. School of Medicine, Maywood,IL 60153.

Female rats were pair-fed using either control(C) or 6.6% (v/v) ethanol(E) liquid diets, containing 21% protein (Sub. Alc.Abuse/Misuse 2:359,1981), on a chronic basis prior to conception and during gestation. Rats were injected intracerebrally with either [^{14}C]- or [^{3}H]-N-acetylmannosamine 16 hours prior to sacrifice. Axolemma fractions were isolated (J. Neurochem. 34:424,1980) from the brains of 20- to 34-day-old offspring of control and ethanol pups. Gangliosides were extracted (Life Sci.3:1227,1964) from axolemma and separated by thin layer chromatography (Lipids 15: 1055,1980). The relative distribution of radioactivity among axolemmal gangliosides was determined by liquid scintillation counting.

Although we did not observe statistical differences in the relative distribution of radioactivity among axolemmal gangliosides from C & E pups, we did observe developmental changes in the ganglioside patterns. At all ages, the largest proportion of radioactivity was found associated with gangliosides GD_{1a} & GT_{1b}. However, whereas GD_{1a} was most heavily labeled at 20 days (∿30%), GT_{1b} had the major proportion of radioactivity at 34 days (∿33%). (The percentage of radioactivity associated with GD_{1a} at 34 days was ∿21% and that of GT_{1b} at 20 days was ∿20%.) Several other developmentally-related trends were observed in the axolemma from both C & E offspring: 1) GQ_{1b} increased from ∿5% at 20 days to ∿10% at 27 and 34 days; 2) GM_1 decreased from ∿10% at 20 days to ∿5% at older ages. The low concentration of monosialogangliosides and the high ratio of GT_{1b}/GD_{1a} in axolemma from mature animals are distinct from the ganglioside patterns of CNS myelin and synaptic membranes , respectively.

An additional interesting observation was the increased yield of axolemma from 20-day-old E pups. Although the axolemma isolation procedure is not quantitative, this observation could be important in light of our previous report of increased CNS myelin (particularly the heavy subfraction) in young E pups (Drug Alc. Depend. 2: 421,1977).

This work was supported by grants from the USPHS (AA03490) and The Schweppe Foundation. M.J. Druse-Manteuffel is the recipient of a Schweppe Foundation Career Development Award.

50.14 MYELIN RECOVERY FROM FETAL AND PERINATAL ETHANOL EXPOSURE. F. E. Lancaster, S. Phillips* and R. C. Wiggins. Department of Biology, Texas Woman's University, Houston, Texas 77030 and Department of Anatomy and Neurobiology, University of Texas Medical School, Houston, Texas 77030.

Timed pregnant Long Evans rats received four dietary regimes from the fifth of gestation throughout lactation: ethanol (5.15%) liquid diet, pair fed liquid diet control, ad lib liquid control, and ad lib lab chow. Pups were cross fostered at birth such that each litter contained eight pups with two original pups and two pups from each other dietary group. Pups were sacrificed at 16, 21, 30 and 52 days of age. Whole brain myelin accumulation was determined quantitatively using preparative ultracentrifugation. Eye opening was delayed and birth weights were lower in the ethanol pups. Myelin accumulation, brain weights, and body weights were depressed in all pups cross fostered to ethanol treated dams during lactation. Pups born to ethanol treated dams also lagged slightly behind other pups when they were cross fostered to pair fed and normal dams. Recovery (after weaning) in body weights and myelin accumulation remained incomplete at 52 days of age.

50.15 REORGANIZATION OF ACETYLCHOLINESTERASE HISTOCHEMICAL STAINING FOLLOWING AN ENTORHINAL LESION IS ALTERED IN ADULT RATS EXPOSED TO ETHANOL IN UTERO. S.L. Dewey and J.R. West, Dept. of Anatomy, College of Medicine, University of Iowa, Iowa City, IA 52242.

Mental retardation is the most deleterious feature of the fetal alcohol syndrome (FAS). Although delays in development may account for some of the reported mental deficiency, it is now clear that prenatal ethanol exposure can result in permanently altered neuronal circuitry (West et al., Science, 211:857, 1981). Since it is important to determine if there are other long-lasting effects of heavy maternal ethanol consumption, we chose to investigate whether the stereotypic reorganization in the dentate gyrus following entorhinal lesions (axon sprouting) was also altered in FAS animals. Within a week following an entorhinal lesion in an adult rat there is an intensification of acetylcholinesterase (AChE) staining in the outer molecular layer of the dentate gyrus and a concomitant increase in the width (and decrease in staining) in the commissural/associational (C/A) zone. We examined this response to similar lesions on the offspring from dams exposed to a liquid diet (Bio-Serv, PR-11) containing 35% ethanol derived calories during days 1-21 of gestation (a developmental period roughly equivalent to only the first and second human trimesters). Litters were culled to eight pups each at birth and cross fostered to normal mothers. They were weaned at 22 days of age and allowed to survive to an age of at least 60 days before receiving an electrolytic unilateral entorhinal lesion. Following at least 30 days survival, their brains were processed for AChE histochemistry using the Geneser-Jensen and Blackstad's modification of the Koelle procedure. The expansion of the C/A zone was significantly greater in the rats exposed to ethanol in utero compared with either normal or pair-fed controls with similar lesions as adults ($p<0.05$). The outer molecular layer in the FAS rats was intensely stained but was narrower than those of rats in either of the lesioned control groups ($p<0.01$). The C/A zone on the non-lesioned side of the ethanol-exposed rats was not significantly different from controls, suggesting that the observed post-lesion differences were probably not due to developmental differences in afferent lamination. Rather, these results suggest that prenatal ethanol may alter the ability of the cholinergic fibers to sprout or their competitive interaction with other afferent systems. Supported by grants AA03884 and AA05523 from NIAAA to J.R.W.

50.16 Prenatal Ethanol Exposure and Rat Hippocampal Development. D.E. Barnes and D. Goldberg.* Neurohistology Laboratory, Veterans Administration Medical Center and Univ. of Fla. Sch. Med., Gainesville, FL, 32610.

Previous studies indicated that prenatal ethanol exposure during the period of rat neurogenesis resulted in altered hippocampal and cerebellar development. Although litter size, birth weight and postnatal weight gain were normal for ethanol-treated animals, the number of hippocampal pyramidal cells were significantly reduced (Dev. Br. Res. 1:33). Thymidine autoradiography was employed to further examine the results of prenatal ethanol exposure.

Pregnant Long-Evans rats were maintained on an ethanol containing liquid diet (35% ethanol-derived calories) during days 10-21 of the gestational period. Control groups were given lab chow and water ad libitum or pair fed the liquid diet with sucrose substituted isocalorically for ethanol. Two or more animals from each group were injected with tritiated thymidine (New England Nuclear, specific activity 20 Ci/mM, 5 mCi p.g.w) on one day of gestation (Days 10-22). At parturition, the offspring were culled to 8 males and fostered to additional control mothers. Offspring were sacrificed at sixty days of age, the brains removed, coded to prevent experimenter bias and embedded in paraffin. Sections were taken at four microns, dipped in Kodak NTB-2, exposed for sixty days and developed in Dektol. Cell counts were made in the dorsal hippocampus of matched sections. The total and labeled cells of regions CA1 and CA3 were enumerated as well as the area of the dentate gyrus and total granule cells.

The lab-chow and sucrose-fed animals were identical in their pattern of labeling. The labeling index (percentage of labeled neurons) of regions CA1 and CA3 was high on gestational day 14, declining gradually to day 19 and dropping sharply on day 20. The ethanol-treated offspring had an erratic pattern of labeling compared to controls and had a significantly ($P<.01$) greater labeling index on gestational days 18 and 19. These results indicate that prenatal ethanol exposure may alter the developmental sequence in addition to the reduction in the numbers of hippocampal neurons.

50.17 TAURINE DEPLETION WITH IMPAIRED CONE FUNCTION IN RHESUS MONKEYS. M. Neuringer*, J.A. Sturman, L. Feeney-Burns*, M.L. Klein*, and D.D. Denney* (SPON: L. Gronke). Oregon Regional Primate Center, Beaverton 97006, Oregon Health Sciences Univ., Portland 97201, and Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

Taurine is an essential nutrient for the cat. Its absence from the diet produces plasma and tissue taurine depletion, reduced electroretinograms (ERG's), and eventual photoreceptor degeneration. Human newborns are partially dependent on dietary sources of taurine: plasma taurine levels are reduced by half when taurine-rich breast milk is replaced by artificial infant formulas containing ≤ 1 μmol% taurine. It is not known whether human vulnerability to taurine depletion persists beyond the neonatal period, or whether taurine depletion leads to functional changes in the retina or nervous system.

We fed an artificial human infant formula containing ≤ 1 μmol% taurine to five rhesus monkeys from birth. Four rhesus infants received the same formula supplemented with 70 μmol% taurine, the level in rhesus milk, and another four received rhesus milk and a stock diet. Until one year of age, plasma taurine levels of the taurine-deprived group were reduced by half. At 10 months, the amplitudes of cone ERG's, evoked by flashes on an adapting background, were reduced 30-60%. Both A-wave and B-wave amplitudes were significantly smaller than in either control group. Rod-dominated ERG's were not affected. At 18 months of age, well past infancy in this species, taurine levels were still reduced by 35% in plasma and by 50% in biopsied muscle tissue. Cone ERG amplitudes were no longer significantly reduced.

In adult rhesus monkeys, a taurine-free semipurified diet produced no plasma or tissue taurine depletion and no ERG deficit, even when fed for several years. However, taurine depletion was produced by a diet which, in addition to lacking taurine, was low in total protein and therefore in the sulfur-containing amino acid precursors for taurine synthesis. Plasma taurine levels of adults fed this diet were reduced 75-80% and their cone ERG amplitudes were reduced 60-70%. Ophthalmoscopic examination did not detect changes related to taurine depletion. Electron microscopy revealed abnormal swelling of cone pedicles.

These data suggest that: 1. Functionally significant taurine deficiency occurs in rhesus monkeys; 2. The deficiency is characterized by specific impairment of cone function; 3. Vulnerability to dietary taurine depletion persists at least throughout infancy; 4. Unlike cats, which show subnormal ERG's only when plasma taurine levels fall below 5% of normal, monkeys show ERG deficits with plasma depletion of only 50%, the same degree of depletion seen in human newborns fed commercial infant formulas.

50.18 IN UTERO EXPOSURE TO LEAD ACETATE IN THE RAT: ASSOCIATED IMPAIRMENT OF CEREBROSPINAL FLUID DYNAMICS IN EARLY POST-NATAL DEVELOPMENT. J.D. Mann, J.D. Charlton*, N.E. Pederson* and R.N. Johnson. Dept. of Neurology and Biomedical Engineering, University of North Carolina Sch. of Med., Chapel Hill, NC 27514

We have previously demonstrated delayed maturation of the cerebrospinal fluid (CSF) flow system in rabbits exposed to lead during the neonatal period (Mann et al., Soc. Neurosci. Abstr. 6:829, 1980). In the present study we tested the hypothesis that in utero exposure to lead is associated with impaired CSF dynamics in early post-natal development. Pregnant albino rats were given either lead acetate (30 mg/kg) or sodium acetate by tail vein on day 16 of gestation. Litter size was reduced to six at the time of delivery. CSF dynamics were tested at 40 or 70 post-natal days in different groups using a previously described technique, (Mann et al., Ann. Neurol. 3:156-165, 1978). Under halothane anesthesia (1% in 0_2), artificial CSF was infused into the cisternal subarachnoid space at a series of constant rates until steady state intracranial pressure was achieved for each infusion rate. A mathematical model of CSF dynamics was used in data analysis for determination of resistance to absorption of CSF, intracranial compliance, and rate of CSF formation. Brain water content was determined at the time of sacrifice. Brain and blood lead content was measured by atomic absorption spectroscopy.

The incidence of ventricular enlargement was 15% in the lead exposed animals compared to 0.8% in controls. Brain water content, and brain and blood lead levels were not different between lead exposed and control groups at either age tested. Resting intracranial pressure was also unaffected by prior exposure to lead. At 40 days of age, maximum resistance to absorption of CSF was increased by 59.8 ± 15.8% (S.E.) in lead exposed animals compared to controls ($p < .02$). Rate of CSF formation at resting pressure was reduced by 29.8 ± 8% in lead exposed animals ($p < .05$). In 70 day old rats there was no significant difference in CSF dynamics when control and lead exposed animals were compared using halothane anesthesia. However, when ketamine hydrochloride (15 mg/kg) was added to the anesthetic regimen, atypical changes occurred in lead exposed animals reflecting deterioration in intracranial pressure regulation.

Hence, in utero exposure to lead on day 16 of gestation in the rat is associated with an increased incidence of ventricular enlargement and abnormal CSF dynamics. The changes in dynamics noted at 40 days are much less evident by 70 days of age.

50.19 DEVELOPMENT OF THE VISUAL EVOKED RESPONSE IN RATS CHRONICALLY EXPOSED TO A HIGH VOLTAGE 60-HZ ELECTRIC FIELD. R. A. Jaffe, R. D. Phillips, C. A. Lopresti* and D. B. Carr*, Neuroscience Group, Biology Dept. and Energy Systems Dept., Battelle Memorial Institute, Pacific Northwest Laboratory, Richland, WA 99352.

Electric fields approximating those generated in the vicinity of some high voltage ac power transmission lines have been shown to affect a variety of nervous system functions in the adult rat including synaptic transmission (Jaffe et al., Bioelectromagnetics 1:131, 1980) and circadian rhythms (Wilson et al., Bioelectromagnetics 2:371, 1981). Persinger et al. (Percept. Mot. Skills 36:1131, 1973) demonstrated that perinatal exposure to an electromagnetic field is capable of subsequently affecting normal rat behavior patterns. The visual evoked response (VER) has been used successfully to detect the subtle effects of various treatments including perinatal malnutrition and low level maternal lead consumption. Thus, the VER seemed well suited for detecting the possibly subtle effects of 60-Hz electric field exposure on the developing rat nervous system.

Two independent series of experiments were performed on 114 male Sprague-Dawley derived albino rat pups, representing 61 litters for experiment 1, and 53 litters for experiment 2. Animals were exposed for 20 hr/day from conception to testing (post-natal days 11-20) to a vertical 65 kV/m, 60-Hz electric field. Sham-exposed animals were housed under identical conditions without the electric field. Each rat pup was anesthetized with urethan (1.1 mg/g, ip) and mounted in a modified sterotoxic frame. Rectal temperature was maintained between 37-39°C. Recordings of the VER were obtained using a small silver ball electrode placed epidurally over the visual cortex. The reference electrode was located in the region of the nasal sinus, ipsilateral to the active electrode. Individual recording sessions began ∿25 min after anesthetic administration and 1-5 hrs after the final electric field or sham exposure. Visual stimuli consisted of 10 μsec light flashes (Grass PS-22, intensity = 16, distance = 15 cm) delivered at 0.2 Hz. Averaged VERs were obtained using a signal-averaging computer with the digitized, averaged response stored on magnetic tape. An averaged VER consisted of 64 responses sampled at 1000 Hz (1 msec/point) for 1024 msec, starting 50 msec before the flash presentation. Three such sets of averaged responses were obtained from each animal. Power spectral analysis (FFT) was performed on the tapered (split cosine-bell window) averaged VER.

The expected age-related changes were clearly evident; however, a detailed analysis of VER component latencies, peak-to-peak amplitude and power spectra failed to reveal any consistent, statistically significant effect of 60-Hz electric field exposure.
This study was supported by the U.S. Department of Energy under contract number DE-AC06-76RLO-1830.

50.20 EFFECTS OF PRENATAL CANNABINOID EXPOSURE ON BRAIN AMINES AND TESTIS FUNCTION IN MALE MICE. S. Dalterio,* R. Steger,* A. Bartke* and D. Mayfield.* (SPON: K. Blum) Depts. of Pharmacology, Anatomy & Obstetrics/Gynecology, University of Texas Health Science Center at San Antonio, San Antonio, Texas, 78284.

Marihuana and its purified constituents have been shown to influence developmental processes in laboratory animals. The present experiments were conducted to further characterize the consequences of prenatal exposure to the major psychoactive, Δ^9-tetrahydrocannabinol (THC), or the non-psychoactives, cannabinol (CBN) or cannabidiol (CBD), to determine whether critical time periods exist for these effects and to determine their mechanisms of action. Pregnant female mice received a single oral dose (50 mg/kg) of either THC, CBN or CBD or sesame oil, 1-4 days prior to parturition. Hypothalamic and whole brain concentrations of norepinephrine (NE), dopamine (DA), serotonin (5-HT) and its metabolite 5-HIAA were measured using HPLC and electrochemical determinations in adults 2 days post-castration. Maternal exposure to CBD 2 or 4 days before parturition significantly ($P<0.01$) depressed (∿40%) NE levels in whole brain in offspring, while CBN exposure on day 1 or 3 reduced whole brain NE by 44%. Hypothalamic NE was depressed 47% only in animals exposed to CBN the day prior to birth. A marked increase ($P<0.01$) in 5-HT content was observed in hypothalamus (70% in CBD and 87% in CBN-treated animals) and in whole brain (66% in CBD and 94% in CBN-treated animals) regardless of exposure day. Hypothalamic 5-HIAA was increased 40% in CBN and 36% in CBD-exposed animals, and in whole brain 42% and 45% by CBN and CBD, respectively. Exposure to CBN and CBD also reduced whole brain DA levels by 35% and 38%, respectively, while hypothalamic DA was reduced significantly (46%) only in those animals exposed to CBN 2 days before birth. Concentrations of brain amines were the same in oil-treated (control) mice, regardless of prenatal treatment day. Seminal vesicles weights were increased by CBD exposure at least 3 days before birth, but were reduced by CBN at these times (308 ± 12/CBD; 164 ± 16/CBN vs 258 ± 13/oil mg; $P<0.05$). Testis weights were not affected, but testicular testosterone levels were reduced after exposure to CBN at 3 or more days before birth (69 ± 17 vs 138 ± 22 ng/ml, $P<0.05$). In this study, a single prenatal THC exposure had no effect. However, in our previous reports perinatal THC exposure affected body weight regulation, pituitary-gonadal function, responsivity of vas deferens to NE in vitro and adult sexual behavior. Therefore, it is evident that (1) both psychoactive and non-psychoactive cannabinoids influence developmental processes; (2) time and/or duration of exposure may be a critical factor; (3) alterations in brain amines may be related to the disruption of reproductive function produced by perinatal cannabinoid exposure. (Supported by NIDA grant DA 02342.)

50.21 EFFECTS OF CAFFEINE ON BEHAVIORAL STATE DEVELOPMENT IN THE NEWBORN RABBIT, L.P. Zeidner*, V.H. Denenberg, E.B. Thoman, P. Kramer*, J. Rowe*, A. Philipps*, J. Raye*. Dept. of Biobehavioral Science and Dept. of Neonatology, University of Connecticut, Storrs and Farmington, CT 06268.

Recent studies in our laboratory (Denenberg et al.,1982 ; Thoman et al., unpublished) have indicated that theophylline, a central respiratory stimulant in common therapeutic usage for control of apnea in premature infants, results in prolonged behavioral state disturbance in both the newborn rabbit and the premature infant. Since the infant rabbit, unlike the human infant, does not convert theophylline to caffeine, the question arises as to the generalizability of these findings to other related methylxanthines. That was the purpose of this study. On Day 1 of life (Day 0 = birth), the sleep-wake behavioral states of rabbits were measured for 2 hr., after which half the animals received 10mg/kg of caffeine by intubation (N=12), whereas the remainder received normal saline (N=12). Behavioral states were then measured for 2 hr. periods on Days 2,3,5,7,15,20,30, and 40. Caffeine sharply reduced active sleep starting on Day 2 and continuing through Day 40. The development of quiet sleep was delayed for 10 days in the drug-treated group. Paralleling the loss of active sleep was a major increase in wake between Days 2 and 40. The drug also affected the intermediate states of sleep-wake transition and active-quiet sleep transition. The data closely parallel our previous results with theophylline and show even more prolonged effects, raising further questions about the therapeutic safety of the methylxanthines in the young organism and the implications of dietary intake of caffeine by the gestating and lactating mother.

50.PO BRAIN DEVELOPMENT AND LITTER SIZE. Stephen Zamenhof and Edith van Marthens*. Mental Retardation Research Center and Brain Research Institute, UCLA School of Medicine, Los Angeles, California 90024.

In the previous work we have demonstrated that prenatal operative restriction of litter size (number in the litter) leads to newborns with increased values of brain parameters. (van Marthens and Zamenhof, Exper. Neurol. 23, 214, 1969).

The present work is a study of the effect of natural litter size (range 2 to 17) on the brain parameters of individual newborns, as well as on the "brain mass" (total of brain weights in a litter). The study was performed on 2725 newborn rats. It was found that brain weight, brain DNA content (index of cell number) and brain protein content (potential for postnatal brain development) were significantly negatively correlated with litter size. ($r = -0.382$; $p < 0.005$; $r = -0.127$, $0.01 < p < 0.025$; $r = -0.311$, $p < 0.0005$, respectively). The highest brain weights in each litter (means for all litters of the same litter size) were also significantly negatively correlated with litter size ($r = -0.296$; $p < 0.0005$). The ratio of brain protein/brain DNA (index of brain cell size) also showed such a correlation ($r = -0.226$; $p < 0.001$). However, the ratio of brain weight/body weight showed a minimum at the mean litter size (9.45; optimum for this strain?) and increased towards lower and towards higher litter sizes. The total neonatal brain masses per litter, the ratios of brain mass/maternal weight at conception, and the ratios of brain mass/average maternal food consumption per 24 hrs, increased linearly with litter size. It is concluded that: 1. Neonatal brain weight, brain cell number, brain protein and brain cell size are the higher, the smaller is the natural litter size. 2. The highest values of neonatal brain weights in each litter are also more favorable when the litter sizes are low. 3. However, the total brain mass produced per litter, and the brain mass produced per food consumed, are more favorable when the litter size is high. (Supported by NIH Grant AG-00162).

51.1 GROWTH FROM REGENERATING GOLDFISH RETINAL CULTURES IN THE ABSENCE OF SERUM OR HORMONAL SUPPLEMENTS: TISSUE EXTRACT EFFECTS. James E. Johnson and James E. Turner, Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

Goldfish retinal cultures have been established as a model for studies of optic nerve regeneration in vitro. Like other neuronal culture preparations, explanted or dissociated retina cultures have required serum or hormonal substitutes for survival and minimal neurite outgrowth in vitro. To determine the minimal requirements for regeneration in culture and to examine the effect of putative endogenous neurotrophic factors from local and target tissues, cultures were prepared in media without serum or defined hormonal supplements. Retinas chopped into 500 μ^2 explants were grown on a polyornithine substrate in Leibovitz (L-15) media with 20 mM HEPES and gentomycin sulfate. Media were supplemented further with either 1) 0.6% methyl cellulose (Dow), 2) 10% fetal calf serum (FCS) (GIBCO) or 3) cellulose and FCS. A dissociated cell preparation was developed to determine the minimal conditions for retinal ganglion cell survival and outgrowth. Retinas treated with 0.1% hyaluronidase and dissociated without serum in 0.1% Pronase and 0.1% DNase were grown under identical conditions. Results indicate that explants taken from retinas 14 days after a prior optic nerve crush are capable of survival and minimal neurite outgrowth in the absence of serum or defined hormonal supplements when grown with methyl cellulose or when dishes are preplated with methyl cellulose. Cultures grown with serum and cellulose showed a 2.5 x increase in the length of outgrowth over cellulose alone. A 2.5 x increase is also seen when explants are grown in media supplemented with cellulose and a crude extract prepared from the target optic tectum. Extracts taken from other brain regions with equal protein concentrations showed only a 1.5 X increase in length. Results from dissociated retinal cultures indicate that individual ganglion cells, unlike the intact explant, do not regenerate outgrowth in the absence of serum or hormonal supplements. Taken together these results suggest a possible role of local endogenous neurotrophic factors in a model of successful central nervous system regeneration.

Supported by NIH Grant No. NS 12070. J.E.T. is also a recipient of NIH Research Career Development Award NS 00338.

51.2 ABSENCE OF STABLE RETINA-MUSCLE SYNAPSES IS RELATED TO ABSENCE OF ACETYLCHOLINE RECEPTOR AGGREGATION FACTOR IN RETINA NEURONS. Jeffrey M. Thompson & Stanley I. Rapoport. Lab. of Neurosciences, Gerontology Res. Ctr. Natl. Inst. on Aging, NIH, Balto. MD 21224.

Chick embryo retina neurons are capable of forming synapses on rat muscle cells in vitro (Puro et al., PNAS, 74:4977-4981, 1977; Ruffolo et al., PNAS, 75: 2281-2285, 1978). These inappropriate synapses are transient and terminate within 7 days in culture. In contrast, chick embryo spinal cord neurons form stable or long-lived synapses on rat muscle cells which remain for over two weeks (Ruffolo et al., PNAS, 75: 2281-2285, 1978; Thompson et al., Develop. Neurosci., in press, 1982). Spinal cord neurons possess a factor which causes aggregation of muscle acetylcholine receptors (AChR) into high density clusters (Podleski et al., PNAS, 75: 2035-2039, 1978; Jessell et al., PNAS, 76: 5397-5401, 1979; Schaffner & Daniels, J. Neurosci., in press, 1982). This study investigated whether retina neurons also possess this factor.

Neural conditioned medium and neuron-muscle cocultures using chick embryo retina or spinal cord neurons were examined for their effect on induction of AChR clusters. Conditioned medium (CM) was prepared by collecting medium from cultures of retina neurons (20 x 10^6 cells/35 mm dish) or spinal cord neurons (5 x 10^6 cells/35 mm dish) on days 2 and 3 after plating, and added to rat myotube cultures (7-10 days after plating) for 24 hr. Cocultures of neurons and muscles were prepared by plating 20 x 10^6 retinal neurons from 8-day chick embryos or 5 x 10^6 spinal cord neurons from 6-day chick embryos on rat myotube cultures. AChR clusters were determined after 24 hr in conditioned medium treatments, and after 1, 3 and 5 days in cocultures. AChR clusters were visualized with tetramethylrhodamine α-bungarotoxin (gift of Z. Vogel and M. Daniels). 46-138 myotubes were counted per dish. The number of clusters in CM treated myotube cultures was: control - 0.52 ± 0.04 clusters (mean ± S.E.M.); retina CM - 0.49 ± 0.03 clusters; spinal cord CM - 0.74 ± 0.04 clusters (N = 9 experiments). The number of clusters in cocultures was: Day 1: control - 0.59 ± .20; retina - 0.53 ± .13; spinal cord - 1.41 ± .06; Day 3: control - 0.66 ± .18; retina - 0.88 ± .28; spinal cord - 3.10 ± .69; Day 5: control - 0.40 ± .15; retina - 0.59 ± .06; spinal cord - 3.27 ± .06 (N = 3 experiments). The increase in clusters using spinal cord CM or in spinal cord cocultures was significant ($p < 0.01$).

The results indicate that while spinal cord neurons possess a factor which enhances clusters of AChR on culture myotubes, retina neurons do not possess such a factor. The results were similar in either CM of cocultures, although cocultures were more dramatic. The absence of an aggregating factor in retina may relate to the lack of stabilization of retina-muscle synapses, as opposed to the stabilization of spinal-cord muscle synapses.

51.3 RESOLUTION OF THE DENERVATION-DEPENDENT PHOSPHOPOLYPEPTIDE IN RAT SKELETAL MUSCLE CYTOSOL. J.A. McLane, S.P. Squinto* and I.R. Held. Neuroscience Research Laboratory, VA Hospital, Hines, IL 60141 and Loyola University Medical Center, Maywood, IL 60153.

Motor neurons influence the muscle cells which they innervate not only by propagation of nerve impulses, but also through trophic actions. Fast axoplasmic transport of substances from their sites of synthesis in neuronal perikarya to the neuronal endings provides a credible mechanism for trophic regulation of muscle. We have shown that within hours after denervation there is an increase in the in vitro phosphorylation of an endogenous cytosolic polypeptide(s) which is temporally correlated with the length of the distal nerve stump remaining attached to the muscle (Trans. Am. Soc. Neurochem. 12:230, 1981). A single major ^{32}P-labeled cytosolic protein has been resolved from in vitro assay mixtures by SDS polyacrylamide gel electrophoresis on cylindrical rods and by exclusion chromatography on Sephadex G-150 or a Waters I-125 HPLC column (Soc. Neurosci. Abstr. 7:931, 1981). We have obtained greater resolution of the cytosolic components of the in vitro assay mixture on SDS slab gels containing a 5-15% acrylamide gradient. With this gel system 45 Coomassie blue staining peptides are reproducibly resolved with ten ^{32}P-labeled polypeptides easily detectable by autoradiography on x-ray film. The major ^{32}P-labeled polypeptide has a relative molecular weight in this gel system of 56K and contains greater than 80% of the total radioactivity. Other, more weakly radiolabeled polypeptides of interest are found to have molecular weights of 47K, 45K and 18K. When radiolabeled cytosol samples from denervated muscles showing maximal increases in cytosolic phosphorylating activity are resolved on slab gels, an increased phosphorylation is found in the major phosphoprotein. Addition of cyclic AMP-dependent protein kinase catalytic subunit to the in vitro assay results in a marked increase in radiolabeling of many polypeptides, especially in the area of the 47K, 45K and 18K proteins, but only a slight increase in $^{32}PO_4$ incorporation into the 56K polypeptide. Addition of 10^{-7} to 10^{-5}M cyclic AMP to in vitro assays results in only a slight increase in total $^{32}PO_4$ incorporation, but when resolved on the SDS slab gel the radiolabeling of several minor phosphopolypeptides is increased and the labeling of the denervation-dependent, 56K phosphoprotein is dramatically reduced. These results and preliminary studies utilizing 8-azidoadenosine 3':5'-cyclic monophosphate, a photoaffinity analogue of cyclic AMP suggest that the 56K phosphoprotein may be the regulatory subunit of the type II cyclic AMP-dependent protein kinase.

Supported by the Medical Research Service of the Veterans Administration, BRSG funds from Loyola University and NINCDS Grant NS-11755.

51.4 NEWLY INSERTED ACH RECEPTORS AT THE NEUROMUSCULAR JUNCTION HAVE A FAST RATE OF DEGRADATION. E.F. Stanley, D.B. Drachman. Johns Hopkins University, School of Medicine, Baltimore, Maryland.

It is generally believed that acetylcholine receptors (AChRs) at the intact neuromuscular junction constitute a homogeneous population with a single slow turnover rate. However, different studies have reported AChR half lives ranging from 6 days (Berg and Hall, 1975) to 13 days (Linden and Fambrough, 1979). We have therefore tested the hypothesis that the turnover rate of junctional AChRs may not be uniform, by comparing the degradation rates of "new" (< 6 days) and "old" (> 6 days) AChRs.

AChRs of mouse diaphragms were labeled in vivo with ^{125}I-α-BuTx, and the loss of radioactivity from the diaphragms of groups of mice killed serially at 2 day intervals for up to 12 days was used to determine AChR degradation rates. "New" AChRs or "old" AChRs were labeled in separate sets of mice: "New" AChRs were labeled by first blocking existing AChRs with non-radioactive α-BuTx, and 6 days later labeling with ^{125}I-α-BuTx. "Old" AChRs were labeled with ^{125}I-α-BuTx on day 0, and their rate of loss was followed from day 6 on.

"New" AChRs were degraded with a half life of 3.6 ± 0.4 days (4 experiments) while "old" AChRs had a much slower half life of 10.0 ± 0.8 days (3 experiments).

Thus, AChRs at the intact neuromuscular junction do not constitute a single homogeneous population. The receptors that have been newly inserted into the membrane are degraded at a faster rate than those that have survived for longer periods. The co-existence of AChRs with slow and fast degradation rates raises two intriguing possibilities: Either there are two or more separable pools of AChRs with intrinsically different degradation rates, or the transition from a fast degradation rate to a slow degradation rate reflects the stabilization of AChRs on the postsynaptic membrane.

51.5 TROPHIC REGULATION OF MUSCLE ENZYME, Ca++ AND cGMP CONTENT BY NERVE. C. L. Weill. Depts. of Neurology and Anatomy, Louisiana State Univ. Med. Ctr., New Orleans, LA 70112.

The trophic phenomena associated with nerve-muscle interactions have been extensively studied, but their molecular foundations have yet to be determined. I present here studies designed to describe in detail and determine the molecular foundations for the trophic effects of nerve on muscle during development.

The specific activities of acetylcholinesterase (AChE), creatine kinase (CK), aldolase (ALD) and lactate dehydrogenase (LDH) were determined on homogenates of cultured chick muscle maintained in the presence and absence of 50% spinal cord-conditioned medium (SC-CM) for 9 days. Relative to controls, the activities of CK, ALD and LDH were 1.3, 1.5 and 2.1-fold higher respectively on day one. By day 5 the activities had declined to 64, 35 and 52% of controls respectively. The mean reduction in activity from day 1 to day 5 was 2.8-fold for CK, 1.5-fold for LDH and 2.5-fold for ALD. In contrast AChE was 20% lower than controls on day 1, and 1.24-fold higher on day 5. Over days 1-5 cellular AChE activity displayed an increase of 1.5-fold. Over 9 days there was no significant difference in total cellular protein of controls relative to SC-CM treated cultures.

The rate of secretion of each enzyme was also measured over 9 days on the same cultures. The rates qualitatively reflected the total cellular content; for CK, ALD and LDH they declined over 9 days while the rate for AChE increased over the same period. The secretion rate for total protein displayed a 1.8-fold pulse increase of 24-36 hr duration on 5 relative to controls.

Calcium influx rates were measured on sister cultures over 8-9 days and found to undergo a mean increase from day 1-8 of 3.8 $\pm$ 1.3-fold. The day 1 values were 58 $\pm$ 14% of controls, while the day 8-9 values were 3.3-fold greater. Total Ca++ uptake was comparable to controls through day 4-5 after which it declined to 38% of control by day 8-9.

The cGMP content of sister cultures was determined by RIA. Control cultures displayed little change in cGMP content over 7 days in culture. SC-CM treated cultures displayed similar levels except during a 24-36 hr period around day 5 when the cGMP rose 2.35 $\pm$ 0.49 (m $\pm$ S.E.)-fold. By day 6 it had declined and remained at control levels.

In conclusion, cultured chick spinal cord neurons secrete factors that alter several functions of cultured muscle; a) enzyme content was altered differentially, CK, ALD and LDH down regulated and AChE up regulated, b) calcium influx was depressed and then increased and c) temporally coincident with the increase in calcium influx rate and a pulse increase in total protein secretion, cellular cGMP displayed a pulse increase of similar duration. The causal relationships between these parameters is under study.

51.6 AN EXTRACELLULAR MATRIX FACTOR THAT ORGANIZES ACETYLCHOLINE RECEPTORS. Earl W. Godfrey*, Ralph M. Nitkin, Bruce G. Wallace and U.J. McMahan, Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

An extracellular matrix preparation (ECM) from the electric organ of Torpedo californica is rich in a factor(s) that organizes the acetylcholine receptors (AChRs) on cultured chick myotubes into distinct clusters (Rubin and McMahan, Soc. Neurosci. Abstr. 6:330, 1980). This factor is of particular interest because the clustering of AChRs at regenerating neuromuscular junctions in vivo may also be directed by components of extracellular matrix (Burden et al., J. Cell Biol. 82:412, 1979). The studies reported here are aimed at identifying the Torpedo AChR organizing factor and learning whether there is a similar molecule at the neuromuscular junction. We have solubilized the Torpedo factor by treating ECM with high salt, have made an antiserum against the high salt extract that binds both to the Torpedo factor and to extracellular matrix at frog neuromuscular junctions, and are now purifying the factor with a view to making a specific antiserum.

The factor influences the organization of AChRs in the following way. As the amount of extract added to a culture is increased the number of receptor clusters per myotube increases and plateaus at a level 3- to 10-fold higher than in control cultures. The response is maximum within 16 hr. The factor causes AChRs in the muscle cell plasma membrane to migrate laterally into clusters; it does not cause an increase in the number of AChRs on the cell surface.

Antiserum was made by injecting high salt extract of ECM into rabbits. The antiserum bound to the factor and blocked its active site. Frog cutaneous pectoris muscles from which nerves and muscle cells had been removed were incubated in the same antiserum and binding sites were examined by light and electron microscopy after immunocytochemical staining. The extracellular matrix of the muscle stained and the stain was concentrated at the former sites of neuromuscular junctions.

To date we have purified the factor about 1000 fold by a sequence of gel filtration, ion exchange chromatography on DEAE-cellulose, and affinity chromatography using Concanavalin A-Sepharose. The activity elutes as an acidic glycoprotein with a broad molecular weight distribution of 60 to 100 kd and has an isoelectric point of pH 4 to 5 as determined by isoelectric focusing.

This research was funded by grants from the Muscular Dystrophy Association and NIH (NS 16440-02) and by postdoctoral fellowships from MDA to E.W.G. and R.M.N.

51.7 AXONS WITH MAJOR TROPHIC DEPENDENCIES ON AXONAL TRANSPORT OR AXON-SHEATH GLIA SHOW DIFFERENCES IN CONCENTRATION OF AXOPLASMIC MEMBRANOUS ORGANELLES. K.R. Seshan*, G.D. Bittner, T.A. Viancour, and M.A. Raymond*. Zoology , Univ. Texas, Austin, TX 78712.

Axoplasmic transport of proteins and other substances synthesized in neuronal somata appears to be a universal phenomenon in nervous systems, and an accepted mechanism for the trophic support of axonal chemical synapses and plasma membranes. Axon-sheath glia also contribute to axonal maintenance in at least some species. Smooth endoplasmic reticulum, micro- and neuro-tubules are the apparent morphological substrates for axoplasmic transport. Exo- and endo-cytotic vesicles are implicated in glia to axon transport. Axoplasmic concentrations and distributions of these membranous organelles should therefore reflect an axon's relative dependence on a particular trophic mechanism.

To investigate this possibility, we have examined two identified axons reported to have different trophic dependencies (see Bittner, Comp. Biochem. Physiol., 68A, 299-306 (1981)). The medial and lateral giant fiber systems of crayfish mediate complementary tail-flip escape behaviors, and appear to make efferent synapses of essentially equivalent number, strength and type. The medial giant axon (MGA) is a single, continuous fiber which terminates in the 6th abdominal ganglion at least 50mm (in adults) from its cell body located in the supraesophogeal ganglion. The lateral giant fiber, however, arises from segmental neurons whose giant axons (LGAs) form septate, electrical junctions which permit uninterrupted spike conduction. In adults, an LGA is typically no more than 5mm from its cell body. Isolated abdominal segments of MGAs survive physiologically and morphologically intact for months, whereas equivalent segments of LGAs degenerate completely within a few days. These and other data suggest that an MGA derives substantial trophic support from its sheath glia, whereas an LGA depends primarily on axoplasmic transport of substances from its cell body.

We have examined cross-sections of LGAs and MGAs in the abdominal nerve cord of P. clarkii. Viewed with a light microscope, basic dyes such as toluidine blue consistently stain LGA axoplasm more densely than MGA axoplasm. Ultrastructurally, the concentration of neurotubules in LGAs is twice that of MGAs, and LGAs contain a much more extensive smooth endoplasmic reticulum. In both axons, smooth endoplasmic reticulum is densest near the axon membrane. Relative concentrations and distributions of vesicles are being determined at the time of this abstract. However, our initial data are consistent with the hypothesis that relative concentrations and distributions of intracellular organelles can reflect different trophic dependencies.

51.8 BIOCHEMICAL SEPARATION OF TARGET- AND SUBSTRATE-MEDIATED RESPONSES OF DEVELOPING SPINAL CORD EXPLANTS. W. L. Muhlach* and E. D. Pollack (SPON: R. Ruth). Inst. Study Develop. Disabil., University of Illinois, Chicago, IL 60608.

The quantity, rate and direction of neuritic outgrowth from developing tadpole spinal cord explants have been shown to be under stage-specific control of their developmental target, i.e. limb mesenchyme (Pollack and Muhlach, Dev. Biol.,'81). Biochemical assays were performed on tissue grown under varying experimental conditions to further elucidate the mechanisms involved in neural tissue response to target influence. The protein content (standardized to DNA) of stage V spinal cord tissue (Taylor-Kollros stages), co-cultured with target tissue (stage V limb) on collagen substrate, was dramatically increased by 52% over control levels (spinal cord cultured alone). Cultures of spinal cord on poly-DL-lysine (PLYS) substrate resulted in a 32% increase in protein content in the absence of target and a 41% increase when target was present. These protein levels correspond to the increases found in neuritic outgrowth under these same conditions. Choline acetyltransferase (CAT) activity was similarly increased over control levels in the presence of target on collagen (29.6%) and on PLYS (33.9%) but was only slightly elevated on PLYS in the absence of target (9.7%). Cultures of spinal cord with skeletal muscle of older tadpoles (st. X-XII) produced a 24.5% increase in protein on both collagen and PLYS but no increase in CAT activity on either substrate. The presence of limb tissue also increased the amount of DNA/culture (by 16.6%) over controls. This increase relates to the motor neuron survival influences of the limb (Pollack, Neurosci. Abstr.,'82). Since the PLYS substrate can mimic the effect of target tissue on protein synthesis by the cord explant, it appears that the target's action in this instance may be a substrate mediated process. However, PLYS alone does not mimic the effect of target on increased CAT activity in the spinal cord tissue. A similar situation occurs in the effect of muscle on protein content (increased), but not on CAT activity of the spinal cord. Thus, it seems that there are several cellular components of the spinal cord response to target tissue: 1) a substrate associated mechanism, probably involving neurite-substratum adhesion, that results in increased protein production and corresponding enhanced neuritic outgrowth; 2) stimulation of functional maturation and other metabolic machinery as those involved in neurite growth rates (Muhlach and Pollack, Dev. Brain Res.,'82) or CAT activity that are not directly associated with the substrate; 3) increased survival of spinal cord cells. (Supported by NIH grant NS 13814.)

51.9 SEPTAL LESIONS INCREASE CHELATABLE ZINC IN MOSSY-FIBER REGION. G.R. Stewart*, F.W. Gage, G.A. Howell and C.J. Frederickson
Chemistry of Behavior Program, Texas Christian University, Fort Worth, Texas, 76129, and Laboratory for Neurobiology, Univ. Texas at Dallas, Richardson, Tx. 75080.

A unique pool of chelatable zinc associated with the hippocampal mossy fibers has been demonstrated repeatedly, but the neurobiological function of that zinc remains unknown. One approach to the problem of function is to determine the responsiveness of the zinc pool to manipulations of hippocampal tissue. In the present work, we have partially deafferented the hippocampus (by septal lesions) and searched for post-lesion changes in the concentration of mossy-fiber-related zinc.

Twenty-five adult, male Sprague-Dawley rats received bilateral medial septum ablations and were sacrificed from 3 to 28 days thereafter for hippocampal zinc assays; 8 additional animals served as unoperated controls. Zinc was assayed by the zinc dithizonate densitometric method of Frederickson et al. (Exp. Neurol., 1981, 73:812). Briefly, dithizone was injected i.p., 15 min were allowed for the formation of the zinc dithizonate chelate in the hippocampus, and the animal was then sacrificed, the brain removed and cut frozen (100 μm), and the density of zinc dithizonate stain in hippocampal sections measured spectrophotometrically in the light microscope. For statistical analysis, all measurements from the mid-hilar region of a single, standard section of dorsal hippocampus were averaged together for each animal, yielding a single value for the intensity of zinc dithizonate staining.

Septal lesions caused a transient increase in zinc dithizonate in the hilus which was maximal (33% increase over control) at 10 days post-lesion and was virtually gone by 21-28 days. Average optical density of zinc dithizonate in the hilus was: 0.373 for controls (n=8), 0.445 at 3 days post-lesion (n=4), 0.498 at 10 days (n=6), 0.453 at 16 days (n=3), 0.392 at 21 days (n=6), and 0.418 at 28 days (n=6) ($p < .025$, 1-way ANOVA; 10-day group exceeds control at $p < .025$ by Dunnett's t statistic).

Whether the observed increase in zinc dithizonate staining reflects an increase in total zinc or an increase in the proportion of zinc which can be chelated is under examination. In either case, the results indicate that mossy-fiber zinc is a labile pool which is dynamically responsive to alterations in hippocampal innervation. Of particular interest is that the time course of the observed change in zinc parallels that of the sympathetic ingrowth occuring after medial septal lesions. Perhaps zinc metalloenzymes are directly involved in regulation of trophic phenomena in the hippocampus, as has been suggested by Crutcher and Davis (Soc. Neurosci. Abs., 1980,6:172.)

51.10 DEVELOPMENTAL ALTERATIONS IN THE PUTAMEN OF FETAL RABBITS DUE TO CHRONIC RESERPINE ADMINISTRATION. V. M. Tennyson, M. Schoenebeck* and P. Gershon*. Depts. of Anatomy & Cell Biology and Pathology (Neuropathology), Columbia Univ., College of Physicians and Surgeons, New York, N.Y. 10032.

During development, nigrostriatal neuroblasts and axons exhibit dopamine (DA) induced fluorescence before their axons have extended beyond the vicinity of the cell bodies. In order to investigate possible developmental effects of growing nigrostriatal axons on the basal ganglia, we repeatedly gave reserpine (0.03-0.14 mg/kg/day) to pregnant rabbits to deplete DA chronically in their fetuses during critical periods of the development of the nigrostriatal system. Reserpine crossed the placenta and depleted fluorescence markedly in the fetal putamen. We showed by electron microscopy (Brain Res Bull 8, No 5/6, 1982) that reserpine treatment caused a marked reduction in the numbers of mature axonal boutons in the putamen (to less than 1/2 that of controls, $p < 0.001$), and the area occupied by growth cones in the reserpine-treated fetuses was twice that of controls ($p < 0.005$). This suggested that the neuropil of the putamen of reserpine-treated fetuses was less mature than that of controls. In this study, we wished to determine whether the decrease in striatal terminals due to reserpine treatment included dopaminergic boutons. We measured the uptake of ^{3}H-DA (a process not antagonized by reserpine). Uptake of ^{3}H-DA was decreased in the putamen of reserpine-treated fetuses to 70% of controls ($p < 0.001$). To determine whether the cell bodies of neuroblasts of the putamen exhibited differences in maturity between control and experimental fetuses, the number of cells was counted and their size estimated by point count planimetry. In control fetuses, there were 3,226 ± 55.8 SE/mm^2 and in sections they occupied an average area of 79.6 ± 0.9 SE /um^2, whereas in the reserpine-treated fetuses, there were 23% more neuroblasts (4,144 ± 92.6 SE/mm^2, $p < 0.001$), but they were 22% smaller (61.2 ± 1.3 SE/um^2, $p < 0.001$). Compared to controls, reserpine-treated neuroblasts were smaller and more numerous per unit area, and thus, less mature. They closely resembled in number and size those cells in the control that had recently migrated away from the subependymal cell plate. A small number of the giant type of neuroblast was also found in the control putamen (14.1 ± 0.9 SE /mm^2). This cell type was somewhat reduced in reserpine-treated fetuses (10.2 ± 0.7 SE/mm^2, $p < 0.01$). The results are consistent with the hypothesis that early stores of DA may affect the ability of dopaminergic axons to reach the striatum and result in a retarded development of postsynaptic structures; however, other non-specific effects of reserpine have not been ruled out.

51.11 INTERCELLULAR MOLECULAR TRANSPORT: INTRA-AXONALLY INJECTED HORSERADISH PEROXIDASE RAPIDLY ENTERS AXON-SHEATH GLIA. T.A. Viancour, G.D. Bittner and K.R. Seshan*. Zoology Department, Univ. Texas, Austin, TX 78712.

Our recent report of Lucifer Yellow CH movement from an injected axon into axon-sheath glia (Viancour et al., Nature 293, 65-67 (1982)) demonstrated molecular exchange between axoplasm and gliaplasm. Because of the low molecular weight of the dye, we did not propose a specific exchange mechanism. The hydrated Lucifer ion is small enough to have diffused through cytoplasmic pores of gap junctions, or it could have been exchanged by axonal exocytosis and glial endocytosis, or it could have passed through the somewhat controversial regions of unrestricted cytoplasmic continuity between crustacean axons and glia reported by Peracchia (Nature, 290, 597-598 (1981)).

To obtain evidence for or against one or more of these mechanisms, we have iontophoretically injected the 40,000-dalton protein horseradish peroxidase (HRP) into giant axons of crayfish (P. clarkii). The large diameter of hydrated HRP should prevent diffusion through the pores of gap junctions, but not through the 15-20nm pores reported by Peracchia; if molecular exchange is by exocytosis/endocytosis then electron-dense HRP reaction product should be found in axo- and glia-plasmic vesicles. To avoid the possibility of HRP movement during or following fixation, we have precipitated the Hanker-Yates, HRP reaction product prior to fixation.

We find HRP reaction product bound to smooth endoplasmic reticula and neurotubules in the injected axon. Following injection periods of one hour or less, reaction product has been found in cytoplasmic vesicles within the glial cells immediately adjacent to the injected axon. Concentrations of such vesicles are often found adjacent to invaginations of the axon membrane.

We conclude that functionally intact, large and complex molecules such as HRP can move rapidly from a crayfish giant axon into the glial cells of its sheath. To date, our evidence favors a mechanism of molecular movement involving axonal exocytosis and glial endocytosis. Our results complement those of Nordlander et al. (J. Comp. Neur., 161, 499-514 (1975)) to provide evidence for a mechanism of rapid, two-way transport of metabolites between axons and axon-sheath glia in crustacea.

51.12 GLIAL FACTOR INDUCES DIFFERENTIATION OF NEUROBLASTOMA x GLIOMA HYBRID CELLS IN CULTURE. S.F. Atweh and B.G.W. Arnason. Dept. of Neurology, The University of Chicago, Chicago IL 60637

Neuroblastoma x glioma (NG) hybrid cells, NG-108-15, possess many neuronal properties including opiate receptors (OR) and choline acetyl transferase (CAT), that can be modulated in culture. Both parameters were shown to increase with time after plating and become maximal at confluence (Atweh, Neuroscience Abstracts, Vol. 7, #139.2,1981; Schnarr and Dahms, Neuroscience Abstracts, Vol. 7, #224.18,1981). Furthermore, there is evidence that NG cells themselves secrete a "factor" which stimulates the increase in OR and CAT. "Conditioned" media obtained from very confluent NG cells increased OR and CAT in non-confluent cells. Glia or glia-derived cells are known to secrete factors that stimulate the growth of neural cells in culture. In this study we tested the hypothesis that NG cells may respond to glial factors.

NG cells were grown in culture medium consisting of Dulbecco modified Eagle's medium and 5% fetal bovine serum. Two or three days after plating the medium was changed. Control flasks received fresh medium. Experimental flasks received "conditioned" medium that had been incubated with semi-confluent C_6 glioma cells for 24 hours, or fresh medium to which was added 1mM dibutyryl CAMP (DbCAMP). The cells were harvested 24 hrs later, counted and homogenized. OR and CAT activity were measured in the homogenate. Cells grown in C_6-conditioned medium exhibited a 55% increase in OR and a 62% increase in CAT activity as compared to controls. The C_6-conditioned medium did not alter the rate of cell division and did not induce any morphological change in the cells. DbCAMP, on the other hand, inhibited cell division and induced a morphological change in NG cells characterized by increased process formation and thickening of processes. In DbCAMP treated cultures CAT activity increased from 80-100%, but there was a 56% decrease in OR.

This data suggests that a glial derived factor(s) can induce the formation of neuronal like properties in NG cells in tissue culture and that this factor(s) has similar effects to those secreted by NG cells. Although DbCAMP induces cell differentiation, the changes induced by DbCAMP are qualitatively different from those induced by the glial "factor". It is still conceivable that some of the effects induced by the glial factor may be mediated by cyclic AMP, especially those related to CAT activation. The data also demonstrates that "growth factors" can modulate surface receptors (such as OR) as well as intracellular enzymes, and that the mechanisms underlying the modulation of receptor may be independent of those affecting intracellular enzymes.

In addition to studying some of the mechanisms underlying the regulation of neuronal functions, this system can be useful in the study of glial-neuronal interaction.

51.13 ROLE OF THE ORIGINAL SYNAPTIC SITE ON ACETYLCHOLINE RECEPTOR CLUSTERING AND NERVE-MUSCLE CONTACT FORMATION IN REGENERATING RAT SKELETAL MUSCLE. M.D. Womble*(SPON: K.F. Barald).Dept. of Anatomy and Cell Biology, University of Michigan, Ann Arbor, MI 48109.

After regeneration of rat or frog muscle, acetylcholine receptors (AchR's) are clustered at original synaptic sites, even in the absence of nerves (Bader, J.Cell Biol.88,1981; Burden,et al., J.Cell Biol.82,1979). In the frog, with subsequent innervation, neuronal contact is found exclusively at former endplate (EP) sites (Marshall,et al.,PNAS 74,1977). Interruption of original nerve supply to non-injured rat muscle induces ectopic sites of AchR clustering and EP formation at contact points with foreign nerve terminals (Lomo & Slater, J.Physiol.303,1980). In the present study, fluorescent α-bungarotoxin binding and a silver nerve stain are used to examine the appearance of AchR clusters and the role of the original EP zone in grafts of the rat soleus muscle. Myofibers of the graft degenerate and are phagocytosed. New fibers regenerate within the surviving basal lamina tubes. Previous work (Womble, Anat.Rec.202,1982) shows, by 5 days after grafting, large EP-like clusters of AchR's appear spontaneously on newly regenerated myotubes in the central third of the muscle. As returning nerve fibers penetrate into the proximal end, new AchR clusters are induced in this region at sites of nerve-muscle contact. Current work shows that EP-like AchR clusters develop only at former synaptic sites, identified by residual acetylcholinesterase (AchE) activity. Most older grafts (up to 60 days) have nerves well into the central zone of the muscle. Nerve fibers appear to seek out and synapse exclusively with the EP-like areas, accompanied by a disappearance of proximal nerve contacts and AchR patches. In cases where nerves do not reach the central zone, the EP-like clusters are lost and proximal EP's are retained. To further test the role of the original synaptic site, the motor endplate (MEP)-containing portion of the soleus muscle was removed at the time of grafting. A previous report (Bader, Dev.Biol.77,1980) showed that as few as 2% of the normal number of EP's are found in 60 day MEP-less grafts. Preliminary results indicate that early MEP-less grafts (up to 20 days) become well innervated and numerous nerve-associated AchR clusters appear throughout the muscle. The number of these contacts begins to decline by 30 days postgrafting. Thus, the original MEP zone may be important in selectively stabilizing some transient nerve-muscle contacts which form early in the regenerative process and later disappear in MEP-less grafts, as nerves withdraw. (Supported by NIH and MDA grants to Bruce M. Carlson.)

51.14 REGULATION OF AChR CLUSTERS BY EXTERNAL CALCIUM CONCENTRATION. S. Bursztajn, J. L. McManaman and S. H. Appel. Neurology Department, Baylor College of Medicine, Houston, TX 77030.

Clustered and diffuse acetylcholine receptors (AChR) are present in cultured rat skeletal muscle. We have investigated the effect of extracellular calcium (Ca^{+2}) concentration on the distribution of surface AChR in cultured rat myotubes. We demonstrate that high CA^{+2} concentration (15 mM) leads to a significant increase in size and stability of AChR clusters without an increase in synthesis of new AChR. Six-day old cultures were incubated in Ca^{++}-free Dulbecco-Vogt modified Eagle's medium to which Ca^{++} (2.5×10^{-5}M - 1.5×10^{-2}M) was added. The final Ca^{++} concentration in the medium was measured with an atomic absorption spectrophotometer. After incubation of myotubes at various Ca^{+2} concentrations for 0-48h, cultures were stained with α-Bungarotoxin (α-BTX) conjugated to tetramethyl rhodamine (TMR), fixed in 2% formaldehyde, and clusters were visualized with the fluorescent microscope and quantitated. Cultures incubated in low Ca^{+2} (2.5×10^{-5}M) culture medium have fewer intact AChR clusters (18.5 ± 7.5%) than those incubated in high Ca^{+2} (1.5×10^{-2}M) medium (93.3 ± 3.7%). In the presence of high Ca^{+2} medium there is a time-dependent increase in the number of clusters per myotube and a two-fold increase in cluster dimensions. Furthermore, the appearance of newly formed AChR clusters following treatment with α-BTX, to block existing clusters, was also accelerated. Under identical conditions the rates of AChR synthesis and degradation are unaffected by high Ca^{+2} concentrations. The effect of Ca^{+2} on ACh receptor clusters appears to be specific for Ca^{+2} since AChR clusters were not affected by other divalent ions or incubation in hypotonic medium. High concentrations of calcium also alter the effects of myasthenic globulin (MG) on AChR cluster dispersal and turnover of surface ACh receptors. MG binds to AChR, accelerates the rate of AChR degradation and causes dispersal of AChR clusters. In the presence of MG, incubation of cells in high Ca^{+2} medium slowed the loss of intact AChR clusters and decreased the rate of AChR degradation. The decreased rate of cluster loss coincided with the decreased rate of AChR degradation. These results indicate that high concentrations of Ca^{+2} stabilize ACh receptor clusters and prevent dispersal of receptors by MG. Our results also indicate that the increased rate of AChR degradation in the presence of MG antibody may be related to the dispersal of intact AChR clusters. (Supported by MDA)

51.15 NEUROCHEMICAL CORRELATES OF HYPERREFLEXIA FOLLOWING SPINAL CORD TRANSECTION. D. J. Jones and O. F. Alcantara*. Depts. Anesthesiology and Pharmacology, The Univ. Texas Health Science Center, San Antonio, TX 78284.

Enhanced sensitivity of motor reflexes following spinal cord transection has been established in both clinical and laboratory animal investigations. Previous studies from this laboratory have established that denervation supersensitivity involving the cyclic AMP system may be a molecular component of hyperreflexia following spinal cord transection (Neurosci. Abstracts, 7:919, 1981). The present work is a description of concomitant changes in NE-containing neuron function that parallel alterations in cyclic AMP system sensitivity following spinal cord transection.

Transection of the spinal cord was performed at the midthoracic level in male Sprague/Dawley rats weighing 150-200 gm. Twenty-four hours following transection, hindlimb flexor reflexes were evaluated. Following various time periods, the flexor reflex was again measured using the same protocol. Subsequently, the animal was sacrificed and cervical (intact) and lumbar (denervated) spinal cord removed. The tissue was then processed for measurements of (a) catecholamine levels (b) NE-uptake or (c) adrenergic receptor binding. In addition, NE-stimulated cyclic AMP accumulation in tissue slices from cervical vs lumbar spinal cord was also measured.

As early as three days following spinal cord transection, spontaneous flexor reflex activity was markedly increased. In addition the amplitude of flexion (excursion) at 0.6 mA was significantly increased. This hyperreflexia is evident at least through 60 days following transection. There occurred a gradual decrease in NE uptake and in NE steady state concentrations below the level of transection such that at 21 days, greater than 95% depletion of NE existed in lumbar spinal cord.

Evidence of denervation supersensitivity was represented by a 3-4 fold greater increase in NE-stimulated cyclic AMP accumulation in lumbar vs cervical cord tissue slices from transected rats. This enhanced response was present as early as 3 days and lasts at least 90 days post-transection. Consonant with this enhanced response is an approximate doubling of the number of beta receptors (B_{max}) in spinal cord below the level of transection. There was no change in apparent K_D.

These data suggest that synaptic supersensitivity exists in lumbar spinal cord following transection and that alterations in adrenergic receptor function and number may be a part of the mediating events for reflex hyperresponsiveness following injury to the cord.

51.16 SCHWANN CELLS PROMOTE THE TRANSFORMATION OF BIPOLAR SENSORY NEURONS INTO PSEUDOUNIPOLAR NEURONS IN VITRO. A.W.MUDGE* (SPON:C.Gunderson) MRC Neuroimmunology Project, Dept. of Zoology, University College London, Gower Street, London, WC1E 6BT.

Cahal described the morphological development of chick sensory neurons which involves a remarkable rearrangement of the neuronal cytoplasm (Cahal,S.Ramon y, Trab. Lab. Invest. Biol., Univ. Madrid 3, 1904). The early neuoblasts are bipolar but as development proceeds, the two processes approach each other and the cells become bell-shaped. During the second half of development the two processes fuse giving rise to a single thick axon which bifurcates - the so-called pseudounipolar form of the sensory neuron.

Sensory neurons dissociated from 10 day old chick ganglia were plated onto collagen-coated tissue culture dishes and treated with cytosine arabinoside to kill the non-neuronal cells. To visualise the arrangement of the neuronal processes, the cultures were stained with a monoclonal antibody (RT97) raised against neurofilament proteins (Wood,J and Anderton,B, Biosci. Reports, 1, 1981), followed by an antibody to mouse IgG coupled to peroxidase: the peroxidase was reacted with diaminobenzidine/H_2O_2. 24 hours after plating the neurons were predominantly bipolar with some multipolar forms. Upto a month after plating, the neurons in the absence of other cell types retained this immature arrangement of their processes. However, when purified Schwann cells (SC) derived from rat sciatic nerve (Brockes J et al, Brain Res. 165, 1979) were added to the 'neuron-alone' cultures (at day 7 after plating) the neurons flattened out and became phase-dark. This change in shape was dependant on the number of SC added to the neurons and with high numbers of SC most of the neurons changed their morphology within 5 days of the SC addition. When such cultures were stained with anti-NF, most of the neurons had assumed the pseudounipolar form or the intermediate bell-shape form. The morphology of the neurons after the addition of fibroblasts was indistinguishable from the neuron-alone' condition.

This study provides a clear example of the ability of glial cells to support the development of neurons. It also illustrates the power of using purified populations of neurons and non-neuronal cells in order to study which properties are intrinsic to the developing neuron and which properties require interactions with other cells.

52.1 CATECHOLAMINE CONCENTRATIONS AND UPTAKE DURING SYMPATHETIC INNERVATION IN THE DEVELOPING CHICK HEART. D. E. Stewart* and M. L. Kirby (SPON: R. Holt). Dept. of Anatomy, Medical College of Georgia, Augusta GA 30912.

Developing sympathetic nerves first reach the heart of the embryonic chick on incubation days (ID) 10-11. Electrical stimulation of cardiac adrenergic nerves does not produce a positive inotropic response until ID 16. This lag between morphological and functional adrenergic transmission may be due to an inadequate density of innervation. To obtain an index of innervation during development, we have studied the ability of the adrenergic nerve terminals in the atria of the chick heart to accumulate [^{3}H]-NE throughout the incubation to 2 weeks post-hatching. Specific neuronal uptake of [^{3}H]-NE was defined as total uptake minus uptake in the presence of desmethylimipramine, a specific uptake blocker. Neuronal uptake of [^{3}H]-NE in atria (in vitro) was first observed on ID 11. [^{3}H]-NE uptake increased gradually through ID 17, reached a peak on ID 19 and then decreased until ID 21. A linear increase in uptake to maximal levels occurred during the first 2 weeks posthatching. To evaluate adrenergic regeneration capabilities and the effectiveness of 6-hydroxydopamine (6-OHDA) in destroying cardiac sympathetic terminals, we administered 6-OHDA (100mg/kg, 2 doses, 8-12 hours apart) in ovo by injecting through the airspace onto the inner shell membrane. [^{3}H]-NE uptake assays were performed 24, 48 and 72 hours after the initial injection of 6-OHDA. Uptake studies revealed that 6-OHDA was effective in reducing neuronal [^{3}H]-NE uptake as early as ID 12. Increases in uptake which occurred between 24-72 hours following 6-OHDA indicate ingrowth of new adrenergic fibers. To correlate cardiac catecholamine concentrations with innervation data, the concentrations (ng/mg tissue) of epinephrine (E) and norepinephrine (NE) in whole hearts were determined by high performance liquid chromatography. Beginning with ID 5, E levels rapidly increased to peak on ID 7 and then decreased and remained at low levels from ID 11 through ID 15. A smaller E peak occurred on ID 17 followed by a decrease which lasted through hatching. NE levels remained lower than E throughout the incubation period until just prior to hatching when NE surpassed E. At 2 weeks posthatching E was again greater than NE. We have observed that, generally, as adrenergic nerves arrive at the heart and innervation density increases (as determined by ^{3}H-NE uptake) catecholamine concentrations (primarily E) decrease accordingly. Between ID 17 and 19 there is a 2-fold increase in neuronal uptake and a 15-fold decrease in cardiac E concentration. It appears that circulating catecholamines may be an integral factor in adrenergic development and maturation. Supported by NIH Grant HD 17063.

52.2 IDENTIFICATION AND EXTIRPATION OF PRESUMPTIVE CARDIAC GANGLION CELL NEURAL CREST IN THE CHICK EMBRYO. M. L. Kirby and D. E. Stewart*. Dept. of Anatomy, Medical College of Georgia, Augusta GA 30912.

Presumptive cardiac ganglion cells can be identified in the bulbar plexus of the chick embryonic heart on the 4th day of incubation. These cells sprout processes and functionally innervate the heart by incubation day 12. The cells which become the cardiac ganglia presumably migrate from the neural crest which is the origin of all the autonomic ganglia. The cardiac ganglia are preganglionically innervated by the vagus nerve and should derive from the vagal area of neural crest which has been identified previously as the neural crest over somites 1-7. In the present study, we have identified the cardiac ganglion cell portion of the vagal neural crest using quail-chick chimeras and then examined the potential of a vagal cardiac ganglion cell lesion by removing various areas of the vagal cardiac neural crest. Using quail to chick chimeras, it was found that the vagal cardiac ganglion cells could be labelled reliably when the neural crest over somites 1 and 2 was transplanted. This type of transplant also resulted in labelling of pulmonary ganglia and the supporting cells (but not neurons) in the thoracic ganglia. Transplantation of neural crest above somite 1 resulted in labelling in cranial nerve ganglia. Transplantation of neural crest over somites 3-5 resulted in labelling of enteric ganglia with no labelling of either cardiac or pulmonary ganglia or supporting cells in the thoracic ganglia. The effectiveness of various neural crest lesions in producing a vagal aneural heart was evaluated using choline uptake in the atrium. Specific neuronal uptake of [^{3}H]-choline was defined as total uptake minus uptake in the presence of hemicholinium, a specific uptake blocker. Uptake in this system was saturable, temperature sensitive and Na^+ dependent. A normal study of [^{3}H]-choline uptake in developing chick atrium showed no choline uptake prior to 7 days of development. Uptake increased rapidly to peak at 10-12 days of development and then dropped to a plateau by 17 days. Bilateral and unilateral neural crest extirpations were performed at many different levels and several different stages of development. The embryos were allowed to develop to stage 34 (day 9) and the atria were assayed for [^{3}H]-choline uptake. [^{3}H]-choline uptake was lowest (40% of normal) following bilateral removal of neural crest over somites 1-3 at stage 9. Unilateral extirpation of this area of neural crest resulted in normal uptake at 9 days of incubation.
Supported by NIH Grant HD 17063

52.3 CATECHOLAMINE UPTAKE AND RELEASE BY CULTURED NEURAL CREST CELLS. G.D. Maxwell and P.D. Sietz*. Dept. of Anatomy, Univ. of Conn. Health Center, Farmington, CT 06032.

Embryonic neural crest cells in vivo give rise to the neurons of the autonomic and most sensory ganglia and, in addition, a variety of nonneuronal cell types. In tissue culture, some neural crest cells develop the capacity to synthesize and store the catecholamine norepinephrine (NE). It is of interest to learn what other neuronal functions, such as neurotransmitter release, are expressed by cells in these cultures.

Quail trunk neural crest cells were grown on thin collagen gels in medium containing 15% horse serum, 10% chick embryo extract and 5 ng/ml 2.5 S NGF. After 42 to 48 hrs. in culture, the neural tubes were carefully removed, leaving behind a population of cells that is highly enriched in neural crest cells. Neural crest cultures were incubated with 1.3μM [^{3}H]NE (specific activity 27 Ci/mmol) for 30 minutes. Cultures were washed and tested for their ability to release radioactivity in response to depolarizing conditions. Release was evoked in the presence of 40 mM K^+ with 1.3 mM Ca^{+2}. Radioactivity returned to baseline when cultures were returned to saline with 6 mM K^+ and 1.3mM Ca^{+2}. This release was inhibited (by > 90%) by the addition of 3 mM $CoCl_2$, indicating Ca^{+2} dependence of the release. The alkaloid veratridine (100 μM) also evoked a similar release of radioactivity from these cultures. Release in response to both conditions was seen after 7 days in vitro (the earliest time examined).

At the conclusion of release experiments, some cultures were processed for glyoxylic acid-induced fluorescence, diagnostic for catecholamines. The fluorescent cells generally had short processes (< 2 times the diameter of the cell body) with occasional longer processes seen on some cells. There was an excellent correlation ($r = 0.97$) between the number of fluorescent cells in a culture and the amount of evoked release. Other cultures were processed for autoradiography to locate radioactivity accumulated in cells. In these cultures, silver grains were observed above both processes and cell bodies in a subpopulation of cells in the culture.

These results indicate that neural crest cells grown in the absence of their normal synaptic inputs and targets develop the capacity to take up and release at least one neurotransmitter. This release is probably mediated by a subpopulation of catecholamine metabolizing cells in the culture.

52.4 INCOMPLETE EXPRESSION OF A CATECHOLAMINERGIC PHENOTYPE IN CELLS THAT TRANSIENTLY APPEAR DURING DEVELOPMENT IN THE FETAL RAT GUT. M.D. Gershon, T.P. Rothman, G.N. Teitelman, T. Joh and D. Reis. Dept. Anatomy and Cell Biol., Columbia Univ. P&S, NY, NY 10032 and Dept. Neurology, Cornell Medical Coll., NY, NY 10021.

Proliferating cells that transiently express some catecholaminergic properties (TC cells) have been found in the gut and other organs of fetal rats and mice. These cells ultimately disappear from the bowel but it has not yet been determined whether their disappearance is due to a change in phenotype or elimination. When present, TC cells have been found to synthesize and contain catecholamine (CA). In rats, both tyrosine hydroxylase (TH) and dopamine beta hydroxylase (DBH) have been demonstrated in enteric TC cells by immunocytochemistry, while in mice the cells contain only TH. This suggests that TC cells may express only some of the constellation of properties that constitute the catecholaminergic phenotype of neurons. In order to test the hypothesis that catecholaminergic expression is incomplete in TC cells the ability of these cells to take up and store ^{3}H-norepinephrine was assessed directly. Fetal rat gut was removed on days E12 and E15 and incubated for 30 min with ^{3}H-NE in the presence of pargyline (0.1mM). Tissue was fixed and prepared for light and electron microscopic radioautography. Simultaneous immunocytochemical demonstration of TH served to mark TC cells. On day E12 no cells or processes were labeled radioautographically by ^{3}H-NE. TC cells, however, were abundant and well developed at this age. In contrast, the gut was heavily labeled by ^{3}H-NE on day E15, although TC cells could no longer be demonstrated with antibody to TH. TH-immunoreactivity was instead confined to axons and growth cones in the maturing enteric plexuses. These fibers also labeled with ^{3}H-NE and were probably the ingrowing axons of the sympathetic innervation of the gut. Although most of the labeling by ^{3}H-NE was of these axons, rare cells that did not display TH also took up ^{3}H-NE. At E12, therefore, TC cells contain TH but do not label with ^{3}H-NE, while at E15 another cell type is found that labels with ^{3}H-NE but does not contain TH. Cells that take up but do not synthesize CA have long been known to be constituents of the adult bowel and have been called amine handling cells (Furness and Costa, Cell Tiss. Res. 188:527-43, 1978). TC cells thus do not show all of the characteristics of the neuronal catecholaminergic phenotype. Uptake of NE following the disappearance of TC cells, therefore, does not indicate that these cells persist after they no longer express TH. The disappearance of TH-marked TC cells is followed by the innervation of the gut by sympathetic neurons and the appearance of amine handling cells. Supported by grants NS15547, BNS81-40896 and HL18974.

52.5 DEVELOPMENT OF SOMATOSTATIN AND VASOACTIVE INTESTINAL PEPTIDE IN THE RECTUM AND REMAK'S GANGLION OF THE CHICK. Miles L. Epstein° and June L. Dahl+, Departments of Anatomy° and Pharmacology+, University of Wisconsin Medical School, Madison, WI 53706

We have used immunocytochemistry to study the development of somatostatin (SOM)- and vasoactive intestinal peptide (VIP)-like immunoreactivity in the hindgut and Remak's ganglion of the chick. SOM-like immunoreactive cell bodies were first found in Remak's ganglion at 5 1/2 days of incubation (d.i.). Immunoreactive fibers were found at 7 1/2 - 8 1/2 d.i. in the wall of the rectum and were seen transversing the smooth muscle at 11 d.i. At 13 d.i., immunoreactive fibers were aligned parallel to the circular smooth muscle. In the newly-hatched chick, extensive SOM-like immunoreactivity was found in the myenteric and submucosal plexuses and in the circular smooth muscle. VIP-like immunoreactivity was first found in the wall of the rectum at 7 1/2 d.i. and cell bodies were clearly visualized in both the myenteric and submucosal plexuses at 9 d.i. VIP-immunoreactive fibers aligned parallel to the smooth muscle were found at 13 d.i. and were extensive by 17 d.i. Immunoreactive fibers were found in Remak's ganglion at that time but few or no cell bodies were visualized. We conclude that SOM cell bodies, which appear early in ontogeny in Remak's ganglion, provide extrinsic innervation to the hindgut of the chick. In contrast, VIP neurons appear to be intrinsic to the rectum and extend processes to Remak's ganglion.

52.6 SHORT-TERM ACTIVATION AND LONG-TERM INDUCTION OF ADRENAL TYROSINE HYDROXYLASE DURING STRESS. S. J. Fluharty,* G. L. Snyder,* E. M. Stricker and M. J. Zigmond. Depts. of Biological Sciences and Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Recent studies from this laboratory indicated that after ivt 6-hydroxydopamine treatment hippocampal tyrosine hydroxylase (TH) is rapidly activated and this change persists until replaced by a long-term induction (Acheson & Zigmond, J. Neurosci. 1:493, 1981). The induction of adrenal TH has been shown to occur during prolonged stress. The present investigations determined whether this induction also is preceded by activation of the enzyme.

Male Sprague-Dawley rats were treated with phenoxybenzamine (PBZ, 20 mg/kg/day, ip), protamine zinc insulin (4-8 units/day, sc), or subjected to cold exposure (5° C) for varying times. Animals were then anesthetized with Equithesin and the adrenals removed and immediately frozen. Prior to the TH assay adrenal catecholamines (CAs) were removed by passing homogenates through a G-25 Sephadex column. This procedure lowered the K_m for pterin cofactor ($6MPH_4$) from 0.96 mM to 0.48 mM without altering V_{max}. TH was assayed by a coupled radioenzymatic decarboxylase microassay at a previously determined suboptimal pH (6.7) in the presence of saturating (10 mM) or subsaturating (0.1 mM) concentrations of $6MPH_4$.

Two days of PBZ treatment increased adrenal TH activity at both 0.1 mM and 10 mM $6MPH_4$ by 70-80%. This induction was apparently preceded by an activation; 30 min after the first PBZ injection, TH activity at 0.1 mM $6MPH_4$ was increased by 36% while at 10 mM $6MPH_4$ or at the pH optimum (6.2) it remained unchanged. Similarly, four days of insulin administration increased adrenal TH activity at both 0.1 and 10 mM $6MPH_4$ by 150-175%, and this induction was preceded by an activation of the enzyme (39% increase only at 0.1 mM $6MPH_4$, 30 min post-insulin). Finally, there was a clear induction of adrenal TH following 36-48 hrs of cold exposure (90-100% increase in the activity at both 0.1 and 10 mM $6MPH_4$). However, the enzyme was not activated 24 hr prior to the induction and experiments are now underway to determine whether an activation had occurred at some earlier time.

These results demonstrate the capacity of adrenal TH to respond rapidly to stress by increasing its activity and to maintain this increase when the stress is prolonged. These changes presumably help to couple CA synthesis and CA secretion during the increased demand associated with sympathetic nervous activity. It remains to be determined whether rapid activation of adrenal TH always occurs during stress, and when it does whether it persists until additional enzyme is induced.

Supported by research grant MH-29670.

52.7 THE DEVELOPMENT OF TEMPERATURE-SENSITIVE NEURONS WITHIN THE PREOPTIC AREA AND ANTERIOR HYPOTHALAMUS OF DOMESTIC CHICK EMBRYOS AND HATCHLINGS. J.W. Reveley* and J.A. Boulant (SPON: B.T. Stokes). Department of Physiology, College of Medicine, Ohio State Univ., Columbus, Ohio 43210.

Previous studies have shown that certain neurons within the preoptic area and anterior hypothalamus (PO/AH) are sensitive to local hypothalamic temperature changes (T_H). Three types of units have been described within the PO/AH region: warm-sensitive, cold sensitive and temperature-insensitive neurons. It was the purpose of this study to examine the thermosensitivities of units within the PO/AH region during different stages of hypothalamic development.

Four stages of development were examined in the domestic chick *(Gallus domesticus)*: 15 days incubation, 19 days incubation, 4 days post-hatch and 12 days post-hatch. A thermode and thermocouple were stereotaxically placed in the rostral hypothalamus of urethanized birds. Hypothalamic temperature was held constant at 37°C, but could be rapidly changed between 32°C and 42°C to determine the thermosensitivity (m) of each unit.

In pre-hatched birds, 60% of the cells were classified as temperature-insensitive. Thirty percent of the cells were classified as either warm-sensitive (i.e. $m \geq 0.8$ impulses/sec/°C) or marginally warm-sensitive (i.e. $0.8 \geq m \geq 0.3$). Ten percent of the cells were classified as either cold-sensitive (i.e $m \leq -0.6$) or marginally cold sensitive (i.e. $-0.6 \leq m \leq -0.3$). The majority of warm-sensitive units were only sensitive to hyperthermic hypothalamic temperatures. In post-hatched birds, 50% of the cells were classified as temperature-insensitive. Forty percent of the cells were classified as warm or marginally warm-sensitive and 10% as cold or marginally cold sensitive. As the birds develop, there is a higher percentage of warm- and cold-sensitive cells vs. marginally warm- or cold-sensitive. In contrast to pre-hatched birds, there is a smaller percentage of warm-sensitive cells sensitive only in the hyperthermic range. Most of the warm-sensitive cells in the post-hatched birds were sensitive over wider ranges of hypothalamic temperature. In addition, there appears to be a time-course with respect to the developmental progression of neuronal thermosensitivity and spontaneous firing rate. This may be linked to the development of thermosensory afferents from skin and deep body thermoreceptors.

(Supported in part by grants from NIH (5-RO1-N514644) and the American Heart Association).

53.1 NEUROTROPHIC MAINTENANCE OF MATURE SKELETAL MUSCLE: CHARACTERIZATION OF TROPHIC PRINCIPLE. H.L. Davis and J.A. Kiernan. Depts. of Clinical Neurological Sciences and Anatomy, The University of Western Ontario, London, Ontario, N6A 5C1, Canada.

Atrophy in a denervated muscle results from the disuse caused by paralysis of the muscle, and from the loss of special neurotrophic substances. Proteins extracted from rats' sciatic nerves have been shown to prevent the non-disuse atrophy of rats' extensor digitorum longus (EDL) muscles denervated for 7 days, when administered by daily intramuscular injections. The present investigation was undertaken to elicit more information about this neurotrophic phenomenon. Atrophy was assessed by measurement of wet weight, content of total protein and cross-sectional areas of types IIA and IIB fibres (in sections stained for ATPase) of EDL muscles.

Extracts of liver, which is a non-neural tissue, were injected daily into rats' EDL muscles denervated for 7 days. The rate of atrophy was as great as in controls, indicating that the trophic effects of the nerve extract were nerve-specific.

Normal muscles were injected with nerve extract for 7 days. They had wet weights and cross-sectional areas of IIA and IIB fibres identical to those of uninjected contralateral controls. This finding, in addition to those from earlier investigations, suggests that the amelioration of denervation atrophy by the nerve extract did not result from inflammatory processes.

Various doses of extract of rat or sheep sciatic nerves were injected into denervated rats' EDL muscles for 7 days. It was demonstrated that the action of the extract was dose-dependent but not species-specific. Greater concentrations of extract of ovine, than of rat, peripheral nerve were required for significant ameliorative effects.

Rats' EDL muscles were denervated for 14 days and were either not treated or were injected with nerve extract (optimal dosage) on all 14 days or only on the first or last 7 days. All denervated muscles injected with extract (for 7 or 14 days) exhibited significantly less atrophy than those that were not injected. Thus, injection of nerve extract caused reversal of non-disuse atrophy. The trophic effects of the extract persisted for at least one week.

53.2 PURIFICATION OF A NEW NEUROTROPHIC FACTOR FROM MAMMALIAN BRAIN. Y.-A. Barde, D. Edgar* and H. Thoenen, Max-Planck-Institute for Psychiatry, Dept. of Neurochemistry, D-8033 Martinsried, FRG

Considerable evidence indicates that developing neurons depend on their environment for survival and differentiation. In order to understand the nature of these interactions, it is necessary to define the factors in the environment which are essential for the developing neurons in molecular terms. So far only one such factor has been purified and characterized - nerve growth factor (NGF). Isolation and characterization of other factors is particularly important in view of the fact that NGF has not yet been isolated from a source relevant to the physiology of the developing nervous system. The present report describes the isolation of a new neurotrophic factor from mammalian brain, the first to be purified since NGF. The assay system used to purify it was a quantitative determination of the number of surviving sensory neurons (isolated from chick embryos) cultured in the virtual absence of non-neuronal cells. The starting material was pig brain and the following purification steps were used: homogenization and acid treatment of the homogenate (pH 4.5), ammonium sulphate precipitation (70%), chromatography on CM-cellulose and hydroxylapatite, and preparative 2-dimensional gel electrophoresis. The material isolated by this procedure has the following characteristics: it is a very basic protein (pI ≅ 10.2) with a molecular weight of 12,300 which migrates as a single band on gel electrophoresis in the presence of sodium dodecyl sulphate. Approximately 1 µg can be isolated from 1 kg starting material after a purification of about 1.4 million-fold with a yield of 5%. The factor has a calculated specific activity of 0.4 ng/ml per unit (1 U permits 50% of maximal neuronal survival), which is essentially identical to that of NGF using the same assay system. This brain neurotrophic factor differs from NGF by immunological and functional criteria: antibodies to NGF do not block its activity and its effect on the survival of chick sensory neurons is additive to that of saturating concentrations of NGF. Furthermore, in contrast to NGF, the brain neurotrophic factor does not promote the survival of cultured chick or rat sympathetic neurons.

53.3 PURIFICATION AND CHARACTERIZATION OF NERVE GROWTH FACTOR FROM BOVINE SEMINAL PLASMA. G.P. Harper* and H. Thoenen. Dept. of Neurochemistry, Max-Planck-Institute for Psychiatry, 8033 Martinsried, West Germany.

Nerve Growth Factor (NGF) has been purified to homogeneity from bovine seminal plasma, which contains around 0.8 mg NGF/ml seminal plasma. NGF exists in the seminal plasma as a high molecular weight complex, analogous to the 7S form of NGF in the mouse submandibular glands. On acidification to pH 3, the bovine NGF complex dissociates into its subunits, revealing a highly basic (pI 9.5-10), low molecular weight (around 15,000 on SDS-polyacrylamide gel electrophoresis) protein with the NGF activity. This isolated bovine NGF thus appears to be rather more basic, and has a slightly longer peptide chain length, than the ß form of mouse NGF. As for mouse NGF, the native form of bovine NGF is a dimer of the peptide chains seen under denaturing conditions. Bovine NGF contains no carbohydrate moieties. The N-terminal amino-acid sequence of bovine NGF is very similar, but not identical, to that of mouse NGF; thus residues 3, 9 and 18, which are threonine, methionine and valine respectively in mouse NGF, are serine, arginine and isoleucine in bovine NGF.

Bovine NGF has exactly the same biological activities as mouse NGF in a wide variety of *in vitro* neural systems, which presumably indicates that the "active site" of NGF proteins (*i.e.* the part(s) of the molecule binding to the NGF-receptor in the cell membranes of target cells) is highly conserved. Such similarities are not seen, however, in the immunological properties of mouse and bovine NGFs, which differ substantially. For example, antisera against bovine NGF are only poorly effective in destroying the sympathetic nervous system (immunosympathectomy) of neonatal rats, and in inhibiting the biological activities of mouse NGF *in vitro*. The most likely explanation for these data is that the parts of the NGF molecule not directly involved in the active site are not subject to conservative evolutionary restraint, and in fact have diverged substantially.

53.4 TWO DISTINCT HIPPOCAMPAL GROWTH FACTORS IDENTIFIED IN VITRO. K.A. Crutcher and F. Collins*. Dept. of Anatomy, University of Utah School of Medicine, Salt Lake City, Utah 84132.

Sympathetic fibers invade the rat hippocampal formation or neocortex following cholinergic denervation of these brain regions. Previous studies have led to the suggestion that such sprouting could be due, in part, to the presence of a factor similar to nerve growth factor (NGF). In order to determine whether such a factor is normally present in the rat hippocampal formation (HF), extracts of this brain region were added to dispersed cell cultures of embryonic chicken ciliary (parasympathetic) or lumbar chain (sympathetic) ganglia. The neurons were plated onto culture dishes which were coated with a substratum-conditioning factor derived from heart-conditioned medium. The extent of neurite elongation from individual cells was measured two hours after exposure to medium alone or medium plus HF extract. The extract was prepared by homogenizing one HF in 2.5 ml of Hank's balanced salt solution and collecting the supernatant after centrifugation (100,000 g for 30 min.).

Exposure to HF extract accelerated the rate of neurite elongation from both parasympathetic and sympathetic neurons. As much as 100 fold dilution of the HF extract still resulted in significant acceleration of neurite elongation. NGF antiserum was added in order to determine whether the HF extract activity could be antagonized. The response of sympathetic neurons was reduced to control levels by the NGF antiserum but the response of parasympathetic neurons was unaffected. NGF antiserum alone had no effect on neurite elongation.

These results provide evidence for the presence of at least two distinct growth factors within the rat HF, one of which may be related to NGF. The sprouting of sympathetic fibers following septal lesions and the affinity of septohippocampal axons for exogenous NGF suggest that a similar factor might be responsible for the normal development of central cholinergic pathways and for sympathetic sprouting following cholinergic denervation. The presence of discrete growth factors might provide the basis for the specificity of other examples of neuronal sprouting within the mammalian CNS.

53.5 SKELETAL MUSCLE CELLS PRODUCE A FACTOR WHICH PROMOTES NEURITE GROWTH IN CULTURE. Raphael Gruener and Judy Christiansen*. Department of Physiology, University of Arizona College of Medicine, Tucson, AZ 85724, U.S.A.

Trophic control by target tissues of their innervation has been well-documented, for the sympathetic nervous system, to be mediated by target-elaborated nerve growth factor (NGF). It is becoming apparent that this upstream regulation may be a general phenomenon. We have therefore examined the possibility that embryonic skeletal muscle cells produce a factor which influences neuronal maintenance, promotes neurite production and provides them with directionality.

Spinal cord cells, from Xenopus laevis embryos, were grown in the presence of defined muscle-conditioned medium (MCM) free of serum and embryo extract. MCM was obtained from embryonic Xenopus muscle cell cultures after 5 days incubation and used as the growth medium for nerve cell cultures. The number of neurites, produced in the culture, as well as the number of neurite-producing neurons, was examined. The effects of MCM were also examined in cultures of PC12 cells and in superior cervical ganglia explants from fetal rat and compared to the effects of NGF. Conversely, the effects of NGF were assayed on Xenopus nerve cell cultures.

We have found that neurite production is greatly enhanced by MCM. These effects are similar to those found for NGF with both factors, however, exerting only target-specific activity. We have also found that the MCM is heat inactivated and is not dialyzable. Finally, pretreating culture chambers with MCM is ineffective in reproducing MCM effects on neurite growth.

We conclude that MCM contains a muscle-elaborated, possibly specific, factor which may be important developmentally and in the adult maintenance of upstream trophic regulation.

Supported in part by grants from the BRSG and the Gerontology Committee of the University of Arizona.

53.6 CYCLIC AMP MAY MEDIATE THE EFFECT OF NGF ON PHOSPHOLIPID METABOLISM, A.E. Traynor The Salk Institute, P.O. Box 85800, San Diego, CA 92037

The NGF induced differentiation in PC12 cells may be mediated by cyclic AMP and calcium (Schubert, D. et. al., Nature, 273:718, 1978). Since NGF increases phosphatidyl-inositol (PI) turnover in these cells (Traynor and Schubert, in preparation) we studied the effects of cyclic AMP and calcium ionophore (A23187) on the PI response. Cyclic AMP (10^{-3}M) was half as effective as NGF in stimulationg PI labelling with $^{32}PO_4$. A23187 stimulated PI labelling in the presence but not the absence of calcium. These results were consistent with the interpretation that PI turnover is preceeded by increased cyclic AMP and calcium flux. However, depolarizing the cells with KCl increased calcium flux and resulted in the initiation of neurite extension but did not stimulate PI labelling. Therefore neurite extension does not require increased PI turnover.

53.7 RETROGRADE TRANSPORT OF NERVE GROWTH FACTOR (NGF) IN GOLDFISH RETINAL GANGLION CELLS. H. K. Yip* and E. M. Johnson (SPON: V. S. Yip). Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Previous studies have shown that NGF, administered at the time of crush, but not 24 hours after, enhances regeneration of goldfish optic nerve. NGF was effective when administered either by intraocular injection or by local application to the lesion site. The site and mechanism of action of NGF is not understood. One of the possibilities is that NGF is retrogradely transported, by either a receptor mediated or non-receptor mediated process, to the cell body and exerts its growth-promoting effect.

For the present study, attempts were made to demonstrate the retrograde transport of ^{125}I-NGF in the normal animal by injection in the optic tectum. The amount of radioactivity transported to the ipsilateral and contralateral retinas was measured in a Gamma counter. Retinas were also processed for autoradiography. No retrograde transport was observed in these animals, suggesting that the retinal ganglion cell processes do not have NGF receptors.

In contrast, when ^{125}I-NGF was microinjected at the optic nerve crush site at the time of lesion, retrograde transport to the ipsilateral retina, but not contralateral retina, was observed. Radioactivity was detected in the ipsilateral retina 2 hours after the injection, peaked at 6 hours and returned to base-line by 16 hours. Autoradiographic examination showed that about 10% of retinal ganglion cells were labelled. No labelling was seen in other retina cells. Injection of ^{125}I-NGF at the site of lesion, 16 or 24 hours after the crush, produced no transport to the ipsilateral retina. These data, therefore, suggest that goldfish retinal ganglion cells do not have NGF receptors and do not normally transport NGF. However, there is a temporal correlation with the ability of NGF to be transported after a lesion to the retinal ganglion cells and its ability to enhance regeneration after a lesion. We suggest that NGF may be capable of exerting positive effects on cells which do not have surface receptors for the factor.

53.8 PRIMARY AMINE SECRETION FROM NEUROMUSCULAR PREPARATIONS. J.R. Musick. Dept. Physiology, Sch. of Med., U. of Utah, Salt Lake City, UT 84108.

Recent investigations using cultured cells to assay for putative trophic factors indicate the motor neurons contain substances affecting skeletal muscle properties and that muscle contains substances affecting motor neurons. Active factors appear to be proteinaceous, including macromolecules and a small peptide(s). Some long-term neuromuscular interactions may be mediated by secretion of trophic factors. In the present study, the fluorescamine assay was used to study the spontaneous secretion of primary amines from the R. catesbeiana sciatic nerve-sartorius muscle. The excised preparation was superfused at 0.35 ml/min with physiological saline and effluents were collected in 10-min intervals for up to 7 hrs. The primary amine efflux decayed according to a double exponential (τ_1 = 6.90 ± 1.0 hrs; τ_2 = 47.6 ± 7.9 hrs; n = 10) following the maximum efflux rate ($\bar{\chi}$ = 2.99 pmoles Leu eq/min/mg). Pooled and concentrated effluents were separated into four primary amine-containing fractions (I to IV) of apparent molecular weight ≥ 1800, 425, 150 and 50 daltons, respectively, by chromatography on Bio Gel P-2.

Fraction III, which contained 78% of the recovered amines was subject to more detailed analysis. It contained the following free amino acids: Lys, His, Arg, Thr, Ser, Glu, Gly, Ala, Met, Ile and Leu. Acid hydrolysis of an equamolar sample increased the amount of 14 amino acids suggesting that fraction III contains a peptide(s) with the following composition: (Lys, Arg, Asx, Thr, Ser_2, Glx_4, Pro, Gly_5, Ala_3, Met, Ile, Leu_2, Tyr, Phe). Further experiments were performed to determine the number of peptides in fraction III. Primary amines and UV absorbing material (λ_{max} 275-280 nm) eluted in the void volume and were separated from smaller amines when fraction III was run on a Sephadex G-10 column using a mixture of phenol, acetic acid and water as an eluent. These results suggest that fraction III contains an aromatic peptide(s) that is ≥ 700 daltons. Fluorescamine derivitives of fraction III were analyzed by reverse-phase HPLC and the initial observations indicated the presence of 2 peptides.

It is concluded that in addition to the well-known secretion of proteins and amino acids, peptides are also spontaneously secreted from neuromuscular preparations. Chemical assay of primary amine secretion at the resolution levels afforded by analytical HPLC columns allows investigation of the parameters affecting secretion of specific molecules. In addition, HPLC purification of secreted peptides allows determination of their chemical structure as well as biological activity.

Supported by NIH grant NS07938.

53.9 NERVE GROWTH FACTOR SYNTHESIZED BY MOUSE FIBROBLAST CELLS IN CULTURE: ABSENCE OF α AND γ SUBUNITS. N. J. Pantazis. Dept. of Anatomy, Univ. of Iowa, Iowa City, IA 52242.

Two high molecular weight forms of Nerve Growth Factor (NGF) have been reported in the mouse submandibular gland, 7S-NGF (Varon, S., Nomura, J. and Shooter, E.M., Biochemistry, 6:2202, 1967) and NGF_1 (Young, M., Saide, J.D., Murphy, R.A. and Blanchard, M.H., Biochemistry, 17:1490, 1978). Both of these forms apparently contain subunits named α, γ and β-NGF. Although mouse salivary glands contain high concentrations of NGF, the salivary glands of other animals contain very little. Therefore, the source of NGF in most animals has not been identified. It is possible that low amounts of NGF are synthesized by many tissues in the animal to locally maintain the peripheral nervous system. The fact that various cell types in vitro synthesize and secrete NGF into their feeding medium (conditioned medium) supports this hypothesis.

What are the biochemical properties of NGF synthesized outside of the mouse salivary gland? Previous work using mouse L929 fibroblast cells in culture (Pantazis, N.J., Blanchard, M.H., Arnason, B.G.W. and Young, M., Proc. Natl. Acad. Sci. USA, 74: 1492, 1977) determined that a protein very similar to β-NGF was synthesized by these cells. Recently, radioimmunoassays have been established which are specific for the α and γ subunits of 7S-NGF. These assays could not detect either α or γ in concentrated samples of fibroblast conditioned medium, whereas the concentration of β-NGF in these samples was 700-800 ng/ml. When samples of pure 7S-NGF from mouse submandibular gland were assayed, the α and γ subunits were readily detectable (β-NGF = 34 μg/ml; α = 57 μg/ml; γ = 94 μg/ml). Since apparently no α or γ is synthesized by fibroblast cells, it would appear that the 7S-NGF molecule is not produced by these cells.

Gel filtration studies of the conditioned medium indicated that a molecule containing β-NGF but not α or γ was present. The molecular weight (M_r) of this complex was greater than 300,000 which is much larger than either 7S-NGF (140,000 M_r) or NGF_1 (116,000 M_r). Mouse fibroblasts, therefore, appear to make a previously undescribed form of NGF which is different from the salivary gland forms of NGF in two respects. The fibroblast molecule has a larger molecular weight and it lacks α and γ subunits. The properties of this new form of NGF are under investigation.

Supported by NIH grant GM28644 and the Lindsay Trust.

53.10 SPINAL CORD NEURONOTROPHIC FACTORS. W. Luyten*, M. Manthorpe, and S. Varon. Depts. of Neuroscience and Biology, Sch. of Med., Univ. of Calif. San Diego, La Jolla, CA 92093.

Various conditioned media (CM) are capable of supporting the 24 hr in vitro survival of dissociated 4-day (Stage 23) chick embryo lumbar spinal cord neurons. Tritration of CM from cultures of chick embryo heart and skeletal muscle cells, rat RN22 Schwannoma, C-6 glioma, astroglia and oligodendroglia and the chick embryo lumbar cord cells themselves revealed trophic activity; at high concentrations most CM also show a neuronotoxic activity. The molecular properties of all these CM-derived factors were similar and somewhat unexpected being heat (90°) and trypsin-resistant and smaller than MW 10^4. The effects of the Schwannoma (RCM) and lumbar cord (LCM) media on neuronal survival and choline acetyltransferase (CAT) activity were further examined in high (3×10^4 cells/cm^2) and low (3×10^3 cells/cm^2) cell seeding density cord cultures.

Lumbar cord cells were seeded on polyornithine-bound neurite promoting factor (J. Neurochem. 37: 759, 1981) in serum free N1 medium (Exp. Cell Res. 125: 183, 1980) as described previously (Dev. Brain Res. 3: 277, 1982). The proportion (%) of seeded cells which survived as neurons was counted at 1 and 5 d using phase-contrast microscopy, and replicate cultures harvested for subsequent CAT assay. The following results were obtained:

1. At low density few (approximately 10%) neurons survive 1 d and none for 5 d.
2. The presence of RCM in low density lumbar cultures dramatically increased survival to 70% by 1 d but none survived for 5d.
3. At high density a considerable neuronal survival (40%) was evident at 1 d and by 5 d 15% were still alive. This density-dependent neuronal survival is shown to be due to a soluble trophic factor present in the high density cultures (but not detectable in low density ones) which is capable of supporting neuronal survival for 1 and 5 d in low density cultures.
4. RCM does not increase 1 d neuronal survival significantly in high density cultures but decreases the expected 15% at 5 d to less than 1%.
5. CAT activity measurements reveal the presence of motoneurons in all surviving populations. As in vivo, there is a temporal increase in CAT activity in culture.

The observation of toxic influences in material which also contains survival-promoting factors deserves further study considering its potential relevance to neuropathology and normal development.

53.11 IONIC CONTROL BY NERVE GROWTH FACTOR IN MONOLAYER NEURONAL CULTURES. Stephen D. Skaper and Silvio Varon. Dept. Biol., Sch. of Med., Univ. of Calif. San Diego, La Jolla, CA 92093.

Nerve Growth Factor (NGF) is required for the survival and development of certain sensory and sympathetic neurons. We have demonstrated previously that, in the absence of NGF and before irreversible changes take place, NGF-responsive sensory and sympathetic ganglionic cells in suspension lose their ability to maintain normal intracellular levels of Na and K. Addition of NGF to such factor-deprived cells results in a restoration of intracellular Na and K within minutes and in a coupled fashion. These and other data have shown that NGF controls the performance of the Na, K-pump in its target ganglionic neurons.

In the present study we have examined the Na and K behaviors, under the influence of NGF, of monolayer cultures from embryonic day 8 (E8) chick dorsal root ganglionic (DRG) neurons. An enriched (75-80%) neuronal preparation obtained by means of a selective attachment step over plastic is seeded into 16 mm culture wells containing a polyornithine substratum, and Eagle's Basal Medium supplemented with fetal calf serum and NGF. After 18 hr the medium is replaced with fresh medium containing NGF or no NGF. ^{86}Rb (as a tracer for K) is added at this time. Over the next 12-15 hr the cultures are assessed for numbers of surviving neurons and radioactivity accumulated by the cells. Cultured E8 chick DRG neurons become unable to maintain their intracellular K level when deprived of exogenous NGF over 4-6 hr. The NGF-deprived and K-depleted neurons reaccumulated K within minutes upon delayed NGF presentation. The occurrence of this K response in culture to exogenous NGF parallels the response seen for enriched E8 neuronal suspensions, including the time at which irreversibility of the K deficit first becomes detectable. Similar experiments performed with ^{22}Na indicate corresponding ionic behaviors for cultured E8 DRG neurons. These consequences of the presence or absence of NGF are observed at E7 and E10 but not at E14, paralleling a previously observed survival response to NGF of E7 and E10, but not E15 chick DRG neurons in culture. This monolayer culture system should provide numerous opportunities for examining the consequences on neuronal survival of the ionic effects of NGF.

53.12 β-NERVE GROWTH FACTOR-LIKE PROTEINS IN HUMAN FETAL SMALL INTESTINE AND ADULT MOUSE BRAIN. M.B. Rosenberg[1*], M.H. Grossman[1], E. Hawrot[2], J.E. Pintar[1*], J.P. Schwartz[3], and X.O. Breakefield[1]. Depts. [1]Human Genetics and [2]Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510, and [3]NIMH, Washington DC 20032.

In rodents, β-nerve growth factor (β-NGF) is essential for the development and maintenance of sympathetic and sensory neurons. This protein has been purified from mouse submaxillary glands, where it is present in large concentrations, and well characterized, but little is known about β-NGF in other mouse tissues or in human tissues.

We have detected proteins in human fetal small intestine and adult mouse brain extracts that resemble mouse submaxillary β-NGF in receptor binding ability and in antigenic determinants. Extracts were tested for competition with ^{125}I-labeled mouse submaxillary β-NGF for binding to receptors on rat pheochromocytoma (PC-12) cells. β-NGF-like proteins were present in small intestine and mouse brain extracts at concentrations of 3-5 ng per mg total protein.

Small intestine extracts were also tested for antigenic resemblance to mouse submaxillary β-NGF. Proteins were separated by SDS polyacrylamide gel electrophoresis, transferred electrophoretically to nitrocellulose sheets, and screened with rabbit antisera to purified mouse β-NGF (donated by E. Johnson, G. Guroff and L. Greene), or with non-immune serum. Two immunospecific bands of molecular weight 24,000 and 43,000 were detected with 2 of 7 antisera tested. A two-site radioimmunoassay, using commercially prepared affinity purified antibodies to mouse submaxillary β-NGF, detected no β-NGF-like determinants in small intestine extracts. Small intestine extracts showed no biological activity using a bioassay involving induction of neurite outgrowth from chick dorsal root ganglia.

These studies indicate that human fetal small intestine contains some protein(s) that binds to β-NGF receptors on PC-12 cells but does not elicit a biological response from chick dorsal root ganglia neurons, and that shares some antigenic determinants with mouse β-NGF. In addition, a β-NGF-like protein that binds to β-NGF receptors on PC-12 cells appears to be present at low levels in adult mouse brain. Studies are underway to determine whether the mouse brain β-NGF-like protein is biologically active and structurally related to β-NGF from the mouse submaxillary gland. J. E. Pintar present address: Division of Endicrinology, Mt. Sinai Sch. Med., NYC, NY

53.13 IN SITU LOCALIZATION OF NGF RECEPTORS IN NEONATAL MICE. P. Bernd and L.A. Greene*. Department of Pharmacology, New York University Medical Center, New York, NY 10016.

Nerve Growth Factor (NGF) has been shown to be critical in the normal development of sympathetic and some sensory neurons. It is not known, however, when these receptors for NGF appear and/or disappear. It is also possible, that other targets for NGF may exist during development. A method of whole body radioautography has been devised in order to localize at the microscopic level possible targets for NGF throughout the body of a neonatal mouse. Animals (postnatal day 1) were injected subcutaneously with iodinated NGF (^{125}I-NGF; 3.88 x 10^4 CPM/ng; 30 ng/g body weight), perfused intracardially with saline and then fixative after 1 to 2 hours (3% glutaraldehyde in 0.1 M potassium phosphate buffer, overnight), dehydrated, embedded in paraffin, sectioned (10 µm), deparaffinized, exposed to Ilford L4 emulsion for 1 to 8 weeks, developed, fixed and stained with hematoxylin and eosin. In addition, certain organs of interest were embedded in Epok 812 and examined by electron microscopic radioautography (flat substrate technique). Control animals were injected with a 100-fold excess of nonradioactive NGF (3 µg/g body weight) in addition to the ^{125}I-NGF. In this manner, specific in situ NGF receptors can be identified.

Examination of 10 µm sections revealed that labelling was localized to previously described targets for NGF, such as dorsal root ganglia and superior cervical ganglia. Labelling was also detected over peripheral nerves, as well as the adrenal medulla. It was also interesting to note that a stream of labelled cells were seen migrating into the adrenal medulla from a nearly paravertebral ganglion that was also labelled. The adrenal medullary cells, therefore, appear to have receptors for NGF prior to reaching their final destination and becoming fully differentiated. The thyroid gland was also found to accumulate label, but electron microscopic radioautography revealed the grains to be localized over the follicular colloid, probably resulting from the uptake of free ^{125}I. Label did not appear to be specifically localized in other peripheral tissues or in the central nervous system. In control experiments, none of the above structures were found to be labelled. It is anticipated that this technique will be applicable to the localization of NGF receptors in prenatal animals. This study was supported by NIH grant #NS 16036, March of Dimes grant #1-704 and a Pharmaceutical Manufacturers Association Foundation fellowship (PB).

53.14 NERVE GROWTH FACTOR (NGF)-DEPENDENT PHOSPHORYLATION IN PHEOCHROMOCYTOMA CELLS. P.J. Seeley* and L.A. Greene* (SPON: A. Chalazonitis) Dept. Pharmacology, NYU Medical Center, New York, NY 10016.

The clonal rat pheochromocytoma line PC12 responds to NGF by cessation of cell division and assumption of the phenotype of a sympathetic neuron. We have examined the influence of NGF on phosphorylation patterns of PC12 and cloned variants of this line. Cultures were labeled with [^{32}P]-inorganic phosphate by incubation at 37°C in a HEPES-buffered Krebs solution. Cell components were fractionated by SDS-polyacrylamide gel electrophoresis and the gels processed for autoradiography. Exposure of PC12 cells to NGF for 1h caused increased phosphorylation of bands corresponding to MWs of ca. 54, 59 and 64kD and decreased phosphorylation of a 62kD band. A significant proportion of the 59kD band represents tyrosine hydroxylase (K. Lee et al., these abstracts). Treatment with 1mM db-cAMP plus or minus 200µM IBMX or with 60mM KCl or 5µM A23187 for 1h enhanced the 59kD band, but to a lesser extent than treatment with NGF. Db-cAMP did not mimic NGF-induced changes in the 62 and 64kD bands, though it did enhance phosphorylations which were not altered by NGF alone (e.g. 14kD). These data are not consistent with a simple cAMP messenger system for NGF. A set of cell responses to NGF which partially overlapped with the above set was detected by alkaline hydrolysis of gels prior to autoradiography. In this case there were enhancements of 40, 46, 59 and 64kD bands.

PC12 cells which had been treated with NGF for $\geq$7d responded to 1h readdition of NGF (after 4h of withdrawal) with increased phosphorylation of 54 and 59kD bands. The 59kD response was markedly less than that for cells without NGF pretreatment. Sister cultures withdrawn from NGF for 4h and then treated with 1mM db-cAMP for 1h had enhanced phosphorylation not only in the 54 and 59kD bands but also at 14 and 57kD. Similar additions of 60mM KCl or 5µM A23187 for 1h gave some enhancement of the 59kD band. There was also, on long-term treatment with NGF, a strong increase in a band at $\geq$300kD which appears to be the microtubule associated protein MAP1.

Cloned variants of PC12, which have restricted responsiveness to NGF, are altered in their phosphorylation pattern on 1h exposure to factor compared with the parent line. In particular, enhancement of the 59kD phosphorylation by NGF is less for variant cells. Basal phosphorylation profiles are different and there are additional NGF-responsive bands for the variant series.

Study of phosphorylation in these systems is a prospectively incisive means of examining second messenger signalling for NGF. This work was supported by grants NS 16036, NS 17888 and from the March of Dimes.

53.15 CALCIUM ENHANCES THE EFFECT OF BRAIN EXTRACT ON ACETYLCHOLINE RECEPTOR LEVELS IN CULTURED RAT MYOTUBES. J. R. Bostwick,* R. B. Moore* and S. H. Appel. (SPON: A. Coats). Department of Neurology, Baylor College of Medicine, Houston, TX 77030.

The number of surface acetylcholine receptors (AChR) in cultured rat myotubes increased 60% when post-fused cells were incubated for four days in medium supplemented with a soluble extract of fetal calf brain. This effect was enhanced by increasing the calcium concentration from 2 mM to 15 mM where a three-fold increase in AChR was observed. Magnesium did not substitute for calcium. In 15 mM Ca^{2+} medium the effect of extract was dose-dependent and saturable. Pre-incubation of the brain extract with trypsin (0.1%, 37°C, 90 minutes) rendered it inactive whereas heating the extract in a boiling water bath for 10 minutes did not reduce the stimulatory effect. Extract-treated myotubes accumulated surface AChR at rates up to 4.3 times higher than controls when measured over 12-hour intervals during the third and fourth days of incubation. In contrast, overall protein synthesis as measured by incorporation of ^{14}C-amino acids was not increased. A proteinaceous aggregate was formed when brain extract was incubated in 15 mM Ca^{2+} medium. This aggregate, but not the remaining medium supernatant, produced the increase in AChR levels when added to cultured myotubes. Activity remained when the aggregate was boiled or redissolved in 20 mM EGTA but not when pre-treated with trypsin. An SDS-PAGE analysis of the aggregate revealed three major protein bands, two of which were not predominant in the protein profile of the brain extract. Furthermore, these two protein bands were not present in an inactive aggregate formed from the extract in serum-free 15 mM Ca^{2+} balanced salt solution. This indicates that the active aggregate may constitute a complex derived from both brain extract and serum proteins. Increases in AChR number were not caused by non-specific effects of the aggregate on myotubes since an aggregate formed from liver extract did not elicit the response. Fractionation of the calf brain extract by high performance liquid chromatography produced 5 discrete peaks of protein. Material eluted at the exclusion limits of the column (> 200,000 daltons) formed an aggregate when added to 15 mM Ca^{2+} medium and increased AChR levels on myotubes. Analysis of this fraction on PAGE showed a single band with a molecular weight of 55,000. This band is predominant in the active aggregate and the whole extract. (Supported in part by grants from the John A. Hartford Foundation and the Robert J. Kleberg, Jr. and Helen C. Kleberg Foundation.)

53.16 SEPARATION OF TWO FACTORS FROM SKELETAL MUSCLE WHICH SUPPORT CILIARY NEURON SURVIVAL AND DIFFERENTIATION. Ken Vaca*, James McManaman*, and Stanley H. Appel. Dept. of Neurology, Program in Neurosciences, Baylor College of Medicine, Houston, Texas, 77030.

Chick ciliary ganglion neurons in dissociated cell culture provide a relatively homogeneous, convenient and sensitive system with which to test for macromolecules which support the survival, growth and differentiation of motor neurons. When grown in a defined medium (Bottenstein & Sato, PNAS 76: 514-517) on a poly-lysine substrate, the cells become pyknotic after 3 to 5 days in culture and degenerate and detach shortly thereafter unless appropriate supplemental macromolecules are provided. In the chick embryo, striated muscle was found to be a particularly good source of such trophic factors which promote the survival and morphological and biochemical differentiation of these motor neurons. Soluble extracts, dialyzed (M.S. cutoff 12-14,000) after high speed centrifugation, of skeletal muscle from several different species were similarly effective. Trophic activity was further purified, using fetal calf muscle as a source, by a series of salt fractionation and column chromatography steps. Two fractions which supported the long-term ($\geq$ 2weeks) survival and differentiation of the ciliary neurons were obtained. One fraction (A) caused the neurons to interconnect in a lush network and the proliferation of non-neuronal cells which often aligned with one or more neuritic processes. Fraction A also enhanced the ability of the cells to acetylate exogenously provided choline. Another fraction (B) failed to support any non-neuronal cells for more than a week in culture but caused a dramatic extension of long, narrow neurites. Furthermore, fraction B was more effective than A in increasing neurotransmitter synthesis, even though survival was somewhat less per culture. Fraction B was purified approximately 1000-fold from the soluble muscle extract. A high K^+ (30 mM) medium increased ACh synthesis to a similar extent, as did partial depolarization with 5 µM veratridine, while having far lesser effect on morphology. The CA^{++} antagonist D600 (10 µM) totally blocked the effect of high K^+ but not fractions A or B. Thus, skeletal muscle may contain more than one distinct macromolecule involved in the control of motor neuron growth and maintenance. These may act independently or in concert with electrical activity to modulate neural development.
(Supported in part by grants from the John A. Hartford Foundation and the Robert J. Kleberg and Helen C. Kleberg Foundation)

53.17 HEART CONDITIONED MEDIUM ELICITS POSTLESION MUSCARINIC RECEPTOR RECOVERY IN VIVO. Amy Rothman Schonfeld, Leon Thal*, Sara G. Horowitz* and Robert Katzman. Dept. of Neurology, Albert Einstein College of Medicine, Bronx, NY. 10461.

Heart Conditioned Medium (HCM) contains a neurotrophic factor which supports the survival and neuritic outgrowth of dissociated peripheral cholinergic neurons in vitro (Helfand et. al., Devel. Bio. 50:541, 1976). Recent work in our laboratory demonstrated that intraseptal administration of HCM stimulates the regenerative growth of injured central cholinergic fibers into iris implants placed in the hippocampus of rats in vivo (Schonfeld et. al., Brain Res. 229:541, 1981; Schonfeld and Katzman, Soc. Neurosci. (abst.) 7:677, 1981). The aims of the present study were to monitor muscarinic cholinergic receptor concentrations during denervation and central innervation of the peripheral tissue targets and to evaluate the effect of HCM on these changes.

For this, heterologous iris implants were inserted in the anterodorsal hippocampus in female rats previously subjected to ipsilateral superior cervical ganglionectomies. At the same time, a cannula was stereotaxically placed in the medial septum. Animals were administered 1 µl of either HCM (prepared by Dr. R. Johnston of Stanford U. according to Helfand et. al. (1976)) or saline as control vehicle. The injection schedule varied with the length of treatment in order to maintain the extent of injection-induced trauma relatively constant among the groups: 0, 4 and 8 days: daily; 16 days: alternate days and 28 days: 3 per week. After decapitation, the brains were rapidly removed, irides were dissected free from surrounding brain parenchyma, weighed and frozen. Levels of cholineacetyltransferase (CAT), the marker enzyme for cholinergic regeneration (Emson et. al., Brain Res. 135:87, 1977), were measured according to Datta, Thal and Wajda (Brit. J. Pharm. 41:84, 1971). Concentrations of muscarinic cholinergic receptors in implants were determined using (^{3}H)-quinuclidenyl benzilate (QNB) as the ligand (Yamamura and Snyder, Proc. Natl. Acad. Sci. 71:1725, 1974).

The results indicate that: (1) a dramatic drop in the number of muscarinic receptors is observed 4 days after denervation; (2) under control conditions, central cholinergic innervation of implants is not associated with muscarinic receptor recovery; and (3) after HCM administration, muscarinic receptor levels begin to increase within 2 weeks and approach the prelesion endogenous concentration following 28 days of treatment. These results support the hypothesis that trophic factors may facilitate the restoration of effective, appropriate connections between nerve fibers and their targets.

53.18 EXTRACT FROM BRAIN STIMULATES NEURITE OUTGROWTH FROM FETAL RAT RETINAL EXPLANTS, J. E. Turner, Y. A. Barde, M. Schwab and H. Thoenen. Department of Neurochemistry, Max-Planck Institute for Psychiatry, 8033 Martinsried, F-R, Germany and Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

The conditioned media from glioma cells (GCM) has been shown to possess neurotrophic qualities when tested with dissociated embryonic peripheral ganglionic neurons (Barde, Y. A., et al., Nature, 274: 818, 1978). In addition, a crude rat brain extract has been shown to enhance the survival of embryonic peripheral neurons in a manner similar to the GCM and was shown not to be NGF. This and other evidence points very strongly to the fact that there are neurotrophic factors in the CNS and that these factors may be elaborated by glial cells. However, these putative factors have not been tested in the developing mammalian CNS. We will report for the first time that a fraction from a pig brain extract (BE) stimulates neurite outgrowth from fetal rat retinal explants.

When BE was added in increasing concentrations to the culture medium, there was a dose dependent increase in the density and length of neurite outgrowth from the explants between 1-100 µg/ml, leveling off between 100-500 µg/ml. The BE mediated increase was approximately 5-fold at 100 µg/ml when compared to control values. BE administration (50 µg/ml) to retinal explants caused a continued, statistically significant, elevation of growth over controls for at least two weeks in culture. Control explants ceased neurite outgrowth after day 11, and subsequently began to show signs of degeneration. In order for BE to elicit its effects it must be present in the medium: BE will not bind to the polyornithine substrate, since no stimulatory effects were noted when explants were placed in control medium after the substrate had been pretreated with BE. Exposure of the explants to NGF or NGF-As had no effect on neurite density or length compared to controls. In addition, NGF did not augment the BE mediated response when added together nor did the combination of BE + NGF-As significantly reduce the NGI's compared to BE alone.

It is suggested that such an extract can be used as a source of putative neurotrophic factors exhibiting in the mammalian CNS an action similar to that of NGF in the PNS of mammals and in the CNS of lower vertebrates like fishes and amphibia.

Doctor Turner was a visiting scientist at the Max-Plank Institute and was supported in part by a NIH Research Career Development Award NS 00338.

53.19 IMMUNOHISTOCHEMICAL LOCALIZATION OF NEURITE EXTENSION FACTOR IN ADULT RAT BRAIN. D. Kligman* and D. M. Jacobowitz (SPON: G.H. Burrows). Lab. of Biochem. Genetics, NHLBI, NIH and Lab. of Clin. Science, NIMH, Bethesda, MD 20205.

Neurite extension factor (NEF) is an acidic protein (Mr = 75,000) isolated from bovine brain which induces neurite outgrowth from chick embryo cerebral cortex neurons in vitro in defined medium (Kligman, D., Brain Research, in press). A monospecific antiserum against NEF (anti-NEF) has been prepared in rabbits by repeated intradermal injections of the purified protein. Immunoperoxidase staining of nitrocellulose blots of total soluble bovine brain proteins separated by SDS polyacrylamide gel electrophoresis under non-reducing conditions reveals only a single stained band (Mr = 75,000). Additionally, anti-NEF IgG bound to protein A-Sepharose quantitatively adsorbs NEF bioactivity from soluble bovine brain extract.

Immunofluorescence microscopy has been used to localize NEF in adult rat brain. Brains were removed from formalin-perfused rats. Cryostat sections were treated with anti-NEF (1:1,000 dilution in PBS) for 1-5 days, followed by fluorescein-conjugated goat anti-rabbit IgG. NEF appears to be localized in the cytoplasm of neurons, not glial cells. In normal rat brain, fluorescent neurons (both cell bodies and fibers) were observed in the cerebral cortex. Fluorescent fibers were visible in the cerebellum, some of the cranial nerve tracts, the olfactory bulb (outer nerve fiber layer) and the reticular formation. The optic nerves were negative. Animals treated with colchicine intraventricularly (75 µg/25 µl PBS), perfused 2 days later, and stained with anti-NEF revealed additional fluorescent neurons; cell bodies were noted in the hippocampus, thalamus, hypothalamus, and amygdala, while axonal processes were noted in the hippocampus. Intraventricular colchicine appears to cause an endogenous buildup of NEF in discrete brain regions which are not immunohistochemically positive for NEF in normal brain. Localization of NEF (a molecule that is biologically active on embryonic neurons) in distinct regions of adult rat brain, some of which are known to sprout after lesioning (e.g. the outer nerve fiber layer of the olfactory bulb or the hippocampus), suggests a possible role for this molecule in neural plasticity and regeneration.

(Supported in part by the Muscular Dystrophy Association.)

53.20 PERIPHERAL NERVE EXTRACT: DEVELOPMENTAL APPEARANCE OF ASYMMETRIC ACETYLCHOLINESTERASE (AChE) IN CULTURED CHICK MUSCLE CELLS IN THE ABSENCE OF INNERVATION. H. Popiela, C. Flowers*, and B.W. Festoff, Dept. Neurology, University of Kansas Medical Center, Kansas City, Kansas 66103 and Veterans Administration Medical Center, Kansas City, Missouri 64128.

The appearance of asymmetric forms of AChE has generally not been detected in cultured chick skeletal muscle cells in the absence of cocultured neurons. To further explore neurotrophic effects of peripheral nerve extracts on muscle in vitro, we re-examined the appearance of various molecular forms of AChE in cultured chick muscle cells in the presence of adult peripheral nerve extract (NE). The various molecular forms of AChE were distinguished by sensitive sucrose gradient sedimentation and radioenzymatic techniques. Muscle cells were dissociated from 11d old chick embryo leg muscle and filtered through polyester cloth with 10 um pores to obtain single cells. These cells were then cultured in Ham's F-12 medium supplemented with 5% horse serum in the presence of 300 ug/ml NE. Cells proliferated during the first 48h of culture, then fused and formed spontaneously contracting myotubes by 6-8d in culture. Total AChE, 5.4S, and 11.5S molecular forms reached activity plateaus by 8d in culture which persisted until cultures were terminated at 21d. Between 1-7d in culture, 19.5S AChE was not detected. However, this asymmetric form abruptly appeared between 7-8d reaching a maximum of 8% of the total AChE and then gradually declined to a level of 2% at 20d. Since 19.5S AChE represented 25% of the total in 11d embryonic muscle tissue, we examined the possible requirement of neuronal presence in culture to attain higher levels of 19.5S AChE. Spinal cord neurons were plated onto 6d muscle cultures and AChE activities were measured between 8-20d. The results showed that 19.5S AChE activity in the presence of spinal cord neurons and NE was no greater than that found in the presence of NE alone. To prevent the development of contractile myotubes, 0.6 uM tetrodotoxin (TTX) or 15 uM d-tubocurarine (dtC) were added to 5d old parallel muscle cultures at a time when myotubes were differentiated but contractile activity had not begun. TTX inhibited further development of myotubes and also the appearance of 19.5S AChE. However, dtC had no visible effect on morphological development, virtually eliminated contraction, but did not interfere with the appearance of any forms of AChE including the 19.5S form. These studies show that adult peripheral nerve extract promotes the developmental appearance of the 19.5S form of AChE in non-innervated muscle cells in vitro.

54.1 PERINATAL INCREASE OF MOUSE BRAIN ESTROGEN RECEPTORS. W. Friedman, B.S. McEwen, J.L. Gerlach*and D. Toran-Allerand. The Rockefeller University and Columbia University College of Physicians and Surgeons, New York, NY.

Binding of the estrogen, ^{3}H moxestrol, to fetal and neonatal mouse brain cytosol receptors was examined to determine the ontogeny of estrogen receptors in specific brain regions. The areas studied were the hypothalamus and cerebral cortex and the ages ranged from embryonic day 15 to postnatal day 18. Cytosol receptor assays here were performed under exchange condition at 25°C for 4h in order to measure receptors which had become occupied by estradiol during tissue homogenization. Tritiated moxestrol (RU2858 from New England Nuclear) was used at 1nM to selectively label putative receptors and not alpha fetoprotein. Scatchard analysis revealed high affinity (Kd=0.4nM) sites and was in good agreement with single point assays at 1nM, which measured 70% of binding capacity.

Binding was initially examined in the whole forebrain. Total binding of ^{3}H-moxestrol in the forebrain begins to increase between embryonic days 15 and 18 and reaches adult levels at postnatal day 9. The increase in binding relative to protein content peaks at postnatal day 9 and then decreases, whereas the amount of binding relative to DNA content reaches a maximum between postnatal days 12 and 15.

The developmental time course of the estrogen receptors was studied in the hypothalamus and three cortical regions. In the hypothalamus binding of ^{3}H-moxestrol is increasing from postnatal day 5 to day 18. The cingulate cortex shows the highest amount of binding, increasing until postnatal day 9 and then declining. In the other two cortical areas studied, the lateral and posterior cortices, binding, when expressed per mg DNA, is somewhat higher between postnatal days 7 and 15 than in adults. When the binding is expressed per mg of protein there is a dramatic decline after day 7, which is probably a result of a large increase in protein content relative to amount of receptor.

The perinatal period, from fetal day 15 to postnatal day 5, shows a great increase in ^{3}H moxestrol binding in both hypothalamus and cortex. The overall increase in binding is 10-20 fold between E15 and P1, with a more gradual increase between P1 and P5. Thus, estrogen receptor levels, while detectable in the mouse at E15, are subject to a sharp and rapid increase in the perinatal period. This increase may be related to the onset of the phase of sexual differentiation known as "defeminization" which appears to involve estrogen receptors responding to estradiol produced from testosterone and which appears to be confined to the very early postnatal period. (Supported by grants from the USPHS, NSF, Rockefeller Foundation, March of Dimes Birth Defects Foundation and Mellon Foundation.)

54.3 PUBERTY ASSOCIATED NEURAL SYNAPTIC CHANGES IN FEMALE RATS ADMINISTERED ESTROGEN. Richard W. Clough and Jorge F. Rodriguez-Sierra. Dept. Anat., Univ. Nebraska Med. Ctr., Omaha, NE 68105

Estradiol benzoate (EB) administration can induce phasic pituitary gland LH secretion, ovulation and vaginal opening in prepuberal female rats presumably through a neural mechanism. This study investigated whether this effect is associated with changes in synaptic profiles in the mediobasal hypothalamus (MBH) and the medial preoptic area (MPOA). Twenty-five-day-old female rats were administered EB (10 µg/rat, sc, in oil) or EB followed by progesterone on day 27 (P; 1 mg/rat, sc, in oil) or they received no treatment. Blood was collected at 1600 h on day 27 and assayed for LH by radioimmunoassay. Rat brains were perfused and the MBH and MPOA were removed and processed using phosphotungstic acid for selective staining of neural synapses.

Group	N	LH(ng/ml)	MBH Synaptic Vol %	MBH Numerical density X 10^6	MBH Synaptic area density/100 μ^2
Control	5	34± 7	.46±.05	.80±.08	4.39±.26
EB	5	1079±364*	1.11±.03*	1.86±.03*	10.57±.85*
EB + P	5	1771±321*	1.06±.06*	1.78±.11*	9.64±.34*

(* = $p<0.05$ compared to control; mean ± SEM)

Serum LH was markedly elevated in the EB and EB + P treated groups at 1600 h 2 days after EB treatment. This acute rise of serum LH was accompanied by an acute increase of synaptic volume percent and numerical density in the MBH. We observed no such change in the MPOA of EB treated animals compared to controls. We are in the process of investigating other neural areas including the medial septal area and the cortico medial amygdala. Data will be presented for these areas as well as data obtained from treating prepuberal male rats with EB. We conclude from this study that estrogens act through a neural mechanism to accelerate maturation of neuroendocrine processes which govern phasic pituitary gland LH release and that this maturation process entails synaptogenesis in the MBH. (Supported by grants from the Univ. of Nebraska Medical Center, by NIMH grant 36419 and by NIH HD-13219.)

54.2 PREPUBERAL EXPOSURE TO ESTROGEN INCREASES THE NUMBER OF NICOTINIC RECEPTORS IN THE MEDIOBASAL HYPOTHALAMUS (MBH) OF THE FEMALE RAT. J. F. Rodriguez-Sierra, B.J. Morley and R.W. Clough. Dept. Anatomy, Univ. Nebr. Med. Ctr., Omaha, NE 68105 and The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131.

Our previous work has centered on an experimental model to induce a precocious surge of serum luteinizing hormone (LH) by administration of 10 µg of estradiol benzoate (EB) to a 25-day-old female rat. Two days after EB at 1600h, but not at 1100h, serum LH concentration is elevated 1000 times basal levels. We have previously shown that prepuberal female rats treated with EB incur a dramatic increase in the number of synapses in the MBH when compared to oil-vehicle controls. The present study was conducted to test the possibility that the increased synaptogenesis after EB treatment involves, at least in part, an increase in nicotinic acetylcholine receptors (NAR) in the MBH. Twenty-five-day-old Sprague-Dawley female rats were administered 10 µg of EB or oil vehicle, sc. On day 27 of age, animals were decapitated at 1600h. Trunk blood was collected, centrifuged at 1500 x g for 10 min at 4°C and serum frozen (-20°C) until radioimmunoassay for LH was performed. The brains were removed from the skull, blocked coronally at the level of the optic chiasma-anterior commissure decussation. The brain was sliced at 1 mm sections thick. Sections were placed in ice, transilluminated and the preoptic area (POA), septal area (SEP), MBH and somatosensory cortex (CX) were removed and placed in ice-cold buffer. Tissue was homogenized, centrifuged at 100,000 x g for 30 min, the supernatant was discarded, pellet was resuspended in Triton X buffer and centrifuged again at 100,000 x g for 30 min. Radioreceptor assay for NAR was performed using α-bungarotoxin (BuTX) as the radioligand.

	(N)	BuTX Binding MBH[a] (fmoles/mg protein
EB	14	89.4±10.5*
Oil	12	62.8± 7.6

[a]Mean ± SEM; *$p<0.05$.

The EB-treated rats exhibited a significant increase in the number of BuTX binding sites in the MBH. The POA and SEP showed a small, but non-significant increase of BuTX binding, while the CX was unaffected by the treatment. The results point to acute morphological and neurochemical changes in the MBH due to EB treatment in prepuberal female rats and suggest that the onset of puberty is partially due to an increase in the number of cholinergic synapses. Supported by grants from NSF (AO-06648) to B.J.M. and NIH (HD-13219) to J.F.R-S.

54.4 PRENATAL EXPOSURE TO ESTROGEN MASCULINIZES AND DEFEMINIZES BEHAVIOR IN THE GUINEA PIG. M. Hines, P. Alsum*, R.A. Gorski & R.W. Goy. Dept. of Anatomy & Lab. of Neuroendocrinology, Brain Res. Inst., UCLA Sch. of Med., Los Angeles, CA, and Wis. Reg. Primate Res. Ctr., U. of Wisconsin, Madison, WI.

Genetic female rats and hamsters treated with estrogen during perinatal critical periods of development show enhanced masculine copulatory behavior (masculinization) and impaired feminine copulatory behavior (defeminization). In these species critical developmental periods are largely postnatal, and it is not known if estrogen has similar effects in species, such as the guinea pig, in which critical periods occur prenatally. Therefore, we treated guinea pigs with estradiol benzoate (EB) or diethylstilbestrol (DES), a synthetic estrogen that is more potent than estradiol, from day 29 to day 68 of pregnancy. Hormones were injected subcutaneously in 0.1 ml oil daily for the first six days and on alternate days thereafter. Doses and the number of female offspring in each treatment group were: 1 µg EB (n=8), 2 µg EB (n=7), 3.3 µg EB (n=8), 1 µg DES (n=4), 3 µg DES (n=6), oil (n=4), and untreated (n=13). Animals were ovariectomized as adults and tested twice for feminine behavior following priming with EB and progesterone, and twice for masculine behavior without hormone replacement. For feminine behavior, the duration of the lordosis response to stroking was assessed hourly for 12 hours following hormone priming. For masculine behavior, a stimulus female was introduced into the home cage for 15 minutes and the number of correctly oriented mounts was recorded. Animals treated with 3 µg DES were clearly masculinized and defeminized. Compared to controls, more of these animals mounted (83% vs. 13%, $p<0.001$), and they mounted more frequently (4.8±2.5 vs. 0.1±0.2, $p<0.01$). In addition, fewer of them showed a lordosis response (50% vs. 100%, $p<0.01$) and the quality of their response was impaired. The peak duration was shorter than controls (1.6±0.7 vs. 11.4±0.7 secs, $p<0.001$) as was the average duration for all responses to stroking (0.8±0.3 vs. 5.7±0.7, $p<0.001$). Similar but less dramatic effects were seen in animals treated with 1 µg DES. Although 75% of these animals showed lordosis, the peak and average durations (6.8±1.9, 3.3±0.8 secs, respectively) were less than in controls ($p<0.01$, $p<0.05$, respectively). In addition, more of these animals than controls mounted (75%, $p<0.05$) and they mounted more often (4.4±3.3, $p<0.01$). There was also some evidence of masculinization in terms of mounting frequency in animals treated with 3.3 µg EB (0.6±0.4, $p<0.05$). These results indicate that estrogen-induced masculinization and defeminization are not limited to animals in which critical periods for sexual differentiation occur postnatally. Supported by NIH grants HD00182, RR00167, MH21312 and NS6594.

54.5 DIFFERENTIAL EFFECTS OF THE PERINATAL STEROID ENVIRONMENT ON TWO PARAMETERS OF SEXUAL DIFFERENTIATION. R. J. Handa*, J. E. Shryne*, J. N. Schoonmaker*, P. Corbier* and R. A. Gorski. Dept. of Anat. and Brain Research Inst., UCLA School of Medicine, Los Angeles, CA 90024 and Lab. d'Endocrinologie, Universite Paris-XI, Orsay.

Previous studies suggest that the presence of a post-partum testosterone surge in male rats may be of importance in the suppression of the development of feminine sexual behavior. In this study we have examined the influence of the perinatal steroid milieu on two parameters of sexual differentiation: the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA) and the positive feedback response to estrogen (E) and progesterone (P) treatment. Sherman rats were divided into groups according to sex and time of gonadectomy (Gx). Females were either Gx'd at 0 h (i.e. in utero), or sham operated and Gx'd at 29 days of age. Males were Gx'd at 0 h, or 6-7, 12-13 or 24 h post partum or sham operated at 0 h followed by Gx at 29 days of age. In addition, another group of males Gx'd at 0 h were injected with 5 µg testosterone propionate (TP) sc immediately after surgery. The induction of a positive feedback response of LH to E and P was performed between 100-120 days of age. Blood was taken by jugular puncture at 29 and 53 h following E treatment and 5 h after P treatment and assayed for LH by RIA. Two weeks later rats were sacrificed and perfused for analysis of SDN-POA volume. In males, a significant ($p<0.001$) increase in the amplitude of the LH surge was exhibited by animals Gx'd at 0 h as compared to those of males Gx'd at later time periods. Treatment with 5 µg TP did not change the amplitude of the LH surge but decreased its incidence. Also, the incidence of the LH surge decreased with time of postnatal Gx from 50% at 0 h to 14% at 24 h. No sham Gx'd males showed an LH surge. In females there was a significant ($p<0.001$) change in the amplitude of the LH surge between those Gx'd at 0 h and 29 days (shams). Furthermore, the amplitude of the surge shown by 0 h females was comparable to those of 0 h males. SDN-POA volume was found to be unchanged in all perinatally Gx'd males but were significantly ($p<0.001$) different when compared to that of sham operated males and females. Treatment with 5 µg TP increased by 50% ($p<0.001$) the size of the SDN-POA of males Gx'd at 0 h, but did not completely restore it to that seen in sham Gx'd males. In addition, a decrease ($p<0.05$) in SDN-POA volume was noted in 0 h Gx'd females when compared to that of sham Gx'd females. Thus, 1) the postpartum testosterone surge is important in the differentiation of LH surge mechanisms but it is without an obvious effect on the development of the SDN-POA. 2) 5 µg TP given immediately after parturition influences the development of the SDN-POA as well as LH mechanisms. 3) In the female rat the ovary may be of importance in normal female sexual development. Supported by AG 01754, GM 07191 and HD 01182.

54.6 ANALYSIS OF THE PATTERNS OF GROWTH HORMONE SECRETION IN TESTICULAR-FEMINIZED (tfm) RATS. W.J. Millard*, J.A. Politch, J.B. Martin, T.O. Fox. Dept. of Neurology, Massachusetts General Hospital, Dept. of Neuroscience, Children's Hospital Medical Center, Harvard Medical School, Boston, MA 02115.

We have previously demonstrated that the sexually dimorphic patterns of growth hormone (GH) secretion in adult rats are not entirely dependent upon the gonadal steroid environment during the early postnatal period. Neither castration of neonatal males nor androgenization of neonatal females resulted in a complete alteration of the respective homotypic GH patterns. Since the development of some behaviors in the rat is affected by steroids during prenatal development, we have begun to investigate whether prenatal "organizing" effects of gonadal steroids influence the GH secretory patterns in adult animals. We examined an androgen-resistant mutant rat, testicular feminization (tfm), maintained as a Stanley-Gumbreck line derived from a King-Holtzman stock. These animals are deficient in androgen receptors and many androgen-dependent characteristics. We compared the GH secretory patterns in these mutants with their normal male and female siblings. If prenatal exposure to steroids is responsible for the adult masculine pattern of GH secretion, then tfm animals should exhibit the female GH secretory profile. All animals, 6-8 months of age, were prepared with intraatrial silastic catheters, and following recovery from surgery, placed in specially designed sampling chambers 48-72 hrs prior to experimentation. Animals were bled via the indwelling catheter every 15 min for 8 hr (900-1600 hr) and the GH levels in the plasma determined by RIA. Normal males displayed the characteristic "episodic" pattern of GH secretion with bursts of GH (values usually > 300 ng/ml) occurring every 3-4 hr and separated by GH trough (values usually < 5 ng/ml) periods of 30-90 min in duration. Females showed an irregular pattern of GH secretion with "pulses" of GH occurring every 1-2 hr; the individual GH peak heights were lower (values < 150 ng/ml) and the GH trough values (10-20 ng/ml) higher than those of normal male animals. The tfm animals displayed GH secretory profiles which resembled those of their normal female littermates, i.e. increased frequency of GH bursts, diminished GH pulse amplitudes and elevated GH trough levels relative to normal males. These data are consistent with the hypothesis that the gonadal steroid environment during the prenatal period of development plays a major role in determining the sexually dimorphic patterns of GH secretion in the rat. Since tfm rats are deficient in androgen receptors, androgen might serve in this capacity. We have not ruled out, however, that non-steroidal factors are involved in the expression of female-like GH patterns in tfm rats.

[Supported by NIH grants, AM26252 (JBM) and HD10818 (TOF).]

54.7 EFFECTS OF PRENATAL EXPOSURE TO FLUTAMIDE ON FEMALE SEXUAL BEHAVIOR AND MUSCARINIC BINDING IN MALE RATS. J. A. Witcher*, G. P. Dohanich and L. G. Clemens. Department of Zoology, Michigan State University, East Lansing, MI 48824.

Sexual differentiation of the rat brain is dependent upon the hormonal environment that prevails during prenatal and early postnatal life. Exposure to perinatal androgen may decrease the ability to respond to estrogen in adulthood. For example, estrogen regimens that activate a high level of female sexual behavior in ovariectomized female rats are usually less effective in activating this behavior in castrated males. Estrogen also has the capability of altering the number of cholinergic muscarinic binding sites in the preoptic and hypothalamic areas of female rats but not of male rats. This sex difference in the potential of estrogen to affect cholinergic activity may have important biological implications since recent evidence indicates that cholinergic transmission in the female rat brain contributes to the regulation of the lordosis response, an estrogen-dependent sexual behavior. An experiment was conducted to determine if male rats exposed prenatally to the antiandrogen, flutamide, would display behavioral and physiological responses to estrogen that are typically feminine in character; specifically, enhanced levels of female sexual behavior and significant changes in muscarinic binding following estrogen treatment in adulthood.

Long-Evans male rats were exposed to flutamide (5 mg/day/mother) or propylene glycol vehicle on days 10-21 of gestation. In adulthood, randomly-selected males (90-100 days of age) were gonadectomized and three weeks later were injected with either estradiol benzoate (10 µg/kg, i.m.) or sesame oil (0.1 ml, i.m.) for three days. Muscarinic binding was analyzed in the medial preoptic area, medial basal hypothalamus, septum, and parietal cortex using a tritiated antagonist, 3-quinuclidinyl benzilate. Male littermates were treated with estradiol benzoate (10 µg/kg for three days, i.m.) and tested for lordosis behavior elicited by stimulus male rats. Although male littermates given prenatal flutamide displayed enhanced lordosis behavior in response to estrogen treatment when compared to propylene glycol controls, no significant changes in muscarinic binding were detected following estrogen treatment in any brain area analyzed. Consequently, prenatal flutamide feminized the behavioral response of males to estrogen without altering the inability of males to exhibit estrogen-induced changes in muscarinic binding. It is suggested that behavioral feminization arising from prenatal exposure to flutamide is not directly correlated to measurable changes in muscarinic binding within the male brain.

54.8 SEX DIFFERENCE IN DENDRITES DURING DEVELOPMENT OF THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA. Ronald P. Hammer, Jr. and Carol D. Jacobson. Lab. of Neurophysiology, NIMH, Bethesda, MD 20205 and Dept. Vet. Anatomy, Iowa State University, Ames, IA 50011.

In the Sprague-Dawley rat, the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA) is larger in volume in the male sex. Results from the present study indicate that by day 10 of postnatal life (PN) the dendritic systems of neurons in the male SDN-POA are more extensive than those of females both in length and pattern of branching. At birth, the dendritic arborizations are similar in the male and female. However, rapid dendritic growth in the male ensues between day 4 PN and day 6 PN. All animals utilized in this study were obtained from lactating females which were bred in the animal colony. A sperm-positive vaginal smear on estrus was defined as day 1 postfertilization (PF). All females delivered on day 23 PF, defined as day 1 PN. Male and female pups were sacrificed by decapitation on either day 2, 4, 6 or 10 PN. Dendritic status was assessed using the Stensass modification of Golgi staining technique. Analysis of Golgi impregnated SDN-POA neurons involved measuring dendritic expanse and number of branches as well as dendritic spines. Somata contained in the region characterized as the SDN-POA are rounded in the neonatal animal. However, they become more elongated during development. These neurons generally extrude three or four primary dendritic branches, the number of which remains constant during early postnatal development. Further branching of the dendritic arbor occurs with the formation of secondary and tertiary dendrites. Rarely does branching beyond this occur prior to day 10 PN. Growth regions on the dendrites are evidenced by varicose regions which are more prominent on terminal branches. SDN-POA neurons are often spiny. The appearance of these spines, which represent further development of the neuropil, is greater in the male after day 4 PN and after day 6 PN in the female. The increase in the male dendritic array after day 4 PN coincides with the previously observed sexual differentiation of the volume of the SDN-POA. These data suggest that the sexual differentiation of the SDN-POA may in part be due to the changing neuronal morphology which is taking place during the time period when gonadal steroids are capable of influencing the resulting adult volume of the SDN-POA. (Supported in part by NIH grants RR07034 and HD-16148).

54.9 NEUROGENESIS OF MOTONEURONS IN THE SEXUALLY DIMORPHIC SPINAL NUCLEUS OF THE BULBOCAVERNOSUS IN RATS. C.L.Jordan, S.M.Breedlove & A.P.Arnold. Psychology Department, UCLA, Los Angeles, CA 90024.

The spinal nucleus of the bulbocavernosus (SNB) consists of motoneurons innervating striated perineal muscles in male rats. Motoneurons in the SNB region are only one-third as numerous in females as in males (Breedlove & Arnold, Science 210 564, 1980), and the number of motoneurons can be increased or decreased by perinatal manipulations with androgen or anti-androgen. It is not yet known whether such manipulation of the number of SNB cells is due to alteration of the proliferation, death or specification of motoneurons. We now report results from thymidine autoradiography indicating that SNB motoneurons are post-mitotic by the 15th day of gestation. Since hormonal manipulations more than a week later can increase or decrease the number of SNB cells, such manipulations are probably mediated by alterations in the death or specification of cells, but not their proliferation.

Fetal Sprague-Dawley rats were exposed to tritiated thymidine via a single ip injection of pregnant dams (5 uCi/g body weight, 45 Ci/mmol) on one of 14 days of gestation (days 9-22) or sc injection of rat pups on either gestational day 23 (day 1 of life) or day 3 of life. All animals were sacrificed in adulthood (day 57) and the lumbar-sacral spinal cords were prepared for autoradiography. After 9 weeks of exposure, SNB cells were considered unlabeled if they had 6 or fewer silver grains over the nucleus, lightly labeled if they had 7 to 11 grains, and heavily labeled if they had 12 or more silver grains over the nucleus. More than 90% of SNB cells incorporate thymidine on gestational day 12, but SNB motoneuron nuclei were never heavily labeled in rats injected with thymidine on the 15th day of development or later, thus indicating the completion of neurogenesis. The table below describes the labeling of SNB cells in males, the pattern of which seems identical in females, despite the scarcity of SNB cells in adult females.

DAY INJECTED	- d9	d10	d11	d12	d13	d14	d15 & later
LIGHTLY LABELED-	28.6%	32.2%	22.8%	17.1%	0%	0%	0.4%
HEAVILY LABELED-	11.4%	5.5%	10.1%	75.0%	4.0%	2.9%	0%
number of cells	(70)	(90)	(79)	(76)	(100)	(70)	(687)

Because appropriate hormone treatment more than a week after the end of mitosis can either increase or decrease the adult number of SNB cells, such alterations probably are due to effects on motoneuronal death rather than proliferation. By extension, the normal development of a sexually dimorphic number of SNB cells is also probably due to differential cell death.

Supported by NIH grant HD15021, RR07009, HD07228.

54.10 ESTRADIOL INCREASES NUMBERS OF NEURONS AND SYNAPSES IN NEONATAL RAT SUPERIOR CERVICAL GANGLION. L. L. Wright and A. J. Smolen, Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Neonatal treatment with gonadal steroids has been reported to alter morphological as well as functional development in various regions of the brain and spinal cord. These regions have been found to be sexually dimorphic, and the gender differences in neuron and synapse numbers dependent upon the level of gonadal steroids during the perinatal period. It has been shown previously that neonatal treatment with testosterone propionate (TP) results in an increase in the number of neurons in the superior cervical ganglia (SCG) of female (Dibner & Black, J. Neurochem. 30:1479-1483, '78) and male (Wright & Smolen, Soc. Neurosci. Abst. 7:5, '81) rats. Since there are normal gender differences in circulating levels of testosterone perinatally which could influence neuron numbers, we compared ganglia of adult male and female rats. We found that the males have 20% more SCG neurons than the females. In some sexually dimorphic CNS regions, estrogen has been found to be the active metabolite of testosterone responsible for gender differences. We therefore investigated the effects of estrogen on the developing SCG neurons and synapses. 17-b-estradiol (E_2) (.05 µg/g) was suspended in oil and administered subcutaneously on alternate days from the day of birth until the time of sacrifice on day 15. Thus, treatment continued throughout the period of normal neuron death (Wright et al. Anat. Rec. 199:217A, '81), and during the time when most synaptogenesis occurs (Smolen & Raisman, Brain Res. 181:315-323, '80). Treatment with E_2 results in a 95% increase in neurons. Studies in progress will determine whether this increase in neuron numbers is due to increased proliferation or decreased neuron death. Synaptogenesis was also altered by estradiol treatment, resulting in a 130% increase in SCG synapses.

Gonadal steroids may modulate neuron and synapse numbers by direct action on receptors within the SCG. Alternatively, the steroids could act at receptors on targets or afferents of the SCG, altering neuron and synapse development by changing the interactions with these cells. Circulating testosterone, possibly via local metabolism to estrogen, may mediate the sex difference in SCG neuron numbers, as it does in sexually dimorphic regions of the CNS. Gonadal steroids may also play a role in the normal development of SCG neuron and synapse populations in both genders, since low levels of estrogen and testosterone are present during the perinatal period in males and females.

Supported by NIH grants NS13768 and NS15952.

54.11 SEXUAL DIFFERENCES IN 2-DEOXY-D-GLUCOSE UPTAKE IN THE BRAINS OF DEVELOPING RATS. C. L. Kornblith, W. W. Youngblood*, and J. S. Kizer*. Biol. Sci. Res. Ctr., Univ. North Carolina Sch. of Med., Chapel Hill, NC 27514.

Structural sex differences have been found in the central nervous system, especially in avian vocal control areas (Nottebohm and Arnold, Science, 194: 211, 1976) and in rodent preoptic area (Gorski et al., Brain Res., 148: 333, 1978; Greenough et al., Brain Res., 126: 63, 1977) and the spinal nucleus of the bulbocavernosus in the lumbar spinal cord (Breedlove and Arnold, Science, 210: 564, 1980). The participation of these structures in courtship or sexual behavior has been demonstrated.

We felt that additional brain regions that are less directly involved in hormonal actions and sexual behavior might also display sexual differences. Such differences could be represented morphologically and/or in functional activity. Furthermore, these differences, particularly in functional activity, might be present only at certain times during development.

In order to locate areas with sexually dimorphic functional activity, we measured the uptake of ^{14}C-2-deoxy-d-glucose (2DG) in the brains of male and female rats of different ages. Eight peripubertal (33 to 37 days of age) and eight adult rats were injected i.p. with 125 uCi/kg of 2DG and returned to a familiar environment. Following a 45 min period during which behavioral observations were recorded at 30 sec intervals, the animals were sacrificed and the brains were prepared according to the autoradiographic method described by Sokoloff et al. (J. Neurochem., 28: 897, 1977). Eight coronal sections from each brain were selected for analysis. A computer-aided, television-based system was used for densitometric measurements. Grey to white matter ratio values for specific areas were averaged across animals of the same sex and age. Between group differences were then examined.

We found very interesting differences in the patterns of functional activity at all levels of the neuraxis as a function of both age and sex. Behavioral differences during the test could not account for differences in functional activity. For both sexes, there was generally greater 2DG uptake in the adult than in the peripubertal animals. Adult proestrus females showed the largest difference in labelling compared to young females. In the young animals there were few significant differences in functional activity between the sexes. For the adults, complex sex differences in the pattern of 2DG uptake were found at several levels of the brain, and varied as a function of the phase of the estrus cycle in the females. Our results suggest that the differences between male and female brains are greater than indicated by previous studies. Supported by HD-14005 and MH-00114.

54.12 ESTROGEN AND PROGESTIN RECEPTORS IN FETAL RAT HYPOTHALAMIC TRANSPLANTS GROWN IN GONADAL STEROID-FREE ADULT HOSTS. C. M. Paden, J. L. Gerlach* and B. S. McEwen. The Rockefeller University, 1230 York Avenue. New York, NY 10021.

Determining the factors which govern the appearance of hypothalamic estrogen receptors during the perinatal period is important in understanding the mechanisms of sexual differentiation in the rat. We have investigated the influence of gonadal hormones on the appearance of estrogen and progestin receptors in fetal rat hypothalamus transplanted into adult host brains. This technique allows for manipulation of the hormonal environment of the developing brain to an extent which is impossible in the fetus in situ.

Fetuses were removed from Charles River CD rats under barbiturate anesthesia on days 15-18 of gestation. Hypothalamic transplants were made onto the choroidal pia overlying the superior colliculus in young adult female CD hosts as previously described (Stenevi, U., et al., Cell Tiss. Res., 205:217, 1980). Hosts were (a) intact or (b) ovariectomized (OVX) and adrenalectomized (ADX) 72 hours previously or (c) OVX-ADX and implanted sc with a 1 cm silastic capsule of estradiol (E_2). E_2 implants were removed 4 weeks later and all hosts were decapitated 8 weeks after transplantation. Estrogen and progestin receptors were assayed in transplant cytosol (MacLusky, N. J. and McEwen, B. S., Brain Res. 189:262, 1980). Saturable binding of radiolabeled E_2 to cytosol protein was found in all hypothalamic transplants. This binding exhibited the steroid specificity of authentic estrogen receptors. Scatchard analysis was linear, giving a K_d of 0.26 nM and B_{max} of 7.12 femtomoles/mg protein. No significant differences in the level of estrogen receptors were observed in transplants from groups a, b or c. In addition, no differences in levels were observed in transplants taken from male or female fetuses on gestational days 17 or 18. Day 15 and 16 fetuses were not sexed. Concentration of ^{3}H-E_2 by transplant neurons in vivo was also demonstrated using autoradiography. No differences in the pattern of concentration between transplants from intact and OVX-ADX hosts were found, and indeed transplants were indistinguishable from host hypothalamus. Saturable binding of ^{3}H-promegestrone to progestin receptors was also detectable in transplants from both intact and OVX-ADX hosts. Progestin receptor levels were significantly increased in both groups when hosts were given 2 sc injections of 10 µg estradiol benzoate 72 and 48 hours before death.

We conclude that exposure to gonadal steroids during either the last week of gestation or the postnatal peroid is not required for the elaboration of hypothalamic estrogen and progestin receptors in the rat. Furthermore, the estrogen receptors which appear under gonadal steroid-free conditions are functional as determined by the ability of estradiol to induce progestin receptors in hypothalamic transplants.

55.1 INNERVATION OF PERIPHERAL NERVE SEGMENTS GRAFTED INTO RAT OLFACTORY BULB. B. Friedman and A. Aguayo, Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4

Using retrograde axon tracing methods it has been recently demonstrated that in the mature mammalian central nervous system, certain neurons grow axons into peripheral nerve segments grafted into the brain or spinal cord (Aguayo et al. In, Advances in Cellular Neurobiology 3:215-234, 1982). It is not known if processes of all types of central neurons will grow into such grafts. The olfactory bulb is a convenient site to study whether large projection neurons (mitral cells) and related small interneurons (periglomerular, granule and short-axon cells) have the capacity to innervate a peripheral nerve graft. The somata of the bulbar projection neurons and interneurons occupy separate lamina and possess distinct morphologies. Among the interneurons, the granule cells are further distinguished by (i) their great number and (ii) their apparent lack of axonal processes.

This study examines the capacity of these various bulbar cell types to grow axons into autologous peroneal nerve segments which have been transplanted into the surgically exposed dorsal surface of the olfactory bulb(s) in adult male Sprague-Dawley rats. The distal portion of the graft is placed extracranially and the distal tip either sutured to the ipsilateral temporalis muscle or inserted into the contralateral olfactory bulb. From 6-8 weeks after grafting , a pledget of gelfoam soaked in 20% HRP was placed onto the extracranial stump of the transected nerve graft. The cut was surrounded by vaseline and parafilm to avoid tracer diffusion.

In cases where there was good fusion of the graft to the olfactory bulb, the tip of the graft was typically located in the granule cell layer. HRP application to the graft produced retrogradely labelled profiles which were identified as mitral cells on the basis of their laminar position, shape and size. To date, none of the bulbar interneurons have been labelled. These findings suggest that bulbar projection neurons can grow into peripheral nerve grafts while the bulbar interneurons apparently lack this capacity. However, it is also possible that the HRP tracing method may be insufficiently sensitive to detect small bulbar interneurons which may have innervated the graft.

55.2 TURNOVER OF OLFACTORY RECEPTOR PROTEINS. R. Schafer and J.C. Dickens*. Dept. Biol. Sciences, North Texas State Univ., Denton.

It has been generally assumed that odorant receptor sites in olfactory receptor membranes are not altered irreversibly or "used up" when they interact with odorants during the transduction process. However, this assumption has never been tested experimentally. Furthermore, the rate of turnover (degredation/replacement) of olfactory receptor molecules has not been measured. Experiments are underway using protein synthesis inhibitors in an attempt to discover the life span of olfactory receptor molecules. These experiments involve long-term recording from the frog olfactory mucosa after application of certain inhibitors. One side of the nose is exposed to an inhibitor in perfusion solution, while the other side serves as a control which is exposed only to the perfusion solution.

Topical application of puromycin, a powerful inhibitor of protein synthesis, inhibits the incorporation of radioactively-labeled amino acids into protein (TCA-insoluble material) in the olfactory mucosa. Experiments so far have achieved a level of about 80% protein synthesis inhibition without affecting electrophysiological responses to odorants over a period of many hours. The tentative conclusion (which agrees with the original assumption) is that olfactory receptor molecules are not "used up" during the transduction process. The experiments so far indicate a receptor half life in excess of eight hours, even in the face of continuous stimulation at one minute intervals.

Vaporous alkylating agents (chemically active odorants) are also being used in this study in a different approach to the problem. In this case, chemically active odorants such as ethylbromoacetate are used to chemically alter and physiologically inactivate the olfactory receptor proteins at the cell surfaces. Recovery of electrophysiological responsiveness should occur as the receptors are regenerated by protein synthesis. Preliminary results using this technique indicate that recovery (if it is possible after such treatment) is a slow process which requires a time course on the order of many hours. (Supported by NSF grant BNS-81-08842 and NTSU Faculty Research Grant 34682 to R.S.)

55.3 DYNAMICS OF OLFACTORY MARKER PROTEIN (OMP) TURNOVER AND TRANSPORT IN MICE. R. M. Kream* and F. L. Margolis, (SPON: E. Cantor) Roche Institute of Molecular Biology, Nutley, N. J. 07110

OMP is a major cytosol protein of 19,000 daltons that is a cell-specific marker of mature olfactory chemosensory neurons. OMP may be labelled in vivo to high specific activities (2000 to 3000 dpm/µg OMP) by intranasal irrigation of mice with [^{35}S]-methionine, [^{3}H]-lysine or [^{3}H]-leucine (Kream and Margolis, Amer. Soc. for Neurochem., Abst. 315, 1982). We now report significant differences in OMP turnover and transport between young and old mice. Two groups of CD-1 female mice, one adult ex-breeder and the other 5-6 weeks of age received 300uCi of [^{35}S]-methionine by bilateral intranasal irrigation at a final concentration of 100µM and specific activity of 50Ci/mmol. Olfactory bulbs and epithelia (epi) were dissected separately from each animal, homogenized and high-speed supernatants were prepared from these homogenates. Acid- precipitable and non-volatile acid- soluble radioactivity was measured. OMP was immunoprecipitated by goat anti-OMP, and immunoprecipitates were separated on exponential gradient SDS gels. Proteins were visualized by a silver-stain and quantitated on a laser scanner. Radioactivity in the OMP band was released by digestion with 15% H_2O_2, and measured by liquid scintillation spectrometry. In adult animals, OMP specific activities (OSA) peak between 1 and 2 days in the epi and at 5 days in the bulb, whereas in young animals, OSAs peak at 4 hr in the epi and at 2 days in the bulb. In adults, OSAs are virtually identical to global cytosol protein specific activity values (CSA) in the epi. By contrast, in young animals OSAs are at least 2-fold higher than CSA values in the epi at early time points. Whereas OSAs are normally 4-5fold higher than CSAs in adult bulbs, in young bulbs these values are 5-8fold higher. In the adult group, OSAs in the bulb begin to exceed OSAs in the epi after 4 days. In young animals, OSAs in the bulbs begin to exceed epi values at 2 days. We conclude that these major differences in OSA values vs. time between age groups demonstrate an accelerated rate of synthesis of OMP in young animals. In both young and old animals, OSAs undergo first-order decline in the epi between 2 and 28 days with apparent $t_{1/2}$s of 5-7 days. However, the $t_{1/2}$ for decline of OSA in young bulbs is 6 days vs 7-10 days in adult bulbs. Thus, the accelerated rate of synthesis of OMP in the epi of young animals is matched by an accelerated rate of degradation in the bulb. We have also measured first-order decline of [^{35}S]-methionine vs. time in extracts of epi and bulbs. In all cases, the specific activity of [^{35}S]-methionine in OMP exceeds that of the free amino acid several fold. This indicates minimal reutilization of labelled methionine. Thus, both the maximum specific activity of OMP, its rate of turnover and speed of entrance into the bulb are elevated in young vs. mature mice.

55.4 EXOGENOUS β-ALANINE ELEVATES OLFACTORY TISSUE CARNOSINE LEVELS IN VIVO AND IN VITRO. T. Kawano*, M. Grillo* and F. L. Margolis Roche-RIMB, Nutley, N. J. 07110, A. Farbman, Dept. Neurobiol. & Physiol., Northwestern Univ., Evanston, Illinois 60201, (SPON: R. Wurzburger).

Carnosine (β-ala-L-his) is present in the olfactory tissue of many vertebrates where it is localized in the chemoreceptor neurons. This dipeptide is enzymatically synthesized from its component amino acids by carnosine synthetase. Under normal, physiological conditions, the tissue concentration of histidine is adequate to saturate the enzyme. Reduction of tissue histidine levels subsequent to consumption of histidine-deficient diets, results in reduced tissue carnosine levels. (Quinn & Fisher, J. Neurochem. 29, 717 [1977]). In contrast, normal tissue concentrations of β-alanine are well below the Km of the synthetase for this substrate. Therefore, we evaluated the impact of increasing tissue β-alanine levels on the content of carnosine in olfactory tissue at various ages, both in vivo and in vitro. Carnosine synthesis begins prenatally in the olfactory tissue of the rat and can first be demonstrated in vitro by incorporation of ^{14}C-β-ala on embryonic day 14 and chemically on embryonic day 16. Dosing pregnant females with β-alanine for two consecutive days results in elevations of olfactory tissue carnosine content. Thus, at 18 days of gestation, controls and β-ala-dosed fetuses contain 10 and 100 pmoles/mg tissue respectively. At 20 days gestation, the equivalent values are 20 and 200. Treatment with β-alanine for several days prior to death resulted in a several-fold elevation of carnosine levels in olfactory bulbs of 1-week old and adult rats. Thus, this phenomenon is exhibited at all ages in vivo. As an extension of these studies, embryonic olfactory epithelium was maintained in organ culture in medium supplemented with 1mM β-alanine. This treatment resulted in the precocial appearance of the developmental increase of tissue carnosine. Taken together, these observations demonstrate that exogenous β-alanine has a significant influence on tissue carnosine content both in vivo and in vitro. Possible mechanisms underlying this phenomenon, are: 1) normal tissue β-alanine levels are below the synthetase Km, 2) β-alanine induces synthetase activity, 3) β-alanine inhibits carnosinase activity. Any of these would result in net carnosine accumulation. The levels of acetylcholine, catecholamines and indoleamines have been reported to be elevated by increased levels of their precursors (Wurtman et. al., Pharmacol. Revs. 32, 315 [1980]). However, the magnitude of the effect of β-alanine on carnosine levels is much larger than in those cases. In addition, we believe carnosine is the first peptide to be so regulated.

55.5 AXONAL ENDINGS OF THE CHORDA TYMPANI AND THE LINGUAL (TRIGEMINAL) NERVE BOTH SYNAPSE IN THE SOLITARY NUCLEUS OF THE HAMSTER. M. Whitehead, B. Kinsella*, and M. Frank. Dept. of Oral Biology, University of CT School Dental Medicine, Farmington, CT 06032.

The chorda tympani and the lingual nerve both innervate the anterior tongue but they mediate different sensations. The chorda tympani is a peripheral branch of the facial nerve which primarily mediates taste; the lingual nerve is a trigeminal branch which subserves primarily pain, temperature, and touch. The connections of these two nerves with the medulla have been in the hamster by cutting either the chorda tympani or the lingual nerve in the cheek and exposing the central stump to HRP. In some animals the chorda tympani was labelled in the middle ear to maximize the Golgi-like filling of afferent axons and to rule-out spread of the enzyme to trigeminal branches. Conversely, to limit HRP to the trigeminal nerve, in other experiments, the lingual nerve was labelled after excising the chorda tympani from the middle ear.

Fibers of the chorda tympani enter the medulla ventral to the vestibular nerve and travel obliquely, dorsomedially through the spinal tract of the trigeminal nerve to reach a point just rostral to the solitary nucleus and dorsolateral to the superior salivatory nucleus. From this point the axons extend caudally through the lateral solitary nucleus, join the solitary tract, and send thin and varicose terminal branches into the nucleus. These axons are oriented in the mediolateral plane and terminate in both the dorsomedial and dorsolateral parts of the solitary nucleus. Fibers of the chorda tympani synapse as far caudally as the level of the area postrema although they are most numerous rostrally. A few labelled fibers travel caudally in the spinal tract of the trigeminal nerve and terminate sparsely adjacent to and within the rostral and caudal extremes of the spinal nucleus of the trigeminal nerve.

Lingual nerve fibers project to both the lateral subdivision of the solitary nucleus at the midpoint of its rostral-caudal extent, and to the dorsal one-third of the spinal nucleus of the trigeminal nerve throughout its extent. Lingual terminals in the solitary nucleus are densely distributed and overlap those of the chorda tympani. Thus peripheral nerves subserving taste and touch both from the anterior tongue synapse in the lateral portion of the solitary nucleus. Gustatory response properties of some neurons in the lateral solitary nucleus suggest a convergence of primary afferent inputs mediating different taste qualities (Travers and Smith, Sensory Processes, 1979). It remains to be seen whether these neurons may also respond to tactile and thermal aspects of gustatory stimuli.

55.6 HEPATIC AND GUSTATORY INTERACTIONS IN THE BRAINSTEM OF RAT G.E. Hermann and R.C. Rogers, Northwestern Univ. Sch. Med., Chicago, IL 60611.

Visceral and gustatory afferents have been implicated in the regulation of physiological and behavioral water and nutrient balance. Indeed, several investigators have found that visceral and gustatory inputs appear to coregulate ADH release, drinking and feeding behavior. Past studies by our group have indicated that this coregulation of functions may be based on overlapping, even convergent, central projections of hepatic and gustatory afferents. We have established, in a series of combined electrophysiological and peroxidase histochemical studies, that the first order projections of hepatic and gustatory afferents to the n. tractus solitarius (NTS) are quite separate and show no evidence of physiologic overlap. Additionally, the hepatic vagal afferent projects mainly upon the left NTS. Very small (100-200u in D), iontophoretic injections of HRP into physiologically-identified zones of the NTS reveal that the immediately subjacent parvocellular RF both sends and receives projections from both the hepatic and gustatory division of this nucleus. Furthermore, both NST divisions send projections to the parabrachial nucleus which converge posteriorly and diverge anteriorly.

These results will form a basis for future studies of visceral afferent alteration of perceived gustatory quality, visceral afferent switching of taste preference behavior and viscero-gustatory coregulation of physiologic water balance. Additionally, these results provide direct anatomical evidence for the observations of Rogers, et al of hepato-gustatory coactivation of neurons in the parabrachial nucleus (J. Autonom. Nerv. Sys., 1: 183-202, 1979). (Supported by the Bane Research Fund, NUMS research committee and NINCDS grant NS 17135 to RCR)

55.7 TASTE RESPONSES IN THE AMYGDALA. Joel R. Morse, Department of Psychology, SUNY at Stony Brook, Stony Brook, NY 11794.

The amygdala has been linked to the control of a variety of survival behaviors and functions. In keeping with this role data indicate that the amygdala samples information from internal and external milieu, including visceral afferent and general sensory information. Sensory responses in all modalities have been recorded from amygdala units with, until recently, the exception of taste. Anatomical and electrophysiological findings in the rat (Norgren, 1976) indicated that gustatory neurons might be found in the amygdala and initial observations in the rabbit proved this to be so (Schwartzbaum and Morse, 1978).

To extend these initial observations units were sampled from the amygdala in 10 rabbits prepared for chronic recording. Four basic taste solutions were delivered to the restrained animals via a multibarreled mouth tube, and responses to these solutions were analyzed. Of 120 amygdala units sampled, 34 were responsive to the tastants. These were localized within, or near, the borders of the central nucleus. Responsive cells were classified as type 1, 2, 3, or 4 depending on the number of tastants to which they responded. Most cells responded to three or more solutions. There were, however, a small number of very selective cells. In all, 25 of the 34 responsive cells could be said to discriminate among tastes. It is likely that this gustatory information arrives at the amygdala via the parabrachial nuclei since the pathway in rat and rabbit are similar. This kind of sensory information could contribute to the amygdala's role in the control of ingestion.

55.8 GOLGI ANALYSIS OF PIRIFORM CORTEX. L. Haberly, Department of Anatomy, University of Wisconsin, Madison, WI 53706

The piriform cortex of the adult opossum (Didelphys virginiana) has been studied with Cox and rapid Golgi techniques.

Most deep pyramidal cells closely resemble those in other parts of the cerebral cortex by virtue of a single apical dendrite, multiple basal dendrites, a large number of small to medium dendritic spines, and a deeply-directed axon. Apical dendrites arborize into tufts of secondary dendrites near the layer I-II border, regardless of depth of the soma. As a result, pyramidal cells in layer II have only a short apical trunk or terminal tufts that emerge directly from the cell body.

With very conservative criteria for categorization, nine different types of non-pyramidal cells have been distinguished. Layer I contains a small number of non-pyramidal neurons with both smooth and spiny dendrites including distinctive fusiform cells with large somatic appendages. The predominant type of non-pyramidal neuron in layer II, as described in other species, is the semilunar cell which has only apically directed dendrites. These apical dendrites can be distinguished from those of pyramidal cells on the basis of a low concentration of dendritic spines that are predominantly large and disc-shaped. A striking feature is the presence of these large spines only on distal dendritic segments. Within layer III, the most frequently encountered non-pyramidal neurons in the present material are multipolar cells with smooth dendrites that resemble the large stellate-basket cells in neocortex. In addition, layer III contains 3 non-pyramidal neuron types with spiny dendrites: a) fusiform and multipolar cells with somatic spines and complex, branched appendages on distal dendrites, b) very large multipolar cells (somas up to 35μm mean diameter) in the ventral part of the cortex with large diameter dendrites that give rise to abruptly-tapering side branches and long filiform spines, and c) multipolar cells with profusely spiny dendrites that closely resemble those of pyramidal cells. In all 3 layers, small neurons with spherical cell bodies and "axoniform" dendrites have been found that resemble the so-called neurogliaform cells that have been described in a variety of brain areas.

A striking feature of the organization of the piriform cortex is that with the exception of the neurogliaform cells, the different types of non-pyramidal neurons tend to be segregated to individual layers or sublayers.

Supported by NSF grant BNS8012067 and NIH grant NS15004.

55.9 OLFACTORY NEOCORTICAL AREAS IN THE CAT. J.L. Price and S.J. Wiegand. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

In addition to the primary olfactory cortical areas which receive direct input from the olfactory bulb, it has recently become apparent that there are olfaction-related areas in the orbital and insular cortex. In order to define these areas in the cat we have recorded physiological responses in the prefrontal and adjacent cortical areas following electrical stimulation of the olfactory bulb. Small injections of wheat germ agglutinin labeled with horseradish peroxidase were then made into the responsive areas to retrogradely label projections from the primary olfactory areas. In other experiments injections of ^{3}H-leucine were made into the largest primary olfactory area, the piriform cortex, to anterogradely label projections to the orbital and insular cortex.

Three cytoarchitectonically distinct areas have been identified which receive direct input from the primary olfactory cortex and which show consistent and relatively short latency responses to olfactory bulb stimulation. The shortest latency responses (15-30 msec) were found in the ventral agranular insular area (AI_V) in the rhinal sulcus immediately adjacent to the piriform cortex. This area was shown to receive a heavy projection from most parts of the piriform cortex, with additional projections from the nucleus of the lateral olfactory tract and the periamygdaloid cortex. Rostral to AI_V slightly longer latency response (25-40 msec) were obtained in the lateral orbital area (LO) and in portions of the ventrolateral orbital area (VLO) on the ventral part of the medial bank of the presylvian sulcus. Both of these areas receive a projection from the anteromedial part of the piriform cortex. There are substantial interconnections between LO and AI_V, and to a lesser extent, between these areas and VLO. AI_V and LO are also interconnected with the medial part of the mediodorsal thalamic nucleus while VLO is interconnected with the submedial nucleus. (See Craig et al., J. Comp. Neurol. 206:28-48, 1982).

Additional, much less prominent olfactory inputs to other areas of the orbital cortex may come from cells deep to the piriform cortex, or from cortico-cortical connections.

Supported by NIH grant NS09518.

55.10 GUSTATORY CORTEX IN THE RAT DELIMITED BY THALAMOCORTICAL PROJECTIONS, PHYSIOLOGICAL PROPERTIES, AND CYTOARCHITECTURE. R. Norgren, E. Kosar, and H.J. Grill Rockefeller University, New York, N.Y. and University of Pennsylvania, Dept. of Psychology, Philadelphia, Pa.

Despite the numerous studies on the cortical location of taste, a clear delimitation of the boundaries of gustatory cortex in the rat has yet to be presented. Traditionally it has been assumed that gustatory cortex is localized within granular insular cortex as defined by Rose ('28). By using a combination of anatomical and physiological techniques, however, we have been able to demonstrate that taste is represented within the agranular insular cortex subjacent to the granular area. Multi-unit responses were recorded during electrode penetrations positioned parallel to the lateral convexity of the brain. As the microelectode was advanced ventrally in the cortex, a transition in response properties was observed. Tactile receptive fields shifted gradually from the vibrissae, to the lips, into the mouth, and onto the tongue. Tactile responses were then replaced by lingual temperature and subsequently by gustatory responses. Ventral to the gustatory area, neurons responded to olfactory stimuli. Marking lesions were placed at sites of transition in these functional properties, i.e., at the border between regions responsive to tongue tactile, tongue temperature, gustatory and olfactory stimuli. Subsequently, the locations of the marking lesions were reconstructed and found to conform strikingly to cytoarchitectural boundaries. Gustatory cortex in the rat is situated just ventral to the thinning and disappearance of layer IV, within agranular cortex dorsal to the rhinal sulcus. Tongue temperature was found to be represented in the cortical area previously termed gustatory, i.e., in ventral granular cortex as layer IV attenuates. Olfactory responses began at the level of or just ventral to the rhinal sulcus in piriform cortex. Following the electrophysiological localization of gustatory cortex, small injections of 3H-leucine were placed within physiologically defined gustatory thalamus. The resultant labeling of thalamocortical projections was confined to agranular insular cortex and confirmed the location of gustatory cortex as determined electrophysiologically. Control injections placed within thalamic nuclei surrounding VPMpc resulted in labeling situated outside of the agranular insular cortex. This study demonstrates that the thalamic projections and functional properties of the lingual tactile, thermal, and gustatory sensory systems coincide with recognized cytoarchitectural subdivisions of cortex.

55.11 LACK OF EFFECT OF CHOLECYSTOKININ ON THE INTEGRATED CHORDA TYMPANI RESPONSE. B. A. Gosnell and S. Hsiao. Department of Psychology, University of Arizona, Tucson, Arizona 85721.

Cholecystokinin (CCK) has been reported to reduce sucrose intake in rats maintained on ad lib food and water (Waldbillig and O'Callaghan, Physiol. Behav., 25:25-30, 1980). This decrease may be mediated by a reduction in the hedonic value of the taste. To determine whether this effect is due to a shift in the sensitivity of gustatory receptors, integrated responses were obtained from the uncut chorda tympani nerve.

Male Long-Evans hooded rats were anesthetized with urethane. The right chorda tympani was exposed and placed over two platinum electrodes. Taste stimuli were: concentrations of NaCl (0.01-0.10 M), sucrose (0.05-0.50 M), and Similac infant formula (normal and half-normal dilution). Approximately 0.25 ml of each stimulus was applied to the anterior tongue and left on for approximately 45 sec, after which the tongue was rinsed with distilled water. The interval between stimuli was a minimum of one minute. After each stimulus was applied at least twice, one ml of either CCK-8 (5 µg/ml, Squibb) or NaCl was infused via jugular catheter, and the stimuli were again tested.

No significant changes were found in the amplitude of the integrated response after CCK infusions as compared to NaCl infusions. The dose of CCK (approx. 10-15 µg/kg), however, is higher than that which consistently reduces food and sucrose intake. It is tentatively concluded that the apparent interaction between CCK and orosensory cues is not due to a change at the peripheral sensory level. This is in contrast to the effect of another feeding-related factor, stomach distention, on the peripheral taste nerves of frogs and toads, as reported by Esakov (Bull. Exp. Biol. Med., 51:257-262, 1961) and Brush and Halpern (Physiol. Behav., 5:743-746, 1970). Future work will include measuring the effect of CCK in taste-related areas of greater integrative capacity.

Supported by NIH Grant AM25381-02.

55.12 EEG-LIKE SIGNALS FROM THE BOVINE VOMERONASAL ORGAN. W.R. Klemm, C.J. Sherry, R.F. Sis*, and D.L. Morris*. Dept. of Veterinary Anatomy, Texas A&M University, College Station, TX 77843.

The vomeronasal organ (VNO) is an accessory olfactory system in the nasal septum that is believed to enhance chemical communication between individuals of the same species; the most generally accepted role is that of allowing males to detect estral females. Other workers have shown that stimulation with certain odorants causes marked increase in the discharge of VNO nerves of the tortoise and the rabbit. We therefore tested the hypothesis that appropriate stimuli would cause generator potentials in VNO sensory cells which collectively would produce recordable field potentials similar to those seen with such sensory systems as the retina or olfactory mucosa. To test the idea, plastic cannulae (10 cm long) were implanted into the VNO ducts of 4 young male castrates under halothane anesthesia. Bilateral incisions (1 cm lateral to the midline, extending 2 cm caudally from the incisive pit) were made through the palatine ridge of the hard palate to expose the junction of the VNO duct and the incisive (nasopalatine) duct. Because the natural topography of the ducts is tortuous, the plastic cannulae were ensheathed in 5 cm metal tubes (12 gauge) which in turn were anchored by sutures to the incisive bone (premaxilla). For recording in the chronic, awake animal, stainless-steel tubing (23 gauge) electrodes were inserted inside the plastic cannulae so that no contact was possible with any skin or mucosa; the sole electrical contact was with the fluids in the VNO and the plastic cannula. Recordings were either between an electrode in the VNO and a subcutaneous reference electrode over the bridge of the nose or bipolar between the two VNO electrodes.

With both kinds of recording, signals were superficially similar to an EEG, exhibiting similar spontaneous amplitude fluctuations. However, many of the large low-frequency components (0.1 to 30 Hz passband) were much slower than found in the typical EEG. Because the recording electrodes double as injection tubes, we are currently investigating the electrical response to perfusion of the VNO with various odorants. Such perfusion commonly elicits licking, chewing, and sniffing movements.

It is not yet clear how much of the signal, particularly during perfusion with chemicals, reflects electrode-potential artifact resulting from fluid motion within the VNO. With that caveat we tentatively propose that these potentials might qualify to be designated, analagously to the ERG and EOG, as the EVNOG, the electro-vomeronasogram.

55.13 CONDITIONED TASTE AVERSIONS MODIFY NEURAL RESPONSES IN RAT NUCLEUS TRACTUS SOLITARIUS. F-C.T.Chang and T.R.Scott. Dep't. Psychology and Institute for Neuroscience, Univ. of Delaware, Newark, DE 19711.

The nucleus tractus solitarius (NTS) has long been suspected of involvement in conditioned taste aversions because of the close anatomical relationship gustatory and vagal afferents have there. We developed a conditioned taste aversion (CTA) to 0.0025 M sodium saccharin (CS) in 12 rats and compared single unit responses from NTS in these animals with those of 12 control rats. Stimuli included the CS plus eleven other salts, acids, sugars and quinine. We found no change in the number of neurons responding to the CS in CTA rats, but a 51% higher mean discharge rate among those which did respond. Post-stimulus time histograms indicated a greater latency-to-peak response from the cells of CTA rats, with the greatest effect occurring for the CS. The across-neuron pattern evoked by the CS had greater similarity with patterns evoked by all other stimuli, implying that the taste quality of saccharin generalized more broadly to those of other chemicals. The largest change in quality occurred for quinine whose neural pattern moved decisively away from those of other non-sweet stimuli and toward those of the CS and sugars. This implies a neural correlate of the rejection response elicited in CTA rats by the now-aversive CS.

Supported by NIH grant NS 10405 and a grant from the University of Delaware Research Foundation.

55.14 CHARACTERIZATION OF DISTINCT MORPHOLOGICAL CLASSES OF OLFACTORY RECEPTOR IN TELEOST FISHES, CARASSIUS AURATUS, AND ICTALURUS PUNCTATUS. Jay F. Muller*(Spon: R.E. Marc). Sensory Sciences Ctr. Univ. of TX Graduate School of Biomedical Sciences, Houston, TX.

Three morphologically distinct classes of olfactory receptor and an additional cell type which represents an early stage of senescence for all three, are proposed, based on the results of this study. These are 1) ciliar cell type I, 2) microvillar cell, 3) ciliar cell type II and 4) rod cell. Retrograde transport of horseradish peroxidase by axons in the olfactory nerve to the olfactory organ of both Carassius auratus and Ictalurus punctatus, analyzed with light and electron microscopy provided evidence that there are four types of cells that contain axons in the organs of both species. Olfactory organs of Carassius were treated with papain and dissociated, providing an isolated cell preparation for correlative morphological information. Distribution of the cell types in Carassius was explored with scanning electron microscopy, a preparation that, in addition, offered evidence for rod cell heterogeneity. Rod processes were observed which showed incomplete fusion of cilia or microvilli, recognizable as derived from each of the three receptor types. This, along with their irregular distribution, led to my hypothesis that the rods represent an early stage of senescence, marked by fusion of the receptors' dendritic surface processes. To test the hypothesis, an acid phosphatase-lead stain, designed for ultrastructural analysis, was performed on Carassius olfactory organs, to indicate specific sites of autolytic activity. Such activity was localized in rod processes, as evidenced by the electron dense reaction product, and examples of each receptor type as progenitors were recognized.

Ciliar cells type I are similar to ciliar olfactory receptors found in all vertebrate classes, and microvillar cells are present in olfactory organs of other fishes and in the tetrapod vomeronasal organ. In Carassius and Ictalurus olfactory organs they are both concentrated in approximately one third the area of each lamella, most proximal to the median raphe. Ciliar cells type II predominate in fishes whose nasal sacs have uniform rather than pulsatile water flow. These cells have been described most often as respiratory type or ciliated non-sensory cells. They are morphologically similar to respiratory type epithelium in the nasal cavities of tetrapods and as such, have motile cilia that beat synchronously, indicative of their respiratory role in fishes. In Carassius they occur singly and in aggregates throughout the organ. In Ictalurus they are segregated from the ciliar type I and microvillar cells, in the outer two thirds of the organ. In Carassius and Ictalurus they contain axons that pass through the olfactory nerve into the olfactory bulb, hence they are receptor-neurons as well as respiratory epithelium. New findings introduced here about the ciliar cell type II and the rod cell open a number of comparative and developmental issues for consideration.

55.15 EFFECT OF STIMULUS COMPLEXITY ON THE RESPONSE OF CENTRAL OLFACTORY NEURONS, K. A. Hamilton and B. W. Ache*. Whitney Marine Laboratory, Univ. of Florida, Rt. 1, Box 121, St. Augustine, FL 32084

Recent efforts to understand olfactory integration have concentrated on quality coding achieved by the convergence of primary afferents onto interneurons within glomerular neuropile. Few physiological studies have examined the nature of the output that leaves higher chemosensory processing centers. Multimodal interneurons descending the circumesophageal connectives from the brain to the lower nervous system in decapod crustaceans respond to stimulation of cephalic sensory structures. Using intracellular recording and staining and backfilling techniques, we have examined the dendritic branching pattern and the effect of stimulus complexity on activation of excitatory descending interneurons during antennular (olfactory) stimulation in the spiny lobster.

Variation in the response of excitatory interneurons is attributable to differences between chemostimulants (ANOVA; n = 31). Two natural mixtures of amino acids plus betaine at concentrations found in potential foods ("crab" and "urchin") are more excitatory than some single components (e.g., glutamate). Other single components (e.g., taurine), however, are as excitatory as equimolar natural mixtures. Most interneurons individually are excited by single components (e.g., taurine and glutamate) that stimulate different primary receptors (Fuzessery, Z. M., et al., Biol. Bull., 154: 226-240, 1978). Response patterns for single components resemble those for mixtures.

Several morphological types of excitatory interneurons can be identified on the basis of dendritic branching pattern. One characteristic that many chemoexcitatory interneurons have in common is extensive branching within the ipsilateral antennal neuropile. These neurons do not appear to contact the olfactory lobes, and thus they presumably are at least third-order chemosensory fibers.

In other crustaceans, high-order descending interneurons like these encode visual information based on stimulus-dependent impulse coordination within an intracting array, rather than in parallel lines (Wood, H. L. and Glantz, R. M., J. Neurophysiol., 43: 741-753, 1980). Because it is unlikely that chemosensory information is further processed per se in lower motor centers which are the targets of these descending cells (Ache, B. W. and Sandeman, D. C., J. Comp. Physiol. A, 140: 295-301, 1980), our results are consistent with the idea that the descending chemosensory "message" also is encoded by interneurons working ensemble.

56.1 BIMODALITY OF AXON SIZE IN THE CAT OPTIC NERVE: A QUANTITATIVE ELECTRON MICROSCOPIC ANALYSIS.

Leo M. Chalupa, Robert W. Williams, and Michael J. Bastiani. Department of Psychology, University of California, Davis CA 95616 and Department of Biological Sciences, Stanford University, Stanford CA 94305.

Previous studies on the size of fibers in the mammalian optic nerve and tract have reported a unimodal diameter spectrum. In view of the strong evidence for discrete conduction velocity groups, particularly in the cat, this unimodal distribution is puzzling. We now report an unequivocal bimodal distribution of fiber size in the adult cat optic nerve. Cats were perfused with mixed aldehydes. The nerves were dissected free and processed for routine electron micrography. A set of micrographs of each ultrathin section was taken at x5000. These micrographs provided a uniform and unbiased sample of the axon population. The following measurements of fiber dimension were made using a Zeiss Videoplan image analysis system: i. internal axon perimeter, ii. area of the axoplasm, iii. diameter of a circle with an equivalent area, iv. fiber diameter (axon and myelin sheath), and v. myelin sheath thickness. Because axon packing density is not uniform throughout the nerve we were particularly careful to test for regional variation in axon size. A peripheral crescent of each nerve had exceptionally high axon packing density. It was found that this peripheral crescent had a relative abundance of smaller caliber axons. Conversely, regions of low density contained a disproportionate number of larger fibers.

In two normal cats a clear bimodal distribution of axon diameter was evident in virtually all regions of both nerves. The total axon population from each nerve also showed a striking size bimodality (n of axons: 12,574 and 11, 936). About 45% of the axons fell under the first peak, 50% under the second peak, and the remaining 5% comprise the extensive tail of the histograms. The first mode of the axon diameter distribution is at 0.8 μm, the second mode is at 2.4 μm. The trough in the spectrum falls at 1.5 μm. The ratio of internal axon diameter to outside fiber diameter was 0.75, and did not vary with axon size. Thus the myelin sheath thickness is a linear function of axon diameter. An analysis of axon diameter in an adult cat which had one eye removed more than two weeks before birth (embryonic day 45) also showed clear bimodality (n of axons: 14,100). Preliminary study of axon size spectrum in an embryonic day 48 cat shows a unimodal diameter distribution with a broad peak at 0.35μm.

Our anatomical results are concordant with data on the velocity of impulse conduction of single fibers in the optic nerve and tract of the adult cat.

56.2 LOSS OF AXONS IN THE CAT OPTIC NERVE: EFFECTS OF PRENATAL UNILATERAL ENUCLEATION.

Robert W. Williams, Michael J. Bastiani, and Leo M. Chalupa. Department of Psychology, University of California, Davis CA 95616 and Department of Biological Sciences, Stanford University, Stanford CA 94305.

We have previously shown that retinal projections are more widespread in fetal than in adult cats. In the present study we asked whether this early and more extensive projection could, in part, result from an excessive number of retinal efferents. Direct estimates of axon number were made from transverse ultrathin sections of the optic nerve. Five nerves have been examined; one taken from a 48 day fetus, two from normal adults, and two from cats which had one eye removed more than two weeks before birth (prior to the 48th day of gestation). Cats were perfused with mixed aldehydes, and following dissection the nerves were prepared for routine electron microscopy. A set of micrographs of each section was taken with a Hitachi HU-11E electron microscope at x5,000 to x25,000. These micrographs provided a uniform and unbiased sample of axon packing density across the entire face of the nerve. The area of the section was measured from a complete low power EM montage taken with a Zeiss EM109.

On embryonic day 48 the optic nerve contained 328,000 ± 17,500 axons (n of micrographs: 167). This estimate of axon number is more than twice that calculated for the two normal adults: 159,000 ± 3,400 and 158,000 ± 4,000 (n of micrographs: 129 and 139). Thus a massive attrition of the ganglion cell population may, in part, underlie the reformation of retinofugal projections which occurs before birth.

We next enquired to what extent prenatal binocular competition contributes to this normal ganglion cell loss. Since prenatal eye removal potentially doubles the postsynaptic target volume available to the spared eye (cf. Rakic, 1979), one might anticipate a total arrest of ganglion cell loss. The two unilateral enucleates had axon counts of 200,000 ± 4,700 and 198,000 ± 4,800 (n of micrographs: 228 and 119). Thus the abolishment of competition between the eyes reduces the cell death incidence from about 50% to less than 40%. This change results in a final neuronal population 25% above normal. These data indicate that although prenatal binocular competition is a significant factor governing the severity of normal ganglion cell loss, other mechanisms must also play a role in establishing the final ganglion cell population size.

56.3 CONTRALATERAL AND IPSILATERAL RETINAL PROJECTIONS IN JUVENILE AND ADULT CHANNEL CATFISH, ICTALURUS PUNCTATUS. P.D. Prasada Rao* and S.C. Sharma. Department of Ophthalmology, New York Medical College, Valhalla, NY 10595.

The retinal projections of the juvenile and adult channel catfish, Ictalurus punctatus, were studied using Horseradish peroxidase (HRP) and radioautographic techniques. The optic fibers do not decussate completely at the level of the optic chiasm and a few project to the diencephalic nuclei and tectum ipsilateral to the retina. A majority of the retinal fibers extend to the contralateral side to form the optic tract, a few of which peel off and project to the suprachiasmatic nucleus (SCN) located ventrolateral to the preoptic recess. The optic tract divides into lateral (LOT) and medial optic tracts (MOT). In the adult fish the LOT is thicker than the MOT, whereas in the juvenile form the reverse is true. The MOT curves laterally and divides into 8-15 medial fascicles of the optic tract (MFOT). The presence of several MFOT might be associated with the multiple optic papillae known to exist in this species. A few fibers of the MFOT and LOT join to form the dorsomedial fascicle of the optic tract (DMFOT) which innervates the nucleus opticus dorsolateralis (NODL) and extends posterodorsally to issue fibers to the nucleus of the posterior commissure (NCP). Subsequently, a few fibers extend further caudal to the posterior commissure, curve laterally and traverse the torus semicircularis to project to the deeper layers of the tectum. The LOT also receives some fibers from the MFOT and projects to the nucleus geniculatus lateralis, pretectal nuclear complex and nucleus corticalis. The stratum fibrosum et griseum superficiale of the tectum is profusely innervated, while the stratum griseum centrale also receives a few retinal fibers. The tractus opticus accessorius arises from the inner margin of the posterodorsal region of the LOT and extends ventromedially to project to the nucleus opticus accessorius (NOA).

The undecussated retinal fibers project to almost all ipsilateral sites similar to those of the contralateral side including the tectum. However, the ipsilateral retinal fibers are mostly located in the anterior part of the tectum indicating that this is the region associated with binocular vision in the catfish. The autoradiographic observations substantiated the analysis of retinal fiber projections based on HRP technique particularly regarding the terminal sites. Since some previous studies also demonstrated the presence of ipsilateral retinal fibers in relatively few aberrant species of teleosts, it is argued that their existence might be an adaptive feature depending upon the environment and the animal's visual capacity having no bearing on the evolutionary status.

56.4 EVIDENCE FOR A RETINAL PROJECTION TO THE SUBSTANTIA NIGRA IN THE RAT, CAT AND MONKEY. A. Frankfurter and R.M. Beckstead. Depts. of Neurological Surgery and Anatomy, University of Virginia School of Medicine, Charlottesville, VA 22908

Fifty years ago, Le Gros Clark described a retinal projection to the substantia nigra in the rat based on Marchi-stained tissue. Gillilan (J.C.N.,1941,74:367-408) using the same method confirmed his finding in a variety of animals,including the cat and monkey. However,Hayhow et.al.(J.C.N.,1960,115:187-216) using the Nauta technique were not able to replicate these earlier studies,and following their report there has been no further discussion in the literature regarding a retinonigral projection.

We are currently re-examining the central distribution of retinal axons in the rat,cat and monkey using horseradish peroxidase as an anterograde tracer.In these animals,we have been able to consistently identify labeled retinal axons in the contralateral substantia nigra,pars reticulata following intravitreal injections.These axons are of extremely fine caliber,and can best be identified by viewing tetramethyl benzidine reacted tissue with darkfield optics through cross-polarizing filters.

Retinal axons enter the substantia nigra by three routes.Some fibers pass through the medial terminal nucleus before sweeping ventrolaterally,while others either perforate the subjacent cerebral peduncle or course around its dorsolateral border.Within the substantia nigra,labeled axonal fragments appear to take a trajectory parallel to the mediolateral axis of the nucleus.These fragments are not characteristic of fibers of passage;some give off sidebranches,while others undulate through the nucleus possibly making en passant pericellular contacts.The distribution of these axons within the substantia nigra is particularly intriguing:in all three species,the majority of labeled axons are located in the rostral half of the nucleus,and their distribution within this segment is roughly coincident with the location of pars reticulata neurons which project to the superior colliculus.For example,in the monkey most of the axons enter the dorsolateral segment of pars reticulata (Beckstead and Frankfurter,J.Neurosci. 1981,1:121-125).Since it has been demonstrated that nigrotectal cells decrease their firing rate following visual stimulation (Wurtz and Hikosaka,Neurosci.Abs.,1981,7:132),it is tempting to propose that the function of this pathway is to inhibit nigrotectal neurons through an interneuronal relay.In addition,our observation of sizable numbers of retinal axons within the substantia nigra may have important implications for assessing the behavioral consequences of nigral lesions.

56.5 AFFERENT AND EFFERENT CONNECTIONS OF THE ACCESSORY OPTIC SYSTEM IN THE CAT, M.T. Feran* and K.L. Grasse (SPON: G. Mandl). Dept of Psychol., Dalhousie Univ., Halifax, Nova Scotia, Canada B3H 4J1.

Recent investigations have demonstrated projections to the inferior olivary complex (IOC) from midbrain sites including the pretectum, oculomotor complex and superior colliculus. Anatomical studies in pigeon and rabbit have revealed an additional fiber projection arising from the accessory optic system (AOS). Although the afferent input to the cat AOS has received some attention, very little is known about the efferent projections of the AOS in this animal.

We have examined the input and output fiber systems of the cat AOS using autoradiographic and HRP tracer techniques. Following microinjections of HRP (0.4 µl of 30% Sigma VI in saline) primarily into the rostral IOC, labelled cells were observed in the periaquaductal gray (PG), the nucleus of Darkschwitch (ND), the interstitial nucleus of Cajal (INC), the posterior pretectal nucleus (PPN), and the nucleus of the optic tract (NOT). When HRP injections were centered more caudally in the IOC, labelling was observed in the PG, the ND, the PPN, and in the dorsal aspect of the medial terminal nucleus (MTN) of the AOS.

Intravitreal eye injections of ^{3} H-proline (2 mi. cu. in 35 µl saline) revealed the dorsal, lateral and medial terminal nuclei (DTN, LTN, MTN) of the AOS. Input fibers of the accessory optic tract (AOT) synapse first in the DTN after leaving the brachium of the superior colliculus, then proceed ventro-medially to the LTN along the base of the midbrain. After leaving the LTN the fibers of the AOT sub-divide into at least two sparse networks of axons: 1 set of fibers span out and penetrate the substantia nigra and cerebral peduncle before terminating in the MTN, while another group of fibers course along the base of the midbrain en route to the MTN. Both sets of input fibers terminate primarily in the ventral MTN. In contrast, the HRP-filled MTN cells follow -ing IOC injections are more heavily concentrated in the dorsal aspect of the MTN.

Thus, there is apparently an internal organization within the cat MTN: while the afferent fiber system from the retina primarily contacts cells in the ventral MTN, the efferent fiber system originates in cells more heavily concentrated in the dorsal region of the MTN.

56.6 DESCENDING PROJECTIONS OF THE MEDIAL TERMINAL NUCLEUS OF THE ACCESSORY OPTIC SYSTEM: A LIGHT AUTORADIOGRAPHIC STUDY IN RAT AND RABBIT. Robert H.I. Blanks[1]; Roland A. Giolli[2]; Yasuhiro Torigoe[3]* Dept. Anatomy[1-3] & Surgery[1], U. Calif. Irvine, Irvine, CA 92717

The medial terminal nucleus (MTN) receives direct retinofugal projections, contains neurons which are speed- and direction-selective for vertically moving visual targets, and on the basis of anatomical and lesion studies, mainly in birds, is thought to be involved with some aspect of visuo-motor control (e.g., optokinetic nystagmus). However, the efferent projections of this nucleus are poorly understood in mammals. The present study examined projections from MTN which had been injected with ^{3}H-leucine in 13 rats and 20 rabbits.

The data from both species revealed remarkably similar results. There are 5 major bundles arising from the MTN to terminate within the midbrain and brainstem. The largest bundle, described previously (Blanks et al., 1982), terminates within the ipsilateral pretectum. The second bundle courses through and around the red nucleus with ipsilateral projections to the interstitial nucleus of Cajal (INC). From this same bundle, axons ascend dorsally through the posterior commissure and then descend to terminate in the contralateral INC, ventral tegmental nucleus of Tsai (VTA) and red nucleus (parvicellular). The third bundle courses medially, ascends the midline to enter the medial longitudinal fasciculus (MLF) and courses within the ventromedial and medial portion of MLF to the posterior medulla. The axons then descend along the midline and terminate within the rostral part of the dorsal cap of the inferior olive. The fourth bundle ascends laterally to the medial lemniscus, turns caudally and distributes many terminals to the ipsilateral midbrain reticular formation, parabrachial and dorsal pontine reticular formation with a smaller bundle distributed to the periaqueductal grey at the level of the oculomotor complex. The fifth bundle courses medially through VTA to the contralateral side, courses posteriorly and dorsally to cerebral peduncle, follows lateral lemniscus, finally at the level of the mesencephalic trigeminal nucleus, the bundle assumes a position between cerebellar white matter and brainstem where it terminates on the large neurons of the superior vestibular nucleus, with some axons continuing caudally to terminate more posteriorly within the vestibular complex. There were no direct projections to the oculomotor nuclei.

These results demonstrate that the MTN has a number of important connections to midbrain and brainstem structures known from physiological studies to be involved with vertical eye movements. These findings, combined with the receptive field properties of MTN neurons, support the general conclusion that this nucleus plays an important role in controlling vertical eye movements.

56.7 DEVELOPMENTAL CHANGES IN PROPERTIES OF SINGLE UNITS IN THE AVIAN ACCESSORY OPTIC SYSTEM, Sheila Burns and Josh Wallman. City College of City Univ. of N.Y., New York, N.Y. 10031.

The accessory optic system has an essential role in stabilizing eye movements. In mature chickens, single units in the nucleus of the basal optic root (nBOR) respond to slowly moving directional stimuli and form two homogeneous and well-defined classes: one which is excited by upward movement and inhibited by downward movement and a second which is excited by movement downward and anterior and inhibited by movement upward and anterior. These two classes of cells are found in separate parts of nBOR; units which respond to upward movement are located in the dorsal part, while units which respond to downward movement are located in the ventral part.

There is anatomical and behavioral evidence that a different pattern exists in young chicks. 2-deoxyglucose studies show that the dorsal and ventral segregation of upward and downward units demonstrable in older chickens is not yet present in young chicks. In addition, measurements of optokinetic stabilizing eye movements show that while mature chickens respond best to movements which are downward and clockwise, young chicks show the greatest gain to movements which are upward and clockwise. These two lines of evidence indicate that a developmental reorganization of nBOR is occurring.

We have begun to study single units in nBOR in chicks less than one week old. Preliminary evidence indicates that there are units that do not fit into the classes described above and that at least some of the units are not sharply directionally tuned. Detailed information on the directional tuning curves of these units and their anatomical location within nBOR will be presented.

56.8

WITHDRAWN

56.9 THE ANURAN NUCLEUS PRETECTALIS (LARGE-CELLED NUCLEUS): NEUROANATOMICAL AND FUNCTIONAL ANALYSIS. Neil Montgomery*, Antony M. Grigonis*, Katherine Fite, Lynn Bengston*, University of Massachusetts, Amherst, Massachusetts, 01003.

Recent studies have demonstrated that the pretectal region is critically involved in mediating horizontal optokinetic nystagmus (OKN). Lesions of either n. pretectalis (nPt) or the pretectal tegmental gray appear to have equivalent effects in reducing OKN.

The pretectal region was investigated using autoradiographic (^{3}H proline), horseradish peroxidase and Golgi techniques. Retinal afferents to nPt originate from the central portion of the retina and project via the axial optic and marginal optic tracts. The primary projection is contralateral with a small ipsilateral component. Fibers related to the axial optic tract arborize first in a relatively cell-free "dense-core" region and then branch throughout the surrounding region. Other afferents to nPt originate from the ipsilateral tectum, the nucleus of the basal optic root, the nucleus of the posterior commissure and the anterior thalamic nucleus rotundus. Three types of neurons occur in nPt; large neurons (25 µm), fusiform neurons (12.5 µm), and stellate neurons (10 µm). Additionally, two cell groups outside of nPt send dendrites into the nucleus; cells in the posterior lateral nucleus and cells in the central gray dorsal to the central thalamic nucleus. Both the large neurons and the fusiform neurons of nPt project to the anterior and caudo-lateral portions of the tectum as well as to the ventral brainstem superficial to the abducens nucleus (n. VI). The stellate neurons appear to be intrinsic to nPt. Cells in the central gray postsynaptic to nPt project directly to n. VI.

The anuran nPt appears similar and perhaps homologous to the nucleus of the optic tract of mammals both in terms of its presumed role in horizontal OKN (Hoffman and Schoppmann, 75), the site of origin of its retinal afferents (Ballas et al., 81) and its central connections (Berman, 77).

56.10 EFFERENT PROJECTIONS OF THE PRETECTAL COMPLEX: DIFFERENT POPULATIONS OF NEURONS PROJECT TO LATERAL THALAMUS AND TO INFERIOR OLIVE OF THE RAT. Richard T. Robertson and Janie L. Callaway*. Department of Anatomy, College of Medicine, University of California, Irvine, CA. 92717.

The pretectal complex consists of several nuclear groups, including the anterior (PA), posterior (PP), medial (PM), olivary (PO) and optic tract (TO) nuclei. Several recent studies have demonstrated both descending projections to the inferior olive complex and ascending projections to the lateral thalamic group. The present studies used the double retrograde labeling technique with two fluorescent markers to determine whether the two projections are axon collaterals from one population of neurons.

Adult Long-Evans hooded rats received injections of either nuclear yellow (5% in water) or a mixture of true blue and granular blue (5% in water) in either the thalamic lateral dorsal nucleus (LD) or the inferior olive complex (IO). After survival periods of 20-48 hrs, animals were sacrificed by aldehyde perfusion and 30 µm serial frozen sections were examined by fluorescence microscopy. Nuclear yellow labels the neuron nucleus yellow; granular and true blue label the cytoplasm blue. Thus, double labeled cells are easily discerned.

Injections in LD resulted in retrogradely labeled neurons in all pretectal nuclei. Most prominent labeling occurred in PO, PA, and PP. Injections in IO resulted in retrogradely labeled neurons in PP, TO, and PA. In fifteen experiments, we have examined more than 2000 labeled neurons. Each of these neurons was labeled by only one compound; in no case have we observed double labeled neurons in the pretectal complex. This lack of double labeled cells appears not to be an artifact of our methodology; in other experiments with different injection sites we commonly have seen double labeled neurons.

These data indicate that the projections to IO and LD originate in separate populations of neurons of the pretectal complex. These results suggest that extra-geniculate visual information destined for either cerebellar or cerebral cortex passes through separate neuronal channels in the pretectal complex.

56.11 SUPERIOR COLLICULUS: INTERACTIONS OF CONVERGING MULTISENSORY INPUTS, M. A. Meredith and B. E. Stein, Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

Visual, auditory, and somatic cells are located in the intermediate and deep laminae of the superior colliculus (SC). Although many of these neurons are influenced by more than one sensory modality (Stein, B. E. and Arigbede, M. O., Exp. Neurol. 36:179, 1972), the manner in which multiple inputs interact to determine cellular activity is not known. The present experiments were initiated to investigate such interactions in order to gain insight into the functional role of multimodal convergence.

Experiments were conducted using cats (n=4) and hamsters (n=3) which were paralyzed with gallamine triethiode and artificially respired with N_2O and O_2, as well as hamsters (n=16) anesthesized with urethane. Visual stimuli consisted of stationary and moving spots and bars of light. Auditory stimuli were hisses delivered by a solenoid-controlled air hose or clicks from an audio-amplifier. Tactile stimuli were delivered by a solenoid-controlled air stream or with an electronically-driven moving coil vibrator. Once a cell was isolated (n=66) its responses to separate visual, auditory and tactile stimuli were tested and optimal stimuli were determined. Combinations of stimuli from these different modalities were then presented simultaneously and at various predetermined intervals.

Despite the fact that "optimal" stimuli in each modality were identified, responses evoked by these separately presented stimuli were often not maximal. For example, cells excited by two or more modalities (n=26) showed facilitory interactions when stimuli were delivered in close temporal proximity to one another. On the other hand, cells were encountered which were excited by one input and inhibited by another (n=15), and suppressive interactions were exhibited by these units. In general, most interactions were generated by paired stimuli delivered within ±100 msecs of one another. Although no cross-modality interactions were seen in cells of the superficial laminae, such interactions were observed in the majority of cells in the intermediate and deep layers.

These data indicate that information from different modalities is integrated in SC neurons through facilitory and/or suppressive interactions. When the behavioral role of the SC is considered, these interactions may serve to enhance the detection and localization of stimuli.

Supported by Grants NS 15912 and NS 06838.

56.12 ULTRASTRUCTURAL CHARACTERIZATION OF THE INTERCOLLICULAR PATHWAY IN THE CAT. Mary Behan, Department of Structural and Functional Sciences, University of Wisconsin School of Veterinary Medicine, Madison, Wisconsin 53706.

Following ablation of the occipitotemporal cortex in the cat, a contralateral hemianopsia results which can be reversed by section of the intertectal commissure or by destruction of the contralateral superior colliculus (Sprague, J.M., 1966, Sci. 153: 1544). To explain this phenomenon, it has been suggested that the superior colliculi functionally suppress each other, and that this effect is mediated by the intertectal commissure. This projection connects the stratum griseum intermediate of the rostral half of the colliculi, and many fibers connect corresponding points in the colliculi (Edwards, S.B., 1977. J.Comp.Neur. 173:23).

In this study, EM-autoradiography has been used to investigate the synaptic connections of the tecto-tectal pathway. In two cats, two injections (0.2-0.3 µl) of ^{3}H-proline or a mixture of ^{3}H-proline and ^{3}H-leucine (50 µCi/µl) were made in the rostral half of the left colliculus. Following a 24-30 hour survival, the animals were perfused and the superior colliculi embedded for electron microscopy. Thin sections were cut from the rostral half of the right colliculus in an area corresponding to the injection sites. Only the stratum griseum intermediale was included in the sections which were subsequently processed for EM-autoradiography.

Based upon vesicle shape, two populations of synaptic terminals are labeled. Type I contains round synaptic vesicles and comprises 62% of all labeled terminals. Most of these terminals make asymmetric contacts upon dendrites, although a few synapse upon dendritic spines. It appears that each type I terminal makes only a single synaptic contact. Synaptic vesicles are scattered unevenly in 79% of the type I terminals, but frequently are clustered at the synaptic contact. The remaining 21% of type I terminals contain densely packed round synaptic vesicles.

Type II terminals, comprising 38% of those labeled, contain pleomorphic or flattened vesicles and make symmetric contacts upon dendrites. Each type II terminal appears to make only a single synaptic contact. Synaptic vesicles are unevenly distributed in approximately 93% of the type II terminals examined, and in some terminals there is clustering of vesicles at the synaptic contact. Preliminary measurements indicate that there is substantial overlap in the size distribution of the two populations of terminals.

While it is certain that many of these labeled profiles are indeed terminals of intercollicular neurons, the possibility exists that some are associated with collaterals of other decussating fiber systems, e.g., the tecto-parabigeminal and tecto-cuneiform projections.

56.13 DISTRIBUTIONS OF CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE ACTIVITIES IN LAYERS OF RAT SUPERIOR COLLICULUS. C.D. Ross, J.L. Park*, K.G. Ledbetter* and D.A. Godfrey, Dept. Physiology, Oral Roberts University, Tulsa, OK 74171

The rat superior colliculus is divided into 7 layers. Superficial layers include (1) stratum (s.) zonale, (2) s. griseum superficiale, (3) s. opticum; deep layers include, (4) s. griseum medium, (5) s. album medium, (6) s. griseum profundum, (7) s. album profundum. Optic nerve fibers proceed through layer 3 and terminate primarily in layers 1 and 2 (Lund, J. Comp. Neurol. 135: 179, 1969). Non-optic pathways terminate in the deep layers.

Activities of the enzymes of acetylcholine metabolism, choline acetyltransferase (ChAT) for synthesis and acetylcholinesterase (AChE) for degradation, were assayed in samples of superior colliculus layers dissected from 20 µm-thick freeze-dried sections cut in the sagittal plane. The average sample size was about 0.15 mm by 0.5 mm in the dorsal-ventral and caudal-rostral orientations, respectively. High AChE activity (150-200 mmoles/kg dry wt/min, 37°) was found in superficial layers 1 and 2, lower activity (30-70) in layers 3, 5, 6 and 7, and intermediate activity in layer 4 (average 80-100). AChE activity in layer 4 was highest caudally (150) and gradually declined to about 30 in the most rostral part of the colliculus. ChAT activity was low to intermediate in all layers (200-500 µmoles/kg dry wt/min, 37°) except in layer 4 (average 600-800). Like AChE, the ChAT activity in layer 4 was highest most caudally (1300) and gradually declined to 200-300 in the most rostral part of the colliculus. (For comparison, average activities for rat whole brain are about 45 mmoles/kg dry wt/min for AChE and 500 µmoles/kg dry wt/min for ChAT.) The relative distributions of both enzymes in the colliculus are consistent with each other except in the superficial layers, where the AChE activity is much higher than would be expected from the activity of the more definitive marker for cholinergic structures, ChAT. The activities in layer 4 could be related to a proposed cholinergic pathway from the substantia nigra terminating in this layer predominantly in the more caudal aspect of the colliculus. A patchy appearance of the AChE stain in the deep collicular layers in cat, monkey and human has suggested a columnar organization that may coincide with the termination of the nigrotectal tract (Graybiel, Neuroscience 4:643, 1979). We are investigating whether the quantitative distributions of ChAT and AChE activities correlate with this appearance of the AChE stain in rat.

In a separate experiment, one week after enucleation of one eye, there were no differences in either ChAT or AChE activities in collicular layers between lesion and control sides.

56.14 EFFECTS OF PICROTOXIN AND BICUCULLINE ON VISUAL RESPONSE OF ZEBRAFISH TECTAL CELLS. P. Sajovic and C. Levinthal, Dept. Biological Sciences, Columbia University, New York City, N.Y. 10027

In previous work we described four types of visual response among tectal cells of the zebrafish. Cells of one class, type I, are not spontaneously active and respond phasically at ON and OFF. Their responses to moving edges, to growing stimuli, to stimuli equal in size and shape to the whole RF, to pairs of spots, and to very small stimuli all suggest that these cells receive inhibitory input from near neighbor cells of the same type in the tectum, as well as excitatory input from retinal fibers (Sajovic and Levinthal, Neuroscience, in press). In order to investigate this hypothesis further we have studied the effects of drugs on physiological properties of type I cells recorded in the SPV layer of the zebrafish tectum.

Small (10-100 nL) injections of drugs were made in the tectum while recording 100-500 microns away with extracellular microelectrodes. Both picrotoxin (saturated solution in 100mN HCl) and bicuculline (5 mM in 165mM NaCl) produce the following effects: (1) Onset of spontaneous bursting multiunit activity. This noise can be recorded at all depths within the tectum. (2) Abolition of the second postsynaptic wave of the field potential elicited in the tectum as the result of a shock applied to the optic nerve. This wave, which is opposite in polarity to the first postsynaptic wave and follows it by 4 ms, can be interpreted as the product of massed inhibitory postsynaptic currents evoked with a delay after the excitatory currents that give rise to the first postsynaptic wave. It is abolished, while the peak value and time to peak of the first wave are unchanged. (3) Alteration of visual response properties of individual type I tectal cells. Some cells which are originally not spontaneously active emit spontaneous bursts after the drug takes effect; others do not. The duration of response to small flashing spots and to stimuli that grow in size both increase significantly. Responses to moving edges, which normally occur mostly as the edge is crossing the RF border, become extended to encompass the entire RF. Finally, the cells show reduced negative spatial summation following drug injection.

All of these effects are fully reversible with time after injection. Bicuculline effects wash out much faster than picrotoxin (about 10 min vs 2 hr). Control injections (of teleost Ringer's solution, 100 mN HCl, and 165mM NaCl) do not elicit any of these effects. The results reported here are consistent with the hypothesis that tectal type I cells receive a delayed inhibitory input, probably via GABA synapses, which determines major properties of the visual response.

56.15 LAMINAR ORIGIN AND CYTOARCHITECTURE OF SUPERIOR COLLICULUS CELLS PROJECTING TO SUBCORTICAL VISUAL SYSTEM STRUCTURES. N. Lugo-García and E. Kicliter, Lab. Neurobiology and Dept. of Anatomy, University of Puerto Rico, Sch. of Med., San Juan, P.R. 00901.

The superficial laminae of the superior colliculus (SC) in the ground squirrel Spermophilus tridecemlineatus are known to project to several visual system nuclei. Among these are the ventral lateral geniculate nucleus (LG_V), pretectum (PT), the parabigeminal nucleus (Pb) and nucleus lateralis posterior (LP). We were interested in comparing the laminar location and cytoarchitecture of collicular cells projecting to each of these structures. Horseradish peroxidase (HRP) was iontophoretically injected into LG_V, PT, Pb and each of the three subdivisions of nucleus lateralis posterior: rostrolateral, rostromedial and caudal LP. After survival periods of 24-48 hours, the animals were perfused intracardially and brain sections processed according to the method of de Olmos and Heimer (1977). In all of the cases labeled cell bodies were located in the superficial laminae of the superior colliculus. After injections into LG_V, PT and Pb, HRP-filled neurons were present in the upper and lower halves of stratum griseum superficiale (SGS) and in the upper portion of stratum opticum (SO). The labeled cells were mainly multipolars with radiating dendrites or fusiform neurons with cell bodies oriented perpendicular to the tectal surface. Some differences were found in the exact location and soma size of the neurons projecting to each of the injected nuclei. Cells labeled after injections into nucleus lateralis posterior were large multipolar neurons specifically located in the lower half of stratum griseum superficiale. These cells were generally larger than those projecting to LG_V, PT and Pb. While only the ipsilateral SC was labeled after injections into rostrolateral LP, after injecting caudal LP labeled cells were also found in the contralateral superior colliculus. No labeling was present in SC after injections into rostromedial LP. These findings indicate a segregation in the superior collicular cells projecting to other visual system structures.

56.16 A POSSIBLE SECOND ASCENDING AVIAN TECTOFUGAL PATHWAY. P.D.R. Gamlin and D.H. Cohen. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

Visually conditioned heart rate change in the pigeon has been developed as a vertebrate model for cellular studies of learning. In this system we have determined that the thalamofugal and tectofugal ascending visual pathways participate in transmitting the conditioned stimulus information. Previous results also suggest the involvement of a third ascending visual pathway, possibly of pretectal origin. However, the lesions on which this hypothesis is based also encroached upon the nucleus dorsolateralis posterior of the thalamus (DLP), a nucleus that has recently been reported to receive a tectal projection. This motivated the present investigation of whether there exists a retino-tecto-DLP-telencephalic visual pathway.

Horseradish peroxidase (HRP) injections in DLP labelled cells in a number of regions, including the optic tectum. Labelled tectal cells were present mainly in layer 13 (the stratum griseum centrale), although a few labelled neurons were also evident in layers 8-10 and 14-15.

Injection of ^{3}H-proline/leucine in DLP indicated that DLP projects to a discrete region of the neostriatum intermedium (NI). The terminal field is located immediately dorsal to the lamina medullaris dorsalis and medial to the caudal aspect of the ectostriatum. It extends from approximately A7.25 to A9.0 in the atlas of Karten and Hodos (1967). A less prominent projection to the hyperstriatum was also observed.

HRP injected into this neostriatal terminal field labelled numerous cells in the posterior region of DLP, extending from A4.5 to A5.25. This confirmed that at least part of DLP projects to NI, and it suggests that the anterior region of DLP may project to the hyperstriatum.

Single unit activity of cells in DLP indicated that 13 of 14 neurons studied were responsive to whole-field illumination of the retina. The latency range was 30-55 msec. Eleven of these neurons responded with excitatory bursts at stimulus onset and termination.

These findings suggest that most cells in DLP are visually responsive with latencies comparable to those of neurons in the nucleus rotundus, the thalamic relay of the tectofugal pathway. The results further suggest a retino-tecto-DLP-neostriatal pathway that transmits visual information to the telencephalon. This would constitute a second tectofugal visual pathway to the telencephalon that parallels the well-described retino-tecto-rotundo-ectostriatal pathway. 56.17 EFFECTS OF LESIONS OF THE CORE NUCLEUS ON VISUAL INTENSITY DIFFERENCE THRESHOLDS IN TURTLES. W. E. Grisham* and A. S. Powers. Department of Psychology, Bryn Mawr College, Bryn Mawr PA 19010.

Preoperative intensity difference thresholds were assessed in eastern painted turtles (Chrysemys picta picta). The method used was to train the animals to discriminate between a very bright and a very dim stimulus. The stimuli were presented on two keys in a standard turtle chamber by a Kodak Carousel projector. The animals were required to make a simultaneous discrimination. After reaching criterion on the training pair (.1 vs. 2.0 log units of optical density) the turtles were trained on a procedure in which 28 trials were given per day, eight with the training discriminanda and four with each of five more difficult discriminations. The animals were always reinforced (with beef baby food) for responding to the brighter stimulus (.1 log units of optical density). Since relatively little data could be collected per day, each threshold determination used data from four consecutive days. To determine the threshold, performance on each of the problems was plotted, and the threshold was taken as the point where the turtle responded correctly 75% of the time (50% being chance). Preoperative criterion was reached when the threshold did not vary more than .04 log units of optical density in two consecutive four-day blocks.

Following achievement of preoperative criterion, each animal was given bilateral electrolytic lesions aimed at the core nucleus (CN) of the dorsal ventricular ridge, the telencephalic termination of the tectofugal visual pathway. Postoperatively, there was no permanent elevation of threshold, even in those subjects with the largest amount of damage to the CN. Subjects with moderate to severe lesions, however, required further practice on the training pair before beginning threshold assessment postoperatively. In addition, there was increased variability of performance in all CN-lesioned subjects: all required substantially more training postoperatively than a control subject with no damage to the dorsal ventricular ridge. The results are consistent with other findings from our laboratory that indicated that turtles with CN lesions had a postoperative deficit on visual intensity discriminations, but were able eventually to relearn them. The present findings contrast with those found after lesions of nucleus rotundus thalami, which projects to the CN. Severe lesions of nucleus rotundus produced permanent elevations in visual intensity difference thresholds.

56.18 THE INFLUENCE OF RETINO-COLLICULAR PATHWAY STIMULATION ON LATERAL GENICULATE CELL RESPONSES. D. Delaunais*, S. Molotchnikoff and C. Casanova*. Dept. de Sciences biologiques, Université de Montréal, Montréal, Canada, H3C 3J7.

The objectives of the present study were to examine how the superior colliculus (CS) influences the responses of lateral geniculate cells (LGN). In anesthetized and paralyzed rabbits two tungsten micro-electrodes were aimed at the CS and LGN in order to record single unit activity simultaneously from both structures. An appropriate stimulus (usually a moving light bar) was positioned in the receptive field (RF) of a collicular unit in order to activate the retino-collicular pathway. This stimulus did not modify the spontaneous activity of the geniculate cell. A second stimulus (usually a LED) was flashed in the RF of the latter. Similarly, this second stimulus did not influence the collicular cell under investigation. Thus, the retino-collicular and retino-geniculate pathways were excited separately. The geniculate stimulus was applied at determined intervals after the collicular cell had fired, in this fashion it was assumed that the colliculo-geniculate fibers were activated and produced a modification of the geniculate responsiveness. Results indicated that there was a significant enhancement or decline of geniculate responses when compared to similar but non-contingent stimulation (That is without initial collicular excitation). The influence was strongest when intervals were between 100 and 300 msec corresponding to the latency of a saccade. Control experiments carried out on retinal ganglion cells indicated that the effects were absent at the retinal level. These results support the notion that the CS contributes to the geniculate message relayed to the visual cortex.

56.19 THE EFFECT OF SUDDEN TACTILE AND AUDITORY STIMULI ON THE VISUAL RESPONSES OF NEURONS IN THE DORSAL LATERAL GENICULATE NUCLEUS OF FULLY AWAKE RABBITS. H. A. Swadlow, T. G. Weyand and P. L. Vera*. Dept. Psychology (U-20), Univ. Conn., Storrs, CT. 06268.

The visual system of the rabbit is especially suited for studies requiring an awake subject because the eye can remain relatively stable for prolonged periods. We have examined the effects of sudden tactile and auditory stimuli upon the visual responses of neurons in the dorsal lateral geniculate nucleus (LGNd) of fully awake, unparalyzed rabbits. All surgical procedures were performed under barbiturate anesthesia several days prior to the first recording session. Principal cells were identified by antidromic activation following electrical stimulation of the visual cortex. Eye position was monitored to an accuracy of 1/3° in early experiments and to within 1/5° in later experiments. We have found that in the fully awake rabbit, sudden auditory or tactile stimulation has a profound effect on the visual response properties of some LGNd neurons. For most concentric sustained cells the response to standing contrast began to diminish appreciably and sometimes disappeared altogether after 2-20 seconds. In most of these cells, however, a sudden auditory or tactile stimulus re-established the response to the visual stimulus at or near its initial high rate. For these cells the auditory and tactile stimulus alone had no effect on the maintained discharge rate of the cell. In order to be sure that this modulation (a) occurred at the LGNd and (b) was not due to subtle eye movements elicited by the arousing stimuli, we tested more than 20 optic tract axons with a sustained, concentric field organization. In no case did we see a facilitation of the visual response following presentation of auditory or tactile stimulus. We conclude that in the fully awake rabbit, the level of arousal has a profound effect on the visual response properties of neurons in the LGNd.

56.20 THE PROJECTION OF THE VISUAL FIELD ONTO THE LATERAL GENICULATE NUCLEUS OF THE FERRET. Kathleen R. Zahs* and Michael P. Stryker. Physiology, Univ. of California, San Francisco 94143

Linden, Guillery, and Cucchiaro (JCN 203:189-211, 1981) have recently presented anatomical findings on the development of the retinogeniculate projection in the ferret, attractive for developmental studies because of the immature state of its binocular visual system at birth. We have begun physiological studies of this charming and gentle animal by mapping the projection of the visual field onto the lateral geniculate nucleus (LGN).

Tungsten microelectrodes were used to record multi-unit and occasional single-unit activity in paralyzed, anesthetized ferrets held in a modified Horsely-Clarke apparatus. Recording sites in vertical electrode penetrations were marked with electrolytic lesions, allowing them to be located in Nissl-stained coronal sections. Although the laminae could be discerned in these sections, they were clearer in autoradiographs prepared after injecting one eye with tritiated proline. At the caudal pole of the LGN, laminae A and A1 took the form of sheets, A1 caudal to A. Rostrally the nucleus was shaped like a "C" and was composed mainly of lamina A.

Receptive fields were plotted at a total of 306 recording sites within the A-laminae in 4 ferrets. All single-unit receptive fields were monocularly driven with ON or OFF centers and antagonistic surrounds. The multi-unit responses were nearly always monocular and were usually of a single center type.

Each LGN represented a single hemifield. The horizontal meridian was found at the dorsal border of the caudal pole of the nucleus and moved ventrolaterally in more anterior sections. The vertical meridian was represented at the medial edge of the dorsal limb of the LGN for the upper visual field and at the medial edge of the ventral limb of the LGN for the lower visual field. Over most of the LGN, lines of projection ran rostrocaudally.

Isoelevation lines took the form of sheets approximately in the plane defined by the rostrocaudal and mediolateral axes. The upper visual field was represented in more dorsal and rostral parts of the LGN; while the lower visual field was represented ventrally and caudally. Isoazimuth lines took the form of sheets in the rostrocaudal and dorsoventral plane, with the more lateral sheets representing the more peripheral visual field. Receptive fields for the two eyes were in register: lines of projection ran caudally from lamina A into A1. The few receptive fields mapped in the C-laminae suggested that lines of projection continued straight through these laminae after passage through A and (sometimes) A1.

56.21 SYNAPTIC ORGANIZATION OF RETINAL AFFERENTS TO CLASS 1 AND CLASS 2 THALAMO-CORTICAL RELAY CELLS IN THE DORSAL LATERAL GENICULATE NUCLEUS. Toni P. Miles* & Salvatore C. Rapisardi Department of Anatomy, College of Medicine, Howard University, Washington,D.C. 20001

We have investigated the synaptic arrangements between optic tract terminals and two thalamo-cortical relay cells in the later-al geniculate nucleus(DLGN) of the adult cat. It has been demonstrated that the physiology of different relay cell classes is highly correlated with their light microscopic appearance (Friedlander etal '81). Using that morphologic criteria, we identified a Y cell by its Class 1 morphology and a cell that could have either X or Y physiology based on its Class 2 morphology.

Two methods were used in this study to identify cells. The Y cell was reconstructed from electron micrographs of 217 consecutive sections, and identified by its large soma (840um^2) and smooth, appendage-free dendrites. The Class 2 cell was visualized using the gold toning method of Fairen and Peters (J Neurocyto,6 '77) which allowed us to identify the whole cell with the light microscope by its soma size (360um^2), and characteristic appendages at dendritic branching points. A long series (300 consecutive sections) was cut with the added advantage that dendritic profiles in the electron micrographs were marked with gold.

After identification of the two cells, individual terminal boutons of retinal terminals that were presynaptic to them were completely reconstructed. The following differences were found in the way retinal terminals were received by the two cells:(1) the Y cell received retinal terminals on dendritic shafts, while retinal input to the Class 2 cell was restricted to the dendrite appendages, (2) all retinal terminals to the Y cell were found within 30um of the soma. Retinal terminals to the Class 2 cell made contact with appendages that were between 30 and 90um from the soma. There were no retinal contacts made within 30um of the soma on any of the Class 2 cell dendrites studied,(3) Retinal terminals presynaptic to the Class 2 cell made more synapses with flat vesicle profiles than did retinal terminals presynaptic to the Y cell and (4) Retinal terminals presynaptic to the Class 2 cell had almost all of their synapses arranged in a triadic arrangement while only a small proportion of the retinal terminals presynaptic to the Y cell had synapses in this arrangement. A triad is defined by the retinal terminal being presynaptic to both a dendrite and a flat vesicle profile, plus the flat vesicle profile is presynaptic to the same dendrite. Clusters of dendritic appendages were found on the great majority of X cells by Friedlander etal. Our data suggests that triadic arrangements are characteristic of the X system and only to a subpopulation of neurons in the Y system.

56.22 MORPHOLOGY AND AXONAL TERMINATION OF THALAMIC INTRALAMINAR NUCLEUS (ILN) NEURONS WHICH PROJECT TO VISUAL CORTEX IN SQUIRREL MONKEY. L. Towns, J. Tigges, M. Tigges and L. Walker*. Kirksville College of Osteopathic Medicine, Kirksville, MO 63501 and Yerkes Regional Primate Center and Department of Anatomy, Emory University, Atlanta, GA 30322.

The thalamic intralaminar nuclei (central medial nucleus, CeM, and paracentral nucleus, PC) have been shown to project to the visual cortex in squirrel monkey (Tigges, et al., in press). In order to further assess the morphology and connections of these thalamocortical neurons, three squirrel monkeys received massive HRP injections in either the occipital lobe or in area MT. After a 72 hour survival period, each animal was perfused under deep anesthesia and the thalami were sectioned and processed by either TMB or DAB protocols to reveal the retrogradely transported HRP.

In coronal sections, numerous labeled somata are seen to extend in a continuous arc from CeM ventromedially into the PC dorsolaterally. Furthermore, two separate, concentric groups of filled cells are seen in PC, one medially and one laterally placed. In both CeM and PC, the labeled somata are round or spindle shaped and typically have two or three principal dendritic processes; the somata and proximal dendrites are oriented parallel to the fibers of the internal medullary lamina of the thalamus in which they are embedded. Generally, the filled neurons of the CeM are smaller and rounder than the labeled neurons in PC which become larger and more elongated as this nucleus passes dorsolaterally. A few very large,well-filled cells are seen in the lateral division of PC. These prominent neurons exhibit a much more diffuse and richly branching dendritic tree than do other neurons in the intralaminar complex.

In a preliminary study, [^{3}H]-amino acids were injected bilaterally into the ILN and the termination of these projections in the visual cortex was studied autoradiographically. The principal site of termination of the ILN afferents was in layers V and VI over a large expanse of the occipital visual area. Some light termination was occasionally seen in layers I-III but lamina IV received no input from ILN.

56.23 LIGHT AND E.M. LOCALIZATION OF CYTOCHROME OXIDASE STAINING IN THE LATERAL GENICULATE NUCLEUS. G. H. Kageyama* and M. Wong-Riley (SPON: C. Brown). U. of Calif. San Fran. CA 94143 and Med. Coll. of Wisconsin, Milwaukee WI 53226.

In the lateral geniculate nucleus (LGN) of the cat, physiologically defined classes of cells can be distinguished on the basis of cell size and distribution. In order to determine whether the different cell types as well as specific neuronal profiles (e.g., dendrite, axon, axon terminal) have distinct levels of metabolic activity, sections of cat LGN were reacted histochemically for cytochrome oxidase (CO) and examined at the light and E.M. levels. In the cat lamina A and A1 were highly reactive, while lamina C was only moderately so. Predominantly large but also a few medium sized intensely reactive neurons were observed within lamina A, A1 and C, and along the interlaminar zones. The size and distribution of the large reactive cells were similar to those reported for type 1 cells and physiologically recorded Y-cells. At the E.M. level, the majority of the intensely reactive neurons were large, confirming our light microscopic observations. In the neuropil, most of the highly reactive mitochondria were found within dendritic profiles, especially those closely associated with synaptic glomeruli. RL axon terminals were almost always nonreactive, while presynaptic profiles with flattened or pleomorphic vesicles (F1, F2 and FD) usually contained one or more moderate to highly reactive mitochondria. The RS terminals often did not contain any mitochondria. When they did, they were usually light to moderately reactive.

In the LGN of cats monocularly deprived at birth, notably fewer reactive neurons were observed in the deprived A, A1 and C laminae and they were small to medium in size. The absence of large reactive neurons within the deprived lamina may be related to the reported paucity of recordable Y-cells from these layers.

Our light microscopic findings imply that large (presumed Y) cells have higher levels of CO activity and that these cells are dramatically affected by early monocular deprivation. Our E.M. findings suggest that specific neuronal profiles in the cat LGN have distinct levels of CO staining. The localization of many intensely reactive mitochondria mainly within dendrites (but also F terminals) indicates that these structures are metabolically very active.

Preliminary data on the primate (macaque and squirrel monkey) LGN suggest that the larger (magnocellular) neurons are more reactive for CO than the medium and small (parvocellular) neurons. However, the dorsal parvocellular lamina 6, which contains both small and medium sized reactive cells, also appears to have elevated levels of CO staining. As in the cat LGN, most of the CO activity in the neuropil was localized within dendrites and F terminals, while RL terminals were consistently nonreactive.

56.24 Behavioral Analysis of Embryonic Neocortical Transplants into the Lateral Geniculate Nuclei in the Rat, R.B. Wallace, G.D. Das*, J. Harnsberger*, J. Gustafson*, Douglas Ross*, Richard Smeyne* and James Thompson*, Lab. of Developmental Psychobiology, University of Hartford, West Hartford, CT 06117.

Prior research has indicated that embryonic neocortical tissue may be successfully transplanted into the cerebella of juvenile host animals (Wallace, R.B. and Das, G.D., Brain Research in press). These studies indicated that although the growing transplants replaced up to 80% of the host cerebellum, these animals were indistinguishable behaviorally from control subjects. Anatomical evaluation indicated that the transplants were fully integrated with the host neuropil. In an effort to extend these results to a sensory system, the following experiment was conducted. Embryonic neocortical tissue from 17 day embryos was transplanted bilaterally into the lateral geniculate nuclei of 10 day old host animals (Long-Evans hooded rats). These animals were then behaviorally compared with animals that had received bilateral LGN lesions and with normal control subjects. Tests employed consisted of Open Field, Neurological Exam, Visual Cliff and an operant brightness task. Following behavioral testing all animals were perfused transcardially with buffered formalin, the brains embedded in the coronal plane, sectioned and stained with H&E for microscopic examination. Microscopic evaluation indicated that in the transplant animals, the neocortical tissue had displaced and replaced the LGN bilaterally and, in some cases, much of the neighboring diencephalic tissue as well. Analysis revealed, however, that in the lesioned animals, the projections from the LGN were spared due to misplacement of the lesions. These data find support in the behavioral analyses which suggested no significant differences between the groups on any of the tasks employed. The point of interest, however, is the fact that there were no behavioral differences between the transplant and control animals although the growth of the transplants had replaced substantial amounts of tissue including the LGN. Additional work remains to be done.

57.1 COUNTS OF SYNAPSES ON IDENTIFIED NEURONS IN THE MOUSE CORTEX. A. Schüz*, A. Münster*, M. Dortenmann* (Spon: C. Wehrhahn). Max-Planck-Institut f. Biol. Kybernetik, Tübingen, W. Germany

Anatomical measurements and theoretical considerations have led to an estimate of a synaptic density of 1 synapse every 1 to 4 µm of axonal length (Braitenberg, 1981, Adv. Physiol. Sci. Vol. 16, Grastyán, Molnár, eds.). This number has been deduced from a synaptic density of $10^9/mm^3$ and an axonal density of 1-4 km/mm^3. We have now traced electronmicroscopically parts of the axonal tree of a Golgi-impregnated pyramidal cell. Its cell body was situated 325 µm below surface on the dorsolateral convexity of the hemisphere. The method consisted in a combination of Golgi-Colonnier, the EM-procedure of Blackstad with slight variations, and the addition of PTA. In spite of an insufficient preservation of the surrounding tissue, collaterals can be followed without loss of synapses. Tracing 70 µm of a collateral beginning at its origin, 17 synapses were found. This number (1 synapse every 4 µm) corresponds to the predicted value. Interestingly, the synapses were not distributed evenly. They were concentrated on 44 µm leaving long pieces at the origin of the collateral free of synapses.

A second point concerns the number of synapses on stellate cell dendrites, measured on PTA-stained material. An intentionally rough treatment of the tissue (acid fixative, exposition to ultrasound) led to a rather selective darkening of stellate cell dendrites. It induced, furthermore, the destruction of mitochondria which made the stain still more selective for synapses and allowed relatively thick sections (2000 Å) to be used. The pictures give a realistic impression of the synaptic density on stellate cell dendrites. By a reasoning akin to the Abercrombie-correction we estimated a density of 3 synapses per μ^2 of dendritic surface or 5 synapses per µ of dendritic length (on dendrites with a diameter of 0.5µ). The density is thus higher than the density of synapses on pyramidal cells (1.5 spines/µ). This shows clearly that the role of spines must not be seen in an increase in the number of possible synapses.

The synapses along a stellate cell dendrite are crowded more densely than in the rest of the tissue. This makes one think that at a certain stage stellate cell dendrites act as attractors for presynaptic elements.

57.2 A STUDY OF RECIPROCAL CONNECTIONS OF CORTICORETICULAR CELLS WITH BRAINSTEM NUCLEI USING ANTEROGRADE AND RETROGRADE TRANSPORT OF WGA-HRP IN CATS, J.I. Franck and R.P. Dum.
Dept. Neurosurgery, Upstate Med. Ctr., Syracuse, NY 13210

We have determined the exact sources of the reticular formation (RF) projections from frontoparietal cortex, and studied the afferent and efferent connections of these same cortical regions with the brainstem and diencephalon.

Ten cats were injected with 2-3 doses of 0.05-0.10µl of 2% WGA-HRP. The tissue was processed using the TMB method after a 2-3 day survival time. Injections in the pontine or medullary RF resulted in heavy retrograde labelling of cortical neurons in the presylvian (PS) gyrus and area 6 (esp. 6aβ) and moderately heavy labelling of rostral anterior ectosylvian gyrus (AEG-SII face area). Only scattered labelling of area 4,3,1 and 2 was noted.

Injections of WGA-HRP into area 6aβ,PS gyrus, or rostral AEG-SII were made in order to map the sub-cortical inputs and outputs of those areas. Densely retrogradely-labelled extra-thalamic nuclei (n.) which project to all of those cortical regions included the ventral tegmental area of Tsai, n. of the fields of Forel (FF),PAG, substantia innominata, and the raphe, coerulear-parabrachial (LC-BCM), and hypothalamic complexes. Smaller projections originated from the subthalamus, n. of the stria terminalis, and RF. Many thalamic n. were heavily labelled, in common, by all cortical injections. These included the intralaminar complex, VA, VL and VMP. In particular, the MD and paraventricular thalamic n. projected to area 6aβ and PS gyrus; and VMB and VBA to the AEG-SII face area.

After all cortical injections, heavy anterogradely labelled terminal fields were found in the pontine gray, caudate, RF, n. of Darkschewitsch, interstitial n. of Cajal, superior colliculus and pretectal n. The AEG-SII face area injection resulted in heavy trigeminal n. labelling. Projections to the tegmental reticular and lateral reticular n. from area 6aβ and PS gyrus were also observed.Dense reciprocal terminal fields were found in all cortically projecting thalamic nuclei and some extrathalamic nuclei including FF and PAG.

This study demonstrated the efficacy of WGA-HRP in the mapping of both afferent and efferent projections. We conclude that: 1) The RF is not a major relay from area 4 to the spinal cord, but rather receives projections from accessory motor and somatosensory regions; 2) Thalamic n. that project to these cortical regions receive heavy reciprocal cortical projections; 3) Many extrathalamic inputs to these cortical regions exist, some of which receive dense, and others, light reciprocal cortical projections; and 4) Many of the extrathalamic n. that receive these cortical projections are known to be involved in the control of eye and head movements.

57.3 AFFERENT AND EFFERENT CONNECTIONS OF SOMATIC MOTOR CORTEX RELATED TO TONGUE CONTROL IN THE RAT. L.D. Aldes*. Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, Texas 77025. (SPON: J.F. DeFrance)

As part of a larger investigation into the neural substrates subserving tongue control in the rat, the organization of afferent and efferent connections of somatic motor cortex related to the tongue was studied with retrograde (HRP) and anterograde (autoradiography) tracer techniques. Microiontophoretic injections of either HRP or tritiated amino acids (leucine, lysine and proline) were made into discrete cortical foci which, upon intracortical microstimulation, yielded the lowest threshold flick responses of the tongue.

Following injections of HRP, retrogradely labeled neurons were found in widely divergent sites including motor and sensory cortex, deep telencephalic nuclei, thalamus, ventral forebrain, hypothalamus, subthalamus and brainstem. The heaviest labeling of cells was seen in the ventrolateral (VL), ventromedial (VM) and posterior (PO) nuclei of the thalamus. Labeled cells were organized into longitudinal columns and occupied distinct topographic regions in each nucleus. Other heavily labeled areas included the contralateral motor and ipsilateral sensory and "taste" cortex; the centrolateral (CL), paracentral (PC) and central medial (CeM) intralaminar nuclei of the thalamus and the dorsal raphe. Moderate labeling of cells in the ventral forebrain and hypothalamus included the substantia innominata, substriatal gray, lateral and magnocellular preoptic nuclei, while distinct cell labeling also was evident in the entopeduncular and subthalamic nuclei, zona incerta, basolateral amygdala, parafascicular nucleus and locus coeruleus. Sparse labeling of cells was found in the midbrain tegmentum, medial parabrachial nucleus, nucleus centralis superior, caudoputamen (CP) and other nonspecific thalamic nuclei.

The course and distribution of labeled axons following injections of tritiated amino acids revealed a correspondingly diverse pattern of efferent connectivity. While reciprocal corticocortical, corticothalamic and corticosubthalamic projections were found, a dense, topographically organized, bilateral, corticostriate projection to the lateral one-third of the CP was seen. Moderately dense projections to the ipsilateral substantia nigra and lateral midbrain tegmentum were observed, while labeled axons were seen bilaterally in the bed nucleus of the anterior commissure and brainstem reticular fields.

Results of this study have demonstrated the diverse nature and topographic organization of both input and output of the somatic motor cortex related to the tongue. These data are necessary for understanding the neural basis of tongue control.

Supported, in part, by NIH grant 05913-0 and a University of Texas Biomedical Research Support Grant.

57.4 AN AUTORADIOGRAPHIC STUDY OF THE AMYGDALOCORTICAL PROJECTIONS IN THE MONKEY. D.G. Amaral and J.L. Price (SPON: B. Claiborn). The Salk Institute, LaJolla, CA; Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO.

As part of ongoing studies of the connections of the primate amygdaloid complex, we have examined amygdalocortical projections autoradiographically in a series of 9 cynomolgus monkeys prepared with single 100µl injections of ^{3}H-amino acids. In 7 of these monkeys bilateral injections were made (aimed at different targets) so that 16 injections were available for analysis; all major divisions of the amygdaloid complex were involved by at least one injection. These experiments demonstrated very substantial projections to the same cortical areas which innervate the amygdala. Moreover, the distribution of these projections varied depending on the amygdaloid nucleus labeled.

The lateral nucleus projects primarily to temporal and insular cortex. All divisions of temporal neocortex (TA, TE, TG and TF-TH) receive input from the lateral nucleus. The ventral portion of the insular cortex is also labeled for much of its rostro-caudal extent. The basal (or lateral-basal) nucleus sends a restricted projection to the rostral, agranular insular cortex and a very few fibers to the temporal neocortex (only to TG) but heavily innervates orbitofrontal and cingulate cortex. The magnocellular division projects most heavily to the medial and lateral orbitofrontal cortex (especially Walker's areas 14 and 12) whereas the parvocellular division projects most heavily to the rostral cingulate cortex (areas 24 and 25). There is a much lighter projection to the regions dorsal to the cingulate cortex including areas 6, 8 and 9. The magnocellular division of the basal accessory nucleus projects to the orbitofrontal cortex and insular cortex while the parvocellular division appears to send fibers to all portions of both the insular and temporal cortices. In all these areas the terminal labeling is concentrated in the deep part of layer I and in layer II, and, in many cases, also in layers V and VI.

These studies were supported in part by NIH grant NS09518 to J.L.P. and by grants from the Clayton Foundation for Research-California Division, and the McKnight Foundation.

57.5 THALAMIC AFFERENTS TO THE CORNEAL AREA OF THE PRIMARY SOMATOSENSORY CORTEX OF THE RABBIT. D.C. Nathanson* and C.F. Cegavske. Department of Psychology, SUNY-Binghamton, Binghamton, NY 13901.

The neural connections from the thalamus to the primary somatosensory cortex (SI) that mediate sensory information from the cornea have not been previously localized. These neurons were identified by first using averaged evoked potentials (AEPs) from the surface of the skull to localize SI, then injecting horseradish peroxidase (HRP) into the underlying corneal area of the cortex.
