Neuroscience

ABSTRACTS

Volume 8, Part 2

12th Annual Meeting
Minneapolis, Minnesota
Oct. 31–Nov. 5, 1982

CONTENTS

Proper citation form for this volume:
Soc. Neurosci. Abstr., Vol. 8, p. xxx, 1982.

Made in the United States of America
International Standard Book Number 0-916110-12-5
Library of Congress Catalog Card Number 75-7761

Published by
Society for Neuroscience
9650 Rockville Pike
Bethesda, Maryland 20814

* 3760 volunteer abstracts, 21 symposium/workshop abstracts.

CHRONOLOGICAL LIST OF SESSIONS

(See page vi for Thematic List of Sessions.)

Continued from Part One Society for Neuroscience Abstracts, Volume 8

Session Number and Title **Page**

8:30 AM Friday

Symposia

Slide Sessions

Poster Sessions

Sessions end at 12:45 PM, Friday, November 5.

THEMATIC LIST OF SESSIONS*

Theme A: Development and Plasticity

Session Number	Title	Type	Day	Time
83.	Axon Outgrowth, Growth Cones, and Guidance Mechanisms I	Poster	Tue	8:30 AM
266.	Axon Outgrowth, Growth Cones, and Guidance Mechanisms II	Slide	Fri	8:30 AM
70.	Cell Lineage and Differentiation I	Slide	Tue	8:30 AM
179.	Cell Lineage and Differentiation II	Poster	Wed	1:00 PM
9.	Development of Invertebrates I	Slide	Mon	8:30 AM
178.	Development of Invertebrates II	Poster	Wed	1:00 PM
122.	Development and Plasticity: Aging	Poster	Tue	1:00 PM
6.	Development and Plasticity: Autonomic Nervous System I	Slide	Mon	8:30 AM
52.	Development and Plasticity: Autonomic Nervous System II	Poster	Mon	1:00 PM
49.	Development and Plasticity: Biochemical and Pharmacological Correlates of Development	Poster	Mon	1:00 PM
168.	Development and Plasticity: Developmental Disorders	Poster	Wed	8:30 AM
89.	Development and Plasticity: Limbic System	Poster	Tue	8:30 AM
23.	Development and Plasticity: Neurotoxicology	Poster	Mon	8:30 AM
50.	Development and Plasticity: Nutritional and Prenatal Factors	Poster	Mon	1:00 PM
142.	Development and Plasticity: Retinotectal Connections	Slide	Wed	8:30 AM
216.	Development and Plasticity: Sensory Systems	Poster	Thu	8:30 AM
53.	Development and Plasticity: Trophic Agents I	Poster	Mon	1:00 PM
110.	Development and Plasticity: Trophic Agents II	Slide	Tue	1:00 PM
51.	Development and Plasticity: Trophic Interactions	Poster	Mon	1:00 PM
190.	Developmental Effects of Activity	Poster	Wed	1:00 PM
217.	Effects of Denervation	Poster	Thu	8:30 AM
54.	Endocrine Control of Development I	Poster	Mon	1:00 PM
249.	Endocrine Control of Development II	Poster	Thu	1:00 PM
180.	Morphogenesis and Pattern Formation I	Poster	Wed	1:00 PM
235.	Morphogenesis and Pattern Formation II	Slide	Thu	1:00 PM
277.	Motor System Development	Poster	Fri	8:30 AM
40.	Neural Plasticity in Adult Animals I	Slide	Mon	1:00 PM
215.	Neural Plasticity in Adult Animals II	Poster	Thu	8:30 AM
181.	Neuronal Death and Synapse Elimination	Poster	Wed	1:00 PM
262.	Regeneration in the Central Nervous System	Slide	Fri	8:30 AM
218.	Regeneration in the Central Nervous System: Forebrain Pathways	Poster	Thu	8:30 AM
248.	Regeneration in the Central Nervous System: Ventral Nerve Cord and Spinal Pathways	Poster	Thu	1:00 PM
12.	Regeneration in the Peripheral Nervous System I	Slide	Mon	8:30 AM
246.	Regeneration in the Peripheral Nervous System II	Poster	Thu	1:00 PM
233.	Retinogeniculate Development	Slide	Thu	1:00 PM
125.	Retinotectal Development and Organization	Poster	Tue	1:00 PM
205.	Role of Activity in Synaptic Sorting and Elimination	Slide	Thu	8:30 AM
121.	Specificity of Synaptic Connections	Poster	Tue	1:00 PM
84.	Sprouting and Sprouting Mechanisms	Poster	Tue	8:30 AM
247.	Synaptogenesis	Poster	Thu	1:00 PM
36.	Synaptogenesis: Molecular Approaches	Slide	Mon	1:00 PM
5.	Visual System: Geniculocortical Development I	Slide	Mon	8:30 AM
82.	Visual System: Geniculocortical Development II	Poster	Tue	8:30 AM
189.	Visual System: Geniculocortical Development III	Poster	Wed	1:00 PM

*Includes contributed paper sessions, symposia, and workshops only.

Theme B: Cell Biology

Session Number	Title	Type	Day	Time
224.	Axonal Organelles, Transport, and Specific Staining	Poster	Thu	8:30 AM
237.	Axoplasmic Transport	Slide	Thu	1:00 PM
243.	Blood–Brain Barrier	Poster	Thu	1:00 PM
283.	Cell Biology: Metabolic Studies	Poster	Fri	8:30 AM
197.	Cell Surface Macromolecules, Receptors, and Membranes	Poster	Wed	1:00 PM
62.	Cell and Tissue Culture	Poster	Mon	1:00 PM
286.	Cellular Aspects of Disease	Poster	Fri	8:30 AM
63.	Glia: Morphology and Function	Poster	Mon	1:00 PM
196.	Identified Neurons	Poster	Wed	1:00 PM
207.	Identifying Neurons and Glial Cells	Slide	Thu	8:30 AM
116.	Membranes and Cell Surface Molecules	Slide	Tue	1:00 PM
203.	Neurogenetics and Gene Expression	Slide	Thu	8:30 AM
64.	Neuronal and Glial Macromolecules	Poster	Mon	1:00 PM
148.	Structure and Function of Neuroendocrine Cells	Slide	Wed	8:30 AM

Theme C: Excitable Membranes and Synaptic Transmission

Session Number	Title	Type	Day	Time
169.	Diseases of Synapses and Axons	Poster	Wed	8:30 AM
102.	Drug Effects on Receptors	Poster	Tue	8:30 AM
115.	Electrophysiological Behavior of Vertebrate Central Nervous System Neurons	Slide	Tue	1:00 PM
287.	Epilepsy	Poster	Fri	8:30 AM
194.	Invertebrate Neurobiology	Poster	Wed	1:00 PM
66.	Ionic Channel Mechanisms	Poster	Mon	1:00 PM
211.	Ionic Channels: Structure and Function	Slide	Thu	8:30 AM
33.	Ionic Mechanisms of Excitable Cells	Poster	Mon	8:30 AM
103.	Membrane Biophysics I	Poster	Tue	8:30 AM
271.	Membrane Biophysics II	Slide	Fri	8:30 AM
227.	Neurobiological Studies of Cells in Culture	Poster	Thu	8:30 AM
259.	Neurobiological Studies of Vertebrate Central Nervous System Neurons	Poster	Thu	1:00 PM
101.	Pharmacology of Synaptic Transmission: Central Nervous System	Poster	Tue	8:30 AM
226.	Postsynaptic Mechanisms: Central Nervous System	Poster	Thu	8:30 AM
135.	Postsynaptic Mechanisms: Peripheral Nervous System	Poster	Tue	1:00 PM
145.	Pre- and Postsynaptic Mechanisms I	Slide	Wed	8:30 AM
239.	Pre- and Postsynaptic Mechanisms II	Slide	Thu	1:00 PM
225.	Presynaptic Mechanisms: Central Nervous System	Poster	Thu	8:30 AM
134.	Presynaptic Mechanisms: Peripheral Nervous System	Poster	Tue	1:00 PM
258.	Sensory Transduction	Poster	Thu	1:00 PM
77.	Synaptic Structure and Function I	Slide	Tue	8:30 AM
133.	Synaptic Structure and Function II	Poster	Tue	1:00 PM
104.	Molecular and Genetic Studies of the Voltage-Dependent Sodium Channel	Symp.	Tue	1:00 PM
171.	Single Channel Recording	Symp.	Wed	1:00 PM

Theme D: Neurotransmitters, Modulators, and Receptors

Session Number	Title	Type	Day	Time
143.	Acetylcholine I	Slide	Wed	8:30 AM
221.	Acetylcholine II	Poster	Thu	8:30 AM
157.	Adenosine: Modulators	Poster	Wed	8:30 AM
146.	Adrenergic Receptors: Biochemistry I	Slide	Wed	8:30 AM
187.	Adrenergic Receptors: Biochemistry II	Poster	Wed	1:00 PM
185.	Alcohol II	Poster	Wed	1:00 PM
111.	Amino Acids	Slide	Tue	1:00 PM
27.	Behavioral Pharmacology I	Poster	Mon	8:30 AM
109.	Behavioral Pharmacology II	Slide	Tue	1:00 PM
28.	Behavioral Pharmacology: Sedatives and Anxiolytics	Poster	Mon	8:30 AM
158.	Benzodiazepines	Poster	Wed	8:30 AM
223.	Biogenic Amines: Phenethylamine, Tryptamine, Serotonin, and Histamine	Poster	Thu	8:30 AM
30.	Catecholamines: Anatomical Localization	Poster	Mon	8:30 AM
252.	Catecholamines: Biochemistry	Poster	Thu	1:00 PM
131.	Catecholamines: Physiological Effects I	Poster	Tue	1:00 PM
264.	Catecholamines: Physiological Effects II	Slide	Fri	8:30 AM
31.	Coexistence of Transmitters	Poster	Mon	8:30 AM
93.	Cyclic Nucleotides	Poster	Tue	8:30 AM
186.	Dopamine Receptors: Biochemistry I	Poster	Wed	1:00 PM
208.	Dopamine Receptors: Biochemistry II	Slide	Thu	8:30 AM
251.	Excitatory Amino Acids	Poster	Thu	1:00 PM
159.	GABA and Benzodiazepines	Poster	Wed	8:30 AM
29.	Hypothalamic Hormones: Anatomical Localization	Poster	Mon	8:30 AM
32.	Interaction Between Neurotransmitters	Poster	Mon	8:30 AM
92.	Muscarinic Receptors	Poster	Tue	8:30 AM
91.	Nicotinic Receptors	Poster	Tue	8:30 AM
26.	Opiates, Endorphins, and Enkephalins: Anatomical Localization	Poster	Mon	8:30 AM
130.	Opiates, Endorphins, and Enkephalins: Characterization, Biosynthesis, and Degradation	Poster	Tue	1:00 PM
61.	Opiates, Endorphins, and Enkephalins: Electrophysiological Effects	Poster	Mon	1:00 PM
60.	Opiates, Endorphins, and Enkephalins: Physiological Effects I	Poster	Mon	1:00 PM
222.	Opiates, Endorphins, and Enkephalins: Physiological Effects II	Poster	Thu	8:30 AM
59.	Opiates, Endorphins, and Enkephalins: Receptors I	Poster	Mon	1:00 PM
107.	Opiates, Endorphins, and Enkephalins: Receptors II	Slide	Tue	1:00 PM
160.	Peptide-Amine Interactions: Modulators	Poster	Wed	8:30 AM
161.	Peptides: Anatomical Localization I	Poster	Wed	8:30 AM
231.	Peptides: Anatomical Localization II	Slide	Thu	1:00 PM
8.	Peptides: Biochemical Characterization	Slide	Mon	8:30 AM
79.	Peptides: Physiological Effects I	Slide	Tue	8:30 AM
281.	Peptides: Physiological Effects II	Poster	Fri	8:30 AM
280.	Peptides: Receptors	Poster	Fri	8:30 AM
156.	Phosphorylation: Calmodulin and Calcium Channels	Poster	Wed	8:30 AM
10.	Receptor Localization and Characterization I	Slide	Mon	8:30 AM
183.	Receptor Localization and Characterization II	Poster	Wed	1:00 PM
234.	Regulation of Transmitter Metabolic Enzymes	Slide	Thu	1:00 PM
76.	Serotonin: Biochemistry and Physiology	Slide	Tue	8:30 AM
38.	Transmitter Cytochemistry and Immunohistochemistry I	Slide	Mon	1:00 PM
188.	Transmitter Cytochemistry and Immunohistochemistry II	Poster	Wed	1:00 PM
282.	Transmitters in Invertebrates	Poster	Fri	8:30 AM
44.	Transmitters and Receptors in Disease I	Slide	Mon	1:00 PM
155.	Transmitters and Receptors in Disease II	Poster	Wed	8:30 AM
132.	Uptake, Storage, and Secretion I	Poster	Tue	1:00 PM
144.	Uptake, Storage, and Secretion II	Slide	Wed	8:30 AM
184.	Uptake, Storage, and Secretion: Cholinergic Systems	Poster	Wed	1:00 PM
260.	Functions of Multiple Transmitters in Neurons	Symp.	Fri	8:30 AM
201.	Substance P as a Neurotransmitter	Symp.	Thu	8:30 AM
35.	Sympathetic Ganglia as Models for Synaptic Transmitter Action	Symp.	Mon	1:00 PM

Theme E: Endocrine and Autonomic Regulation

Session Number	Title	Type	Day	Time
88.	Brain Ventricular Systems	Poster	Tue	8:30 AM
73.	Cardiovascular Regulation: Central Transmitters I	Slide	Tue	8:30 AM
119.	Cardiovascular Regulation: Central Transmitters II	Poster	Tue	1:00 PM
21.	Cardiovascular Regulation: Functional Aspects I	Poster	Mon	8:30 AM
209.	Cardiovascular Regulation: Functional Aspects II	Slide	Thu	8:30 AM
120.	Cardiovascular Regulation: Hypertension and Stress	Poster	Tue	1:00 PM
39.	Endocrine and Autonomic Regulation: Central Pathways I	Slide	Mon	1:00 PM
118.	Endocrine and Autonomic Regulation: Central Pathways II	Poster	Tue	1:00 PM
19.	Hormonal Control of Behavior I	Poster	Mon	8:30 AM
267.	Hormonal Control of Behavior II	Slide	Fri	8:30 AM
20.	Neural Control of Immune System	Poster	Mon	8:30 AM
113.	Peripheral Autonomic Nervous System I	Slide	Tue	1:00 PM
153.	Peripheral Autonomic Nervous System II	Poster	Wed	8:30 AM
152.	Pineal Gland	Poster	Wed	8:30 AM
22.	Regulation of Autonomic Functions I	Poster	Mon	8:30 AM
74.	Regulation of Autonomic Functions II	Slide	Tue	8:30 AM
18.	Regulation of Pituitary Function	Poster	Mon	8:30 AM
154.	Respiratory Regulation	Poster	Wed	8:30 AM

Theme F: Sensory Systems

Session Number	Title	Type	Day	Time
288.	Auditory Cortex	Poster	Fri	8:30 AM
16.	Auditory and Vestibular Sensory Organs	Poster	Mon	8:30 AM
7.	Chemical Senses: Olfaction and Taste I	Slide	Mon	8:30 AM
55.	Chemical Senses: Olfaction and Taste II	Poster	Mon	1:00 PM
95.	Evoked Potentials I	Poster	Tue	8:30 AM
265.	Evoked Potentials II	Slide	Fri	8:30 AM
72.	Pain I	Slide	Tue	8:30 AM
220.	Pain: Modulation I	Poster	Thu	8:30 AM
230.	Pain: Modulation II	Slide	Thu	1:00 PM
17.	Retina: Intrinsic Organization I	Poster	Mon	8:30 AM
37.	Retina: Intrinsic Organization II	Slide	Mon	1:00 PM
244.	Sensory System: Somatosensory Cortex	Poster	Thu	1:00 PM
147.	Sensory Systems in Invertebrates I	Slide	Wed	8:30 AM
195.	Sensory Systems in Invertebrates II	Poster	Wed	1:00 PM
245.	Skin, Muscle, and Visceral Receptors	Poster	Thu	1:00 PM
15.	Somatosensory Cortex and Thalamus	Slide	Mon	8:30 AM
25.	Spinal Cord I	Poster	Mon	8:30 AM
43.	Subcortical Auditory Pathways I	Slide	Mon	1:00 PM
94.	Subcortical Auditory Pathways II	Poster	Tue	8:30 AM
289.	Subcortical Somatosensory Pathways	Poster	Fri	8:30 AM
56.	Subcortical Visual Pathways I	Poster	Mon	1:00 PM
71.	Subcortical Visual Pathways II	Slide	Tue	8:30 AM
112.	Subcortical Visual Pathways III	Slide	Tue	1:00 PM
129.	Transmitters in Sensory Systems	Poster	Tue	1:00 PM
191.	Visual Cortex: Cortical and Subcortical Relationships	Poster	Wed	1:00 PM
193.	Visual Cortex: Extrastriate Visual Areas I	Poster	Wed	1:00 PM
232.	Visual Cortex: Extrastriate Visual Areas II	Slide	Thu	1:00 PM
192.	Visual Cortex: Intrinsic Organization of Striate Cortex I	Poster	Wed	1:00 PM
204.	Visual Cortex: Intrinsic Organization of Striate Cortex II	Slide	Thu	8:30 AM
138.	Functions of Extrastriate Visual Cortex in Primates	Symp.	Wed	8:30 AM
69.	Physiological Insights Derived from Nerve Traffic Analysis in Conscious Man	Symp.	Tue	8:30 AM

Theme G: Motor Systems and Sensorimotor Integration

Session Number	Title	Type	Day	Time
140.	Basal Ganglia	Slide	Wed	8:30 AM
276.	Basal Ganglia: Functional Relationships	Poster	Fri	8:30 AM
48.	Basal Ganglia: Structural Relationships	Poster	Mon	1:00 PM
123.	Cerebellum I	Poster	Tue	1:00 PM
238.	Cerebellum II	Slide	Thu	1:00 PM
47.	Control of Posture and Movement I	Poster	Mon	1:00 PM
78.	Control of Posture and Movement II	Slide	Tue	8:30 AM
212.	Control of Posture and Movement III	Poster	Thu	8:30 AM
272.	Control of Posture and Movement IV	Poster	Fri	8:30 AM
274.	Disorders of the Motor System and Corrective Methods	Poster	Fri	8:30 AM
213.	Invertebrate Motor Function	Poster	Thu	8:30 AM
114.	Motor Systems: Cortex I	Slide	Tue	1:00 PM
150.	Motor Systems: Cortex II	Poster	Wed	8:30 AM
210.	Motor Systems: Spinal Cord and Brainstem I	Slide	Thu	8:30 AM
250.	Motor Systems: Spinal Cord and Brainstem II	Poster	Thu	1:00 PM
275.	Motor Systems: Spinal Cord and Brainstem III	Poster	Fri	8:30 AM
90.	Muscle	Poster	Tue	8:30 AM
124.	Muscle Afferents	Poster	Tue	1:00 PM
45.	Oculomotor I	Slide	Mon	1:00 PM
80.	Oculomotor II	Poster	Tue	8:30 AM
117.	Oculomotor III	Poster	Tue	1:00 PM
149.	Reflex Function	Poster	Wed	8:30 AM
273.	Sensorimotor Integration	Poster	Fri	8:30 AM
198.	Vestibular System	Poster	Wed	1:00 PM
269.	Vestibular System and Vestibulo-Ocular Reflex	Slide	Fri	8:30 AM
81.	Visuomotor Integration	Poster	Tue	8:30 AM
173.	Springing into Action: Mechanism and Function of Spring-Like Properties of Neuromuscular Systems	Wkshp.	Wed	1:00 PM
4.	Theoretical Approaches to Motor Control	Symp.	Mon	8:30 AM

Theme H: Structure and Function of the CNS

Session Number	Title	Type	Day	Time
285.	Brain Metabolism	Poster	Fri	8:30 AM
219.	Comparative Neuroanatomy	Poster	Thu	8:30 AM
57.	Cortex and Cortico-Subcortical Relationships I	Poster	Mon	1:00 PM
268.	Cortex and Cortico-Subcortical Relationships II	Slide	Fri	8:30 AM
13.	Diseases of the Central Nervous System I	Slide	Mon	8:30 AM
65.	Diseases of the Central Nervous System II	Poster	Mon	1:00 PM
24.	Epilepsy: Kindling	Poster	Mon	8:30 AM
126.	Epilepsy: Kindling and Pharmacology	Poster	Tue	1:00 PM
139.	Epilepsy: Pharmacology	Slide	Wed	8:30 AM
279.	Evoked Potentials and EEG	Poster	Fri	8:30 AM
240.	Limbic System and Hypothalamus I	Slide	Thu	1:00 PM
278.	Limbic System and Hypothalamus II	Poster	Fri	8:30 AM
58.	Limbic System and Hypothalamus: Structure	Poster	Mon	1:00 PM
284.	Spinal Cord II	Poster	Fri	8:30 AM
182.	Subcortical Organization	Poster	Wed	1:00 PM
202.	Application of Video Enhancement and Intensification Techniques to Neurobiology	Wkshp.	Thu	8:30 AM
229.	Functional Correlates of Brain Transplantation	Symp.	Thu	1:00 PM

Theme I: Neural Basis of Behavior

Session Number	Title	Type	Day	Time
241.	Aging	Poster	Thu	1:00 PM
163.	Alcohol I	Poster	Wed	8:30 AM
256.	Angiotensin and Drinking	Poster	Thu	1:00 PM
166.	Behavior and Learning in Invertebrate and Simple Vertebrate Preparations	Poster	Wed	8:30 AM
14.	Biological Rhythms I	Slide	Mon	8:30 AM
151.	Biological Rhythms II	Poster	Wed	8:30 AM
46.	Circuitry and Pattern Generation I	Slide	Mon	1:00 PM
214.	Circuitry and Pattern Generation II	Poster	Thu	8:30 AM
290.	Drugs of Abuse	Poster	Fri	8:30 AM
96.	Effects of Chronic Drug Administration and Neurotoxicology	Poster	Tue	8:30 AM
164.	Feeding and Drinking	Poster	Wed	8:30 AM
206.	Feeding and Drinking: Central Mechanisms and Neuropharmacology	Slide	Thu	8:30 AM
75.	Feeding and Drinking: Central and Peripheral Mechanisms	Slide	Tue	8:30 AM
255.	Feeding and Drinking: Cues for Need State	Poster	Thu	1:00 PM
257.	Feeding and Drinking: Metabolic Aspects	Poster	Thu	1:00 PM
165.	Feeding and Drinking: Neuropharmacology	Poster	Wed	8:30 AM
263.	Human Behavioral Neurobiology	Slide	Fri	8:30 AM
177.	Human Neuropsychology	Poster	Wed	1:00 PM
176.	Interhemispheric Relations	Poster	Wed	1:00 PM
106.	Invertebrate Learning and Behavior I	Slide	Tue	1:00 PM
236.	Invertebrate Learning and Behavior II	Slide	Thu	1:00 PM
42.	Learning and Memory: Electrophysiological and Pharmacological Studies	Slide	Mon	1:00 PM
86.	Learning and Memory: Electrophysiological Studies	Poster	Tue	8:30 AM
11.	Learning and Memory: Lesion Studies I	Slide	Mon	8:30 AM
85.	Learning and Memory: Lesion Studies II	Poster	Tue	8:30 AM
87.	Learning and Memory: Pharmacological Studies	Poster	Tue	8:30 AM
108.	Monoamines and Behavior	Slide	Tue	1:00 PM
97.	Monoamines and Behavior: Chronic Administration and Long-Lasting Effects	Poster	Tue	8:30 AM
98.	Monoamines and Behavior: Human Mental Disorders and Animal Models	Poster	Tue	8:30 AM
253.	Monoamines and Behavior: Movement and Reflexes	Poster	Thu	1:00 PM
254.	Monoamines and Behavior: Unit Recording Studies and Self-Stimulation Studies	Poster	Thu	1:00 PM
175.	Motivation and Emotion	Poster	Wed	1:00 PM
167.	Neuroethology I	Poster	Wed	8:30 AM
270.	Neuroethology II	Slide	Fri	8:30 AM
41.	Neuropeptides and Behavior I	Slide	Mon	1:00 PM
100.	Neuropeptides and Behavior II	Poster	Tue	8:30 AM
99.	Neuropeptides and Learned Behavior	Poster	Tue	8:30 AM
162.	Opiates, Endorphins, and Enkephalins	Poster	Wed	8:30 AM
141.	Pain II	Slide	Wed	8:30 AM
174.	Pain III	Poster	Wed	1:00 PM
128.	Psychotherapeutic Drugs	Poster	Tue	1:00 PM
242.	Sleep	Poster	Thu	1:00 PM
127.	Stress, Hormones, and the Autonomic Nervous System	Poster	Tue	1:00 PM

137 SYMPOSIUM. GENETIC CORRELATES OF MENTAL DISEASE. S. Matthysse*, McLean Hospital/Harvard Medical School (Chairman), L. Heston*, Univ. of Minnesota, S.S. Kety, McLean Hospital/Harvard Medical School, K.K. Kidd*, Yale Univ. Medical School.

This symposium will review the state of knowledge in the genetics of affective disorder, schizophrenia and Alzheimer's disease. New genetic methods, including restriction endonuclease polymorphisms, will be discussed. Current diagnostic practices will be examined in the light of genetic knowledge.

Brief summary of individual topics:

Dr. Heston - family studies of Alzheimer's disease, frequency of familial recurrence, comparison of familial and non-familial cases.

Dr. Kety - current status of the genetics of schizophrenia and schizophrenia spectrum illnesses.

Dr. Kidd - current status of the genetics of affective disorder, assessment of reports of genetic linkage, prospects for the use of restriction endonuclease polymorphisms for linkage analysis.

Dr. Matthysse - implications of genetic thinking for diagnostic classification.

Time will be reserved for open discussion.

138 SYMPOSIUM. FUNCTIONS OF EXTRA-STRIATE VISUAL CORTEX C.G. Gross, Princeton Univ. (Chairman); L.G. Ungerleider, Lab. of Neuropsychology, N.I.M.H.; C.G. Gross, Princeton Univ.; J.M. Allman, California Institute of Technology; R. Desimone*, Lab. of Neuropsychology, N.I.M.H.

The study of visual cortical mechanism currently faces an embarrassment of riches and a poverty of explanations. In the last decade, thanks initially to Allman and Kaas and to Zeki, there has been a population explosion of visual areas. Now there are at least a dozen visual areas in the cortex of cats and monkeys and more are coming. What are they all doing?

One type of visual cortex consists of the various prestriate areas, each of which contains a retinotopically organized representation of the contralateral visual field. Each of these areas seems to be specialized for analysis of different stimulus dimensions. Another type of visual cortex is inferior temporal (IT) cortex, which is not retinotopically organized. IT neurons usually have bilateral receptive fields and often show selectivity for complex stimuli.

Dr. Ungerleider will review the anatomical interconnections of various extra-striate areas and trace the flow of visual information through them. She will propose that there may be a dorsal occipito-parietal system crucial for the perception of spatial relations and a ventral occipito-temporal system crucial for object recognition and memory.

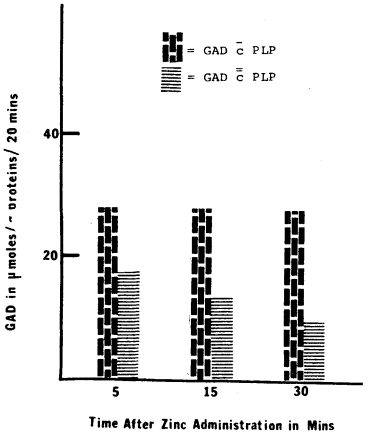
Dr. Gross will review the properties of IT, an area crucial for pattern recogniton. He will contrast IT with MT, an area involved in the processing of visual motion, and STP, a polysensory area in the temporal lobe.

Dr. Allman will discuss the analysis of motion and form by prestriate neurons, particularly in Areas MT and DL. He will suggest ways in which this analysis may underlie perceptual phenomena, such as discrimination of relative motion and of figure from ground.

Dr. Desimone will consider the filtering of chromatic and spatial information in Area V4 and will examine the possibility that inferior temporal neurons may act as shape filters.

139.1 THE NATURE AND MECHANISM OF ZINC-INDUCED EPILEPTIC SEIZURES. M. Ebadi, M. Itoh* and S. Swanson*. Dept. of Pharmacology, Univ. of Neb. Coll. of Med., Omaha, NE 68105.

The intracerebroventricular injection of $ZnCl_2$ in concentrations of 0.2 µmol/10 µl caused epileptic seizures rapidly characterized by rearing, running fits, jumping, retropulsion, vocalization, and convulsions. The convulsive episodes became manifested in fasiculation of facial muscles, jerking of head, myoclonic movements of the limbs, and sometimes, tonic-clonic convulsions. The latency periods between the administration of $ZnCl_2$ and the appearance of paroxysmal behaviors and movements were between 70 to 150 seconds. The ICV administration of GABA (0.4 µmol/10 µl) was able to block, prevent or rapidly reverse the Zn^{++}-induced epileptic seizures. When glutamic acid decarboxylase (GAD) was assayed in the absence of pyridoxal phosphate (PLP), the activities were significantly reduced in hippocampus with more pronounced effects seen after 30 mins incubation periods. The effect was specific for hippocampus but not other brain areas studied. The administration of $ZnSO_4$ did not alter the level of PLP in hippocampus, which has the highest concentration of Zn^{++} and the lowest level of PLP. The concentrations of PLP and Zn^{++} are negatively correlated (r = -0.53) in 14 regions of rat brain. Using Sephadex G-75 and Sephadex G-150 column chromatographies calibrated with proteins of known molecular weights, three separate zinc binding proteins with apparent estimated molecular weight of 210,000, 25,000 and 15,000 daltons respectively were detected in brain. The characteristics of these zinc binding proteins were not identical to hepatic or renal zinc-thioneins, since the administration of Zn^{++} did not increase their contents. Furthermore, comparative elution patterns showed that those peaks containing high activity of GAD possessed little or no zinc binding proteins. (Supported by a grant from Am. Epilepsy Fdn.)



139.2 PUSH-PULL PERFUSION OF PENTYLENETETRAZOL IN THE BRAIN STEM AND CEREBRAL CORTEX OF "ENCEPHALE ISOLE" CATS. F. Velasco, M. Velasco* and R. Romo* Sci. Res. Dept. Natl. Med. Ctr. IMSS - P.O. Box 73-032, México, D. F.

The role of the brain stem in the generation of pentylenetetrazol (PTZ) seizures was studied by perfusing the convulsant through a push-pull cannula in various places of the brain stem. Animals were immobilized in the stereotaxic frame by means of C2-C3 spinal cord transection and EEG from right and left motor cortices, EMG from neck muscles and ocular movements were recorded through implanted electrodes.

Perfusions from 0.2 to 1.0 ml of a solution containing 10 mg of PTZ/ml in the mesencephalic reticular formation (MRF), induced either myoclonic twitching of neck and head muscles and EEG interrupted discharges, or EEG sustained rhythmic discharges and muscular tonic clonic seizures, similar to those seen when PTZ is injected systemically. Perfusion of pontine reticular formation (PRF) induced EEG spindle bursts and muscular hypotonia. In other areas of the brain stem PTZ induced ocular movements in the form of tonic deviation or nystagmus, but no EEG or muscular seizures.

Similar perfusions of PTZ in the motor cortex induces focal EEG interrupted discharges with occasional muscular twitching, and in the suprasylvian cortex EEG interrupted discharges without clinical seizures.

Results suggest that PTZ has a differential effect in various structures of the CNS and that its convulsive properties result from its action on MRF.

139.3 THE EFFECT OF TAURINE ON ACUTE EPILEPTOGENIC FOCUS. D. Marcano de Cotte*, A. Alvarez*, J. R. Pérez*, M. A. Requena*, E. Vallecalle* and B. Drujan* (SPON: N. Wexler). Dept. of Physiology, J. M. Vargas Medical School, Universidad Central de Venezuela and Dept. of Neurochemistry, I.V.I.C., Apartado de Correos 47697, Caracas 1041, Venezuela.

Taurine is after glutamate the free amino acid with the great est concentration in the mature brain. It has been considered a putative inhibitory neurotransmitter in the central nervous system and retina. There is evidence that both human epilepsy and experimental epilepsy is accompanied by changes in the brain taurine concentrations. In animals with an experimental epileptic focus produced by application of cobalt to the brain surface, the site of the induced seizures activity shows lowered taurine levels. Repeated injections of taurine abolish seizure activity and reverse the abnormalities in brain amino acid levels which accompany severe epilepsy (Van Gelder, N. M., Brain Research, 47: 157, 1972).

The present study has been performed to investigate the effect of i.v. administration of taurine on the electrical activity of the epileptogenic focus induced by Penicillin applied on the right sensitive-motor cortex of adult Sprague Dawley rats. Taurine (100 mg/Kg body weight) was administered by the tail vein at 15, 30, 60 and 120 min. before the application of 1 mg of Sodium Penicillin G. The EEG was unipolarly recorded by means of silver ball electrodes applied to the pia and screw electrodes attached to the skull.

When taurine was administered 60 and 120 min before the application of penicillin, the delay of appearance of the focus was increased, the frecuency and spike amplitude decreased. The spread of epileptogenic focus to the opposite hemisphere was retarded when compared to control animals. Fifty per cent of the animals showed a reduced post-discharges frecuency. In 11 out 13 rats, taurine abolished the seizure activity completely.

In our experiments taurine is a powerful antiepileptic agent and the maximal antiepileptic effect was observed when the amino acid was administered 60-120 min. before the penicillin. This suggests that a better knowledge of the taurine metabolism is required to explain its antiepileptic activity.

This work was supported by a Grant from Consejo de Desarrollo Científico y Humanístico de la Universidad Central de Venezuela.

139.4 TAURINE AND THE ONTOGENESIS OF AN EPILEPTOGENIC FOCUS IN THE RAT. A. Alvarez*, M. A. Requena*, E. Vallecalle*, D. Marcano de Cotte* and B. Drujan* (SPON: H. J. Finol). Dept. of Physiology, J. M. Vargas Medical School, Universidad Central de Venezuela and Dept. of Neurochemistry, I. V. I. C., Apartado de Correos 47697, Caracas 1041, Venezuela.

Previous reports have shown a consistent deficit of taurine in both epileptic human cerebral cortex and cobalt chronic cortical foci in cats and mice. Taurine is the free amino acid with the greatest concentration in the inmature brain. On the other hand, it has been shown that brain taurine in developing rats is derived from the mother, both in utero prior to birth and from the milk after birth.

In the present study we have investigated the effect of taurine administration to female Sprague Dawley rats before pregnancy, throughout gestation and throughout waning, on the development of EEG epileptic activity of the pups. Taurine (200 mg/Kg body weight) was administered intraperitoneally to the mothers and epilepsy was induced by application of 1 mg of Sodium Penicillin G on the right sensitive-motor cortex of pups at different post-natal ages. The EEG was unipolarly recorded by means of silver ball electrodes applied to the pia and screw electrodes attached to the skull.

Pups of 15, 18, 21 and 23 days of post-natal life did not show difference in the latency of appearance of the epileptic focus, spike amplitude and spike frecuency when compared to control animals. However, in the 50% of the animals which received taurine the epileptic activity remained localized to the application site and the other 50% showed a spread epileptic activity to the opposite sensitive-motor cortex. A spread to visual cortex was never observed. Furthermore, no post-discharges or generalized hypersynchronized activity was observed. These was significative different to control animals which always present post-discharges and, after the 21th day show seizure activity.

These results may suggest that the resistance of the most inmature brain (less of 15 days of post-natal life) to epileptic activity could be related to its high concentration of taurine.

Determination of brain taurine concentration in normal and epileptic animals from 1 to 30 days of age are being carried out.

This work was supported by a Grant from Consejo de Desarrollo Científico y Humanístico de la Universidad Central de Venezuela.

139.5 BIOCHEMICAL CORRELATES OF THE ANTICONVULSANT ACTION OF TAURINE IN THE GENETICALLY EPILEPTIC RAT. Douglas Bonhaus*, Hugh Laird and Ryan J. Huxtable*. Department of Pharmacology, College of Medicine and Department of Pharmacology & Toxicology, College of Pharmacy, University of Arizona, Tucson, Arizona 85721

Taurine (2-amino ethane sulfonic acid) is a potent anticonvulsant in a variety of experimental epilepsies. In the genetically epileptic rat, taurine has been shown to increase intracerebral electroshock thresholds and to decrease the intensity of sound induced seizures. The anticonvulsant action of taurine in this model is persistent. A single bilateral injection of 200 nMoles taurine into the inferior colliculi produced a statistically significant increase in intracerebral electroshock threshold for eighteen days. However, taurine did not alter intracerebral electroshock thresholds of control, genetically seizure resistant, rats (Huxtable, R. and Laird, H., Can. J. Neuro. Sci. 5: 215, 1978). The mechanism of the anticonvulsant action of taurine is not known. Few biochemical actions of taurine have been found that correlate with its anticonvulsant effect. Therefore, we find it interesting that taurine increases glutamic acid decarboxylase activity in tissue homogenates prepared from brains of epileptic rats, in as much as this enzyme produces gamma-aminobutyric acid, an inhibitory neurotransmitter. Taurine, in the presence of pyridoxine, increased glutamic acid decarboxylase activity in seizure susceptible rats to 126 ± 10 (mean ± S. E.) percent of control values ($p < 0.05$, paired Student's t test). Taurine is without effect on the glutamic acid decarboxylase activity of seizure resistant rats. These biochemical findings are intriguing, because they correlate with the differential effect of taurine on the electroshock threshold of the two strains. These findings may, therefore, offer some insight into the mechanism of the anticonvulsant action of taurine. (Supported by USPHS HL 19394).

139.6 PRENATAL EXPOSURE TO ELECTROCONVULSIVE SEIZURES, A BENZODIAZEPINE ANTAGONIST AND AN AGONIST: EFFECTS ON POSTNATAL DEVELOPMENT OF BENZODIAZEPINE BINDING AND SEIZURE THRESHOLDS. D.W. Gallager, Dept. Psychiat. and Sect. Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06508.

Electroconvulsive seizures and the specific benzodiazepine antagonist, Ro15-1788, administered during the period of fetal benzodiazepine (BZ) binding site proliferation significantly decreased the density of cortical BZ sites in exposed offspring at various postnatal (PN) ages. Significant decreases in electroshock seizure threshold were observed in offspring following these prenatal treatments.

Total 3H-diazepam binding was decreased in cerebral cortical tissue from offspring following maximal electroshock seizures (MES) administered to pregnant rats on days 16, 18, and 20 in gestation. Scatchard analysis of membranes from MES-exposed and sham offspring showed that the decrease in specific 3H-diazepam binding was due to a decrease in the total number of binding sites without a significant change in affinity (Sham: KD = 4.2 nM, Bmax = 1419 fmol/mg protein; MES: KD = 4.4 nM, Bmax = 1292 fmol/mg protein). MES administered at other times in gestation did not result in significant BZ site alterations in exposed offspring. Decreases in electroshock seizure thresholds of MES-exposed offspring were also observed. Mean thresholds (measured at PN 14 through 17) were 9.5 ± 0.2 mA in control and 8.7 ± 0.1 mA in MES exposed offspring.

Subcutaneous administration of 20 mg/kg of the benzodiazepine antagonist Ro15-1788 to pregnant rats on days 14 through 17 in gestation also resulted in significant decreases in BZ site density as compared with offspring from control rats treated in parallel with vehicle (dilute Tween 80). Scatchard analysis of cortical membranes from offspring exposed prenatally to Ro15-1788 had a KD of 4.1 nM and a Bmax of 1155 fmol/mg protein as compared vehicle control offspring with a KD of 4.2 nM and a Bmax of 1345 fmol/mg protein. This prenatal treatment also resulted in significant decreases in seizure threshold. Mean electroshock seizure thresholds were 8.7 ± 0.2 mA for vehicle and 7.7 ± 0.2 mA for offspring exposed prenatally to Ro15-1788. In contrast, chronic prenatal treatment with the potent BZ agonist clonazepam (2 mg/kg s.c. daily to pregnant rats on days 14 through 20 in gestation) produced no significant alterations in BZ sites or seizure threshold in exposed offspring.

The data suggest that there may be similarities in maternal electroshock seizures and prenatal exposure to a BZ antagonist (but not an agonist). In addition, significant alterations in BZ binding appear to be associated with changes in seizure thresholds in developing animals.

139.7 DO GABA AGONISTS HAVE ANTICONVULSANT PROPERTIES ON THE PENICILLIN FOCUS IN RATS? R.G. Fariello and G.T. Golden. Medical Service, Neurology Section, VA Hospital and The University of Texas Health Science Center at San Antonio, Texas 78284.

It has been suggested that impaired GABA mediated inhibitory function plays an important role in the generation of penicillin induced epileptiform activity. We have, therefore, tested the action of i.v. administered direct GABA agonists on the activity of such an acute penicillin focus in rats. Under urethane anesthesia (1 g/kg), 200 and 400 IU of Na penicillin were injected in the sensorymotor cortex of two groups of rats. Progabide, 3APS, THIP were injected i.v. and their effect compared to the effect of Dilantin and of ethanol and DMSO which were used as solvents for Progabide. Total duration of spike activity, spike amplitude and spike frequency were compared between treated animals and control non-treated animals.

Immediate, transient spike suppression was noted only with Progabide (≥ 10 mg/kg, LD50 = 50 mg/kg i.v.). The average life of the focus was not altered by any of the compounds. Progabide decreased the spike frequency after the initial suppression effect in a non-statistically significant way. 3APS transiently decreased spike frequency in 2 out of 6 injections. THIP did not significantly affect penicillin spike but at doses greater than 5 mg/kg induced burst of spikes and polyspikes on the EEG. Dilantin increased spike frequency for about 30 minutes after injection.

These results differ from our own and other laboratory findings on the action of direct GABA agonists on penicillin spikes in cats, whereas the observed Dilantin potentiation is in agreement with previously reported studies in cats and rats. Since spike amplitude and duration were not affected in our experiments, we conclude that spike frequency, amplitude and duration of focal activities are not useful variables to be examined for prediction of anticonvulsant activity. Progabide showed the most consistent and persistent immediate transient suppression of spike activity. The relevance of this phenomena to the clinical anticonvulsant effect of Progabide and other direct GABA agonists is discussed.

139.8 MULTIPLE PHENYTOIN BINDING SITES: IDENTIFICATION AND CHARACTERIZATION IN BRAIN MEMBRANE. A.C. Bowling* and R.J. DeLorenzo, Dept. of Neurology, Yale Medical School, New Haven, CT 06510

Previous studies in our laboratory have demonstrated that micromolar concentrations of benzodiazepines inhibit the Ca^{2+}-calmodulin dependent protein kinase system in brain membrane (Science 213: 546, 1981). We have also shown that micromolar affinity benzodiazepine receptors exist in brain membrane which are distinct from the previously described nanomolar affinity benzodiazepine receptors (Science, in press). Benzodiazepine inhibition of protein kinase activity and benzodiazepine binding to the micromolar receptors correlate significantly with benzodiazepine inhibition of maximal electric shock-induced seizures. Displacement studies demonstrated that micromolar concentrations of phenytoin displace [^{3}H]-diazepam from the micromolar receptor. These findings suggest that the micromolar benzodiazepine receptor may represent a phenytoin receptor in brain membrane.

To examine the possible existence of specific phenytoin binding sites, receptor binding assays were performed on rat synaptic membrane utilizing a wide range of [^{3}H]-phenytoin concentrations (10^{-9} M to 10^{-3} M). Saturation studies demonstrated the existence of micromolar affinity phenytoin binding sites with a K_D of approximately 100 μM. Saturation studies in the nanomolar range revealed the presence of a second distinct class of specific phenytoin binding sites which exhibited a K_D of approximately 15 nM. It is possible that a third class of binding sites exists with a K_D of approximately 600 nM; however, the binding in this concentration range may represent low levels of binding to the micromolar affinity phenytoin binding sites. Displacement studies on the micromolar affinity phenytoin bindings sites demonstrated that micromolar concentrations of two other major anticonvulsant agents, diazepam and carbamazepine (Tegretol), displaced specifically-bound [^{3}H]-phenytoin. Conversely, we have shown that phenytoin displaces [^{3}H]-diazepam which is specifically bound to the micromolar benzodiazepine receptor.

These findings suggest that the micromolar phenytoin binding site is identical to the micromolar benzodiazepine receptor and thus this binding site may be a clinically-relevant phenytoin receptor which serves to mediate the anticonvulsant and neuronal stabilizing properties of phenytoin. These results are consistent with the hypothesis that specific phenytoin recpetors exist in brain membrane and that these binding sites may regulate some of the effects of several major anticonvulsants on neuronal tissue. The micromolar phenytoin receptor may represent a generalized anticonvulsant receptor that binds certain classes of anticonvulsant agents that are effective in inhibiting maximal electric shock-induced seizures.

139.9 EFFECTS OF α-METHYL-P-TYROSINE (α-MPT) ON PINEALECTOMY-INDUCED SEIZURES IN THE RAT. C. A. Stockmeier and D. E. Blask*. Dept. of Anatomy, University of Arizona, Tucson, AZ 85724.

Pinealectomy in gerbils or partially parathyroidectomized (PthX) rats causes seizures usually characterized by wild running followed by clonus, tonus and occasionally death. Norepinephrine (NE) is implicated in several animal seizure models. α-MPT lowers catecholamine levels in the gerbil telencephalon and makes the animal more susceptible to pinealectomy-induced seizures. To see whether inhibition of catecholamine synthesis exacerbates seizures in rats, we tested the effects of various doses of α-MPT on seizures in partially PthX rats that were later pinealectomized (PinX). Male Long-Evans rats (21 days old) were partially PthX. One week later, 4 groups of 9-10 PthX rats were PinX while a fifth group was sham-PinX. Groups of rats received an i.p. injection of either saline, 15, 25 or 35 mg of α-MPT 24 and 12 hours prior to pinealectomy and one more injection immediately after pinealectomy; the sham-PinX group received 35 mg of α-MPT according to the same schedule. Animals were observed continuously for eight hours after pinealectomy, and both the onset and type of each seizure were recorded. Seizures were recorded as follows: 1= wild run, 2=clonus + 1, 3=tonus + 1 + 2 and 4=death + 1 + 2 + 3. No convulsions were observed in the PthX, sham-PinX rats which received 35 mg of α-MPT. 90% of the control group of PthX rats that were PinX and injected with saline had convulsions and averaged 3.5 convulsions per rat during the 8-hour period. Averaged over the 8-hour period, none of the treatments with α-MPT changed the mean number of convulsions per convulsing rat, the number of rats that convulsed per number at risk or the latency to onset of any type of convulsion as compared with saline controls. However, significantly fewer convulsions occurred in rats treated with 15 or 35 mg of α-MPT as compared with the 25 mg treatment group. The 25 mg injections of α-MPT reduced by 49% the mean latency to onset of the first tonic convulsion when compared with saline controls. Conversely, latency to onset of the first tonic convulsion was restored to control values by 35 mg α-MPT. The analysis of data over time showed that during the second hour after pinealectomy, the 25 mg dose caused significantly more tonic convulsions per convulsing rat. Furthermore, a greater percentage of convulsions occurring during that hour were tonic when compared with saline controls. The high and low doses of α-MPT, thus, tended to diminish the seizures while the middle dose appeared to augment seizures early in the observation period. Therefore, these results do not unequivocally implicate the modification of catecholamine synthesis in convulsions induced by pinealectomy in PthX rats. Hence, the use of NE receptor agonists and antagonists may more clearly delineate the role of NE in this seizure model.

139.10 A COMMON ANTICONVULSANT DRUG EFFECT ON STANDARDIZED SLEEP EEG POWER SPECTRAL PROFILES IN THE RHESUS MONKEY. M. B. Sterman and R. A. Kovalesky*. V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. of Anatomy, Sch. of Med., UCLA, Los Angeles, CA 90024.

This study explored a new approach to the application of electroencephalogram (EEG) power spectral analysis in the search for an objective, quantitative evaluation of anticonvulsant drug effects on the primate central nervous system. Standardized EEG samples were drawn from the slow wave sleep state. Four rhesus monkeys were adapted to restraining chairs and to prolonged recording in an isolation cubicle. Chronically placed electrodes provided for the monitoring of sleep-waking states and of bipolar frontal, central and occipital EEG traces, bilaterally. Baseline spectral density data were drawn from standard successive and spaced recording nights, and from post-intramuscular saline injection recording nights. These were compared with identical data drawn 1.5-2.0 hours after a single, acute intramuscular administration of six compounds in counterbalanced order, including: diazepam, carbamazepine, dipropylacetic acid, diphenylhydantoin (DPH), phenobarbital and pentobarbital, the latter providing a non-anticonvulsant control. All dose values were in the range of low clinical norms and were confirmed by serum samples drawn immediately after EEG samples. Baseline measures showed stability across all non-drug test conditions, particularly those derived from sensorimotor cortex. Identical post-drug power spectral profiles indicated a unique and significant attenuation of 4-7 Hz activity bilaterally in central cortex for all test compounds except pentobarbital and DPH, when compared to baseline values. Since pentobarbital has no anticonvulsant action and DPH is ineffective in this regard when administered intramuscularly, these data indicate a common action of the remaining anticonvulsant drugs on central cortical EEG substrates. Other neurophysiological findings suggest that this may reflect an altered cortical response to intrinsic somatosensory thalamocortical afferent discharge in sleep, resulting from reduced neuronal excitability.

Supported by the Veterans Administration.

139.11 ELEVATION OF CSF FOLATE LEVELS FOLLOWING GRAND MAL SEIZURES IN UNTREATED PATIENTS. M.J.W. Brennan, J. Costa*, P. Ruff* and P. Sutej*. MRC Brain Metab. Res. Group, Univ. of the Witwatersrand and South African Inst. Med. Res., Johannesburg 2001, S. Africa

Folates exhibit both direct and facilitatory excitatory actions on neurons in the cat cerebral cortex (Davies, J. and Watkins, J.C., Biochem. Pharm., 22: 1667, 1973) and frog spinal cord (Loots, J.H. et al., J. Neural Transm., in press) and have potent convulsant properties in experimental animals. Olney and coworkers have demonstrated that injection of folates into the amygdala (Nature, 292: 165, 1981) or striatum of adult rats is capable of reproducing the sustained limbic seizures and disseminated pattern of brain damage characteristically associated with injection of kainic acid. This pattern conforms to that observed in autopsied brains of human epileptics. Since folates are present in central nerve endings and are released by depolarization in a partially Ca^{2+} dependent manner (Brennan, M.J.W. et al., Neurosci. Lett., 27:347, 1981) they might be involved in the initiation or spread of seizure activity in the brain. We have measured folate levels in the CSF of 8 male patients (28-60 yrs) who presented with a definitive history of grand mal seizures. Two presented in status epilepticus; none were receiving or had received antiepileptic drugs. Lumbar punctures performed 1-12 hours after seizures had ceased showed CSF folate levels (measured by Lactobacillus casei) of 20.5 ± 4.2 ng/ml (mean$\pm$S.E.M.) significantly raised compared to a group of age-matched controls (6.7 ± 1.3) Specimens were microscopically and bacteriologically normal. This finding coupled with the biochemical, anatomical and electrophysiological data already discussed supports the idea that folates released from nerve endings might interact with receptors (Ruck, A. et al., Nature, 287: 852, 1980) to play a role in the spread of seizures in the brain.

139.12 CHINABERRY JUICE: A NATURAL PRODUCT EXTRACT WITH ANTIEPILEPTIC PROPERTIES. B.B. Wannamaker, B.I. Diamond, D. Hammond*, J.R. Koonce*, W. Walter*. Department of Neurology, Medical University of South Carolina, Charleston, South Carolina 29425 and Department of Psychiatry, Medical College of Georgia, Augusta, Georgia 30912.

Chinaberry juice (CJ) was reported by an epileptic patient to effectively control her generalized tonic-clonic seizures and was used safely for longer than 14 years. A very interesting feature of her treatment was that CJ was consumed only once per week. CJ is obtained by boiling the berries of Melia azedarach (China-tree, Pride of India) which is indigenous to the southern United States. The pulp is then strained away and the remaining brew consumed.

CJ was administered to rats intraperitoneally (i.p.) 30 minutes prior to electroshock (140V, 0.05 msec, via corneal electrodes). The latency to seizures was increased and the duration of seizures was decreased. 73% of animals were protected against any seizure activity. CJ blocked i.p. and subcutaneous pentylenetetrazol (60 and 85mg/kg, respectively) induced seizures. The protective effect against pentylenetetrazol was seen also when animals consumed ad lib CJ for 2 days. Further, those animals which were protected by CJ were protected from daily pentylenetetrazol challenge for greater than 48 hours after CJ withdrawal. CJ did not block allylglycine (150mg/kg) induced seizures. Toxicity was seen with large i.p. doses of CJ; an estimate of the i.p. LD_{50} is four times the oral effective dose.

Numerous medicinal uses of extracts of Melia azedarach are purported. The literature reveals that extracted principles have effects against gastric ulcers, malaria and eczema; cardiovascular depressant effects and diuretic activity are described. Recently, experiments demonstrated antimitotic activity. Our patient experience and our preliminary studies indicate that chinaberry juice does contain substance(s) with effective antiepileptic activity which may have unique pharmacologic properties.

140.1 SOMATOSTATIN IN THE NEOSTRIATUM AND SUBSTANTIA NIGRA IN NORMAL HUMAN BRAIN AND IN HUNTINGTON'S DISEASE. P.E. Marshall*, G.D. Burd, and D.M.D. Landis (SPON: K.J. Sweadner). Dept. Neurology, Massachusetts General Hospital, Boston, MA. 02114

Huntington's Disease (HD) is accompanied by degeneration of most of the neurons in the caudate and putamen. In contrast to all other peptides thus far studied, the concentration of somatostatin is remarkably increased in the atrophic neostriatum in HD. We have used immunocytochemical techniques to compare the cellular distribution of somatostatin immunoreactivity in normal and HD brain.

Brain tissue obtained post-mortem from patients with HD and from age-matched patients without neurological abnormality was fixed by immersion in either 10% formalin, a modified Bouin's solution, or paraformaldehyde-lysine-periodate for 1 day to 6 weeks. Somatostatin-like-immunoreactivity (SLI) was demonstrated in 40μM Vibratome sections with unlabeled antibody techniques.

Neuronal perikarya containing SLI in normal neostriatum were 12-16μM in diameter, and gave rise to 2-4 dendritic processes. Stained cells were present throughout the caudate and putamen, sometimes in groups of 2-5. No clear staining was evident in the globus pallidus. In the substantia nigra (SN), varicose processes containing SLI were distributed sparsely among pigmented neuronal perikarya in the pars compacta and among their dendritic processes in the reticulata.

SLI was also present in medium-size neurons in the atrophic putamen and caudate in HD, and their dendritic arborizations appeared similar to those in normal brain. We have not detected a clear difference in the proportion of cells in the neostriatum containing SLI in normal brain as compared to HD brain. However, in HD brain there was a distinct population of varicose fibers containing SLI in the neostriatum. The fibers with SLI in the SN were identical to those in normal brain.

The increased concentration of SLI in the atrophic neostriatum in HD may be accompanied by an increase in the concentration of axon-like varicose fibers containing SLI. (Supported by NS 16367 and 00353)

140.2 EFFECTS OF KAINIC AND IBOTENIC ACID ON THE NEOSTRIATAL SOMATOSTATIN SYSTEM OF THE RAT. G.D. Burd, P.E. Marshall*, M.F. Beal*, D.M.D. Landis and J.B. Martin. Department of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Several neuropathological and neurochemical abnormalities which occur in Huntington's Disease (HD) are also observed in animals that have received striatal injections of kainic acid, including severe loss of small and intermediate size neurons, relative preservation of large neurons, and reductions in levels of several peptides and transmitters while dopamine levels are unaffected. Somatostatin levels are elevated in the neostriatum of HD brains. Immunocytochemical studies of HD brain do not demonstrate a disproportional survival of somatostatin-like-immunoreactive (SLI) neurons, but there does appear to be an increase in the concentration of varicose fibers with SLI. In the present study, we contrast lesions induced by kainic acid (KA) and ibotenic acid (IA) in rats with changes observed in HD.

Neurons containing SLI are present throughout the caudatoputamen, often in groups of 2-5 cells. Cell bodies are spherical (10μm diameter) with radial dendrites or bipolar (16 by 8μm). Often one of the dendrites is thicker than the others and branches into thinner processes; fine axonal processes occasionally originate from large dendrites. Many of the dendrites have varicose contours. At the ultrastructural level, the neurons are characterized by deeply invaginated nuclei and dendrites that appear to lack spines; they can be identified as medium aspiny neurons. A distinct population of fine beaded fibers containing SLI appears to originate from a region ventral to the anterior commissure and to distribute in the ventral and central caudatoputamen. Other fine, SLI fibers are present along the lateral ventricle.

Five to 7 days after injection of KA (5.9nmole) into the neostriatum, there is a well-circumscribed region in which all medium and small neurons degenerate. Four doses of KA (1.2-9.4nmole) yielded a graded response in SLI levels (no change to 57% decrease) as determined by radioimmunoassay (RIA). With IA (126nmole), fewer neurons degenerate and some SLI neurons are still present 6 days after the lesion; RIA data shows a decline of 13% compared to controls. Using a higher dose of IA (190nmole), there is a decline of 43%. We did not detect changes in SLI neurons or processes contralateral to the injections.

There does not appear to be selective survival of neurons containing SLI in rat neostriatum in KA- or IA-induced lesions, and we have not yet identified the appearance in the lesioned areas of varicose fibers like those seen in HD. (Supported by NS 16367 and NS 00353)

140.3 SYNAPTIC ORGANIZATION OF IMMUNOREACTIVE SOMATOSTATIN NEURONS IN THE RAT CAUDATE NUCLEUS. M. DiFiglia and N. Aronin. Dept. of Neurology, Mass. General Hospital, Boston, MA 02114 and Depts. of Medicine and Physiology, Univ. Mass. School of Medicine, Worcester, MA 01605.

Recent studies in our laboratories (DiFiglia and Aronin, J. Neurosci., in press) have used the peroxidase-antiperoxidase immunocytochemical method to examine the neuronal localization of immunoreactive somatostatin (iSS) in the rat caudate nucleus at the light and electron microscopic levels. Light microscopic results showed that iSS was contained within small to medium size neurons (9-20 μm in size). The dendrites of labeled cells were visible for long distances from the soma (up to 120 μm), were of different diameters, and exhibited smooth or irregular contours, varicosities, and fine beaded processes. At the ultrastructural level all iSS neurons had a deeply indented nucleus and a rich cytoplasm including well developed Golgi apparatus and small stacks of rough endoplasmic reticulum. The above features have been found in Golgi and Golgi-EM studies (see DiFiglia et al, J. Neurocytol., 9, 1980) to be associated with medium size aspiny neurons. This cell type has been observed to have a short axon.

In four rats examined for SS immunoreactivity, labeled fibers and terminals also were observed throughout the caudate nucleus. In an attempt to determine the morphologic features and synaptic connections involving these elements, we examined caudate neuropil in serial thin sections. Axonal fibers with SS immunoreactivity were mostly unmyelinated and of small diameter (0.08-0.2 μm). They gave rise to swellings along their course and to terminals which contained many pleomorphic vesicles and few large granular vesicles. Labeled boutons (N=51) were measured at the level of their synaptic contacts and showed a mean length of 0.57 μm (SD±0.22) and a width of 0.36 μm (SD±0.10). Of the total population sampled, 74.5 % (N=38) synapsed with the shafts of small or large dendrites and 23.5 % (N=12) contacted dendritic spines. Some of the spines were also postsynaptic to unlabeled axon terminals. Axosomatic synpases formed by iSS boutons were observed infrequently (2%; N=1). Serial sections also showed that some labeled terminals contacted more than one postsynaptic element. Most of the synaptic membrane densities appeared to be symmetric and had a mean overall length of 0.25 μm (SD±.09).

Taken together these results suggest that many of the iSS axons present in the rat caudate nucleus arise from medium size aspiny neurons and that they form intrinsic synaptic connections at least in part with caudate spiny neurons.

The somatostatin antiserum was generously provided by Drs. G. Nilaver and E. Lichtenstein. This research was supported by NIH grants NS 16367 (MD) and AM 01126-01 (NA).

140.4 RAPID ONSET OF SENSORIMOTOR DISORDER COINCIDES WITH ALTERATIONS IN NEOSTRIATAL DOPAMINE AND DOPAC LEVELS AFTER 6-HYDROXYDOPAMINE MICROINJECTION. C. A. Altar and J. F. Marshall. Dept. of Psychobiology, University of California, Irvine CA 92717.

The unilateral injection of 6-hydroxydopamine (6-OHDA) into the mesotelencephalic dopamine projection of rats results in a neglect of stimuli applied to the contralateral body surface (Marshall, J. F., Brain Res., 177:311, 1979). 6-OHDA neurotoxicity occurs within minutes *in vitro* (Heikkila, R. and Cohen, G., Mol. Pharm., 8: 241, 1972) and, if 6-OHDA inhibits impulse flow and dopamine release in nigrostriatal neurons, as do electrothermic lesions of this pathway (Walters, J.P. *et al*, J. Pharm. Exp. Ther., 186:630, 1973), sensory neglect and increases in neostriatal dopamine should appear almost immediately after 6-OHDA microinjection.

Freely moving male Fisher 344 rats received 8 μg injections of 6-OHDA via previously implanted cannulas whose tips terminated in the left ventral tegmental area. Rats were tested for their ability to orient to a 4-g force applied by a von Frey hair to 11 left or right body surfaces 30 min before and 10, 30, 50, 70, 90, and 110 min and 3 and 24 hr post-injection or were killed at 0, 10, 50, or 110 min post-injection. Dopamine, DOPAC, and HVA concentrations in the left and right neostriata of rats in the latter group were measured by HPLC with electrochemical detection. Somatosensory localization was measured in the former group as the percent of the total orientation score of the right body side compared to that of the left.

Somatosensory localization contralateral to the 6-OHDA injection declined to 70% at 10 min, 10% at 30 min, and remained at only 5% of ipsilateral localization scores at all subsequent times. The sensory neglect developed in a caudal to rostral manner.

Dopamine, DOPAC, or HVA concentrations were equal in the left and right striata at 0 and 10 min. Dopamine and DOPAC were elevated in the left striata compared to the right by 50% or 80% at 50 or 110 min, respectively, while HVA was increased only at 110 min post-injection. At no time did dopamine, DOPAC, or HVA levels in the right striata differ from control (0 min) values.

The rapid onset of both sensory neglect and increased dopamine content of the left striata is consistent with previous reports of decreased dopamine release from, and subsequent accumulation within, nigrostriatal nerve terminals after inhibition of impulse flow. 80% increases in neostriatal DOPAC have also been observed (di Giulio, A.M. *et al*, Eur. J. Pharm., 52:201, 1978) 60 min after γ-butyrolactone injection. Together, these results suggest that DOPAC may be produced intraneuronally *without* prior dopamine release and recapture by nigrostriatal terminals if impulse flow in this pathway has been blocked.

140.5 ASYMMETRIC DOPAMINE AND SEROTONIN METABOLISM IN THE NUCLEUS ACCUMBENS AND SUBSTANTIA NIGRA OF THE TRAINED CIRCLING RAT. Bryan K. Yamamoto* and Curt R. Freed (SPON: D.G. Whitlock). Depts. Med. and Pharm., U. Colo. Sch. Med., Denver, CO 80262

We have previously shown that the trained circling rat has increased dopamine metabolism in the caudate contralateral to the circling direction. Using this model we have investigated whether other brain areas known to be integrated with the caudate in the regulation of movement also show asymmetric neurotransmitter metabolism during circling. Both dopamine and serotonin (5HT) metabolism were studied in substantia nigra (SN) and nucleus accumbens (NA). Male Sprague Dawley rats were water deprived for 23 hrs and randomly chosen to be trained to turn either left or right for sucrose/water reward. After a one week training period, regional neurotransmitter activity was studied by sacrificing animals before, during, and after circling. SN and NA were bilaterally dissected and dopamine, 5HT and their metabolites were assayed by HPLC. Prior to circling, dopamine, DOPAC, 5HT, and 5HIAA concentrations were the same on both sides in all experiments. Results at all time points were calculated as the ratio of concentrations on the contralateral relative to the ipsilateral side. Elevated ratios indicate enhanced metabolism on the contralateral side. * Indicates significantly different from baseline ($p<0.05$). Values are Mean ± SE, n=6 at each time point.

N. ACC. CONTRALATERAL/IPSILATERAL CONCENTRATIONS RATIOS

	Baseline	Peak Circling	End Circling	2 hr Post-circling
Dopamine	1.01±.13	1.44±.05*	1.22±.11	1.11±.11
DOPAC	0.97±.13	1.90±.43*	1.46±.16*	1.51±.15*
5HT	0.86±.09	1.27±.33	1.34±.10	1.36±.22
5HIAA	1.04±.13	1.40±.28	1.26±.07	1.14±.19

SUB. NIGRA CONTRALATERAL/IPSILATERAL CONCENTRATION RATIOS

	Baseline	Peak Circling	End Circling	2 hr Post-circling
Dopamine	1.14±.23	0.94±.18	1.03±.06	1.40±.33
DOPAC	1.09±.15	0.73±.06	1.11±.13	1.11±.15
5HT	1.04±.08	1.23±.04*	1.37±.12*	1.47±.24*
5HIAA	1.04±.06	1.27±.09*	1.30±.08*	1.33±.17*

These data provide evidence for asymmetrically increased dopamine metabolism in the contralateral nucleus accumbens of the intact and undrugged rat without significant changes in 5HT or 5HIAA. Conversely, the substantia nigra contralateral to the trained circling direction showed enhanced 5HT metabolism but no changes in dopamine or DOPAC.

140.6 ASYMMETRIC CAUDATE TYROSINE HYDROXYLASE ACTIVITY IN THE TRAINED CIRCLING RAT. M.E. Morgan*, B. K. Yamamoto* and C. R. Freed Depts. Med. and Pharmacol., U. Colo. Sch Med. Denver, CO 80262.

We have previously shown enhanced accumulation, release, and catabolism of dopamine (DA) in rats trained to circle. The metabolism was increased in caudate contralateral to the turning direction. To further elucidate the mechanism of these changes, caudate tyrosine hydroxylase (TH) was studied. Male Sprague Dawley rats, 200-300g, were water deprived 23 hr and trained to circle 360° in a left or right-handed direction for a 10% sucrose reinforcement for 7 daily sessions. During the 8th session of circling behavior, animals were sacrificed at varying times, left and right caudate were removed and stored at -70° C. Each caudate was assayed within 24 hr for TH activity, DA and DOPAC concentrations using the methods of Nagatsu et. al. (Anal. Biochem. 9: 122-126, 1964) and Freed and Asmus (J. Neurochem. 32: 163-168, 1979), respectively. Enzyme activity (nmoles tyrosine oxidized/g/hr) was measured as a function of 6-methyltetrahydropterin (6-MPH4) concentrations from 0.04 to 1.0 mM. Lineweaver-Burk plots were used to analyze the kinetic parameters for TH. Although curvilinear relationships were seen with this technique, data were fit by linear regression analysis. Results are expressed as the ratio of enzyme activity or catechol concentration in caudate contralateral to the circling direction compared to ipsilateral caudate.

	Time (min) 0	20	70	280
Turns/min	0	11.1±.6	5.4±.4	1.2±.1
	Contralateral/Ipsilateral TH Ratio			
Km	1.09±.23	1.56±.29	1.33±.28	1.05±.11
Vmax	0.91±.15	2.02±.29*	1.32±.33	1.02±.09
	Contralateral/Ipsilateral Catechol Ratio			
DA	0.98±.03	1.65±.19*	1.18±.13	1.01±.09
DOPAC	0.91±.08	1.70±.20*	1.41±.22	1.04±.08

Values are Mean±SE, n=5; *Significantly different from 0 and 280 min, $p<0.05$.

The apparent Km for 6-MPH4 was not significantly changed with circling. However, the apparent Vmax was relatively increased in contralateral caudate when circling was most intense (20 min). DA and DOPAC contralateral concentration ratios were also significantly increased at this time point. These data are the first to show rapid asymmetric enhancement of TH activity during a specific motor task.

140.7 ELECTRICAL STIMULATION OF VARIOUS THALAMIC NUCLEI DIFFERENTIALLY AFFECTS THE RELEASE OF DOPAMINE IN THE TWO CAUDATE NUCLEI AND THE TWO SUBSTANTIAE NIGRAE, A. Cheramy*, M.F. Chesselet*, R. Romo*, V. Leviel* and J. Glowinski*.(SPON: S. Chorover), Groupe NB, College de France, Paris 75231, France.

The release of tritiated dopamine (^{3}H.DA) continuously synthetized from ^{3}H-tyrosine was measured in halothane anaesthetized cats by means of push-pull canulae implanted in both caudate nuclei (CN) and substantiae nigrae (SN), during and after unilateral electrical stimulations of various thalamic nuclei: 100uA, 1-2v, trains(100ms of 0.5msec shocks at 300Hz) delivered for 10min at 0.25 Hz. Stimulation of the ventralis lateralis and ventralis medialis nuclei (VL/VM) induced prolonged asymmetric changes of DA release in CN and SN (increase in the ipsilateral CN, decrease in contralateral CN, opposite responses in the SN) while the stimulation of the parafascicular(Pf) and adjacent centrum medianum (CM) nuclei induced a bilateral symmetric inhibition of DA release in both CN and both SN. More anterior stimulations of the CM induced an increase in DA release in the contralateral nigra. Stimulations of the centralis lateralis and paralamellar part of the medio-dorsal nucleus also induced only contralateral effects: inhibition of ^{3}H.DA release in the CN and SN. Stimulations of median nuclei had no effects. Thus the changes in DA release observed were highly dependent upon the exact site of stimulation and these results not only confirm the role of thalamic circuits in the control of DA transmission in CN and SN[1] but also suggest that different nuclei are involved in different patterns of changes in DA release such as those induced by different pharmacological manipulations of the SN or stimulation of other systems: both motor (VL/VM) and some non-specific sensory (CM/Pf) thalamic nuclei (or fibers passing through them) seem to be involved in the bilateral control of the two nigro-striatal dopaminergic pathways but while the stimulation of motor nuclei reproduced the asymmetric changes observed with stimulation of sensory afferences,[2] dentate nucleus of the cerebellum or changes in DA dendritic release,[3] the stimulation of the CM/Pf complex induced symmetric modifications as observed when GABA-ergic transmission is modified in one SN.[4]

40.8 THE GABAERGIC PALLIDO-NIGRAL COMPLEX IN THE RAT DEMONSTRATED BY GLUTAMIC ACID DECARBOXYLASE IMMUNOCYTOCHEMISTRY. W.H. Oertel[+], E. Mugnaini[°], C. Nitsch*[¢], D.E. Schmechel*[#] and I.J. Kopin[@]. [+]Dept. Neurology, Technical Univ., Muenchen, FRG; [°]Dept. Biobehav. Sci., Univ. of Conn., Storrs, CT 06268 USA; [¢]Max-Planck Inst., Frankfurt, FRG; [#]Div. Neurology, Duke Univ., Durham, NC 27710 USA; and [@]Lab. Clin. Sci., NIMH, Bethesda, MD 20205 USA.

The globus pallidus (GP), the entopeduncular nucleus (EPN, the rodent homologue of the primate GP pars medialis), the substantia nigra pars reticulata (SNR), and the ventral pallidum are viewed as similar histologically, histochemically, and with respect to afferent innervation patterns. These nuclei are subsumed under the term "tier III" by H.J.W. Nauta (1979). The cytological similarities would assume larger significance if the neurons of these nuclei shared chemical properties. GABA has been proposed as transmitter of pallidofugal and nigrofugal projections (Penney & Young, 1981; Starr & Kilpatrick, 1981). We therefore investigated the localization of GABAergic neurons in rat GP, EPN and SNR by immunocytochemical methods using an antiserum to glutamic acid decarboxylase (GAD), the biosynthetic enzyme for GABA.

Normal rats and rats that had received a unilateral stereotaxic injection of colchicine (20 µg) near the area of interest 36 hr prior to sacrifice were perfused with buffered 4% formaldehyde/0.4% glutaraldehyde. Floating vibratome sections (25 µm) were processed with the PAP procedure for light and electron microscopy.

By light microscopic criteria near the site of colchicine injection, practically all neurons in GP and EPN and the large majority of neurons in SNR were GAD-immunoreactive. By contrast, only a few small neurons were GAD-positive in SN pars compacta. In GP, EPN and SNR, a large number of GAD-positive axon terminals were observed. These boutons contained pleomorphic synaptic vesicles and commonly formed symmetric synaptic junctions with dendrites and cell bodies, as already shown by Ribak et al. (1976, 1979). Postsynaptic elements were also GAD-immunoreactive in GP and EPN. In SNR numerous GAD-positive and fewer GAD-negative postsynaptic dendrites and cell bodies were observed.

We confirm the predominant GABAergic nature of boutons in GP, EPN and SNR. Furthermore, the data indicate that GABAergic neurons are the predominant cell type in the rat pallido-nigral complex and support the notion that "tier III" nuclei are inhibitory.

140.9 PROJECTION NEURONS OF THE PARS RETICULATA OF THE SUBSTANTIA NIGRA IN MONKEY AND CAT: MULTIPLE RETROGRADE CELL-LABELING WITH FLUORESCENT DYES. Robert M. Beckstead, Dept. of Anatomy, Univ. of Virginia Schl. of Med., Charlottesville, VA 22908

The pars reticulata of the substantia nigra (SNR) is increasingly appreciated as a major outroad for the activity of the corpus striatum. The three major targets of SNR projections are the thalamus (VA-VL complex, MD and intralaminar nuclei), the intermediate gray layer of the superior colliculus, and the caudal midbrain reticular formation including the pedunculopontine nucleus. Our lab has mapped the intranigral distribution of SNR cells that project to each of these structures in monkeys using the HRP method (Beckstead & Frankfurter, Neuroscience, 1982). In order to gain some impressions about the degree to which individual SNR cells send collateral branches to more than one of the three major targets, we have injected two or all three of them with fluorescent dyes (Evans Blue, Propidium Iodide, Granular Blue, Fast Blue, Nuclear Yellow) in six squirrel monkeys and eight cats. The best results were obtained in the monkey brain with injections of Evans Blue in the thalamus, Granular Blue in the colliculus and Nuclear Yellow in the reticular formation. The distributions of neurons in SNR that contained only one dye are consistent with our earlier HRP data such that nigrothalamic and nigroreticular cells are numerous and widely scattered throughout all zones of SNR. Nigrotectal cells, on the other hand, are restricted to rostral and lateral zones of SNR. Double labeling of cells indicates that many of the more caudally located nigroreticular cells also send a collateral to the thalamus as do a smaller number of very rostrally located nigrotectal cells. The highest frequency of double-labeling occurs in laterally located cells that project to both the colliculus and caudal midbrain reticular formation. Less than ten cells in any given case could be confidently identified as containing all three dyes and these cells are all located laterally in the rostral half of SNR. In the cat, thalamic injection of Granular Blue and tectal injection of Nuclear Yellow indicate that most nigrotectal cells are located in the middle of the mediolateral expanse of SNR in its rostral one-half or so. Nigrothalamic cells flank the nigrotectals both medially and laterally. Where these groups border one another, several cells contain both dyes indicating that about 10 to 20% of SNR neurons in the cat send collaterals to both the thalamus and colliculus. In conclusion, our results indicate that several SNR projection neurons send collateral branches to two or three of the major targets, but the majority of SNR cells appear to project to only the thalamus, colliculus or reticular formation.

140.10 NIGRAL SYNAPTIC ACTIONS ON TECTAL NEURONS. AN INTRACELLULAR HRP STUDY. A.B. Karabelas* and A.K. Moschovakis* (SPON. A.Paldino). Dept. Neuroscience, Albert Einstein Coll.Med., Bx., NY 10461

Intracellular recording was employed to determine the pattern of evoked PSPs in tectal neurons during nigral stimulation in barbiturate anesthetized intact cats. Corticotectal fibers traversing the substantia nigra are activated during nigral stimulation. Therefore, synaptic effects of nigral stimulation were compared to effects of pericruciate cortex and cerebral peduncle stimulation. Postsynaptic tectal neurons were intracellularly injected with HRP.

Nigral stimulation elicited monosynaptic IPSPs in tectal neurons with latencies of 1.5-1.83msec (mean latency: 1.65msec). Cerebral peduncle and cortical stimulation had no synaptic effect on these neurons. Most of the HRP labeled tectal neurons were located in the stratum griseum intermedium (SGI) and fewer in the stratum griseum profundum (SGP). They were small to medium size(300-1000μ^2) neurons with various soma shapes (fusiform, granular, conical, ovoid or stellate) and isodendritic or leptodendritic branching pattern. Their axons (1-2.5μ in diameter) consistently emitted collaterals. Intrinsic varicose collaterals were confined in the deeper tectal layers. Extrinsic collaterals were observed to terminate in the central gray and the midbrain reticular formation (MRF). The pattern of traced axonal trajectories suggests that tectal neurons receiving monosynaptic inhibitory nigral input give rise to either crossed or uncrossed descending projections. Moreover, their axon may branch to the opposite superior colliculus.

Nigral and cerebral peduncle stimulation evoked monosynaptic EPSPs in another group of tectal neurons with latencies of 0.65-1.65msec (mean latency: 1.04msec) and 0.8-1.35msec (mean latency: 1.16msec) respectively. Cortical stimulation, when effective, also elicited EPSPs. These neurons were located in both the SGI and SGP. They were large (950-3500μ^2) usually triangular cells with spherical or ovoidal dendritic fields. Their axons (4-7μ in diameter) followed crossed descending trajectories. Only one axon emitted a bifurcating collateral terminating in the MRF and the interstitial n. of Cajal.

IPSPs preceded by a brief EPSP were recorded from a third group of tectal neurons during nigral stimulation. Latencies of these EPSPs were similar to the latencies of pure evoked EPSPs. These neurons were located predominantly in the SGI. They were medium size to large (600-1700μ^2)cells with multipolar somas and radiating or occasionally vertical dendritic fields. Their axons (2-4μ in diameter) followed either crossed or uncrossed descending trajectories and rarely emitted intrinsic and/or extrinsic collaterals.

The morphophysiological data obtained in this study establish the existence of inhibitory monosynaptic nigral input to tectal projection neurons. It is also suggested that excitatory potentials are due to concomitant activation of corticotectal fibers. (Supported by NIH NS-07512).

140.11 FUNCTIONAL REGULATION OF GABA TURNOVER IN DEEP AND SUPERFICIAL LAYERS OF SUPERIOR COLLICULUS: INFLUENCE OF DOPAMINERGIC TRANSMISSION. M. R. Melis* and K. Gale. Dept. of Pharmacology, Georgetown Univ. Sch. of Med. and Dent., Washington, DC 20007.

The nigrotectal pathway represents an important descending outflow from the basal ganglia. Recent evidence has indicated that this pathway includes an inhibitory GABAergic component, originating in substantia nigra pars reticulata and terminating in the deep layers of superior colliculus (SC). In the present studies we evaluated the turnover rate of GABA in the deep and superficial layers of the SC and determined whether this index of GABAergic function was sensitive to manipulations of dopaminergic (DA) transmission. To estimate GABA turnover rates, we measured the initial rate of accumulation of GABA (over 90 min) following local microinjection of the irreversible inhibitor of GABA transaminase, gamma-vinyl-GABA (Casu and Gale, Life Sci 29:681, 1981), applied unilaterally to the deep and superficial layers of SC via indwelling cannulae. The rate of accumulation of GABA was 1.0 and 1.2 nmol/mg prot/min, respectively, for the deep and superficial layers of SC. Stimulation of DA transmission by treatment with cocaine (30mg/kg ip at 30min intervals), amphetamine (10mg/kg sc) or apomorphine (3mg/kg sc at 30min intervals) significantly decreased the rate of accumulation of GABA in the SC; this effect was consistently more pronounced in the deep layers than in the superficial region:

Rate of Accumulation of GABA: Percent of Control

	Saline	Apomorphine	Amphetamine	Cocaine
Superficial SC	100 ± 6	80 ± 5	85 ± 4	85 ± 4
Deep SC	100 ± 6	70 ± 6	60 ± 5	55 ± 4

The dopamine-receptor antagonist, haloperidol (2mg/kg ip), did not affect the rate of accumulation of GABA in SC when given alone, but prevented the depression in GABA turnover in SC produced by the DA agonists. This suggests that tonic DA transmission is not necessary for the maintenance of the basal turnover rate of GABA in SC, but that augmentation of DA transmission can suppress the utilization of GABA in this nucleus.

Studies performed in rats in which one eye was removed indicated that the influence of apomorphine on GABA turnover in the superficial layer of SC may be dependent on activity in visual pathways. In contrast, it appears that the influence of DA agonists on GABA turnover in the deep layers of SC is dependent upon neural connections between the striatum and tectum via substantia nigra. We propose that stimulation of DA receptors in striatum causes a disfacilitation of nigrotectal GABAergic projections which in turn produces a net disinhibition of neurons in SC.

140.12 FUNCTIONAL REGULATION OF GABA TURNOVER IN THE MESENCEPHALIC RETICULAR FORMATION: INFLUENCE OF DOPAMINERGIC TRANSMISSION. Judith A. Childs* and Karen Gale (SPON: J. Neale). Dept. of Pharmacology, Georgetown Univ. Sch. of Med. & Dent., Washington, D.C.

The nigrotegmental pathway is one of four major efferent pathways from substantia nigra (SN). Our previous evidence (Soc.Neurosci.Abstr.,64.21(1981)) suggests that this projection is, at least in part, GABAergic. The purpose of the present studies was to determine whether dopaminergic drugs influence the turnover rate of GABA in the terminal region of this projection. The rate of accumulation of GABA was measured in rats following microinjection of the GABA transaminase inhibitor, gamma vinyl-GABA (GVG, 20 ug/ul), placed unilaterally into regions of reticular formation (RF) surrounding and including the pedunculopontine nucleus (PPN). Apomorphine (3 mg/kg sc), a dopamine agonist, was injected at 1/2-hour intervals. The rate of accumulation of GABA at timepoints during the first 90 min following GVG administration was used as an index of GABA turnover. Under these conditions, apomorphine treatment caused an enhanced rate of GABA turnover in the areas containing nigrotegmental terminations. These results are in direct contrast to those obtained in the terminal regions of the nigrotectal pathways (Melis and Gale, this volume). Moreover, in apomorphine-treated rats, GABA agonists placed in the vicinity of the PPN caused contraversive circling, in contrast to the ipsiversive circling observed with placement of GABA agonists into the tectal region. Our results suggest that the descending outflows from the basal ganglia may be differentially influenced by dopamine receptor stimulation. A possible role of striatonigral projections in the mediation of these effects is being investigated.

Supported by HHS grants DA-02206 and MH-32359.

141.1 MORPHINE SELECTIVELY REDUCES C FIBER PAIN IN HUMANS. B.Y. Cooper, C.J. Vierck, Jr. and O. Franzen*. Dept of Neuroscience, College of Medicine University of Florida, Gainesville, FL, 32610.

In previous experiments with monkeys, we have confirmed the difficulties that have been encountered in rodents in achieving the expected hypalgesic effects of morphine at low doses. While reflexive measures give approximate estimates of pain threshold, they do not reliably reflect the intensity of suprathreshold stimulation and are relatively insensitive to morphine. The frequency of intertrial behaviors reflects highly individualistic response patterns that are not specific to pain paradigms but are highly sensitive to morphine. Operant escape latencies are highly correlated with pain in most animals but are susceptible also to the non-specific effects of morphine. Of the pain correlates we have examined, only operant response force accurately quantifies pain, is sensitive to morphine, and is resistant to non-specific effects (Cooper and Vierck, Soc. Neurosc. Abst., 6: 430, 1980; Vierck et al., Progress in Psychobiology and Physiological Psychology, 1982). Yet the doses necessary to produce hypalgesia in monkeys by this measure (1-2 mg/kg; M. speciosa) are 10 to 20 times higher than those used therapeutically in humans. While the differences may be due to disimilar opiate receptor distribuiton or concentration in the two species, the differences are likely to be due to other factors as well.

Morphine preferentially reduces C fiber input to spinal cord cells of the rat at relatively low doses (.5 mg/kg; Jurna and Heinz, Brain Res., 171: 573, 1979). Thus, it is possible that the reduction of pain originating in C fibers is the most important clinical effect of systemic morphine. In the present study, human subjects were trained to attend selectively to either the fast (A-delta) or slow (C fiber) pain sensations following a strong electrical stimulus. A powerful reduction of C fiber pain by morphine was found. But there was no evidence of reductions in A-delta pain. It is likely that A-delta pain is reduced only at higher systemic doses, such as those commonly used in laboratory animal experiments. Experiments using stimuli which elicit primarily A-delta pain may not yield results that are relevant to the common clinical use of morphine -- that is, administration of a low dose by a systemic route. Reduction of A-delta pain could result from epidural or intraparenchymal administration of opiates, where the local concentrations of morphine are much higher. The study of mechanisms of systemic morphine analgesia should proceed with the development of humane models of C fiber pain in animals. (This research sponsored by PHS grant NS 07261.)

141.2 PITUITARY-ADRENAL AXIS AFFECTS SENSITIVITY TO MORPHINE ANALGESIA. S.J. Slater*, J.W. Lewis, G.W. Terman*, and J.C. Liebeskind, Dept. of Psychology, University of California, Los Angeles, CA. 90024. (SPON: A.N. Taylor)

Repeated exposure to painful/stressful stimulation causes a dramatic sensitization to morphine analgesia. This enhanced responsiveness can be produced by a variety of stressors (e.g., hotplate, footshock), is critically dependent on the number and intensity of stress exposures, is specific to the environment in which the stimulation occurred, persists several days following the last stress experience, and is dependent upon changes within the brain (Sherman et al., 1981; Lewis et al., 1982). Since pituitary and adrenal hormones (e.g., ACTH, corticosterone) are thought to influence morphine analgesia and are released by stress, the following investigations were undertaken to describe the role of this endocrine system in stress-induced potentiation of morphine analgesia.

Groups of male rats were brought into the testing environment daily for 7 days where they received either footshock stress (2.5 mA, 3 min), an injection of the synthethic glucocorticoid dexamethasone (400 µg/kg, s.c.), or no stress and served as controls. On Day 8, animals were returned to the test room and their analgesic response to morphine (5 mg/kg, s.c.) was assessed using the hot-plate test. In other rats receiving either 7 days of footshock or no stress, blood samples were collected in the test room on Day 8 and serum corticosterone levels were determined by RIA.

Animals receiving either footshock or dexamethasone demonstrated enhanced morphine analgesia ($p < .01$, compared to controls). Basal pain response latencies were also increased in these rats ($p < .05$) suggesting the development of a conditioned analgesic response. Finally, compared to controls, rats exposed to chronic footshock displayed significantly elevated serum corticosterone levels on Day 8 ($p < .05$).

Thus, stress-induced potentiation of morphine analgesia appears to be associated with alterations in the pituitary-adrenocortical axis. Those animals most sensitive to morphine had higher serum corticosterone and, presumably higher ACTH levels; and the enhancing effects of chronic stress were mimicked by chronic steroid administration. These data suggest that repeated exposure to painful/stressful stimuli may come to elicit a conditioned release of pituitary-adrenal hormones that serve to facilitate morphine analgesia. At this time, however, we are unable to discern which hormone, ACTH or corticosterone, is responsible for this effect. (Supported by NIH grant NS07628.)

141.3 CONTINUOUS INTRATHECAL INFUSION OF MORPHINE OR ARTIFICIAL CSF ON THE DORSUM OF THE SPINAL CORD VIA AN OSMOTIC MINIPUMP REDUCES AUTOTOMY IN NERVE SECTIONED RATS. Z. Wiesenfeld-Hallin, Department of Clinical Neurophysiology, Huddinge University Hospital, S-141 86 Huddinge, Sweden.

Rats often respond to limb nerve section by performing autotomy in the deafferented region. This behavior may be an experimental model to study certain aspects of chronically painful conditions that can arise after peripheral nerve lesion or amputation in man. There is evidence that abnormal properties of the nerve sprouts in the neuroma that is formed subsequent to nerve section underly autotomy behavior. Factors such as stress and genetic variations also have important effects on autotomy (Wiesenfeld and Hallin, Physiol. Beh., 1981, 27).

In this study the effects of intrathecally administered analgesics on autotomy were examined. An intrathecal catheter extending to the lumbar enlargement (LE) was inserted through the cisterna magna (Yaksh and Rudy, Physiol. Beh., 1976, 17) in male Sprague-Dawley rats. After one week of recovery the sciatic nerve was sectioned and ligated unilaterally. An osmotic minipump (Alza, model 2002) delivering a nominal dose of 240 µg/day morphine HCl or an equivalent volume (12 µl/day) of artificial CSF was connected to the catheter. Autotomy was scored daily for the 14 days that the pump was delivering the solution. After completion of the experiments the rats were perfused and the spinal cord was examined to determine the location of the catheter tip.

Autotomy was significantly reduced during the 14 day period of infusion of morphine HCl and artificial CSF in rats in which the catheter tip was located on the dorsum of the LE in comparison to rats where the catheter tip was under the dorsal roots or rostral or caudal to the LE. Autotomy in rats infused intrathecally where the catheter tip was properly localized was also significantly reduced in comparison to rats that underwent sciatic nerve section but did not receive drugs intrathecally.

The observed reduction in autotomy in rats infused with analgesic substances on the LE further enhances the relevance of this animal model for experimental studies of chronic pain. The results support previous observations (Wiesenfeld and Gustafsson, Brain Res., in press) that both morphine HCl and artificial CSF have analgesic effects by this method of administration. The catheter tip must be accurately positioned to obtain analgesia because the small volumes infused are highly localized. Continuous intrathecal infusion of drugs may be a useful technique in experimental studies of chronic pain conditions.

141.4 DEPLETION OF BRAIN SEROTONIN DOES NOT AFFECT AUTOANALGESIA. W. T. Chance and K. Minnema*. Department of Surgery, University of Cincinnati Medical Center, Cincinnati, OH 45267.

Recent reports have suggested that stress-induced analgesia may be mediated by at least two separate neurochemical systems. Thus, analgesia induced by prolonged stress appears to be opioid in nature, while the analgesic response to acute stress is not attenuated by classical opiate antagonists. We have previously reported that analgesia induced by acute stress may be classically conditioned to appropriate environmental stimuli. This conditioned analgesia is also resistant to blockade by naloxone and naltrexone, suggesting nonopioid mediation. Since much of the pain and analgesia literature has focused upon CNS serotonergic (5-HT) systems, we investigated the effects of depletion of brain 5-HT with para-chloroamphetamine (PCA) upon analgesia elicited by footshock and classical conditioning procedures. Analgesia was assessed using a radiant-heat tail-flick procedure, employing basal responses of approximately 3 sec and a cut-off criterion of 8 sec. In the first experiment PCA (10 mg/kg) was administered (ip) to 14 female S-D rats, while 15 additional rats were injected with saline. One week later, footshock (1 ma, 15 sec) was administered to half of each group of rats, while the remaining rats received control manipulations. Tail-flick latencies were again determined immediately after the footshock. Across the next 7 days tail-flick latencies continued to be assessed in PCA and control rats prior to the administration of footshock to determine classically conditioned analgesia. All rats were immediately sacrificed following the last tail-flick test, with their brains being removed and frozen in liquid N_2. In the second experiment analgesic testing was begun on male, S-D rats 10 days after the administration of PCA (10 mg/kg, ip, n = 21) or saline (n = 18), with all rats being sacrificed 1 week thereafter. The brains of these rats were separated into forebrain and brainstem sections by a vertical cut at the level of the superior colliculus. In these experiments CNS monoamine levels were determined primarily by HPLC procedures following homogenization in formic acid-acetone. Although PCA reduced whole brain 5-HT by 60% and 5-hydroxyindoleacetic acid (5-HIAA) by 68%, no significant effects were observed on analgesia elicited by footshock or within the classical conditioning paradigm. Whole brain levels of norepinephrine (NE) or dopamine (DA) were not affected by either PCA or the conditioning treatments. In the second experiment PCA again had no effect on either analgesic response, while brain stem 5-HT and 5-HIAA were reduced by 50%. No effects of any treatments were observed on brain stem catecholamines or metabolites (homovanillic acid, dihydroxyphenylacetic acid, 3-methoxytyramine). Thus, these data de-emphasize a role of CNS 5-HT in the mediation of autoanalgesic responses.

141.5 HYPERALGESIA AND ANALGESIA INDUCED BY THE SAME STRESSOR. Dennis D. Kelly, Pierre A. Lemaire* and Donald S. Leitner
New York State Psychiatric Institute and Dept. of Psychiatry, Columbia University, New York, NY 10032

When an animal's responsivity to pain is tested following exposure to a stressor, the method selected to measure pain is a major determinant of the results obtained and the conclusions drawn. For example, the time course of analgesia induced by a brief, forced cold-water swim ranges from minutes to hours depending upon whether pain thresholds are measured by operant liminal escape, reflex flinch-jump (FJ) or reflex tail-flick (TF) procedures. In the present pair of experiments, we observed that a single stressor, inescapable footshock, produced both analgesia and hyperalgesia in the same subject depending upon how pain thresholds were measured. Moreover, both effects were enhanced by hypophysectomy.

In Exp I five male albino rats were exposed to inescapable footshock stress (IFS) consisting of 300-msec shocks of 3.5 ma repeated at 2-sec intervals for 5 mins, the same parameters reported by Millan et al (Pain, 1980, 8, 343-353) to induce tail-flick analgesia. Each rat was exposed four times to IFS and combined FJ/TF testing occurred either 0, 15, 30 or 60 mins later. Three no-stress baseline FJ/TF test days separated the IFS sessions. The sequence of exposure to the IFS conditions was counterbalanced across rats in an incomplete Latin Square design. FJ thresholds were decreased for 30 mins following IFS, while TF thresholds were increased. These paired results demonstrate that the method employed to assess pain thresholds can determine the direction of threshold shifts induced by stress.

In Exp II 14 male hypophysectomized (HYPOX) and 14 sham operated adult rats were exposed to IFS followed by FJ/TF testing 10 mins later. The animals were stressed twice during the 2nd postoperative week and twice again in the 14th week following regeneration of the neurohypophysis (and recovery of water balance). Following sacrifice in the 15th week the adrenals and testes of all rats were dissected and weighed, and any tissue remnants in the sella turcica were fixed and sectioned to determine pituitary status. The results were as follows: Normal FJ and TF thresholds did not differ between HYPOX and sham rats in the 2nd week, nor in the 14th week when adjusted for divergence in body weight. However, when stressed, HYPOX rats displayed both potentiated TF analgesia and potentiated FJ hyperalgesia. The greater responsivity to FJ shocks would suggest that the potentiation of TF analgesia induced by IFS in HYPOX rats was not due to a motor deficit.

141.6 REDUCTION OF MORPHINE ANALGESIA AND BASAL NOCICEPTION FOLLOWING CENTRAL PARACHLOROPHENYLALANINE TREATMENT. J.H. Kordower, R.J. Bodnar, A. Reches, D.A. Simone*, M.M. Wallace and S. Fahn. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367 and Dept. of Neurology, Columbia Univ. Col. of Physicians and Surgeons, New York, NY 10032.

Systemic administration of the tryptophan hydroxylase inhibitor, parachlorophenylalanine (PCPA) increases an animal's sensitivity to noxious electric shock and decreases the analgesic effects of morphine. The time course of such effects appears to parallel PCPA-induced serotonin depletion. However, this route of administration also elicits other non-specific peripheral effects including lethargy, illness and neglect of the ventral surface of the body. To determine whether PCPA-induced alterations in pain thresholds were due to central, rather than peripheral, mechanisms, four groups of eight rats each received an intracerebroventricular injection of a 1 mg dose of PCPA, a 3 mg dose of PCPA, normal saline or an equimolar hypertonic saline solution respectively. Flinch-jump thresholds were determined prior to injection, 0.5 h following injection and then at daily intervals for 1 week following injection. While animals treated with either of the vehicle solutions or the lower PCPA dose failed to display shock threshold changes, the 3 mg PCPA dose significantly decreased jump thresholds at 0.5, 48 and 120 h following injection.

To assess whether central PCPA administration reduced morphine analgesia as a function of pretreatment interval, groups of eight rats each received an intracerebroventricular injection of a 3 mg dose of PCPA at either 0.5, 24, 48 or 72 h prior to administration of a 5 mg/kg dose of morphine. A fifth group received a normal saline injection 0.5 h prior to the opiate. PCPA effects upon morphine analgesia varied as a function of pretreatment interval in that morphine analgesia was unaffected 0.5 h after PCPA, diminished after 24 h elapsed, eliminated at 48 h after PCPA and recovered at 72 h after PCPA. Vehicle-treated animals displayed normal morphine analgesia. These data will be discussed in terms of the relative effectiveness of central PCPA injections to deplete brain serotonin and norepinephrine as a function of pretreatment interval. Supported by NIH GRSG 5-S05-RR-07064.

141.7 THE ROLES OF CONTROLLABILITY AND STRESS DURATION IN ANALGESIC RESPONSES OF MSG-TREATED RATS. J. Toole*, J. Williams* and K. King. Psychology Dept., Kenyon College, Gambier, Ohio 43022.

Recent research has shown that stress-induced analgesia (SIA) in laboratory rats probably comes in at least two forms. Stressors of short duration (such as a cold-water-swim (CWS), continuous shock, or injections of 2-deoxyglucose (2-DG) produce an analgesia which is temporally bound to the stimulus and which is not naloxone-reversible. Long-lasting stressors such as an 90-minute train of inescapable shocks lead to activation of a naloxone-reversible analgesic mechanism. Surprisingly, these shocks do not produce SIA if the animal is allowed to escape the shocks. This mechanism, unlike the other, can be reinstated 24 hours after the noxious stimulus by exposure to a few "priming" shocks.

Neonatal treatment with monosodium L-glutamate (MSG) produces selective damage in basal hypothalamic areas which are involved in B-endorphin and ACTH release. Preliminary data indicate that MSG-animals do not show the normal analgesic response to short-term stressors like CWS and 2-DG. No information is available on the response, if any, of these animals to the long-term form of stressor. It was the purpose of these two experiments to investigate interactions between MSG-damage, the two forms of SIA and the factor of shock-controllability.

In the first experiment 13 animals which had been treated with MSG and 21 normal littermates (7 of whom were randomly selected for injection with naloxone) were all found to show SIA after a 3-min swim in 2°C water. Injection with 2-DG, however, failed to produce SIA. For experiment 2, the MSG, normal, and naloxone subjects were randomly divided into two groups which received either 80 escapable or 80 inescapable tail-shocks. While most groups showed SIA, the variable of escapability did not produce consistent results. Not only did all the inescape groups (including naloxone) show SIA, but the normal-escape group did as well; only the MSG-escape group failed to show SIA. Strangely, this group, as well as all the others except the naloxone group, did show an analgesic response when given five priming shocks 24 hours later. The inconsistency of this pattern indicates that inability to control shock may not be requisite for the induction of SIA of the long-term, reinstatable type. Two consistent patterns were seen with regard to the MSG animals: 1) MSG animals have significantly higher baseline pain thresholds; 2) MSG rats show both forms of SIA in a manner virtually indistinguishable for the normal controls. These two findings indicate the preservation of basic analgesia mechanisms concomitant with a resetting of their sensitivity, and are discussed in light of the probable circuits damaged by MSG.

141.8 TAIL PINCH HYPERALGESIA: DOPAMINE AND OPIOID MODULATION. D.A. Simone*, R.J. Bodnar, A. Reches, J.H. Kordower and S. Fahn. (SPON: R.J. Bodnar). Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367 and Dept. of Neurology, Columbia Univ. Col. of Physicians and Surgeons, New York, NY 10032.

Mild, non-noxious, oscillating pinches to a rat's tail elicit hyperphagia and hyperalgesia. Moreover, tail pinch (TP) reduces the analgesic responses following morphine and cold-water swims. Since TP hyperphagia appears to be mediated in part by dopaminergic and opioid mechanisms, based upon observed reductions following 6-hydroxydopamine (6-OHDA) and naloxone respectively, animals receiving these manipulations as well as rats receiving chronic morphine were assessed for TP hyperalgesia. In Experiment 1, groups of rats received either intracerebroventricular (icv) 6-OHDA (250 ug) and systemic desimiprimine (DMI: 40 mg/kg), icv vehicle and systemic DMI, or icv and systemic vehicle. Jump thresholds were measured in the presence (TP) and absence (NO TP) of TP prior to and up to four weeks after injection. 6-OHDA rats continued to display TP hyperalgesia despite increased jump thresholds in both TP and NO TP conditions. In contrast, DMI alone produced a transient loss of TP hyperalgesia which was due to increased TP jump thresholds. 6-OHDA increased the amount of time eating, licking and gnawing the food pellets relative to the DMI and vehicle groups.

In Experiment 2, nine rats received intraperitoneal injections of naloxone at doses of 0, 0.1, 0.5, 1, 5 and 10 mg/kg in counterbalanced fashion 5 min before jump threshold determinations following TP and NO TP conditions. Naloxone altered TP hyperalgesia as a function of dose in that the 0.1 and 0.5 mg/kg doses eliminated the hyperalgesia by lowering NO TP jump thresholds. While the 1 and 5 mg/kg doses failed to alter TP hyperalgesia, the 10 mg/kg dose eliminated this effect by increasing TP jump thresholds. Furthermore, while the amount of time eating chewing and gnawing decreased at high naloxone doses, this effect failed to differ significantly from vehicle values.

In Experiment 3, rats received 14 daily subcutaneous injections of either morphine (10 mg/kg, n=9) or vehicle (n=6) and both TP and NO TP jump thresholds were determined prior to and 1 and 14 days following the injection sequence. While vehicle rats displayed TP hyperalgesia, chronic morphine eliminated TP hyperalgesia 1 day after the injection sequence by lowering NO TP jump thresholds. Chronic morphine failed to alter TP hyperphagia. These data suggest that both dopaminergic and opioids modulate TP hyperalgesia, but the modulation involves complex and dissociable components. Whereas 6-OHDA alters both TP and NO TP thresholds, various naloxone doses and chronic morphine differentially alter one, but not the other. (GRSG 5-S05-RR-07064)

141.9 EVIDENCE FOR TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION-INDUCED ANALGESIA IN SEVERAL PAIN MODELS IN THE RAT. J.A. Heltzel and K.M. Westphall* (SPON. H. Bantli) Biosciences Research Lab., 3M, St. Paul, MN 55144.

Various forms of electrostimulation have been shown to be efficacious for the relief or reduction of pain in the laboratory animal as well as the clinical setting. However, transcutaneous electrical nerve stimulation (TENS) has not been well-studied in the classical laboratory animal models. Woolf et al.(1977,1980) have reported that percutaneous stimulation increases tail flick latency in the heated bath/tail immersion paradigm, commenting that similar findings were obtained with TENS. We confirm the latter finding and report TENS-induced analgesia in two other classical models (chemical writhing and radiant heat/tail flick) in the rat.

In each model TENS was delivered through self-adhering, reusable electrodes (3M,No. 6225) placed bilaterally at the base of the tail for the tail flick tests and across the lower thoracic region for the irritant-induced writhing. A balanced current (∿10mAmp, 100 Hz, 200 μsec width) was applied for 30 minutes.

The latency of the flexor withdrawal reflex was measured by immersing the tip of the tail in a 49°C bath. Baseline latencies were recorded, stimulation was applied, and post-TENS latencies were measured so that each animal served as its own control. Unstimulated rats were included in blind studies as a control for bias. Greater than 70% of the TENS group displayed significantly longer latencies, being 30-60% of baseline values ($p < .005$); these increases persisted for at least one hour post-stimulation.

In a similar design noxious radiant heat was delivered to the tip of the tail by a focused beam with an automated system for the timing of withdrawal latencies. The difference in latency before and after the application of TENS was compared to the latency difference recorded for restrained, unstimulated controls. Under blind conditions, post-TENS latencies were significantly longer than post-restraint controls (paired t-test, $p < .05$).

Writhing behavior induced by chemical irritants such as phenyl quinone or acetic acid is less well-defined in rat than in mice. Rats were observed for a period of 30 minutes following the intraperitoneal injection of irritant under blind conditions. A writhe consisted of body elongation followed by marked and prolonged contracture of the abdominal muscles. Pretreatment with TENS significantly reduced the number of writhes in treated rats (15.9 ± 9.8, n = 15) compared with untreated controls (31.6 ± 15.6, n= 15), $p < .05$, unpaired t-test.

Investigation of TENS-induced analgesia is being continued in other traditional pain models. Concurrent efforts are underway to define neurochemical correlates of TENS-induced analgesia.

141.10 DETERMINATION OF LEVELS OF MONOAMINE NEUROTRANSMITTERS AND THEIR METABOLITES IN REGIONS OF RAT CNS FOLLOWING ANALGESIA INDUCED BY TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION. K.M. Westphall* and J.A. Heltzel. Biosciences Research Lab., 3M, St. Paul, MN 55144.

Transcutaneous electrical nerve stimulation (TENS) has been shown to be efficacious for the relief of several types of clinical pain ranging from acute post-operative incisional pain to chronic low-back pain. In a companion abstract we report evidence for TENS-induced analgesia in several traditional pain models in the rat (Heltzel & Westphall, 1982). Preliminary studies in our laboratory have indicated changes in the level of some monoamines and their metabolites during TENS-induced analgesia in the rat. To date, only Wehne and Yucun (1981) have observed changes following low-frequency electroacupuncture applied transcranially in serotonin and norepinephrine in whole rat brain minus cerebellum.

Analgesia was evaluated in the heated bath/tail immersion paradigm by measuring tail flick withdrawal latencies before and immediately after the application of 30 minutes of TENS (100 Hz, 200 μS, ∿10 mAmps). Self-adhering electrodes were placed bilaterally at the base of the tail. Following the second test, animals were sacrificed by decapitation; 100-200 mg samples of brain and spinal cord were taken for quantitation by fluorometric methods. Unstimulated rats served as a source of control tissue.

Serotonin (5-HT) and its major metabolite, 5-hydroxyindoleacetic acid (5-HIAA) were extracted in acidified butanol and reacted with orthophthaldialdehyde to form fluorescent products, according to the method of Curzon and Green (1970). Norepinephrine (NE) and dopamine (DA) were quantitated fluorometrically using the method of Chang (1964) with slight modification following selective adsorption on alumina and elution into acetic acid. All results are expressed in terms of nanograms per gram wet weight (± SEM).

No change was demonstrated in the level of 5-HIAA, NE, or DA following TENS-induced analgesia in several rat brain or spinal cord regions: cerebral cortex, cerebellum, brainstem, upper cervical or lower lumbar cord. However, in three replicate studies, a significant 23% decrease in 5-HT in cerebellum was found in TENS-treated rats (100 ± 7, n=9) versus unstimulated controls (130 ± 10 n=6), $p < .05$ (Student's t-test). 5-HT content in all other areas examined remained the same. Two-way analysis of variance was run to assess day-to-day assay variability.

To the best of our knowledge, no one has examined regional changes in monoamine tissue levels following electrostimulation-induced analgesia. Others have implicated serotonergic mechanisms mediating peripheral electroacupuncture analgesia (Cheng and Pomerantz, 1981) and central stimulation-produced analgesia (Akil and Liebeskind, 1975). Furthermore, these same workers reported divergent results following catecholaminergic manipulations.

141.11 CORTICAL POWER SPECTRUM ANALYSIS OF PATHOPHYSIOLOGICAL PAIN. A.C.N. Chen & S.F. Dworkin. Pain Center; Dept. of Psychiatry & Beh. Sci.; Dept. of Oral Medicine, Univ. of Washington, Seattle, WA. 98195, U.S.A.

Brain activity as objective measures of human pain has recently became an intense focus of research. Prior studies (Chen et al., 1979; Carmon et al., 1981) show that exogenous noxious stimuli can evoke brain activity that is proportional to the painfulness experienced. Studies of brain activity during natural endogenous pain will provide further information on cortical mechanism of human pain. Although EEG has been recorded in clinical headache patients, few conclusive results have been consistently reported. Recently, advances in quantative EEG methods, such as the analysis of cortical power spectrum (CPS), have provided precise data suitable for statistical analysis of brain states.

This report describes the study of CPS in pathophysiologic pain, using acute dental pain as a model. Eleven 'walk-in' patients in an emergency dental clinic were recorded 10 min. prior to treatment for acute pain from tooth pulp pathology. One week later, 10 min. recording during non-pain states served as control. Subjective pain and anxiety scales were gathered before and after each recording. Each ten minutes of continuous CPS recording consisted of 10 spectrum/stage, 6 epochs/spectrum, and 10sec./epoch; each spectrum was stored, averaged, transformed, plotted by the Pain Microcomputer System (Dworkin et al., 1981).

Results of seven subjects, four of the elevens had confounding medications, showed significant cortical power reduction along all frequency bands (.5-50Hz) when pain states were compared to non-pain states. The magnitude of reduction also appeared to correspond to the subjective pain report. Rank order analysis of pain intensity suggests that cortical power changes in the alpha band may be inversely related to subjective painfulness, indicating that pain and α-desynchronization is closely associated. This study suggests that brain activity can be measured from clinical pain patients, and that the development of an objective pain measuring system seems feasible. Currently, we are studying other types of pathophysiological pain, post-operative pain, low-back pain, and the interactive effects on CPS of analgesic drugs and pain. The resulting additional analyses will be discussed.

141.12 MEASUREMENT OF PAIN IN RATS BY USE OF EVOKED POTENTIALS. C. G. Smith, S. Majidi-Ahi*, and N. Baxter*. Mount Holyoke College, Dept. of Biological Sciences, South Hadley, Mass. 01075

Epidural electrodes were surgically implanted over the frontal lobes of rats. Electroencephalographic recordings from the electrodes were digitized and averaged by a SYM microprocessor during programmed random repetitive stimuli. Thermal pain, electric shocks, and neutral sensory stimuli were used. A long latency waveform comparable to the "P-300" wave described in human subjects (Carmon, A., Mor, J. & Goldberg, J., Exp. Brain Res., 25:103, 1976) was observed. The evoked response could be transferred to a neutral sensory stimulus by conditioning. Morphine and enkephalin agonists selectively abolished the response. Rats treated neonatally with capsaican did not show the waveform.

It is proposed that this technique provides an objective measurement of the affective component of pain stimuli, and can be used as a measure of analgesia which avoids some of the problems inherent in behavioral tests such as the tail flick assay.

142.1 NASAL AND TEMPORAL HEMI-RETINA DIFFER IN THEIR GROWTH INTERACTIONS WITH GOLDFISH OPTIC TECTUM. J. Cronly-Dillon* and C.A. Stafford* (SPON: J. Kulikowski). Dept. of Ophthalmic Optics, U.M.I.S.T., Manchester, U.K.

Cronly-Dillon et al (1980) have shown that reciprocal growth regulating interactions take place between regenerating optic axons and tectal cells. Using changes in soluble tubulin and protein synthesis as indicators of cell growth interactions it was previously found that regenerating optic fibres stimulate biosynthetic changes in tectal cells and that the tectum exerts a retrograde growth promoting influence on the retina.

We have now compared the growth interactions induced by regenerating fibres from a nasal vs a temporal hemiretina and found that during the first stage of growth into the tectum, while growing axons are in the stratum opticum, the growth interactions induced between tectum and retina are significantly greater for a nasal hemiretina than for temporal hemiretina. Elsewhere Berry et al (1980) have shown that adhesive contacts between ingrowing axons and their target neurons induce changes in the growth and pattern of target neuron dendrites. Also Halfter et al (1981) have shown that chick retinal neurites from a nasal hemi-retina are more adhesive than those from a temporal hemi-retina. Thus the adhesive contacts established by the more adhesive nasal fibres appear to induce greater growth changes in tectal cells than their temporal counterparts. These and other results will be discussed in relation to retinotectal pattern formation.

142.2 INDUCTION OF PEPTIDE-LIKE IMMUNOREACTIVITY (PLI) IN THE ANURAN OPTIC NERVE. R.O. Kuljis and H.J. Karten. Depts. of Psychiatry and of Neurobiology, S.U.N.Y. at Stony Brook, N.Y. 11794.

PLI has been shown in various classes of amacrine cells in vertebrate retinae. Ganglion cell layer elements, however, have been consistently negative (Brecha, Karten & Laverack,'79; Karten, Reiner and Brecha,'82). Interestingly, the anuran optic tectum displays a complex laminar pattern of PLI in an area which is in receipt of a massive retinofugal input (Kuljis & Karten,'81). Furthermore, retinal deafferentation is rapidly followed by marked reduction or dissapearance of most of the immunoreactive bands at this level (Kuljis & Karten,'82). Both latter findings suggest either a retinal contribution to PLI tectal laminar patterns or a transsynaptic effect.

Sixteen specimens of Rana pipiens were subjected to unilateral optic nerve ligation for one to 24 days. Substance P-, leucine-enkephalin-, cholecystokinin octapeptide- and bombesin-like immunoreactivity was analyzed in the retinae, optic nerves and optic tecti, on both sides, by means of the peroxidase-anti-peroxidase and fluorescence methods.

PLI is observed in the form of a dense array of fine longitudinal fibers, for all of the aforementioned substances, in the retinal stump of the optic nerve immediately adjacent to the ligature. The stain can be blocked by preabsorbing each of the antisera with the appropriate synthetic substance. No changes are observed in PLI patterns in the retina, nor is there any staining in the cerebral stump of the ligated nerve, nor in the contralateral optic nerve. The optic tectum contralateral to the ligation displays the changes we have described previously in retinal deafferentation experiments (Kuljis & Karten,'82).

These observations support the possibility that retinal ganglion cells contribute to PLI in the tectum, in spite of the fact that PLI cannot be normally demonstrated in their somata and processes. The clarification of this issue needs further experimental assessment. It is possible, in fact, that PLI observed in ligated optic nerves is a post-traumatic response, not reflecting a normal feature of retinal ganglion cells.

Supported by 1-F05-TW02947 (R.O.K.) and EY02146 (H.J.K.).

142.3 ABILITY OF THE COBALT METHOD AND INABILITY OF THE RADIOAUTOGRAPHIC METHOD TO ADEQUATELY DETECT REGENERATING RETINTOTECTAL AXONS. A.D. Springer. Department of Anatomy, New York Medical College, Valhalla, N.Y. 10595.

In a previous study (Springer, JCN, 199:87, 1981) the distribution of regenerating goldfish optic axons was evaluated with [^{3}H]proline radioautography. Early in regeneration silver grains representing optic axons were concentrated in appropriate tectal laminae, but were also located in inappropriate tectal laminae. Later in regeneration, the silver grains were only observed in appropriate laminae. The early dispersion of silver grains in the tectum could represent transneuronal leakage of label from optic fibers in correct laminae to secondary tectal fibers. This study sought to determine whether label in inappropriate laminae represents label leakage or the presence of optic axons and whether regenerated axons in inappropriate tectal laminae are transient.

Cobaltous-lysine was applied to the regenerating optic nerve at various times following nerve crush (18-76 days post-crush with fish maintained at 20°C). Abnormally large numbers of cobalt-filled optic fibers were found coursing between the appropriate tectal laminae. Many aberrant fibers were located superficially in the stratum marginale and deep in the stratum periventriculare. The aberrant fibers were still apparent at the latest time point examined. Filled cells were not observed in the tectum, indicating that aberrant cobalt-filled fibers were optic axons and not transneuronally filled secondary processes.

The cobalt data suggest that: 1) radioautographic silver grains overlying the stratum marginale and stratum periventriculare probably represent optic axons and not leakage of labelled substances from regenerating axons, 2) transient axons as shown by radioautography are not transient when cobalt is used as a tracer; transient axons with radioautography may be related to regenerating axons carrying more label than regnerated axons, thereby making regenerated axons less detectable with radioautography, 3) the dispersion of axons throughout the tectal layers could reflect an abnormally large number of axons in the tectum during regeneration, 4) many regenerating fibers traverse tectal regions that they do not normally cross, 5) the final retinotectal projection may ultimately be carved from an abundance of regenerating fibers if the aberrant fibers eventually disappear and 6) the cobalt method is sufficiently sensitive to detect the presence of regenerating fibers at all stages of regeneration. (Supported by EY-03552)

142.4 RETINAL HISTOGENESIS AND THE DEVELOPMENT OF THE IPSILATERAL RETINO THALAMIC PROJECTION IN XENOPUS. S.G. Hoskins and P. Grobstein. Dept. Biol., Pharm. Phys. Sci., Univ. of Chicago, Chicago IL 60637.

A new retinofugal projection, that to the ipsilateral thalamus, develops in Xenopus during metamorphosis. We have studied the ontogeny of this projection and the histogenesis of the retina, to determine how the two processes are related.

We analyzed the development of the projection using anterograde transport of HRP applied to cut optic nerves. Labelling in ipsilateral terminal zones was first seen at tadpole stage 54. Between stages 54 and 66 (end of metamorphosis), reaction product density increased in ipsilateral thalamic terminal zones. Even in 1-6 month postmetamorphic frogs, however, the intensity of label was not comparable to that seen in adults. The immaturity of the projection at stage 66 was also evident in the distribution of label within the ipsilateral nucleus of Bellonci. In adults, label is fairly homogeneously distributed through this terminal zone. At stage 66, it was located in two subregions with an intervening label-sparse area. Labelling was similarly non-homogeneously distributed in 1, 2½, and 6 month postmetamorphic frogs.

To determine when ganglion cells giving rise to the ipsilateral projection are born, we injected tadpoles with ^{3}H-thymidine, let them metamorphose, and then injected HRP into the rostral thalamus to retrogradely label the ipsilaterally projecting ganglion cells. Since new cells are added primarily at the retinal periphery, the ^{3}H-thymidine injections at any given stage labelled the cells which at that time lay at the periphery. After metamorphosis, this ring of label separated earlier-born (central) from later-born (peripheral) cells. In tadpoles thymidine-injected before stage 54, nearly all HRP-filled cells were located peripheral to the thymidine ring. In cases injected at stage 54, HRP-filled cells were found in the vicinity of and peripheral to the ring. In cases injected at stages 56-58, significant percentages of HRP-filled cells lay central to the ring. We conclude that the vast majority of ipsilaterally-projecting cells are born at and after st. 54, the stage when an ipsilateral projection is first seen.

To determine whether postmetamorphic ganglion cell production could play a role in the postmetamorphic development of the ipsilateral terminal fields, we injected ^{3}H-thymidine into frogs at stage 66 and killed them several months later. Significant numbers of cells were evident peripheral to the labelled ring. Thus, cell addition continues postmetamorphically. Our previous retrograde HRP studies in adult frogs showed that ganglion cells at the extreme retinal periphery are among those which project ipsilaterally to the thalamus. We conclude that addition of ipsilaterally projecting ganglion cells continues postmetamorphically.

142.5 RE-ESTABLISHMENT OF THE IPSILATERAL OCULO-TECTAL PROJECTION AFTER OPTIC NERVE CRUSH IN THE FROG: EVIDENCE FOR SYNAPTIC REMODELLING DURING REGENERATION. J.R. Adamson* and P. Grobstein. Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL 60637.

Following optic nerve crush, the crossed retino-tectal projection (CP) and the ipsilateral oculo-tectal projection (IP) in the frog are both re-established. During this process there is a phase when ganglion cell terminals in the CP are abnormally located. Whether these terminals form functional synapses is unclear. The IP is a map of the binocular visual field of one eye on the ipsilateral tectal lobe; it depends on the CP and a topographic intertectal relay. Whether the IP has a disorganized phase during regeneration is unknown. Since the visual field represented at a given locus in the IP reflects retinal input to a corresponding locus in the CP, functional synapses made by mislocated retinal terminals might be detected as abnormalities in the IP. To see if abnormalities exist, we have electrophysiologically mapped the CP and IP in Rana pipiens at various times after optic nerve crush.

A coarse topographic map was rapidly re-established in the CP, usually within about four weeks. The multiunit receptive fields (MRF's) were however greatly enlarged, with diameters up to three times normal. Single unit receptive fields and simultaneously recorded MRF's from the undisturbed eye were normal. We conclude that, at early stages of regeneration, terminals representing unusually wide areas of the retina are present at each tectal locus. MRF sizes declined to normal levels over about three months.

The re-establishment of the IP similarly involved the rapid appearance of a grossly topographic map with enlarged MRF's, and a later decline in MRF size. The sizes of IP MRF's were closely correlated with those of CP MRF's in the opposite tectal lobe at all times. Some IP MRF's seen at early times included part of the monocular field of the regenerating eye. The CP MRF's seen at the same time were expanded such that tectal loci normally receiving retinal afferents representing binocular visual field were also receiving input from those representing monocular field.

The re-establishment of the IP, like that of the CP, thus involves an initially disorganized map and a progressive recovery of order. The abnormalities in the IP closely reflected those of the CP, as would be expected if they result from effective synapse formation by mislocated retinal terminals. Consistent with this, enlarged IP MRF's could be abolished by small lesions at corresponding points in the opposite tectal lobe. Such lesions, as in normal animals, left the IP at surrounding tectal loci intact. It seems likely then that the observed changes in the IP during regeneration reflect a process of synaptic remodelling in the CP as the retinal area represented by ganglion cell terminals at particular tectal loci becomes progressively more restricted.

142.6 ABERRANT CROSSED PARABIGEMINO-TECTAL PROJECTIONS IN RATS WITH NEONATAL RETINAL LESIONS. J.A. Stevenson and R.D. Lund. Dept. Anatomy, Medical Univ. of South Carolina, Charleston, S.C. 29425.

Previous work has shown that the axonal projections arising from the ipsilateral retina and contralateral parabigeminal nucleus (PBN) distribute to similar regions of the superior colliculus (SC) in the normal adult pigmented rat. Furthermore experimental animals which had one eye removed at birth, producing an enlarged ipsilateral retino-SC projection in the adult, have a similarly enlarged crossed PBN projection to that same SC. In bilaterally enucleated animals the PBN projection is not as greatly enlarged. These results indicate that there may be some form of interaction between retinal and PBN afferents to SC such that the retinal projection establishes conditions or boundaries which may govern the PBN terminal distribution (Stevenson and Lund, J. Comp. Neurol., 206:1982).

To examines the degree of precision of such interactions the present experiments have examined the influence of partially expanded ipsilateral retino-SC projections on crossed PBN projections to the same SC. Neonatal rats received partial lesions of their left retinae . At adulthood the projections from right eye and left PBN to right SC were assessed using ^{3}H-proline autoradiography and degeneration, respectively. Patches of aberrant ipsilateral retino-SC projection appeared in regions corresponding to gaps in the crossed retino-SC projection (Lund and Lund, Exp. Neurol., 40:37 1973). In those cases in which such abnormal patches of ipsilateral retinal projection appeared within the region of SC which normally receives crossed PBN afferents, there were spatially corresponding, localized areas of abnormally high density PBN projection. When no aberrant retinal projection was present, the PBN projection appeared normal.

This result indicates that the ipsilateral retinal projection does more than simply establish boundary conditions for crossed PBN termination in SC. The interactions between these two afferent projections may be very precisely localized and potentially useful in refining the topography of the PBN projection.

142.7 MUTANTS AND CELL MARKERS IN XENOPUS LAEVIS: APPLICATIONS TO STUDIES OF EYE DEVELOPMENT. R. Tompkins*, D. Krotoski-Gwozdzowski* and R. K. Hunt*. (Spon: R. K. Murphey). Dept. of Biology, Tulane Univ., New Orleans, LA 70118 and Dept of Biophysics, Johns Hopkins Univ., Baltimore, MD 21218.

Surgical rearrangement of parts of eyebuds of amphibian embryos has long been used to define the developmental potentials of various parts of chimeric eyes. The lack of an adequate cell marker in these experiments led to controversial interpretations based on presumed fates of the chimeric parts. We have developed a fertile, stable, apparently normal strain of tetraploid(4n) Xenopus laevis which permits the identification of every cell in 2n/4n chimerae regardless of the state of differentiation of each cell. Diploid and tetraploid cells were distinquished by their cell size, nuclear size, nucleolar number, and DNA content.

We have used the 4n cell marker in heterotopic grafting strategies to demonstrate instances of regulative alterations in prospective retinotectal connections. 2n/4n chimerae have also been used to identify instances of both regulation and mosaicism in growth pattern in neural retina, pigmented retinal epithelium, and iris. Tetraploid cell size is sufficiently large during development to permit intracellular dye injections. This has led to studies of developing retinal neuron morphologies. Tetraploid embryos have been tolerized to one of our inbred diploid strains. This has permitted subsequent grafting of diploid neural tissues-- such as tectal fragments-- into the cell marked tetraploid host at any age without immunological complications. Finally, several mutants have been isolated which effect eye development. These include an undergrowing "tiny eye" mutant, an overgrowing "enlarged eye" mutant, and a neural cell lethal mutant which causes the autonomous death of neural cells just prior to feeding stage. These mutants, among others, not only provide interesting natural experiments for analysis but also permit the development of normal eye tissues -- either diploid or tetraploid -- to be challenged in subtle ways in chimeric eyes. Supported by NSF grants BNS 80-22451 to R. T. and BNS 77-26987 to R. K. H.

142.8 MOSAIC AND REGULATED PATTERNS IN RETINAL GROWTH AND RETINOTECTAL INNERVATION FOLLOWING HETEROTOPIC GRAFTING OF GENETICALLY-MARKED EYE-BUD FRAGMENTS IN XENOPUS. R.K. Hunt*, L.A. Faulkner*, B. Szaro*, K. Conway*, and R. Tompkins* (SPON: D. Fambrough). Biophysics Dept., Johns Hopkins Univ., Baltimore, MD. 21218 and Biology Dept. Tulane Univ., New Orleans, LA 70118.

The embryonic eye-bud in Xenopus frogs has a developmental program for patterned retinotectal connections, as revealed by 'mosaic' retinotectal patterns from embryonically grafted eyes and certain combinations of fused eye-bud fragments (rev. Curr. Tops. Develop. Biol. 15: 216, 1980). We recently confirmed, by exchanging genetically marked grafts between (pigmented) 4n embryos and (diploid) albino embryos, that the developmental program in grafted eye-bud tissue can be modified--leading to a 'regulated' normal retinotectal nerve pattern--following (i) surgical misalignment of whole eye-buds in body space at stage 26, or (ii) surgical recombination of a dorsal half-bud with an anterior half-bud at late optic cup stages (Biophys. J. 37, 59a, 1982). Here we report on wedge-grafts between two different angular positions on the stage 32+1 eye-bud (Anteroventral, AV vs. Dorsal, D), exchanged between (pigmented)4n donor embryos and (diploid)albino host embryos (in Rearing solution: 5% Steinberg-15% Holtfreter salines, MS-222 1: 5000 anesthesia, at 22^{o}). These wedge-grafts, which represent the full thickness of the eye-bud and 30+10^{o} in angular extent at surgery, heal within 72 hours. Orthotopic wedge-grafts (D-into-D,AV-into-AV) showed that each region had a characteristic groth pattern, revealed by the color marker in pigment retina (PR) and iris, and by the cell size marker in neural retina (NR). D-into-D grafts contributed little to iris; and their derivative sector in PR and NR showed limited addition of new cells from the ciliary margin at metamorphic stages. AV-into-AV wedge-grafts showed marked widening of their derivative sector, in iris during larval growth and in PR and NR added during metamorphic climax. All orthotopic-graft chimerae showed normal visuotectal projections, assayed electrophysiologically at termination after metamorphosis. AV-into-D heterotopic grafts gave two distinct classes of result. The AV-program was retained and expressed in one class (20%), so that (i) the angular territory of graft-derived tissue increased to 160^{o} in larval iris and post-metamorphic PR and NR, and (ii) the sector of visuotectal projection subtended by graft-derived NR mapped to a caudomedial triangle of tectum, duplicating the projection from the host's own AV-retinal sector. The second class (80%) showed 'regulated' normal visuotectal projection and a D-like growth pattern appropriate to the graft's new site of implantation: no widening of graft territory in larval iris, and limited addition of new NR and PR at metamorphic stages. We infer that pattern regulation affects both the mapping properties of the graft's derivative neurons and local programs for growth. Supported by NSF (BNS8022451; PCM7726987).

142.9 SINGLE CELL TECHNIQUES FOR THE DEVELOPING XENOPUS RETINOTECTAL SYSTEM. D.S. Sakaguchi*, R. Tompkins*, R.K. Hunt* and R.K. Murphey (SPON: H. Molinari). Dept. of Biol. Sci., SUNYA, Albany, N.Y., Dept. of Biol.,Tulane Univ., New Orleans, La.,and Jenkins Biophy. Lab, Johns Hopkins Univ., Baltimore, MD.

We have developed an in vitro preparation and applied intracellular dye injection techniques to the study of the developing Xenopus visual system. The animal we use is a strain of tetraploid Xenopus laevis developed by one of us (R.T.). The retinal ganglion cells in tadpole stages of these animals are larger in diameter than their diploid counterparts (15 vs 8u respectively). The experimental preparation consisted of isolating the retina and after removal of the lens and pigment retinal epithelium, viewing the ganglion cells from the vitreal surface. The preparation was transilluminated and viewed with Nomarski optics. Ganglion cells were impaled with microelectrodes filled with Lucifer Yellow or hexamminecobalt chloride and examined in animals between stages 26-50 (Nieuwkoop and Faber, 1956). A broad continuum of morphologies was observed. The earliest cellular profiles were of neuroepithelial form (stages 25-28), irregular in shape and bearing few if any processes. Cells examined at later stages (after stage 28) ranged from unipolar to multipolar and exhibited increasing dendritic complexity with age. The earliest we saw "mature" dendritic forms was at stages 39/40.

As a complement to the single cell techniques we filled ganglion cell axons by immersing an isolated brain in a pool of hexamminecobalt chloride with optic nerves and eyes still attached, but outside the pool of staining solution. After a diffusion period (10 hours) the eyes were processed as wholemounts and the cobalt intensified according to the procedure of Bacon and Altman (1977). The ganglion cells could be divided into two general classes based on soma size, large cells constituting less than 10% of the total population and a small class constituting the remainder. Within these two classes we observed a variety of dendritic patterns. Data regarding axon fasciculation confirmed the gross radial order of optic axons, but just as the single cell technique has demonstrated it is variable. A small percentage of ganglion cell axons do not merge with adjacent fascicles but instead merge with distant fascicles, thereby taking an indirect route to the optic disc. We are currently extending the intracellular technique to an isolated eye, optic nerve and brain preparation in an attempt to fill single ganglion cells from the eye to the brain. By examining both ends of the ganglion cells we hope to provide high resolution techniques for the continued study of the retinotectal system.Supported by NSF Grants to R.T., R.K.H. and R.K.M.

143.1 EFFECT OF AF64A ON NEUROBLASTOMA X GLIOMA HYBRID CELL LINE NG-108-15: A NEUROTOXIN SELECTIVE FOR CHOLINERGIC CELLS. K. Sandberg*, R.L. Schnaar, I. Hanin, and J.T. Coyle. (SPON: L. Tune,) Div. of Child Psychiatry, Depts. of Psychiatry, Pharmacology and Neuroscience, Johns Hopkins Univ. School of Med., Baltimore, MD and Dept. of Pharmacology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA.

Intraventricular injection of the ethylcholine mustard aziridium ion (AF64A) induces a persistent and significant reduction in acetylcholine (ACH) levels and in the choline high affinity uptake process in mouse brain (Mantioni et al., Science 213:579, 1981). We have previously demonstrated a selective reduction in markers for cholinergic neurons in the striatum without reduction in presynaptic markers for other neuronal populations after in situ injection (Coyle, et al., Trans Am. Soc. Neurochem 13:271, 1982). In the present study, AF64A's effect on the neuroblastoma x glioma hybrid cell line, NG-108-15, was examined in an attempt to elucidate the neurotoxic mechanism of this drug. NG-108-15 possesses a high affinity choline uptake system (7.8 pm/mg prot-/min) and choline acetyltransferase activity (CAT) which trebles upon differentiation (from 133 to 377 pmole/mg prot/min). These cells release ACH upon depolarization and form neuromuscular synapses in culture. (Hamprecht, Int.Rev.Cytol. 49:99, 1977).

Cytotoxic effects of the drug were monitored by the release of lactic dehydrogenase (LDH) into the incubation medium. AF64A caused cell death of NG-108-15 within 48 hours at concentrations from 50-200 μM. Differentiated NG-108-15 showed a three-fold increased susceptibility to the cytotoxic action of AF64A as compared to undifferentiated NG-108-15 and to a non-cholingeric neuroblastoma cell line. A kinetic study indicated a 70% decrease in specific activity of CAT after 2.5 hours of exposure to 100 μM AF64A; at this time point, LDH activity in the cells or in the medium was not significantly different from control. Cytotoxic effects with increased LDH activity in the medium appeared over the subsequent twenty-four hours. Hemicholin- ium-3, the potent antagonist of the choline high affinity uptake process, suppressed the toxic effects of AF64A in a dose-related manner. The results of these studies indicate that AF64A exhibits selective cytotoxic effects against this cholinergic cell line that is dependent upon the activity of the choline transport process; furthermore, inhibition of CAT activity is an early event that precedes the cytotoxic action of the drug. This compound appears to be a cholinergic-specific neurotoxin and offers promise as a tool for selectively lesioning cholinergic systems. (This research is supported by USPHS Grant NS-18414 and KS is supported by NIH Training Grant GM 07445).

143.2 IOTROCHOTIN, A NOVEL FACTOR FROM A CARIBBEAN SPONGE, INCREASES RELEASE OF NEUROTRANSMITTERS. J.V. Martin and W.O. McClure. Dept. Biol. Sci., Univ. Southern Calif., Los Angeles, CA 90007.

Several species of marine organisms collected during the 1978 Alpha Helix Caribbean Expedition have been identified as sources of substances which affect the release of acetylcholine and choline from a synaptosomal preparation (Martin, J.V. and W.O. McClure, Trans. Am. Soc. Neurochem., 11:85, 1980). One sponge in particular, Iotrochota birotulata, has been selected for more intensive study. Extracts of this organism contain a molecule which can, at high doses, release all radioactivity from synaptosomes preloaded with tritiated choline. The active agent, or "iotrochotin" (IOT), has a molecular weight of approximately 12,000 as determined by Sephadex G50 chromatography, used in these studies as a crude purification step. IOT is completely inactivated by heating at 90°C for 5 min, but is resistant to treatment with trypsin. Release of radioactivity shows a sigmoid dependence on the dose of IOT, but the data do not generate a linear Hill plot. The time course of action is extremely rapid, and is complete by the earliest time point measured, at 1 min.

The mechanism of action of IOT does not appear to be a simple direct effect on trans-membrane fluxes of either Ca^{2+} or Na^{+}. Removal of Ca^{2+} from and addition of 1 mM EGTA to the synaptosomal incubation medium reduces the effect of IOT by 28%, although this treatment dramatically inhibits release due to electrical stimulation. Removal of Na^{+} from the incubation medium reduces release due to 10^{-4} M veratridine by 57%, but inhibits the effect of IOT by only 14%. In addition, tetrodotoxin inhibits veratridine induced release of radioactivity by 95%, while inhibiting the effect of IOT by 12%. Finally, if ion fluxes were major components of the action of IOT, one might expect that depolarization of the synaptosomal membrane would result. The average change in membrane potential of synaptosomes was measured using the fluorescent dye DiO-C_5-(3), and there was no effect of a dose of IOT which would have caused a major release of radioactivity.

Not only cholinergic synaptosomes can be influenced by IOT. Synaptosomes preloaded with tritiated norepinephrine or gamma-aminobutyrate also released radioactivity as a result of treatment with IOT. It is felt that IOT is a toxin which interacts with a presynaptic mechanism other than the regulation of metal ion fluxes but common to systems of neurotransmitter release. When purified, IOT may be a useful tool in studying mechanisms of release. (Supported by NSF Grants BNS 76-80657 and BNS 77-06782, the Dreyfus Foundation, and Nelson Research and Development Co., Irvine, CA.)

143.3 MONOCLONAL ANTIBODIES TO RAT BRAIN CHOLINE ACETYLTRANSFERASE William L. Strauss* and Marshall Nirenberg. (SPON: M.D. Schneider) Lab. Biochemical Genetics, NHLBI, NIH, Bethesda, MD.

Four monoclonal antibodies have been prepared to rat acetyl CoA: choline O-acetyltransferase (EC 2.3.1.6, CAT). The enzyme was purified approximately 100,000-fold from whole rat brain by precipitation with acetic acid at pH 4.5, fractionation with 40-60% $(NH_4)_2SO_4$, CM-Sephadex chromatography (Ryan and McClure (1979) Biochemistry, 18: 5357) and affinity chromatography on coenzyme A-hexane-agarose. The enzyme preparation was applied to the affinity column in the presence of 10 mM acetylcholine to increase the affinity of CAT for coenzyme A and eluted with 10 mM acetyl coenzyme A. BALB/c mice were immunized with the purified enzyme (greater than 60% CAT estimated after SDS-PAGE). Fusion of spleen cells with P3X63· Ag8 myeloma cells resulted in 4 CAT-specific colonies (anti-CAT 1-4) out of 93 hybridomas. Hybridomas directed towards CAT were identified by their ability to precipitate the enzyme in the presence of protein A at pH 8.5. Incubation of anti-CAT 1-4 with CAT followed by precipitation with rabbit anti-mouse IgG and protein A on formalin-fixed S. aureus reduced enzyme activity in the supernates 38, 26, 30 and 34%, respectively. This amount of precipitation is consistent with the value calculated, using the law of mass action, from estimates of the reactant concentrations (CAT, 3.5 x 10^{-10} M; hybridoma antibody, 3.3 x 10^{-8} M) and of the equilibrium dissociation constant (10^{-7} M). A mixture of the four antibodies (each at 25% of the usual concentration) precipitated 40% of the enzyme activity. The ability of conditioned medium to precipitate CAT was reduced greater than 50% by prior treatment with protein A to remove antibodies. Anti-CAT 1, 2 and 3 inhibited the enzyme to the same extent that each precipitated activity. Anti-CAT 4 was less effective in inhibiting CAT (21%) than in precipitating the enzyme (34%). Hybridoma antibody-dependent enzyme inhibition was reversed by dissociation of immune complexes via dilution. CAT activity was partially recovered from [CAT · anti-CAT · rabbit anti-mouse IgG· Protein A] immune precipitates by suspending the pellets in fresh buffer for 3 hr. The specificity of the hybridoma antibodies was confirmed further by two dimensional gel electrophoresis of immune precipitates. Each of the four antibodies selectively precipitated a protein with a molecular weight of 67,000, corresponding to the value for affinity-purified CAT. Anti-CAT 1, 3, and 4 cross reacted with 14-day embryonic chick brain CAT, precipitating 46, 15 and 19% of the enzyme, respectively, suggesting that portions of the enzyme were conserved during evolution. These antibodies should be useful for the identification of mRNA coding for CAT and for the generation of cDNA probes for the choline acetyltransferase gene.

143.4 IMMUNOHISTOCHEMISTRY OF CHOLINE ACETYLTRANSFERASE IN THE RAT BRAIN M. V. Sofroniew[1], F. Eckstein[2]*, H. Thoenen[2] and A. C. Cuello[1]*. [1]Departments of Human Anatomy and Pharmacology, University of Oxford, South Parks Road, Oxford OX1 3QX, U.K.; [2]Max Planck Institute for Psychiatry, Dept. of Neurochemistry, Martinsried, FRG.

The enzyme choline acetyltransferase (ChAT) is responsible for the synthesis of acetylcholine and currently represents the most useful marker for cholinergic neurons. In this study, cholinergic neurons were examined in the rat brain by immunohistochemical detection of ChAT. ChAT was purified from pig brain and antisera and monoclonal antibodies were generated against ChAT of over 95% purity as previously described (Neurosci., 6:993, 1981; EMBO J., 1:in press, 1982). The monoclonal antibody generated was useful for immunohistochemical detection of ChAT only in the pig CNS. However, several antisera showed immunohistochemical reactivity with ChAT of other species. These antisera gave staining identical to the monoclonal antibody when compared in the pig CNS, and various other tests verified their monospecific nature (EMBO J., 1:in press, 1982). Detailed immunohistochemical studies were conducted using Wistar rats 220-280 g fixed by perfusion with 4% paraformaldehyde/0.01% glutaraldehyde. Vibratome sections 25 or 50 μm thick were prepared and immunohistochemically stained free-floating as previously described (Neurosci., 6:619, 1981). As expected, motor neurons in the ventral horn of the spinal cord and nuclei of the cranial nerves were positively stained. Preganglionic sympathetic neurons in the intermediolateral nucleus were also stained. In the forebrain, a large number of ChAT-positive neurons was found forming a continuous group in the nucleus of the diagonal band of Broca and medial septum. Many ChAT neurons were also present in and around the area of the medial forebrain bundle and nucleus basalis (Meynert) and intermingled in the white matter at the ventral border of the internal capsule and striatum. In the neostriatum, many single ChAT neurons were evenly scattered throughout the caudatoputamen and groups of ChAT neurons were found intermingled in the white matter along the medial border of the globus pallidus. In the midbrain, ChAT neurons were present in the red nucleus and Edinger-Westphal nucleus. ChAT neurons in most areas were large (20-30 μm). Although ChAT neurons and their proximal processes were well visualized in this study, terminal fields and fiber tracts were not well stained. In some cases, such as the interpeduncular nucleus, a diffuse dark staining was noted throughout the neuropil of a circumscribed area, but could not clearly be defined to punctate fibers or terminals. Thus, although work remains to be done on improving the visualization of cholinergic terminal fields, neural perikarya in certain areas (listed above) can unambiguously be identified as cholinergic. (Supported by NIH NRSA 1 F32 NS06956-01, the Wellcome Trust and the Deutsche Forschungsgemeinschaft.)

143.5 APPLICATION OF A SELECTIVE RETROGRADE LABELING TECHNIQUE TO THE IDENTIFICATION OF ACETYLCHOLINE SUBCORTICOSPINAL NEURONS. M.F. Paré, B.E. Jones and A. Beaudet. Lab. of Neuroanatomy, Dept. of Neurology and Neurosurgery, Montreal Neurological Inst., McGill University, Montreal, Quebec H3A 2B4.

It has been proposed that neurons may be distinguished according to their neurotransmitters by selective terminal uptake and retrograde axonal transport of their radiolabeled transmitter. Recently Bagnoli et al. (J. Neurosci. 81: 691-695, 1981) demonstrated selective retrograde radioautographic labeling of acetylcholine neurons in the septum following injection of ^{3}H-choline into the hippocampus. In the present study the same technique has been applied to the identification of brain stem acetylcholine neurons which project to the spinal cord.

^{3}H-choline (10-100µCi of 80 Ci/mmol in 0.1-0.5µl distilled water) was injected through a glass micropipette into the first right cervical segment of the spinal cord in rats anesthetized with Nembutal. The animals were sacrificed 20 hours later by perfusion of an ice cold solution of 10mM Hepes buffer containing 110 mM Mg^{++} followed by a 4% paraformaldehyde solution in the same buffer. The brains were rapidly removed and frozen with dry CO_2 gas. Twenty µm-thick sections were cut in a Cryostat, touch mounted on gelatinized slides, dried with a blow dryer, and processed for radioautography of diffusable substances by apposition of emulsion pre-coated coverslips.

Two patterns of radioautographic labeling were evident in the brain stem following spinal injections of ^{3}H-choline. First, anterograde axonal and terminal labeling which is known not to be specific for cholinergic neurons was present in spinoreticular, spinocerebellar, and spinothalamic pathways. Second, retrograde axonal and perikaryal labeling was evident in certain subcorticospinal systems. In the medulla, nerve cell bodies within the nuc. reticularis gigantocellularis, nuc. raphe magnus and the medial, inferior and lateral vestibular nuclei were labeled on the ipsilateral and to a lesser extent contralateral side. In the pons, a few cell bodies within the nucleus reticularis pontis caudalis were detected. In the midbrain, cells of the contralateral red nucleus were heavily labeled. Many regions known to project to the cervical spinal cord, such as the nuc. reticularis parvicellularis and the nuc. reticularis pontis oralis contained no labeled cells. Most significantly the noradrenaline locus coeruleus neurons which project to this region were not labeled. In view of this demonstration of selective retrograde labeling with ^{3}H-choline, it is proposed that certain rubrospinal, vestibulospinal and medial medullary reticulospinal cells may be cholinergic. (Supported by a studentship and grants MA 6464 and MA 7366 from the Medical Research Council of Canada).

143.6 ACETYLCHOLINESTERASE-CONTAINING NUCLEUS BASALIS NEURONS OF THE LATERAL HYPOTHALAMUS PROJECT TO THE SPINAL CORD. J. H. Haring* and J. N. Davis (SPON: E. Busse). Neurology Research Laboratory, Veterans Administration Medical Center, Durham, NC 27705 and Departments of Medicine (Neurology) and Pharmacology, Duke University, Durham, NC 27710.

Acetylcholinesterase-containing neurons of the basal forebrain are arranged in a discontinuous column extending from the medial septum to the lateral hypothalamus, and may represent a highly collateralized cholinergic analog of the catecholaminergic locus coeruleus projection. Although the locus coeruleus is known to have spinal projections, no comparable projection has been identified for cholinergic neurons of the basal forebrain. Therefore retrograde transport of horseradish peroxidase (HRP) or the fluorescent dye bisbenzimide (Bzb) and acetylcholinesterase (AChE) histochemistry were used to test the hypothesis that basal forebrain cholinergic neurons project to the spinal cord.

Large, nonspecific injections of either 10% Bzb or 50% HRP were made at middle thoracic levels of the spinal cord. In several rats, HRP crystals were applied to lesions of the thoracic cord. Following 48 hour survivals, numerous fluorescent neuronal nuclei and HRP-filled perikarya were seen in regions known to have a conspicuous projection to the spinal cord (e.g. motor cortex and red nucleus). In contrast to the sparse HRP labeling observed in the paraventricular nucleus, numerous Bzb labeled nuclei were observed in neurons of not only the paraventricular nucleus but the lateral hypothalamus as well, thus demonstrating a differential sensitivity of these projections for Bzb and HRP. Sections having Bzb labeling were photographed, stained for the presence of AChE and the identical regions rephotographed in order to compare retrograde labeling with AChE activity. Although AChE staining often did not correlate with Bzb fluorescence, a small number of fluorescent neuronal nuclei appeared to correspond to AChE-containing perikarya in the lateral hypothalamus. The observation of these retrogradely labeled, AChE-positive neurons suggests a small descending cholinergic pathway originating in neurons of the basal forebrain.

Further support for the hypothesized cholinergic basal forebrain-spinal cord projection is found in the appearance of sympathetic fibers in the spinal cord distal to a complete transection. This phenomenon has also been reported to follow lesions of other cholinergic forebrain nuclei (medial septal nucleus, ventral pallidum), and may represent a common response which follows the destruction of any constituent of the basal forebrain cholinergic column.

143.7 ACETYLCHOLINE AND γ-AMINOBUTYRIC ACID SYNTHESIS BY DISSOCIATED CEREBRAL CORTICAL CELLS IN VITRO. W.E. Thomas. Department of Neurobiology, Harvard Medical School, Boston, MA 02115

Primary cultures were prepared from dissociated embryonic rat cerebral cortex. The cortical cells attained a mature appearance after approximately 3 weeks in vitro and cultures were routinely maintained for 6-8 weeks. Mature cultures contained both neurons and nonneuronal cells. The presence of neurons in such cultures was determined by two methods, indirect immunofluorescence of tetanus toxin binding and staining with the excitable-cell-specific dye merocyanine 540.

The synthesis of acetylcholine (ACh) and γ-aminobutyric acid (GABA) was determined by incubating cultures with ^{3}H-choline or ^{3}H-glutamate for 10 min. The cultures were then extracted and the extract analyzed by high voltage electrophoresis. The radioactivity comigrating with standard ACh and GABA was quantified. In the presence of labelled choline, the cultures accumulated choline and synthesized ACh. Choline uptake was significantly reduced by 50 µM hemicholinium-3. The synthesis of ACh by intact cultures was inhibited 50-80% by naphthylvinylpyridine (250 µM); however, in lysed cultures, greater than 90% of ACh synthesizing activity was inhibited by this compound. The rate of ACh synthesis increased linearly with increasing concentrations of choline and began to saturate near 50 µM choline. Synthesis of GABA from labelled glutamate was also detected. This synthesis was linearly related to glutamate concentration and began to plateau in the range of 25 µM glutamate. The synthesis of ACh and GABA from 5 µM choline and 50 µM glutamate, respectively, was linear for at least 30 min. Autoradiographic studies demonstrated specific accumulation of labelled GABA by a subpopulation of neurons. GABA uptake was almost completely eliminated by diaminobutyric acid (1 mM) but unaffected by β-alanine (2 mM).

The synthesis and accumulation of both compounds from their respective precursors showed a similar dependence on culture age; the rate of synthesis increased constantly during the first 3 weeks the cortical cells were in culture, thereafter, it declined. The addition of muscle or various other nonneuronal cells caused only a slight enhancement in the ability of cortical cells to synthesis ACh and GABA. The synthesis of ACh and GABA is interpreted to be supportive of the use of these compounds as neurotransmitters by cortical neurons in vitro. Various lines of evidence have supported the presence of GABAergic neurons in the cerebral cortex in vivo; however, the existence of cholinergic neurons is less certain. The presence of cholinergic function in culture could reflect either the intrinsic presence of cholinergic cortical neurons or the result of developmental influences on a subpopulation of neurons.

143.8 SIMULTANEOUS DETERMINATION OF ACETYLCHOLINE AND CHOLINE IN NEURONAL TISSUE BY HPLC WITH ELECTROCHEMICAL DETECTION. P. E. Potter*, J. L. Meek and N. H. Neff. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

We have developed a rapid, simple, sensitive, and specific method for the determination of acetylcholine (ACh) and choline (Ch) using HPLC with electrochemical detection. The method is based on the separation of ACh and Ch by reverse phase HPLC and mixing the effluent with acetylcholinesterase and choline oxidase, which converts choline to betaine and 2 H_2O_2. Production of H_2O_2 is continuously monitored electrochemically.

ACh and Ch are separated on a 15 cm Bio-Rad Bio-Sil ODS-5 column with a mobile phase of 0.01M sodium acetate buffered to pH 5 with 0.02M citric acid and containing 0.0025M tetramethylammonium chloride and 4 mg/L sodium octyl sulfate, at a flow rate of 0.8 ml/min. A solution of 0.2M sodium phosphate, pH 8.5, containing acetylcholinesterase (Sigma, 2 U/ml) and choline oxidase (Sigma, 1 U/ml), is added to the effluent from the column at a flow rate of 0.5 ml/min. Ch and ACh are converted to H_2O_2 in a postcolumn reaction coil (30 m of 30 gauge Teflon tube to give a delay of 2.5 min). The H_2O_2 produced is detected by oxidation at a potential of +0.5V across a platinum electrode in a Bio Analytical Systems LC4-A electrochemical detector.

Under these conditions the retention times of Ch and ACh are 4.5 min and 13.5 min respectively. 3-Dimethylamino-1-propanol (retention time 5.5 min) may be used as an internal standard. If determination of only ACh is desired, sodium octyl sulfate can be omitted from the mobile phase and the concentration of tetramethylammonium chloride increased to 0.005M. This reduces the retention time of ACh to 4 min.

The sensitivity of detection with this method is 1 pmol for Ch and 2 pmol for ACh. When pure acetylcholinesterase is used, choline esters such as butyrylcholine, α-methylacetylcholine, valerylcholine and phosphocholine are practically undetectable.

ACh and Ch levels in hippocampal extracts from rats killed by microwave irradiation were .19±.02 and .34±.04 nmol/mg protein (±S.E.M.) respectively. These correspond to levels obtained by gas chromatography-mass spectrometry (Costa et al., J. Clin. Pharmacol. 21:2565, 1981).

HPLC-EC offers many advantages over conventional methods for determination of ACh. Both ACh and Ch can be measured in the same sample, yet it uses equipment commonly found in many laboratories. Because no prior derivatization or separation of ACh and Ch is required, sample preparation is rapid. The method is simple and reproducible and offers excellent sensitivity and specificity.

143.9 THE CHOLINE CYCLE: EVIDENCE FOR BIOSYNTHESIS OF CHOLINE FROM SERINE AND METHIONINE IN RAT BRAIN. J.K. Blusztajn* and R.J. Wurtman
M.I.T., Cambridge, MA 02139

We have previously shown that bovine and rat brain synaptosomes synthesize phosphatidylcholine (PC), by sequential methylation of phosphatidylethanolamine (PE), catalyzed by an enzyme, phosphatidylethanolamine N-methyltransferase (PeMT), which utilizes S-adenosylmethionine (SAM) as a methyl donor. PC synthesized by this pathway (apparent Vmax = 17 pmol/mg protein/10min.) has a much shorter half-life than other, previously-described synaptosomal pools of PC, such that after 30 min. of incubation 30% of the newly-formed PC was hydrolyzed to free choline (Ch). The specific activity of the newly-formed Ch was 88 ppm, whereas that of the newly-formed PC was only 2 ppm, so that the relative enrichment of the synaptosomal Ch pool was 44-fold higher than that of PC. The rate of PE methylation was markedly stimulated by monoamines (Leprohon et al. in this volume).

When synaptosomes were incubated with 20 μM [^{14}C-U]-serine (S), incorporation of this amino acid into phospholipids proceeded linearly for 10-15 min. After 10 min. of incubation the radioactivity in the ethanolamine moiety of PE was 1.25 fold higher than that of S moiety of the phosphatidylserine (PS) (1.4 pmol/mg protein). (The incorporation of S into phospholipids was stimulated by Ca++ and Ni++ and was inhibited by Zn++; monoamines had no effect on this process; it could be increased ten-fold by increasing the serine concentration.) Thus the 14C-S-derived PS is rapidly decarboxylated to PE. This PE may serve as a substrate for the PeMT.

We conclude that rat brain synaptosomes synthesize Ch de novo utilizing S and methionine (M) as its ultimate precursors. S serves as a donor of the ethanolamine portion of the Ch molecule and M, after conversion to SAM, donates the three methyl groups. Some of this newly-formed Ch may be available for neuronal acetylcholine synthesis. It is possible that the incorporation of S into PS and the liberation of Ch from PC is catalyzed by base exchange enzyme, such that the phosphatidic acid moiety of the PS and PC is recycled.

143.10 THE IMMUNOHISTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE-LIKE IMMUNOREACTIVITY AT THE LIGHT AND ELECTRON MICROSCOPIC LEVELS WITHIN THE CENTRAL NERVOUS SYSTEM OF THE GUINEA PIG. B. Maley, R. Elde, B. Wainer and A. Levey Univ. of Minnesota Sch. of Med., Minneapolis, Mn. 55455 and Univ. of Chicago, Chicago, Il. 60637

Monoclonal antibodies raised in response to the bovine form of choline acetyltransferase (ChAT) have been previously demonstrated to be specific for the enzyme and to exhibit cross-reactivity to a variety of mammalian forms using biochemical methods (Levey et al., Brain Res., 234:469,1982). It was the purpose of the present investigation to study its use as a immunohistochemical marker in one species, the guinea pig. Using a modification of the peroxidase, anti-peroxidase (PAP) method we have identified ChAT-like immunoreactivity throughout the central nervous system of the guinea pig.

Subsequent to a perfusion of 4% paraformaldehyde-0.1% glutaraldehyde in 0.1M phosphate buffer, 100 μm coronal sections of several guinea pig brains were stained using anti-ChAT, followed by the PAP procedure, reacted with 3,3'-diaminobenzidine and hydrogen peroxide. The sections were then either dehydrated and mounted on gelatin coated slides or embedded in plastic for ultrastructural studies. Control sections incubated either with rat IgG or without the primary antibody were run concurrently with the remainder of the tissue and typically lacked immunostaining.

Examination of the sections revealed an extensive network of immunostained neurons throughout the rostrocaudal extent of the guinea pig brain. Nuclear regions containing ChAT immunostained neurons included the nucleus of the diagonal band of Broca, caudate nucleus, putamen and all the cranial nerve motor nuclei. In addition, immunostained fibers were visible as fascicles of cranial nerve motor nuclei and as diffuse fibers within the cortex. At the ultrastructural level ChAT immunoreactivity could be found within the neuronal cell body and large primary dendrites.

Results of the present investigation indicate a network of ChAT immunostained neurons using a monoclonal antibody in the guinea pig similar in distribution to those previously described in the cat and the rat. In addition, we have demonstrated that the monoclonal antibody to ChAT does recognize the enzyme from other species.

143.11 TOPOGRAPHIC ANALYSIS OF THE INNERVATION OF THE RAT NEOCORTEX AND HIPPOCAMPUS BY THE BASAL FOREBRAIN CHOLINERGIC SYSTEM. M. McKinney*, J. Hedreen* and J.T. Coyle. Div. of Child Psychiatry and Depts. of Neuroscience, Psychiatry, Pathology and Pharmacology, Johns Hopkins School of Medicine, Baltimore, MD 21205

The innervation of rat cerebral cortex (Cx) and hippocampus (Hip) by a contiguous system of large neurons in the basal forebrain located in the globus pallidus (GP), lateral preoptic area (LPA), diagonal band (DB) and medial septum (MS) was topographically mapped by retrograde tracer methods with horseradish peroxidase (HRP) and with fluorescent dyes, fast blue (FB) and nuclear yellow (NY). Acetylcholinesterase (AChE) histochemical staining was performed 5 hrs after pretreatment with an AChE inhibitor to reveal AChE reactive cell bodies in the basal forebrain complex. In addition, the effects of excitotoxin lesions to the rostral and caudal aspects of the basal complex on the specific activity of choline acetyltransferase (CAT) was determined in subareas of the neocortex and in the Hip.

Excitotoxin lesions affecting the MS and DB caused a 64%* reduction in CAT activity in the Hip, 32%* in the occipital Cx, 13%* in the lateral Cx and 6% in frontal cortex; in contrast, lesion of the ventral medial GP caused a 59%* decrease in CAT in the frontal Cx, 50%* in the lateral Cx, 20%* in the occipital Cx and 7% in the Hip. Discrete injections of retrograde tracers in the various areas of the Cx and Hip revealed a gradient of distribution of labeled neuronal cell bodies in the basal forebrain complex consistent with the lesion studies. While labeled cells were noted virtually throughout the basal forebrain complex after discrete injections in the frontal Cx on one hand or the Hip on the other, the former caused the greatest percentage of labeled cells located in the GP whereas the latter was associated with the greatest percent of labeled cells in the MS/DB. Collatoralization of these projections was further demonstrated in studies of separate and non-overlapping injections of FB and NY in the frontal Cx and in the parietal Cx. Consistent with results from composite maps of single injection cases, the distribution of FB and NY labeled cells in the GP overlapped after the dual injections. Cell counting techniques indicated that nearly 20% of the retrograde labeled cells in the GP were unequivocally dually labeled with NY and FB. Thus, we conclude from these studies that the neurons within the basal forebrain cholinergic complex exhibit a topographically organized pattern of innervation of the Cx and Hip but that a significant degree of collatoralization of these projections occurs. 143.12 KINETIC STUDIES OF CHOLINE ACETYLTRANSFERASE AND MUSCARINIC RECEPTOR BINDING IN AGED C57BL/6J MICE. Steven B. Waller* and Edythe D. London (Spon: J.E. Moreton) Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, National Institutes of Health, Baltimore City Hospitals, Baltimore, Maryland 21224.

We have demonstrated previously that choline acetyltransferase (ChAT) activity is higher in the cerebral cortices, striata and hippocampi of aged C57BL/6J mice than in the same brain regions of young mice (S.B. Waller, D.K. Ingram, M.A. Reynolds and E.D. London, Abstr. Soc. Neurosci. 7:186, 1981). The current investigation was initiated to determine if these increases in regional ChAT activities reflect changes in the Km's for substrates or in Vmax, and whether they are associated with changes in muscarinic receptor binding.

Specific activities of ChAT were determined radiometrically in brain regions of 6-, 12- 18- and 24 month old male C57BL/6J mice. The effects of substrate concentrations on ChAT activity were studied by varying the concentrations of acetyl-CoA and choline chloride in enzyme incubations. Km and Vmax were calculated by the Eadie-Hofstee method. The densities of muscarinic binding sites (Bmax) and the ratio of high to lower affinity binding sites were measured with [3-H]quinuclidinyl benzilate as the ligand in displacement assays with carbamylcholine, as previously described (M. McKinney and J.T. Coyle, J. Neurosci. 2:97,1982).

Kinetic studies of ChAT activity revealed that age differences were due to elevated Vmax values in older mice. These age-related increases in Vmax for ChAT in the cerebral cortices and striata were associated with significant reductions in muscarinic receptor densities. For example, in the cerebral cortices, the Vmax for ChAT was significantly higher in 18- and 24 month old mice than in younger mice, while the total muscarinic receptor density was significantly reduced in 18- and 24 month old mice compared with values in younger animals. However, in the hippocampus, both the Vmax for ChAT and the Bmax for muscarinic receptor binding were significantly higher at 24 months than in younger animals. There were no age differences in the ratios of high to lower affinity muscarinic binding sites.

The results indicate that with aging in the C57BL/6J mouse, regional changes occur in the concentration of ChAT protein and density of muscarinic receptors. There is no evidence for changes in affinities for the enzyme substrates or receptor ligands. Further studies may help elucidate the relationships between age effects on these pre- and postsynaptic markers for cholinergic transmission.

144.1 EVIDENCE FOR TWO KINDS OF ACETYLCHOLINE RELEASE BY AN IDENTIFIED RETINAL NEURON. Richard H. Masland, Massachusetts General Hospital, Harvard Medical School, Boston MA 02114.

The cholinergic neurons of the rabbit retina make up a small subset of the amacrine cells. They are positioned with mirror symmetry lining the inner synaptic layer, about half of them in the conventional position of amacrine cells and half "displaced" to the ganglion cell layer (Masland and Mills, J. Cell. Biol, 1979; Hayden et al., Science, 1980; Vaney et al., J. Comp. Neurol, 1981).

In an attempt to understand the functional meaning of this peculiar geometry, I have been studying the light-stimulated release of 3H-acetylcholine from isolated retinas incubated in the presence of 3H-choline and then rapidly superfused in a small-volume chamber. When the retina is stimulated by flashing light, the rate of appearance of 3H-ACh in the medium increases, with a latency shorter than the temporal resolution of the system (5 sec.) When the flashing light is turned off, the rate of appearance of 3H-ACh rapidly returns to basal levels. A 1 minute stimulation with steady light causes a burst of ACh release at stimulus onset and a second burst at stimulus cessation. That the bursts represent separate ON and OFF transients -- rather than a resultant of slower, opposing releases -- was shown by experiments carried out in the presence of 2-amino-4-phosphonobutyrate, an agent known to selectively eliminate the transmission of ON responses to the proximal retina: steady light then caused ACh release only at stimulus OFF. Taken together, these results indicate that ACh acts in the retina as a conventional (relatively fast) neurotransmitter, with enhanced release occurring at the moments of light illumination or dimming

There is a substantial release of ACh in the dark: the peak light-evoked release exceeds the dark release by only a factor of 5. Exposure of the retina to medium containing 20 mM Mg++ and 0.2 mM Ca++ entirely prevented the release of ACh evoked by light or by stimulation with large (3 mA) electrical currents, but it depressed the release of ACh in the dark by only 35%. Evidence from the neuromuscular junction (Katz and Miledi, Proc. Roy. Soc. Lond., 1981 suggests that the resudual release may represent non-quantal ACh leakage. This possibility is supported by the finding of Ariel and Daw (J. Physiol., 1982) that some ganglion cells have their spontaneous activity, but not their light evoked response, enhanced by anticholinesterase -- implying a light-independent release of ACh.

It thus appears that the cholinergic amacrine cells release ACh in two ways. The first is rapid and conveys information about changes in illumination from cell to cell. The second may be a non-quantal background leak, unaffected by the functional state of the neuron.

144.2 AFFINITY FOR ^{3}H-DESIPRAMINE BINDING CORRELATES WITH THE POTENCY OF INHIBITION OF ^{3}H-NOREPINEPHRINE UPTAKE BLOCKERS BUT NOT SUBSTRATES OF UPTAKE. S. Arbilla*, M. Sette*, R. Raisman*, M. Briley*, and S.Z. Langer. Dept. of Biology, Synthélabo-LERS, 75013 Paris, France.

^{3}H-desipramine (^{3}H-DMI) binds to specific high-affinity sites in the peripheral and central nervous systems. Lesion experiments in the brain using 6-OH dopamine and in the peripheral nervous system using surgical denervation have shown that high-affinity ^{3}H-DMI binding sites are localised on noradrenergic nerve terminals. As previously reported for the heart and brain, the inhibition of ^{3}H-DMI binding, in the rat vas deferens, by blockers of ^{3}H-norepinephrine (^{3}H-NE) uptake is highly correlated with their potency at inhibiting ^{3}H-NE uptake (Table 1)(correlation coefficient =0.95 n=6). Previous studies have not, however, investigated the ^{3}H-DMI binding and ^{3}H-NE uptake potencies of substrates for the neuronal uptake of ^{3}H-NE. Investigation of ^{3}H-NE uptake substrates such as, dopamine, tyramine, metaraminol and norepinephrine showed, however, that they were much less potent at inhibiting the binding of ^{3}H-DMI than would be predicted from their potency at blocking the uptake of ^{3}H-NE into the vas deferens. This result suggests that although the ^{3}H-DMI binding site is associated with the uptake mechanism for ^{3}H-NE, it would seem that the ^{3}H-DMI binding site and the substrate recognition site for the neuronal uptake of ^{3}H-NE are not identical. It is interesting to note that a similar situation exists for the ^{3}H-imipramine binding site and the uptake of serotonin.

Table 1.	IC_{50} (^{3}H-DMI binding) (μM)	IC_{50} (^{3}H-NE uptake) (μM)
Inhibitors		
Desipramine	0.005	0.037
Nisoxetine	0.008	0.068
Imipramine	0.117	0.713
Cocaine	4.400	4.270
Fluoxetine	4.600	10.110
Substrates		
Dopamine	7.500	1.780
Tyramine	30.000	2.170
Metaraminol	34.500	0.399
(-)Norepinephrine	112.000	2.600

These results suggest that ^{3}H-DMI may bind to the recognition site of a unit that modulates neuronal uptake of NE, rather than to the substrate recognition site of the transporter.

144.3 ATP HYDROLYSIS MEDIATES CALCIUM EFFECTS ON NEURONAL MEMBRANE UPTAKE OF ^{3}H-(-)NOREPINEPHRINE IN RAT CEREBRAL CORTEX. E.D.Hendley Y.H. Ehrlich, S.R. Whittemore* and D.G. Atwater*. Univ. Vermont Coll. Med., Burlington, VT 05405.

The uptake of ^{3}H-(-)norepinephrine was determined in synaptosomal preparations (resuspended P_2) of rat cerebral cortex. These were incubated for 1 min at 30°C, in Krebs-Ringer bicarbonate-buffered medium (KRB) containing EDTA, ascorbic acid and nialamide (10uM). Cocaine, 10 uM, was used to define specific, neuronal membrane accumulation of ^{3}H-(-)norepinephrine at 4 concentrations, from 0.05 to 0.2 uM. Vacuum filtration on Millipore filters (0.45u pore size)was used and the kinetic constants, apparent Km and Vmax were determined. We tested the effects on uptake of removal of either Ca^{++} or Mg^{++}, or both, from whole KRB, and confirmed the findings of T.D. White (J. Neurochem. 24:1037, 1975) using whole brain synaptosomes, that removing both divalent cations from the medium reduced Vmax for uptake of norepinephrine, and that adding back either Ca^{++} or Mg^{++} restored uptake rates to the same levels as with whole KRB. The ability of Mg^{++} (1.2 mM), in the absence of Ca^{++}, to restore uptake rates was not affected by the addition of APP(NH)P, 200 uM, a non-hydrolyzable analog of ATP. In contrast, the ability of Ca^{++} (1.275 mM), in the absence of Mg^{++}, to restore uptake rates was markedly reduced by the addition of APP(NH)P. We concluded that Mg^{++}, in the absence of Ca^{++}, alters uptake by means of an ion effect, whereas Ca^{++}, in the absence of Mg^{++}, appears to require the hydrolysis of ATP. The ID_{50} for APP(NH)P inhibition of this Ca^{++}-induced effect on uptake was approximately 20 uM. Inhibition of uptake by APP(NH)P in Mg-free KRB was similar whether Ca^{++} concentration in the medium was 1.275 or 2.55 mM. Experiments currently in progress are designed to test whether the effects of Ca^{++} described above involve a protein kinase-mediated protein phosphorylation, or an ATPase-mediated hydrolysis of ATP, both of which processes can be blocked by use of APP(NH)P.

144.4 IDENTIFICATION OF A SPECIFIC BINDING SITE FOR RESERPINE ON CHROMAFFIN GRANULE MEMBRANES. James A. Weaver* and Jean D. Deupree. Dept. of Pharmacology, Univ. of Neb. Med. Ctr., Omaha, NE 68105.

Reserpine is a specific, competitive inhibitor of biogenic amine transport into neurosecretory vesicles which suggests the existence of a specific binding site for reserpine on the amine transporter. This binding site for reserpine was identified and characterized by conducting ^{3}H-reserpine binding assays with bovine adrenal chromaffin granule ghosts in 0.3 M sucrose containing 1.0 nM ^{3}H-reserpine (28 Ci/mmole), 50 mM N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES) pH 7.5, 0.1 mM EDTA, 4.0 mM $MgCl_2$ and 4.0 mM ATP at 30°C. Reserpine binding was initiated by addition of chromaffin granule ghosts to this assay medium and terminated, after ^{3}H-reserpine binding reached equilibrium, by filtration. Under these assay conditions reserpine, harmine and norepinephrine produced a dose dependent inhibition of ^{3}H-reserpine binding with potencies identical to those observed for the inhibition of catecholamine transport by each compound. These results suggest that specific binding of reserpine to the catecholamine transporter of chromaffin granules may be analyzed by determining the difference between ^{3}H-reserpine binding in the presence and absence of saturating concentrations of norepinephrine. Further evidence that reserpine was binding to the catecholamine site on the transporter was that a) the Kd (7 ± 1 nM) obtained for catecholamine sensitive reserpine binding was similar to the Ki (2.0 ± 0.3 nM) obtained for inhibition of catecholamine transport by reserpine, b) the time required for specific reserpine binding to reach equilibrium was identical to the time required for maximal inhibition of catecholamine transport by reserpine, and c) the binding site density (18 ± 5 nmoles/mg protein) was in the predicted range. Specific reserpine binding to chromaffin granules was found to be dependent upon the presence of Mg^{++} and ATP and inhibited by an uncoupler of oxidative phosphorylation, carbonylcyanid-p-trifluoromethoxy phenylhydrazone (FCCP). These results suggest that binding of reserpine to the catecholamine site on the biogenic amine transporter of chromaffin granules can be analyzed in vitro and that binding is dependent on the presence of Mg^{++}, ATP and/or an electrical potential across the granule membrane. (This research was supported by NIH, Grant No. 15157.)

144.5 PROPERTIES OF SYNAPTOSOME-STORED ^{3}H-DOPAMINE AND ^{3}H-NOREPINEPHRINE. G.S. Takimoto*, J.D. Stittsworth, Jr. and J.K. Stephens* (SPON: D. Turriff). Department of Biomedical Sciences, University of Illinois College of Medicine at Rockford, Rockford, IL 61107.

Striatal and hypothalamic synaptosomes were prepared from striatal slices incubated in the presence of ^{3}H-dopamine (DA) and hypothalamic slices incubated in the presence of ^{3}H-norepinephrine (NE). Synaptosomes which were prepared from tissue slices incubated in the presence of ^{3}H-DA + nomifensine (striatum) or ^{3}H-NE + desmethylimipramine (hypothalamus) were utilized as blanks and retained approximately 15% of the ^{3}H measured in control samples, suggesting that ^{3}H-DA and ^{3}H-NE were preferentially accumulated by their respective nerve terminals. When the loaded synaptosomes were exposed to 0.1-10μM reserpine for time periods up to 20 minutes, the spontaneous efflux of ^{3}H-DA was greatly accelerated, whereas the spontaneous efflux of ^{3}H-NE was unaffected. Measurement of vesicular and extravesicular stored ^{3}H-NE by employing a hypotonic lysis procedure indicated that ^{3}H-NE did not accumulate in the extravesicular compartment subsequent to treatment with reserpine. However, the accumulation of ^{3}H-DA and ^{3}H-NE by striatal and hypothalamic synaptosomes not subjected to the loading procedure could be prevented in the presence of reserpine suggesting that the vesicular uptake of transmitter in both tissues was equally susceptible to reserpine inhibition. The spontaneous efflux of ^{3}H-DA could also be enhanced in the presence of the DA uptake blocker, nomifensine, whereas ^{3}H-NE efflux was unaffected by treatment with the NE uptake blocker, desmethylimipramine. Tyramine, d-amphetamine and 53mM KCl effectively enhanced ^{3}H-DA release from loaded striatal synaptosomes, however, under similar incubation conditions using loaded hypothalamic synaptosomes, d-amphetamine and 53mM KCl were less effective releasing agents. ^{3}H-DA and ^{3}H-NE retained by the striatal and hypothalamic synaptosomes were probably not associated with storage sites containing newly-synthesized transmitter since the spontaneous efflux of neither ^{3}H-DA nor ^{3}H-NE was affected by the addition of unlabelled L-tyrosine to the incubation medium. The results suggest that ^{3}H-DA retained by striatal synaptosomes is incorporated into storage sites more susceptible to depletion by reserpine, d-amphetamine and 53mM KCl than ^{3}H-NE retained by hypothalamic synaptosomes under similar experimental conditions. (Supported by Illinois Heart Association grant-in-aid N-17 and BRSG grant 58107)

144.6 RELEASE AND METABOLISM OF DOPAMINE IN STRIATAL DIALISATES OF RATS: EFFECT OF NARCOTIC ANALGETICS AND NEUROLEPTICS. G. Di Chiara and A. Imperato*, Institute of Experimental Pharmacology and Toxicology, Chair of Toxicology, University of Cagliari, Cagliari, Italy.

Brain dyalysis in vivo has been developed by Ungerstedt and collaborators as a means to study the release of dopamine (DA) in vivo. We have applied this technique to the study of the release of dopamine (DA) and of its metabolites by analyzing striatal perfusates with reverse-phase HPLC. Rats were anaesthetized with halothane and stereotaxically implanted with a 200 μm capillary (3 x 50 Amicon Vitafiber Unit) inserted transversally through both striata. Ringer was passed through the capillary at a rate of 2 μl per min. Every 10 min the effluent was collected from the other end of the capillary into 5 μl of 1 N perchloric acid and directly injected into a HPLC apparatus equipped with a reverse-phase (Nucleosyl ODS 5 μm) and with an electrochemical detector (BAS). A citrate-acetate buffer with octyl-sulfate as ion paring reagent was used to measure DA while a similar buffer, but without octyl-sulfate, was used to measure DA-metabolites DOPAC and HVA. Basal release of DA ranged from 14 to 32 pgr in 10 min. Morphine produced a biphasic effect on DA release. While doses of 0.1-0.25 mg/kg i.v. increased DA-release by more than 100 % the basal levels, higher doses (1.0 - 20 mg/kg i.v.) decreased it by about 50%. All these effects were blocked or reversed by naloxone (2 mg/kg i.v.). DOPAC and HVA-levels were increased through all the doses tested. Other narcotic analgetics (methadone, dextromoranmide) showed a similar pattern. Apomorphine (0.1 mg/kg) administered at the peak of the morphine effect (0.25 mg/kg s.c.) rapidly dropped DA-release to levels lower than the basal ones. These results suggest that narcotic analgetics exert opposite effects on DA-transmission, stimulating DA-release at low doses and depressing it at higher ones. Classic neuroleptics also had a biphasic effect on DA-release. Thus haloperidol while at higher doses (0.1 - 2 mg/kg i.v.) reduced DA-release up to 80%, at lower doses (0.01-0.025 mg/kg i.v.) increased DA-release. These results indicate that classical indexes of DA-function such as DA synthesis and DA-firing are only indirect since do not necessarily reflect the actual release of DA from pre-synaptic terminals. The present method seems to be adeguate to estimate this fundamental parameter.

144.7 UPTAKE AND PROCESSING OF ANGIOTENSINOGEN BY NEUROBLASTOMA CELLS IN CULTURE. D L Clemens, T. Okamura*, and T. Inagami. Dept. of Biochemistry, Vanderbilt University, Nashville, TN 37232.

All of the components of the renin-angiotensin system have been reported in brain tissue, leading to the concept of an intraneuronal pathway of angiotensin formation. However, study of the pathway in brain tissue is complicated by the inevitable heterogeneity and vascular contamination of brain tissue. Cloned, cultured cells offer obvious advantages of cellular homogeneity and ease of experimental manipulation. We have screened a variety of neuroblastoma cells of rat and mouse origin and found many that contain renin, angiotensin-converting enzyme, and generate angiotensins (Okamura et al, Proc. Natl. Acad. Sci., U.S.A., 79:6940-6943, 1981). When grown in serum free, defined medium, these cells produce renin substrate and release it into the culture medium. Renin substrate is found predominantly in the culture medium and relatively little is found associated with the neuroblastoma cell pellet. Renin, on the other hand, is not secreted into the culture medium, but is found predominantly in intracellular granules. This situation raises the question of whether neuroblastoma cells can use exogenous substrate for the production of angiotensin I. We have found that exogenous renin substrate added to neuroblastoma cells is taken up by the cells and converted to angiotensin I. The uptake mechanism is energy dependent (can be blocked by 2,4 dinitrophenol and 2-deoxyglucose) and shows saturable kinetics. The uptake and conversion of angiotensinogen to angiotensin I is observed only in cell lines with specific renin acitvity, and is not blocked by lysomotropic agents (NH_4Cl, imidazole, or chloroquine). The intracellular site of action of renin in the pathway is substantiated by the failure of specific anti-renin antisera to block the generation of angiotensin by intact neuroblastoma cells, whereas angiotensin generation by lysed cells is totally inhibited by the specific antirenin antisera.

It is concluded that neuroblastoma cells have a capacity for receptor mediated uptake of renin substrate and for specific processing of the prohormone to angiotensin I. The specific uptake and proteoytic processing in neuroblastoma cells may reflect a process with a counterpart in normal neuronal cells.

144.8 COPPER CHELATES: POTENT RELEASERS OF LHRH FROM ISOLATED HYPOTHALAMIC GRANULES. G.E. Rice* and A. Barnea. Green Ctr. Reprod. Sci., Depts. of Ob-Gyn. & Physiol., Univ. of Texas Health Sci. Ctr at Dallas, Dallas, TX 75231.

It has been shown that administration of copper salts stimulates secretion of LHRH from the hypothalamus. We have recently shown that copper, in the form of CuATP, is an extremely potent releaser of LHRH from isolated hypothalamic granules. As ATP appears to be a requirement for the release of other peptides and biogenic amines from secretory granules, we have addressed the question: What is the role of ATP in the copper-stimulated release of LHRH from isolated hypothalamic secretory granules? Granules were prepared from hypothalami of adult male rats and incubated at 37° for 3 min in buffered medium (control), buffered medium containing $CuCl_2$ (0.5mM), or buffered medium containing $CuCl_2$ and one of the following chelating agents: ATP (1mM); tartarate (1.5mM); histidine (1mM); BSA (1mM) or EDTA (0.5mM). At the end of the incubation, LHRH contained in the granules was separated from LHRH released into the medium by gel filtration chromatography. The LHRH recovered in the granule fraction was quantified by RIA. LHRH release (% above control, mean ± SE) was as follows:

	$CuCl_2$	CuATP	CuTartarate	CuHistidine	CuBSA	CuEDTA
Release	13 ± 5	53 ± 5	46 ± 6	11 ± 5	16 ± 2	-2 ± 4

Both CuATP and CuTartarate markedly stimulated LHRH release from the granules and moreover did so with a similar potency. In contrast, CuHistidine, CuBSA, CuEDTA and $CuCl_2$ were ineffective. In addition, we assessed the temperature requirement for the CuATP-stimulated release of LHRH and found that release was 4% from granules incubated at 4°C, 15% at 23°, 13% at 30° and 58% at 37°C. These results are suggestive that a phase-change occurs in the phospholipids of the granule membrane between 30 and 37°C and that such a change facilitates CuATP-stimulated release of LHRH. In summary, we demonstrate that chelates of copper stimulates LHRH release from isolated hypothalamic granules and that this stimulation is related to the equilibrium constants (K_1) of the complexes. LHRH release is stimulated by copper chelates having a $K_1 \leq 10^6$ (CuATP, CuTartarate) but not by those having a $K_1 \geq 10^9$ (CuHistidine, CuBSA, CuEDTA). As it is known that in biological systems copper is present in a chelated form, our results are consistent with the view that chelated copper plays an important role in the release of LHRH from hypothalamic neurons.

144.9 TWO DIFFERENT FORMS OF INACTIVE RENIN IN NEUROBLASTOMA CELLS. T. Inagaki*, D.L. Clemens, and T. Inagami. Dept. of Biochemistry, Vanderbilt University School of Medicine, Nashville, TN 37232.

The demonstration of the coexistence of renin and angiotensins in neuroblastoma cells (T. Okamura et al., Proc. Natl. Acad. Sci., 78:6940, 1981, M.C. Fishman et al., Science, 214:921, 1981) suggested the possible intracellular mechanism of angiotensin formation in the central nervous system in contrast to the well known extracellular mechanism in plasma. We have investigated a inactive form of renin in order to clarify a regulatory mechanism of renin activity in the cells. Mouse neuroblastoma cells Neuro 2-a had a high level of renin activity, while rat neuroblastoma cells B103 showed no renin activity in the cell lysate or in culture medium. However, brief treatment of cell lysate of B103 with 1.5 M NaCl/40 mM dithiothreitol was found to cause generation of a large amount of renin activity, whereas Neuro 2-a showed only a minor degree of activation upon the NaCl/dithiothreitol treatment. Sephadex G-200 column chromatography of Neuro 2-a lysate showed that NaCl/dithiothreitol activatable inactive renin was found in fractions corresponding to 110,000 molecular weight. Moreover, octyl-sepharose chromatography of the cell lysate also showed an existence of trypsin activatable prorenin which can be activated by trypsin. The molecular weight of the prorenin was estimated as 55,000 by gel filtration on a calibration column of Sephadex G-200. Furthermore, NaCl/dithiothreitol activatable inactive renin was not activated by trypsin; trypsin activatable prorenin was not activated by NaCl/dithiothreitol. These experiments indicated that NaCl/dithiothreitol activatable inactive renin is different from trypsin activatable prorenin. In a separate experiment, renin inhibitor was separated from Neruo 2-a lysate by anti-renin IgG-Sepharose and renin-agarose affinity chromatography. The finding suggested that NaCl/dithiothreitol activatable inactive renin is renin-inhibitor complex. The present results indicated that neuroblastoma cells have two different systems of regulation of renin activity; renin-inhibitor system and prorenin-renin system.

144.10 IN VIVO RELEASE OF NEUROHYPOPHYSEAL PEPTIDES FROM RAT SPINAL CORD Q.J. Pittman, J. Simpson*, D. Ko* and K. Lederis*, Dept. of Pharmacology & Therapeutics, Faculty of Medicine, University of Calgary, Calgary, Alberta. Canada.

There is now evidence that the neurohypophyseal peptides arginine vasopressin (AVP) and oxytocin may function as neurotransmitters in brain. Immunocytochemical studies have established the presence of immunoreactive AVP or oxytocin in neurons in the hypothalamus and in neuronal processes throughout widespread areas of the brain. In spinal cord, AVP and oxytocin fibers appear to innervate dorsal horn and the intermediolateral cell columns. To further characterize this hypothalamic-spinal projection, we have perfused the spinal cord in vivo and carried out radioimmunoassays for AVP and oxytocin in the perfusate.

In urethane-anesthetized rats, a polyethelene cannula was introduced through the cisterna magna and threaded down the spinal cord in the sub-dural space. Through this cannula a KREBS solution was infused at 30 µl/min. A second, pull cannula was placed at the level of the cisterna magna to withdraw fluid at an identical rate. A plug of petroleum jelly placed in the 4th ventricle prevented contamination of the perfusate by cerebrospinal fluid from more rostral areas. Three 30 min. perfusions were carried out; after the first 30 min. sample was collected, the paraventricular nucleus (PVN) was stimulated through a bipolar electrode for the duration of the second perfusion period. Following termination of the electrical stimulation, a third perfusion was carried out for a final 30 min. period.

Perfusates were assayed for AVP or oxytocin using sensitive radioimmunoassays which show little cross-reactivity for other related peptides. In control perfusates, AVP levels ranged from 0.87 - 22.67 pg/ml; oxytocin levels ranged from 2.3 - 8.5 pg/ml. During stimulation of the PVN, levels of both AVP and oxytocin were elevated to 2.44 times (AVP, n = 6) and 19 times (oxytocin n = 6) control levels. The third perfusate showed reduced levels of these peptides approximating levels seen in the first control perfusates. The increase in the levels of these peptides during stimulation was not likely due to contamination of spinal perfusate by blood-borne peptides. When AVP was infused into the jugular vein at a rate of 0.01 µg/kg/min. for the duration of a 30 min. perfusion, AVP levels of the spinal perfusates were not elevated.

These studies support the existence of a hypothalamic-spinal cord pathway and provide further evidence that the neurohypophyseal peptides may act as transmitters.

144.11 MEMBRANE DEPOLARIZATION RESULTS IN BOTH SP RELEASE AND DECREASED NET PEPTIDE SYNTHESIS IN SYMPATHETIC NEURONS IN VITRO. J.A. Kessler, J.E. Adler, W.O. Bell* and I.B. Black. Div. of Developmental Neurology, Cornell University Medical College, New York, New York 10021.

Mechanisms regulating the putative peptide neurotransmitters, substance P (SP) and somatostatin (SS), were compared in a variety of neuronal populations in culture. SP increased more than 25-fold within 48 hours in sympathetic neurons in the rat superior cervical ganglion (SCG) in vitro, and peptide levels remained elevated in cultures maintained for 4 weeks. Identity of the peptide was authenticated by combined high pressure liquid chromatography-radioimmunoassay. Veratridine prevented the increase in SP in vitro, and tetrodotoxin blocked the veratridine effect, suggesting that sodium ion influx and membrane depolarization prevent the increase in SP.

To investigate the mechanisms mediating the effects of membrane depolorization, SP release into the culture medium and ganglion peptide content were simultaneously examined after veratridine treatment. Veratridine-(or potassium-) induced membrane depolarization released SP from sympathetic neurons by a calcium-dependent process. Consequently, at least some of the effects of the drug can be attributed to release and subsequent depletion of ganglion peptide. However, the inhibitory effects of veratridine on ganglion peptide content (150 pg less than control) were far greater than could be accounted for by the quantity of peptide released (30 pg), suggesting a separate effect on net synthesis (synthesis less catabolism) of SP. Viewed in conjunction with previous studies in vivo, our observations suggest that trans-synaptic impulses, through the mediation of post-synaptic sodium flux, release SP from sympathetic neurons and also regulate peptide metabolism.

To determine whether the processes regulating SP in sympathetic neurons reflect generalized mechanisms, a different peptide transmitter, SS, was examined in sympathetic neurons, and SP was examined in a different neuronal population, special sensory neurons in the nodose ganglion. Explantation resulted in significant increases in SP in both sympathetic and sensory neurons, and in SS in sympathetic neurons. In each instance the increase was prevented by veratridine, and tetrodotoxin blocked the veratridine effect. Our observations suggest that there may be a group of regulatory mechanisms which govern peptide transmitter metabolism throughout the nervous system. 144.12 SEQUENTIAL SECRETION (QUEUING) OF COORDINATELY SYNTHESIZED NEUROPEPTIDES. S. Arch and A. Linstedt*. Biological Laboratories, Reed College, Portland, OR 97202.

The bag cell neurons of Aplysia californica synthesize, transport, and secrete a group of polypeptide substances. These molecules may have a common origin in a single translational product. Despite the evidence for coordinate synthesis, we have found that at least two of the posttranslational product peptides are not transported coordinately. After a 6-hr pulse of labeling in ^{3}H-leucine, one of these labeled peptides (AP) appears in transport considerably earlier than the other (ELH). This situation allowed us to examine the organization of the secretory terminal. Since the arrival times at the terminals for the labeled peptides differ, it should be possible to determine if the order of arrival is relevant to access to active secretory sites. The least complex prediction would be that free mixing of vesicles occurs in the terminal and arrival order is not preserved at secretion. In fact, when bag cell organs are challenged with a high $[K^+]_o$ depolarizing medium after both labeled peptides have reached the terminal, only labeled AP (earlier arrival) is secreted in abundance. If a short period of recovery is allowed and a second challenge performed, both labeled peptides are secreted. Thus, free mixing does not appear to occur. Instead, arrival order is maintained as though the vesicles were entering a queue. We have explored the nature of the queuing process by exposing the cells to colchicine or procaine shortly before a first-secretion challenge. Both agents disrupt the order in the queue. Since each is known to affect microtubule organization, there is reason to believe that one element in the constraining structure of the terminal is polymerized and anchored microtubules. While the physiologic significance of secretory queuing is not obvious, its occurrence is entirely consistent with the evidence for extensive fibrous protein structuring in the axonal and terminal cytoplasm of neurons.

145.1 A PRESYNAPTIC LOCUS OF ACTION FOR TETANUS TOXIN: QUANTAL ANALYSIS OF EFFECTS ON MONOSYNAPTIC TRANSMISSION IN MOUSE SPINAL CORD NEURONS IN CULTURE. G. K. Bergey, H. Bigalke* and P. G. Nelson. Lab. of Developmental Neurobiology, NICHD, Bethesda, MD 20205.

Morphological evidence from intact preparations has demonstrated that, after reaching the ventral spinal cord, tetanus toxin moves trans-synaptically to presynaptic endings on the motoneurons. To date, however, no direct physiologic evidence has been presented to establish a presynaptic locus of action for the toxin in the central nervous system where tetanus produces its major effects. We report here the observed presynaptic effects of tetanus toxin on identified monosynaptic connections between pairs of fetal mouse spinal cord neurons grown in dissociated cell cultures.

Intracellular recordings were made with 4 M KAc-filled microelectrodes using conventional bridge circuits. Cultures used for recordings were 4 to 8 weeks old and were washed free of horse serum and placed in MEM with 1% fetal calf serum. Purified tetanus toxin was applied to yield a final concentration of 100 ng/ml. A computer program for on-line analysis of PSPs was used to determine PSP amplitude and quantal parameters using a modified PDP 11/34 computer. Recordings were done in media containing a final concentration of 6 mM calcium and 6 mM magnesium to reduce spontaneous synaptic activity yet permit evoked synaptic transmission.

After a latent period of about 40 to 60 minutes tetanus toxin (100 ng/ml) produced increased excitation characterized by paroxysmal depolarizing events. Inhibitory synaptic transmission was preferentially reduced by tetanus but excitatory transmission was also later reduced and blocked by the toxin. In these studies quantal analysis was restricted to EPSPs selected so that corrections for nonlinear summation were not necessary. Inhibitory postsynaptic potentials were not used for quantal analysis because saturation was often present due to the proximity of the IPSP reversal potential to the resting membrane potential when KAc electrodes were used.

Quantal analysis (sample time 18 to 195 minutes) was performed on 7 monosynaptic excitatory connections at various times after the onset of convulsant action produced by the toxin. The averaged amplitude of the evoked EPSP was noted to progressively diminish while the number of failures increased. The quantal number diminished parallel to the reduction in EPSP size while the mean quantal size was not reduced. Postsynaptic responses to GABA, glycine and glutamate were not affected by the toxin. These results demonstrate that tetanus toxin acts to reduce presynaptic release of transmitter rather than affecting postsynaptic sensitivity.

145.2 TRANSMITTER RELEASE AS A FUNCTION OF HOLDING POTENTIAL AT THE SYNAPSE OF THE BARNACLE PHOTORECEPTOR. Jon H. Hayashi*, John W. Moore, and Ann E. Stuart, Univ. of North Carolina, Chapel Hill, N.C., and Duke Univ., Durham, N.C.

Input/output relations at the photoreceptor (PR)/ second-order (I-cell) synapse in the giant barnacle were obtained by making simultaneous intracellular recordings from the pre- and postsynaptic cells. The axons of the 4 median PRs travel in the median ocellar nerve (MON) to the supraesophageal ganglion where upon entry they arborize abruptly and contact the I-cells. A PR's axon was impaled just before this arborization (about 1/40 λ from the release sites) and an I-cell was impaled in its soma. The MON was led through an extracellular high-resistance barrier separating two chambers; the PRs' terminal voltages could be altered by passing current between these chambers with bath electrodes. The potential of the impaled PR was fed back to this current-passing circuit in order to generate square voltage steps in the PRs. In separate experiments, simultaneous recordings were made from 2 PRs, one providing feedback and one following. Since waveforms in the 2 PRs were similar in amplitude and rise time, we expected that equivalent control was exerted over all 4 PRs.

Depolarization of the PRs causes them to release a transmitter that hyperpolarizes the I-cell (Stuart & Oertel, Nature 275:287, 1978). When we held the PR voltage at its dark resting potential (-60mV), depolarizations from this level evoked hyperpolarizations in the I-cell that decayed even though the PR's voltage was maintained. Hyperpolarizations of the PR caused a slight (3-5mV), steady depolarization of the I-cell. Thus there is continuous release from this synapse in the dark. To determine the transfer function, the PRs were held 10-20mV negative to the dark resting potential, where release is shut off, then depolarized from this level. The peak responses of the I-cell were plotted as a function of the voltage to which the PR was stepped. Input/output relations rose exponentially, producing a 10-fold change in I-cell voltage for a presynaptic change ranging from 5.4-11.2 mV (n = 7).

When the PR's holding potential was changed to new steady levels, the position of the input/output curve shifted along the PR voltage axis. In addition, the maximal response of the I-cell increased as the PR's holding potential became more negative. This "synaptic adaptation" occurred in less than 0.5 sec of a shift in potential. It was observed over the physiological range of presynaptic potentials. Thus the range of presynaptic voltages over which the PR releases transmitter changes with a PR's steady membrane potential, normally set by the intensity of incident light.

145.3 **PRESYNAPTIC CALCIUM DIFFUSION AND TRANSMISSION AT THE SQUID GIANT SYNAPSE.** R.S. Zucker and N. Stockbridge*, Physiology-Anatomy Dept., Univ. of Calif., Berkeley, CA 94720 and Physiology Dept., Duke Univ., Durham, N.C. 27710.

We have applied a mathematical model for intracellular calcium movements, developed initially for the frog neuromuscular junction, to explain a number of observations obtained at the squid giant synapse (Charlton *et al.*, 1982). A presynaptic action potential is accompanied by an influx of calcium ions that continue to be detectable with arsenazo III microspectrophotometry for several seconds. Nevertheless, transmitter release occurs phasically, lasting only about 2 msec. A second action potential is accompanied by an identical calcium influx, but transmitter release is increased (facilitated) if the action potentials are separated by 50 msec or less.

The model is described in an abstract by N. Stockbridge and J.W. Moore. The presynaptic terminal is represented as a long cylinder, 50 μm in diameter. Calcium influx during an action potential was represented as a square pulse with amplitude and duration equal to that estimated by Llinas *et al.*, (1981). Intracellular calcium diffused radially with 97.5% of the total calcium rapidly binding to fixed cytoplasmic sites (Brinley *et al.*, 1977; Baker & Schlaepfer, 1978). Calcium was removed from the terminal by a surface pump at the rate of 2×10^{-4} cm/sec (Dipolo, 1976). Mitochondrial buffering of weak calcium loads is negligible (Requena & Mullins, 1979) and was ignored. The temporal kinetics of endoplasmic reticulum buffering are yet to be determined (Blaustein *et al.*, 1978) and have not been included. Transmitter release was taken as proportional to the square of the submembrane calcium concentration (Charlton *et al.*, 1982).

Equations representing these processes were solved for two action potentials separated by different intervals, with the following results: 1) A brief release of transmitter, dropping to 10% in 2 msec, followed each action potential. 2) The second action potential released more transmitter than the first, with facilitation decaying with a rapid phase lasting about 5 msec and a slower phase lasting about 50 msec. 3) The total free calcium in the terminal was removed very slowly, with a time constant of about 5 sec. These predictions match experimental results.

The behavior of this model for squid synapses is similar to its behavior at frog neuromuscular junctions, except that facilitation is briefer in squid. This is due to the more rapid diffusion of calcium into the large central core of the giant squid terminal, and the lower level of calcium binding used in this simulation. The dramatic differences in time scale between transmitter release and facilitation on the one hand and calcium removal from the terminal on the other are due to the fact that the former processes are limited by the rapid diffusion of calcium away from transmitter release sites while the latter is limited by the calcium extrusion pump.

145.4 ACTH CAUSES LONG-LASTING POTENTIATION OF TRANSMITTER RELEASE FROM FROG MOTOR NERVE TERMINALS. M. F. Johnston*, E. A. Kravitz, R. Rahamimoff, and H. Meiri. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115, and Dept. of Physiology, Hebrew Univ.-Hadassah Med. Sch., Jerusalem, Israel.

Recent reports of low transmission safety factor at some motor endplates (Grinnell and Herrera, J. Physiol. 307: 301) suggest that a capability for increasing transmitter release might be important for muscle function under normal conditions where synaptic depression is likely. Use-dependent effects such as facilitation and potentiation act and subside quickly, while longer-term modulation can be induced by exogenous agents such as catecholamines (Kuba, J. Physiol. 211: 551) and Substance P (Steinacker, Nature, 267: 268).

We report here that adrenocorticotrophic hormone (ACTH) and related peptides can produce long-lasting potentiation of both evoked and spontaneous transmitter release in cutaneous pectoris and sartorius preparations. Following a 15-30 minute bath application of 0.5-3 μM bovine ACTH, α-melanocyte stimulating hormone, or synthetic ACTH(1-24), endplate potential (EPP) amplitude and miniature endplate potential (MEPP) frequency increase up to two-fold over control levels and persist for as long as the penetration remains stable (up to five hours). The preparation does not respond further to subsequent trials of hormone. MEPP amplitude remains constant, so the EPP effect reflects a rise in quantal content. Synthetic ACTH(4-10) is ineffective.

ACTH-induced increases in EPP amplitude and MEPP frequency are seen in the presence of normal Ca^{++} or low Ca^{++}/high Mg^{++}. MEPP frequency also increases in response to ACTH in solutions with no added Ca^{++}.

Hormone treatment produces no changes in muscle fiber resting potential or tension. The rise in EPP quantal content and MEPP frequency in the face of constant MEPP amplitudes argues strongly for a presynaptic site of action for these peptides.

Since these hormone actions do not depend on the level of extracellular Ca^{++}, we doubt that mechanisms involving only an increase in the terminal's surface membrane Ca^{++} permeability can explain these results.

145.5 TEMPORAL FACILITATION OF GRADED ANTIDROMIC POTENTIALS IN AN ELECTROTONICALLY COUPLED NUCLEUS: A MODEL FOR FACILITATION AT ELECTROTONIC SYNAPSES. Michael V.L. Bennett and George Pappas. Dept. Neuroscience, Albert Einstein Col. Med., Bronx, NY 10461, & Dept. Anatomy, U. Illinois, Coll. Med., Chicago, IL.

The electromotor neurons of the stargazer, Astroscopus, are electrotonically coupled as shown by direct measurement, and gap junctions are plentiful in the electromotor nucleus. Graded antidromic stimulation produces graded depolarizations that decay with a time constant of about 50 msec. Gradedness arises from activation of additional axons whose impulses spread to the cell whose potential is being recorded. The slow time course results from passive recharging of the membrane capacity according to its time constant. In many cells antidromic invasion fails at the initial segment or first node. Increase in the antidromic volley can facilitate invasion because of depolarization spread from adjacent cells. Depolarization remaining from a previous antidromic volley can also facilitate invasion. For this reason,the graded antidromic depolarizations show pronounced facilitation. They also show summation and, at short intervals, depression. Facilitation occurs with both paired and tetanic stimulation and can more than double the size of a test response. During a tetanus the peak depolarization can be increased 5 fold over the initial response because of the combined effect of summation and facilitation. In this system increase in response amplitude results from increase in amplitude of what is in effect the presynaptic potential. The duration of facilitation is determined by the passive membrane time constant. Increase in the duration of the presynaptic impulse could also facilitate the response at an electrotonic synapse and the time course could then well outlast the membrane time constant. However, calculations show that the degree of facilitation is greater if the membrane time constant is long compared to the impulse duration. These results provide a model for temporal effects in electrotonically coupled systems such as the dendrodendritic networks in mammalian CNS. Regions of low safety factor for conduction, changes in impulse properties and long membrane time constants could interact to allow temporal effects over intervals long compared to the propagated impulse and to mediate neuronal processes considerably more subtle than precise synchronization of firing.

Supported in part by NIH grant NS-07512, NIH HD-04248 and NIH NS-12627.

145.6 FACILITATORY TRANSMITTER INCREASES THE CONTENT OF cAMP IN SINGLE NEURONS OF APLYSIA. Lise Bernier*, Vincent F. Castellucci, Eric R. Kandel, and James H. Schwartz. Center for Neurobiology and Behavior, College of Physicians and Surgeons of Columbia University, and New York State Psychiatric Institute, New York, N. Y. 10032.

Short-term sensitization of the gill and siphon-withdrawal reflex in the marine mollusk Aplysia is a simple form of learning that lasts for 20 min to an hour. Underlying the behavioral change is a cascade of biochemical events that leads to enhanced release of transmitter. The first step in this cascade was postulated to be an increase in cAMP within sensory neurons. We have developed labeling protocol with ^{32}Pi which permits us to measure reliably the synthesis of cAMP in single neurons. We have found that application for 5 min of 0.2 mM serotonin, the putative facilitatory transmitter, increased the cAMP content of individual sensory neurons 3-fold. The response is specific to serotonin: dopamine, a transmitter that does not produce sensitization, did not increase cAMP in these cells. Physiological stimulation of the facilitator neurons which results in release of the endogenous facilitatory transmitter also increased the content of cAMP in sensory cells 3.5-fold, but did not affect other neurons of the ganglion. We studied the time course of the increase in cAMP in sensory cells stimulated with serotonin, and found that it parallels very closely the time course of the short-term form of presynaptic facilitation. Short-term sensitization can be converted to the long-term form lasting for weeks by repeated training. In animals trained for long-term sensitization, the amounts of cAMP in sensory neurons was found to be the same as in naive controls, suggesting that a persistent elevation in the cyclic nucleotide is not the molecular basis of long-term memory.

Sensory neurons in the pleural ganglion also mediate sensitization, and they too show a serotonin-sensitive adenylate cyclase (Pollock, Camardo, Bernier, Schwartz and Kandel, these abstracts). Thus, this kind of cyclase may be an important component in mediating a general class of synaptic plasticity involved in learning.

145.7 PLEURAL SENSORY NEURONS OF APLYSIA: A NEW PREPARATION FOR STUDYING THE BIOCHEMISTRY AND BIOPHYSICS OF SEROTONIN MODULATION OF K^+ CURRENTS. J. D. Pollock*, J. S. Camardo*, L. Bernier*, J. H. Schwartz, and E. R. Kandel (SPON: Claude Ghez). Center for Neurobiol. & Behav., P & S, Columbia Univ., and N.Y.S. Psychiatric Institute, N. Y., N. Y. 10032.

Sensory neurons in the abdominal ganglion of Aplysia show presynaptic facilitation in response to stimulation of interneurons thought to be serotonergic. 5-HT decreases a novel K^+ current by a cAMP-dependent phosphorylation (Camardo et al., Neurosci. Abstr., 7, 836, 1981). Protein phosphorylation leads to an increase in the duration of the action potential, prolongs Ca^{++} influx, and enhances transmitter release. These events underlie sensitization of the gill-withdrawal reflex. The two sensory clusters in the abdominal ganglion that innervate the siphon and mantle shelf each contain approximately 24 cells that are about 40 μm in diameter. The small number of cells and their size limit biochemical studies. We therefore have now examined two symmetrical clusters of sensory neurons in the paired pleural ganglia with receptive fields in the tail and body wall (Walters et al., Neurosci. Abstr., 7, 353, 1981). Each cluster contains about 200 similar cells that are on average 60 μm in diameter. These neurons also show presynaptic facilitation (Walters et al., 1981) and 5-HT delays repolarization of their action potential. Since the availability of these clusters would greatly aid future molecular studies of sensitization, we sought to determine whether the current modulated by 5-HT in the pleural sensory cells resembles that of the abdominal sensory cells in its biophysical properties and its dependence in cAMP.

We first analyzed the action of 5-HT on the pleural cells by voltage clamp. The 5-HT-modulated outward current can be detected within 5 msec of depolarization from -50 to 0 mV, and shows no inactivation after sustained depolarization. The decrease is unaffected when Ba^{++} is substituted for Ca^{++}. Intracellular injection of cAMP simulates the action of 5-HT. In addition, application of 5-HT stimulates the synthesis of cAMP to an extent (3.7X) similar to that found in sensory neurons of the abdominal ganglion (Bernier et al., 1982).

We conclude that 5-HT increases the activity of an adenylate cyclase in these pleural cells and that 5-HT and cAMP decrease a net outward current with properties similar to the serotonin-sensitive K^+ current in the abdominal cells. These findings suggest that the same molecular mechanism for presynaptic facilitation operates in the two sensory systems. That a mechanism involving cAMP and protein phosphorylation underlies sensitization in these pleural cells is of further interest because their larger size and number will permit a detailed biochemical analysis of the intracellular events that accompany elevation of cAMP by 5-HT.

145.8 DECREASE IN INTRACELLULAR CA ACCOMPANYING A SEROTONIN-INDUCED REDUCTION OF OUTWARD CURRENT IN IDENTIFIED NEURONS OF HELIX ASPERSA. M.B. Boyle and S.J. Smith*. Department of Physiology, Yale University School of Medicine, New Haven, CT 06510.

A serotonin-induced reduction in net outward current depending both on voltage and on extracellular Ca has been described in identified molluscan neurons. Different investigators have attributed the outward current reduction either to increases in inward Ca current or decreases in outward K current. To further define the role of Ca in this serotonin (5HT) response, we have used Arsenazo III to measure intracellular free Ca in the identified cells of Helix previously studied by Paupardin-Tritsch et. al. (Br. Res. 217:201-206).

Optical absorbance of dye-filled cell bodies was measured simultaneously at 570, 610, 660, and 700 nm. The bath contained 10 mM Ca. Two voltage-clamp protocols were used. In the first, cells were steadily depolarized to between -20 and +20 mV. During such depolarizations, sustained increases in intracellular Ca were observed. In the second, cells were depolarized once per minute from -40 mV through a sequence of steps lasting a few seconds to voltages between -30 and -10 mV. Each pulse sequence led to a transient increase of intracellular Ca, and recovery back to baseline occurred with repolarization to the holding potential. 5HT was applied iontophoretically. When 5HT was applied during steady depolarization, Ca concentration was seen to decline and then to recover along a time course similar to that of the current response. If 5HT was applied during repetitive depolarizing pulse sequences, the baseline Ca also declined. In addition, the depolarization-induced Ca transients were reduced in a graded manner corresponding in magnitude and time course to the onset and recovery of the current change.

We conclude that: 1) the inward current response is not due to an increased Ca current; instead, the 5HT effect is accompanied either by a reduction in inward Ca current or stimulation of Ca removal from cytosol; 2) the decreases in intracellular Ca could themselves account for the decreased outward current, by reducing activation of Ca-dependent K current. Cyclic AMP has previously been implicated in the mechanism of the 5HT inward current response, and reduction of intracellular Ca by 5HT is therefore reminiscent of the cAMP-mediated stimulation of Ca removal in heart by epinephrine. Suppression of intracellular Ca transients by 5HT during voltage-clamp pulses raises the possibility that 5HT-induced increases in action potential duration could be associated with decreases rather than increases in Ca accumulation during action potentials. It will be important to resolve this issue since increased Ca entry during action potentials has been proposed as a mechanism for increased transmitter release in heterosynaptic facilitation. Supported by NIH Grant NS16671.

145.9 STIMULATION OF ADENYLATE CYCLASE IS NECESSARY FOR 5HT ACTIVATION OF A K+ CHANNEL IN APLYSIA NEURON R15.
José R. Lemos* and Irwin B. Levitan (SPON:B.Gähwiler) Friedrich Miescher-Institut, P.O.Box 273,CH 4002-Basel, Switzerland.

Serotonin (5HT) causes an increase in K+ conductance in Aplysia neuron R15. A great deal of evidence suggests that the activation of this K+ channel is mediated by the stimulation of an adenylate cyclase and a consequent increase of intracellular cAMP (Drummond, et al.,1980). In order to test whether cyclase stimulation is a necessary step in the sequence of events that leads to the increase in K+ conductance, we injected a GDP analog, GDPβS, into cell R15 and measured its response to 5HT. GDPβS has previously been shown to inhibit many cyclase systems in vitro (Cassel, et al. 1980), apparently by competing for the GTP binding site on the regulatory subunit of adenylate cyclase, and we have found that it also inhibits 5HT-stimulated cyclase in membranes from Aplysia nervous system.

Following its pressure injection into voltage-clamped R15's, GDPβS has no apparent effects on electrical activity. However, within minutes, the response of R15 to 5HT is markedly altered. If low concentrations (μM intracellular) of GDPβS are used, the 5HT activation of K+ conductance is totally blocked. This effect persists for many hours. On the other hand, the cell's response to dopamine is unaffected by GDPβS injection. (Dopamine affects a different conductance than 5HT (Wilson and Wachtel, 1978) and its action is not mediated by cAMP). Ten to 24 hours after GDPβS injection the cell can again respond to 5HT in a normal manner. Thus the stimulation of adenylate cyclase appears to be a necessary step in 5HT activation of a K+ channel in cell R15.

In contrast, much higher concentrations (mM intracellular) of GDPβS produce quite different results in R15. Direct effects on membrane conductance are observed after 1-2 hours. In addition the response to 5HT is markedly enhanced: large increases in K+ conductance, which cannot be reversed by washing, are observed at 5HT concentrations as low as 10 nM. GDPβS has no detectable effects on Aplysia phosphodiesterase or protein kinase activities, or on serotonin binding. The mechanism of action of GDPβS at high concentrations is being investigated.

145.10 CHLORIDE CHANNELS OPENED BY CHOLINERGIC AGONISTS IN SNAIL NEURONS.
P. Ascher* and S.D. Erulkar[1]. Laboratoire de Neurobiologie, Ecole Normale Supérieure, 75005 Paris, France.

The elementary properties of cholinergic Cl^- channels of snail neurons have been analyzed using the various configurations of the patch-clamp technique (Hamill, O.P. et al., Pflügers Arch., 391:85, 1981). After incubation of the isolated oesophageal ganglion in trypsin (TPCK Worthington, 1 mg/ml, 30 min at 32 °C), the connective tissue sheath was removed and the neurons gently agitated until the somas separated from the axons. The isolated cell bodies were transferred to Falcon culture dishes on which they adhered. In order to identify the Cl channels, we relied on the fact that suberyldicholine (SUB) is a selective agonist of the Cl system and does not activate either excitatory channels or the inhibitory K^+ conductance (Ger, B.A. and Zeimal, E.V., Brain Res., 121:131, 1976 ; Kehoe, J.S., Adv. Pharmacol. Therap., 8:285, 1979). On "outside-out" patches, a prolonged activation of Cl^- channels was obtained with SUB 25 nM or ACh 250 nM or Carbachol 1000 nM. At higher concentrations the receptors appeared to become desensitized and shortly after drug administration, were no longer activated.

The majority of the records showed channel openings with a single conductance state of 15 ± 2 pS, the value being similar for all three agonists. However, in some records, "partial" conductances were observed similar to those described by Hamill and Sakmann (Nature, 294:462, 1981) and Trautmann (Nature, in press). In addition, with ACh and Carb, but not with SUB, some "outside-out" patches showed excitatory cationic channels as well as Cl selective channels. Both types of channels had similar conductances, but the reversal potential for the Cl^- channel was 0, and that for the excitatory channels, - 20 mV (the composition of the "internal" solution was (mM) : KCl, 75 ; EGTA, 5.5 ; $CaCl_2$, 0.5 ; Tris Cl, 10 ; that of the external solution was (mM) : NaCl, 80 ; KCl, 4 ; $CaCl_2$, 10 ; $MgCl_2$, 5 ; Hepes, 5 ; Glucose, 10).

Neither the histograms of open times for outside-out patches nor the noise spectra obtained in the "whole-cell" configuration could be fit to a single time constant (cf. Gardner, D. and Stevens, C.F. J. Physiol., 304:145, 1980). A reasonable fit was obtained with two time constants ; for equiactive concentrations the value of the slow time constant varied in the order $\tau_{Carb} < \tau_{ACh} < \tau_{Sub}$ as described at the frog neuromuscular junction.

In contrast to Cl^- channels obtained in "outside-out" patches, Cl^- channels could only be obtained rarely with the "cell-attached" configurations (25 nM SUB present in the electrodes). This is tentatively attributed to the difference in the surface of the membrane analyzed with the same pipette in the two configurations.

145.11 DESENSITIZATION OF GABA RECEPTOR OBSERVED IN APLYSIA.
Mitsuhiko Matsumoto*, Kohichiro Takashima*, Masanori Shozushima* and Makoto Sato. Dept. Physiol., Sch. Med., Iwate Med. Univ., Morioka, 020 JAPAN.

Many cells in R_B group of the abdominal ganglion are hyperpolarized by a topical application of GABA. The hyperpolarization is associated with a characteristic, rapid increase in membrane conductance toward Cl^-. This type of receptor activity was evaluated by GABA-induced current and conductance change measured under voltage clamp of the resting membrane.

The response to a sustained application of GABA was characterized by an initial rapid increase in conductance followed by an exponential decay to the original value despite the presence of GABA. This decay of the response was found to be largely due to the receptor desensitization.

The rate of desensitization (α) increased when the concentration of GABA increased, showing a sigmoidal curve in α-log[GABA] relation. This relationship suggested that a binding of another GABA molecule to the activated receptor induces the state of desensitization.

The binding of GABA to the desensitizing site was found independent to the voltage across the receptor membrane, whereas the binding to the activating site of the same receptor showed a characteristic voltage dependence. This observation suggested a functional or structural difference between two binding sites in the same receptor moiety.

On the basis of these results, we propose an allosteric model that the activated receptor-GABA complex makes additional binding with a GABA molecule in order to be desensitized.

145.12 RUTHENIUM RED ENHANCES DESENSITIZATION OF ACETYLCHOLINE RECEPTORS.
Angeles B. Ribera and William L. Nastuk. Dept. of Physiology, Columbia Univ., NY, NY, 10032.

Calcium ion (Ca^{++}) influx increases across the agonist-depolarized postjunctional membrane (PJM). Nastuk and Parsons (J Gen Physiol 56:218, 1970) postulated that desensitization (DS) of the acetylcholine receptor involves the accumulation of Ca^{++} at the inner surface of the PJM. On this basis, inhibition of mitochondrial or sarcoplasmic reticular Ca^{++} sequestration would produce an increase in the intracellular Ca^{++} level and hence enhance DS. We tested this prediction by applying Ruthenium red (RuR) to block mitochondrial Ca^{++} transport in frog sciatic nerve-sartorius muscle preparations.

DS was assayed by measuring the decline in transient depolarizations of the PJM during repetitive iontophoretic application of carbachol (carb). The standard test consisted of a 1 Hz 45 sec train of 10 msec duration carb pulses. A DS level of less than 10% was obtained in control experiments with the preparation bathing in Ringer solution containing 1.8 mM Ca^{++}. After muscle preparations were treated with 1 μM RuR, the standard test produced a 28% DS level. In these RuR treated preparations, the intensification of DS was evident even when the carb train consisted of 5 msec pulses. Under these conditions the standard test produced a DS level of 24%. After RuR treatment the PJM desensitized to repetitively applied carb with a time course similar to that observed in the presence of high (10 mM) extracellular Ca^{++}.

In another series of experiments, the effect of RuR on DS was enhanced by elevating the extracellular Ca^{++} concentration to 10 mM: in RuR treated preparations the neuromuscular junction was perfused with Ringer solution containing 10 mM Ca^{++}. Under these conditions, the standard test produced a 53% DS level.

In addition we found that RuR treatment led to a reduction in the PJM sensitivity. Three different methods were used to determine the PJM sensitivity: (1)iontophoresis of carb, (2)miniature end plate potential amplitude, and (3)microperfusion of carb. By all three tests, the PJM sensitivity was found to be reduced 50%.

We also found that, following RuR treatment, nerve evoked neuromuscular transmission was blocked. RuR may block presynaptic Ca^{++} channels and hence reduce the quantal content (Alnaes and Rahamimoff, J Physiol 248:285, 1975).

These results add further support to the Nastuk-Parsons intracellular model of DS. In addition, the finding that the PJM sensitivity was reduced after RuR treatment raises the interesting possibility that, prior to the application of carb, the PJM was partially desensitized by the RuR treatment. Alternatively, RuR itself may act directly on the PJM to reduce the sensitivity to carb.

146.1 REGIONAL AND SPECIES COMPARISON OF BRAIN α_2-RECEPTOR STATES. D.C. U'Prichard and B.D. Perry Dept. of Pharmacology, Northwestern University Medical School, Chicago, Illinois 60611

The brain α_2-adrenergic receptor (R) exists in two states, differentiated by high (α_2H) or low (α_2L) affinity for agonists. Agonist (^{3}H-epinephrine, ^{3}H-EPI) and partial agonist (^{3}H-p-aminoclonidine, ^{3}H-PAC) radioligands, at low concentrations, selectively label the α_2H state. Antagonists also have demonstrated heterogeneous interactions with the α_2-R, though in a manner reciprocal to agonists. In competition (Ki of rauwolscine, RAUW, vs ^{3}H-EPI 15 nM and vs ^{3}H-RAUW 1 nM, Perry and U'Prichard, Eur. J. Pharmacol. 76:461) and saturation studies (biphasic ^{3}H-RAUW Scatchard where K_D α_2L=1.0 nM, K_D α_2H=40 nM), antagonists have higher affinities for the α_2L state such that ^{3}H-RAUW, at low concentrations, will selectively bind to the α_2L state. Guanine nucleotides and Na^+ will shift the equilibria between the α_2L and α_2H states in favor of α_2L, which is reflected by reciprocal changes in ^{3}H-PAC (↑) and H-RAUW (↑) binding. We have used ^{3}H-PAC (α_2H-selective) and ^{3}H-RAUW (α_2L-selective) to measure relative α_2-R state densities and α_2L/α_2H ratios in 30 bovine, 10 rat and 30 human brain regions, and, in selected regions, have further examined the pharmacology of these α_2-R states in an attempt to analyze regional and species differences in α_2L/α_2H equilibria. Sample values of single point ^{3}H-RAUW binding (Na-K-PO_4 buffer) follow, (% frontal cortex binding): BOVINE (Bmax f.ctx.=160 fmol/mg-prot) caudate:120, cingulate gyrus:115, ant. hypothal.:100, cerebellum:80, sup. colliculus:80, putamen:70, post. vent. medulla: 41, amygdala:40, dorsal pons:14 RAT (Bmax f.ctx.=140 fmol/mg-prot): caud:110, hypothal:96, pons/med:70, cbl:50 HUMAN (Bmax f.ctx.=150 fmol/mg-prot) caud: 80. Sample values for ^{3}H-PAC (Tris HCl buffer): BOV (Bmax f.ctx.=110) caud:40, cing gyr:100, ant. hypo:106, cbl:68, put:50, sup. coll:29, amyg:99, post vent med:24, dorsal pons:12, RAT: (Bmax f.ctx.=140) caud:80, hypothal:90, pons/med:88, cbl:32, HUMAN (Bmax f.ctx.=60) caudate:85. The ratio, % ^{3}H-RAUW f.ctx bind./% ^{3}H-PAC f.ctx binding, was variable across regions within a species (BOV: caud=2.8, amyg=0.4) and across species within a region (BOV: caud=2.8, HUMAN: caud=1.0). Na^+ increased the ratio in all regions (compared to f.ctx values without Na^+). K_D values for ^{3}H-RAUW were lower in bov caud than in other bov regions with an α_2L/α_2H ratio near 1.0 (K_D caud=1 nM, K_D ctx, cbl=2.6) and somewhat higher (K_D= 4.0 nM) in the amygdala (ratio, 0.4). Agonist Ki values in the caud were higher than in regions with a ratio of 1 (Ki, nM: EPI; caud=280 ctx=170, cbl=150: PAC; caud=8, ctx=5, cbl=5) and antagonist Ki values were lower (Ki, nM: YOH; caud=2, ctx=8, cbl=7). The results demostrate that both regional and species differences exist for the α_2L/α_2H equilibria and further demonstrate the need for careful characterization of a given α_2-R system before the effects of experimental manipulation (chronic drug, stress) can be correctly interpreted. 146.2 GENETIC ANALYSIS OF AN INVERSE RELATIONSHIP BETWEEN BRAINSTEM α_2-ADRENERGIC RECEPTORS, AND PNMT ACTIVITY AND EPINEPHRINE LEVELS IN RATS. B.D. Perry, J.M. Stolk*, G. Vantini*, J. Hurst*, and D.C. U'Prichard. (SPON: E.M. Silinsky) Dept. of Pharmacology, Northwestern Univ. Medical School, Chicago, IL 60611 and Neuroscience Program, Maryland Psychiatric Research Center, Baltimore MD 21228

There is substantial evidence that genetic factors influence the activity of adrenal and brain catecholamine biosynthetic enzymes. Of particular interest is the relationship, in inbred strains, of adrenal and brainstem phenylethanolamine-N-methyltransferase (PNMT) activity and the levels of brain epinephrine (EPI) formed in the brainstem as a result of PNMT activity. We wished to compare these parameters with the levels of brainstem α_2-receptors (α_2-R) since brain EPI is thought to exert many actions, specifically with regard to control of blood pressure, by activating α_2-R. Breeding colonies of F344 and BUF rats were established from parental stock obtained from Microbiol. Assoc. (Bethesda MD) and hybridization was commenced after two generations of in-house parental strain brother-sister mating. Adrenal and brainstem PNMT were assayed by the methods of Axelrod (J.Biol.Chem. 237, 1657, 1962) and Pendleton (J.Pharmacol.Exp.Ther. 208, 24, 1979), respectively. Brainstem EPI was assayed by HPLC-ECD. α_2-R in washed brainstem membranes were assayed using the agonist, ^{3}H-p-aminoclonidine (PAC), which selectively labels α_2H states, and the antagonist, ^{3}H-rauwolscine (RAUW), which has some selectivity for α_2L states. PNMT and EPI data for male rats are shown below.

Group	N	Adrenal PNMT	Brain PNMT	Brain EPI
F344	23	6.12	0.262	10.77
BUF	36	1.42	0.232	6.46
F344xBUF (F_1)	57	3.86	0.243	9.07

PNMT is expressed as U/tissue (U=1.0 nmol product/hr, 37°) and EPI as ng/tissue. Similar differences were observed in adrenal PNMT for females. In a limited sampling of the above tissue (N=6-12, for each group: males) both brainstem RAUW and PAC binding was 2-3 fold lower in F344 than in BUF, and values for F_1 hybrid were intermediate. For all parameters examined, the differences between F344 and BUF values were significant at at least $P < 0.01$. In females, medullary α_2-R binding was more markedly lower (4-5 fold) in F344 than in BUF (N=5). The results indicate that marked differences between F344 and BUF rats for adrenal PNMT are reflected in similar, but smaller, brainstem PNMT differences and substantial differences in EPI levels. Brainstem α_2-R appear to co-vary in an inverse manner with PNMT and EPI, suggesting that, in the brainstem, EPI content may be a prime regulating factor of α_2R density. The genetic differences are quite specific since, at present, we have observed no significant differences between F344 and BUF for brainstem β- and opiate receptors, and norepinephrine and dopamine content. (Supported by USPHS MH 32842 and NS 15595)

146.3 REGULATION OF RAT CEREBRAL CORTEX α_2-RECEPTOR AFFINITY STATES AFTER ELECTROCONVULSIVE SHOCK AND ANTIDEPRESSANT TREATMENT. A. Garcia*, C.H. Wang, A.I. Salama and D.C. U'Prichard. Dept. of Pharmacology, Northwestern Univ. Sch. Med., Chicago, IL 60611, and Dept. of Biomed. Res., ICI Americas Inc., Wilmington, DE 19897.

Chronic electroconvulsive shock (ECS) and antidepressant (AD) treatments down-regulate β-adrenergic receptors (β-R). Some ADs also cause functional α_2-receptor (α_2-R) subsensitivity, but are reported to cause both increases and decreases in rat brain α_2-R sites labeled with ^{3}H-agonists (^{3}H-clonidine, CLO and ^{3}H-p-aminoclonidine, PAC) which selectively label high affinity α_2(H) receptor states. We have recently characterized binding of the α_2-antagonist ^{3}H-rauwolscine (RAUW) to cortex membranes (Perry and U'Prichard, Eur. J. Pharm. 76, 461, 1981). RAUW labels both α_2(H) and α_2(L) states. Studies were performed to determine whether increases in cortex CLO and PAC sites after AD treatment represented increases in the total α_2-R population, and whether ECS treatment also regulated α_2-R. ECS (100 mA, 300 ms) was administered via ear clips once daily for 1-7 days. All rats receiving ECS experienced generalized tonic-clonic seizures. Animals were sacrificed 18 hr after 1-6 ECS, and 2, 3 or 6 days after 7 ECS. Thawed, washed cortex membranes were assayed for β-R (0.4 and 1.2 nM ^{3}H-dihydroalprenolol, DHA), and for α_2-R using CLO (0.2-16 nM), PAC (0.2-2.5 nM) and RAUW (0.8-8.5 nM). In all α_2-R studies, Kd and Bmax values were determined using 5 ligand concentrations. No Kd change was observed with treatments. ECS significantly reduced DHA binding at each time over 6 days treatment, with a maximum effect (-22%) at day 4. Recovery to control levels began during the daily ECS schedule (day 5), and β-R were no different from control at 6 days after the 7th ECS. Generally, ECS caused an increase in α_2-R binding which returned to control during the ECS schedule. However the time courses of Bmax increases (20-50%) differed for each ligand: the increase in CLO was apparent at day 2, peaked at day 3 and was no longer seen at day 4; increases in PAC and RAUW Bmax did not appear until days 3 or 4, peaked at day 5, and returned to control by 2 days after the 7th ECS. The results suggest that chronic ECS treatment may have sequential effects on cortex α_2-R: (1) an initial subsensitivity seen as the increase in CLO Bmax with no change in RAUW at days 2-3; (2) a subsequent supersensitivity seen as the increase in total α_2-R measured with RAUW. The proposed α_2-R supersensitivity coincides with, and may result in, the the onset of return of β-R to normal levels at day 5 ECS. In preliminary experiments, rats given imipramine (10 mg/kg bid) after 4 weeks showed an increase in cortex CLO Bmax with no change in RAUW Bmax, suggesting that AD treatment does not cause α_2-R supersensitivity but may cause subsensitivity. (supported in part by USPHS grant NS 15595)

146.4 CHANGE OF BETA-ADRENERGIC RECEPTOR NUMBER IN CEREBRAL MICROVESSELS OF SPONTANEOUSLY AND DOCA-SALT HYPERTENSIVE RATS. M. Trabucchi, H. Kobayashi*, S. Magnoni*, A. Cazzaniga*, P.F. Spano* Dept. of Pharmacology and Therapeutics University of Brescia, Italy.

It has been extensively recognized that central and peripheral catecholaminergic neurons play an important role in the regulation of blood pressure. Changes in synthesis, content and turnover of catecholamines are reported in several brain regions, sympathetic ganglia and peripheral tissues of spontaneously (SHR) and DOCA-salt hypertensive rats. Various experimental observations suggest that microvasculature function is altered in hypertension. In fact, morphological studies show the presence of brain capillary injuries in experimental hypertensive monkeys and in human patients affected by essential hypertension. Biochemical evidences suggest that blood-brain barrier (BBB) permeability is increased in SHR. In addition, a diminished response of brain microvessel adenylate cyclase to catecholamines has been reported in SHR.

On the basis of these observations, β-adrenergic receptor function has been measured in cerebral microvessels of spontaneously and DOCA-salt hypertensive rats, using the specific radioligand ^{125}I-iodohydroxybenzylpindolol (Kobayashi H. et al, J. Neuroch. 34, 1383-1388, 1981). The results show that both in genetic and in experimental hypertension a significant reduction of β-receptor number may be detected, without relevant changes of the affinity values. (Bmax: 154 ± 8 and 110 ± 6 fmol/mg prot., Kd 82 ± 9 and 74 ± 5 pM for Wistar and SHR, respectively; Bmax: 168 ± 9 and 125 ± 4 fmol/mg prot., Kd: 120 ± 7 and 112 ± 9 pM for controls and DOCA-salt treated rats, respectively). The reduction of β-adrenergic receptor number may be the consequence of an altered pattern of central adrenergic transmission or of an increase of plasma catecholamines level. The observed change of β-adrenergic receptors may be involved in the functional alterations induced by hypertension in the brain.

146.5 MAGNESIUM AND GTP AFFECT THE INTERACTIONS OF ANTAGONISTS WITH β-ADRENERGIC RECEPTORS ON MEMBRANES FROM RAT LUNG AND S49 LYMPHOMA CELLS. Margarita L. Contreras*, Barry B. Wolfe, and Perry B. Molinoff, Dept. of Pharmacology, Univ. of Pennsylvania, Philadelphia, PA.

The effect of Mg^{++} on the binding of antagonists to β-adrenergic receptors was examined. Membranes from rat lung or wild type S49 lymphoma cells were incubated with either ^{125}I-iodohydroxybenzylpindolol (IHYP) or ^{125}I-iodopindolol (IPIN) in the presence of increasing concentrations of Mg^{++} up to 180 mM. In both tissues, concentrations of Mg^{++} above 0.4 mM caused a dose-dependent decrease in the amount of specifically bound IHYP and IPIN. In membranes prepared from wild type cells, IPIN binding was decreased by approximately 40% in the presence of maximally effective concentrations of Mg^{++}. In the absence of Mg^{++}, GTP increased the amount of IHYP bound to membranes prepared from rat lung and S49 lymphoma cells. This effect of GTP on antagonist binding to β-adrenergic receptors has been previously reported in studies of L6 cells (B.B. Wolfe and T.K. Harden, J. Cyclic Nucl. Res. 7:303, 1982). In studies carried out in the presence of GTP, Mg^{++} caused a dose-dependent decrease in the binding of the radioligand. The amount of radioligand bound at each concentration of Mg^{++} was, however, greater than that bound in the absence of GTP. To determine if the effects of Mg^{++} and GTP on binding of antagonists to the β-adrenergic receptor required the guanine nucleotide binding protein (G/F), dose response curves for Mg^{++} were carried out with membranes from cyc^- cells which lack the G/F protein. A Mg^{++} dependent decrease in the amount of IPIN and IHYP bound was observed suggesting that the G/F protein is not required for the effect of Mg^{++} on the binding of antagonists. The GTP induced increase in IPIN and IHYP binding to the β-adrenergic receptor was not seen, however, in studies with cyc^- membranes suggesting that this effect is dependent on the presence of the G/F protein. Scatchard analysis of IHYP and IPIN binding to rat lung and S49 membranes in the presence of 0, 5, and 50 mM Mg^{++} showed that Mg^{++} affected the binding of antagonists by decreasing the affinity of the receptor for antagonists. No effect on the density of receptors was observed. GTP increased the binding of antagonists through a decrease in the K_D value rather than a change in the density of receptors. Scatchard analysis of the binding of IPIN and IHYP to cyc^- membranes revealed an effect of Mg^{++} on the K_D value. The results suggest that the effects of GTP and Mg^{++} on the interactions of antagonists with β-adrenergic receptors are through different mechanisms. (Supported by the USPHS NS 18479)

146.6 ANTIBODIES TO THE β-ADRENERGIC RECEPTOR: FUNCTIONAL CHARACTERIZATION AND RECEPTOR IMMUNOLOCALIZATION IN BRAIN. C.D. Strader*, V.M. Pickel, T.H. Joh, M.W. Strohsacker*, R.G.L. Shorr*, R.J. Lefkowitz*, and M.G. Caron*. Howard Hughes Med. Inst. Lab., Dept. of Med. and Biochem., Duke Univ. Med. Ctr., Durham, NC and Lab. of Neurobiology, Cornell Univ. Med. College, New York, NY.

Antibodies against the frog β-adrenergic receptor (βAR) were raised in rabbits. Adrenergic receptor of the β_2 subtype was extracted from frog erythrocyte membranes in digitonin and purified by affinity chromatography and high performance liquid chromatography (HPLC) according to Shorr, et al. (Proc. Natl. Acad Sci. USA 79: 2778-2982, 1982). Antibodies could be detected in rabbit serum by immunoprecipitation of either purified [^{125}I]-βAR or of solubilized βAR bound to the high-affinity antagonist [^{125}I]-iodocyanopindolol ([^{125}I]-CYP); the titer of antibodies to the βAR was measured as 3.3 pmol βAR bound per ml serum.

Binding of antibody to membrane-bound βAR in frog erythrocyte membranes could be demonstrated by specific labeling with [^{125}I]-goat anti-rabbit IgG. Further characterization of these antibodies showed no interference with antagonist binding to the βAR: incubation of membrane-bound or solubilized βAR with antiserum did not inhibit binding of [^{125}I]-CYP to the receptor and had no significant effect on the K_D of [^{125}I]-CYP binding. In the presence of antibody, purified radioiodinated βAR migrated with an apparent larger molecular size on HPLC, demonstrating the existence of an antibody-receptor complex. The antibody did not bind to βAR solubilized from the turkey erythrocyte (βAR of the β_1 subtype) either labeled with [^{125}I]-CYP or purified and radioiodinated.

Antiserum or purified IgG to the βAR was immunocytochemically localized and compared with localization of tyrosine hydroxylase (TH) in the frog and rat brain. Many regions containing TH labeled processes also contained neurons having specific immunoreactivity for the receptor including, most prominantly, the cerebellum, hippocampus, hypothalamus, neostriatum, and anterior thalamic nuclei. In the hippocampus of the frog, TH was localized by electron microscopy in axons and axon terminals, whereas the immunoreactivity to the βAR was distributed throughout the dendrites and the perikarya. This immunocytochemical localization of the βAR agrees with the receptor distribution reported by Palacios and Kuhar (Science, 208: 1378-1380, 1980) for autoradiography of ligand binding sites using [^{3}H]dihydroalprenolol. Postsynaptic dendritic membranes in these preparations were specifically immunolabeled.

The properties of this antibody promise to make it a useful tool for further characterization and localization of the βAR in its various physiological and pathophysiological states.

146.7 ^{3}H-PARA-AMINO-CLONIDINE BINDING TO α_2-ADRENOCEPTORS IN CAT CORTEX AND SPINAL CORD. J.R. Howe* and T.L. Yaksh* (SPON: R.M. Weinshilboum). Dept. of Pharmacology, Mayo Clinic, Rochester, MN 55905.

Para-amino-clonidine (PAC) has been reported to be a selective ligand for α_2-adrenoceptors in mammalian CNS. We have characterized ^{3}H-PAC binding to homogenates of cat frontal cortex and cat spinal cord. Triplicate incubation tubes on ice received 50 µl of ^{3}H-PAC, 50 µl of various drugs in 0.1% ascorbic acid, and 0.9 ml of tissue suspension diluted 60-fold in 50 mM Tris buffer. For routine experiments, tubes were incubated at 37°C for 10 min and the incubation terminated by rapid filtration over Whatman GF/B filters. The filters were immediately rinsed with three 5-ml washes of ice-cold buffer. Filters were counted by liquid scintillation spectrometry at 35-40% efficiency. Specific binding was defined as that portion of the total that was not displaced by 10 µM (-)-norepinephrine or 1 µM PAC. Specific ^{3}H-PAC binding was saturable and rapidly reversible. Scatchard transformation of data from equilibrium saturation experiments resulted in biphasic plots. K_D and B_{max} values for both the high and low affinity ^{3}H-PAC sites were calculated using computer-assisted nonlinear regression analysis. Mean K_D (nM) and B_{max} (fmoles/mg protein) values obtained from 8 experiments using spinal cord and 4 experiments using cortex are:

	K_{D_H}	B_{max_H}	K_{D_L}	B_{max_L}
Spinal cord	.45	7.1	9.3	56
Cortex	.52	28	9.1	149

Competition experiments were conducted using .13 nM ^{3}H-PAC. K_i values for unlabelled PAC agree well with K_D values for ^{3}H-PAC. K_i values determined for catecholamine stereoisomers indicate that the sites labelled by ^{3}H-PAC exhibit stereoselectivity. The rank order affinity of the stereoisomers for ^{3}H-PAC sites is: (-)-epinephrine > (-)-norepinephrine > (+)-epinephrine > (+)-norepinephrine. Competition experiments with subtype-selective adrenergic agonists and antagonists confirm that the sites labelled by ^{3}H-PAC possess a pharmacologic profile characteristic of α_2-adrenoceptors. We conclude ^{3}H-PAC labels α_2-adrenoceptors in cat frontal cortex and cat spinal cord. (Supported by Mayo Foundation and NS 16541.)

146.8 STRIATAL BETA-ADRENERGIC RECEPTORS REGULATE DOPAMINE RELEASE, T.D. Reisine*, M.F. Chesselet, C. Lubetzki, A. Cheramy and J. Glowinski. Groupe Neurobiology, INSERM U. 114, College de France, Paris, France.

The effect of beta-adrenergic receptor agonists and antagonists on the spontaneous release of ^{3}H-dopamine (^{3}H-DA) continuously formed from ^{3}H-tyrosine was studied both in vitro using rat striatal slices and in vivo in halothane-anaesthetized cats implanted with push-pull cannulae in the caudate nucleus. In vitro, (-) isoproterenol (10^{-6}M) stimulated ^{3}H-DA release whereas (+) isoproterenol (10^{-6}M) did not. The (-) isoproternol effect was blocked by propranolol (10^{-6}M) and practolol (10^{-5}M) but not by phentolamine (10^{-5}M). Furthermore, the stimulation of ^{3}H-DA release was tetrodotoxin (5×10^{-7}M) insensitive. In vivo, (-) isoproterenol (10^{-6}M) facilitated ^{3}H-DA release in the caudate nucleus. Propranolol (10^{-6}M) blocked this action and slightly reduced local ^{3}H-DA release by itself. The short-term effect of (-)-isoproterenol on in vitro ^{3}H-DA release was not accompanied by a change in DA synthesis nor did it appear to be mediated by cyclic-AMP, since cyclic-AMP's actions on ^{3}H-DA efflux and synthesis were blocked by α -methyl-p-tyrosine whereas (-) isoproterenol could still stimulate ^{3}H-DA release under such conditions. Thus, activation of striatal beta-adrenergic receptors, possibly located on DA terminals can potentiate DA release through a cyclic-AMP independent mechanism. These data suggest that noradrenergic neurons or possibly circulating noradrenaline can exert an important control over striatal DA transmission. The implications of such an interaction will be discussed.

146.9 PRESYNAPTIC LOCATION AND AXONAL TRANSPORT OF β_1-ADRENO-RECEPTORS IN RAT BRAIN. B. E. Levin. Lab. of Neuropharmacology, VA Medical Center, East Orange, NJ 07019.

Synthetic enzymes and other proteins are generally thought to be synthesized in the neuronal cell body and anterogradely transported to the nerve terminal. Hypothalamic lesions in the ascending noradrenergic axons of locus coeruleus neurons with 6-hydroxydopamine have been shown to produce accumulation of norepinephrine synthetic enzymes proximal to the lesion. In the present study, similar injections of 2 µl 6-hydroxydopamine (4 µg/µl) into the median forebrain bundle in the left rostral hypothalamus led to the progressive accumulation of {^{3}H} dihydroalprenalol ({^{3}H} DHA) binding over a 2 d period proximal to the lesion. Binding activity plateaued from 2-5 d and accumulation could be completely blocked by a second injection in these axons closer to the cell body. Scatchard analysis showed that the accumulation proximal to the lesion after 2 d was due to an increased number of binding sites (B_{max}: lesioned = 173 ± 10, versus unlesioned = 128 ± 11 fmol/mg protein; $p < 0.05$) rather than altered affinity which was actually lower on the lesioned (11.5 ± 0.9 nM) compared to the unlesioned side (8.7 ± 1.0 nM; $p < 0.05$). Competitive binding studies with the β_2-adrenoreceptor antagonist, Zinterol, showed that 56.8 ± 4.6% of hypothalamic membrane receptors were of the β_2- and 43.2 ± 2.5% were of the β_1-sub-type in unlesioned brain. Accumulation of {^{3}H} DHA binding proximal to the lesion was exclusively due to an increase in the number of β_1-receptors (105 ± 15 lesioned versus 55 + 8 fmol/mg protein unlesioned; $p < 0.005$) since the number of β_2 receptors was unchanged. There was no comparable transport of α_1 ({^{3}H} WB-4101) binding sites in this system. Therefore, β_1-adrenoreceptors appeared to be localized to, and undergo transport in, presynaptic noradrenergic neurons in rat brain.

147.1 SYNAPTIC INTERACTIONS IN THE OLFACTORY LOBE OF THE MOTH *MANDUCA SEXTA*. I. D. Harrow and J. G. Hildebrand. Dept. of Biological Sciences, Columbia University, New York, N. Y. 10027.

Olfactory signals detected by primary sensory neurons in the insect antenna are conveyed by afferent axons in the antennal nerve to the antennal lobe (AL) of the brain for synaptic processing. The AL contains two general classes of interneurons: local and output. Matsumoto and Hildebrand (*Proc. Roy. Soc. Lond. B215:* 249-277, 1981) described the morphology and responses of these neurons to various odors applied to the antenna. The work presented here is aimed toward gaining an understanding of information processing in the olfactory pathway of the moth *Manduca*. Our approach is to probe the synaptic interactions between the different types of neurons in the AL.

Intracellular recording from, and staining of, individual neurons in the AL are accomplished with glass microelectrodes filled with 5% Lucifer Yellow CH. In response to electrical stimulation (0.1 msec) of the ipsilateral antennal nerve, AL type-I output neurons show complex postsynaptic responses typically comprising a relatively early, compound ipsp (graded with different stimulus intensities) followed by a compound epsp and burst of spikes. The compound ipsp (up to 10 mV) can follow afferent stimuli only when they are delivered at low frequency (< 10 Hz), and the latency of the ipsp, measured from the stimulus artifact, is relatively long (∿ 10 msec). These observations suggest that the inhibitory input is probably indirect via at least one inhibitory interneuron. Injection of hyperpolarizing current simultaneously with afferent stimulation reverses the sign of the psp, indicating that the ipsp is due to chemical neurotransmission. Moreover, the reversal potential is negative with respect to the resting potential, suggesting that an increase in Cl^- or K^+ conductance underlies the ipsp. Instantaneous frequency analysis of the spiking activity in the same output neuron reveals that the late excitatory component of the complex response (∿ 150 Hz peak instantaneous frequency) is time-locked to the electrically evoked afferent input. This suggests that a likely function of the early inhibitory input to an output neuron is to synchronize the late excitatory responses. This would enhance the signal-to-noise ratio at this level in the olfactory pathway.

In future experiments we shall seek to identify the antennal afferent inputs that evoke the complex response by applying odors to the antenna. We also plan to characterize the neurons that mediate the inhibitory and excitatory inputs to the output neurons of the AL.

These studies have been supported by NIH grant AI-17711 and NSF grant BNS 80-13511.

147.2 THE DYNAMIC SENSITIVITY OF A LOCUST MULTIPOLAR JOINT RECEPTOR. Andrew S. French and Janice E. Kuster*. Department of Physiology, University of Alberta, Edmonton, Canada. T6G 2H7

Insects contain two morphologically distinct types of mechanoreceptors. Type I, or cuticular mechanoreceptors, are bipolar neurons with a single ciliary dendrite terminating in a dense tubular body, surrounded by a dense dendritic sheath. They are always associated with the cuticle. Type II, or multipolar sensilla, have many dendrites which terminate in unspecialized naked endings. They are found in deeper tissues, lining the internal organs, associated with muscles and in the joints. Studies of sensory transduction in insect mechanoreceptors have concentrated on the Type I sensilla because their location makes them relatively easy to stimulate and to record from. A few studies have been made of the Type II receptors in leg joints, which can be stimulated by moving the limbs.

Type I sensilla are often rapidly adapting and in the frequency domain their response increases with frequency while there is a constant phase lead of the response relative to the stimulus. This type of behaviour is characteristic of a system which performs fractional differentiation of the input signal. Although a number of suggestions have been made, there is no satisfactory explanation for the location or the mechanisms of such fractional differentiation. We have suggested that the visco-elastic properties of the tubular body may contribute to the dynamic behaviour, in analogy to similar contributions by mechanical components in vertebrate mechanoreceptors such as the Pacinian corpuscle or the muscle spindle.

In the present work we have performed linear systems analysis of one of the multipolar joint receptors in the metathoracic leg of the locust, using both sinusoidal and random mechanical stimuli to the joint while recording the afferent action potentials in the axon extracellularly. The sensillum is tonically active with a mean rate of firing which increases in proportion to joint extension. Sinusoidal stimulation produces modulation of the rate of firing around this mean rate to give a smoothly sinusoidal response when measured as the peri-stimulus time histogram. However, phase-locking of the action potentials to a repetitive stimulus causes distortion of the frequency response function above about 1 Hz. Random stimulation substantially reduces the phase-locking problem and allows the frequency response function to be determined up to about 10 Hz. The results, measured under a range of different stimulus conditions, indicate that a fractional differentiator model can account for the behaviour of these Type II sensilla, suggesting that adaptation behaviour arises in the dendritic membrane rather than in the mechanical components surrounding insect mechanosensory cells.

147.3 SENSITIVITY TO DIMMING AS A FUNCTION OF BACKGROUND LIGHT INTENSITY IN THE BARNACLE'S VISUAL SYSTEM. Kathleen A. French and Ann E. Stuart. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27514.

The slight dimming of light evokes a protective reflex response in barnacles. In the giant barnacle, it has been shown that dimming leads to a hyperpolarization of the photoreceptors (PRs) and a depolarization of second- and third-order cells (Stuart and Oertel, 1978). Very small changes in PR voltage can lead to impulses in third-order cells (Shaw, 1972). To begin to explore the basis of this sensitivity, we have studied the responses of median PRs and third-order cells (A-cells) to step decreases in light. Backgrounds ranged over 6 log units ($10^{-7.2}$ to 0.33 mW/cm^2).

By recording extracellularly from the A-cell's axon, we determined the minimum percent decrease in illumination ($\Delta I/I$) required to evoke impulses from it at different background intensities (I). For a dim background ($10^{-5.4}$ mW/cm^2), $\Delta I/I$ was as high as 0.9, while for a bright background of 10^{-1} mW/cm^2 the threshold $\Delta I/I$ dropped to 0.03. Thus, these cells are increasingly sensitive to dimming as the background becomes brighter.

To obtain a more accurate measure of the A-cell's response, we recorded intracellularly from its soma. The preparation was perfused with saline containing tetrodotoxin to block the cell's impulses, so that the amplitude of the excitatory postsynaptic potential (EPSP) elicited by dimming could be measured. At any given background, the amplitude of this EPSP increased rapidly with $\Delta I/I$ over a range that narrowed with increasing background intensity. The dimming of brighter backgrounds by any given value of $\Delta I/I$ produced larger EPSPs. For example, in one experiment, decreasing the light intensity by half produced an 8mV EPSP at $10^{-4.2}$ mW/cm^2 and a 16 mV response at $10^{-2.4}$ mW/cm^2.

To determine whether changes in PR voltage could account for the effect that background has on the A-cell's sensitivity, we recorded intracellularly from PRs near their terminals. In contrast to the observations on A-cells, the voltage changes in a PR remained nearly constant when different backgrounds were dimmed by the same values of $\Delta I/I$ below about 0.8. Above that value the responses diverged from one another.

We conclude that, over a range of 4-5 log units of light intensity, A-cells are increasingly sensitive to the dimming of a constant light as this background is made brighter. This increase in sensitivity cannot be due simply to the size of the voltage change in the receptors' terminals.

147.4 CONTOUR SENSITIVITY AND ELECTROANATOMY OF CRAYFISH SUSTAINING FIBERS. B. Waldrop, M.D. Kirk and R.M. Glantz . Dept. of Biology, Rice University, Houston, TX 77251

Crayfish sustaining fibers (SFs) are tonic light-ON interneurons identified individually on the basis of their corneal receptive fields. Intracellular recordings show large (20-40 mV) EPSPs which can be affected by extrinsic current. I-V and I-f relationships are quite linear, allowing comparison of voltage and frequency data. Dye injections have revealed that the SFs have uniplanar dendritic arbors in a common layer of the second optic ganglion, the Medulla. The location of each cell's dendrites within the retinotopic columnar organization of the medullary neuropil predicts that cell's corneal receptive field.

Sensitivity of a SF to light varies within its receptive field. Detailed contour sensitivity maps have shown that a correlation exists between areas of high sensitivity on the cornea and the density of secondary and tertiary dendritic branches in the corresponding region of the neuropil, but apparently not to a degree which is sufficient to explain the observed variation of three log units of light sensitivity.

A compartmental electrtonic model of the SFs was constructed to determine if dendritic location and electrotonic decrement could play a role in contour sensitivity. The general solutions of the cable equations for DC current spread through dendritic trees (Rall, W., Exp.Neurol., 1:491-527, 1959) were used, along with an estimate of the specific axoplasmic resistivity (55 Ω-cm) and the geometry of the dye-filled SFs, to iteratively calculate a value for Rm, the specific membrane resistivity, which best predicts the observed input resistance (mean Rin for 14 preparations, 7.8 MΩ). The range of values for different cells is 8000-12,000 Ω-cm^2. We then applied Rall's algorithms to determine the decrement of DC potentials from various points on the dendritic tree to the probable site of spike initiation in the axon. A large transverse process seen in each SF, which serves as a summing point for the dendritic branches, appears to minimize differences between distal and proximal branches. Our computations indicate that for equal currents injected into the most proximal and the most distal terminal branches, the voltages at the spike initiating zone should differ by about 10%. Therefore the observed differences in sensitivity must be due to other factors, such as synaptic density or magnitude of synaptic conductance changes. The linear I-V, I-f, and spatial summing properties of the SFs indicate that their discharge is a remarkably faithful reflection of their synaptic inputs.

This project was supported by NSF grant BNS 79-10335 to R.M.G.

147.5 **LATERAL INHIBITION MECHANISMS OF MOVEMENT DETECTORS.** **R.B. Pinter Departments of Electrical Engineering and Zoology, University of Washington, Seattle, Washington, 98195.**

Many cells of visual systems respond preferentially to small objects which are moved or dimmed or brightened. In some cases, (e.g., dragonfly ventral cord object-movement units) the unit response resembles a spatial logic operator of an "exclusive-or" form (Olberg, R. J. Comp. Physiol. 141, p. 327, 1981) but in others the preference or selectivity functions are less steep (Palka, J. J. Insect Physiol. 13, p. 235, 1967, in locust DCMD).

Lateral inhibition of the Hartline-Ratliff type accounts well for response on peripheral levels in Limulus lateral eye, where the inhibition is linear up to large variations in the input variables even though Lange corrections (Barlow, R.B., Jr., and Lange, G.D. J. Gen. Physiol. 63, p. 579, 1974) are indicated for large amplitudes of eccentric cell generator potential.

A system of linear lateral inhibition does not however account well for movement detectors' sharp small object selectivity which is inherently nonlinear. Given a simplified form of Hartline-Ratliff linear lateral inhibition, in one dimension (i), where the ith cell's transmembrane potential is represented by e_i, the input is I_i and k a constant,

$$\frac{de_i}{dt} = I_i - e_i - ke_{i-1} - ke_{i+1}, i = 1,2,\ldots \quad (1),$$

it can be shown that the second order unperturbed form of non-linear lateral inhibition

$$\frac{de_i}{dt} = I_i - e_i - k_1 e_i e_{i-1} - k_1 e_i e_{i+1}, i = 1,2,\ldots \quad (2)$$

has the property of sharper small object selectivity than (1), along with movement detector properties not found in (1): input intensity dependent selectivity and latency. The latter two properties will not be found in any linear system. If the terms $-(k_2 e_i e_{i-2} + k_2 e_i e_{i+2})$ are added to equations (2) object edge sensitivity is considerably reduced.

In the compound eye, the inputs I_i are derived from visual space by approximately Gaussian angular sensitivity functions. Including this smooths the object angular sensitivity functions but causes the preferred size to vary with input intensity and the latency to vary with size of object, as found in movement detectors.

It is of interest that one kind of lateral inhibition produces several nonlinear properties of movement detectors. These properties are inter-related and not a one-to-one mapping on any coefficients or terms of the inhibition.

147.6 ACTIVATION OF VIBRATION RECEPTORS INITIATES SWIMMING IN A SEMI-INTACT LEECH PREPARATION. P. D. Brodfuehrer and W. O. Friesen. Dept. Biol., Univ. of Virginia, Charlottesville, VA 22901.

Leeches, Hirudo medicinalis, respond to surface waves by initiating swimming movements toward the source of the waves (Young, Dedwylder and Friesen, J. Comp. Physiol., 144:111, 1981). Detection of surface waves is mediated by vibration receptors located at the sensilla (Friesen, J. exp. Biol., 92:255, 1981). Fourteen sensilla are located circumferentially over the middle annulus of each mid-body segment, while fewer sensilla are located on the head and tail segments. Previous attempts to initiate swimming in a semi-intact leech preparation by wave stimulation have been unsuccessful. Using the fact that serotonin increases the probability of swimming in an isolated nerve cord (Willard, J. Neurosci., 1:936, 1981), we applied 50 µM serotonin to a semi-intact preparation and observed an increase in the number of spontaneous swimming episodes. When the rate of spontaneous swimming episodes was about two per 10 minutes, we could elicit up to 20 swimming episodes by wave stimulation in a 10 minute period. (In an active preparation swimming could be reliably initiated by surface waves 75% of the time.) Once wave stimulation ceased, the rate of spontaneous swimming episodes again returned to one or two per 10 minutes. This indicates that semi-intact leeches were swimming in response to wave stimulation and that this preparation is an accessable system in which to study the mechanism by which vibration receptors activate the swimming rhythm.

The precise locus of serotonin action is not yet known. We have characterized the afferent response of the vibration receptors to near-field stimulation both with and without serotonin and have observed no difference in the amplitude (250 µV) or duration (10-12 ms) of the vibration response in the dorsal posterior nerve. Serotonin does, however, increase the activity in the connectives and in the dorsal posterior nerve. For example, the dorsal excitor motor neuron, cell 3, occasionally fires 1-5 spikes in response to surface waves in the absence of serotonin. When the semi-intact leech is bathed in serotonin, surface waves evoke bursts of spikes in cell 3 which are reminiscent of the type of activity seen in cell 3 during swimming. Hence, serotonin appears to be exerting its effect centrally. Supported by NIH grant NS 14965.

147.7 INTRACELLULAR STIMULATION OF MECHANOSENSORY CELLS INITIATES SWIMMING IN THE MEDICINAL LEECH. E. A. Debski and W. O. Friesen. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

Tactile stimulation of an innervated body wall flap elicits swimming episodes in an otherwise isolated chain of leech ganglia . Any or all of the classical mechanoreceptors of the leech, the touch (T), pressure (P), and nociceptive (N) cells, could be mediating this swimming response. Yet published observations have suggested that swimming cannot be reliably obtained by individual stimulation of T, P, or N cells (Weeks and Kristan, J. exp. Biol. 77: 72, 1978). We have found that, contrary to these previous findings, intracellular stimulation of all three types of mechanoreceptors can elicit swimming episodes. Intracellular stimulation of individual N cells is most effective for swim initiation, P cell stimulation is somewhat less effective, and intracellular stimulation of a single T cell rarely leads to swimming activity. However, simultaneous stimulation of two T cells in adjacent ganglia reliably evokes swimming. The effectiveness of the three cell types fatigues rapidly; this observation could account for the failure of previous researchers to recognize the swim initiating capabilities of these cells. Stimulation of N cells, for example, will elicit only about four swim episodes in succession. For P and T cells, fatigue occurs even more rapidly. We found that the ability to initiate swimming can be temporarily restored to N cells by electrical stimulation of a segmental nerve (DP), while T cell effectiveness recovers following mechanical stimulation of a body wall flap attached to the ventral nerve cord.

Our attempts to elicit swimming activity in a nearly isolated nerve cord by lightly stroking a body wall flap revealed that such stimulation is initially very effective. However, this effectiveness also decreases with repeated stimulation, so that following five or six stimulus presentations, swimming activity is no longer produced. The ability of body wall stroke to initiate swimming recovers spontaneously or following the mechanical manipulation of another body flap. The T cell that innervates the body flap fires in rapid bursts while the remaining T cells in the ganglion are usually silent (N and P cells fire rarely, if at all, during body wall stroke). The effect of this stimulus on T cells in adjacent ganglia has not yet been examined. Experiments are currently underway to determine if T cell activity is necessary for this type of swim initiation.

147.8 NEURAL BASIS OF ULTRASOUND AVOIDANCE IN THE CRICKET TELEOGRYLLUS OCEANICUS. T.G. Nolen and R.R. Hoy, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

Tethered, flying crickets respond to pulses of ultrasound by bending their abdomen, legs and antennae away from the sound source (Moiseff, Pollack and Hoy, P.N.A.S. 75:4052). In the field, this behavior would allow them to fly away from echolocating, insectivorous bats, possible predators of crickets. We find that the ultrasound response is different from that elicited by the species calling song (i.e. 4.5 to 5 kHz). We show that an identified auditory interneuron (Interneuron 1, Int-1) is an important component of the neural circuit mediating ultrasound avoidance.

Tethered, flying crickets respond to single, 30 msec ultrasound pulses (30 kHz) by making short latency (35 msec) phasic abdomenal flexions away from the side of stimulation at a threshold of 57.7 ± 5.7 dB SPL (mean ± SD, N = 65 animals). However, single pulses near the calling song frequency (e.g. 5 kHz) elicit no response in 85% of those tested, even at 100 dB (a negative response was elicited in 15%, but only at >=100 dB, N = 56 animals). As a comparison, the threshold to the temporally patterned calling song is 55 dB.

Intracellular recordings show that Int-1 is broadly tuned between 18 and 50 kHz (thresholds between 40 and 60 dB) but has a high threshold peak of sensitivity near the calling song (threshold at 5 kHz of 50 to 70 dB). 5 kHz mediates both inhibition (IPSP's with reversal potentials near resting potential) as well as excitation, such that spike rates at threshold +10 dB are lower than those elicited by ultrasound. As a result, Int-1 is maximally excited by ultrasound (between 20 and 40 kHz).

Finally, Int-1 appears to play a direct role in the behavioral response to ultrasound. When a 30 kHz pulse was presented to a flying cricket, a burst of action potentials was elicited in Int-1 (spike rate approx. 200 Hz), followed by activation of the contralateral abdominal steering muscles (the dorsal longitudinal muscles or DLM's). When the spike rate in Int-1 was reduced below a critical level by hyperpolarizing current injection, the DLM response was abolished. Above the critical level, the DLM response was positively correlated with the spike rate in Int-1. The reduction in the DLM response was reversible.

In the absence of ultrasound stimulation, electrical excitation of Int-1 in a flying animal was followed by strong activation of the contralateral DLM's. The DLM's could not be activated unless the animal was flying.

These results strongly suggest that the bilateral pair of Int-1's are necessary and sufficient components of the ultrasound avoidance behavior.

147.9 ELECTRONMICROSCOPY RESOLVES SPECIAL JUNCTIONS IN "TRANSSYNAPTIC" COBALT-COUPLED NERVE CELLS IN GIANT FIBRE SYSTEMS (GFS) OF FLIES (Drosophila, Musca & Calliphora). U.Bassemir*, N.J.Strausfeld, J.P.Bacon* and R.N.Singh*. EMBL, D-69 Heidelberg, West Germany; SUNY Albany, Albany, New York 1222; T.I.F.R., Bombay, India.

Stereotyped passage of cobalt ions occurs between certain neurons of the GFS in Drosophila, Musca and Calliphora. In Drosophila paired homolateral Giant Descending Neurons (GDNs) are cobalt-coupled to antennal inputs, small field visual interneurons (Col As), Tergotrochantal Motorneurons (TTMs) and Peripherally Synapsing Interneurons (PSIs). GDNs are also coupled in the brain via several Giant Commissural Interneurons (GCIs) and are directly coupled at their terminals in the mesothoracic ganglion. In Musca and Calliphora, GDNs are not coupled to PSIs or to GCIs but are coupled to certain male-specific visual neurons in male flies (MLG 1).

X-ray emission spectroscopy of fine grain electron-dense material in filled cells of Musca generated by a highly sensitive silver intensification method for use on intact brains shows the precipitates to be cobalt (sulphide)-silver deposites. CoS-Ag precipitates are localized at mitochondria, neurofilaments and pre- and postsynaptic membrane specializations. In cobalt-coupled neurons the secondarily filled cells contain fewer CoS-Ag grains which are first resolved at synaptic areas and in mitochondria. CoS-Ag precipitates are also localized at special gap junction-like structures that are shared by the pre- and postsynaptic membranes of cobalt-coupled neurons (e.g Col A cells and GDNs, in Musca). Cells presynaptic onto GDNs, but never cobalt-coupled do not exhibit these structures and do not contain CoS-Ag.

Iontophoretic injection of the fluorescent dye, Lucifer Yellow, into GDNs of Musca after electrophysiological recordings can also reveal Lucifer-coupling between GDNs at their endings, between GDNs and Col A cells and,in one case, between a GDN and the MLG 1 neuron in a male. Dye coupling and cobalt coupling of GDNs to other neurons in Musca is equivalent although structural resolution with cobalt-silver is superior.

We suggest that "transsynaptic" cobalt-coupling occurs specifically between neurons sharing gap junction-like structures and that cobalt-coupled neuronal pathways are possibly functional pathways in the insect central nervous system. We are pursuing the functional nature of cobaltomissive pathways by intracellular recordings and by electronmicroscopy of the GDN to TTM and PSI connections in Drosophila. Cobalt-coupling is also being used by us for analysing abnormal neuronal pathways in mutants of Drosophila affecting the sensory input and for the analysis of cell arrangements in the mouse cerebellum.

147.10 HIGH VOLTAGE ELECTRON MICROSCOPE STUDY OF RETINAL DEGENERATION IN DROSOPHILA, William S. Stark, Kiran Srivastava* (Div. Biol. Sci., Univ. Missouri, Columbia, MO 65211) and Stanley D. Carlson* (Dept. Entomology, Univ. Wisconsin, Madison, WI 53706).

We used High Voltage Electron Microscopy (HVEM) to study the defects involved in retinal degeneration of the compound eye and underlying neuropile in white-eyed Drosophila. This technique allows the convenient use of relatively thick (0.25-0.5 μm) sections with good resolution of cells, organelles and membranes. We studied 3 types of retinal degeneration: 1) induced by intense light (blue and UV); 2) caused by mutant alleles of the rdgA gene (BS12 and PC47); and 3) caused by the mutation $rdgB^{KS222}$.

1) Bright blue and UV light damages the eye (Miller et al. 1982, Invest. Ophth. Vis. Sci. Suppl. 22, p.66). Cytoplasm of the retinular cells is not homogeneous but appears to be coagulated into a series of coarse electron dense strands that extend parallel to the microvillar direction. The microvilli are reduced and appear nonpatent. Large fluid filled spaces are proximal to the basement membrane. Second order cells are present but disorganized by gliosis. There are no remains of retinular cell axons. The threshold for damage is between 18.5 to 18.7 log quanta/$cm^2 \cdot s$ (for blue) and below 17.9 (for UV) given 30 s stimuli.

2) The mutants $rdgA^{BS12}$ and $rdgA^{PC47}$ cause severe vs gradual degeneration (Johnson et al. J. Insect Physiol. 28, 1982, 233-242). PC47 has a normal retina and visual projection when newly-emerged. The R1-6 photoreceptor subset (somata and axons) of PC47 aged 1 wk is in an advanced state of lysis. R7/8 are better preserved. Higher order neurons look normal. In newly-emerged BS12, R1-6 have small rhabdomeres and few mitochondria. R7 and R8 are recognizable but their rhabdomeric microvilli are deranged, divided into double sets or in several orientations. The presence of pseudocartridges beneath the basement membrane shows that an axonal projection begins. But where the synaptic cartridges should be in the lamina ganglionaris (first optic neuropile) there are no axons, only a gliosis. Second order neurons, if present, are disorganized. The retina in week-aged BS12 is very degenerate, though the lamina looks curiously less degenererate than in PC47 due to lack of degenerating axon terminals.

3) These results can be compared with recent studies of white-eyed $rdgB^{KS222}$ (Stark and Carlson, Cell and Tiss. Res. 1982 in press) whose degeneration is light-induced. After 1 wk of cyclic lighting, R1-6 show dense, nonpatent microvilli and cytoplasm that seems coagulated into an electron-dense reticulum. R1-6 axons are degenerate and in the process of phagocytosis by adjacent epithelial glia. R7/8 and higher order cells are normal.

In summary, Drosophila have different retinal degenerations.

147.11 CERCAL SENSORY SYSTEM IN A PRIMITIVE INSECT. John S. Edwards. Max Planck Institut fur Verhaltensphysiologie, Seewiesen, Federal Republic of Germany and Zoology Department, University of Washington, Seattle, WA., 98195.

The cercal sensory system now known from a series of pterygote insects, notably orthopteroids, has its presumed origin among the primitively wingless insects (Apterygota). The Thysanura (silverfish, firebrats) are modern apterygotes that may be considered to reflect the level of cercal sensory organization of the stem pterygotes.

In the thysanuran Thermobia domestica the median caudal filament and the paired lateral cerci all bear mechanoreceptor hairs of at least three types arranged in a repeating pattern of segments on which distal arrays of filaform sensilla are similar to the Notoptera. The afferent nerve of the median filament is devided laterally, and is fused with the lateral cercalnerves. Central projections of median and lateral nerves partially overlap in three regions of arborization.

Within the CNS four giant interneurons occupy positions that appear to be homologous with those of orthopteroid counterparts. Extensive presynaptic sites occur on at least 2 giant interneurons in the penultimate ganglion. Type 1 synapses occupy sites on circular axon profiles of cells ca.25μm in diam. Post synaptic cells are generally small (ca.0.15μm in diam,) grouped in parallel sets of up to 12. with triads frequent. These synapses are the first reported to occur directly on giant axons of an orthopteroid insect.

Behavioral responses indicate an ability to localize sources of mechanoreceptor stimuli delivered as directional airpuffs from the posterior sector. The behavior of animals deprived is not significantly different from normal. The caudal filament alone can mediate escape responses to airpuffs. The functional relationship of input to the terminal ganglion from lateral cerci and caudal filament remains obscure.

Supported by an Alexander von Humboldt Award, and NIH grant NB 07778.

148.1 CYTOCHEMICAL LOCALIZATION OF TYPE I HYDROGEN IN CIRCUMVENTRICULAR ORGANS AND THE HYPOTHALAMO-NEUROHYPOPHYSIAL SYSTEM. J.Y. Summy-Long, R. Salisbury*, M. Marietta* and J. Weisz*. Dept. of Pharmacol. (J.S.-L), Div. Rep. Biol., Dept. Ob/Gyn, M.S. Hershey Medical Ctr., Penn State Univ., Hershey, PA 17033.

Using cytochemistry, it is possible to differentiate between two types of reducing equivalents, termed Type I and Type II hydrogen (H), made available from NADPH. The NADPH is generated in cytoplasm by dehydrogenases of the hexose-monophosphate shunt (e.g. glucose-6-phosphate dehydrogenase, G6PD). In peripheral tissues, Type I H is of functional importance in hydroxylation of steroids and drugs. Cellular utilization of Type I H in these tissues requires its transfer from NADPH along the electron-transport chain to the terminal oxidase, cytochrome P-450. Activities of G6PD and the NADP hydrogen-transport chain can be identified histochemically using neotetrazolium chloride. In this system,Type I H generated by the oxidation of glucose is trapped by neotetrazolium as it passes along the cytochrome chain. As neotetrazolium is reduced,it form a blue formazan precipitate. Adult male Sprague Dawley rats (300-400g) were decapitated and different portions of the brain frozen (-70°C) in n-hexane. Saggital sections of brain were cut at 14μ in a cryostat. Sections were incubated in medium containing 5mM glucose-6-phosphate,3mM NADP, 10mM KCN and 4.5mM neotetrazolium chloride dissolved in 0.05M glycyl glycine buffer, pH 8.0, which contained 20% polyvinyl alcohol to prevent loss of soluble enzyme. The medium at 37°C was saturated with nitrogen just before use. After incubation for 20 min at 37°C,sections were rinsed, then fixed and counter-stained with methyl green-pyronin. A regional localization of Type I H was observed. Formazan was localized in cells of circumventricular organs including the subfornical organ,the vascular organ of the lamina terminalis,subcommissural organ and pineal gland. Dense reaction product was found in large neurons in the subfornical organ and in the apical cytoplasm of columnar cells in the subcommissural organ. Type I H was prominent throughout the hypothalamo-neurohypophysial system. Formazan precipitate was seen in some,but not all,magnocellular cells in the supraoptic and paraventricular nuclei,the zona interna of the median eminence and the neurohypophysis. When present in cells,the formazan was extra-nuclear but frequently clustered in peri-nuclear zones. Formazan precipitate was not associated with capillary endothelial cells,but was prominent in arterioles within the CNS. Identification of factors that modulate Type I H formation at these sites is possible by microspectrophotometry. This approach will be useful in delineating the functional significance of the presence of Type I H in these, as well as other,sites in the brain. Supported by Grants #HL 25726 and NICHHD #HD 09524.

148.2 ESTROGEN ALTERS NERVE CELL NUCLEOLI IN RAT HYPOTHALAMUS. R.S. Cohen* and D.W. Pfaff. Dept. of Anatomy, Univ. of Illinois at the Med. Center, Chicago, IL. 60612 and The Rockefeller University, New York, N.Y. 10021.

Estrogen is accumulated from the blood by nerve cells in the ventromedial nucleus (VMN) of the hypothalamus and can facilitate female reproductive behavior by acting on this region of the brain. In hypothalamus and pre-optic area, such estrogen effects apparently involve RNA and protein synthesis. Through their connections to the midbrain, neurons in the ventromedial hypothalamus influence the circuitry for female reproductive behavior, and this appears to comprise a mechanism for sexual motivation. If estrogen effects on behavior include alterations of nerve cell RNA synthesis, estrogen treatment adequate to induce feminine behavior should alter the appearance of ventromedial hypothalamic nerve cell nucleoli, primary sites of RNA synthesis in these as in other cells. We, therefore, ovariectomized 12 female rats and waited one month for estrogen levels to decline. Then, six were given daily injections of 10μg estradiol benzoate, while six control animals were given vehicle injection only. After 15 days of injection, all estrogen-treated rats showed lordosis behavior, and none of the controls did. All rats were perfused and brain tissue dissected and processed according to standard electron microscopic procedures. Thick and thin sections through the ventrolateral portion of the VMN of the hypothalamus, which contains a high density of estrogen-binding cells, were taken for light and electron microscopy. With light microscopy we noticed protuberances on the surface of some neuronal nucleoli, which were more frequent in the ventromedial hypothalami of estrogen-treated than in control female rats. Cells with protuberances on the nucleolar surface occurred more than twice as often in the estrogen-treated compared to the control group (58% of ventromedial neurons in estrogen-treated rats had nucleolar protuberances, compared to 27% in controls). Ultrastructural examination of the VMN of the hypothalamus revealed cells with aggregations of electron dense material corresponding to the nucleolar surface features we described above. At high magnification, this material can be seen to be separated from the nucleolus by a narrow gap, penetrated by strands of this electron dense material which connect it to the main portion of the nucleolus. Steroid hormone actions in many tissues require an increased capacity for protein synthesis and so involve a greater rate of synthesis of ribosomal RNA. Previous ultrastructual results (Cell Tissue Res. 217:451, 1981) indicated increased synthesis of a secretory product by the large amounts of rough endoplasmic reticulum in estrogen-activated hypothalamic cells. This would require increased synthetic rates for rRNA in these nerve cells, which would be reflected at the nucleolar level. Supported by NIH grants NS 15889 and HD-05751.

148.3 IMMUNOREACTIVITY TO NEUROPHYSINS I AND II IN DYE-COUPLED MAGNOCELLULAR HYPOTHALAMIC NEURONS. P. Cobbett*, K. G. Smithson*, B. A. MacVicar & G. I. Hatton. Neuroscience Program and Psychology Dept., Michigan State University, E. Lansing, MI, 48824.

Oxytocin (OT) and vasopressin (VP) are released from the neurohypophysial terminals of hypothalamic neurons. To achieve sufficient plasma hormone concentrations, homotypic neurons must either fire in synchrony or have a high degree of coordinated excitability. Such activity may be produced or facilitated by electrotonic coupling of neurons, which is indicated where dye-coupling of neurons is present. We have investigated the presence of OT and VP in neurons injected with dye in hypothalamic slices where dye-coupling has previously been shown (Science, 211:1187, 1981). Slices were prepared from 30-70 day-old rats of both sexes. The slices were incubated in gassed (95% O_2, 5% CO_2) medium (310 mosmol). Neurons of the paraventricular nucleus (PVN) were injected intracellularly with Lucifer Yellow CH. Precautions to prevent artifactual dye-filling of neurons were taken. After injection, slices were fixed in paraformaldehyde, dehydrated and cleared in methyl salicylate. Tissue was then briefly viewed under epifluorescence and the type and number of neurons containing dye were determined. Slices were then rehydrated, immersed in Bouin's fixative, dehydrated, embedded in polyethylene glycol, and sectioned at 5 μm. Mounted sections were alternately reacted with antibodies to the neurophysin (NP) associated with OT (NPI) or VP (NPII). Subsequent incubations with a biotinylated secondary antibody, avidin-biotin-HRP complex, and 3,3'-diaminobenzidine produced a brown reaction product. Sections were examined to determine the immunocytochemical identity of dye-filled neurons. To date, 82 PVN injections have been made and all dye-filled neurons were magnocellular. Sixty-eight single cells and 14 dye-coupled pairs were observed: 2 pairs were dendro-dendritically coupled, and the others were apparently coupled dendro- or soma-somatically. Of the single neurons, 10 have been identified immunocytochemically: 4 were NPI positive and 6 were NPII positive. Three soma-somatically coupled pairs were NPII positive, but no dendro-dendritically coupled pairs have yet been identified. These data are evidence that dye-coupling in the PVN is genuine. If artifactual, then "coupled" neurons would contain different hormones in some instances since OT and VP neurons coexist in close proximity in the nucleus. The hypothesis that coordinated activity of homotypic neurons may be produced by electrotonic coupling is also supported by the data. Taken together these data suggest that VP neurons are coupled soma-somatically, but that OT neurons, if coupled, may have dendro-dendritic junctions.

148.4 SUPRAOPTIC NEURONS IN RAT HYPOTHALAMO-NEUROHYPOPHYSIAL EXPLANTS: ULTRASTRUCTURAL AND IMMUNOCYTOCHEMICAL CHARACTERIZATION OF ELECTROPHYSIOLOGICALLY-IDENTIFIED MAGNOCELLULAR NEURONS. T.A. Reaves, Jr., M.T. Libber* and J.N. Hayward. H. Houston Merritt Electron Microscopy Lab., Dept. Neurology and Neurobiology Program, University of North Carolina, Chapel Hill, N.C. 27514.

Using a double-labeling technique which combines immunocytochemistry with intracellular-recording and -injection of Lucifer Yellow (LY), we described three chemical cell types within the magnocellular (MgC) neuroendocrine system (JCN 193:777'80). We now report the combination of this double-labeling technique with a new procedure that produces insoluble osmophilic polymers in LY injected cells (Maranto, Soc.Neurosci.Abstr. 7:418'81). We find that electrophysiologically studied rat supraoptic (NSO) MgC neurons can be LY-injected, immunocytochemically identified, UV-irradiated and studied by light(LM)- and electron(EM)-microscopy.

Using rat hypothalamo-neurohypophysial explants (Sladek and Knigge, Endocrin. 101:1834'77), we recorded intracellularly from pituitary-antidromically identified NSO neurons with 2% LY-filled glass micropipettes and iontophoretically-injected (5-10 nA,DC) those neurons with LY. Fixed explants were vibratome sectioned (30-50 uM). LY-filled neurons were located with fluorescence microscopy and chemically identified using primary rabbit anti-rat neurophysin antiserum (RN#4, Dr. A.G. Robinson) and a secondary antiserum tagged with rhodamine. Sections containing double-labeled neurons were soaked in a diaminobenzidine (DAB) solution and irradiated under UV light in DAB until LY fluorescence faded below visibility. Irradiated sections were then osmicated, embedded in Epon and sectioned for LM and EM.

Antidromically identified NSO neurons were either silent or displayed spontaneous firing patterns. We identified immunocytochemically (double-labeled) about 50-75% of LY-injected neurons as neurophysin (NP) containing. UV irradiation (7-15 min) of LY-NP somata resulted in a dark DAB photo-oxidation product (DAB-POP) within each LY marked cell. We find a direct correlation between the intensities of the LY fluorescence and that of DAB-POP within marked neurons. At the ultrastructural level, a fine granular DAB-POP is distributed throughout the cytoplasm of LY-NP neurons. The ultrastructural features of some injected neurons are well preserved and show intact synaptic boutons innervating the DAB-POP filled soma, axon or dendrites. Other injected neurons display swollen mitochondria or endoplasmic reticulum and have electron dense nuclear spots. These results are similar to those we find in goldfish (Reaves et al., Neurosci.Lett. in press '82).

These results suggest the feasibility of morphological (LM/EM) and intracellular electrophysiological analysis of the rat hypothalamo-neurohypophysial explant to model neuroendocrine function. (Support by NIH Grant NS-13411 and a Neurobio. Fellowship to MTL)

148.5 LHRH IN FETAL HYPOTHALAMUS: IN VIVO AND IN VITRO STUDIES. J. Matthews-Bellinger, J.C. King, W.H.J.Douglas* and A.A. Arimura*
Dept. of Anat., Tufts Univ. Sch. of Med., Boston, MA 02111 and Laboratories for Molecular Neuroendocrinology and Diabetes, Depts. of Med. and Anat., Tulane Univ. Sch. of Med., New Orleans, LA 70114.

Dispersed monolayer cultures of neurons offer a simplified yet versatile system to examine modulators of neurosecretion. In contrast to other neuropeptides, LHRH has been particularly difficult to detect within dissociated cultured neurons, although the peptide has been detected by RIA in the medium. Preoptic/hypothalamic regions from 18 day rat fetuses were dissociated either by a modified sieving technique or by mild trypsinization combined with gentle trituration, and plated at $5 - 7 \times 10^4$ viable cells/cm^2 of culture dish. Medium consisted of a 1:1 mixture of Ham's F-12: Dulbecco's MEM supplemented with glucose (to 620 mg%), insulin (20mU/ml), penicillin, streptomycin, glutamine, and 10% fetal calf serum. Non-neuronal cells were allowed to form a sparse background layer, after which further proliferation was suppressed with cytosine arabinoside (2×10^{-6}M) (on day 4 or 5). Neurons attach and extend neurites within 3 to 4 days after plating. Maturing cultures contain a variety of neuronal cell types with soma ranging from 5 to 25 µm in diameter. The majority are bipolar or tripolar with extensive fine neurites typically branching at a distance from the cell body.

Neuropeptide producing cells were identified by immunocytochemistry using the peroxidase-anti-peroxidase method of Sternberger. Cultures were fixed for 15 minutes at 21 °C in 5% acrolein in Sorensen's buffer, washed, then pretreated sequentially with $NaIO_4$, $NaBH_4$, and DMSO. Cultures were incubated for 2 to 3 days at 4°C with primary antisera in the presence of 0.4% triton-X. A small percentage of neurons in these cultures are immunopositive for substance P, somatostatin or tyrosine hydroxylase. In contrast, the majority of neurons are immunoreactive with LHRH antiserum # 422. Reaction is completely abolished when the antiserum is preabsorbed with synthetic LHRH. Immunopositive LHRH is concentrated in the cell body, extending only 10-20 µm along neurites. Antiserum # 422 requires the free N- and C- terminals of LHRH for binding and probably indicates the presence of active decapeptide hormone. In vivo perikaryal LHRH is not revealed with antiserum # 422 either in adult or in day 18 fetal rat brains. However, LHRH is detected in perikarya of both adult and fetal brains with an antiserum that allows modifications of both the N-and C-terminals (#419), as expected for larger precursor forms. A conversion of LHRH molecular species in vitro from an inactive to an active form within perikarya is suggested.

148.6 PROTOCEREBRAL NEUROENDOCRINE SYSTEM OF THE TOBACCO HORNWORM: MORPHOLOGY AND PHYSIOLOGY OF IDENTIFIABLE NEUROSECRETORY CELLS. Grant M. Carrow*, Ronald L. Calabrese and Carroll M. Williams*. (Spon: Edmund A. Arbas). The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Cell bodies of protocerebral neurosecretory cells (NSC) in isolated, desheathed brains from pupae of the tobacco hornworm, Manduca sexta, were distinguished according to size, position, and reflective opalescence. Individual NSC were stained by intracellular injection of lucifer yellow or horseradish peroxidase. Dendritic arborizations of stained NSC from both lateral and medial groups were concentrated in the cortical region between the groups, a finding which suggests interactions among the cells. Moreover, a medial NSC was found to be dye-coupled at the midline of the brain to an axon collateral of a lateral cell. Branched terminals of the NSC were located in the corpora cardiaca and in the corpora allata, thereby confirming multiple neurohemal sites.

Intracellular penetration of the NSC somata in isolated, desheathed brains revealed resting membrane potentials of -30 to -40 mV, broad (20-40 msec) overshooting action potentials, and postsynaptic potentials. The cells were electrically responsive to depolarizing current injected through the intracellular microelectrode. Replacement of the bathing medium with a high K+ medium also depolarized the cells. Extracellular stimulation of the nerves joining the neurohemal organs to the brain resulted in antidromic impulses recorded in the cell bodies. The pattern of axonal projections determined physiologically agreed with that determined morphologically.

Certain of the cells under study synthesize and release prothoracicotropin (PTTH), a polypeptide hormone which regulates development. Our ongoing research is aimed at the use of the system described here, along with the stimulated release and assay of PTTH (Carrow et al., 1981, PNAS, 78:5866), to identify the PTTH neurosecretory cells and to study their neuronal and hormonal control throughout development.

Supported by NSF grant BNS-8121551 to RLC and an NIH grant to CMW.

148.7 STRUCTURE OF INDIVIDUAL NEUROSECRETORY CELLS OF THE BRAIN IN CRICKETS. M. D. Zaretsky* and W. J. Loher* (SPON: E. Marg). Depts. of Zoology and Entomology, Univ. of California, Berkeley, CA 94720.

Individual neurosecretory cells of the pars intercerebralis of the brain in crickets, Teleogryllus commodus, are shown to have diverse and complex structures when injected with the fluorescent dye Lucifer Yellow (LY) (Stewart, W., Cell, 14: 741, 1978). The action potentials recorded intracellularly with the dye-injecting electrodes are of 7-50 msec duration, typical of insect neurosecretory cells. These experiments indicate there are neurosecretory cells of the pars intercerebralis that do not communicate directly with the organs of the retrocerebral complex. In addition, LY injections reveal additional arborizations and finer details of the structure of neurosecretory cells whose general features have been discovered by cobalt sulfide staining via the nerves to the corpora cardiaca, corpora allata and hypocerebral ganglion (Mason, C. A., Z. Zellforsch., 141: 19, 1973; Koontz, M. and Edwards, J. S., J. Morph., 165: 285, 1980).

The cells of the pars intercerebralis may be grouped according to structure and location of their axons and arborizations. There are cells with axons that cross the midline within the protocerebrum, running ventrally and emerging from the posterior surface of the brain in the nerves of the corpora cardiaca (NCC I), a pathway that has been described by many different histological techniques in several insect groups. Iontophoretic injection of LY demonstrates not only do the axons of these cells branch extensively in the protocerebrum, but also that they arborize in the deutocerebrum and tritocerebrum.

There is a distinct group of cells of the pars intercerebralis that do not have axons that leave the brain. The axons of these cells branch extensively in the protocerebrum and deutocerebrum. A region of prominent, repeated axonal branching is located medially and ventrally near the oesophageal foramen. This area has been described in another species of cricket, Acheta domesticus, as a neurohaemal region, containing neurosecretory fibers (Geldiay, S. and Edwards, J.S., Z. Zellforsch., 145: 1, 1973). These cells also arborize extensively in the more dorsal and lateral regions of the brain. The location of their somata, the extensive branching of their axons in a neurohaemal area and the long durations of their action potentials suggest that the cells of this group are neurosecretory.

148.8 A VISUALLY INDUCED, GABA MEDIATED IPSP IN A CRUSTACEAN NEUROSECRETORY CELL. M. D. Kirk and R. M. Glantz. Dept. of Biology, Rice Univ., Houston, TX 77251.

A discrete group of neurosecretory cells, analogous to the Medulla Externa X-organ of other crustacea, has been found in the crayfish. There are approximately 20 of these cell bodies clustered at the proximal-medial edge of the second optic neuropil of the crayfish eyestalk. The morphology of these neurosecretory cells (obtained from lucifer yellow and HRP injections) is as follows: A short neurite leads from the soma to a profusion of fine dendrites within the medullary neuropil. The dendrites lie in a single vertical plane within the second tangential cell layer of the Medulla. One or two axons originate near the cell body, and project distally terminating proximal to and within the first optic neuropil (L amina).

Using a semi-intact eye-cup preparation (Kirk et al., 1982) intracellular recordings were made from the neurosecretory cell bodies. Action potentials actively invade the soma and are extremely long in duration (½ width = 7 msec). The most remarkable characteristic of the cells is their response to light stimuli directed to the cornea of the eye. They are inhibited by step increases in illumination and the response lasts for the duration of the stimulus. Transient off-inhibition is commonly present. The IPSP reverses near resting membrane potential and appears to be Cl^- dependent. Iontophoresis of gamma-aminobutyric acid (GABA) within the neuropil produces an IPSP with a similar reversal potential and GABA also densensitizes the light response. Release of the neurohormone is proposed to induce dark adaption (and circadian?) migration of visual screening pigments and/or changes in photoreceptor sensitivity, therefore the light induced IPSP provides a pathway for sensory control of neurosecretion.

Supported by a NIH predoctoral training award (EY-07024-03) and NSF research grant (BNS 79-10335).

148.9 NEUROPEPTIDE SYNTHESIS AND RELEASE IN ISOLATED NEUROSECRETORY CELLS OF THE CRAYFISH. H. Aréchiga, L. Rodríguez-Sosa* and T. de la Vega*. Dept. Physiol., Ctr. Research and Advanced Studies, IPN., Apartado Postal 14-740, México, D.F. 07000.

The eyestalk of crayfish is known to release several neurohormones of peptidic nature. No information is available as to the specific cells related to their synthesis and release. In previous studies (see Aréchiga, H. and Huberman, A. Peptide modulation of neuronal activity in crustaceans. In: The Role of Peptides in Neuronal Function. J.F. Barker and T.G. Smith, Eds. Marcel Dekker, Inc. 1980. p. 317-349), we have characterized a neuropeptide which reduces the excitability in the crustacean nervous system. This neurodepressing hormone (NDH) is mostly located in the eyestalk. This report presents evidences on the location and some properties of the cells of origin of NDH. The experiments were carried out in adult specimens of the crayfish Procambarus clarki and Procambarus bouvieri, of either sex. Intermolt animals were only used. The eyestalks were incubated in a mixture of collagenase and papain, in calcium-free saline solution (Van Harreveld's). Various combinations of enzyme concentrations and incubation times were tested until chosing the most appropriate. Cell disaggregation was followed under microscopic control with a Zeiss inverted microscope. NDH was recovered from the tissue samples by extraction in acetone and chloroform and successive stages of Sephadex G-25 and G-15 columns, followed by paper electrophoresis. Its determination was made by its ability to reduce the tonic firing rate of isolated abdominal stretch receptors of crayfish. Cells recovered after dispersion of various regions of the eyestalk were tested for NDH. This mapping showed that more than 75% of NDH content in cell bodies was in the ventromedial region of the medulla terminalis. Groups of these cells were incubated in high-potassium solutions ranging from 10 to 80 mM. NDH was released in proportion to potassium concentration, up to ~ 80% of the total content of the cells. The amount released increased with time of incubation within a 30 min. range. After depletion, cells were incubated in a mixture of aminoacids (Gibco's MEM) and NDH content was followed by sampling at 10 min. intervals. In 1-2 hours, there was a full recovery of the basal hormone level. This result was not obtained after incubating the cells in saline solution or if protein synthesis inhibitors were added to the aminoacid mixture.

This results indicate that NDH synthesis is confined to a restricted population of neurons in the eyestalk, and that its release may take place outside the terminals, in a place near or at the cell body.

148.10 IN VITRO PEPTIDE SYNTHESIS AND NEUROSECRETION FROM A CRAB NEUROHAEMAL ORGAN. E. Stuenkel* (Spon: I. M. Cooke). Bekesy Laboratory of Neurobiology, Univ. of Hawaii, Honolulu, HI 96822.

^{3}H-labelled peptide secretion from single X-organ-sinus gland (XOSG) preparations was studied. This neurosecretory system has discrete somata (X-organ, XO), axon and terminal (sinus gland, SG) regions. A single XOSG of Cardisoma carnifex was mounted in a double chamber apparatus which permits: 1) separate superfusion of somata and terminals, 2) intracellular electrode recordings from somata and nerve terminals, and 3) extracellular recording of impulse activity in the XOSG tract as it passes the barrier between the chambers. Peptide secretion was stimulated by selective exposure of somata or terminals to a 10 min pulse of saline containing 113 mM K^+ (10XK).

XOSG-specific protein and peptides were radiolabelled in vitro (5 hr pulse : 19 hr chase) with ^{3}H-leucine (130-170 Ci/mM). Peptides produced in the somata and those axonally transported to the terminals were analyzed by SDS-PAGE, HPLC and bioassay. Results indicate that radiolabel in the peptide fraction (10,000 daltons) is associated with at least 5 separate XOSG-specific peptides. Crustacean hyperglycemic hormone(s) and erythrophore concentrating hormone represent 3 or 4 of the peptides radiolabelled. In 5 experiments intracellular terminal records were made during 10XK depolarizing pulses with simultaneous collection of superfusate samples for direct correlation of release from and electrical activity in the nerve terminals. Selective application of 10XK to the SG terminals showed a depolarization, with spiking, lasting approx. 2 min before attainment of a non-spiking plateau 25-30 mV depolarized from rest potential (-20 to -25 mV absolute). An increase in ^{3}H-efflux from the SG terminals appeared in superfusates approx. 2 min subsequent to the application of 10XK to the SG and lasted throughout the exposure to 10XK. No increase in ^{3}H-efflux was seen from the XO somata although simultaneous intracellular recordings from the XO and SG show that depolarization of similar magnitude occurs in both on application of 10XK to the SG. Selective application of 10XK to the XO somata also showed a depolarization, with spiking, to reach a stable level of approx. -20 to -25 mV absolute; simultaneous recording from the SG terminals revealed only a 6-10 mV depolarization. Under these conditions no increase in resting ^{3}H-efflux is seen from either the XO or the SG. In all cases there was recovery to pre-test rest potential, activity and ^{3}H-efflux rates after return to normal saline. The peptide nature of the 10XK-induced increased ^{3}H-efflux from the SG terminals was confirmed by high voltage paper electrophoresis (50-60 V/cm; pH 1.9; 1-2 hr) prior to and subsequent to acid hydrolysis, and by HPLC. Supported by NIH grant NS 15453 to I. M. Cooke.

148.11 PREDOMINANT PEPTIDES IN LYSATES AND PERFUSATES OF THE SINUS GLAND OF CARDISOMA CARNIFEX: ISOLATION AND AMINO ACID COMPOSITIONS. R. Newcomb* (SPON: H. Gillary). Bekesy Laboratory of Neurobiology, University of Hawaii, Honolulu, Hawaii 96822.

The predominant peptides of a major invertebrate neurosecretory structure, the crustacean sinus gland, have been purified by reversed phase liquid chromatography (RPLC) from the crab Cardisoma carnifex. Peptides were characterized by 1) RPLC elution properties relative to known peptides, 2) amino acid composition, 3) bioassay and 4) elution properties of their fluorescamine derivitives. Nine peptides were constantly present in large quantity and several other peptides were present in variable and/or lesser quantity (approx. 10 µg total peptides/sinus gland). All of these peptides were unique to the sinus gland and not found in the surrounding nervous tissue. Based on the amino acid compositions, the peptides were divided into three distinct groups. One set of eight peptides is explicable as variable cleavage fragments from one or several parent peptides of M.W. ca. 3000 daltons. The amino acid compositions of these peptides are not identical to any previously published for sinus gland peptides. Another set of three distinct peptides have amino acid compositions similar to those published by Keller (J. comp. Physiol. 141, 445) for the hyperglycemic hormone of various species, and at least two of these show hyperglycemic activity. An erythrophore concentrating hormone of the crab was shown to be indistinguishable from that of the shrimp (Fernlund, B.B.A. 371, 304) both in its RPLC elution properties, and in its absorbance and fluorescence characteristics. Experiments in which the peptides and amino acids in perfusates of the sinus gland were analyzed as fluorescent derivatives demonstrated that the majority of these peptides (about 2 pmol or 1% of each peptide per sinus gland in 10 min) were released by depolarization with 10X K^+. There was no release of peptides observed in zero Ca^{++}, normal or 10% hypoosmotic normal salines, and peptide release in 10X K^+-zero Ca^{++} perfusates was variable relative to normal 10X K^+ perfusates. A small and variable quantity of amino acids (<1% of total sinus gland amino acids) was released by depolarization by the 10X K^+ and a large amount of amino acids (about 20% of total sinus gland amino acids) was released over a 50 min zero Ca^{++} perfusion. Thus, peptide release was specific in the sense that it was independent of amino acid release and was also not due to the decrease in $[Na^+]$ in the 10X K^+ perfusion. The characterization of the peptides in the sinus gland has allowed the study of the significance of the proteolytic processing of small peptides at the sinus gland nerve terminals as related to the final forms released. Supported by NIH grant NS 15453 to I. M. Cooke.

148.12 MONENSIN-INDUCED CHANGES IN BAG CELL ULTRASTRUCTURE: RELATION TO IMPAIRED PRODUCTION OF NEUROSECRETORY PEPTIDES. Michael E. Yates and Robert W. Berry. Dept. of Cell Biol. and Anat., Northwestern Univ. Med. School, Chicago, IL 60611.

Treatment of various mammalian cell types with monensin produces marked dilation of the Golgi apparatus and impairs the release of secretory proteins (Tartakoff & Vassalli, J. Exp. Med. 146, 1332-1345, 1977). In the bag cells of Aplysia californica, 10uM monensin produces a dramatic impairment of processing of precursor and intermediate proteins which give rise to the neurosecretory peptides AP and ELH (Yates & Berry, Soc. Neurosci. Abst., 1981). We have therefore performed an ultrastructural study of bag cells exposed to monensin in order to determine whether the biochemical blockades could be due to changes in Golgi apparatus function arising from disruption of its structural integrity.

Bag cell organs of Aplysia were exposed to 10uM monensin in artificial seawater and nutrients (experimental) or were incubated in seawater and nutrients alone (control) for 6 or 16hr. The organs were fixed in 3% glutaraldehyde for 4hr, postfixed in 1% OsO_4 (0.1M phosphate buffer) for 1.5hr, dehydrated, and embedded. Electron micrographs revealed the presence of large vacuoles and an absence of "normal" Golgi apparatus in experimental cells at both time points. Control cells contained Golgi profiles with classical morphological characteristics, while the large vacuoles present in monensin-treated cells were absent. The ultrastructure of all other observed organelles appeared identical in control and experimental cells. The vacuoles in bag cells exposed to monensin for 16hr often contained a single, round, electron dense aggregate of material closely associated with the vacuole membrane at a single point. Furthermore, terminal varicosities of rough endoplasmic reticulum (RER) containing similar electron dense cores were often present at 16hr. Neither of these structures were apparent in control cells. We conclude that the impaired processing of the precursor and blockade of subsequent cleavages is very likely due to the effects of monensin on the Golgi apparatus. It is probable that a disruption of formation of Golgi-derived vesicles is responsible for the blockade of late steps in the processing sequence. The apparent self-association of electron dense material in dilated Golgi elements indicates that this material does not require a limiting membrane to form a dense core. The association of the core with the membrane of these vacuoles may represent a secretory protein-membrane protein interaction allowing for segregation of material as it exits the Golgi apparatus. The dense core material in the terminal varicosities of the RER may be self-associated precursor protein.

149.1 SYSTEM IDENTIFICATION OF HUMAN TRICEPS SURAE STRETCH REFLEX. R.E. Kearney, I.W. Hunter and P.L. Weiss. Biomedical Engineering Unit, Faculty of Medicine, McGill University, Canada, H3G 1Y6.

The interpretation of stretch-evoked reflex responses is complicated by the fact that the observed pattern will depend upon both the underlying reflex mechanisms and the time course of the stretch used to evoke the response. The objective of the present study was to use engineering systems analysis techniques to identify the dynamics of the human triceps surae (TS) stretch reflex in terms of its impulse response by deconvolving the position input from the observed response.

Subjects were instructed to maintain a tonic contraction at a level ranging from 0-20% of the maximum voluntary contraction. Their ankles were then driven according to a repeated, computer-generated, stochastic pattern with a peak-to-peak amplitude which varied from 0.025 to 0.25 rad. Position, torque and smoothed, rectified surface EMG's were recorded and ensemble averaged over 25 stimulus presentations.

Impulse response functions identified between ankle velocity and TS EMG accounted for about 60% of the observed EMG variance. However, the impulse responses were noisy and the predicted EMG was systematically smaller than the observed EMG during the dorsiflexing phases of displacement and larger than predicted EMG during the plantarflexing phases.

These findings suggested that a direction dependent nonlinearity might be present. Consequently, we computed the impulse responses relating half-wave rectified velocity to TS EMG and found that the resulting impulse responses were less noisy and accounted for significantly more variance (mean 70%) than did those relating ankle velocity to TS EMG.

These uni-directionally rate sensitive impulse response functions were dominated by a large peak at about 40 ms followed by a smaller period of reduced activity. This is consistent with its mediation by spindle primary afferents. Although the shape of the impulse response remained unchanged, its amplitude, which provides a measure of relative gain, varied systematically with the level of contraction and the displacement amplitude. Multiple regression analysis demonstrated that most of the variation in the impulse response amplitude could be attributed to a linear increase with level of contraction (measured by average EMG) and a linear decrease with displacement amplitude.

149.2 PHASE LEAD OF EXTENSOR EMG ON WRIST FLEXION DURING LIGHTLY-DAMPED OSCILLATIONS, POSTURAL TREMOR, AND PHYSIOLOGICAL ACTION TREMOR OF THE HAND. R. N. Stiles. Department of Physiology and Biophysics, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.

A major question in motor control is whether neural feedback normally accentuates or attenuates resonant neuromuscularlimb oscillations. The purpose of this study was to quantify relative neural feedback phase for resonant hand oscillations obtained under three different conditions. System damping was also quantified under conditions for which this damping is positive, i.e., for lightly-damped oscillations.

Using a small accelerometer, lightly-damped oscillations, postural tremors and physiological action tremors were detected from the unsupported hand of normal human subjects. Damped oscillations (DOs) were produced by tapping the subject's hand at a rate of about 1/sec. Bipolar surface EMGs were detected from two wrist extensors. Raw EMGs were digitized, full-wave rectified and smoothed, producing amplitude-demodulated EMGs. The relative phase between highly-correlated EMG modulation and the negative of acceleration (i.e., hand position) of the resonant hand oscillations was obtained by cross-spectral analysis. Damping ratios were calculated for different peaks of the DOs for DO frequencies between 4 and 9 Hz. EMG-wrist flexion phase was calculated for both normal (physiological) and enhanced (large-amplitude) postural and action tremors.

Results show that: (1) For damped oscillations, reflex damping increased (became more positive) with increased phase lead of extensor EMG signal on wrist flexion. (2) There was a larger phase lead of EMG on wrist flexion during physiological action tremor than during normal postural hand tremor. This phase advance was associated with an increased displacement amplitude of the action tremor relative to that of the postural tremor. (3) The phase lead of extensor EMG on wrist flexion decreased with increased displacement amplitude of either postural or action tremor of the hand.

These results suggest that feedback damping of resonant hand oscillations may normally increase during times of voluntary hand movement as a result of a mechanism that advances the phase of the neural feedback signal on wrist flexion. Results also suggest that tremor amplitude may be enhanced above normal levels as a result of decreased reflex damping. (Supported by USPHS Grant NS 14730.)

149.3 THE DETECTION OF SYNCHRONY USING RECTIFIED NEUROGRAMS AND ELECTROMYOGRAMS: CONSIDERATIONS WITH RESPECT TO SPIKE-TRIGGERED AVERAGING. T.M. Hamm. Dept. of Physiol., Univ. of Arizona Health Sci. Ctr., Tucson, 85724.

A test for synchrony between the reference event (an afferent or motor unit action potential) in a spike-triggered average (STA) and other (non-reference) events has been employed in which the area of an averaged, rectified neurogram or electromyogram (EMG) is compared to the area of the corresponding average of the high-pass filtered neurographic (or EMG) signal (Milner-Brown et al, J. Physiol. (Lond.)228:285-306,1973; Roscoe et al, Proc. Int. Union Physiol. Sci. XIV:227-228,1980). This test has been demonstrated to be a sensitive measure of afferent and motor unit synchrony (Roscoe et al, 1980), although its dependence on the signal-to-noise ratio (S/N) of the reference event and on the S/N and variance band (the distribution of times of occurrence with respect to the reference) of non-reference events poses limitations on its use and interpretation. This report provides a further analysis of the effects of these factors on this synchronization test. In particular, the test's ability to detect multiple events which are 'loosely' correlated with the reference has been investigated. It has been argued that such events would contribute significantly to a postsynaptic potential obtained by STA (Kirkwood and Sears, J. Physiol. (Lond.)322:287-314, 1982).

Simulations were performed in which the probability density functions of signals with several correlated events and the expected values of those signals after rectification were calculated. These simulations yield the relations between the increase in signal variance in the presence of correlated events, which is responsible for the increased area of the rectified average, and the S/N and variance band of such events. The number of correlated events and the probability of discharge near the reference event were shown to be interchangeable in that a number of non-reference events with low probabilities of discharge make a contribution to the rectified average which is approximately equal to that of a single event with a correspondingly higher probability.

These results indicate that this test for synchrony is capable of detecting multiple events which are loosely correlated. Moreover, the critical role of variance suggests a test for synchrony in which the variances of reference-triggered and randomly-triggered signals are compared. Such a test would be independent of effects of the reference event's S/N.

149.4 CAN THE ELECTRICAL THRESHOLD OF GROUP Ia & Ib AXONS BE REVERSED IN HUMAN SUBJECTS? C.J. Heckman*, S.M. Condon*, R.M. Enoka, and R.S. Hutton. Dept. of Kinesiology, Univ. of Washington, Seattle, WA 98195.

After prolonged vibration of the Achilles tendon in cats, the electrical threshold of group Ia fibers is increased above that of Ib afferents (Coppin et al., J. Physiol., 210:18, 1970). Ia receptor threshold to stretch activation remains unchanged (Fetz et al., J. Physiol., 293:173, 1979). The possibility of similar findings in human (N=4) soleus muscle was investigated indirectly by alternately measuring (EMG) tendon tap (T) and Hoffmann (H) reflexes before and after 20 minutes of vibration (100Hz) applied to the Achilles tendon. The foot was strapped at a 90° ankle angle. Reflexes were elicited and vibration was applied while the subjects maintained a constant low-level plantar flexion static force (~86N) under conditions of visual monitoring of force feedback. The inter-stimulus interval (ISI) per reflex type was 10 seconds and the ISI between alternate reflex stimuli was 5 seconds. Percent change in intra-reflex magnitudes between control and post-vibration conditions was calculated using the average of 16 responses elicited over 160 seconds during each recording sequence.

In all subjects, immediately after vibration, H-reflexes were either abolished or markedly reduced as compared to control mean responses. In contrast, T-reflexes initially showed moderate to marked enhancement above control levels. The time course of recovery for the post-vibration H-wave responses varied across subjects but H-waves remained depressed in 3 of the 4 subjects for greater than 35 minutes. T-waves returned to control values within 15-30 minutes. Three of the 4 subjects were re-tested and these findings were replicated. Similar decrements in the H-reflex or enhancement in the T-reflex could not be induced by 20 minutes of sustained static force alone. The depth of H-reflex depression appeared to parallel the magnitude of the soleus tonic vibration reflex and the degree of perceived sensory illusion of foot movement (usually into dorsiflexion) during vibration.

In re-testing another subject, H-reflexes were elicited alternately at 1.2 and 1.8 X threshold (Th). Initial post-vibration H-waves at 1.2 X Th were negligible (<5% of control) but were present (83% of control) at 1.8 X Th. M-waves were still present before and after vibration as were T-reflexes. These findings were also replicated in another previously tested subject. In all, the results are in accord with the predicted outcome on spinal reflexes using the Coppin et al. paradigm and offer indirect evidence that similar reversals in group Ia electrical thresholds above Ib axons might be produced in humans. Further experimentation using, for example, microneurographic recording techniques appears warranted.

149.5 TOPOGRAPHIC WEIGHTING OF HOMONYMOUS SINGLE IA AFFERENT INPUT TO MEDIAL GASTROCNEMIUS MOTONEURONS. Sylvia M. Lucas, Tim C. Cope and Marc D. Binder. Dept. of Physiol. & Biophys., Univ. of Washington, Sch. of Med., Seattle, WA. 98195.

Last year we reported that homonymous group Ia input to cat medial gastrocnemius (MG) motoneurons is "topographically weighted" in that afferents innervating a given intramuscular compartment provide relatively stronger synaptic input to motoneurons innervating the same compartment than to motoneurons innervating other compartments within the muscle (Lucas and Binder, Neurosci. Abstr. 7: 561, 1981). We have subsequently performed a series of experiments to determine whether differences in Ia projection frequency and/or average EPSP amplitude underlie this topographic weighting. In 10 barbiturate-anesthetized cats we have studied 186 single Ia afferent-motoneuronal connections using the spike-triggered averaging technique. The motoneurons were classified as either "same branch" or "other branch" depending upon whether the Ia afferent and motor axon were contained in the same or different intramuscular nerve branches. No difference was found in the connectivity of Ia afferents to the "same branch" and "other branch" motoneurons (95%, N=102 vs 94%, N=84, respectively). However, the mean EPSP amplitude was larger in the "same branch"(92±8 μV; N=97) than in "other branch" (77±7 μV; N=79) motoneurons. This difference was most striking (statistically significant, $p<0.05$) with putative large motoneurons (rheobase ≥ 10 nA), for which the mean "same branch" EPSP was 82±12 μV (N=48) while that in the "other branch" cells was 52±5 μV (N=37). In 60 cases it was possible to compare the EPSPs produced by a "same branch" afferent and an "other branch" afferent in the same motoneuron. The mean ratio of the "same branch" to "other branch" EPSPs was 1.7, which was both statistically significant and consistent with the value of 1.8, which we had previously found for aggregate EPSPs. Again the weighting appeared strongest in putative large motoneurons (ratio = 2.0; N=27). These results suggest that the topographic weighting of homonymous Ia afferent input to cat medial gastrocnemius motoneurons is mediated by a gradient of synaptic strength rather than by a gradient of connectivity.

149.6 Mechanical Properties of the Primate Forelimb during Imposed Displacement. F. Lenz*, S. Schloegel*, W. Tatton, R. Tasker*, (Spon. J.Wojtowicz), Playfair Neurosci. Unit, Univ. of Toronto, Toronto, Canada.

It has been proposed that the function of the stretch reflex is to improve the linearity or 'spring-like' properties of muscle (Nichols and Houk, J. Neurophys. 39(1976) 119). We have computed mechanical properties of primate forelimb muscle-joint systems as a step in understanding how reflexes might function in the control of the whole limb.

Torque motor imposed extensions of the metacarpophalangeal joint, the wrist and the elbow in squirrel monkeys evokes reflex electromyographic (EMG) activity in the flexor muscles acting across these joints. Joint angle, EMG response and tension were measured; acceleration and velocity were calculated from position records by numerical differentiation. Since not all trials evoked a reflex response, trials were separated according to the the presence or absence of an EMG reflex response and averaged as separate groups (termed reflex and non-reflex trials). The tension (corrected for inertial effects) and displacement at the end of limb segment distal to the joint were used to estimate average stiffness of the joint for reflex and non-reflex trials.

At each joint studied, the positional dependence of tension was significantly less linear (as judged by regression analysis) for non-reflex trials than for reflex trials. 'Non-reflex stiffness' was significantly greater in distal than in proximal joints but 'reflex stiffness' values for the three joints were not significantly different. Both measures of stiffness were independent of velocity. The inertial moments of the three limb segments varied by three orders of magnitude. Over similar ranges of baseline EMG activity and velocity, the reflex EMG response, expressed as a fraction of the maximium response to electrical stimulation of the motor nerve, was four times less in distal flexors than in elbow flexors. Therefore reflex activity appears to compensate for differences in the mechanical properties of different muscle-joint systems to produce a linear displacement-tension relation characterized by similar average stiffness across each of three contiguous joints in the primate forelimb. (Supported by: TGH Found., Ont. Heart Found., MS Soc. of Canada, MRC MA5218)

149.7 SPECTRAL ANALYSIS OF CROSSED EXTENSOR CONTRACTIONS IN THE DECEREBRATE CAT. S. A. Burgstahler* and E. K. Stauffer. Sch. of Med., Univ. Minn., Duluth, MN 55812.

When the peroneal nerve is stimulated in a decerebrate cat, reflex contraction of the contralateral extensor muscles is produced in the hindlimb. Superimposed on the contractions are small amplitude oscillations detectable in high gain force and acceleration recordings from (1) isolated muscles and (2) the intact limb. The purpose of this study was to determine the frequency and amplitude characteristics of the contracting plantaris muscle during the crossed extension (X-EXT) reflex. These findings were then compared with stretch-evoked oscillations observed in intact limbs.

Experiments were performed on eleven cats decerebrated at the midcollicular level. In eight cats, the left hindlimb was denervated except for the nerve supplying plantaris. Records of muscle force, acceleration, and electromyographic (EMG) activity were obtained before, during, and after stimulation (100 Hz, 10-15 sec) of the contralateral peroneal nerve. Following a series of X-EXT reflexes, dorsal roots L_7- S_2were severed and the reflex was evoked again. In the remaining cats, limbs were kept intact with oscillations recorded during X-EXT reflexes and following a quick dorsiflexion-release of the foot. Spectral density estimates of filtered force (3-30 Hz) and acceleration were calculated from isometric and anisometric data respectively.

Isolated plantaris muscles oscillated within a broad range of frequencies, 6-25 Hz. There was no significant change ($p> 0.80$) in the frequency of oscillation before (11.9 ± 2.5* Hz) versus after section of the dorsal roots (11.6 ± 1.4 Hz), but amplitude decreased significantly (0.8 ± 0.2 g vs 0.2 ± 0.1 g respectively, $p< 0.02$). To date our results from anisometric preparations with intact hindlimbs show a frequency of 14.5 ± 0.5 Hz and an acceleration of 0.5 ± 0.3 cm/sec^2 following crossed extensor stimulation. This is in contrast to anisometric recordings of an isolated plantaris muscle which oscillated at 19.0 ± 1.5 Hz with an amplitude of 159.3 ± 24.9 cm/sec^2. Anisometric recordings of stretch-evoked clonus from intact hindlimbs gave a frequency of 12.4 ± 0.4 Hz at an acceleration of 12.7 ± 4.9 cm/sec^2. These findings are consistent with a "final common pathway" whose input signal has a baseline frequency that tends to remain constant but whose amplitude can be altered by inputs from other sources. The observed changes of the pathway's output signal can be explained by changes of the external load.

*All values are $\bar{X}$ ± S.E.M.

149.8 Differences between the crossed extension reflex and the flexion reflex in the decerebrate cat. A.M. Moudy* and J.A. McMillan (SPON: D.E. Phillips). Biology Department, Montana State Univ., Bozeman, MT 59717

A widely-accepted tenet of spinal cord physiology is that the crossed extension reflex (CER) is a crossed component of the ipsilateral flexion reflex (FR) and, as such, is mediated by interneurons in the FR pathway. In this report we provide evidence to suggest that the CER may in fact be independent of the FR in some important respects.

Experiments were performed on young adult cats. Initial surgical procedures, including a midcollicular decerebration, were carried out under ketamine anesthesia. Indwelling stimulating electrodes were placed in the left sciatic nerve. Isometric tension was recorded simulataneously from the left semitendinosus (FR) and the right quadriceps femoris group (CER).

The CER consistently demonstrated prolonged central summation, or "windup", at frequencies of stimulation lower than those which evoked such summation of the FR. In some cases the CER developed "reflex tetanus" at frequencies producing much less obvious summation of the FR. Such observations do not support the concept that interneurons which mediate the ipsilateral FR are also directly responsible for mediation of the crossed CER.

In three experiments it was possible to evoke the CER with stimuli below the threshold necessary to evoke the FR. Even though these were not consistent observations, they still suggest that the CER is not mediated solely by primary afferents and interneurons which first evoke the FR.

Previous work in our laboratory has pointed out that the CER is affected differently than is the FR by descending influences from suprasegmental and supraspinal inputs (McMillan and Koebbe, Exp'l. Neurol., 73:233-242, 1981). The results presented in the present report are consistent with these earlier findings in that they emphasize some important differences between the CER and the FR.

In conclusion, we propose that the relationship between the CER and the FR is not as intimately interdependent as is classically considered.

(This work was supported in part by NSF Grant #ISP-8011449)

149.9 IDENTIFICATION OF SKELETOFUSIMOTOR ACTION IN REFLEXIVELY ACTIVATED MUSCLE Stephen E. Grill*, W. Zev Rymer, Corey L. Cleland Neuroscience Program and Physiology Dept., Northwestern Univ. Med. Sch., Chicago, IL, 60611

The existence of skeletofusimotoneurons (β) has now been directly documented with electrophysiological techniques in reduced preparations. Recordings from muscle spindle afferents in reflexively active muscles of decerebrate cats have been used to derive several indirect criteria for skeletofusimotor action. Here we describe the results of experiments in which these criteria were tested directly by examining the fusimotor input of characterized spindle afferents.

The criteria used to recognize β-activity on spindles rely on the finding that γ-motoneurons are activated well below extrafusal threshold, whereas β-motoneurons are activated above extrafusal threshold (presumably along with α's). Therefore, we attribute fusimotor effects occuring well above extrafusal threshold to β-fibers. We compared apparent fusimotor effects on spindle afferents at various levels of EMG and force, varying the level of motor output by invoking the crossed extension reflex (CER). Thirty-five spindle afferents have been classified to date as to showing fusimotor effects above extrafusal threshold. Thirty-seven percent (13/35) showed static fusimotor effects during hold phases of ramp stretches, 48% (14/29) showed static fusimotor effects during ramp releases, 29% (10/35) showed dynamic fusimotor effects during ramp stretches, and 66% (23/35) increased their rates in parallel with tension under isometric conditions.

After afferent discharge patterns were characterized, the cats were anesthetized, S1 and L7 ventral roots were sectioned and small fascicles were tetanically stimulated. Direct evidence for β-input onto muscle spindles was obtained if increasing the rate of stimulation of efferent filaments above extrafusal fusion frequency resulted in increasing discharge of the spindle afferents. In this way we showed that 7 of the 10 afferents studied received at least 1 β-fiber, 4 received 2, and 2 received 3. We found 7 β-statics and 8 β-dynamics. Two of the 3 afferents for which we could not demonstrate β-innervation showed no fusimotor effects above extrafusal threshold during the physiological characterization. One afferent that received 2 β-fibers did not display fusimotor effects above extrafusal threshold.

Our data suggest that spindle afferents that show fusimotor effects above extrafusal threshold are usually innervated by skeletofusimotor fibers. β-fibers may extend the range of fusimotor action to cover the full range of motor output.

149.10 Identification of Spinal Interneurons Mediating the Clasp-Knife Reflex in the Cat
Corey L. Cleland, W. Zev Rymer, Stephen E. Grill* Neuroscience Program and Physiology Dept., Northwestern Univ. Med. Sch., Chicago, IL 60611

The clasp-knife reflex, first described in spastic human patients, occurs in decerebrated cats that have had their dorsolateral spinal funiculi sectioned. The reflex consists of powerful and sustained inhibition of homonymous motor output when an extensor muscle is stretched beyond a certain length. Contrary to earlier beliefs, group III and IV muscle afferents are probably responsible. We have identified a population of spinal interneurons that we believe mediate the clasp-knife reflex in the cat. Previously, we demonstrated that these interneurons are potently excited by the same muscle afferents that generate the clasp-knife reflex and that the static and dynamic input-output properties of the interneurons are similar to those of the clasp-knife reflex. In this communication we report that these interneurons inhibit extensor motoneurons and that their activity is closely correlated with decreases in emg during the clasp-knife reflex.

These interneurons were shown to inhibit MG motoneurons by using spike-triggered averaging to correlate the extracellularly recorded activity of interneurons and the intracellularly recorded membrane potential of extensor motoneurons. In 4 chloralose anaesthetized and spinalized cats we found that 3 pairs produced an average with a prominent hyperpolarization 1-3 ms following the occurrance of the interneuronal action potential.

Direct correlations between interneuronal activity and motor output were obtained by simultaneously recording interneuronal activity and the emg from the soleus muscle. In 7 unanaesthetized but decerebrated and dorsal hemisectioned cats, all 6 interneurons showed a time course of activity paralleling the time course of inhibition of the emg.

Taken together, our studies provide 3 lines of evidence that these interneurons mediate the clasp-knife reflex. First, the interneurons have the appropriate afferent and efferent connections. Second, the static and dynamic input-output properties of the interneurons and the clasp-knife reflex are similar. Finally, the activity of the interneurons shows a tight and undissociable correlation to clasp-knife inhibition.

149.11 LOW FORCE FEEDBACK GAIN IN THE STRETCH REFLEX OF THE DECEREBRATE CAT FOLLOWING DORSAL HEMISECTION OF THE SPINAL CORD, J.J. Cath* and P.E. Crago (Spon: J.T. Mortimer). Applied Neural Control Lab., Case Western Reserve University, Cleveland, Oh. 44106.

Decreases in stretch reflex stiffness have been observed following dorsal hemisection of the spinal cord in decerebrate cats. It has been postulated that the lesion would interrupt descending inhibitory projections to tendon organ pathways and that this release would increase force feedback gain and thus decrease stiffness. This hypothesis was tested by measuring force and EMG responses to imposed length disturbances before and after a reduction in muscle gain. EMG responses remained the same in the face of drastic reductions in muscle force, implying that the gain of force feedback is low in these preparations.

Cats were anesthetized with halothane and nitrous oxide and a midcollicular decerebration was performed by aspiration. The soleus muscle was dissected and connected to a force transducer mounted on a length servomechanism. Anesthesia was then discontinued. EMG was recorded from fine intramuscular wire electrodes and was processed by full wave rectification and low pass filtering.

The stiffness of the stretch reflex was evaluated by recording a series of responses to ramp and hold stretches at various initial forces and initial lengths prior to spinal cord hemisection. In all cases, initial force was graded by crossed extensor reflexes. A dorsal hemisection of the cord at T9-10 was then performed under light anesthesia. A series of responses was measured at a nearly constant initial force with the initial length adjusted to prevent the appearance of the clasp-knife reflex. These responses served as the controls for estimating the gain of force feedback from tendon organs.

Muscle gain was reduced by intravenous administration (2 mg/Kg) of dantrolene sodium. Finally, a series of responses was recorded with length disturbances identical to those designated above as controls, but at an initial force that resulted in the same value of initial EMG as was recorded in the controls. Ensemble averages of the responses in each series were constructed.

The initial force and the change in force due to the length disturbance were typically half of the values measured prior to muscle gain reduction. If force feedback was contributing to the stretch reflex, the EMG response should have been greater after the drug administration since the autogenetic inhibition would have been lower. However, the two EMG responses were virtually identical, implying that the gain of force feedback was negligible and probably no different from the values reported by others for the decerebrate cat with an intact spinal cord.

This research was supported by NSF grant number PCM-7915319.

149.12 NEONATAL STRETCH REFLEXES, G. L. Gottlieb, B. M. Myklebust, G. C. Agarwal and R. D. Penn Dept. of Physiology, Rush Med. Ctr., Chicago, IL 60612.

Previous studies have demonstrated that in the normal adult, activation of the soleus muscle (SOL) by rapid mechanical stretch, tapping the SOL tendon, or electrical stimulation of the tibial nerve (H-reflex) evokes SOL EMG activity at monosynaptic latencies (30-50 ms), while the shortening antagonist tibialis anterior muscle (TA) is electrically quiet [1]. In contrast, in patients with spasticity due to a perinatal insult (ie, cerebral palsy (CP)), activation of SOL evokes simultaneous EMG activity of comparable magnitudes and equal latencies in TA and SOL. We have termed this phenomenon "reciprocal excitation" to contrast it with the normal spinal cord circuitry of reciprocal inhibition [2,3]. These findings are suggestive of a developmental error in the CP spinal cord, in addition to the brain insult. To quantify the magnitude of reciprocal excitation in CP we have computed the "TA:SOL reflex ratio" by measuring the ratio of the peak-to-peak amplitudes of the stretch-evoked EMG, 30-50 ms after the tap.

To investigate the normal development of the reflex ratio, preliminary studies have been performed on normal neonates (1-10 days) and a small number of children up to 6 years old. Surface EMG activity from TA and SOL was recorded when tendon taps were delivered to SOL and TA tendons.

Neonates demonstrate a TA:SOL reflex ratio which is larger than in the normal adult but smaller and more variable than in CP. This ratio decreases with age, and by 6 years it is in the range of the normal adult.

The normal neonate's spinal cord shows hyperexcitability with respect to the normal adult's, which apparently decreases during normal development. The relative contributions of spinal cord hyperexcitability and reciprocal exciation to the elevated neonatal TA:SOL ratios we have observed are under investigation.

149.13 *TACTILE PLACING IN FORELIMB AND HINDLIMB OF NORMAL AND SPINALIZED KITTENS.* *N.S. Bradley*, J.L. Smith and J.R. Villablanca. Depts. Kinesiology & Ment. Ret. Res. Cntr., UCLA, Los Angeles, CA 90024*

Early work by Bard led to the conclusion that tactile placing (TP) is a cortically dependent reflex. Forrsberg, et al. (Acta Physiol. Scand. 92:114, 1974) however, have reported the presence of TP in the hindlimbs (HL) of spinalized kittens. Preliminary testing in our laboratory of cats 8-9 months of age, spinalized (T-12) at 2 or 12 weeks of age, failed to elicit HL placement. We thus decided to quantify the time course and characteristics of TP development in normal and spinalized kittens to determine if behaviors are similar.

Tactile placing was tested from 3-62 days of age in 15 kittens from 3 litters. Spinal transections (T-12) were performed in 9 kittens at 14-16 days of age. All kittens were tested for forelimb (FL) dorsal, lateral, and medial TP, and the HL tested for dorsal TP with the hip joint at 90°. Additionally, spinalized cats were tested for HL-TP with the hip joint in further extension (120°). Onset, duration and force of contact were measured by a force transducer attached to the triggering stimulus. Latency of placement was recorded by downward displacement of an adjacent horizontal plate overlying a second transducer.

Normal kittens rarely demonstrated FL-TP before the 3rd week (0-8% of trials) or HL-TP before the 5th week (0-17% of trials). By the 4th week, dorsal FL-TP occurred 32% of trials with an average latency of 1113 ms. By the 5-6th week, HL-TP occurred 21% of trials with an average latency of 1143 ms. Therefore, there was a gradual increase in frequency and a decrease in latencies of TP response over the two month period suggesting an ongoing maturational process (Villablanca & Olmstead, Develop. Psychobiol. 12: 101, 1979). Additionally, responses of normals were noted to be discrete movements of small amplitude. Spinal kittens demonstrated similar responses in FLs, but not in HLs. In only 10 of 675 HL trials (1.5%) over the post-transection period observed did the paw contact the horizontal plate without associated airstepping or other reflex augmenting movements. Of the 10 trials, average placement latency was 912 ms. Typically, HL contact triggered abrupt withdrawal, airstepping, and banging of the paw against the vertical wall housing the contact transducer. Thus, the HL behaviors of normal and spinalized kittens differed in both contextually associated behaviors and probability of occurrence.

Results suggest that tactile placing does not develop in spinalized kittens. Those HL responses interpreted by others as TP in spinalized cats may be tactile-triggered airstepping or withdrawal responses. We conclude that tactile placing requires the involvement of supraspinal centers.

149.14 EFFECTS OF DORSAL RHIZOTOMY ON DOG FEMORAL CONDYLAR CARTILAGE. B.L. O'Connor*, M. Palmoski*, K.D. Brandt*. (SPON: J. DiMicco) Depts. Anat. and Med., Indiana Univ. Sch. Med., Indianapolis, IN 46223.

Neuropathic arthropathies are complications of diabetes mellitus, tabes dorsalis, syringomyelia, leprosy, and other disorders that affect the peripheral and central nervous system. The joint lesions resemble an exaggerated form of osteoarthritis and are generally thought to result from a breakdown of protective muscular reflexes owing to decreased or abolished sensory input. In the absence of such reflexes, the joint may be subjected to increased microtrauma during day-to-day activities, the cumulative effect of which is the formation of severe osteoarthropathy.

We tested this hypothesis by performing dorsal rhizotomies (L4 through S1, inclusive) to desensitize the left hind limbs of dogs that were then permitted to exercise ab lib in roomy pens for up to 16 months. Appropriate sham operated control animals were also prepared. Prior to sacrifice, patellar reflexes were tested to verify their absence in the experimental operated animals and their presence in sham operated animals. Spinal cords of the sacrificed animals were examined histologically using the Kluver-Barrera stain, and showed dorsal column degeneration in the experimental animals but not in the sham operated controls.

The articular cartilage of the femoral condyle of the left (operated) knees and the right (non-operated controls) were examined for biochemical (water and uronic acid content, and 35S uptake for newly synthesized proteoglycans), histological (Safranin-O affinity, fibrillation, cloning, hyper- or hypocellularity, tidemark invasion by blood vessels, subchondral bone cysts) and gross evidence of osteoarthritis.

No abnormalities were identified in any of the joints examined. The water content of operated and nonoperated knee cartilage was about 70% in both the experimental and sham rhizotomized animals. No statistically significant difference in 35S incorporation or uronic acid content was observed between operated and nonoperated sides in either group. Both the gross and histological appearance of the cartilage were normal.

It is concluded that complete desensitization of a limb plus ad lib exercise will not necessarily result in a Charcot joint, and that some additional factor, possibly an acute joint injury, is required to initiate the development of neuropathic arthropathies. Supported by PHS Grant AM26951 to B.L. O'Connor.

149.15 THE PAIRED H-REFLEX AND ITS CORRELATION WITH EEG COHERENCE AND ACADEMIC PERFORMANCE IN NORMAL SUBJECTS PRACTICING MEDITATION. R. K. Wallace, P. J. Mills*, D.W. Orme-Johnson , M. C. Dillbeck*, and E. Jacobe*. Dept. of Biology, Maharishi Intern. Univ., Fairfield, IA 52556.

Studies using the paired H-reflex to investigate the neurophysiological effects of meditation (TM) have reported: 1) a decrease in both the amplitude of the activity of the frontalis muscle and in the amplitude of the H-reflex during meditation (Chenard,1982), 2) a significant correlation between flexible performance on a concept learning task and paired H-reflex and frontal EEG coherence (Dillbeck et.al.,1981), and 3) a significant correlation between paired H-reflex recovery, high alpha coherence and creativity (Haynes et.al.,1977). In addition, we noted a longitudinal facilitation at intervals 100, 150, 200,and 250 msec. in experimental males practicing an advanced TM program, while the experimental females and controls showed no significant change (Wallace et.al.,1979).

In our present investigation we have replicated previous research correlating EEG parameters and paired H-reflex recovery and further noted a significant correlation between paired H-reflex recovery and academic performance in subjects practicing meditation. The subjects were 13 male (mean age 22 years, mean length TM practice, 48 months) and 9 female (mean age 21 years, mean length TM practice 45 months) healthy university students. The paired H-reflex correlated significantly with EEG alpha and theta coherence at intervals 100-1000 msec.. The H-reflex correlated with academic performance (student grade point average) at intervals 150-500 msec.. The H-reflex did not correlate with SAT scores or WAIS IQ.

Although the area is not well understood, previous research has found the H-reflex to be sensitive to changes in states of awareness. For example, Van Boxtel (1976) showed that a constant alpha index is accompanied by stable H-reflex amplitudes and a decreasing alpha index (indicative of drowsiness) is accompanied by decreasing H-reflex amplitudes. Pivak and Mercier (1979) showed that during nonrapid eye movement (NREM) sleep (stages 2 and 4) the H-reflex facilitation period was significantly reduced. The part of the H-reflex recovery curve most sensitive to changes in states of awareness is the facilitation period of 100-300 msec. (Gassell,1970). This period also most highly correlated with the EEG parameters and academic performance. These findings suggest that the H-reflex, in particular the facilitation period of the recovery response, may be an indicator of awareness or wakefulness level. Whether the results reported here are unique to participants of the TM program is unknown. Further research is necessary to extend these findings to a larger and more general population.

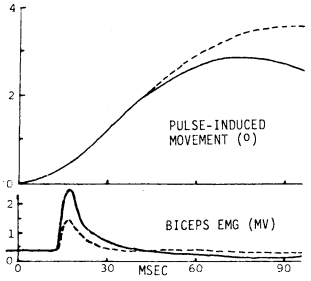
149.16 Learned Change in the Spinal Stretch Reflex: Effects on Movement and Antagonist Muscle Behavior. D.J. Braitman, J.R. Wolpaw, V.A. Kieffer*. (SPON: K.D. Barron). Arm. For. Radiobio. Res. Inst., Bethesda, Md. 20014 & Center Labs & Res., NYS Dept. Hlth, & Depts. Neurol. & Anat., Albany Med. Coll., Albany, N.Y., 12201.

Monkeys can gradually change spinal stretch reflex (SSR) amplitude (amp) without change in initial muscle length or background EMG (Wolpaw et al. NS Abst.7:249(1981)). We studied concurrent changes in movement and antagonist muscle behavior.

Five monkeys learned to keep elbow angle at 90° (±1.5°) against steady extension force. If this angle was held for a randomly selected 1-2s period, and if the average absolute value of biceps EMG (from chronic i.m. electrodes) for the final 0.2s was 1.0-1.5 X a set value, a brief force pulse extended the elbow 3-4°. SSR amp was measured as the average absolute value of biceps EMG 12.5-21.5ms after pulse onset minus background EMG amp. Under the Control condition, reward occurred at 100ms. Under the SSR↑ or SSR↓ condition, reward occurred only if SSR amp was more (SSR↑) or less (SSR↓) than a criterion value. Control condition data were obtained for 10-50 days. SSR amp was stable over this period. Then the animal was exposed to the SSR↑ and SSR↓ conditions in succession for prolonged periods. With imposition of each condition, SSR amp changed appropriately over 10-20 days (Wolpaw & Seegal, this vol.).

The first 40ms of pulse-induced movement did not change with SSR amp. After 40ms, movement was inversely related to SSR amp (Fig.). This 20-25 msec delay between the SSR and its apparent effect on movement was presumably the time necessary for muscle contraction following excitation.

Triceps EMG was minimal under all three conditions. Thus the antagonist does not appear to play a major role in SSR amp change or the accompanying post-40ms change in movement.



Pulse-induced movement and biceps EMG amplitude from one animal. Solid lines are a day's data (>3,000 trials) under the SSR↑ condition; dashed lines, a day's data under the SSR↓ condition. Note that background (pre-pulse) EMG and the first 40 msec of movement are the same for the two days.

149.17 CHARACTERISTICS OF M SPIKES IN CAT MOTONEURONS AND THEIR SIGNIFICANCE FOR THE MEASUREMENT OF SMALL COMPOSITE Ia EPSPs.

R.M. Reinking*, T.M. Hamm, B.R. Botterman and D.G. Stuart.
Dept. of Physiol., Univ. of Arizona Health Sci.Ctr., Tucson 85724.

Some characteristics of intracellularly recorded M spikes in cat motoneurons have been determined in order to evaluate techniques for subtracting this spike from recordings of homonymous monosynaptic composite Ia EPSPs evoked by stimulation of intramuscular nerve branches (viz., Neuroscience Letters 24: 35-41, 1981).

Antidromically conducted M spikes were recorded in 44 hyperpolarized hamstring motoneurons in three deeply anesthetized cats with sectioned dorsal roots. The decay of the M spike was characterized by multiple components, resulting in the M spike being larger at late times than has been supposed. Comparison of the longest time constant of the M spike with that of the motoneuron membrane and of the time course of the M spike with the results of a simulation indicate that the time course can be attributed to the passive electrical properties of the cell.

Averaging normalized, individual M spike records yielded a composite M spike for use in the measurement of Ia EPSPs ("subtraction method"). This method was compared to previous methods requiring extrapolation of the M spike ("extrapolation method") or recording EPSP waveforms above and below the M spike threshold ("addition method"). Estimates of EPSP amplitude (in mV) by these methods in 19 motoneurons gave the following results:

Subtraction Method	Addition Method	Extrapolation Method
2.84 ± 1.75	2.82 ± 1.88	3.45 ± 1.73

Comparison of the subtraction and extrapolation methods in a larger number of cells (n=117) gave similar results.

A comparison of EPSP estimates by the subtraction method with the measured EPSP value in cells (n=12) in which the maximum EPSP was attained at a stimulus strength subthreshold to that of the M spike gave the following results:

EPSP Amplitude	Estimated EPSP	Difference
2.84 ± 1.61	2.90 ± 1.55	-0.06 ± 0.30

These results indicate that the M spike makes a significant contribution to the apparent amplitude of small, composite Ia EPSPs and that accurate estimates of EPSP amplitude in the presence of an M spike can be obtained by the subtraction or the addition method, while the extrapolation method results in an average overestimation of 0.3 - 0.6 mV.

150.1 SUPERFICIAL AND DEEP AFFERENT INPUTS TO SINGLE NEURONES IN THE SENSORY AND MOTOR CORTEX OF MACACA FASCICULARIS. M. Sirisko* and B.J. Sessle (SPON: A.T. Storey). Faculty of Dentistry, University of Toronto, Toronto, Canada M5G 1G6.

The activity of single neurones in the face motor cortex and adjacent sensory cortex was recorded extracellularly in ten barbiturate-anaesthetized monkeys in which continuous monitoring was made of blood pressure, expired CO_2 and rectal temperature. Afferent inputs to cortical neurones were tested by the use of electrical stimulation of the exposed facial, hypoglossal and temporalis muscle afferent nerves, the oral mucosa and facial skin, and by the use of natural (tactile, pressure, jaw and tongue stretch) stimuli applied to the orofacial region. Neurones projecting directly to the brainstem were identified by their antidromic response to stimulation of the facial, hypoglossal or trigeminal motor nucleus. In eight of these same animals, the motor cortex representation of the face, tongue and jaw had previously been determined in the unanaesthetized state by a systematic intracortical microstimulation examination of evoked muscle activity. Histological verification was made of selected microelectrode tracks.

Single and multi-unit antidromic activity evoked from the brainstem motor nuclei could be recorded from the precentral cortex within the confines of the motor cortex as defined by microstimulation. Afferent inputs were tested in 60 of these corticobulbar projection neurones (estimated mean conduction velocity of 20 m/sec): 20% of these neurones had a deep (muscle afferent) input; none were found with a superficial (cutaneous or oral afferent) input. The other major population of neurones (n=197) recorded comprised non-projection neurones that received superficial and/or deep inputs. Thirty-seven neurones excited only by cutaneous or oral afferent stimuli had latencies of 4-8 msec and were confined primarily to postcentral areas 1 and 3b. Most of the 133 neurones activated exclusively by one or more of the deep inputs had latencies and thresholds indicative of Group I or II muscle afferent excitation; although some were found in areas 4 and 3b, these neurones were predominantly confined to area 3a, and spontaneously discharged with a characteristic bursting pattern. Neurones with convergent superficial and deep inputs (n=27) were primarily located postcentrally, in area 3b. These findings indicate that in the anaesthetized monkey, deep inputs from facial, tongue and jaw muscles predominantly pass to neurones in area 3a of the sensorimotor cortex and that more caudally located neurones receive superficial or convergent afferent inputs.

150.2 PARALLEL MODULATION OF FORELIMB STRETCH REFLEX AND SCALP RECORDED EVOKED POTENTIALS, D.J. Crammond* and W.A. MacKay, Department of Physiology, University of Toronto, Canada, M5S 1A8.

Although in nonhuman primates the components potentially involved in a long latency transcortical reflex loop are well studied, there is yet a paucity of information from human experiments or indications as to the functional operation of such a system. In an effort to evaluate this further in humans, subjects were seated with right arm raised to shoulder level and elbow resting at 90° in the manipulandum of a DC torque motor. The signal to the motor produced a 70 msec ramp torque maintained for a further 50 msec, in either the flexion or extension direction. The subject either reacted to the torque perturbation to oppose the displacement or remained totally passive. Trials were repeated every 2 sec. The EMG from both triceps and brachialis muscles was rectified and integrated and scalp recorded perturbation evoked potentials (EP's) were recorded at a gain of 74,000: bandwidth D.C. to 1 KHz. The EP signal was recorded over C3 on the 10.20 system for placement (the contralateral forearm somatic sensory cortex), with reference to the linked mastoid processes. The EP, EMG's arm position and torque measured at the wrist were collected for each trial and averaged on a PDP-11 computer, the number of averages varying from at least 300 up. As a control the procedure was repeated with the subject's arm resting over but not stimulated by the manipulandum.

In the passive condition there was very little or no reflex EMG recorded. In the EP, a negative wave often began 60 to 70 msec after the onset of the torque perturbation. A late positive peak of about 300 msec was seen in some subjects. In the react condition, late stretch reflexes appeared in the EMG record. The EMG onset latencies varied from approximately 40-70 msec depending on the subject or muscle group studied. However, in the EP, a clear divergence from the control or passive condition was always evident at 60-70 msec when a consistently positive plateau developed lasting for up to 50 msec and often producing a positive D.C. shift for several hundred milliseconds on top of which late positive components at 200 msec may be superimposed. Prior to the divergence at 60-70 msec, the EP trace was identical in the react and passive conditions. The results show that there is a different cortical response to the forelimb perturbation depending on the subject's reaction. Regarding a central contribution to late, long loop reflex EMG components, a cortical divergence of response patterns at 60-70 msec indicates that the early EMG reflex components in the react condition (40-70 msec) are probably not transcortical reflexes although descending cortical signals could influence their modulation at other levels. However, late EMG components starting at about 70-80 msec could involve modifiable transcortical loops. Supported by the MRC of Canada.

150.3 CORTICAL CELL RESPONSE TO UNLOADING DURING A MAINTAINED POSTURE. E.M. Schmidt, J.S. McIntosh, and L.L. Glenn. Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Many precentral neurons have intense and prolonged discharges during accurate small movements Fromm & Evarts (Neurosci. Lett. 5:259, 1977). Evarts & Fromm (Neurosci. Lett. 5:267, 1977) suggested that the intense discharge of these neurons during small movements might be due, in part, to sensory input. They tested this hypothesis by applying torque pulses to a manipulandum at various times during the task. However, the movements induced by the pulses were large compared to the small accurate movements (5° pulse as compared to about a 1° movement) and may have provided considerably more sensory input to the neurons than was present with small movements. To circumvent this, we tested the hypothesis with smaller torques that unloaded rather than stretched the active muscles.

A monkey (Macaca mulatta) was trained to perform a wrist flexion-extension task (±30°) against a simulated spring load (.136 NM/Rad) produced by a torque motor. The hand was in an open position and coupled to the torque motor by a form fitting rubber mold, in an open position, to eliminate finger movements during the task. The monkey was required to maintain wrist flexion or extension for a random period (1.0 to 1.25s) within alternating target zones 12° in width. At the end of the hold period, a 30ms torque pulse was introduced that unloaded the contracting muscles and resulted in an approximately a 1.5° wrist movement.

Single cell activity was recorded in the arm area of the precentral cortex. Discharge rates for 100 units were recorded; 70 were well-related to the task. This sample was composed of 28 pyramidal tract neurons (PTNs) and 42 non-PTNs. Of the PTNs, 54% (15) responded to the unloading pulse and 43% (18) of the non-PTNs responded. Each group of neurons was subdivided into flexor or extensor units depending on the phase of the movement in which they were active. The discharge of the majority of neurons (23 of 33) was inhibited during the unloading, starting at latencies between 5 and 25ms (12.3 mean). The largest single grouping of cells exhibited inhibition when the active movement was unloaded. This response is consistent with Evarts' findings and suggests that these neurons are recipients of sensory inputs that may be part of a long-loop reflex which helps stabilize the position of the wrist.

150.4 SENSORY RESPONSES OF PYRAMIDAL TRACT NEURONS IN UNANESTHETIZED RHESUS MONKEY. Steven P. Wise, Christoph Fromm* and Edward V. Evarts. Laboratory of Neurophysiology, N.I.M.H., Bethesda, Md. 20205.

Pyramidal tract neurons (PTNs) were identified in precentral motor cortex (MI) and postcentral somatic sensory cortex (PoC) of monkeys trained to pronate and supinate the forearm. 199 PTNs in MI and 72 PoC PTNs were isolated in the present study. Every putative PTN was tested by the spike collision method and no unit was accepted if it failed to show the predicted collision properties. In MI 74% of the task-related PTNs responded to the limb displacements, while in PoC 85% did so. PTN responses to passive ramp-and-hold displacements of the forearm were examined and fell into three categories: transient, sustained and combined transient-sustained.

Larger PTNs (those with shorter antidromic latencies) tended to exhibit transient responses to passive limb displacement. Conversely, smaller PTNs more frequently showed sustained responses. The mean antidromic latency of MI PTNs that showed only transient responses was 1.5 ± 0.9 ms while those that showed only sustained responses (2.9 ± 1.6 ms) or combined transient-sustained responses (2.5 ± 1.2 ms) had longer antidromic latencies. PoC PTNs had generally longer antidromic latencies than MI PTNs, but a similar pattern was observed: smaller PTNs were more likely to show sustained responses. The effect of electrode sampling bias towards larger PTNs exaggerates the contribution of transient-only responses to the total PTN sample. By applying the correction function of Humphrey and Corrie (J. Neurophysiol. 41: 216, 1978) for microelectrode sampling bias it can be seen that the vast majority (64%) of MI PTNs which have sensory responses to limb displacements show sustained responses.

This finding offers clues concerning the functional significance of feedback to somatic sensorimotor cortex during voluntary movement and shows that a substantial population of MI PTNs receive continuous feedback during posture as well as during the dynamic phase of movement.

150.5 MOTOR-DEPENDENT NEURONAL ACTIVITY IN PREMOTOR AND MOTOR CORTEX FOLLOWING VISUOSPATIAL CUES. M. Weinrich, K.-H. Mauritz* and S.P. Wise. Lab of Neurophysiology, NIMH, Bethesda, MD 20205

"Responses" of neurons in the premotor and motor cortex to visual stimuli have been reported. To investigate the contingency of these activity patterns on planned movements we have recorded the activity of single neurons in these cortical fields of two unanesthetized rhesus monkeys while they performed a motor task. A key feature of the task is that the monkeys were presented with physically identical visual stimuli in two conditions: one requiring a movement, and the other requiring the monkeys to withhold a movement.

Monkeys were seated in a primate chair facing a tangent screen. A "position" spot and a "target" spot were projected on the screen; the monkeys were otherwise in darkness. Their left arms were enclosed in a plastic brace which allowed motion at the elbow. A potentiometer measured the angle around the elbow and controlled the "position" spot. The "target" spot was controlled by a computer. First, the animals were required to align the two spots for 1.3 sec. Next, in 5/6 of the trials, termed "go" trials, the computer would move the "target" to one of five randomly chosen locations on the screen and simultaneously brighten it. The animals had to maintain their original position for a randomly varied delay (0.8-2.4 sec), after which the target dimmed to its original luminance. This dimming was the cue for the animals to realign the spots within 1.2 sec. For the remaining "no-go" trials, the computer brightened the target without moving it. After a randomly varied delay (0.8-2.4 sec) the light dimmed. The monkeys had to remain in their original positions throughout the period when the target was brightened.

Activity following the brightening of the target was of two types. 198 neurons responded transiently to the target jump. The mean peak activity of these transients was approximately the same for the "no-go" trials as in the trials requiring a movement. 150 neurons with sustained activity following the visual cue were recorded. 80% of these neurons had greater activity during "go" trials, and the mean activity during "go" trials was greater than twice the activity during "no-go" trials. These results suggest that some aspects of sustained activity elicited by visual stimuli from premotor and motor cortex neurons may be contingent on planned motor acts.

150.6 RECIPROCAL SUPPRESSION OF ANTAGONIST MUSCLE ACTIVITY BY SINGLE CORTICOMOTONEURONAL CELLS IN THE PRIMATE. R.J. Kasser* and P.D. Cheney. Departments of Anatomy and Physiology, University of Kansas Medical Center, Kansas City, Kansas, 66103.

Motor cortex cells which are functionally coupled to motoneurons of muscles coactivated with the cell during voluntary movement (agonist muscles) may be identified in awake monkeys by the appearance of a transient postspike facilitation in spike-triggered averages of rectified EMG activity. Since these cells are most likely monosynaptically connected to motoneurons of facilitated muscles, they have been referred to as corticomotoneuronal (CM) cells (Fetz & Cheney, J. Neurophysiol., 44: 751, 1980). We wished to test whether such cells, in addition to facilitating one or more agonist muscles, also simultaneously inhibit the antagonist muscles. Rhesus monkeys were trained to make wrist movements alternating between two target zones - one in flexion and the other in extension. EMGs from 4-6 forearm flexor and extensor muscles were recorded differentially with pairs of multistranded stainless steel wires inserted pericutaneously. CM cells are usually tonically active during only the agonist phase of an alternating movement and become inactive during the antagonist phase. To maintain CM cell activity throughout the entire wrist movement cycle, glutamate was iontophoresed through one barrel of a double-barreled microelectrode while simultaneously recording cell discharge through a tungsten microelectrode contained within the second barrel. Glutamate iontophoresis currents ranging from 70 to 321 nA (mean 190 nA) increased the activity of motor cortex cells an average of 34 Hz during the agonist phase of movement and 27 Hz during the antagonist phase without significantly altering the detailed structure of the response pattern during movement. Functional effects of 20 wrist movement related motor cortex cells on flexor and extensor wrist muscles were tested by computing spike-triggered averages separately for each set of muscles. Nine of these cells had no effect on either flexor or extensor muscles despite a strong correlation between the cell's activity and wrist movement. Of the remaining cells, five produced postspike facilitation in one or more of the agonist muscles and postspike suppression in one or more antagonist muscles. Five cells produced only postspike facilitation of agonist muscles and had no effect on the antagonists. One cell produced only postspike suppression of antagonist muscles and had no effect on agonists. In conclusion, our results suggest that some motor cortex cells, like muscle spindle Ia afferents, have reciprocally organized connections with flexor and extensor motoneuron pools. (Supported by NIH grant NS16262).

150.7 PT STIMULATION PRODUCES CONDUCTANCE DECREASE IPSPs IN NEURONS OF THE MOTOR CORTEX OF CATS. L. Bindman*, C. Woody, E. Gruen*, and R. Betts* (SPON: R. Pay). Depts. of Anatomy and Psychiatry, UCLA Medical Center, Los Angeles, CA 90024.

Effects of pyramidal tract (PT) stimulation at the level of the facial nucleus (100 μs pulse of up to 10 mA or train of 2 to 6 pulses 10 ms apart, delivered every sec) were studied in intracellular recordings from 62 cells of the motor cortex of awake cats. Technical procedures have been described elsewhere (Woody and Black-Cleworth, J. Neurophysiol., 1973; Tzebelikos and Woody, Brain Res. Bull., 1979). Of these cells 10 showed an IPSP that decreased with hyperpolarization and, in 5 of the ten cells, the IPSP was reversed with additional hyperpolarizing current. In 9 of the cells, it was possible to measure a decrease in resistance at the time of the IPSP. This IPSP has been recognized previously by other investigators and is thought to reflect an increase in chloride conductance.

In 30 of the remaining cells, a quite different IPSP was found within the same 35-120 msec period following PT stimulation. In each of these cells, the IPSP increased in size with the application of hyperpolarizing current and could not be reversed with hyperpolarization. With depolarizing current the IPSP decreased in size. The input resistance of 8 of these cells was determined by computer analysis and showed an increase in resistance during the IPSP. This was done by comparing the magnitude of a continuously repeated (20 ms on, 20 ms off) bridge pulse during the IPSP with that prior to the PT shock that elicited the IPSP. Analysis of six additional cells showed a more complex conductance change with a hump of increased resistance at the peak of the IPSP appearing within a broader trough of decreased resistance. Conductance decrease IPSPs have been reported previously (Siggins et al, Science, 1971; Engberg and Marshall, Acta. Physiol. Scand., 1971; Smith and Weight, Nature, 1977), but not in neurons of the motor cortex. Conductance decrease IPSPs were seen in these cells irrespective of whether antidromic spikes were produced by PT stimulation. (Supp. by BNS 78-24146, HD 05958, and AFOSR 81-0179).

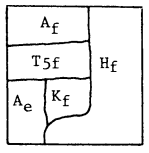
150.8 RESPONSES OF RAT CEREBRAL CORTEX TO MEDULLARY PYRAMIDAL TRACT STIMULATION. T. A. Harrison and A. L. Towe. Dept. of Physiol. & Biophys., Univ. of Washington Sch. of Med., Seattle, WA 98195.

The major component of the response in the cerebral cortex of anesthetized rats to medullary pyramidal stimulation is a large, short-latency, short-duration, surface-positive potential thought to result from antidromic invasion of PT neurons. Because published accounts contain indications that this response may not be purely antidromic, a study was undertaken to further characterize this response and to determine the manner in which it is produced. As in previous studies, this response (here called the A component) was recorded over most of the parietal and frontal cortex. Its initial and peak latencies varied with recording position; it occasionally exceeded 1.0 mV in peak amplitude. At many recording sites, a small, surface-positive component could be seen preceding the main A component; it showed no latency variation with recording position, and never exceeded 0.1 mV in amplitude. The A component was more widely distributed than this small, early component, attaining its maximal amplitude in contralateral hindpaw primary cortex, with a secondary maximum in contralateral forepaw primary cortex. It extended caudolaterally into somatosensory area II, apparently forming a separate, smaller amplitude distribution. Latency and amplitude decreased with iterative stimulus rates above 50 Hz. The A component disappeared soon after a KCl-induced spreading depression developed, but recovered more rapidly than did the primary response to contralateral forepaw stimulation. Intravenous injection of strychnine sulfate increased the A amplitude to 130-140% of control, whereas the primary response more than doubled in amplitude. Laminar recordings revealed little or no change in the A component down to deep layer III; below that level, the A component rapidly reversed in polarity, becoming a large negative response below layer V. These properties, associated with synaptic rather than purely antidromic responses, are the same as those of the r wave found in the woodchuck and also present in the slow loris and opossum. A similar component has been observed in the rabbit and phalanger, but is absent in the cat, raccoon and macaque monkey. It is concluded that the A component in the rat is an r wave and that it is synaptically mediated by activation of pyramidal tract collaterals, probably within the cortex. It is suggested that the small, early, surface-positive component that is often obscured by the large r wave, and that shows characteristics associated with purely antidromic events, is the true antidromic response. [Supported by USPHS grants NS05136 and 1T32-NS07097]

150.9 INTERNAL ORGANIZATION OF THE HINDLIMB AREA OF THE RAT MOTOR CORTEX. C.F. Sievert* and E.J. Neafsey (SPON: G.C. Gaik). Dept. of Anatomy, Loyola University Stritch School of Medicine, Maywood, Illinois 60153.

Although a hindlimb area in rat motor cortex has been previously described (Hall and Lindholm, Brain Research, vol. 66, 1974), the detailed internal organization of this region was unknown. The present study investigated the internal organization of the hindlimb area by mapping movements elicited by intracortical microstimulation (.25 msec pulses, 10-100 μamps, 350 Hz, 300 msec trains) in the motor cortex of adult Long-Evans rats. The rats were anesthetized with Ketamine HCl (100 mg/kg, IP) and placed in a sterotaxic frame. A small craniotomy was made and a glass insulated tungsten microelectrode (80-120 μ exposed at tip) was inserted perpendicular to the cortical surface to a depth of 1.7 mm. In each rat 30-50 penetrations spaced approximately .5 mm apart were made in an area extending from 1 mm rostral to bregma 4 mm caudally, and from 1 mm off the midline 3 mm laterally. Stimulation currents at each point were initially 100 μamps and were then reduced gradually to threshold (the lowest current reliably evoking a movement).

The drawing below depicts the typical size, location and internal organization of the hindlimb area as determined thus far in 4 rats. Bregma is denoted by B. The movements elicited included hip flexion, H_f; knee flexion, K_f; ankle flexion, A_f; ankle extension, A_e; and toe five flexion, T_{5f}. Not all movements were found in each animal, but the results in each animal were close to that illustrated. Just anterior to the hindlimb area trunk and forelimb movements were found, while posteriorly tail movements were seen occasionally.



Following HRP injections into the lumbar enlargement, a large patch of labeled neurons was found in the hindlimb area as defined by electrical stimulation in the same animal. It is interesting to note that after HRP injections into the cervical enlargement there was a large patch of lightly labeled cells in the hip area of the hindlimb motor cortex. This labeling may be due to collateral branches to the cervical enlargement from fibers projecting to the lumbar enlargement as described by Shinoda in the cat. These collaterals may be functional in control of coordinated hindlimb and forelimb movements.

150.10 THE MOTOR CORTEX OF THE RAT: CONNECTIVITY AND SINGLE UNIT DISCHARGE DURING MOVEMENT. J. P. Donoghue. Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

The motor cortex (MI) of the rat consists of two cytoarchitectonic areas: an agranular area, called the lateral agranular field (AG_1) and an area with a granular layer IV, which overlaps part of the first somatic sensory (SI) cortex (Donoghue and Wise, Neurosci. Abs. 7:18, 1981). However, the role of these areas in the control of movement is not understood. In the present study, the sources of inputs to AG_1 were identified with axonal pathway tracing methods and, the discharge pattern of single units in this subdivision of the rat MI cortex during motor activity was recorded.

Following injections of horseradish peroxidase restricted to AG_1, labeled cells are found ipsilaterally in the frontal agranular cortex rostral to AG_1, the SI cortex, and the second somatic sensory area. Labeled cells in SI are predominantly in the dysgranular areas. Each ipsilateral projection arises primarily from cells in layers III and V, but a few labeled cells are present in layers II and VI. Commissural inputs to AG_1 arise from cells in layers II-VI of the contralateral AG_1. Thalamic inputs to AG_1 arise from the ventrolateral complex and the ventromedial, central lateral, and posterior nuclei.

The activity of single units in MI and SI cortex was studied in behaving rats trained to repeatedly press a fixed bar with their forelimb. Water reinforcement was given after forelimb force exceeded a set level. Unit discharge in the forelimb region of AG_1 was related to changes in forelimb force. One group of units in AG_1 increased discharge rate up to 100ms prior to a change in force and peak discharge in these cells was as much as 50 impulses per second over background. Another group of AG_1 units decreased discharge before or during force changes. Both groups of units were located near sites where intracortical microstimulation at 30 uA or less produced movements of the forelimb. In addition, units in this region appeared to be activated by input from noncutaneous receptors. Units in the forelimb area of SI cortex, where cells are activated by light tactile stimuli to the forelimb, often showed a burst of activity when the rat's paw made contact with the bar.

These studies show that the lateral agranular field of rat MI cortex receives convergent inputs from: (1) two cortical areas involved in sensory information processing; (2) a rostromedial agranular cortical field; (3) contralateral MI; and (4) thalamic nuclei known to receive input from subcortical motor centers. This multiplicity of sensory and motor inputs and the early modulation of unit discharge prior to force changes suggest that neurons in AG_1 are important in the processing and execution of central and peripherally guided motor programs.

150.11 IS THERE A VESTIBULAR INPUT TO THE RAT CEREBRAL CORTEX ? S.E. Knowles, J.K. Chapin and D.J. Woodward. Dept. Cell Biology, Univ. of Texas Health Science Center, Dallas, Texas, 75235.

The aim of this study was to determine if neural projections from the vestibular nuclei of the rat are relayed to the neocortex. In particular we wished to determine whether: 1) cortical area(s) receive vestibular input; 2) these vestibular areas are associated with other modalities; and 3) the thalamic relay nuclei might be involved in this system. Both anatomical and electrophysiological techniques were used to examine these pathways.

Iontophoretic injections of HRP containing 1-3% L-lysophosphatidyl choline were made at various cortical and thalamic sites. HRP injections into areas including ventrobasal (VB) thalamus resulted in retrogradely labelled neurons in the contralateral vestibular nuclei. This same region of VB thalamus could be retrogradely labelled by HRP injections placed in the central SI dysgranular zone (DZ). This zone is situated in SI between the forepaw and head representation spanning approximately 2 square mm. DZ is unresponsive to light cutaneous touch of the periphery in the anesthetized animal, but exhibits deep and cutaneous receptive fields in the awake animal. Cytoarchitechtonically, DZ lacks a thick layer IV and is thus readily discernable by light microscope.

Single unit recordings were obtained from neurons in the DZ of halothane anesthetized rats. Histogram analysis showed evidence of excitation following electrical stimulation of the medial or superior vestibular nuclei (single pulse or train of 3, 0.2 msec width, 1.5 msec separation, 0.2-0.7 mAmp, 0.5-1 Hz) with latencies ranging from 8-30 msec. Excitatory neuronal responses have been recorded in deep layers of the cortex (>1 mm below pial surface) which were frequently followed by a trough of inhibition (lasting up to 70 msec).

In summary, the present results indicate that a portion of the dysgranular zone (DZ) of primary somatic sensory cortex of rat may receive a vestibular input. This input may converge upon cells with deep and/or cutaneous receptive field properties in the awake animal. The ventrobasal thalamus is a likely relay nucleus in this projection which may play a role in motor coordination.

150.12 CORTICAL AFFERENTS TO THE VIBRISSAE MOTOR CORTEX IN THE RAT. R.R. Terreberry* and E.J. Neafsey. (SPON: F.W. LaVelle). Dept. of Anatomy, Loyola University Stritch School of Medicine, Maywood, IL 60153.

A recent microstimulation study from our laboratory has reported that the vibrissae area in the rat motor cortex is organized into discrete zones controlling either the ipsilateral or contralateral vibrissae (Terreberry and Neafsey, Anat. Rec. 202: 189A, 1982). The present study investigated the cortical afferent projections to the vibrissae motor cortex by mapping retrogradely labeled cortical neurons following injections of horseradish peroxidase conjugated with wheat germ agglutin (HRP-WGA) into the vibrissae motor cortex. The rats were anesthetized with Ketamine HCl (100 mg/kg,IP) and placed in a stereotaxic frame. The cisterna magna was opened to prevent cortical swelling and a small piece of bone (2x5 mm) was removed just rostral to bregma on one side. The vibrissae motor cortex was identified by locating the region where intracortical microstimulation (.25 msec pulses, 5-100 μamps, 350 Hz, 300 msec trains) evoked either ipsilateral or contralateral vibrissae movements. Then .02-.03 μl of a 2% solution of HRP-WGA (Sigma) in physiological saline was injected into the vibrissae motor cortex using a 1 μl Hamilton syringe fitted with a 50 μm diameter tip. After survival periods of 2-2½ days, the animals were reanesthetized, transcardially perfused with 1.25% glutaraldehyde and 1% paraformaldehyde, and the tissue was processed for HRP histochemistry according to the TMB procedure of Mesulam (J. Histochem. Cytochem. 26: 106-117, 1978).

Retrogradely labeled neurons were found in several cortical areas, including the ipsilateral primary vibrissae somatosensory cortex (SI), bilaterally in the secondary somatosensory cortex (SII) and in the homotypic areas of the contralateral primary motor cortex (MI). Positively labeled cells in SI were organized into two different patterns. One pattern consisted of labeled neurons in both the supragranular (layers II,III) and the infragranular (layer V) layers of SI cortex. This pattern of labelling was found at both the medial and lateral borders of the vibrissae SI where there appeared to be "breaks" or "gaps" between the granule cell aggregates of layer IV. The second type of labelling pattern consisted of a narrow band of labeled cells in the infragranular layer V only. This band was not continuous but was broken up into clusters of labeled cells that may correspond with the vibrissae "barrels" of SI. This pattern was found in the intermediate portion of vibrissae SI, not at the borders. No positively labeled cells were found in the contralateral SI. Positively labeled cells in SII were located in layers II,III and V with the ipsilateral SII showing more label than the contralateral SII.

Supported by NIH grant NS16146 and BRSG RR05368 from Loyola Univ.

150.13 A COMPARISON OF THALAMIC AFFERENTS TO THE ROSTRAL AND CAUDAL FORELIMB REGIONS OF RAT MOTOR CORTEX. E. Luke Bold*and E.J. Neafsey. Dept. of Anatomy, Loyola University Stritch School of Medicine, Maywood, IL 60153.

Two separate forelimb motor areas have recently been described in rat frontal cortex (Neafsey and Sievert, Brain Res. 232, 1982). The present study investigated the organization of thalamocortical projections to these functionally similar, yet spatially separated cortical areas by mapping retrogradely labeled thalamic neurons following injections of HRP or HRP conjugated with wheat germ agglutinin (WGA-HRP) into either the rostral forelimb region (RFL) or the caudal forelimb region (CFL). Under Ketamine anesthesia, the RFL or CFL regions were identified by locating the points where intracortical microstimulation (.25msec. pulses, 100uamps or less, 300 msec. train @ 350 Hz) evoked digit or wrist movements rostral or caudal to an area where neck movements were elicited. Then .01-.02 ul of a 30% HRP solution (Sigma VI) or a 5% solution of WGA-HRP (Polysciences and Sigma) in physiological saline was injected into the physiologically defined RFL or CFL using a 1 ul Hamilton syringe fitted with a 50 um diameter pipette tip (typical diameter of injection site= 1.5 mm). After survival periods of 1 to 2 1/2 days, the animals were reanesthetized, transcardially perfused with 1.25% glutaraldehyde and 1% paraformaldehyde and the tissue processed for HRP histochemistry according to the TMB procedure of Mesulam (J. Histochem. Cytochem. 26, 1978).

Following both injections, retrogradely labeled neurons were found in the same basic set of thalamic nuclei which included the ventromedial (VM), ventrolateral (VL), intralaminar, and posterior (PO) nuclei. A few labeled cells were found within the ventrobasal complex (VB) only following large CFL injections but were never seen following RFL injections. Also, RFL injections consistently labeled cells in the paralamellar mediodorsal nucleus (MDpl) whereas such labeling was not observed following CFL injections.

The basic similarity of thalamocortical projections to the two forelimb areas suggests that both are subdivisions of primary motor cortex, a notion also supported by the low microstimulation thresholds found in both areas. The significant labeling in PO is of special interest because some lemniscal afferents to the thalamus terminate in this nucleus (Lund and Webster, JCN 136, 1967), suggesting that PO may transmit peripheral sensory information directly to motor cortex. It is tempting to speculate that this part of PO in the rat may be the homolog of the primate VPLo nucleus since both nuclei are located dorsal to VB and caudal to VL and both PO and VPLo project to layer III of motor cortex (Herkenham, Science 207, 1980; Friedman and Jones, J. Neurophysiol. 45, 1981).

150.14 COMPONENTS OF THE NEUROMAGNETIC RESPONSE OF THE HUMAN SENSORIMOTOR CORTEX. F. Richer, R. Johnson* and J. Beatty. Department of Psychology, University of California, Los Angeles, CA 90024.

Using a superconductive magnetometer with a 1-cm. resolution, evoked magnetic fields can be recorded from the scalp of normal humans above the sensorimotor cortex during a simple reaction time task.

The movement-related field is recorded for the 500 msecs preceding and following simple finger flexions executed in response to a brief 800 Hz tone using the onset of the flexor EMG activity as temporal reference. Average evoked fields are computed from about 120 finger flexions at each of 24 scalp locations covering an area of 50 cm^2 centered at C3 in the EEG derivations. The field reverses polarity along the axis connecting C3 to the vertex and the point of polarity reversal, which indicates the location of the current source producing the field, is in close agreement with the location of the finger representation on the sensorimotor cortex as determined by somatosensory evoked fields. The amplitude distribution of the different components of the neuromagnetic response reflect current sources orthogonal to the Rolandic fissure and tangential to the surface of the scalp. A depth triangulation procedure is used to confirm the cortical nature of the sources and to determine their depth with a precision of a few millimiters. Both pre-EMG and post-EMG components of the field could be identified.

The precise localization of these independent components as well as their relative sensitivity to movement force and movement perturbations is being investigated.

151.1 NEUROPHYSIOLOGICAL STUDIES OF THE VENTRAL LATERAL GENICULATE-SUPRACHIASMATIC NUCLEUS PROJECTION IN THE RAT. G. A. Groos* and B. Rusak. Physiology Laboratory, Univ. of Leiden, The Netherlands.

The hypothalamic suprachiasmatic nuclei (SCN) are involved in the generation and photic entrainment of circadian rhythms in mammals. Entrainment is mediated in part by a direct retino-hypothalamic tract (RHT), but other visual structures may also mediate photic effects on rhythms. A projection from the ventral nucleus of the lateral geniculate ($_{V}$LGN) has been identified anatomically as reaching the rat SCN. We conducted an electrophysiological study of single SCN and $_{V}$LGN cells in the rat to examine the functional organization of this pathway. We used antidromic stimulation techniques to identify the cells of origin of the $_{V}$LGN-SCN projection and to characterize their photic responsiveness. We also examined photic responses of SCN cells in rats which the $_{V}$LGN had been destroyed.

We recorded extracellular single-unit activity in the SCN and $_{V}$LGN of 38 urethane-anesthetized male Wistar rats; we also recorded SCN activity in 8 rats that had sustained complete bilateral $_{V}$LGN lesions. Photic stimuli consisted of diffuse white light of varying intensities presented to the eye contralateral to the $_{V}$LGN or SCN recording site. Cells projecting to the SCN were activated antidromically by applying constant current stimulation (0.1-0.5 mA, 0.1-0.2 msec) to the SCN while recording in the contralateral $_{V}$LGN. Recording and stimulation sites were verified histologically.

Visually responsive cells in the SCN responded tonically to changes in the level of retinal illumination. A large proportion of $_{V}$LGN cells in our sample (83/353) showed functional properties similar to those of SCN cells. Their receptive fields lacked an obvious antagonistic center-surround organization, and they either increased (67/83) or decreased (16/83) their firing rates tonically with increasing retinal illumination. A number of cells in the dorsal portion of the $_{V}$LGN could be activated antidromically by SCN stimulation with a latency of 3.0-6.5 msec. Their following of high-frequency stimulation and the results of collision tests indicated that these were genuine antidromic responses. Other $_{V}$LGN cells that projected to the SCN did not respond to either monocular or binocular retinal illumination. Destruction of the $_{V}$LGN did not alter the visual responsiveness of SCN cells.

These studies provide electrophysiological evidence for a $_{V}$LGN-SCN projection originating in cells near the dorsal border of the $_{V}$LGN. At least some of these units showed photic responses similar to those of SCN cells, but destruction of the $_{V}$LGN did not alter SCN photic responses. The functional significance of the existence of two similar visual inputs to the SCN remains to be established. (Supported in part by ZWO of The Netherlands.)

151.2 CIRCADIAN RHYTHM DISSOCIATION INDUCED BY PERIODIC FEEDING IN RATS WITH SUPRACHIASMATIC LESIONS. F. K. Stephan. Department of Psychology, Florida State University, Tallahassee, FL 32306.

Rats with lesions of the suprachiasmatic nucleus (SCN) were maintained in constant darkness and placed on restricted feeding schedules with 1h access to food twice per day. When both schedules had a 24h period and food access was spaced 12h apart, all rats with SCN lesions displayed anticipatory activity to both feedings. In the first experiment, the period of one schedule was then changed to 25h while the other continued with a period of 24h. None of the rats with SCN lesions were able to anticipate both schedules simultaneously. In a second experiment, 24h and 24.5h schedules were used. Five of six rats with SCN lesions anticipated both schedules for at least 9 days and 2 of these anticipated both schedules for 48 days. This forced dissociation of activity into two components with different periods is consistent with the hypothesis that entrainment of activity by restricted food access is mediated by more than one circadian pacemaker. These pacemakers are functionally independent of the SCN, a major pacemaker in the circadian system of rodents.

151.3 SUPRACHIASMATIC HYPOTHALAMIC NUCLEUS ORGANIZATION IN THE MACAQUE MONKEY: CYTOARCHITECTURE IN RELATION TO DISTRIBUTION OF RETINO-HYPOTHALAMIC AFFERENTS AND VASOPRESSIN NEURONS. R. Y. Moore and J. P. Card, Depts. of Neurology and Neurobiology, SUNY, Stony Brook, Stony Brook, NY 11794.

The suprachiasmatic nucleus (SCN) in the macaque monkey, as in other mammals, is the principal site of termination of retinal afferents to the hypothalamus (Hendrickson et al, 1972; Moore, 1973). The intent of the present study was to provide a detailed analysis of the distribution of the retinohypothalamic projection (RHT) to the SCN and relate this to the cytoarchitecture and the distribution of vasopressin (VP) neurons in the nucleus. In Nissl material the SCN appears rostrally as a thin nucleus above the optic chiasm comprised largely of small neurons. More caudally the SCN becomes oval and then round in appearance with the compact, small neuron population surrounded by a more loosely organized set of larger neurons. In material prepared by the autoradiographic tracing technique after injection of tritiated amino acid in one eye, dense labeling is found over the rostrocaudal extent of the SCN but concentrated in the ventral, parvocellular portion of the nucleus. Labeling is more dense in the rostral portion of the SCN than caudally and greater on the contralateral than the ipsilateral side. VP immunoreactivity is evident in neuronal perikarya and axons over the rostrocaudal extent of the SCN. The neurons are smaller and less densely stained than those in the supraoptic (SON) or paraventricular (PVA) nuclei and the axons are much finer than those arising from neurons of SON and PVA. The VP immunoreactive neurons of SCN are scattered through the nucleus and extend dorsally and laterally well beyond what would appear in Nissl material to be the confines of the nucleus. At mid-SCN, for example, VP perikarya and axons extend laterally to the border of SON and dorsally to the border of PVA. The center of the nucleus where the RHT terminates, however, is always free of elements exhibiting VP immunoreactivity.

These data indicate that the extent of the SCN in the macaque monkey is substantively greater than would be predicted from either cytoarchitecture or the area of termination of the RHT. As in the rat, VP neurons appear to be principally SCN interneurons which are segregated from the area of RHT termination. The similarities in organization of the SCN in rat and monkey suggest that the organization of the SCN in the generation of circadian rhythms is similar in these divergent mammalian species. Supported by NIH grant NS-16304.

151.4 AN ANALYSIS OF IMMUNOHISTOCHEMICALLY DISTINCT CELL AND FIBER SYSTEMS WITHIN THE SUPRACHIASMATIC NUCLEI OF THE GOLDEN HAMSTER BRAIN. J. P. Card and R. Y. Moore, Departments of Neurology and Neurobiology, SUNY, Stony Brook, Stony Brook, NY 11794.

The organization of the suprachiasmatic nuclei (SCN) of the golden hamster were investigated by cytoarchitectonic and immunohistochemical analysis. Examination of Nissl-stained coronal sections throughout the rostrocaudal extent of the optic chiasm (OC) reveal that the SCN consist of compact cellular masses situated over the caudal third of the OC on either side of the third ventricle. Each nucleus is approximately 650 μm in length and achieves its greatest height (600 μm) and width (300 μm) in the intermediate third of the rostrocaudal axis. With the exception of the rostral fourth of each nucleus, the SCN are fused along their ventromedial borders between the dorsal surface of the OC and the ventral limit of the third ventricle. Immunoperoxidase staining of tissue with antibodies generated against vasopressin (VP), vasoactive intestinal polypeptide (VIP; provided by J.Walsh), somatostatin (SS), avian pancreatic polypeptide (APP, provided by J. Kimmel), and 5-hydroxytryptamine (5-HT) reveal distinct and consistent subfields within each nucleus in all animals examined. VASOPRESSIN. Neurons displaying VP-like immunoreactivity are present throughout the rostrocaudal extent of the SCN and are relegated almost exclusively to the dorsal and medial aspects of each nucleus. A dense plexus of immunoreactive fibers is present in the dorsomedial aspect of the SCN as well as within a circumscribed area at the ventrolateral extent of the caudal third of the SCN/OC interface. VIP. Immunoreactive perikarya are absent from the rostral third of the SCN, but occur in large numbers throughout the remaining portions of the rostrocaudal axis. In this area, immunoreactive neurons are concentrated within the ventral third of the SCN throughout their mediolateral extent, including the ventral aspect of the area in which the two nuclei are fused. Immunoreactive fibers are found throughout the SCN, but are most dense in the dorsal half of each nucleus. SOMATOSTATIN. Immunoreactive perikarya are restricted to the dorsomedial aspect of the SCN with the major concentration occurring within the intermediate third of the rostrocaudal axis. Immunoreactive axons are present throughout the SCN with the densest concentration occurring within a vertical column filling the lateral third of each nucleus. APP. APP-like immunoreactivity is restricted to axons which form a dense plexus in the ventral and lateral aspects of the SCN. No immunoreactive axons are present in the dorsomedial portion of the nuclei. 5-HT. Axons exhibiting 5-HT-like immunoreactivity form a dense plexus within the ventromedial portion of the SCN. Scattered fibers also occur within the dorsal half of each nucleus. Supported by grant NS-16304.

151.5 GLUCOSE UTILIZATION OF THE SUPRACHIASMATIC NUCLEI IN THE DIURNAL SQUIRREL MONKEY. W.J. Schwartz, S. Eagan,* & M.C. Moore-Ede. Dept of Neurology, Massachusetts General Hospital & Dept of Physiology, Harvard Medical School, Boston, MA.

Accumulated evidence using a variety of techniques indicates that an endogenous circadian "clock" is located in the suprachiasmatic nuclei (SCN). A part of this evidence is from studies using the rate of SCN glucose utilization (measured by the ^{14}C-labeled deoxyglucose method) as a marker for the level of functional activity in the nuclei. In the rat, the SCN are metabolically active during the light period of a 12 hr : 12 hr light-dark cycle, and metabolically inactive during the dark (J comp Neurol 189:157). We now report our preliminary observations on SCN metabolic activity in the squirrel monkey (*Saimiri sciureus*). We initiated this study (a) to compare the pattern of SCN glucose utilization in this diurnal primate with that in the nocturnal rat, and (b) to determine whether visualizing the SCN in this larger mammal might allow resolution of metabolic heterogeneities corresponding to the localized distribution of SCN afferents and neuropeptides.

Adult male squirrel monkeys, weighing approx. 900 g, were housed in isolation chambers at approx. 26° C with food and water ad libitum and trained to sit quietly in metabolic chairs. Intravenous catheters were inserted at least 2 wks before the experiments. Unanesthetized animals were then injected either at mid-darkness or mid-light with 125 µCi/kg 2-deoxy-D-[1-^{14}C]glucose (sp. act. 60 Ci/mole). After 45 min, animals were sacrificed with pentobarbital; brains were frozen, 30 µ thick coronal sections cut, and autoradiographs prepared as described previously.

The SCN were active in monkeys injected during lights-on and relatively inactive during lights-off. Metabolic activity during the daytime was non-uniform both in its distribution and amount - the flattened anterior poles of the nuclei were more active than were the ovoid posterior poles. This autoradiographic image corresponded closely to the three-dimensional shape of the SCN described using anatomical reconstructions (Neurosci Lett 17:295).

Thus, the SCN of both a diurnal primate and a nocturnal rodent are metabolically active during the light portion of the day. Moreover, the observed metabolic heterogeneity within the squirrel monkey SCN may provide clues for future studies aimed at understanding SCN substructure and function.

151.7 GLUCOCORTICOIDS MEDIATE THE PHOTOPERIODIC CONTROL OF THE SIZE OF THE RECEPTIVE FIELD FOR GROOMING REFLEXES IN CATS WITH PONTILE LESIONS. R. F. Johnson* (SPON: W. Kaelber). Dept. of Psych., Univ. of Iowa, Iowa City, 52242.

Electrolytic lesions of the pons and adjacent tegmentum induce grooming reflexes in the cat. The grooming reflexes are elicited by tactile stimulation of the cat's skin, a stimulation which imitates the frequency, intensity, and excursion of the self-imposed stimulation produced when a cat normally grooms, and, the reflexes occur without the orientation to the skin seen in normally integrated grooming behavior. The physiological bases of the grooming reflexes involve a deficit of serotonin, confined to the superior colliculus, and a dysfunction of the seasonal rhythm in glucocorticoids.

The size of the receptive field for the grooming reflexes exhibits seasonal fluctuations that are controlled by photoperiod. Photoperiod also controls the seasonal rhythm of glucocorticoids in normal cats. An investigation was undertaken to determine if glucocorticoids mediate the photoperiodic effect on the size of the receptive field.

Four cats with lesion-induced grooming reflexes were bilaterally adrenalectomized and placed on a constant replacement therapy of hydrocortisone (3 mg/cat/day) and desoxycorticosterone pivalate (5 mg/cat/month). Six control cats exhibiting lesion-induced grooming reflexes were subjected to laparotomy. The size of the receptive field was allowed to stabilize while both groups were on a photoperiod of LD 17:7 and, subsequently, the groups were switched to LD 15:9, LD 10:14, and LD 8:16 for six weeks each. After the photoperiodic manipulations both groups (while stabilized at LD 8:16) received a single injection of L-5-hydroxytrytophan (5-HTP, 5 mg/kg).

The results indicated that the different photoperiods produced changes in the size of the receptive field of the control cats as predicted from previous longitudinal studies. The size of the receptive field of the adrenalectomized group remained constant during the photoperiodic manipulations. Both groups displayed a decrease in the size of the receptive field after the injection of 5-HTP.

It is concluded that glucocorticoids are a mediator of the photoperiodic effect on the size of the receptive field. Glucocorticoids are the critical factor removed by adrenalectomy as is indicated by the fact that neither mineralcorticoids nor adrenalin affect the size of the receptive field whereas hydrocortisone produces changes over a wide range of dosages. The efficacy of 5-HTP in the adrenalectomized cats indicates that photoperiod does not affect the size of the receptive field by effecting changes in serotonin and that the effect of serotonin does not require changes in the levels of glucocorticoids.

151.8 PHASE CHANGES OF EATING AND ACTIVITY CIRCADIAN RHYTHMS IN YOUNG AND OLD FEMALE RATS.
Z. M. Wenzel and P. K. Randall.* Andrus Gerontology Cntr., Univ. Southern California, Los Angeles, CA 90007

One aspect of temporal organization is the phase of various biological rhythms; disruption of these relations may impair homeostatic function. This study was designed to assess whether temporal disorganization, as indexed by changes in phases, occurs during aging in the rat.

Fifteen female, Fischer-344 rats (6-months-old (n=8) and 24-months-old (n=7)) were maintained ad libitum in a controlled environment under four sequential lighting conditions of 8 days each: LD:12:12, LL:24, DL:12:12 and DD:24, with a return to LD baseline for 8 days after each condition. All animals were videotaped continuously during the conditions, and several behaviors were scored. Spectral analysis was performed; the 24-hour period typically showed the highest spectral density. Phase was determined from the coefficients of the 24-hour period, and represents the hour of peak activity.

The phase of eating and activity changed across lighting conditions, as expected ($p<.001$). There was an age difference in the phase of eating ($p<.05$) and an age by condition interaction in the phases of both eating and activity (EAT: $p<.001$ ACT: $p<.05$). Young and old animals differed in eating and activity phases in the LD:12:12 condition (EAT: (mean hr±S.E.) young= 24.72±.32 old=23.75±29 ACT: young=26.46±.62 old=23.11± .97). Thus, old animals eat, and are active, earlier in the day than young in light-dark conditions. Alterations of phase resulting from different lighting conditions are dependent on both age and the behavior observed.

These data suggest that phases of the circadian components of the eating and activity rhythms change with age.

151.9 PHASE AND PERIOD OF FEMALE HAMSTER RUNNING RHYTHMS DURING THE ANNUAL REPRODUCTIVE CYCLE. L.P. Morin. Long Island Reseach Institute, Health Sciences Center, SUNY, Stony Brook, NY 11794

When given access to running wheels, female hamsters tend to initiate locomotor activity earlier on estrous cycle days when estradiol is available. The change in running onset time is probably caused by an estradiol-induced change in the circadian wheelrunning period. Because the phase angle difference (ϕ) in a light-dark cycle and the free running locomotor rhythm (τ) of female hamsters are sensitive to the effects of estradiol (Morin et al., Science 196:305, 1977), several experiments were designed to determine a) whether changes in ϕ of the wheelrunning rhythm occur following spontaneous recovery of estrous cycles during prolonged exposure to LD 6:18, b) whether τ changes in association with spontaneous estrous cycle resumption in constant darkness (DD) and c) whether changes in ϕ might be sufficiently great to promote photostimulation of animals still in LD 6:18. The experiments also permitted an assessment of the effect of wheel access on latency to LD 6:18 induced estrous cycle loss and resumption.

The results showed: 1) ϕ and τ shortened in all animals housed in prolonged LD 6:18 or DD; 2) abrupt changes in ϕ and τ were associated with spontaneous resumption of estrous cycles in LD 6:18 or DD; 3) after 25 wk in LD 6:18, there was wide variability in ϕ among the animals. The variability was greater than among animals housed in LD 6:18 for only 8 wk. With one exception, the greatest ϕ was not sufficient to permit photostimulation as predicted by an existing model (Elliott, J.A., Proc. 35:2330, 1976); 4) in general, ϕ in LD conditions predicted later τ; 5) loss of estrous cycles by animals housed in LD 6:18 occurred about 5.2 wk earlier if animals were housed without access to running wheels. Latency to estrous cycle resumption was roughly the same (24.4 ± 0.3 vs 23.5 ± 0.4 wk).

151.10 ENTRAINMENT OF SPLIT CIRCADIAN RHYTHMS IN HAMSTERS. Z. Boulos and L.P. Morin. Long Island Research Institute, SUNY, Stony Brook, NY 11794.

Male hamsters that showed splitting of their circadian activity rhythms following long-term exposure to constant illumination (LL) were maintained under light-dark (LD) cycles with 2-h dark segments, and with periods of 24.00 h, 24.23 h or 24.72 h. In all cases, at least one of the split components entrained to the LD cycles. Under 24.00 h cycles, the onset of the entrained component preceded dark onset by 0.5-2 h, while under 24.23 h and 24.72 h cycles, the entrained component phase-led dark onset by about 3 h and 9 h, respectively. In some animals, the second split component continued to free-run (for up to 60 days) before finally merging with the entrained component, while in others, the second component also entrained to the LD cycles but maintained a constant phase angle of 8-13 h relative to dark onset. This latter result was obtained in cases where the period of the LD cycle was shorter than that of the split components as well as in cases where it was longer, implying that split components can be both phase-advanced and phase-delayed by 2 h of darkness.

Animals that showed stable entrainment of both split components were again allowed to free-run in LL for several weeks. The LD cycles were then reinstated, but instead of overlapping with the first component, as it did before, the dark segment was made to overlap with the second. The entrainment patterns which ensued were similar to the ones obtained initially, indicating that the two split components are affected by darkness in a qualitatively similar fashion. These results are evidence that the pacemaker system underlying circadian activity rhythms in hamsters is composed of two mutually coupled oscillators, or populations of oscillators, each with its own bidirectional phase response curve.

151.11 PINEALECTOMY SHORTENS THE PERIOD OF THE CIRCANNUAL BODY WEIGHT RHYTHM OF GOLDEN-MANTLED GROUND SQUIRRELS(SPERMOPHILUS LATERALIS). I. Zucker. Dept. of Psychology,University of California, Berkeley, CA. 94720.

Female golden-mantled ground squirrels were maintained from birth (June,1980) in a 14L:10D photoperiod at a temperature of 23±2°C. Between July 30 and August 5,1980 animals were pinealectomized (Pinx;N=11) or sham-pinealectomized (sham-Pinx;N=12). On September 19,1980 all animals were transferred to a 10L:14D photoperiod for the duration of the experiment. Body weight and reproductive condition were monitored at weekly intervals. Timing of the peak in body weight in 1980 did not differ between Pinx and sham-Pinx groups (Nov. 8±8 days vs Oct. 25±7 days); nor were trough weights achieved earlier in Pinx than in sham-Pinx squirrels (April 25,1981±10 days vs May 15±9 days, $p>.05$). However, the subsequent peak in body weight occurred earlier in Pinx than in sham-Pinx animals (Sept. 1, 1981±9 days vs Sept. 27±8 days, $p<.05$). The period of the circannual body weight cycle, measured peak to peak, was 296±12 days for Pinx animals and 337±5 days for sham-Pinx squirrels ($p<.008$). Absolute peak and trough weights did not differ between the groups. Thus, pinealectomy produces a substantial shortening of the period of the circannual body weight rhythm without affecting body weight regulation per se. These findings suggest that hormones of the pineal gland affect the period of circannual oscillations. The modification of the period of mammalian clocks by the endocrine system, previously established for circadian rhythms, has been extended to oscillations with a period of approximately one year. Endocrine influences on basic timing processes appear to be widespread.

151.12 THE EFFECTS OF PROTEIN MALNUTRITION ON REM SLEEP IN RATS OF THREE AGE GROUPS. L. Cintra*, S. Diaz-Cintra*, W.Forbes and P.J.Morgane. Worcester Foundation for Expt. Biology, Shrewsbury, MA 01545

In order to extend our previous studies (Expt.Neurol. 57:440-450, 1977) on effects of protein malnutrition on REM sleep we analyzed the amount and circadian distribution of REM sleep in rats of 60,90 and 220 days of age using both a 12/12 light/dark cycle and 24 hour dark cycle. Previously we showed, using groups combining malnourished animals with dietary-reversal animals,that malnourished rats showed a significant increase in REM during the dark period. In the present studies, using animals maintained on an 8% or 25% protein diet we found no significant differences in amount of REM between normal and malnourished rats at 60 days of age but significant differences in total 24 hr REM at both 120 and 220 days of age. In calculating REM dark-light ratios between the age groups on both diets using a 12/12 light/dark cycle we found no differences between the 60, 90 and 220 day old normals vs malnourished. The total amount of REM per 24 hrs in the 25% animals showed a significant decrease between 60 and 120 days and from 120 and 220 days. The malnourished animals showed a significant decrease from 60 to 120 days followed by a significant increase from 120 to 220 days. In general,REM dark/light ratios in both normal and malnourished animals increase between 60 and 120 and 120 and 220 days and are not significantly different between the 25 and 8% animals in all age groups. On the 24 hr dark schedule there was no significant difference between 60 and 120 day groups in total 24 hr REM % but there was a significant decrease in amount of REM between 60 and 120 days and a non-significant decrease between 120 and 220 days. On the 24 hr dark cycle, comparing the 1st 12 hours with the 2nd 12 hr period, there was no significant differences between the 8 and 25% animals at 60 days of age but there were significant differences between groups at both 120 and 220 days of age. In comparing normals vs malnourished the groups do not show significant differences in dark/light ratios on the 12/12 cycle but in the 24 hr dark cycle we found a different REM distribution for the malnourished in that significantly more REM occurs in the dark at 120 and 220 days of age. A significant REM redistribution at 220 days on the 12/12 light/dark cycle, i.e., increase in REM in the light in malnourished rats compared to normals is one main finding as is the significant increase in REM in malnourished compared to normals on the 24 hr dark cycle at 220 days. Overall, it appears that whereas normal animals show decreased REM on both the 12/12 and 24 hr dark cycles, malnourished animals tend to increase total REM by 220 days on both cycles. The affects on REM in the 3 age groups may be related to morphological changes we have demonstrated in raphe and locus coeruleus and to the marked increases in biogenic amines we have shown in malnutrition. 151.13 ENTRAINMENT TO FOOD AND LIGHT SCHEDULES IN VMH LESIONED RATS. R. Mistlberger* (SPON: R. Rosenberg). Sleep Lab., Univ. of Chicago, Chicago, IL 60637

When access to food is restricted to a single mealtime every 24 hrs., rats and other mammals show increases in locomotor activity and changes in other physiological variables which anticipate the mealtime by 1-2 hrs. This anticipation appears to involve the entrainment of an endogenous circadian timing mechanism since it occurs only when the periodicity of food access is within the circadian range.

There is little information on the neural substrate of this mechanism. It appears to be anatomically separate from mechanisms controlling free running, light entrained rhythms since food entrained rhythms are not abolished by suprachiasmatic nucleus lesions as are most free running rhythms. There is one report that ventromedial hypothalamic (VMH) lesions prevent food entrainment of corticosterone and temperature rhythms of female rats in light-dark (LD) cycles (Krieger, D.T., Endocrinology 106:649, 1980). The present study addresses the following points: is the effect specific to females or the variables tested; is there recovery of function over time; and do VMH rats simply require longer exposure to food schedules before showing entrainment?

Tilt cage activity of 6 hyperphagic VMH male rats was continuously monitored in LD (lights on 9:00) and displayed on computer generated actograms. Four weeks following surgery food access was restricted to 11:00-13:00. Four rats showed consistent anticipatory activity within 4-12 days, whereas 1 showed weak and 1 showed no entrainment up to the 16th day. At twelve weeks following surgery food access was restricted to 11:00-13:00 in constant dim light. All the rats showed anticipatory activity, although the precise latency in some cases was obscured due to free running rhythms. The rat which did not entrain during LD food restriction showed consistent anticipatory activity by day 10, suggesting either a recovery of function or a difference based on ambient lighting. More rats will be tested to separate these possibilities.

Currently, 7 hyperphagic VMH females are being tested in LD. After 15 days of restricted feeding initiated 5 weeks following surgery 6 rats show no consistent anticipation. One rat showed anticipatory activity by day 10. As a group, the VMH females tend to be more obese and show worse entrainment than the males, suggesting a sex difference possibly relating degree of obesity with impairment of entrainment. Histological analysis will be done to assess equivalency of lesions.

Entrainment to LD cycles among the 13 VMH rats was variable. Some entrained to LD during ad-lib and restricted feeding, but not to mealtime, indicating that the effects of VMH lesions on LD entrainment can be independent of effects on food entrainment.

151.14 A CHEMICAL GATING THEORY OF CIRCADIAN RHYTHMS. G. A. Carpenter, Northeastern University, Boston, MA. S. Grossberg, Boston University, Boston, MA.

This work develops a model of circadian rhythms in which each term has a concrete physical interpretation. One key component of the pacemaker is a chemical which gates, or multiplies, signals by mass action, and which replenishes itself slowly. The pacemaker not only exhibits the properties which other models have, such as characteristic phase leads and lags and Aschoff's rule, but also, under certain circumstances, can exhibit period doubling (48-hour days) and spontaneous, long-term,periodic modulation of duration and intensity of activity (biorhythms). To account for experiments in which complex activity such as wheel-turning is the circadian rhythm being measured, the model is augmented to include the effects of fatigue and learned incentive. In this case the model accounts for such important properties as long-lasting aftereffects on period and duration of activity; and split rhythms for diurnal and nocturnal animals. The interactions within the model cause the chemical gating substance to oscillate with a circadian rhythm, as do various neural modulators and transmitter substances.

151.15 PINEAL MELATONIN INFLUENCES SEROTONIN METABOLISM IN THE AVIAN BRAIN. V.M. Cassone* and M. Menaker. Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

Indoleamine and catecholamine levels in the brainstem (pons and medulla) and diencephalon of 5 and 8 week old cockerels were determined by HPLC-EC. A daily rhythm of serotonin (5HT) content was found in the diencephalon; levels were higher at mid-day than at midnight ($p<0.01$). No day-night difference in 5HT could be determined in the brainstem nor could a day-night difference be demonstrated in either tissue for norepinephrine (NE), dopamine (D), homovanillic acid (HVA), 5-hydroxy-indoleacetic acid (5-HIAA) or n-acetyl serotonin (NAS).

Brains of cockerels pinealectomized at 2 weeks after hatching were also analyzed at 5 and 8 weeks as above. While pinealectomy had no effect on mid-day levels of 5HT in either the brainstem or diencephalon, midnight levels of diencephalic 5HT were elevated above levels found in intact controls ($p<0.01$) and above mid-day levels for both intact and pinealectomized cockerels ($p<0.05$).

Injections of melatonin (0.5 mg/kg I.P. in sesame seed oil) into pinealectomized cockerels two hours before sacrifice lowered midnight diencephalic 5HT content when compared to cockerels injected with oil at the same time ($p<0.01$). Brainstem 5HT content, however, was increased by melatonin injection ($p<0.05$). HPLC-EC analysis of these tissues for melatonin revealed an inverse correlation between diencephalic 5HT content and diencephalic melatonin content ($p<0.01$) and a direct relationship between brainstem 5HT content and brainstem melatonin content ($p<0.05$).

In addition, cockerels which had been injected with melatonin had elevated levels of diencephalic 5-HIAA ($p<0.01$). No effect of melatonin on brainstem 5-HIAA could be determined.

These results indicate that pineal melatonin may act by increasing 5HT turnover and/or release in the diencephalon and 5HT content in the brainstem. They suggest a link between the circadian secretion of pineal melatonin and the regulation of 5HT projections to the diencephalon from the raphe nuclei.

151.16 PHOTIC REGULATION OF CYCLIC NUCELOTIDE LEVELS AND N-ACETYLTRANSFERASE ACTIVITY IN THE CULTURED AVIAN PINEAL. J.S. Takahashi and M. Zatz*. Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, Maryland 20205.

The avian pineal gland expresses a circadian oscillation of serotonin N-acetyltransferase activity and of melatonin release in vitro. In addition, light-dark cycles can entrain the rhythm of melatonin release in culture. Thus, the avian pineal contains a circadian oscillator and a photoreceptor, which regulate the synthesis of melatonin. Previous studies have suggested that cyclic nucleotides may be involved in the regulation of the enzyme, N-acetyltransferase. However, a clear relationship between cyclic nucleotide levels and enzyme activity has not been established.

We have measured cyclic AMP and cyclic GMP levels in cultured chick pineal glands and found that light exposure of the gland reduces the levels of both nucleotides. In pineals cultured for 6 hours in darkness, cAMP levels (57.5 ± 4.0 pmol/mg protein, $N = 54$, $\bar{x} \pm SE$) and cGMP levels (12.1 ± 0.9 pmol/mg protein, $N = 54$) were higher than those found in pineals exposed to 6 hours of light (cAMP: 14.9 ± 1.5, $N = 12$; cGMP: 5.28 ± 0.58, $N = 11$). Ten minutes of light exposure after 6 hours of darkness rapidly reduced cyclic nucleotide levels (cAMP: 19.7 ± 1.1, $N = 53$; cGMP: 4.43 ± 0.33, $N = 53$). The reduction of cAMP and cGMP levels by light preceded the reduction of N-acetyltransferase activity by light.

To determine which nucleotide, cAMP or cGMP, regulates N-acetyltransferase activity, the level of each nucleotide was increased by exposing pineals to selective stimulation by forskolin (an activator of adenylate cyclase) or to sodium nitroprusside (an activator of guanylate cyclase). Forskolin prevented the reduction in N-acetyltransferase activity by light; whereas sodium nitroprusside had no effect. Furthermore, addition of 0.25 mM 8-bromo cAMP prevented the light effect on enzyme activity; whereas, addition of 0.25 mM 8-bromo cGMP did not. Thus, the intracellular levels of both cAMP and cGMP are correlated with N-acetyltransferase activity. However, pharmacological experiments strongly suggest that cAMP, rather than cGMP, regulates the activity of this enzyme.

(J.S.T. is a Pharmacology Research Associate in the National Institute of General Medical Sciences.)

151.17 OPTIC EFFERENTS INFLUENCE PHOTIC ENTRAINMENT OF THE APLYSIA EYE CLOCK. Wesley P. Jordan and Marvin E. Lickey, Department of Psychology, University of Oregon, Eugene, OR 97403.

Each eye of Aplysia californica is a circadian clock. In constant darkness, a rhythm of compound action potentials (CAPs) can be recorded in vitro from the optic nerve of an isolated eye. Efferent fibers in the optic nerve contribute to the resetting of the phase of the CAP rhythm in vitro (Prichard & Lickey, 1981). This suggests that efferent activity also may influence the phase of the eye clock under entrained conditions in vivo. We tested this hypothesis in animals with one optic nerve cut before they were placed in 24-hr LD cycles of 1 to 16 hr of light per cycle.

The following table shows the median phases (relative to dawn) of the CAP rhythms from eyes attached to or isolated from the cerebral ganglion. There appeared to be two stable phases for both attached and isolated eyes in a 1-hr photoperiod. In both cases, one population of phases anticipated dawn by about 3 hr, while the other population of phases anticipated dawn by about 13 hr. This bistability disappeared in longer photoperiods. When the photoperiod was 2 or 6 hr, the phases of the rhythms were distributed unimodally, but the phases of attached and isolated eyes were different. While the CAP rhythm for attached eyes anticipated dawn by 1 to 3 hr in both LD 2:22 and LD 6:18, the phases of isolated eyes anticipated dawn by 12 hr in LD 2:22, but by only 5 hr in LD 6:18. The phase of the isolated eye rhythms appeared to follow dusk by 10 to 11 hr at these photoperiods. When the photoperiod was 9 hr or greater, the phases of both attached and isolated eyes were near dawn.

Photoperiod	Attached eye	Isolated eye
1	3 & 13	13 & 3
2	3	12
6	1	5
9	3	3
12	3	2
16	1	-1

Attachment to the cerebral ganglion in vivo affects the phase of the attached eye. If the phase of the rhythm from an isolated eye can be taken as the phase of the ocular pacemaker unaffected by the rest of the circadian system, then components of the system outside of the eye probably influence the phase of the ocular clock via efferent activity in the optic nerve. (Supported by NIH F32 NS06425 and NSF BNS 81-08168)

151.18 OPTIC NERVE PROJECTIONS TO CENTRAL GANGLIA OF APLYSIA. L. Olson* and J. Jacklet (SPON: R. Oesterreich). Dept. of Biol. SUNY Albany, Albany, N.Y. 12222

The optic nerve of Aplysia carries information from the circadian pacemaker located in the eye to the cerebral ganglion of the CNS. The clock driven synchronous activity of secondary neurons in the eye is high during the day and declines at night, coinciding with locomotor rhythms of the animal (Block, 1981). Studies have established that an intact optic nerve is necessary for normal expression of circadian locomotor rhythms (Lickey et al., 1976). We have examined the central projections of the optic nerve using horseradish peroxidase (HRP) backfilling of the optic nerve and ^{3}H-leucine labelling of cells in the eye with subsequent visualization of axon tracts by autoradiography.

HRP was introduced to the cut end of the optic nerve and processed for light or electron microscope analysis. These studies show that the optic nerve enters the dorsal surface of the ganglion parallel to the rhinophore nerve (RN) and continues within the sheath for a short distance before dipping into the ganglion. It then travels within the cell body layer, associated with a cluster of small opaque neurons between neuron clusters C and D of Jahan-Parwar and Fredman's (1976) classification, before entering the neuropil between cell clusters C and A. At this point the tract enlarges considerably, with a major bundle continuing posteriorly to leave the ganglion along the cerebral-pleural (C-P1) connective. In the neuropil area between clusters C and A a few fibers fan out laterally in both directions distinct from the C-P1 tract; these fibers often appear beaded. Efferent axons, from monopolar cell bodies located along the RN, enter the optic tract in this area, and branch or arborize in this same area of neuropil. Preliminary ultrastructural studies of HRP filled axons in the optic nerve proper show axon profiles which contain dense-core vesicles of a similar morphology to those described in the secondary cells of the eye (Luborsky-Moore and Jacklet, 1976).

Labelled fibers from neurons of eyes incubated in ^{3}H-leucine (10^{-6} M) confirm and extend HRP data. In addition to the large bundle of fibers exiting the ganglion along the ipsilateral C-P1 connective, these studies reveal another large tract which crosses the midline; a large group of these fibers leave along the contralateral C-P1 connective. Fibers leaving the ganglion may be terminating in the pleural ganglion, or may be contacting vascular spaces along the connective.

These studies have indicated an unexpectedly extensive projection of optic fibers within the Aplysia CNS, consistent with the idea that clock information may be widely distributed in the CNS to pattern daily behavior. Continuing studies are examining ultrastructural details of optic nerve projections.

151.19 EFFECT OF EXTERNAL LEVEL OF CALCIUM ON THE CIRCADIAN ACTIVITY OF THE CRAYFISH. Beatriz Fuentes-Pardo, Leticia Verdugo-Díaz† and Virginia Inclán-Rubio†. Depto. de Fisiología, División de Investigación. Facultad de Medicina. U.N.A.M. México 20, D.F. México.

Calcium has been recognized as an important element in many infradians or high frequency cellular oscillators suggesting that periodical activity is a common property of most biological systems. It has been also suggested that a population of high frequency interacting oscillators can give rise to circadian oscillations, i.e., it is possible that some calcium- dependent oscillators when coupled, can generate a twenty-four hours rhythm We have approached this problem by investigating wheather the electrical response to light (ERG) recorded from the isolated eyestalk of crayfish during four or more days, is modified by changes in the external level of calcium. The excised eyestalk were immersed in normal, calcium-free or calcium-rich saline solution and both, ERG and the position of the shielding pigments were obtained. The ERG amplitude showed a circadian rhythm with periods about 20 or 26 hours in calcium-free or calcium-rich saline solution respectively. Besides the circadian changes the isolated eyestalk showed superimposed high-frequency oscillations (two hours period) that were also modified by calcium external level. The shielding pigments remained in the light adaptation position and there were not any noticeable circadian oscillation in either calcium-free or calcium-rich solution. Since circadian changes were not observed in the shielding pigment position, the ERG fluctuation is not attibutable to changes of the input, i. e. the external level of calcium is not affecting the position of pigmentary effectors but is acting on the receptor level. The fact that the eyestalks in isolation exhibit changes in its ERG circadian rhythm depending of the calcium level, strongly supports the idea that calcium plays an important role on some oscillators involved in the generation of the ERG circadian rhythm, in particular those responsible of the high frequency oscillation.

151.20 A PROTEIN SYNTHESIS INHIBITOR BLOCKS THE EFFECT OF SEROTONIN AND 8-BENZYLTHIO-cAMP ON THE APLYSIA EYE CIRCADIAN RHYTHM. A. Eskin, Dept. of Biology, Univ. of Houston, Houston, TX 77004.

Serotonin (5-HT) phase shifts a circadian rhythm in the Aplysia eye. The identification of cellular mechanisms involved in phase shifting by 5-HT should help in determining the molecular components of the circadian oscillator because 5-HT must perturb some part of the oscillator to phase shift the rhythm. Our previous work established that 5-HT phase shifts by activating adenylate cyclase and increasing cAMP. We recently began experiments to determine if protein synthesis is required for phase shifting by 5-HT because inhibitors of protein synthesis phase shift the rhythm (Rothman and Strumwasser, 1976, Jacklet, 1977).

We compared phase shifts produced by various 6 hr treatments in the presence and absence of the protein synthesis inhibitor anisomycin (aniso). Aniso rapidly and reversibly inhibits protein synthesis by over 90% in the abdominal ganglion and eye and has no effect on many neurophysiological parameters (Schwartz et al, 1971, Jacklet, 1980). At phase CT06-12 aniso (10^{-6}M) by itself does not phase shift (-0.1±0.7 hr, N=5, 95% C.I) and 5-HT (10^{-5}M) produces an advance phase shift (+2.5±1.5, N=7). The phase shift normally produced by 5-HT was significantly inhibited when eyes were treated with 5-HT plus aniso (+0.6±1.4, N=5). To investigate the specificity of the inhibitory action of aniso, we determined whether other effects of 5-HT in the eye, which also may be mediated by cAMP, were blocked by aniso. 5-HT, during the second hour of treatment, inhibits by 90% spontaneous neural activity from the eye. A similar amount of inhibition (99%) was produced by 5-HT in the presence of aniso. 5-HT produces a large and long lasting increase in the photosensitivity of the eye as measured by ERGs. Aniso also did not interfere with the effect of 5-HT on the ERG. These data suggest that aniso blocks the phase shifting effect of 5-HT at some point beyond cAMP. Examining this idea, we found that the phase shift normally produced by 10^{-3}M 8-benzylthio-cAMP (+3.1±0.8, N=10) was absent when eyes were treated with 8-BT-cAMP plus aniso (+0.9±0.5, N=8). All together these results suggest that 5-HT phase shifts the rhythm by increasing cAMP which then leads to an increase in protein synthesis. Thus, a protein synthetic event appears to be a cellular mechanism involved in phase shifting by 5-HT. It is possible that this synthetic event is part of the clock machinery of the cell. 5-HT may now be used as a probe to identify the synthetic events that are important for circadian timing. Our results are particularly interesting with respect to information processing because very few effects of transmitter substances are blocked by protein synthesis inhibitors.

Supported by NSF grant BNS 7924133.

152.1 *IN VITRO* β-ADRENERGIC STIMULATION OF PINEAL MELATONIN PRODUCTION AND N-ACETYLTRANSFERASE ACTIVITY IN THE RAT. C. M. Craft and R. J. Reiter. Dept. of Anatomy, The Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284.

Norepinephrine (NE), released from post ganglionic sympathetic fibers, stimulates melatonin production and secretion by augmenting the activity of N-acetyltransferase (NAT). *In vitro* studies of the rat pineal gland stimulated with β-adrenergic agonists are well established. The usual parameter measured in these studies is NAT activity which is purported to be the rate-limiting enzyme for melatonin synthesis. The purpose of this study was to examine the responsiveness and time course of NE stimulated cultured glands by measuring melatonin content (ng/gl/h) by radioimmunoassay (RIA) and comparing it to NAT activity (pm/gl/h) in the same pineals. Male Sprague-Dawley rats were maintained in a photoperiod of daily 14:10 LD cycle (lights on at 0600 h) three weeks prior to culturing. Individual glands were cultured in BGJ_b medium for at least 24 h before NE stimulation. Initially, melatonin concentration in the medium was measured by RIA to determine the viability of the culture over a four-day period without NE. The melatonin level on day 2 (37 ng ± 3) or day 3 (39 ng ± 3.4) was significantly higher ($p<.001$) than on day 1 (22 ng ± 2) or day 4 (20 ng ± 1.8). NAT activity at the end of the 4 day period was low. In another experiment, the dose response to NE (10^{-5}M to 10^{-8}M) was analyzed after 48 h in culture. Melatonin levels (1 ng ± .1 to 6 ng ± .8) in the glands and NAT activity (2.3 pm ± 1.2 to 47 pm ± 8) were both dose dependent and significantly greater than controls when stimulated for 3 h with 10^{-5}M and 10^{-6}M. The melatonin levels in the medium (2.3 ng ± .05 to 3 ng ± .6) were not significantly different at any concentration. In the last experiment, the time course study used 10^{-6}M NE after 24 h initial incubation and the glands and media were analyzed at .5, 3.5, 6, and 24 h. Both melatonin content (glands: 2 ng ± .6 to 10 ng ± 2.8; media: 7 ng ± 3.8 to 20 ng ± 2.5) and NAT activity (48 pm ± 12 to 315 pm ± 21) at 3.5 and 6 h were significantly different than the 6 h control. The melatonin content shifted from the glands to the medium with the greatest amount in the medium after 24 h, while NAT activity was low at this time point. These data indicate a much greater melatonin content as measured by RIA in the glands and media as compared to earlier methods which measured [^{3}H]-melatonin by thin layer chromatography. The NAT activity during 24 h in culture is similar to reported values. Therefore, we suggest that the NE stimulation of pineal glands *in vitro* shows a dose response and time course response which can be quantitated in the glands and media by measuring radioimmunoassable melatonin and NAT activity. (Supported by NSF Grant No. PCM 8003441.)

152.2 ALTERATIONS IN PINEAL N-ACETYL-TRANSFERASE ACTIVITY AND MELATONIN CONTENT IN MALE SYRIAN HAMSTERS RENDERED DIABETIC WITH ALLOXAN. Thomas H. Champney, George C. Brainard and Russel J. Reiter. Dept. Anatomy, The Univ. of Texas Health Sci. Ctr., San Antonio TX 78284.

Recently, insulin was shown to be the most effective inactivator of pineal N-acetyl-transferase (NAT) activity in an *in vitro* broken cell preparation (Namboodiri, M. A. A., J. T. Favilla and D. C. Klein, 1981, Science, 213: 571). The purpose of this study was to test the *in vivo* effects of insulin on pineal melatonin content and NAT activity. Syrian hamsters, rendered diabetic by an intravenous injection of alloxan monohydrate (60 mg/kg), were maintained under long photoperiods (14:10 LD) with lights on at 0600. Two separate experiments were conducted. For the first experiment, control and diabetic animals were killed at 2000, 0200 and 0400h three days after alloxan injection. In the second study, animals were killed at 1600, 2400, 0400 and 0600h three days after injection. Pineals and trunk blood samples were collected. Blood glucose levels were determined by glucose test strips (bG Chemstrip, Bio-Dynamics). Control hamsters had blood glucose values of approximately 40 mg/dl. Hamsters with blood glucose values over 180 mg/dl were considered diabetic. Pineal NAT activity was measured by a radioenzymatic assay for the first experiment only, while pineal melatonin levels were measured by radioimmunoassay for both experiments. NAT levels were significantly ($p<0.05$) increased by alloxan diabetes at 2000h, but were unaffected at 0200 and 0400h. However, melatonin levels were higher than those in corresponding control hamsters at 1600h ($p<0.02$), but lower at 2000 ($p<0.02$), 0400 ($p<0.01$) and 0600 h ($p<0.01$). These results indicate that experimentally-induced diabetes, presumably through depressed levels of insulin or increased titers of blood glucose, can alter the melatonin content of the hamster pineal gland. The mediation of reproductive and neuroendocrine processes by the pineal is well documented (Reiter, R. J., 1981, Am. J. Anat., 162: 287-313). Therefore, the observed alterations in pineal melatonin content may have subsequently affected other endogenous rhythms. Further experiments are planned to examine the physiological consequences associated with these effects. (Supported by NSF Grant No. PCM 8003441.)

152.3 THE INFLUENCE OF LOW IRRADIANCES OF BLUE AND GREEN LIGHT ON PINEAL MELATONIN CONTENT IN THE SYRIAN HAMSTER. G. C. Brainard, B. A. Richardson*, T. S. King, and R. J. Reiter. Dept. Anat., Univ. Texas Health Science Center, San Antonio, TX 78284.

Cool white fluorescent light irradiances of 0.186 μW/cm² or above suppress nocturnal pineal melatonin content in the Syrian hamster, whereas irradiances of 0.019 μW/cm² or below do not suppress pineal melatonin (Brainard et al., Brain Res. 233, 75-81, 1982). Using red, yellow, green, blue and near-ultraviolet fluorescent light sources at irradiances of 0.928 and 0.20 μW/cm², it has been demonstrated that blue and green fluorescent light produce the greatest depression of nocturnal melatonin in the hamster (Brainard and Reiter, Endocrinology, Suppl., 1982, in press). The purpose of the following study was to determine which color of light, blue or green, is most efficient for suppressing nocturnal pineal melatonin content. Three sets of 21 adult male Syrian hamsters each were adapted to a light:dark cycle of 10:14 (lights on 0700 hours). In each set, 7 animals each were exposed to either green light, blue light or darkness during the nocturnal melatonin peak (0200-0500 hours). The irradiances used for each set were 0.186, 0.074 or 0.019 μW/cm². After twenty minutes of exposure, pineals were removed from animals and later assayed for pineal melatonin content by radioimmunoassay. Data were analyzed initially by one-way ANOVA and significance established by Newman-Keuls test. Animals exposed to 0.186 μW/cm² of either blue or green fluorescent light for twenty minutes had significantly ($P<0.001$ and $P<0.01$, respectively) suppressed pineal melatonin contents compared to those of unexposed animals. Animals exposed to 0.074 μW/cm² of blue light had significantly suppressed pineal melatonin contents ($P<0.01$) compared to those of unexposed animals. In contrast, animals exposed to 0.074 μW/cm² of green light had pineal melatonin contents which were not significantly different from those of unexposed animals. Finally, animals exposed to 0.019 μW/cm² of either blue or green light had pineal melatonin contents which were not significantly different from those of unexposed animals. At each irradiance tested, blue light caused a 20% to 25% greater depression of pineal melatonin compared to that induced by green light. These data demonstrate that the blue wavelengths of light are the most efficient wavelengths of visible light for suppressing nocturnal pineal melatonin content in Syrian hamsters. These findings indicate that photic control of the pineal gland may be at least partially chromatic. (Supported by NSF Grant No. PCM 8003441.)

152.4 EFFECTS OF PHOTOPERIOD ON N-ACETYLINDOLEALKLAMINES IN SERUM, PINEAL, RETINA, & HYPOTHALAMUS OF THE GOLDEN HAMSTER. L.J. Grota and G.M. Brown. Dept. of Psychitary, University of Rochester, Rochester, NY 14642 and Dept. of Neuroscience, McMaster University, Hamilton Ontario

Male golden hamsters were housed in light:dark (LD) cycles of 14:10, LD 2:22, or LD 22:2 for 8 weeks when they were killed at 3 hour intervals beginning 1 hour after the onset of darkness. Immunoreactive melatonin was determined in pineal, retina, and hypothalamus by immunohistochemical methods on frozen 10 μ sections. N-acetylserotonin and melatonin in serum were determined by specific radioimmunoassay. Testes were weighed at the time of sampling. Testes weights did not differ among LD 14:10 and 22:2 animals (3.34 ± 0.04 gm, N=45 and 3.32 ± 0.01 gm, N=80) but these were heavier than LD 2:22 animals (1.11 ± 0.09 gm, N=79). Within the LD 2:22, testes weights showed a 24-hour rhythm with the heavier weights at 13:00 and 16:00 hours relative to the other 6 points measured (Lights on at 0:00) but these values were below those from LD 14:10 and LD 22:2. No 24-hour or light:dark rhythm of immunoreactive melatonin was observed in hypothalamus or in retina of animals from any LD cycle. In contrast to these data, immunoreactive melatonin in sections from pineal showed a 24-hour rhythm with a crest 6-8 hours after dark onset in LD 14:10 and LD 22:2 but this rhythm was not observed in LD 2:22. N-acetylserotonin levels in serum did not display a 24-hour rhythm in LD 14:10 and LD 22:2 but there was a rhythm in serum N-acetylserotonin in LD 2:22 with a crest just after the onset of darkness ($F=3.26$, $df=7/66$, $p < .01$). Melatonin levels are being determined at this time.

In a second study, male golden hamsters housed in LD 12:12 were placed into LD 2:22 (lights on at 0:00) and killed 0, 0.5, 1, 2, 4, or 8 weeks later. Gonadal weight and serum were obtained. Testicular weights are maintained from 2.5 and 3.5 gm for 4 weeks and atrophy to 0.875 gm by 8 weeks. Serum N-acetylsertonin levels were higher at 18:00 hours (dark) than at 6:00 hours (light) when animals were housed on LD 12:12). By 4 weeks in LD 2:22, N-acetylserotonin levels were higher at 6:00 than at 18:00 hours. Melatonin levels were significantly elevated .5 (111.5 ± 21 pg/ml, N=12) and 4 (636 ± 115 pg/ml, N=15) weeks after the onset of LD 2:22 relative to animals on LD 12:12 (25 ± 22 pg/ml, N=12). These data indicate that N-acetylserotonin and melatonin levels in hamster serum are altered by short photoperiod and that these changes preceed atrophy of the testes.

152.5 SEASONAL VARIATION IN RAT PINEAL VASOTOCIN. M.M. Prechel*, T.K. Audhya* and D.H. Schlesinger* (SPON: G.L. Humphrey). Department of Biochemistry and Biophysics, Loyola University Medical Center, Maywood, IL 60153.

Arginine vasotocin (AVT) has been proposed as a principle pineal hormone, yet there is little agreement in the literature concerning endogenous levels of AVT, and physiological variations in these levels. Major inconsistencies in the amount of AVT-immunoactivity extractable from rat pineal glands in this laboratory over a period of years, led to the study of pineal AVT-activity as a function of season.

Rats (King, Oregon, WI) were housed in L:D 14:10 with water and Purina rat chow ad libitum. Groups of 24 or 40 males and females, 28-30 days old, average 80-85 grams, were sacrificed each week between 8:15-9:30 a.m. (Central Standard Time) from July 1980 through September 1981. Pineal glands were removed, pooled, homogenized in 0.1 N acetic acid with 10^{-6}M pepstatin (an acid protease inhibitor), and then heat denatured to precipitate large proteins. Supernatants were studied by AVT radioimmunoassay (Fernstrom, et al., Endocrinology 106:243, 1980).

For most of the year pineal AVT-immunoactivity ranged between 1.8 and 7.7 pg/gland; the average value from Sept. through July was 4.1 ± 0.3 pg/gland (mean ± S.E.M.: N=48). However, both years in early August pineal AVT-activity increased several hundred fold. A value of 1720 pg/gland was measured on 8/16/80, and 1170 pg/gland on 8/10/81.

Thus we conclude that the basal level of rat pineal AVT-activity is extremely low (4.1 pg/gland), but that the activity increases dramatically at a precise time each year. This seasonal fluctuation provides an explanation for the inconsistency in previously reported rat pineal AVT-activity values.

152.6 THE EFFECT OF OLFACTORY BULBECTOMY ON PINEAL INDOLES IN THE RAT. George M. Anderson*, Augustus R. Lumia*+, Bennett A. Shaywitz, J. Gerald Young and Donald J. Cohen*. Labs. Develop. Psychobiol. & Neurochem., Yale Univ. Sch. of Med., New Haven, CT 06510 & +Dept. Psychology, Skidmore College, Sartoga Springs, NY 12866.

Olfactory bulb removal results in profound changes in the sexual behavior and development of male and female rats. Neuroanatomical and neurochemical studies suggest that the effects are mediated through the hypothalamus. However, clear changes in hypothalamic neurotransmitter levels or steroid receptors have not been previously observed. The known effects of pinealectomy in causing precocious sexual development, the influence of the estrous cycle on rodent pineal indoles, and the importance of the suprachiasmatic nucleus in regulation of diurnal rhythms in the pineal have prompted us to examine the effect of bulbectomy on the pineal. Sprague Dawley rats were bulbectomized or sham-operated at 5 days of age then raised in mixed litters. At approximately 60 days of age the animals were sacrificed during the dark period (12hr light/dark cycle) and the brain and pineal removed. The brain was dissected into hypothalamus, striatum, pons, and cortex. Pineal indoles and brain neurotransmitters and metabolites were measured by HPLC with fluorometric and/or amperometric detection. A significant (p=.05) lowering of pineal melatonin (MEL) was seen in the bulbectomized animals (MEL 1.43 ± .25, N=22, 14M/8F) compared to the sham animals (MEL 1.96 ± .26, N=30, 16M/14F). No sex differences were seen in the MEL levels of bulbectomized animals (means 1.41 and 1.45) and no significant sex difference was seen in the sham animals (male 2.16 ± .28, female 1.74 ± .24). A complimentary change was seen in the serotonin (5-HT) levels of bulbectomized animals: a significant (p=.04) increase being observed in pineal 5-HT of bulbectomized animals (5-HT 116 ± 12, N=17) compared to sham animals (5-HT 87.0 ± 12, N=25). We will present results of the analyses of additional pineal indoles (tryptophan, 5-hydroxytryptophol, and 5-hydroxyindoleacetic acid 5-HIAA), and brain neurotransmitters (norepinephrine, dopamine, and 5-HT) and metabolites (homovanillic acid) and 5-HIAA). The changes seen and the implications of a demonstrated neurochemical connection between the olfactory bulb and the pineal will be discussed.

152.7 PINEAL-INDUCED ALTERATIONS IN PROLACTIN SYNTHESIS AND SECRETION IN BLINDED FEMALE HAMSTERS, K.M. Orstead* and B. Benson. Department of Anatomy, University of Arizona, Tucson, AZ 85724.

Hamsters subjected to optic enucleation or short photoperiods show marked depressions in pituitary and blood prolactin (PRL) levels. These effects are either reversed or prevented by removal of the pineal gland. This study was designed to determine whether pinealectomy would prevent the reduced in vitro synthesis and release of PRL by pituitaries from blinded female hamsters.

Adult, female golden hamsters were either blinded, blinded and pinealectomized (blind/pinx) or blinded and sham-pinealectomized (blind/sham). Controls were either left intact, pinealectomized (pinx) or sham-pinealectomized (sham). After surgeries, all animals were maintained in a long (L:D=14:10) photoperiod for 12 weeks. Upon sacrifice, homologous pairs of hemipituitaries were incubated for two hr at 37°C in 1.0 ml of oxygenated Kreb's Ringer bicarbonate buffer containing 100 mg% glucose plus 20 μCi ^{3}H-leucine. Serum, pituitary and media PRL-like immunoreactivities (PRLa) were estimated with the use of NIH anti-sera to rat PRL, rPRL-I-5 for iodination and either a standard hamster serum or pituitary pool. Presumptive, newly-synthesized ^{3}H-PRL in pituitary and media samples was separated by polyacrylamide disc gel electrophoresis and the incorporation of radiolabelled precursor quantified by liquid scintillation spectrophotometry.

Serum levels of PRLa in blind and blind/sham groups were significantly depressed when compared to controls. Pinealectomy of blinded hamsters completely prevented the depressions in serum PRLa levels. Both the content and concentration of PRLa in pituitaries of blind and blind/sham groups were significantly reduced when compared to controls. Also, pinealectomy totally prevented the reductions in pituitary PRLa levels of blinded animals. In addition, both the PRLa content and concentration in incubation media from blind and blind/sham groups were significantly reduced when compared to controls. Pinealectomy of blinded hamsters prevented these depressions, completely restoring the ability of their pituitaries to release PRLa into the incubation media. Furthermore, the total amounts of ^{3}H-PRL synthesized by glands from blind and blind/sham groups were significantly less than those of controls. However, pinealectomy of blinded animals only partially prevented the reductions in ^{3}H-PRL synthesis in vitro.

From these results, we conclude that pituitaries from blinded female hamsters show a significantly diminished ability to synthesize and release PRL in vitro. This phenomenon appears to be pineal-dependent, since pinealectomy completely prevents decreased release, and partially prevents depressed synthesis of PRL in vitro. Supported by NIH grant HD-08795.

152.8 5-METHOXYTRYPTAMINE: EFFECTS ON THE NEUROENDOCRINE-REPRODUCTIVE AXIS OF THE FEMALE SYRIAN HAMSTER. B. A. Richardson*, M. K. Vaughan, T. S. King, L. J. Petterborg*, and R. J. Reiter. Dept. of Anatomy, The Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

In the Syrian hamster, the pineal transduces ambient photic information into a chemical signal that determines the level of reproductive activity. Although the hormone(s) involved in this response remain an enigma, the pineal methoxyindole, melatonin (Mel), is the leading candidate. However, recent data on male hamsters (Pévet et al., 1981, J. Neural Transm. 51: 303) suggest that another pineal 5-methoxyindole, 5-methoxytryptamine (5-MT), may play an important role in pineal-mediated gonadal collapse in the Syrian hamster. Therefore, to determine the influence of 5-MT on the reproductive physiology of female Syrian hamsters, adult animals were maintained in a 14:10 (lights on at 0600h) light:dark cycle and divided into the following groups: 1) injected daily (1700h) with vehicle and received weekly implants of 25 mg beeswax pellets; 2) injected daily (1700h) with 25 μg Mel; 3) injected daily with Mel and received weekly implants of Mel pellets (1mg Mel in 24 mg beeswax); 4) injected daily with Mel and received weekly implants of 5-MT (1 mg 5-MT in 24 mg beeswax); 5) injected daily (1700h) with 50 μg 5-MT; 6) injected daily with 5-MT and received weekly implants of Mel; and 7) injected daily with 5-MT and received weekly implants of 5-MT. All female hamsters receiving 25 μg Mel injections for 9 weeks became acyclic. These animals also demonstrated a significant ($p<0.001$) decrease in uterine weight. Mel injections also resulted in a marked suppression of both pituitary ($p<0.001$) and plasma ($p<0.001$) prolactin (PRL) whereas the gonadotrophins (LH and FSH) were unaffected. The influence of afternoon injections of Mel on estrous cyclicity and uterine weight, but not pituitary and plasma PRL, were negated by either Mel or 5-MT implants. Nine weeks of daily 5-MT injections resulted in 78% of these animals being acyclic and significant decreases in uterine ($p<0.001$) weight and pituitary ($p<0.001$) and plasma ($p<0.001$) PRL. Like Mel injections, the effects on cyclicity and uterine weight were completely blocked by either Mel or 5-MT implants. These results suggest that 5-MT, like Mel, can have an inhibitory influence upon the reproductive physiology of female Syrian hamsters. The ability of both Mel and 5-MT pellets to prevent the actions of either indole when injected implies that the site(s) of action is the same for Mel and 5-MT. However, since the inhibitory influence of 5-MT in the present paradigm was less than Mel at twice the dose, it is felt that 5-MT is a less physiologically active compound than Mel. (Supported by NIH Postdoctoral Fellowship 1 F32ND 05900 to BAR, HD 07139 to TSK and NSF Grant No. PCM 8003441 to RJR.)

152.9 COUNTER-ANTIGONADOTROPIC EFFECT OF MELATONIN ADMINISTERED VIA THE DRINKING WATER. Finley P. Gibbs* and Jerry Vriend* (SPON: David E. Scott) Departments of Anatomy University of Missouri, Columbia, MO 65212, and University of Manitoba, Winnipeg, Manitoba, Canada R3E OW3

Our hypothesis was that since hamsters drink 80-90% of their water at night and since plasma melatonin levels are high at night that we could augment the natural fluctuation of plasma melatonin by putting it in the drinking water. Further, since injections of melatonin are most effective in producing gonadal atrophy when given late in the photoperiod, melatonin given via the drinking water could be equally effective. Preliminary experiments using RIA indicated that doses in the range of 2 to 5 ug/ml in the drinking water would produce a circadian rhythm of plasma melatonin approximately in the physiologic range (10 to 100 pg/ml). Melatonin was dissolved in ethanol and then further diluted in tap water to concentrations ranging from 0.059 ug/ml to 320 ug/ml. The solutions were prepared twice a week, and the drinking bottles were covered with aluminum foil to protect the melatonin from damage by light.

Two protocols were used, one to demonstrate the antigonadotropic effect of melatonin and the other to elicit the counter-antigonadotropic effect. In the antigonadotropic protocol 100 g intact male hamsters were housed in a 14:10 LD cycle four or five per cage for ten weeks. Contrary to our hypothesis there was no effect of melatonin in the drinking water on testis weight (dose range: 0.059-50 ug/ml). The counter-antigonadotropic protocol involved the use of 100 g male hamsters which were blinded and housed under similar conditions. They received melatonin in concentrations ranging from 1.8-320 ug/ml. At ten weeks the blinded hamsters receiving no melatonin had the expected drop in testis weight to 0.56 g. In the range of 2.4 to 10 ug/ml there was a highly variable response, but generally higher doses resulted in higher testis weights. In the range of 20-320 ug/ml the blind hamsters had mostly normal appearing large testes (mean = 3.2 g).

In conclusion: 1) We produced the well known counter-antigonadotropic effect of melatonin by administering it via the drinking water. 2) We could not produce the anti-gonadotropic effect. (Supported in part by funds from the University of Missouri's Biomedical Research Support Award and the Manitoba Health Research Council).

152.10 CORTICOSTERONE AND N-ACETYLSEROTONIN (NAS) RESPONSES TO STRESS: EFFECT OF HOUSING CONDITIONS AND TYPE OF ENVIRONMENTAL STIMULATION. Jo Seggie, G.M. Brown, L.Campbell* and L. Grota, Departments of Neurosciences & Psychiatry, McMaster University, Hamilton, Ontario, L8N 3Z5.

Preliminary observations in our lab suggested that NAS may be stress responsive. NAS is a hormone secreted by the pineal gland whose synthesis in the pineal is regulated by a B-adrenergic sympathetic input which originates in the superior cervical ganglion. Since stress elevates circulating norepinephrine and epinephrine and the pineal lacks a blood brain barrier we investigated the possibility that NAS is responsive to various types of environmental stimuli under different housing conditions. Separate groups of animals were either sacrificed in the undisturbed state or exposed for three minutes to a variety of stimuli (novel environment, cold water, noise and ether vapour) and then decapitated for collection of blood at 0, 5, 15, 30 or 60 minutes after the end of stimulation. Corticosterone was measured in the same samples as an indication that animals responded to these stimuli. These experiments were conducted at the beginning of the light phase of a 12 hr. light/dark cycle. All subjects had ad lib food and water but half of each group were housed singly, half were housed in groups of four. Corticosterone levels, measured by competitive protein binding evidenced an increase to all stimuli. Cold water elicited the largest response while the other stimuli had equivalent responses. Housing condition did not effect the response. NAS levels measured by specific radioimmunoassay were found to interact with time and type of stimulation. Housing conditions had no effect on NAS levels. Cold water, novel environment and noise did not affect NAS levels. In contrast to these data three minutes of ether exposure resulted in an immediate drop in plasma NAS levels.

These data indicate that NAS does not rise in response to stimuli which produce a corticosterone rise and presumably a catecholamine rise. In fact ether produced a rapid drop.

153.1 CHRONIC SYMPATHETIC DENERVATION ALTERS PHOSPHATIDYLINOSITOL RESPONSE IN THE PAROTID GLAND, M. R. Hanley *, M. D. Dibner and C. P. Downes* (SPON: S. H. H. Chan). *MRC Neurochemical Pharmacology Unit, Cambridge University, Cambridge CB2 2QH England.

The parotid gland of the rat responds to agents such as substance P, carbachol and phenylephrine with a phosphatidylinositol (PI) response. This can be measured by ^{3}H-inositol incorporation, ^{32}P incorporation into PI, or polyphosphoinositide formation. Adult Sprague-Dawley rats underwent unilateral superior cervical ganglionectomy or sham operation to determine whether adrenergic denervation affected the PI response. After 10-14 days, the incorporation of ^{3}H-inositol into PI following substance P, carbachol or phenylephrine stimulation was greatly reduced in the operated side as compared with that seen in innervated contralateral parotids or in tissue from sham-operated control rats. Further studies indicated that sympathetic denervation led to a decrease incorporation of ^{32}P into PI. In contrast, phosphatidic acid synthesis and inositol-1-phosphate formation were normal. Moreover, it appears that the rapid decrease in triphosphatidylinositol stimulated by substance P may be attenuated in denervated salivary glands. Thus, sympathetic denervation of the rat parotid apparently inhibits PI resynthesis. Further studies should elucidate the exact causes and nature of these effects. (M. D. Dibner is a visiting scientist from E. I. du Pont Glenolden Laboratory).

153.2 SMALL INTENSELY FLUORESCENT (SIF) CELLS IN THE STELLATE GANGLION OF THE RAT AND GUINEA-PIG. V. A. Woodmansee, L. J. Lehman*, and D. G. Emery. Dept. of Zoology, Iowa State University, Ames, IA 50011.

Characteristics of a small intensely fluorescent (SIF) cell population in the stellate ganglion were examined in rats and guinea-pigs using the formaldehyde-induced fluorescence technique for monoamines of Loren et al. (Histochem. 52:223, 1977). Species differences can be observed in characteristics of the SIF cell populations.

Rats contained a larger population of SIF cells per ganglion (267) than did guinea-pigs (118). A larger number of SIF cells per milligram tissue was observed for rats (267/mg) vs. guinea-pigs (32/mg). Little difference was observed between the SIF cell populations in left vs right ganglion for either species.

SIF cells were categorized as Type I or Type II using the morphological characteristics described by Chiba and Williams (Cell Tiss. Res. 162:331, 1975). Table 1 shows these results. In rats, Type I cells had processes, and were sometimes mixed in clusters with Type II cells. Type II cells had no processes and were found in clusters with other SIF cells. Guinea pig SIF cell types were also mixed within clusters which were smaller than those found in rats.

Rat SIF cells were of larger diameter larger (10.4 μm) than guinea-pig cells (8.8 μm). Type I and Type II SIF cells did not differ in diameter in either species.

The data presented above for rats corresponds well with similar data obtained by others for the SIF cell population in the superior cervical ganglion of rats. Guinea pig data shows some deviation to other studies, particularly in the percentages of SIF cell types seen.

Currently, immunohistochemical studies are being carried out to determine the putative neurotransmitters in each of these SIF cell populations:

Table 1. SIF CELL TYPES IN THE STELLATE GANGLION

	Number (%) Type I Cells		Number (%) Type II Cells	
Ganglion	Rat	Guinea Pig	Rat	Guinea Pig
1L	21(10%)	44(37%)	188(90%)	75(63%)
2R	57(16%)	19(16%)	304(84%)	99(84%)
3L	16(5%)		295(95%)	
4L	7(7%)		88(93%)	
5R	21(12%)		156(88%)	
6L	66(13%)		429(87%)	
7R	28(13%)		194(87%)	
X	(11%)	(26%)	(89%)	(74%)

153.3 CATEGORIES OF AXONS IN THE FELINE ANSAE SUBCALVIAE. D.G. Emery. Dept. of Zoology, Iowa State University, Ames, Iowa 50011.

In most cats three major sympathetic nerves arise from the stellate ganglion. The anterior and posterior ansae subclaviae pass around the subclavian artery and join near the middle cervical ganglion, and one or more nerves arise from the caudal margin of the stellate ganglion and innervate the heart and other thoracic viscera. Previous studies have shown that the major of these nerves, the inferior cardiac nerve, contains mostly unmyelinated postganglionic and myelinated sensory axons. One objective of this study was to determine if either of the ansae subclaviae contain populations of unmyelinated sensory axons, which are known to exist and to function as pain pathways to the heart.

Sections of the ansae were examined by electron microscopy to determine the number of axons. Dorsal root ganglionectomies and ventral rhizotomies caused selected populations of axons to degenerate. By counting the number of surviving axons the composition of the functional categories of axons was deduced.

The results (Table I) show that the posterior ansa is very similar to the inferior cardiac nerve, consisting of 80% unmyelinated, mostly postganglionic axons and myelinated sensory and postganglionic axons. The anterior ansa also contains many unmyelinated axons (60%), the greatest part of which (60%) are postganglionic. The remainder includes many unmyelinated sensory axons (26%). The myelinated fibers are roughly evenly divided amongst preganglionic, postganglionic and sensory categories. It was also shown that most of the largest myelinated axons in both ansae degenerate after dorsal root ganglionectomy and are thus sensory. Autoradiography of sections of the anse and inferior cardiac nerve after injection of ^{3}H-leucine into dorsal root ganglia revealed labelled myelinated and a few labelled unmyelinated axons. Thus it seems that all the nerves from the stellate ganglion contain some unmyelinated sensory axons, but only the anterior ansa has a large number.

Table I. Average Numbers of Axons in the Ansae Subclaviae

	Anterior Ansa		Posterior Ansa	
Condition	#Myelinated	#Unmyelinated	#Myelinated	#Unmyelinated
1. Normal	3808	5505	2126	8258
2. Pre & post gangl.	2529	5241	858	11267
3. Postgangl.	1109(29%)	3285(60%)	808(38%)	6753(82%)
4. Sensory (#1-#2)	1279(34%)	1413(26%)	1268(60%)	0
5. Pregangl. #1-(3+4)	1420(37%)	807(15%)	50(2%)	1505(18%)

153.4 SEROTONERGIC NEURONS OF THE SMALL INTESTINE: DISTRIBUTION AND INTERACTIONS WITH OTHER NEURONS. S.M. Erde, M.D. Gershon, D.L. Sherman*. Dept. Anatomy and Cell Biol., Columbia Univ. P&S, New York, NY 10032.

Serotonergic neurons have recently been shown to be present in the enteric nervous system (ENS). We have studied the distribution of these neurons in the guinea pig small intestine. In addition, interactions between serotonergic, noradrenergic and other neurites in the myenteric plexus were analyzed. Serotonergic neurons and neurites were demonstrated by light and electron microscopic radioautography following incubation with ^{3}H-serotonin (^{3}H-5-HT; 0.5uM) in the presence of desmethylimipramine (10 nM) or 5-hydroxydopamine (1.0mM; 5-OHDA) to prevent uptake of ^{3}H-5-HT by noradrenergic axons. When $NaMnO_4$ (3%) was used for postfixation instead of OsO_4, simultaneous recognition of serotonergic (radioautographically labeled) and noradrenergic elements (50nm dense cored vesicles loaded with 5-OHDA) was possible. The density of innervation was estimated quantitatively by measuring uptake of ^{3}H-5-HT or ^{3}H-norepinephrine (^{3}H-NE) as a function of distance down the bowel. Serotonergic neurons were found to comprise about 3% of the neurons of the myenteric plexus. Essentially all serotonergic perikarya are situated at the periphery of a ganglion and expose a surface to the surrounding basal lamina. Bundles of serotonergic axons run in interganglionic connectives and ramify around neurons in innervated ganglia. Some ganglia receive a dense serotonergic innervation, some receive almost no serotonergic innervation, and some have densely innervated and non-innervated portions. There is thus a pronounced non-equivalence of ganglia. While the density of the serotonergic innervation seemed to vary widely between adjacent segments of small intestine, no change was detected in density as a function of distance from pyloric to ileocolic sphincters. In contrast, the noradrenergic innervation showed a proximo-distal decline in density. Axo-axonic interactions between serotonergic and other elements including noradrenergic and putative cholinergic axons occur and apparent noradrenergic synapses on serotonergic perikarya were also found. Serotonergic synapses are most frequently axo-somatic but axo-dendritic contacts occur as well. These observations indicate that the ENS is more complex than previously imagined. Individual myenteric ganglia differ from one another and enteric neurons interact with one another in a variety of ways. The significance of the innervation of serotonergic neurons by noradrenergic terminals remains to be established. Supported by NIH grant NS12969.

153.5 POTASSIUM DICHROMATE LOCALIZATION OF CHROMAFFIN ORGANS ASSOCIATED WITH THE INFERIOR MESENTERIC GANGLION (IMG). J.A. Mascorro* (SPON: F.E. Dudek). Department of Anatomy, Tulane University School of Medicine, New Orleans, LA 70112.

Paraganglia (PG) represent small groups of adrenal medullary-like cells that appose most sympathetic ganglia and which show a chromaffin reaction for catecholamines. They are regarded as secretory because of similarities with the endocrine adrenal medulla in terms of morphology and catecholamine release following stimuli. Similar chromaffin cells (SIF cells) also occur within sympathetic ganglia and reportedly can inhibit or excite neurons by releasing catecholamines onto the nerve cell. Thus, it seems necessary to reexamine the apposition of chromaffin organs with sympathetic ganglia, and to search for vascular connections that could carry paraganglion catecholamines into the ganglion. The present work addresses this issue by locating PG in association with the IMG as well as by studying their morphology and topographical relation with the IMG.

Six adult cats were anesthetized and perfused with glutaraldehyde in phosphate buffer. The retroperitoneal tissue blocks were then treated with a potassium dichromate/glutaraldehyde combination (Mascorro, J.A., Tissue and Cell, 9:447, 1977) which produced a gross chromaffin reaction in organs apposed to the IMG and presumed to be true PG. The position and number of these "paraganglia" was noted and photographed macroscopically. IMG showing dichromated organs were processed for electron microscopy for ultimate verification and detailed study.

The IMG was located around the base of the inferior mesenteric artery (IMA) where the artery originated from the abdominal aorta. The ganglion proper appeared flattened, irregularly shaped or in strips on either side of the IMA. All ganglia possessed at least one associated paraganglion, and usually more; one IMG displayed five discrete chromaffin bodies, the largest being 1 mm in length. Histological study showed a connective tissue plane between the chromaffin bodies and IMG and, furthermore, that chromaffin cell groups were prominent within the ganglion. The ultrastructural features of paraganglion and intraganglion chromaffin cells were identical and included many blood vessels and catecholamine granules. Vascular routes between the two organs were not noted but should not be excluded based upon present samples. It is of paramount importance now to pursue the hypothesis that chromaffin cells lying next to the IMG, or residing within the ganglion, can release catecholamines into the ganglion environment.
(Appreciation is extended to Dr. J.T. Weber and NIH Grant EY03731 for support.)

153.6 A COMPARATIVE STUDY OF INTRINSIC PROPERTIES OF CAT SOLAR PLEXUS NEURONS. D.L. Decktor, P.R. Rogenes and W.A. Weems, Dept. Physiol. & Cell Biol., Univ. Texas Med. Sch. at Houston, Houston, Tx. 77025

Neurons located within sympathetic ganglia of the solar plexus can be classified according to 1) location, 2) rhythmic firing behavior, and in many instances, 3) efferent fiber pathway. In previous studies, we have described certain intrinsic properties of neurons located within left celiac ganglia (LCG), left renal ganglia (LRG) and superior mesenteric ganglia (SMG). Within each of these ganglia efferent neurons having axons in specific nerve trunks were identified. Yet, no systematic comparison of intrinsic properties between solar plexus neurons classified as described above has been performed. The purpose of this study was to provide such a comparison to determine if these neurons are relatively homogeneous with respect to their intrinsic properties or whether the total cell population is comprised of a number of distinct subgroups whose intrinsic properties differ. Solar plexus ganglia (LCG, LRG and SMG) were studied in vitro. Stimulating electrodes were placed on nerves of the celiac and mesenteric plexus and the left renal nerves. Transmembrane potentials were monitored by intrasomatic electrodes. Input resistance and time constant were measured for each neuron. From these values total input capacitance was calculated. The amplitude and duration of the afterspike hyperpolarization (ASH) were measured and the rhythmic firing mode of the neuron assessed. Efferent neurons were identified by antidromic activation. Significant differences in intrinsic neuronal properties were observed between neurons of the LRG and SMG ganglia. LRG neurons exhibited higher input resistances (mean value, 27.9 MΩ) and lower input capacitances (mean value, 645 pF) than SMG neurons (18.3 MΩ and 1045 pF respectively). Mean values of input resistance and input capacitance for LCG neurons were 24 MΩ and 790 pF respectively. All neurons tested fired in a rhythmic firing mode. Seventy-one percent were phasic and 29% were tonic. Tonic neurons exhibited higher input resistances (mean value, 28 MΩ) and lower input capacitances (mean value, 631 pF) than phasic neurons. If it is assumed that specific membrane capacitance is constant, then differences in input capacitance between ganglia and between phasic and tonic neurons would reflect differences in neuronal geometry. The distribution of ASH durations obtained from SMG neurons was shifted to the right of distributions observed in the LCG or LRG. No significant differences were noted when intrinsic properties of subpopulations of efferent neurons within a particular ganglion were compared. It was concluded from these studies that neuronal geometry and the distribution of ASH durations vary significantly within and among ganglia of the solar plexus. Therefore solar plexus neurons cannot be represented as a a single population with similar intrinsic properties. (Supported by N.I.H. grant HL21351)

153.7 ENKEPHALINERGIC INHIBITION IN PARASYMPATHETIC GANGLIA OF THE CAT URINARY BLADDER. W.C. deGroat and M. Kawatani*(SPON: A.M. Booth). Dept. Pharmacology, Univ. Pittsburgh, Pittsburgh, PA 15261

Previous experiments have shown that dense networks of leucine enkephalin terminals surround the ganglion cells in the urinary bladder of the cat. These terminals which arise from preganglionic neurons in the sacral spinal cord are eliminated after transection of the sacral ventral roots or the pelvic nerve. The administration of exogenous leucine enkephalin inhibits transmission in bladder ganglia by a presynaptic mechanism which is in turn blocked by naloxone.

The present study was undertaken to determine whether endogenously released enkephalins might also modulate transmission in vesical ganglia. In previous experiments we have shown the repetitive stimulation (20-30 Hz,2-5 sec) of preganglionic axons in one branch of the pelvic nerve to the bladder produced a prolonged inhibition (20-40 sec) of the postganglionic discharge elicited by stimulation of preganglionic axons in another branch of the pelvic nerve. The possibility that this heterosynaptic inhibition was modulated by endogenous enkephalins was examined by determining its sensitivity to the opiate antagonist, naloxone.

Experiments were conducted in situ on cats anesthetized with chloralose. Heterosynaptic inhibition elicited by 2-5 sec trains of stimuli at 10-40 Hz ranged from 50-80% depression of the evoked response and persisted for 20-60 sec after the termination of the stimulus. Intravenous (20-50 µg/kg) or intraarterial (5-10 µg/kg) administration of naloxone reduced the duration and magnitude of the heterosynaptic inhibition in 8 of 9 experiments. On the average the duration of inhibition was decreased by 50% and the magnitude of inhibition by 30%. The effects of naloxone persisted for 1-2 hours. Naloxone did not alter the amplitude of the postganglionic potentials elicited by single shocks to a preganglionic nerve or the facilitation of transmission elicited by trains of stimuli at frequencies of 1-3 Hz. Naloxone did not reduce the homosynaptic depression of transmission following a single postganglionic discharge using the double shock technique. Heterosynaptic inhibition was not altered by other receptor blocking agents including adrenergic (dihydroergotamine), muscarinic (atropine), purinergic (theophylline) or GABAergic (picrotoxin).

In summary, the presence of L-Enk in preganglionic nerve terminals in bladder ganglia, coupled with the finding that naloxone, an opiate antagonist, reduces the ganglionic depressant actions of exogenous L-Enk as well as heterosynaptic inhibition suggests that L-Enk may be an inhibitory cotransmitter in the sacral parasympathetic outflow to the urinary bladder.

153.8 REFLEX ACTIVITIES IN PARASYMPATHETIC FIBERS INNERVATING THE PAROTID AND SUBMANDIBULAR GLANDS IN RABBITS. R. Matsuo* (SPON: K. Kusano). Dept. of Oral Physiology, Dental School, Osaka Univ., Osaka JAPAN

In order to evaluate the neural control mechanisms subserving reflex salivary secretion, the volume of secretion from parotid and submandibular glands was measured, and associated electrical activity in parasympathetic fibers serving these glands was recorded, in adult rabbits.

Electrical stimulations were applied to lingual and/or glossopharyngeal nerves in sympathetically decentralized animals. A more copious submandibular salivary secretion was induced by lingual nerve stimulation at 10 to 20 Hz than in the case of glossopharyngeal nerve stimulation. On the contrary, parotid secretion was strongly induced by glossopharyngeal nerve stimulation at 10 to 20 Hz.

Through functional single fiber analysis, about 50 % of the parasympathetic preganglionic fibers innervating the submandibular galnd responded to lingual nerve stimulation; about 40 % and 10 % of fibers responded to electrical stimulation of the infraorbital nerve and the glossopharyngeal nerve, respectively. As a result of repetitive electrical stimulation applied to the respective sensory nerve, parasympathetic submandibular fibers could be classified into three types according to the mode of reflex discharges. The fibers which increased their spontaneous discharges at 10 to 20 Hz stimulating rate were termed E-type fibers, while those which unchanged them were N-type fibers and those which decreased them were I-type fibers.

About 70 % of the postganglionic parasympathetic fibers innervating the parotid gland responded to stimulation of the glossopharyngeal nerve. The rest responded to stimulation of lingual and/or infraorbital nerves. Three modes of discharges (E-, N-, I-type) were also recorded in postganglionic fibers innervating the parotid gland. It was often observed that the effect of glossopharyngeal nerve stimulation was sustained for prolonged period after stimulation.

These results suggest that the afferent information via the lingual nerve plays an important role in reflex submandibular gland secretion, while information via the glossopharyngeal nerve plays an important part in reflex parotid gland secretion. The functional significance of three types of reflex discharges in parasympathetic fibers will be discussed.

153.9 IDENTIFICATION OF NEURONS IN THE SUPERIOR CERVICAL GANGLION INNERVATING THE CORNEA OF THE CAT. C. Frioni, C. Morgan, I. Nadelhaft, W.C. de Groat, P.J. Jannetta. Dept. Neur. Surg. & Pharm., Univ. Pitt. Sch. Med. & V.A. Hosp., Pittsburgh, PA

The cornea receives both sensory and autonomic innervation. In previous studies in the cat we have used HRP to trace sensory axons to the ophthalmic division of the trigeminal ganglion. The present experiments were designed to explore the autonomic innervation of the cornea. Catecholamines (CA) have been identified in the cornea of a variety of species. While the superior cervical ganglion (SCG) has been thought to be the primary source of this sympathetic input, direct evidence for this is lacking. We have therefore employed the following nerve tracing techniques to determine if neurons innervating the cornea were located in the SCG. In five cats HRP was injected into the substantia propria of the cornea. As a control for the possible spread of HRP and uptake by tissue surrounding the eye a similar amount of HRP was placed on the opposite, undamaged cornea. To identify possible neurotransmitters in SCG neurons in two cats, True Blue was injected into the substantia propria and sections of the SCG were processed for various peptides using FITC.

In the HRP experiments many cells were labeled on the experimental side (28-159; x = 64) and were located largely in the rostral half of the SCG. A few cells were lightly labeled on the control side, showing that some HRP can also be taken up either by the undamaged cornea or surrounding tissue. However, in view of the much larger number of cells on the experimental side it is reasonable to assume this HRP was taken up primarily by corneal axons. Cells were lightly labeled in the True Blue injected animals. Alternate sections of SCG were processed for leucine-enkephalin (LENK), methionine-enkephalin, substance P and vasoactive intestinal polypeptide (VIP). Only LENK and VIP were identified in these ganglia, but were not contained within True Blue labeled cells. LENK was seen in axon terminals presumably following dendrites and perikarya of ganglionic neurons. VIP was identified in cell bodies dispersed evenly over the ganglion.

We conclude the cornea in the cat does indeed receive an autonomic innervation from the SCG and that these axons are probably the source of CA terminals reported by others. Although the function of these axons in the cornea is unknown, it has been proposed that in other sensory systems, the sympathetic system modulates the sensitivity of receptors. A similar function may apply here. Since peptides were not observed in True Blue labelled neurons one might presume they are not transmitters here. However, caution must be used here as it is possible our methods were not sensitive to low levels of peptides. VIP has not been identified before in the SCG. While its function is unknown, it is possible that VIP is a cotransmitter in cholinergic neurons in the SCG.

153.10 SYMPATHETIC OUTFLOW IN THE PELVIC AND PUDENDAL NERVES. R.P.Kuo*, D.C.Kuo, W.C.deGroat, T.Hisamitsu*, K.B.Thor, and M.G.Backes*, (Spon: J.W.Yip)., Dept. of Pharmacol., Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

According to the traditional view, the sympathetic outflow to the pelvic viscera is contained in the hypogastric and lumbar colonic nerves, whereas the parasympathetic outflow is present in the pelvic nerve (PELN). However, in the course of a horseradish peroxidase (HRP) tracing study of the efferent component of PELN, we discovered that this nerve contained a large population of sympathetic postganglionic axons from the sympathetic chain ganglia. This report describes the distribution of sympathetic chain ganglion cells projecting to PELN and contrasts this population of cells with those which send axons into the pudendal nerve (PUDN), a nerve which also serves an important role in the regulation of pelvic visceral function.

In these studies neurons in the sympathetic chain ganglia of cats were labeled either with fluorescent dye (true blue) or with HRP applied to the central cut ends of PELN or PUDN. After appropriate time for transport the animals were perfused with fixative and the chain ganglia were removed and processed for tracer. A considerable variation was noted between animals in the anatomy of the chain ganglia at the sacral and caudal lumbar levels. Although it is generally accepted that in the cat there are seven lumbar and three sacral ganglia on either side we observed several instances where ganglia were either absent or adjacent ganglia were fused. The anatomy was more variable at the sacral level where fusion of the left and right chain ganglia was occasionally seen. A total of 3485-3850 paravertebral neurons (uncorrected for double counting) in the ipsilateral and contralateral L6-S3 sympathetic chain ganglia projected to PELN. The majority (82%) of labeled cells were concentrated in the ipsilateral S1 and S2 ganglia. Paravertebral contribution to PUDN could be discerned in L5-S2 ganglia, with the highest concentrations in L7 and S1. Of the total 5086-5624 cells counted, 5018-5349 were located ipsilaterally.

In conclusion, the present results demonstrate that PELN, which is generally thought to carry primarily parasympathetic efferent axons, has a considerable population of sympathetic postganglionic fibers from the sacral chain ganglia. The number of sympathetic neurons projecting to PELN was about 60% of that to PUDN, a somatic nerve which would be expected to contain a large sympathetic constitutent. It remains to be determined whether the postganglionic sympathetic component in PELN has different functional properties compared to those in the hypogastric and lumbar colonic nerves. Supported by NSF Grant PCM F906093 and NIH Grant 1-F32-NS07006.

153.11 INTRACELLULAR RECORDINGS IN THE INFERIOR MESENTERIC GANGLION OF THE RAT. D.L. Kreulen. Department of Pharmacology, College of Medicine, University of Arizona, Tucson, AZ 85724.

The inferior mesenteric ganglion, a prevertebral sympathetic ganglion, is located in the mesentery adjacent to the inferior mesenteric artery which supplies the colon. The ganglion consists of two lobes of unequal and variable size joined by commisural-like fibers. The ganglia are innervated by a preganglionic nerve trunk, the intermesenteric nerve (IMN) which is joined along its course by lumbar splanchnic nerves. Two groups of post-ganglionic fibers project from the ganglia, the right and left hypogastric nerves (HGN) and the lumbar colonic nerves (LCN). Ganglia, with surrounding mesentery and blood vessels were removed from rats and pinned in an organ bath which was constantly superfused at 37°C. Nerve trunks were stimulated with bipolar platinum electrodes (pulse duration: 0.2-0.5 msec). The mean resting membrane potential was -55 mV ± S.E. 2.1 mV (n=29) and the mean rheobasic current was 0.18 nA ± S.E. 0.02 nA (n=15). The mean input resistance was 65 MΩ ± S.E. 14 MΩ (n=11).

Ninety-nine per cent of neurons tested received synaptic input via all of the nerve fibers. This input consisted of excitatory post-synaptic potentials (e.p.s.p.) and action potentials. The synaptic responses were often dispersed over a time period of 70-100 msec and some cells fired more than one action potential in response to a single shock. The average conduction velocities of the fastest conducting fibers were: IMN 1.3 M/sec ± S.E. 0.2 M/sec (n=26); HGN: 0.4 M/sec ± S.E. 0.03 M/sec (n=39); LCN: 0.3 M/sec ± S.E. 0.03 (n=7). When the colon was attached to the ganglion, continuous synaptic input was recorded in some of the ganglion cells. If the colon was distended by injecting Krebs solution into the lumen, the frequency and amplitude of e.p.s.p.'s increased. Cutting the LCN eliminated this synaptic input from the colon. Support USPHS NIH NS 14304 and HL 27781.

153.12 THE EFFECT OF VARIOUS ANESTHETIC AGENTS ON THE HISTOCHEMISTRY OF AUTONOMIC NERVES IN THE URINARY BLADDER. J.A. McConnell and G.S. Benson*. Dept. of Neurobiology and Anatomy and Div. of Urology, Univ. of Texas Med. Sch., Houston, TX 77125.

Previous studies of biopsied human urogenital tissue have indicated that anesthetics or other agents used during surgery cause depletion of norepinephrine (NE) in peripheral nerves. This hypothesis was tested with further analysis of human tissue and by examining nerve fibers in bladders of dogs treated with various anesthetic and/or preanesthetic agents, and these data compared with that from control animals.

Experimental tissue included 1) surgical biosies from patients undergoing cystectomy or ureteral reimplantation and 2) bladders from adult mongrel dogs anesthetized with one or more agents used routinely during human surgery, specifically sodium pentothal, atropine sulphate, scopolamine, ketamine, fluothane and ethrane. Control tissue came from unanesthetized human organ donors and from dogs anesthetized with sodium pentobarbital. (In previous work on rats, this anesthetic had no apparent effect on peripheral nerve NE.) Tissue samples were taken from each of the three regions of the bladder. Part of each sample was frozen and processed for NE-containing fibers with a glyoxylic acid (GA) cryostat method and for acetylcholinesterase (AChE) with a direct-coloring method. The remainder was processed for electron microscopy (EM), both with routine fixation and with glutaraldehyde-dichromate for the specific localization of NE.

Bladder tissue from humans and dogs given anesthetic agents demonstrated time-dependent changes in both the number and brilliance of GA-fluorescent fibers but not in AChE-positive nerves. Human tissue from short-term surgery (ureteric reimplantation) and dog tissue from the later stages (2-4 hrs) of pentothal or ketamine anesthesia, or the early stages of fluothane or ethrane anesthesia (1-2 hrs) had only slight decreases in fluorescent fibers compared to controls. Short-term anesthesia (1-2 hrs) with pentothal or ketamine and long-term anesthesia with fluothane and ethrane (2-6 hrs) caused significant decreases in the number of visualizable adrenergic fibers and in the level of their fluorescence.

With the EM, few small dense core vesicles were seen in long-term inhalant-anesthetized humans and dogs, but many were found in the control dogs. Human tissue from organ donors or short-term surgery had intermediate numbers of these vesicles.

These results suggest that anesthetics deplete peripheral NE either on a short-term basis from which the nerves recover (pentothal and ketamine), or over a longer period, the end point of which is yet undetermined (fluothane and ethrane).

Supported in part by USPHS(NIAMDD) grant 5 K08 AM11824-12(GSB)

153.13 EFFECTS OF SYMPATHETIC ACTIVATION PROCEDURES UPON VENOUS MEMBRANE POTENTIAL IN INTACT RATS. W.J. Willems* (SPON: Z.J. Bosnjak), VAMC Research and Dept. Neurology, Medical College Wisc., Milwaukee, WI 53226.

The precise role of sympathetic activity in the control of vascular electrical parameters "in vivo" is poorly understood. This study was designed to document some effects of sympathetic activation upon intracellular potential of venular smooth muscle in intact rats with normal circulatory control. Following IP sodium pentobarbital anesthesia, tracheostomy, and femoral artery cannulation, male Sprague-Dawley rats were subjected to midline abdominal laparotomy. Mesenteric loops, with circulation and innervation intact, were suffused with physiologic saline solution at 37°C equilibrated with 5% CO_2-95% air. Intracellular membrane parameters were monitored in small mesenteric veins (300-600 um) with flexibly mounted glass microelectrodes (40-80 Megohms), using standard electrophysiologic techniques. The proximal portion of some mesenteric arteries and veins were cradled upon hook electrodes to permit stimulation with 0.7 msec square waves. The amplitude was adjusted to give a supramaximal constriction at 10 Hz frequency. Diameter response was monitored with Vickers split-image optics. Cutaneous pinch stimuli, blood withdrawal, and direct perivascular electrical stimulation were used to activate sympathetic input during intracellular impalements. During light periods of anesthesia, these procedures produced both measurable changes in both blood pressure and excitatory phenomena in single cells of venular smooth muscle. Excitatory phenomena observed after reflex activation included the initiation of transient electrical depolarizations (1-2 mV amplitude) which resembled excitatory junction potentials that others have reported to be elicited by "in vitro" perivascular stimulation. Waveforms resembling excitatory junction potentials also were found after averaging electrical responses to repeated single supraxaximal perivascular stimuli. More often, however, reflex activation of sympathetic activity was associaued with graded electrical depolarization or, when anesthesia was relatively deep, no measurable electrical change. Although venous electrical responses to sympathetic activation varied somewhat, the direction of the response, when present, was invariably excitatory. These measurements may help to clarify the role of excitatory electrical changes in neural control of mesenteric venular smooth muscle "in vivo". (Supported by NHLBI and VA Research grants).

153.14 MEDULLARY SINGLE UNIT RESPONSES TO CHORDA TYMPANI STIMULATION. J.S.Eisenman. Dept. of Physiology, Mt. Sinai School of Medicine, New York, N.Y. 10029.

As part of a program to study physiological activation of salivation in rats,I have attempted to localize and characterize neurons in the superior salivatory nucleus by electrical stimulation of the chorda tympani (CT).The CT was exposed in urethane anesthetized rats by a ventro-lateral approach,cut distally and placed on Pt-Ir stimulating electrodes (interelectrode distance, 2 mm).Extracellular unit responses were recorded using glass micropipettes (5-12μ tip) filled with Niagra Sky Blue,in 0.5M Na acetate.After ablation of one cerebellar hemisphere,the micropipette was placed,using surface landmarks,in the region of the nucleus,at or just caudal to the root of the facial nerve.A lateral angle of 32° was used to align the penetration with the dorsoventral axis of the nucleus.Unit responses were studied for latencies to CT stimulation and frequency following at intensities of 2X threshold.Responses which had invariant latencies and could follow two stimuli at 100/sec or more,were provisionally classified as antidromic or presynaptic axonal.Dye spots were placed iontophoretically to mark track positions and recording sites were localized histologically.In all, 112 units were studied,having a mean latency of 15.4 msec (range:2.7-37.1),SD=7.9.

Seventy units were localized to the area of the superior salivatory nucleus.Of these,5 (7%) formed a distinct group with short response latencies of 5.1-8.3 msec;the remainder had latencies of 11.0-37.1 msec.High frequency-following,100-450/sec,was found in 52 units.Units localized outside of the nucleus had similar latency and frequency-following ranges.However,of 42 such units,significantly more (18,or 43%) had short latencies (2.7-8.3 msec); 24 units had latencies of 12.5-31.6 msec.Based on location,latency and frequency-following,36 units were classified as antidromically activated preganglionic parasympathetic neurons.These had a mean latency of 20.2 msec,SD=6.2,frequency-following of 100-450/sec.The comparable group of 24 cells outside of the nuclear area,had a mean latency of 19.9 msec,SD=6.6.Since the short-latency responses were much more prevalent outside of the nucleus, they were not classed as salivatory neurons.These may represent activity originating from afferent fibers.

Measurement of conduction distances in several specimens,gave values of 15-17 mm.Mean conduction velocity for presumed preganglionic cells is, thus,0.8 M/sec;short-latency responses would have velocities as high as 6.3 M/sec.

Supported by NSF grant BNS 7907245.

153.15 **ALTERATIONS IN THE CERVICAL VAGUS NERVE IN STREPTOZOTOCIN DIABETES IN THE RAT: A COMPUTERIZED MORPHOMETRIC STUDY.** **S.Y. Felten*, J.K. Szynal*, and D.L. Felten** (SPON: W.J. Anderson). Departments of Pharmacology and Anatomy, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

Diabetes was induced in 10 two month old male Sprague-Dawley rats by tail vein injection of 65 mg/Kg streptozotocin. All animals were diabetic at 48 hours after injection (blood glucose levels over 300 mg %) and remained diabetic until they were sacrificed at 6 months of age. The rats were anesthetized with Nembutal and perfused through the left ventrical with a solution of 1.5% glutaraldehyde - 0.5% paraformaldehyde in 0.08 M Sorensen's phosphate buffer. Cervical vagus nerves were removed and processed for routine electron microscopy. 1 um sections were cut, stained with toluidine blue, and observed and photographed (final magnification of 925X). Photographic montages were placed on a Summagraphics ID series digitizing tablet and analyzed using the QUANTAGRAPH computerized morphometric analysis system. Measurements were made of 1.) blood vessel number, diameter, cross-sectional area, and percent of nerve occupied by blood vessels; 2.) myelinated axon number, density, diameter, area, and percent of nerve occutied by axons; 3.) myelin profile diameter, area, thickness, and myelin area/axon area ratios; and 4.) unmyelinated axon number and unmyelinated/myelinated axon ratios.

Significant differences between control and diabetic rat vagus nerves ($p<0.05$ using a two-tailed unpaired student's t-test) include decreases in the total number of myelinated axons, and in the average diameter of myelinated axons. Large decreases were observed in the number of unmyelinated axons ($p<0.001$) in diabetic rats. In addition, the overall cross-sectional area of the cervical vagus nerve was significantly decreased.

153.16 CATECHOLAMINE SECRETION BY SAPONIN-SKINNED CULTURED ADRENAL MEDULLARY CHROMAFFIN CELLS. J.C. Brooks and S. Treml*. Marquette Univ. Sch. of Dent., Milwaukee, WI 53233

Isolated adrenal medullary chromaffin cells are receiving considerable attention in studies of the mechanism of catecholamine secretion. Secretion can be easily monitored for cells grown as monolayers in short-term culture in response to various secretagogues. However, the secretory apparatus itself is not accessible to direct chemical manipulation, exclusive of membrane effects, because of the semipermeable barrier function of the membrane. It is also difficult to distinguish between membrane effects, effects on the secretory apparatus itself, and interactions between the two. In an effort to gain direct access of drugs and proteins to the secretory apparatus we have used saponin to permeabilize the cells by the "skinning" process used with skeletal and smooth muscle cells.

In order to determine the minimum time required to skin the cells, monolayer cultures were exposed to 0.01% saponin for varying periods in the presence of the vital dye trypan blue. By direct visual observation, an optimal exposure time of 160 sec. was determined. The saponin treatment had no significant effect upon the total catecholamine content of the cells, nor did the cells appear different under phase contrast microscopy. Catecholamine and dopamine-beta-hydroxylase were released upon exposure of the treated cells to media with various calcium concentrations in the presence of exogenous Mg-ATP. Both Mg-ATP and calcium were essential for secretion. Secretion initiated by either of these agents was nearly complete after 10 min. of incubation. At this point calcium-induced catecholamine secretion was about 6-fold higher than that for cells incubated in calcium-free medium. Calcium-induced secretion was unaffected by mepacrine, an inhibitor of phospholipase A_2, or several drugs expected to influence secretion, including pargyline and N-ethylmaleimide. Reserpine caused a slight reduction of calcium-induced catecholamine secretion. Lactic dehydrogenase was released from cells by the saponin treatment and during the subsequent incubations, indicating that the treatment causes membrane permeability to molecules as large as protein.

The use of saponin to permeabilize chromaffin cells in culture appears to be a simple means for allowing the presentation of exogenous substances directly to the cell's secretory machinery. It should offer the opportunity to use chemical treatments and specific antibodies to cellular components to determine the role of these components in the secretory process. The techniques should also be applicable to a wide variety of cells known to secrete by an exocytotic mechanism.

WITHDRAWN

153.18 ADENOSINE MODULATION OF SYNAPTIC EFFICACY IN THE SUPERIOR CERVICAL GANGLION OF THE RAT. Barbara K. Henon and Donald A. McAfee. City of Hope Research Institute, Duarte, CA 91010.

Activation of adensine receptors in the CNS appears to cause inhibition of synaptic transmission by an unknown mechanism. Sympathetic ganglia also have adenosine receptors and we report here that the adenosine analog, 2-chloroadenosine, inhibits single evoked cholinergic EPSPs in the ganglion. EPSPs were recorded intracellularly from postganglionic neurons in the presence and absence of 2-chloroadenosine in the Locke solution. The average EPSP amplitude declined by 42 $\pm$ 9% of control in 10 μM (n=5) and 27% in 5 μM 2-chloroadenosine (n=2). Peak inhibition occurred in about 10 min and the effects were reversed in normal Locke solution within 30 min. There was no change in the input resistance of postganglionic neurons.

The same concentration of 2-chloroadenosine (10 μM) that inhibits EPSP amplitude was found to increase the number of synaptically evoked action potentials recorded intracellularly in response to a preganglionic stimulus train (20 Hz for .75 sec). The pulse train was delivered every 20 sec. Normally the response exhibits considerable synaptic depression with a few stimuli eliciting spikes and the remainder subthreshold EPSPs. In the presence of 2-chloroadenosine, more of the EPSPs exceeded threshold and the number of action potentials gradually increased to 181 $\pm$ 12% of control over a period of 10-12 minutes (8 trials on 4 cells). The facilitative effects of 2-chloroadenosine were reversed by washing in normal Locke solution for 20-30 min.

We have previously shown that adenosine inhibits Ca-dependent potentials by activation of adenosine receptors on the somata of postganglionic neurons (Henon and McAfee, 1979; Henon et al., 1980 Soc. Neurosci. Abst.). Our preliminary voltage-clamp studies have confirmed that adenosine inhibits the voltage sensitive Ca current. Inhibition of the single EPSPs by 2-chloroadenosine is consistent with this observation if it also inhibits Ca channels on presynaptic nerve terminals in the ganglion.

Increases in the number of intracellularly recorded spikes/train in the presence of 2-chloroadenosine is consistent with previous findings that adenosine reduces the amount of synaptic depression recorded extracellularly during repetitive preganglionic stimulation. Synaptic depression is also reduced by low Ca^{2+} in the medium and may result from the depletion of readily releasable ACh during the train. The mechanism by which 2-chloroadenosine inhibits single responses and yet facilitates repetitive activity in the ganglion is complex and is the object of future study. Understanding of this mechanism could lead to insights into the actions of adenosine in the CNS.

153.19 ADRENALINE HYPERPOLARIZATION AND Na^+ PUMP IN SYMPATHETIC GANGLIA. P.E. Rafuse* & P.A. Smith. Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Ionic concentration gradients in neuronal tissue are maintained, at least in part, by an electrogenic, ouabain sensitive sodium pump. It has been suggested that the catecholamine induced hyperpolarization of both peripheral and central neurones may involve stimulation of the activity of this pump (Koketsu & Nakamura, Jap. J. Physiol., 26, 63, 1976; Kuba & Koketsu, Prog. Neurobiol., 11, 771, 1979; Phillis & Wu, Prog. Neurobiol., 17, 141, 1981; Segal, Brain Res., 206, 107, 1981). This hypothesis was examined using the sucrose gap technique to record responses from the IXth or Xth paravertebral sympathetic ganglia of the amphibians, *Rana catesbeiana* or *Rana pipiens*. Although adrenaline (Adr, 10μM-1mM) depolarized the membrane potential of 2 out of 10 preparations tested, the majority exhibited hyperpolarizing responses which were especially prone to desensitization. High concentrations of acetylcholine (10mM) produced a biphasic response, a depolarization followed by an afterhyperpolarization (ACh_{AH}) which has been shown to result from activation of the electrogenic Na pump (Smith & Weight, Nature, 267, 68, 1977). When the ACh_{AH} and hence the electrogenic Na^+ pump were inhibited by 10μM ouabain, application of Adr (20-200μM) still promoted membrane hyperpolarization. Under these conditions however, the rates of onset and offset of Adr hyperpolarization were somewhat slower than in the control situation. In another series of experiments, ganglia were stored overnight in K-free Ringer at 5°C. This treatment inhibits the Na^+ pump and causes accumulation of intracellular Na^+. When these preparations were examined in K-free Ringer, Adr (200μM) consistently produced a hyperpolarization of membrane potential. Re-administration of normal Ringer's containing 2mM K^+ for 1.5-2 min also promoted a transient hyperpolarization. This K^+-activated hyperpolarization (K_H) is due to the reactivation of the Na^+ pump which promotes hyperpolarization whilst accumulated Na^+ is disproportionately exchanged for K^+ (Akasu & Koketsu, Jap. J. Physiol., 26, 289, 1976). Following blockade of the K_H and hence the electrogenic pumping of Na^+ by 1μM ouabain, Adr still promoted a hyperpolarization of membrane potential. The mean amplitude of this response was 75.7 ± 17.5% of control (n=6). In two experiments the Adr hyperpolarization was actually enhanced in ouabain; in four others it was reduced. This reduction may have been attributable to desensitization. These results show that Adr can still promote hyperpolarizing responses when the Na^+ pump is apparently blocked. This observation questions, but may not necessarily invalidate, the hypothesis that Na^+ pump activation may be involved in the hyperpolarizing action of Adr.

153.20 CATECHOLAMINES ENDOGENOUSLY MODULATE THE Ca^{++} DEPENDENT K^+ CONDUCTANCE WHICH UNDERLIES THE SLOW INHIBITORY POSTSYNAPTIC POTENTIAL (S-IPSP) IN MAMMALIAN PARASYMPATHETIC GANGLIA. P. Shinnick-Gallagher, M. Yoshimura*, and J.P. Gallagher, Dept. of Pharmacology, Univ. of Texas Med. Br., Galveston, TX 77550.

We have previously shown that the S-IPSP in cat vesical pelvic ganglia is due to direct muscarinic activation of a K conductance. We observed that superfusion with (1μM) phentolamine (15-20 min) enhances the amplitude of the S-IPSP in 75% of the cells. Superfusion of NE (10nM to 100μM) depressed the S-IPSP and the iontophoretically induced ACh hyperpolarization recorded in the same cell. These effects were usually accompanied by a membrane hyperpolarization (4-8mV) and conductance increase. When the membrane potential was voltage clamped NE still depressed the slow-inhibitory postsynaptic current (S-IPSC) and the ACh-induced outward current. NE did not affect the decay phase (τ) of the S-IPSC. At the 1μM concentration these effects occurred in every cell tested, even in cells where NE itself generated no outward current. NE shifted the concentration response curve for ACh in an uncompetitive manner. To test whether NE acted by blocking channels opened by ACh, we measured the voltage sensitivity of the NE effect on the ACh-induced outward current. The effect of NE did not appear to be voltage dependent. The reversal potential for the ACh-induced hyperpolarization was also not affected by NE. These data coupled with the lack of a NE effect on τ suggests that NE may not be exerting its primary effect by blocking channels directly. Since NE is known to inhibit Ca currents through activation of an alpha-adrenoceptor, the previous experiments implied that NE may be affecting a Ca mechanism and suggested that the S-IPSP may have a Ca component. The ACh hyperpolarization persists in a zero Ca/10mM Mg solution at a time when synaptic transmission is blocked. However, when the preparation is superfused with the zero Ca media for a longer time period, the ACh hyperpolarization is diminished in amplitude (20 min) and eventually blocked (40 min). Solutions containing more potent Ca antagonists, Cd (.3mM) or Mn (1mM), rapidly eliminated both the synaptic response and ACh hyperpolarization. Taken together (v.s.) these data suggest that the S-IPSP is due to a Ca dependent K conductance (g K_{Ca}) increase. The fact that the S-IPSP and ACh hyperpolarization can be observed under voltage clamp conditions that do not require depolarizing step suggests that the muscarinic hyperpolarization is due to an increased calcium conductance coupled to an ACh receptor, not to voltage dependent Ca entry, and that the resulting increase in intracellular Ca activates a potassium conductance. These data suggest that endogenous NE modulates the S-IPSP by inhibiting Ca entry through a postsynaptic alpha-adrenoceptor and probably not by blocking channels. (Supported by NS16228).

153.21 TOPOGRAPHY OF RAPHE-SPINAL PATHWAYS. J.B. Cabot and N. Bogan*. Department of Neurobiology and Behavior, S.U.N.Y. at Stony Brook, Stony Brook, New York 11794.

Vertebrate spinal cord contains major serotonergic terminations within dorsal horn(DH), ventral horn(VH) and the sympathetic preganglionic cell column(SPN). Neurons giving rise to these projections are located exclusively within the brainstem and include cells within the caudal pontine/medullary raphe complex(CPMR). The present series of anterograde ARG, retrograde HRP and immunohistochemical(IHC) studies, while focused primarily upon the identification of the specific CPMR subnucleus (i) projecting to the SPN, establish more generally the funicular trajectories and laminar termination patterns of avian CPMR-spinal pathways.

The pigeon (Columba livia) CPMR can be divided into at least 3 major subnuclei: obscurus(Rob), pallidus(Rpa) and magnus(Rmα,Rmβ). In normal and colchicine treated pigeons IHC staining with anti-5HT indicates that: (a) cells within each subnuclear region exhibit 5HT-like immunoreactivity; (b) among subnuclei the density of 5HT-like immunoreactive neurons is non-uniform, and none of the gigantocellular cells in Rmα stain positively; and (c)5HT neurons within CPMR give rise to axons localized to the dorsolateral(DL), ventrolateral(VL) and the superficial marginal layers of the ventral white matter (high cervical spinal cord).

Injections of HRP confined to the right hemicord in high cervical, brachial and thoracic segments result in labeling of neurons in all subnuclei (n=25). The laterality of labeling is complex: caudal Rpa, caudal Rmα, bilaterally; Rob, rostral Rpa, rostral Rmα, Rmβ, ipsilaterally. Combining thoracic HRP injections with bilateral dorsal quadrant lesions of high cervical cord clearly demonstrated that rostral Rpa, rostral Rmα and Rmβ give rise to spinally directed axons traveling principally in the DL and lateral white matter.

Injections of ^{3}H-amino acids throughout the rostrocaudal extent of CPMR confirm and extend the HRP data (n=10). The results suggest that neurons along the rostrocaudal axis of CPMR give rise to spinal laminar projections in the dorsoventral plane of the spinal grey. Specifically, injections: (a) confined to rostral Rpa, rostral Rmα and Rmβ result in terminal labeling primarily in the superficial layers of DH (I,II) and SPN;(b) centered in caudal Rmα and the rostral ½ of Rpa result in dense labeling of the intermediate spinal laminae, around the central canal, in SPN and VH; and(c) encompassing caudal Rpa reveal the presence of a distinctive "terminal ringing" of lamina IX motoneurons.

The combined HRP, ARG and IHC data strongly suggest that the funicular trajectories and laminar patterns of termination of CPMR neurons reflect, at least partially, the axonal projections and terminals of 5HT cells located in CPMR. (Supported by HL24103)

153.22 IS THE DIET-DEPENDENT EXCRETION OF 5-HYDROXYINDOLEACETIC ACID (5-HIAA) RELATED TO CHANGES IN THE INTESTINAL MUCOSA? J. L. Colmenares, V. Tortorici*, O. Restrepo* and A. G. Angulo-Colmenares. Servicios de Endocrinología y Anatomía Patológica. Hospital Militar "Dr. Carlos Arvelo", Caracas, Venezuela.

Previous work has shown that the synthesis and release of serotonin (5-HT) from the enterochromaffin (EC) cells is dependent on the amount of ingested protein and on the relation in the ingested protein between tryptophan (Tp) and the large neutral amino acids (Tp/LNAA; Colmenares, J. L. and R. J. Wurtman, Metabolism 28:820, 1979). Then a peripheral endocrine signal is generated by the EC cells in response to the diet. The question remained if the variations in 5-HT synthesis and release were due to changes in the number of intestinal mucosa cells which -contrary to serotoninergic neurons- vary with the diet.

Groups of Sprague-Dawley rats were fed diets I) 18% casein hydrolizate, Tp-free; II) 18% casein, 0.22% Tp; III) 8% casein, 0.10% Tp or IV) 18% casein supplemented with Tp up to 0.44% Tp; for 5 or 16 days. 24-hours prior to sacrifice urines were collected and 5-HIAA determined. Urinary 5-HIAA was related to Tp ingestion confirming previous reports. Plasma Tp, gut and blood 5-HT were measured. At 5 days they were decreased in group I; diet IV failed to produce increases even at 16 days. Diet III gave intermediate values. Diet II was used as a control.

The experiment was repeated for 5 days but prior to sacrifice rats were intubated with buffered formalin. Duodenal samples were embedded in paraffin and sections were stained with the diazo method for EC cells. The thickness of the mucosa, submucosa and muscular layers remained constant in all groups. A double-blind counting of the number of cells positive to the diazo staining showed a 60% decrease in group I, but there were no differences among groups II, III and IV.

In a third experiment rats were fed diets I or II for 5 days when they were intubated with 10 mg of a Tp solution or water. The following 3-hour excretion of 5-HIAA increased in the animals receiving Tp independently of the diet. Preliminary results indicate that only animals on diet I intubated with Tp showed an increase in diazo-positive cells.

These results suggest that the EC cells are saturated with 5-HT at high protein intake; that gut 5-HT decreases to mantain the circulating levels of 5-HT; and that the decreases in gut 5-HT during short term periods apparently are not due to decreases in mucosa thickness nor to the lack of the synthetic enzymes in the EC cells. An hypothetical model is presented to describe the EC cell system.

154.1 DOSE-DEPENDENT EFFECTS OF A γ-AMINOBUTYRIC ACID DERIVATIVE ON MEDULLARY AND PHRENIC RESPIRATORY NEURONS. P. M. Lalley, Dept. of Physiology, Univ. of Wisconsin, Med. Sci. Ctr.,Madison,WI 53706.

Baclofen administered intravenously can either stimulate or depress intercostal motoneurons, depending on the dose (Lalley, P.M., Br. Res. Bull. 5: 565, 1980). In this study, the effects of baclofen on medullary and phrenic neurons were investigated. Inspiratory activity recorded from the C_5 branch of the phrenic nerve increased following low doses of baclofen. Spike frequency within each inspiratory burst increased after lowest effective doses (0.5-1.0 mg/kg i.v.) without appreciable change in inspiratory duration (T_i) or expiratory silent period (T_e). After higher doses (1-4 mg/kg i.v.), T_i was either greatly prolonged, with little or no change in T_e, or the inspiratory discharge was continuous. Spike frequency at these higher doses was often reduced. Control phrenic nerve activity was largely reinstated by bicuculline (100-300 µg/kg i.v.). Extracellular and intracellular recording from phrenic motoneurons revealed increases in action potential frequency and T_i after 0.5-1 mg/kg, accompanied by depolarization. Higher doses (2-4 mg/kg i.v.) resulted in hyperpolarization, decreases in spike frequency and further prolongation of T_i. Medullary inspiratory neurons of the dorsal and ventral respiratory groups were stimulated by baclofen (0.5-2 mg/kg) and depressed by doses greater than 2 mg/kg. Expiratory neurons were depressed after doses of baclofen which increased phrenic nerve activity. When phrenic nerve activity was depressed by doses greater than 2 mg/kg, expiratory neurons sometimes discharged continuously. Microelectrophoretic application of baclofen (10 mM, pH 3) to medullary inspiratory neurons resulted in depression of firing at all effective current strengths (20-100 na). It appears that lower i.v. doses of baclofen increase inspiratory activity by suppressing an unidentified population of inspiratory-inhibiting neurons, whereas higher doses depress medullary inspiratory neurons and phrenic motoneurons.

154.2 RESPIRATORY DEPRESSION PRODUCED BY GLYCINE INJECTED INTO THE CISTERNA MAGNA OF THE CAT. R.A. Gillis*, A. Buller*, P. Hamosh*, A.M.T. Da Silva*, J.A. Quest* and J.R. Holtman, Jr. (SPON: W.E. Norman). Depts. of Pharmacology, Physiology and Pulmonary Medicine, Georgetown University Schools of Medicine and Dentistry, Washington, D.C. 20007.

The purpose of our study was to determine the effect of centrally administered glycine on pulmonary ventilation in the cat. Animals were anesthetized with - chloralose and trachael airflow was measured using a Fleisch no. 1 pneumotachograph. The flow signal was integrated to obtain tidal volume (V_t).

Administration of glycine (0.8-64.8 umol) into the cisterna magna of 7 animals resulted in a dose-related decrease in respiratory minute volume ($\dot{V}_e$). The highest dose tested (64.8 umol) resulted in a decrease in $\dot{V}_e$ from 454 ± 35 to 156 ± 44 ml/min ($p < 0.05$). This decrease was due primarily to a reduction in V_t which dropped from 31 ± 2 to 12 ± 2 ml ($p < 0.05$). The 2 largest doses tested, 21.6 and 64.8 umol, also produced a decrease in respiratory rate (f) from 14 ± 1 to 11 ± 1 breaths/min and 15 ± 1 to 12 ± 1 breaths/min ($p < 0.05$), respectively. Apnea occurred in 2 of 7 animals with the 64.8 umol dose. The respiratory depressant effects of glycine, over the dose range used in this study, appear to be localized to the CNS since intravenous glycine (64.8 umol) had no significant effect on respiratory activity.

In an attempt to determine the site of glycine to depress respiration when given by intracisternal injections, this substance was applied topically to the intermediate area of the ventral surface of the medulla using paired Perspex rings (W. Feldberg, Neuroscience 1: 427, 1976). Application of a dose of 13.3 umol of glycine produced apnea in 4 of 5 animals tested.

These results demonstrate that intracisternal administration of glycine causes pronounced respiratory depression. The CNS site of action for this effect may be the intermediate area of the ventral surface of the medulla. Supported by a grant from NHLBI (HL 29562).

154.3 β-ALANINE, TAURINE AND GLYCINE: EFFECTS ON CENTRAL RESPIRATORY REGULATION: P. Wessberg*, J. Hedner*, T. Hedner* and J. Jonason* (SPON: T. K. Harden). Dept of Pharmacology, Univ. of Göteborg, Göteborg, Sweden.

Several amino acids which normally occur in the CNS, like β-alanine, taurine and glycine, exert a general depressive influence on neuronal activity. In order to investigate the possible action of these amino acids on central respiratory regulation, we have studied the effects of intracerebroventricular (icv) injections on basal and CO_2 induced respiratory performance.

Halothane anesthetized rats with chronic icv catheters were studied in a whole body plethysmograph. The following respiratory parameters were registered: tidal volume (V_T), respiratory frequency (f), minute volume ($\dot{V}_E$), inspiratory time (T_I), expiratory time (T_E), respiratory time (T_{TOT}), "inspiratory drive" (V_T/T_I) and "respiratory timing" (T_I/T_{TOT}). Moreover, heart rate (HR) and mean arterial pressure (MAP) were recorded. The icv injections of β-alanine, taurine and glycine (0.01-1 mg) were given in the lateral brain ventricles.

All amino acids induced a decrease in f and V_T which was immediate and longlasting. In some animals periods of apnea were seen. Evaluation of the respiratory time intervals indicated that the effects on f were due primarily to a prolongation of T_E. Both V_T/T_I as well as T_I/T_{TOT} decreased after icv administration of the amino acids. Apart from the effects on basal ventilation the CO_2 induced respiratory response was blunted after β-alanine, taurine and glycine. A decrease in HR and MAP was seen after all agents.

In conclusion, this study shows that the putative amino acid neurotransmitters β-alanine, taurine and glycine have depressive effects on respiratory activity when administered by the central route. In spite of the high doses used it may be speculated that β-alanine, taurine and glycine may have a role in the central regulation of breathing during physiological or pathophysiological conditions.

(Supported by grants from the Swedish Medical Research Council, proj. nos. 2862 and 2464.)

154.4 CARDIO-RESPIRATORY DEPRESSION PRODUCED BY CENTRALLY ADMINISTERED TAURINE IN THE CAT. J.R. Holtman, Jr., A. Buller*, A.M.T. Da Silva*, P. Hamosh* and R.A. Gillis*. Depts. of Pharmacology, Physiology and Pulmonary Medicine, Georgetown Univ. Schools of Med. and Dent., Washington, D.C. 20007

Studies in this laboratory have focused on the possible role of inhibitory amino acids in the central control of the respiratory and cardiovascular systems. In the course of these studies we have found that taurine(2-aminoethanesulfonic acid)depresses both respiratory and cardiovascular activity.

The effects of taurine(0.8-64.8 umol)were studied following intracerebroventricular (i.c.v.) and intracisternal (i.c.) injections in cats anesthetized with -chloralose. A femoral vein and artery were cannulated for systemic administration of drugs and measurement of blood pressure, respectively. A trachael cannula was inserted so that airflow could be determined by using using a Fleisch no. 1 pneumotachograph. The flow signal was then integrated to obtain tidal volume (V_t). Inspiratory and expiratory durations (T_i and T_e) were determined from rapid tracings of V_t.

After i.c.v. injectjon,taurine caused dose-related decreases in minute ventilation($\dot{V}_e$). With the largest dose tested (64.8 umol), $\dot{V}_e$ decreased from 492 ± 30 to 201 ± 43 ml/min ($p < 0.05$). The decrease in $\dot{V}_e$ was caused by a dose-dependent decrease in V_t which changed from 30 ± 2 to 12 ± 2 ml($p<0.05$). Apnea occurred in 2 of 7 animals given the 64.8 umol dose. Neither respiratory frequency (f) nor T_i and T_e durations were significantly changed. The cardio-depressant effect of taurine was evidenced by a dose-related decrease in mean blood pressure (MBP) with the highest dose producing a decrease from 112 ± 7 to 82 ± 12 mm Hg ($p < 0.05$).

Respiratory depression of a greater magnitude was seen when taurine was administered by i.c. injection. The maximal decrease in $\dot{V}_e$ was from 495 ± 59 to 64 ± 14 ml/min ($p < 0.05$), V_t from 27 ± 3 to 5 ± 1 ml ($p < 0.05$) and f from 18 ± 1 to 12 ± 2 breaths/min ($p<0.05$). Again T_i and T_e were not significantly changed. Apnea occurred in 5 of 6 cats receiving 64.8 umol taurine. In contrast to i.c.v. administration, taurine by i.c. administration did not cause hypotension. The cardio-depressant effects of taurine, over the dose range in this study, appear to be localized to the central nervous system since intravenous taurine (64.8 umol) had no significant effect on cardio-respiratory activity.

These data demonstrate that both i.c.v. and i.c. injections of taurine depress respiratory activity,while i.c.v. injections also lower MBP. From these findings, it appears that the site of action for taurine-induced hypotension differs from the site of action for taurine-induced respiratory depression.

154.5 PICROTOXIN PRODUCES CARDIO-RESPIRATORY STIMULATION BY BLOCKING THE VENTRAL MEDULLARY GABA SYSTEM. K. A. Yamada* and R. A. Gillis* (SPON: G. J. Blake). Dept. of Pharmacol., Georgetown Univ. Schs. of Med. and Dent., Washington, DC 20007.

We have previously reported that a tonically active GABAergic system influencing respiratory and cardiovascular function may exist at the intermediate area of the ventral surface of the medulla. Both GABA and muscimol were shown to act at this site to produce cardio-respiratory depression, while bicuculline was shown to stimulate ventilation and increase arterial pressure and heart rate. To test further for the existence of a GABAergic system at the ventral surface of the medulla, we evaluated the cardio-respiratory effects of another antagonist of GABA, namely picrotoxin. This agent was applied to the intermediate area of the ventral surface of the medulla (50-100 ug) of 5 chloralose-anesthetized cats while monitoring tidal volume (V_T), respiratory rate, blood pressure (BP), and heart rate (HR). These doses increased minute ventilation from 387 ± 30 to 476 ± 73 ml/min by increasing V_T from 26.7 ± 1.7 to 33.6 ± 2.2 ml ($p < 0.05$), as rate was unchanged. BP was increased from 161 ± 7 to 187 ± 10 mm Hg and HR from 224 ± 13 to 256 ± 14 beats/min ($p < 0.05$). Picrotoxin (50-150 ug) applied to the intermediate area of three chloralose-anesthetized cats which had become apneic after GABA administration re-established spontaneous breathing and reversed GABA-induced hypotension. These data are consistent with our hypothesis that GABA may be an important inhibitory neurotransmitter regulating pulmonary ventilation and cardiovascular activity from the intermediate area of the ventral surface of the medulla.

154.6 ACUTE SARIN TOXICITY: COMPARISON OF CENTRAL NERVOUS SYSTEM AND NEUROMUSCULAR EFFECTS. D.L. Rickett, N.L. Adams*, R.E. Foster, J.F. Glenn, W.T. Gregory*, T.C. Randolph*, and R.K. Traub*. Neurotoxicology and Experimental Therapeutics Branch, U.S. Army Medical Research Institute of Chemical Defense, APG, MD 21010.

Sarin (GB) is an organophosphorus anticholinesterase agent which is more susceptible to atropine and oxime therapeutic treatment than soman. This responsiveness to therapy is thought to be due to the relatively slow rate, compared to soman, at which GB-inhibited cholinesterase ages. Disagreement exists concerning both the sites and mechanisms of actions thought to be responsible for GB's toxicity. The present study was conducted to examine the acute toxicity of GB and to identify the relative significance of its actions on the central nervous system (CNS) and at the periphery. Using Dial-urethane anesthetized cats, recordings were made of medullary respiratory-related units, phrenic nerve discharge on the side contralateral to unit recording, electromyographic activity and contractions of the diaphragm leaflet innervated by the monitored phrenic nerve, airflow, blood pressure and electrocardiographic activity. Blood gases and expired CO_2 were also monitored. Sarin was administered via the femoral vein at a rate of one ml/min in a concentration of 3.0 µg/ml/kg. GB infusion was stopped when spontaneous respiration ceased, whereupon diaphragmatic neuromuscular blockade was tested by administrations of supramaximal stimulation of the phrenic nerve (10 & 100 Hz, 0.5 msec pulse, 0.5 sec duration) and artificial respiration was initiated. GB infusion was then continued at the previous rate but at three times the initial concentration and diaphragmatic responsiveness was tested at varying intervals. The results show that there was a loss of synchronous discharge of respiratory-related units. This disruption of normal neuronal activity preceeded GB-produced respiratory arrest and was maximally reflected as a loss of phrenic nerve discharge. At the time that spontaneous respiration ceased, tetanic contractions of the diaphragm could be elicited by phrenic nerve stimulation. It was not possible to establish the dose of GB required to block the diaphragm since in most cases, cardiac failure and loss of blood pressure precluded further infusion of GB. At the time of respiration arrest, $PaCO_2$ was within normal range while PaO_2 was depressed. The findings in this study strongly suggest that GB toxicity, like soman toxicity, is acutely mediated through a loss of central respiratory drive; this results from disruptions of normal patterned activity in respiratory-related unit discharge. GB also appeared to be more cardiotoxic than soman. Although the CNS actions of GB remain to be elucidated, our observations suggest that normal ionic conductances are altered.

154.7 TRH AND TRH ANALOGUES IN CENTRAL RESPIRATORY REGULATION. J. Hedner*, T. Hedner*, P. Wessberg*, D. Lundberg* and J. Jonason* (SPON: G. R. Breese). Dept of Pharmacology, Univ. of Göteborg, Göteborg, Sweden.

Recent immunohistochemical studies have shown that the tripeptide TRH has an extensive distribution in autonomic regulatory brainstem areas. As this area includes the structures involved in respiratory regulation, we have investigated the respiratory effects of TRH and TRH analogues administered centrally to anesthetized rats.

The rats were lightly anesthetized with halothane and studied in a whole body plethysmograph. The respiratory parameters: frequency (f), tidal volume (V_T), inspiratory time (T_I), expiratory time (T_E) and tidal respiratory time were studied. Moreover, minute ventilation ($\dot{V}_E$) and the quotients inspiratory drive (V_T/T_I) and respiratory timing (T_I/T_{TOT}) were calculated. Mean arterial blood pressure (MAP) and heart rate (HR) were continuously registered. Injections were given into the lateral brain ventricles or into the fourth ventricle according to a procedure earlier described (Hedner et al, 1981).

TRH resulted in a dose-dependent stimulation of f and $\dot{V}_E$ while V_T was slightly decreased after injection into the lateral as well as into the fourth ventricle. MAP and HR were not significantly changed in the dose range used (0.05-5 µg). All respiratory time intervals, T_I, T_E and T_{TOT}, were significantly shortened. Inspiratory drive increased while respiratory timing decreased. The response to a CO_2 challenge (5% or 10% CO_2 in O_2) was not changed compared to the control except for the f response which was lowered after increasing amounts of CO_2 in the inhalation gas mixture.

TRH in the deamidated form had no effect on the respiratory performance. DN 1417, a potent TRH analogue (Fukuda et al 1980) was found to be approximately ten times as potent as TRH as a respiratory stimulant even though the maximum f response did not reach the peak value seen after TRH.

The results indicate that TRH is a specific respiratory stimulant with an action within the CNS. Most probably the action is closely related to neurones involved in the basal regulation of breathing.

154.8 MONOSYNAPTIC CONNECTIONS OF PULMONARY STRETCH RECEPTORS WITH P CELLS. D.B. Averill*, W.E. Cameron, and A.J. Berger. Department of Physiology and Biophysics, Univ. of Washington, Seattle, WA. 98195.

The nature of the synaptic connections between single slowly-adapting pulmonary stretch receptors (PSRs) and respiratory neurons in the tractus solitarius (TS) region have not been investigated. The present study examined these connections by utilizing the technique of cross-correlation analysis of the discharge intervals recorded for single PSRs and TS respiratory neurons. Data were obtained from 10 adult cats that were anesthetised, paralyzed, and artificially ventilated. The extracellular activity of single PSRs was recorded with a "floating" metal microelectrode placed in the nodose ganglion. The activity of single respiratory neurons was recorded with low impedance metal or glass microelectrodes placed in the medulla 0-2 mm rostral to the obex. The region of central termination for PSRs was identified by the occurrence of a terminal potential (tp) and a focal synaptic potential (fsp) in the spike-triggered average of extracellular field potentials. The only respiratory units studied were those within a limited distance (500 µm) from the observation of a tp and fsp. The discharge of the PSR and TS unit were recorded simultaneously on FM tape. Interspike intervals for both neuronal discharges were determined off-line; a minicomputer (LM^2) was used to construct cross-correlation histograms (CCH) for these simultaneously occurring interspike intervals. Respiratory units were classified as Iα, Iβ or P cells. In a few cases, tests were not performed to differentiate between Iα and Iβ cells; these units were classified as I_{nd}. Cross-correlation histograms were compiled for 14 PSR-TS unit pairs. The results of the crosscorrelation analyses are summarized below.

	CELL TYPE			
	P	Iα	Iβ	I_{nd}
Total	3	7	2	2
Monosynaptic Connections	3	0	0	0

The mean latency from PSR spike to the peak probability of the discharge for the P cells was 2.1 msec. This short latency along with the increased probability of discharge observed in the CCHs between PSRs and P cells indicate monosynaptic excitatory connections. The inability to demonstrate a change in probability of discharge for I cells may be explained by either 1) PSR afferents do not have synaptic connections with I cells or 2) cross-correlation analysis of neuronal events over repeated respiratory cycles (reference events>15K) may not be sufficiently sensitive to detect a weak synaptic connection between PSRs and I cells.

154.9 HYPOXIA POTENTIATES REFLEX BRONCHOCONSTRICTION INDUCED BY LUNG DEFLATION IN DOGS. E.H. Vidruk* (SPON: Peter D. Spear). John Rankin Laboratory of Pulmonary Medicine, Department of Preventive Medicine, University of Wisconsin, Madison, WI, 53706.

Bronchomotor reflexes are known to play an essential role in controlling the caliber of both normal and diseased airways. How factors such as blood gas composition interact with these reflexes has not been explored. The purpose of this study was to determine whether alterations in arterial oxygen tension (PaO_2) affect the magnitude of reflex bronchoconstriction. Experiments were performed in anesthetized (i.v. chloralose, 100 mg/kg, and urethane, 500 mg/kg), paralyzed (i.v. Flaxedil, 2-4 mg/kg) and mechanically ventilated dogs. In each dog, the uppermost portion of the intact extrathoracic trachea was isolated in situ from the rest of the respiratory tract. Continuous monitoring of pressure within the isolated segment (P_S) provided an index of bronchomotor tone with an increasing P_S indicating bronchoconstriction and decreasing P_S, bronchodilation. Reflex bronchoconstriction was induced by stopping the ventilator during expiration (10-30 sec) and permitting the lungs to deflate spontaneously. This maneuver resulted in an increase in the P_S which was reversed upon reinstitution of ventilation and which returned to baseline within 30-60 sec. When this maneuver was employed during ventilation with normoxia (PaO_2, 72-90 mmHg), P_S increased by 1-23 cm H_2O (N=13). When repeated during ventilation with hypoxia (PaO_2, 29-49 mmHg), the increase in P_S ranged from 0.1-10 times greater than that with normoxia (N=13). By contrast, when done during ventilation with 100% O_2 (PaO_2> 200 mmHg) the increase in P_S was greatly attenuated (N=11; range 0-50% of normoxic results). Hypoxia and hyperoxia in most cases did not change baseline P_S from its normoxic value. Changes in oxygenation were accomplished by changing the concentration of O_2 in the inspired gas. Arterial CO_2 tension and pH remained virtually the same during hypoxia and hyperoxia as during normoxia. The reflex bronchoconstriction was essentially completely eliminated by bilateral cervical vagotomy (N=4). Bilateral neurotomies involving only the superior laryngeal nerves reduced the magnitude of the reflex by at least 50% (N=4). Bilateral neurotomies involving only the caudal pararecurrent nerves reduced the magnitude of the reflex by 50% in 3 dogs but was without effect in 1 dog.

The potentiating effect which hypoxia has upon bronchoconstrictor reflexes may be a mechanism underlying the responses of hyperreactive airways. These data also suggest that hyperoxia may be useful in preventing the full expression of reflex bronchoconstriction.

154.10 SHORT TIME SCALE CORRELATIONS BETWEEN RESPIRATORY NEURONS OF THE CAT BRAINSTEM. L.S. Segers*, R. Shannon*, and B.G. Lindsey. (Spon: S. Saporta). Univ. So. Florida, Dept. Physiology, Tampa, FL 33612

Recent anatomical and electrophysiological studies have provided evidence for axonal projections between respiratory neurons of the medulla (nucleus ambiguus (NA), nucleus retroambigualis (NRA), area of the retrofacial nucleus (RFN)) and pons (nucleus parabrachialis medialis, Kolliker-Fuse nucleus). Preliminary studies of the temporal relationships of spike trains of simultaneously recorded pontine-medullary and pontine-pontine neuron pairs have been done. These studies, using cross-correlational methods, are designed to detect correlations indicative of synaptic interactions between neurons. Cats were decerebrated, vagotomized, paralyzed, and artificially ventilated. Neurons were recorded extracellularly using 2, 3, or 4 tungsten microelectrodes. Contralateral phrenic nerve activity was recorded. Eighty pairs of pontine-ventral respiratory group (NA, NRA) neurons have been studied. Short time scale correlations in this sample were rare: the cross-correlogram for one neuron pair had small peaks on both sides of the origin, similar to high-frequency oscillations observed by others. Twenty pairs of pontine-RFN neurons have been studied. Two of these pairs yielded evidence of synaptic interaction. A pair of expiratory (E) neurons contained a peak that straddled the zero lag, indicating the presence of a shared input to these two neurons. A pontine inspiratory (I) neuron and a RFN IE phase-spanning neuron exhibited a peak to one side of the zero lag, suggesting an excitatory projection from the IE to the I neuron. Eighteen pairs of pontine respiratory neurons have been analyzed. One of eight pairs of I neurons exhibited a peak that straddled the zero lag, indicating a shared input. One of eight pairs of pontine IE neurons also exhibited evidence of a shared input. These preliminary data 1) show that cross-correlational analysis is sufficiently sensitive to detect interactions between distant pontine and medullary neuron pairs and 2) suggest that interactions between medullary and pontine neurons are rare, "weak", or limited primarily to specific subgroups of respiratory neurons. These data are consistent with the antidromic studies of Bianchi and St. John.

154.11 TIMING OF THE RESPIRATORY CYCLE BY STIMULATION OF THE CENTRAL NUCLEUS OF THE AMYGDALA. R.M. Harper, R.B. Trelease* and R.C. Frysinger. Dept of Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA 90024

Changes in respiratory pattern associated with different sleep-waking states or behavior reflect differences in the timing of transitions between inspiratory and expiratory phases of the respiratory cycle. The "pneumotaxic area" situated in the parabrachial pons is involved in the CNS control of respiratory phase switching, as indicated by both stimulation and lesion studies. The central nucleus of the amygdala (ACE) projects heavily to the parabrachial pons, as well as to medullary respiratory areas, and thus is a prime candidate for exerting forebrain control over respiratory cycle timing.

Anesthetized cats were prepared with bipolar stimulation electrodes in the ACE, together with EEG and EOG electrodes to assess state. Diaphragmatic electrodes were placed in the crura to record EKG and respiratory-related EMG. A pressure monitoring catheter was advanced into the aorta from the femoral artery. After 1 wk recovery, cardiorespiratory responses to both single pulse and short train electrical stimulation of the ACE were recorded in awake, undrugged, and unrestrained animals.

Short (300-500 msec) 90 Hz trains of 0.2 msec pulses produced rapid onset sustained inspiration and a rise in blood pressure. Single pulse stimulation during the expiratory phase resulted in an immediate switch to inspiration, and repetitive single pulses, close to the spontaneous respiratory rhythm, led to "paced" respiration (Fig 1); these responses occurred in the absence of a blood pressure rise. The effectiveness of a single pulse depended on its relationship to the respiratory cycle.

The ACE thus appears to be capable of altering the timing of inspiratory onset. This effect may be mediated through its anatomical relationship to the "pneumotaxic area" of the pons, or through its projections to the medulla. The widespread forebrain projections to the amygdala may thus provide considerable input from "higher" nervous structures to respiratory control systems.

Supported by HL 22418-04 and AHA-GLAA 678-IG2.

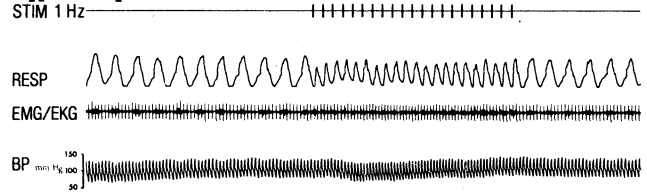

Figure 1. Repetitive single pulses of the ACE paces inspiration.

154.12 DISCHARGE OF DIAPHRAGM MOTOR UNITS DURING SLEEP. G.C. Sieck, R.B.Trelease, and R.M. Harper. Department of Anatomy and Brain Research Institute, UCLA, Los Angeles, Ca. 90024.

Diaphragm motor units are the final output of respiratory neural drive. Sleep states can markedly influence the activity of other respiratory muscles, but state influences on diaphragm motor control remains controversial. The present study examined the discharge of diaphragm motor units during different sleep-waking states in order to assess the changes in diaphragm neuromotor control. Adult cats were instrumented with electrodes for monitoring sleep-waking states (i.e., EEG, EOG, lateral geniculate nucleus activity and EKG). Pairs of insulated fine wires were inserted into costal and crural regions of the diaphragm. Recordings were obtained from unrestrained animals during quiet waking (AW), quiet sleep (QS) and rapid eye movement (REM) sleep. Motor unit signals were digitized (at 10kHz) and spike waveform and amplitude characteristics were examined. Autocorrelation histograms were calculated on discharge intervals of each motor unit. When the activity of two motor units was recorded simultaneously, cross correlation histograms were calculated to assess their discharge coupling. Repetitive patterns of motor unit discharge were observed in three general interval ranges: 1) 30-40 msec; 2) 60-70 msec; and 3) 90-110 msec. The slower periodicities (90-110 msec) were typical of crural motor units showing tonic discharge. The fastest periodicities (30-40 msec) were detected in motor units that were phasically, but inconsistently recruited with inspiration. Intermediate periodicities (60-70 msec) were detected in motor units that were phasically and consistently recruited with inspiration. During QS, periodicities were often attenuated and in some cases, the period duration slowed compared to AW and REM. Generally, recruitment was delayed during sleep states compared to AW. Most striking was the disappearance of activity of some motor units during REM sleep. During inspiration, the discharge rates of some motor units progressively increased (augmenting pattern). This augmenting pattern was slowed during QS compared to AW and REM. Cross correlations between motor unit discharges showed short-latency (<5msec) and longer latency periodic (25 to 70 msec) discharge coupling. Short-latency synchrony was not affected by state. Longer latency discharge coupling was usually attenuated during QS and the period duration was slowed compared to AW and REM. Cross-correlations further showed a constant order of recruitment of motor units during each state. These results demonstrate the pronounced influence of sleep-waking state on diaphragm motor unit recruitment and discharge.

154.13 POSTURAL EFFECTS ON INTERCOSTAL MUSCLE ACTIVITY IN SLEEP. T. Dick, P. L. Parmeggiani* and J. Orem. Dept. of Physiology, Texas Tech University Health Sciences Center, School of Medicine, Lubbock, TX 79430.

Intercostal muscle activity (IMA) has both respiratory and postural components. Some postural reflexes are suppressed in sleep. For example, righting reflexes are suppressed with the voluntary assumption of sleep postures, but we report here a dramatic, tonic, postural influence on the intercostal muscles in nonrapid eye movement (NREM) sleep.

IMA was studied in six freely moving cats. The animals had electrodes for recording the electroencephalogram, the electro-occulogram, and pontogeniculo-occipital waves as well as electromyograms from the neck and two intercostal muscles. During the 5- to 8-hr recording sessions, the animals were unrestrained within a shielded recording chamber. The data were recorded on a polygraph and an analog tape recorder. We noted the posture and movement on the polygraphic recording. We compared IMA recorded from the same muscle as the cat lay curled on opposite sides. In one position, the intercostal muscle was on the downward or convex side of the cat; in the other, the intercostal muscle was on the upward or concave side. Half-wave rectified and integrated IMA was summed over 9-s periods. A mean and standard deviation were calculated for 9-s periods while the cat lay in a given posture and stage of sleep. We tested differences between the means of IMA in the two positions using the t-test.

In NREM sleep, IMA was significantly greater in 87% (20 of 23) of the cases when the intercostal muscle was on the animal's concave rather than the convex side. This postural effect was strongest in intercostal muscles showing inspiratory activity (presumably the external intercostal muscles).

In REM sleep, the intercostal muscles, like many other muscles, are hypotonic or atonic, but some residual respiratory activity generally persists. In 69% of the cases, this residual respiratory activity was significantly greater when the muscle was on the concave side.

In conclusion, posture influences intercostal muscle activity in sleep. Cervico-labyrinthine reflexes may mediate the effects demonstrated here. Furthermore, slowly adapting, pressure receptors in the skin that inhibit ipsilateral but facilitate contralateral intercostal activity may be involved. The postural effect is often evident even in REM sleep.

154.14 PROLONGED ALTERATION OF RESPIRATORY CONTROL IN THE NEWBORN DOG AFTER CHRONIC MATERNAL HYPERCAPNIA. K.L. McGilliard*, S.E. Jones* and G.D. Olsen* (SPON: E.T. Iwamoto). Dept. of Pharmacology, Sch. of Medicine, Oregon Health Sci. Univ., Portland, OR 97201.

In previous studies, it was demonstrated that both infants and puppies chronically exposed to opiate analgesics *in utero* showed blunted ventilatory responses to CO_2 during the first few weeks of life (Olsen and Lees, J. Pediatr. 96:983, 1980; McGilliard *et al.*, Respir. Physiol. 47: in press). One possible explanation for altered respiratory control in opiate-dependent neonates is that the developing chemoreceptors were exposed to a high level of CO_2 due to the respiratory depressant action of opiates on the mother. Abnormal chemoreceptor development might then occur in a chronic hypercapnic environment. If so, exposure of the fetus to chronic hypercapnia in the absence of drugs should produce alterations in respiratory control similar to those which were opiate-induced. To test this hypothesis, a pregnant bitch was exposed to an environment of 5% CO_2, 21% O_2 from the 2nd week of gestation until parturition. Respiratory control was assessed in the offspring from birth until 6 weeks of age. In the first week of life, P_{ACO_2} and V_T of CO_2-exposed puppies were significantly lower and respiratory rate was significantly higher than control, while $\dot{V}_E$ was similar in the two groups. During the remaining 5 weeks of the studies, V_T, $\dot{V}_E$, $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ were lower than control. At the same time CO_2-response curves of CO_2-exposed puppies were significantly displaced to the right of control and slopes were decreased by at least 25%. Data obtained from 6-week-old puppies are shown below:

	Control	CO_2-exposed	
$\dot{V}_E$	420 ± 45 (SE)	340 ± 29	$ml \cdot min^{-1} \cdot kg^{-1}$
V_T	9.92 ± 0.39	7.47 ± 0.32	$ml \cdot kg^{-1}$
Rate	44 ± 5	46 ± 4	min^{-1}
P_{ACO_2}	38.2 ± 1.3	38.2 ± 1.0	mmHg
$\dot{V}_{CO_2}$	9.44 ± 0.62	7.70 ± 0.59	$ml \cdot min^{-1} \cdot kg^{-1}$
CO_2-response:			
Slope	42.4	26.3	$ml \cdot min^{-1} \cdot kg^{-1} \cdot mmHg^{-1}$
Position[1]	37.8	43.4	mmHg

[1] P_{ACO_2} when $\dot{V}_E$ = 400 $ml \cdot min^{-1} \cdot kg^{-1}$

The results suggest that *in utero* exposure to a hypercapnic environment produces significant alterations in ventilatory control in the newborn puppy. Since differences remained at the conclusion of the study, the possibility exists that prolonged or permanent disruption of normal chemoreceptor development has occurred. (Supported by USPHS, NIH Grants HD-10034, HD-07084 and HL-05918).

155.1 INFLUENCE OF FREEZE/THAW AND ACID DEPROTEINIZATION ON MEASUREMENT OF GABA IN CSF. T.N. Ferraro* and T.A. Hare, Thomas Jefferson Univ., Phila., PA 19107

CSF-neurotransmitter studies are becoming a popular method of characterizing certain neuropsychiatric disorders. Investigations of GABA levels in CSF have served as a prototype documenting the utility of this approach only after careful consideration has been given to a number of in vivo and in vitro factors which influence such determinations. Recently, two additional studies of in vitro variations influencing CSF GABA levels have been reported. Abbott et al. (J. Neurochem. 37: 1042, 1981), utilizing a radioreceptor assay, reported increases of CSF GABA levels following multiple freeze/thaw cycles. Using the confirmed ion-exchange fluorometric (I-E/F) procedure we examined the effect of multiple freeze/thaw cycles on CSF GABA levels (N=12). Results demonstrate that levels are not increased by freeze/thaw. Reported differences may be related to the release of substances interfering with the ^{3}H-muscimol binding in their assay.

Perry et al. (J. Neurochem. 38: 766, 1982), utilizing an I-E/F procedure, found that deproteinization with 0.5% sulfosalicylic acid (SSA) results in lower values for CSF GABA than those seen previously using the I-E/F procedure but following deproteinization with 5.0% SSA. They concluded that 5.0% SSA had produced elevated values via on-column hydrolysis of conjugated forms of GABA known to be present in CSF. We have systematically evaluated the effects of final SSA concentrations ranging from 0 to 10% in CSF. Prior to treatment, CSF was placed in a boiling H_2O bath for 2 min. to avoid enzyme mediated increases of GABA (Arch. Neurol. 38: 491, 1981). SSA concentrations of 0, 0.05, 0.1, 0.5 and 1.0% correlated linearly with CSF GABA values ($r = 0.99$, $p < .001$). However, concentrations greater than 1.0% produced a plateau revealing GABA values to be 1.6-fold higher than those of acid-free aliquots. Comparison of acid-free and plateau values by linear regression revealed a highly positive correlation ($r = 0.99$, $p < .001$ N=8). Thus, GABA in CSF evidently exists as free and loosely bound pools. Assuming an equilibrium between these pools, measurement of strictly free GABA would appear less likely to reflect alterations of CNS function. Therefore, it seems preferable to deproteinize CSF with final SSA concentrations greater than 1.0%.

155.2 A CENTRAL CHOLINERGIC DEFICIT IN DIETARY THIAMIN DEFICIENCY Gibson, G.E., Pelmas, C.J.* and Blass, J.P., (SPON: F. Plum) Cornell Medical College, Burke Rehabilitation Center, White Plains, New York 10605.

Thiamin deficiency impairs short-term memory in man and thus may be a useful model of the metabolic encephalopathies that lead to dementia. Previous studies demonstrated that the combination of pyrithiamin poisoning and dietary thiamin deprivation decrease the performance of rats on an elevated taut string (i.e. the tight rope test). About 40% of the treated animals had reduced scores within 2 days and severe neurological deficits by day 12 (e.g. ataxia, loss of righting reflex, death). Pharmacological manipulations of this impaired behavior suggested a central cholinergic muscarinic deficit in the early stages of thiamin deficiency. To determine whether these changes were due to an action of pyrithiamin that was unrelated to thiamin metabolism similar studies have now been done on animals with dietary thiamin deprivation.

Male Wistar rats (55-65 g) received either a thiamin deficient diet ad lib. or a complete diet (ad lib. and pair fed controls). Animals in the two control groups maintained tight rope test scores of 11 for 25 days. The thiamin deficient animals divided into a responding (i.e. scores decreased more than 4 points for 2 or more consecutive days) and a non-responding group. In 5 experiments 33% of the thiamin deficient animals ($n = 75$) were responders whose performance was significantly ($P<0.05$) lower than nonresponders after 6 days of treatment. Other neurological signs such as ataxia or loss of the Wooley-White reflex were not apparent until day 21.

Injections of thiamin or cholinergic agonists partially ameliorated these deficits. Thiamin increased scores by 2.1 ± 0.2 ($n = 10$). The cholinesterase inhibitor physostigmine (2.4 ± 0.2; $n = 36$) and nicotine (2.3 ± 0.6; $n = 12$) partially ameliorated the deficit due to thiamin deficiency. The beneficial effect of physostigmine was blocked by the central nicotinic blocker mecamylamine (0 ± 0.13; $n = 15$) and the muscarinic blocker atropine (0.1 ± 0.2; $n = 19$), but not by the peripheral muscarinic blocker methatropine (2.1 ± 0.4; $n = 15$).

Thus, dietary thiamin deficiency leads to similar behavioral changes as pyrithiamin poisoning although neurological symptoms occur only after longer treatment periods in the dietary model. Furthermore, pyrithiamin caused a central muscarinic lesion, but dietary thiamin deficiency lead to a central, cholinergic muscarinic and nicotinic deficit that appears behaviorally important. Supported in part by grants NS 15125, NS 16997, the Burke Foundation, The Brown & Williamson Tobacco Company and the Will Rogers Institute.

155.3 THE BINDING OF ^{3}H-GABA TO SYNAPTIC MEMBRANES OF SPONTANEOUSLY HYPERTENSIVE RATS. Godfrey Tunnicliff* (SPON: G.K. Matheson). Laboratory of Neurochemistry, Indiana University School of Medicine, Evansville, IN 47712.

Evidence that central nervous system GABA mechanisms are involved in the regulation of blood pressure comes from various sources. For instance, the administration of GABA or certain of its agonists either directly or intracerebrally produces decreases in arterial pressure. Bicuculline can reverse this effect. On the other hand, sub-convulsive doses of antagonists of GABA tend to cause an elevation of blood pressure. In light of these observations both sodium-independent and sodium-dependent binding of ^{3}H-GABA to synaptic membranes prepared from the brain of spontaneously hypertensive rats (SHR) were measured and the results compared to those obtained from Wistar-Kyoto (WKY) controls.

The greatest effects were seen in the cerebral cortex and the data are shown in Table 1:

Table 1. ^{3}H-GABA Binding to Cortical Synaptic Membranes.

Strain	n	Na^+-independent	Na^+-dependent
WKY	5	2.5 ± 0.2	81 ± 9.5
SHR	5	1.8 ± 0.2	62 ± 7.0

Binding units are pmol/mg protein.

A 28% decrease in sodium-independent (receptor) binding and a 23.5% decrease in sodium-dependent binding was obtained in the hypertensive animals. A Scatchard analysis of the binding data revealed that in both cases the reduction in binding was the result of fewer binding sites rather than to differences in affinity constants.

These results are consistent with the evidence that a reduced GABA neuronal activity is related to increases in blood pressure and possibly to the development of hypertension.

155.4 β-ADRENERGIC RECEPTOR COUPLED ADENYLATE CYCLASE IN NORMAL AND DYSTROPHIC CHICK PECTORALIS. J. E. Steiss, B. L. Raney*, R. Dulos* and P. V. Sulakhe. Dept. of Physiol., Col. of Med., Univ. of Sask., Saskatoon, Canada, S7N 0W0.

This study was undertaken to determine whether muscle sarcolemmal bound, β-adrenergic receptor-linked adenylate cyclase system is affected in the very early stages of muscular dystrophy. We chose the genetically dystrophic chick as a model in which the superficial pectoral muscle becomes dystrophic around the post-hatch age of 4 weeks. We investigated the activities of adenylate cyclase (AC) in the absence and presence of AC activators (NaF, Gpp(NH)p and isoproterenol), the number of receptors (β-AR) by using [^{3}H]-dihydroalprenolol (DHA) binding assay and cholera toxin dependent ribosylation of G/F proteins that mediate the coupling between β-AR and AC. Pectoralis (PT) was obtained from embryos (normal (N) and dystrophic (D)) incubated for varying periods (11 d to 19 d) and from hatched chicks (1 d to 14 d). The following major observations were made: Basal AC of N-PT, prior to hatching, was greater (2- to 3-fold) than of D-PT; post-hatch basal AC activities of N- and D-PT were similar. On the other hand, fold-stimulations by NaF, Gpp(NH)p and isoproterenol + Gpp(NH)p of the basal AC were greater for D-PT compared to N-PT at various pre- and post-hatch periods examined. The total number of β-AR in N- and D-PT steadily increased, reaching a plateau around 6 d post-hatch. There was no significant difference in the receptor number (expressed as fmol/mg protein) between N- and D-PT except at 14 d post-hatch, in which case D-PT had a greater number of β-AR. Two polypeptide regions corresponding to 55K and 50K dalton were labelled following incubation of muscle homogenate with ^{32}P-NAD and cholera toxin. This was examined in 19 d embryos and 14 d hatched chicks. ADP-ribosylation of both polypeptide regions was higher (2- to 3-fold) in D-PT relative to N-PT. We concluded that the observed greater stimulation of AC in D-PT by NaF, Gpp(NH)p and isoproterenol results from either an increased amount of G/F coupling proteins or greater efficacy of coupling between the β-AR and AC. Our results also show that the G/F protein-requiring coupling process is affected at early stages of muscle development in the genetically dystrophic chick.

JES is a Post-Doctoral Fellow of MRCC; this work is supported by a grant from MDAC to PVS.

155.5 ADRENERGIC, OPIATE AND BENZODIAZEPINE RECEPTOR BINDING STUDIES IN DYSTROPHIC MOUSE BRAIN. M. Wilkinson, Diane Wilkinson* and R. Bhanot. Depts. Physiol. Biophys. & Obst. Gynaecol., Dalhousie University, Halifax, Nova Scotia, Canada.

In addition to muscular symptoms, myotonic dystrophy is characterised by CNS abnormalities such as gross structural changes, disturbances in sleep-related growth hormone secretion, and depressive illness. In dystrophic (dy) mice, spontaneous seizures and unusual calcium ion accumulation by brain mitochondria have been described. We have now investigated whether the CNS of dy mice demonstrates changes in neurotransmitter receptor binding when compared with the brains of control mice. We examined brain tissue from male 129/ReJ-dy (5-7 weeks old) and female 129 $B6F_1$/J-dy (6 months old) mice, together with their respective controls. Crude P_2 membranes were prepared by standard methods. Receptor binding assays were performed as reported (Wilkinson & Grovestine, Can. J. Physiol. Pharmacol. 59 504, 1981). β-adrenergic ([^{3}H]-dihydroalprenolol) binding was significantly reduced (Scatchard analysis) in whole brain (less cerebellum; -37%), cerebral cortex (-18%) and cerebellum (-35%) of male dy mice. Whole brain binding in female dy mice was reduced by 24%. There was no change in binding affinity (K_D) in any brain area. Benzodiazepine ([^{3}H]-flunitrazepam) binding sites in whole brain and cerebellum of male and female dy mice appeared normal. In addition, the stimulatory effects of GABA (10^{-4}M) on benzodiazaepine binding was identical in dy and control membranes.

Opiate ([^{3}H]-naloxone) binding was also unaffected in whole brain of male 129/ReJ-dy mice (5 weeks old) and in forebrain (less cerebellar and cerebral cortex) of female 129 $B6F_1$/J-dy mice (3 months old). In view of the changes observed in β-adrenergic binding sites we have also examined the binding of an α-adrenergic ligand ([^{3}H]-dihydroergocryptine). Single point assays (1.5nM) revealed that in forebrain of 129 $B6F_1$/J-dy females the number of α-adrenergic sites was reduced by 30% whereas in cerebral cortex the number was unchanged.

In conclusion, there appears to be a specific reduction in the number of adrenergic binding sites in dystrophic mouse brain. This alteration may be related to the known abnormally high excretion of catecholamines. Our results reemphasise the need to study extra-muscular membrane sites in this disease.

Supported by Muscular Dystrophy Association & MRC of Canada.

155.6 A SPONTANEOUS AND IRREVERSIBLE ANIMAL MODEL RESEMBLING HUNTINGTONS DISEASE (HD): BEHAVIORAL AND BIOCHEMICAL CORRELATES. A. Hitri*, R.L. Borison and B.I. Diamond, Psychiatry Department, Medical College of Georgia and Downtown V.A., Augusta, GA, 30912.

We and others have previously shown that the administration of β,β-iminodipropionitrile (IDPN) to various animal species for seven days produces head and neck choreatic movements. These movements resemble those observed in hyperkinetic movement disorders and are preferentially antagonized and exacerbated by dopamine antagonists and agonists respectively. In the present studies we examined the underlying biochemical correlates of this behavior. Male Sprague-Dawley rats (200-250 g) were administered IDPN (75 mg/kg, i.p.) daily for seven days and behavior quantitated over the ensuing month. Rats were sacrificed, brains removed, and the caudate nucleus dissected out. Striatal tissue was assayed for dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), 3-methoxytyramine (3MT) and homovanillic acid (HVA) levels spectrofluorometrically, using the technique of Westerink and Korf (1975). DA receptor binding studies (using tritiated spiroperidol as the ligand) were also measured in striatal tissue by the modified method of Fields et al. (1977). Seven day IDPN administration to rats produced head and neck choreatic movements that lasted until sacrifice (one month), and in other animals at least for three months. These movements were persistent and spontaneous during this period and disappeared during sleep. Striatal DA, DOPAC, 3MT and HVA levels were significantly decreased from saline control animals. However, DA release, as measured by the 3MT/DA ratio, was increased over control values. The spiroperidol binding to striatal tissue in control animals exhibited two binding sites, one with a K_d of 103 pM and the other with a K_d of 1.62nM. The number of receptors associated with the high affinity site was 14.9 fmoles/mg tissue, and the low affinity site contained 67.5 fmole/mg tissue. IDPN treatment eliminated the specific binding for the low affinity site and significantly reduced the number of receptors at the high affinity site (1.08 fmole/mg tissue). The loss and reduction of DA receptors, together with the increased release of DA (although levels are falling), resemble the biochemistry of the DA system in HD, as well as much of that observed in the kainic acid model of HD. However, the kainic acid model fails to pharmacologically mimic the behavior of HD due to the necessity of using a DA agonist, and therefore appropriate pharmacologic testing may be misleading; this problem appears to be avoided in the IDPN model, suggesting its greater suitability as a pharmacologic model.

155.7 DOPAMINE RECEPTOR BLOCKADE OF AMOXAPINE: COMPARISON OF GC 8-OH AMOXAPINE PLASMA LEVELS AND DOPAMINE RADIORECEPTOR ACTIVITY. A.L.C.Pottash[1], T.E.Barker*[2], F. Goggans*[2], D.M.Martin*[1], A.W.Caswell*[1], M.S.Gold[1]. Psychiatric Diagnostic Laboratories of America and Research Facilities, Fair Oaks Hospital, Summit, NJ;[1] and Psychiatric Institute of Fort Worth, Fort Worth, Texas.[2]

Amoxapine is a new subclass of tricyclic antidepressant designated chemically as 2-chloro-11-(1-piperazinyl) dibenz (b,f)(1,4) oxazepine. Antidepressant activity of amoxapine is related to the blockade of Norepinephrine and Serotonin. There are two major metabolites, 7-OH-Amoxapine and 8-OH-Amoxapine and it appears that these metabolites are responsible, more so than the parent compound, for pharmacological effects. 8-OH-Amoxapine is comparable to the parent compound's Norepinephrine reuptake blocking properties, however it is extremely potent on serotonin reuptake blockade. It has been demonstrated that 7-OH-Amoxapine has significant dopamine receptor blockade in laboratory animals and as such its dopamine (DA) blocking and neuroleptic activity in humans should be studied. We have recent data in amoxapine treated humans which demonstrates potent DA blocking effects in some patients and negligible effects in others. Plasma samples were obtained on thirty (30) patients maintained on amoxapine therapy for at least three (3) weeks. Plasma was assayed for 8-OH-Amoxapine by gas liquid chromatography and for dopamine receptor blocking activity by a Radio Receptor Assay (RRA). Significant dopamine blocking activity was noted by RRA in samples independent of plasma 8-OH-Amoxapine level. 7-OH-Amoxapine concentrations correlate with dopamine blocking activity by RRA. High concentrations of 7-OH-Amoxapine and RRA activity may be correlated with akathisia, E.P.S., galactorrhea, antipsychotic efficacy. Implications of these data, RRA level versus side effect ratings will be discussed. Occasional patients who are administered this compound on a chronic basis form high amounts of 7-OH-Amoxapine and who have high amounts of DA blocking activity may be at risk for tardive dyskinesia.

155.8 THE EFFECTS OF TRIMETHYLTIN ON DOPAMINERGIC AND SEROTONERGIC FUNCTION OF THE CENTRAL NERVOUS SYSTEM. D.L. DeHaven, T.J. Walsh* and R.B. Mailman. Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514 and Neurotoxicology Div., HERL, US EPA, Research Triangle Park, NC 27711

Trimethyltin (TMT) is a neurotoxic organometal which produces selective lesions in the limbic system, in particular the pyramidal cell fields of the hippocampus (Brown et al., Am. J. Pathol., 97:59, 1979). Acute administration of this compound also produces such behavioral effects as increased locomotor activity, hyperreactivity, and memory deficits in a variety of paradigms (Walsh et al., Neurobehav. Toxicol. Teratol., 4:177, 1982). The present studies provided neurochemical data relevant to those behavioral and pathological changes. Functional changes in dopamine (DA) and serotonin (5-HT) systems were determined by measuring the effects of TMT on concentrations of DA, 5-HT and their metabolites in brain. Male Long-Evans hooded rats (ca. 120 days old) were administered TMT hydroxide (3 or 7 mg/kg, IG) or vehicle (0.9% saline) and sacrificed for neurochemical analysis 7 days later. From each brain, the striata, olfactory tubercles, nucleus accumbens, and hippocampus were dissected and analyzed for dopamine, serotonin and their acidic metabolites, DOPAC, HVA and 5-HIAA by HPLC with EC detection (Kilts et al., J. Chromatog., 225:347, 1981). In some animals Scatchard analyses of the binding of ^{3}H-spiperone to individual striata were also performed using (+)-butaclamol to assess non-specific binding. The results of these experiments revealed that TMT had no effects on the affinity or number of ^{3}H-spiperone receptors in the striatum and did not alter the concentration of DA or its metabolites in any region examined. Although serotonin concentrations were not significantly altered, both 5-HIAA concentrations and the 5-HIAA/5-HT ratio were increased. Since the ratio of 5-HIAA/5-HT is an estimate of serotonin turnover, this suggests that increases in 5-HT turnover result from TMT treatment of adult rats. This effect of TMT on serotonergic function suggests that this neurotransmitter may be involved in the behavioral sequelae resulting from TMT-induced neurotoxicity. (Supported in part by NIH Grants ES-01104 and HD-03110 and EPA C R809644010).

155.9 OPEN TRIAL OF CLONIDINE IN DYSTONIA MUSCULORUM DEFORMANS. Donald Kay Riker, Howard Hurtig*, C. Raymond Lake, Paul Copeland*, and Robert Roth. Depts. Pharmac. & Psych., Yale Univ. Sch. Med., New Haven, CT; Depts. Neurol. & Medicine, Hosp. Univ. Penn., Phila., PA; Dept. Psych., Unfrm. Serv. Univ. Health Sci., Bethesda, MD.

Dystonia musculorum deformans (DMD) is an inherited movement disorder which provokes powerful movements and postures of limbs, neck, or trunk. Its etiology and progression are uncertain. Pathology and therapeutics have failed to suggest a mechanism or treatment. High levels of plasma dopamine-beta-hydroxylase and norepinephrine (NE) have been reported in DMD (New Eng J Med 288:284,1973; Adv Neurol 14:307,1976). To support these data we assayed NE levels in plasma and CSF, and assessed the efficacy of clonidine (C), a drug known to reduce NE metabolism.

Non-Jewish, sporadic patients were admitted to the Clinical Research Center at H.U.P. Five patients had rostral-segmental dystonia with torticollis. Four patients exhibited generalized dystonia (onset before 21). Diet was devoid of amines and stimulants. Dystonia was rated daily (0-5) in each body part. Blood was drawn through in-dwelling lines at 0800hrs in supine and standing position (2 hours after C). Lumbar puncture was performed the morning after each admission; patients later began C (50or100ug tid p.o.). After 3-11 days patients returned home on this dose (10-17days). If readmitted C was raised daily (max=1.5mg/day). Plasma/CSF NE, 3-methoxy-4-hydroxyphenethylene glycol (MHPG), and homovanillic acid (HVA) were assayed.

Patients presented with plasma NE values (Supine=550-1837; Stand=1086-5094pg/ml) above +1SD and up to 9-fold the normal mean (Supine:292+1SD=430; +2SD=568; Stand:538+1SD=830; +2SD=1122pg/ml). CSF NE values (465-921pg/ml) were above +1SD and up to 3.5-fold the normal mean (251+1SD=414;+2SD=577pg/ml). Plasma MHPG (1.95-5.67ng/ml) was within ±2SD's of normal mean (3.44±1.54ng/ml); most CSF MHPG values (5.54-11.76ng/ml) were below the normal mean (10.93±2.71ng/ml). Except for one hypertensive, no dysautonomia was noted. C reduced plasma & CSF NE to within, or below, normal limits dependent on dose. Plasma & CSF MHPG were weakly responsive; plasma HVA reacted transiently to dose shifts. However, C did not improve generalized dystonia. Segmental patients claimed transient worsening or improvement at low-doses. Simple torticollis in one patient did resolve.

In summary: 1) increased central (CSF) and peripheral (plasma) NE is a sign of DMD; 2) reduction of NE hypermetabolism does not reduce generalized dystonia. Reducing NE metabolism is likely to benefit only if increased metabolism were responsible for disorder, not if it is compensatory.--Supported by the Dystonia Medical Research Foundation, Beverly Hills, CA

155.10 EFFECTS OF ACUTE AND CHRONIC LITHIUM TREATMENT ON SEROTONIN UPTAKE IN BLOOD PLATELETS OF MANIC-DEPRESSIVE PATIENTS. R. C. Arora, P. J. Goodnick* and H. Y. Meltzer. Ill. State Psychiatric Institute and the Department of Psychiatry, Univ. of Chicago Pritzker School of Medicine, Chicago, IL. 60637.

A decrease in the Vmax (a measure of the number of uptake sites) of serotonin (5-HT) uptake in the blood platelets of patients with bipolar or unipolar depressive disorders has been reported by many investigators. This decrease is present during the acute phase as well as after recovery and appears to be a marker for vulnerability to develop depression or mania. While most first generation antidepressant drugs other than monoamine oxidase inhibitors decrease 5-HT uptake, the effect of acute or chronic treatment with lithium carbonate (Li) on human platelet, as on rodent brain 5-HT uptake, has been controversial with some studies reporting no effect and others significant decreases or increase.

Platelet 5-HT uptake was studied in patients with affective disorders at the onset of an acute episode, while on placebo, after 2-4 weeks of Li treatment and again after 1 year or more of Li treatment. The method used has been described earlier (Arora, R.C. and Meltzer, H.Y., Clin. Chim. Acta., 112:225, 1981). Unmedicated bipolar patients had significantly decreased Vmax (9.4 ± S.D. 2.0 pmoles/10^7 platelets/min. in 21 bipolar patients vs 11.9 ± S.D. 2.5 pmoles/10^7 platelets/min in 37 normal controls (p .005). The mean Vmax decreased further after 2-4 weeks of Li treatment in 14 manic patients (from 9.52 ± S.D. 2.0 pmoles/10^7 platelets/min to 7.44 ± S.D. 1.9 pmoles/10^7 platelets/min, $p < .005$). Vmax decreased in 11 of 14 manic patients and the mean decrease was 33% (range 12-50%). Six of these patients were restudied after 12 or more months of the continuous Li treatment. In 3 of these 6 patients, Vmax increased by 100% or more. A total of 14 patients treated with Li for more than one year, were also studied. Vmax was 17.00 ± S.D. 6.43 pmoles/10^7 platelets/min which was significantly greater than the Vmax of unmedicated bipolar patients or normal controls. Thus, our results indicate that Li produces time dependent changes in the Vmax in platelet uptake in most, but not all patients. If this also occurred in brain, it could be related to the sometimes rapid onset antimanic effects of Li treatment and the more slowly developing prophylactic effects of Li treatment on recurrent unipolar or bipolar disorders (Supported in part by USPHS MH 30059 and MH 25116).

155.11 AUTORADIOGRAPHS OF PARKINSONIAN VS. NORMAL HUMAN STRIATUM SUGGEST THAT HUMAN NIGROSTRIATAL DOPAMINE TERMINALS BEAR MANY TYPES OF BRAIN RECEPTORS. A. Larsen*, D. Calne, R. Quirion, M. Herkenham and C.B. Pert. National Institute of Mental Health and National Institute of Neurological and Communicative Disorders and Stroke, Bethesda, MD 20205.

It has been elegantly demonstrated that Parkinson's Disease is associated with the degeneration of dopaminergic cell bodies in the substantia nigra and dopamine loss from the terminals of the striatal projections (Bernheimer et al., 1973; J. Neurolog. Sci. 20:415-455). A careful study of the cellular elements of normal vs. parkinsonian and male vs. female striata has failed to demonstrate any significant differences (Bottcher, Acta Neurologica Scand. 1975, 52, suppl 62, 1-87).

Over the last two years, we have subjected the striata of 5 parkinsonian patients and 6 non-parkinsonian patients to a procedure which autoradiographically visualizes brain receptors (Herkenham and Pert, J Neurosci., in press). We have experienced the usual difficulties in finding control and unequivocally diagnosed diseased brains which are well-matched for age, time elapsed from death to autopsy and all steps of subsequent processing.

Recently, we (A.L.) had the opportunity to obtain at autopsy a striatum from our 60-year-old NIH female patient who died from a pulmonary thromboembolism after suffering from Parkinson's Disease unresponsive to L-DOPA for four years, having reached the most severe stage (Hoehn and Yahr V) of extreme rigidity at the time of her death, which occurred 18 hours before autopsy. A striatum from a 68 year old male NIH patient who died from sepsis from aplastic anemia almost 23 hours before autopsy provided a well-matched control, biased, if at all, against the direction of the results we expected from previously examined, less well-matched material. Striata were frozen on dry ice immediately after removal and maintained at -70°C until cryostat sectioning. All storage, cutting, and subsequent receptor labeling and analysis was conducted in parallel.

Our previous impressions were confirmed in this well-controlled study: the parkinsonian striatum contained substantial (26-58%) losses in ^{3}H- diazepam, naloxone, spiperone, D-Ala-DLeu enkephalin and neurotensin binding, labeled under well-characterized receptor-related conditions. Cortically localized beta-adrenergic receptor levels were not significantly different. Visualization of these patterns of receptor loss will be presented. Like rat (e.g., see Bowen et al. and Quirion et al, this meeting), human nigrostriatal projections seem richly encrusted with numerous brain receptors offering great potential for endogenous modulatory control and exogenous therapeutic manipulation.

155.12 IMMUNOREACTIVE VASOACTIVE INTESTINAL PEPTIDE IN CEREBROSPINAL FLUID. N.S. Sharpless, L.J. Thal*, M.J. Perlow, K. Tabaddor*, J. Waltz*, K. Shapiro*, J. Engel, Jr. and P.H. Crandall*. Albert Einstein College of Medicine, Bronx, NY 10461

Vasoactive intestinal peptide (VIP) is localized in the synaptosomal fraction of mammalian central nervous tissues suggesting a role for VIP in neurotransmission. To gain insight into the relationship between VIP and neurological disease, we used a sensitive radioimmunoassay to measure VIP concentrations in lumbar and ventricular cerebrospinal fluid (CSF) from patients with various neurological disorders and in 2 hr aliquots of cisternal fluid removed continuously from rhesus monkeys. Aliquots of CSF (400 µl) were incubated 24 hr at 4° C with 300 µl of phosphate buffer (0.06 M, pH 7) containing albumin (1.5%), aprotinin (2000 KIU/ml), and rabbit antiserum to VIP (donated by G. Nilaver). ^{125}I-VIP (100 µl) was then added and the mixture was incubated at 4° C for 3 more days. Antibody-bound and free ^{125}I-VIP were separated with 10 mg of dextran coated charcoal. A standard curve was generated by analyzing synthetic porcine VIP (0.5 to 100 fmol) in artificial CSF. The limit of sensitivity of the assay was 2.5 fmol per ml of CSF. Dilution curves of VIP-like immunoreactivity in human CSF and of synthetic porcine VIP added to artificial or human CSF were parallel. VIP in concentrated pools of human ventricular CSF and of monkey cisternal CSF co-eluted with synthetic porcine VIP on a column of Sephadex G-25. In the monkeys, a circadian pattern of CSF VIP concentration was observed in 2 of 3 animals, with highest levels occurring at night and lowest during the day. VIP levels were similar in the first and last 6 ml of a total of 24 ml of CSF withdrawn from the lumbar region of 3 Alzheimer patients and in samples of ventricular and lumbar CSF from the same seizure patients, indicating that there is no significant craniocaudal CSF VIP concentration gradient. Nevertheless, mean VIP levels were slightly higher in lumbar CSF from patients with multiple sclerosis (6.5 fmol/ml;N=12), Alzheimer's disease (8.7 fmol/ml;N=8), epilepsy (8.9 fmol/ml;N=10), and a mixed group of patients with various disorders (9.5 fmol/ml;N=29) than in ventricular CSF from patients with multiple sclerosis (4.4 fmol/ml;N=11), dystonia (5.6 fmol/ml;N=13), Parkinson's disease (5.4 fmol/ml; N=15), or epilepsy (4.5 fmol/ml;N=8). Highest ventricular fluid VIP concentrations were seen in hydrocephalic children before shunt insertion and lowest in patients with acute cerebral trauma. The mean concentration of VIP was significantly decreased in lumbar CSF from patients undergoing aneurysm surgery. The results suggest that there are differences in CSF VIP concentrations in different patient populations which may provide insight into the underlying nature of their disorder. (Supported by NIH grant NS-09649 and by a grant from the Dystonia Medical Research Foundation).

155.13 GROWTH HORMONE RESPONSES IN UNTREATED HUNTINGTON'S DISEASE PATIENTS: EVIDENCE FOR DIFFERENT SUBGROUP POPULATIONS. A. Martinez-Campos+, P. Giovannini+, G. Scigliano+, A. Novelli+, E.A. Parati, T. Caraceni+ and E.E. Müller+. Department of Pharmacology, University of Milan, Istituto Neurologico "C. Besta", Milan, Italy.

Evidence has been provided for the existence of an altered growth hormone (GH) responsiveness to dopaminergic (DA) stimuli in patients with Huntington's Disease (HD), though contradictory findings have been reported in the literature. Previously, we demonstrated GH hyperresponsiveness to the DA agonists bromocriptine, apomorphine and l-dopa in most of 30 HD patients washed out of therapy (Müller et al., Adv. Neurol. 23: 319, 1979). These findings were at variance with reports by others of GH hypo-normo responsiveness to the same drugs in HD patients clinically undistinguishable from ours.

In this study we decided to re-evaluate this problem in a group of 12 untreated HD patients with the use of bromocriptine (Parlodel, Sandoz, 2.5 mg orally) and/or lisuride (Dopergin, Schering, 0.2 mg orally), an ergoline derivative with potent DA-mimetic properties. Baseline GH levels were not significantly different in patients or sex-and-age-matched controls. Of the 12 patients investigated, lisuride induced a significantly lower GH response than in controls in 6, a normal GH response in 3 and a significantly greater GH response in 3 subjects. Bromocriptine, administered to 7 of the same subjects elicited GH responses qualitatively superimposable to those induced by lisuride (GH hyporesponsiveness in 4, normoresponsiveness in 2 and hyperresponsiveness in 1 subject). In addition, application of a potent and long-acting met-enkephalin analogue (FK 33-824, Sandoz, 0.5 mg/ iv), which to increase GH secretion requires, at least partly, the integrity of hypothalamic DA function, reiterated the findings obtained with the DA agonists. Three of the bromocriptine and lisuride hyporespnders were FK 33-824 non-responders, while 3 bromocriptine and lisuride normoresponders had a proper GH response to the opioid peptide. In individual patients GH responsiveness to DA agonists was unrelated to the clinical parameters considered (age, dementia, duration and/or severity of the disease, hyperkinesia, emaciation).

These data obtained in untreated HD patients demonstrate that: 1) the pattern of GH responsiveness to DA-mediated stimuli does not accur at random but is reproducible and reflects in many subjects the existence of a disturbed DA control of GH secretion; 2) HD subjects, though clinically indistinguishable one from another can be divided into subgroups according to a neuroendocrine index.

155.14 DECREASED BRAIN DOPAMINE SYNTHESIS RATE IN STREPTOZOTOCIN-DIABETIC RATS. C. D. Himmel* and M. E. Trulson (SPON: R. Stillman). Lab. for Neurobiology, Univ. of Texas at Dallas, Richardson, TX 75080.

Glucose administration completely suppresses the discharge rate of dopamine-containing substantia nigra neurons in rats (C. F. Saller and L. A. Chiodo, Science, 210, 1980, 1269), but it is not known whether hyperglycemia alters central dopamine metabolism. Accordingly, we investigated the rate of dopamine synthesis in diabetic rats with blood glucose levels 5-6 times higher than those in normal rats. Female Sprague-Dawley rats were made diabetic by injections of streptozotocin (75 mg/kg, i.p.) dissolved in citrate buffer (pH 4.5), while control rats received injections of buffer only. Diabetes was verified by glucosuria and hyperglycemia. Rats were maintained on ad libidum food and water for 4-6 weeks after induction of diabetes, and then killed by decapitation for neurochemical analysis. In insulin replacement studies, diabetic rats (4-6 weeks after streptozotocin) were administered protamine zinc insulin (4 IU/kg, s.c.) every 12 h for 10 consecutive days prior to the time of assay. Control and diabetic rats were administered a decarboxylase inhibitor (RO4-4602, 800 mg/kg, i.p.) and subgroups of rats were killed for assay of L-3,4-dihydroxyphenylalanine (DOPA) in the corpus striatum and limbic forebrain (nucleus accumbens, olfactory tubercle, and frontal cortex) 0, 30 or 60 min later. The tissues from 3 rats were pooled for all assays, and DOPA was measured spectrofluorimetrically after isolation by ion-exchange chromatography. DOPA accumulation was significantly decreased by 43.2% in the corpus striatum (2.25 $\pm$ 0.09 nmol/g/h) as compared to vehicle control (3.96 $\pm$ 0.11 nmol/g/h) and by 30.4% in the limbic forebrain (2.24 $\pm$ 0.10 vs 3.22 $\pm$ 0.12 nmol/g/h in the vehicle control). Mean blood glucose levels for all diabetic rats was 594.1 $\pm$ 13.3 mg% as compared to 99.8 $\pm$ 4.4 mg% for vehicle controls. Insulin replacement therapy restored both DOPA accumulation and blood glucose levels to normal. Receptor binding studies revealed that the B_{max} of ^{3}H-spiroperidol binding in the corpus striatum was significantly increased by 34.6% in diabetic rats (28.8 $\pm$ 0.9 pmol/g) as compared to vehicle controls (21.4 $\pm$ 1.2 pmol/g). These data confirm a previous report (Lozovsky, et al., Science, 214, 1981, 1031). We also observed a significant increase in ^{3}H-spiroperidol binding of 32.0% in the limbic forebrain (16.1 $\pm$ 0.9 pmol/g) as compared to vehicle control (12.2 $\pm$ 1.1 pmol/g). These changes in receptor binding were also restored to normal by insulin replacement therapy on the treatment regimen described above. These data demonstrate that the in vivo rate of dopamine synthesis is reduced in untreated diabetic rats. Furthermore, these changes are apparent in both the nigral-striatal and meso-limbic dopamine systems. The increased dopamine receptor binding may be a compensatory mechanism to offset the decreased dopamine synthesis rate.

155.15 ENZYMATIC DECONJUGATION OF CATECHOLAMINES (CA) IN HUMAN AND RAT PLASMA AND RED BLOOD CELLS (RBC). S. Yoneda* N. Alexander, N. Vlachakis* (SPON: B. Newman) Univ. So. Cal. Sch. of Med. Los Angeles, CA 90033

The evidence that conjugated CA may be converted to free CA (Buu & Kuchel, Life Sci. 24:783, 1979) and that they represent a large proportion of the pool of released CA indicates the potential physiological significance of conjugated CA. We have developed a new enzymatic method for hydrolysis of conjugated CA. Our method hydrolyses both sulfate and glucuronide conjugation of CA completely and is applicable not only to plasma but also to RBC whose conjugated CA cannot be measured by acid hydrolysis (unpub. obs.). Furthermore, the method is more reliable, sensitive and simpler than acid hydrolysis or lyophilization, because it has better and more consistent recovery of internal standards, lower blanks and no added steps for hydrolysis. In our study the CA results obtained by enzymatic hydrolysis were compared to those of acid hydrolysis plus heating (95°C) with a radioenzymatic assay. Plasma total CA and conjugated CA are expressed in pg/ml and % (mean+SEM), respectively, and RBC values are shown in parenthesis:

HUMAN (n=6)		NOREPI (NE)	EPI (E)	DOPAMINE (DA)
Enzy.	Total	1733±145(866±88)	294±18(292±46)	4076±482(274±659)
Hydr.	Sulf.C.	67±1 (42±5)	85±3 (62±4)	99.2±0.3(100)
	Gluc. C.	6±1 (0)	3±1 (0)	0.5±0.1(0)
Acid	Total	1354±167	226±16	4490±529
Hydr.	C.	65±2	86±3	99.7±0.2
RAT (n=5)				
Enzy.	Total	563±40	119±21	1762±264
Hydr.	Sulf.C.	41±1	14±5	8.6±1.8
	Gluc. C.	8±3	27±2	90.6±1.7
Acid	Total	443±36	138±38	314±54
Hydr.	C.	33±7	40±10	95.3±2.2

In human plasma, CA are conjugated almost entirely with sulfate while in rat plasma, glucuronides are the main conjugates of E and DA but not NE. Acid hydrolysis of rat plasma is significantly less than by enzymatic hydrolysis (p 0.01), which may reflect high stability of glucuronide CA conjugation. In human RBC, free NE and E is higher than in plasma (Alexander et al., Life Sci. 29: 471, 1981) however, conjugated NE and E are lower in RBC than in plasma (NE, p 0.001; E, 0.1 0.05). The direct evidence presented here of RBC sulfate conjugates along with reported RBC sulfotransferase activity, indicates that RBC are a site of sulfate conjugation for CA.

156.1 ENDOGENOUS PROTEIN PHOSPHORYLATION IN CHICK AND RAT SYNAPTIC MEMBRANES. R.G. Sorensen* and J.A. Babitch. Chemistry Dept., Texas Christian Univ., Ft. Worth, TX 76129.

We have compared the cAMP-mediated and Ca^{2+}-mediated protein kinase (PK) activities endogenous to synaptic membranes prepared by an identical procedure from chick (avian) and rat (mammalian) brain. Both species showed similar responses towards the protein kinase effector molecules, cAMP and Ca^{2+}. Half-maximal stimulation ($K_{0.5}$) of cAMP-PK activity occurred at 0.4-0.8 µM cAMP. The $K_{0.5}$ of Ca^{2+}, CaM-PK activity occurred at 1-2 µM Ca^{2+}_{free} both in the absence or presence of CaM added to the reaction mixture suggesting that the CaM present in these membranes was able to modulate Ca^{2+}, CaM-PK activity. After EGTA-treatment to remove the endogenous CaM, no significant response towards Ca^{2+} was measured in the absence of CaM and the $K_{0.5}$ was increased to 15 µM Ca^{2+}_{free} in the presence of CaM. There was a difference in the maximal levels of kinase activity in these membranes with chick membranes containing 57% less cAMP-PK activity, but 65% more Ca^{2+}, CaM-PK activity than the rat membranes as measured by liquid scintillation counting of ^{32}P in gel slices cut from the polyacrylamide gels used to separate the labelled membrane polypeptides. Similar results were determined when either low (5 µM) or high (5.8 mM) concentrations of ATP were added to the reaction mixtures.

Besides certain species differences in the molecular weights of the resulting phosphoproteins, we observed several major differences with respect to the absence or presence of some of the phosphoproteins. Chick membranes lack the cAMP-requiring, microtubule-associated phosphoprotein, MAP_2, and one of the 2 neuron-specific, cAMP-requiring and Ca^{2+}, CaM-requiring phosphoproteins (Protein Ib, although Protein Ia is present), and the Ca^{2+}-requiring, CaM-independent, ACTH-sensitive phosphoprotein, B50.

Several effector substances were tested for their ability to modulate Ca^{2+}, CaM-PK activity of both membrane preparations. The phenothiazines, TFP, FLU and CPZ, all inhibited this activity and the inhibition appeared to be specific towards CaM because the phenothiazine analogue, CPZ-sulfoxide, had no effect on Ca^{2+}, CaM-PK activity. Also found to inhibit Ca^{2+}, CaM-PK activity were dibucaine and ACTH.
(Supported by Research Grant NS-12485-07 from NIH.)

156.2 ANALYSIS OF GLUCOCORTICOID AND CYCLIC AMP EFFECTS ON PROTEIN EXPRESSION AND PHOSPHORYLATION IN HIPPOCAMPAL SLICES USING TWO-DIMENSIONAL GEL ELECTROPHORESIS. A.M. Etgen and E.T. Browning. Dept. Biol. Sci., Rutgers Univ., New Brunswick, NJ 08903 and Dept. Pharmacol., Rutgers Med. School, Piscataway, NJ 08854.

Steroid hormones and cyclic nucleotides regulate many intracellular events in the nervous system, including protein expression and phosphorylation. Since the hippocampus is the primary CNS target for glucocorticoids and since the electrophysiology of hippocampal slices has been extensively investigated, we utilized 2-dimensional polyacrylamide gel electrophoresis (2-D PAGE) to examine the effects of corticosterone (CORT) and cyclic AMP (cAMP) on protein expression and phosphorylation in rat hippocampal slices. Analysis of Coomassie- and silver-stained gels from slices indicated that the protein patterns were indistinguishable for slices derived from left vs right and dorsal vs ventral hippocampus. Exp.1 examined the effects of cAMP and CORT on protein phosphorylation. Transverse hippocampal slices were prepared from gonadectomized, adrenalectomized adult female Sprague-Dawley rats which had (+CORT) or had not (-CORT) received steroid replacement via 5 mm Silastic implants (cholesterol:CORT, 1:1). Single slices (+ and -CORT) were incubated in low phosphate (0.2 mM) Yamamoto's medium for 3 hr with ^{32}Pi. Slices from +CORT animals were incubated with 10 nM CORT. cAMP synthesis was stimulated during the final 20 min by 20 uM forskolin, which directly activates most, if not all adenylate cyclases. cAMP levels in slices were measured using a modified Gilman binding assay. In the absence of forskolin, all slices had similar cAMP levels regardless of steroid treatment (2.0-2.5 pmole/mg protein). Forskolin elevated cAMP levels in both + and - CORT slices by 40- to 60-fold. Analysis of the autoradiograms of 2-D gels from ^{32}P-labeled slices revealed that forskolin also increased the phosphorylation of two spots (55K & 62K; pI's near 7) in both + and - CORT slices. CORT decreased the phosphorylation of glial fibrillary acidic protein (GFA). Forskolin stimulated GFA phosphorylation in CORT treated slices. Exp.2 investigated the effects of CORT on protein expression in hippocampal slices prepared from + and -CORT animals and maintained in standard Yamamoto's medium. After a 1 hr equilibration, ^{35}S-methionine was added to the slices, and the incubation was continued for 2.5 hr. Proteins were fractionated by 2-D PAGE. Initial results indicate that CORT may regulate the incorporation of ^{35}S-methionine into several proteins, including putative vimentin, GFA and several other unidentified proteins. 156.3 GTP-PREFERRING PROTEIN PHOSPHORYLATION SYSTEMS IN BRAIN MEMBRANES: POSSIBLE ROLE IN ADENYLATE CYCLASE REGULATION. Y.H. Ehrlich, S.R. Whittemore*, R. Lambert*, J. Ellis*, S.G. Graber*, and R.H. Lenox. Depts. Psychiatry, Biochemistry and Physiology/Biophysics, Univ. of Vermont College of Medicine, Burlington, VT 05405.

Previous studies in our laboratory have demonstrated that when brain membranes are preincubated under dephosphorylating conditions, adenylate cyclase (AC) activity is inhibited. Conversely, preincubation under phosphorylating conditions(with ATP and $MgCl_2$) stimulated adenylate cyclase activity, whereas thiophosphorylation with ATP-γ-S during preincubation resulted in irreversible activation of AC. Assays carried out with ATP-γ-[^{35}S] have identified a protein band with apparent MW of 54,000 daltons (54K) whose phosphorylation correlated significantly with AC activation (Whittemore et al., Neurochem. Res. 6:775, 1981; Neurosci. Abst. 7:920, 1981, and manuscript submitted for publication). In the present studies, we have examined whether this mode of regulation may involve endogenous protein phosphorylation systems that prefer to utilize GTP, rather than ATP, as a phosphate donor.

Preparations containing synaptic membranes (shocked P_2) from the neostriatum or cerebral cortex of decapitated rats were incubated with [γ-^{32}P]GTP or [γ-^{32}P]ATP of equal specific activity and then subjected to SDS-slab gel electrophoresis and autoradiography to identify the endogenously phosphorylated proteins. In reactions carried out with 1µM $GT^{32}P$ and 10 mM $MgCl_2$, a major substrate was a phosphoprotein band with MW of 54K and a minor band had a MW of 33K. Substituting $MnCl_2$ for $MgCl_2$ resulted in a marked increase in the phosphorylation of these proteins. In fact, in the presence of Mn++, the 54K and 33K protein substrates were phosphorylated by $GT^{32}P$ but not by $AT^{32}P$. Further characterization of the phosphorylation of the 54K and 33K substrates by GTP revealed that this activity is inhibited by cyclic AMP, independent of Ca++-ions and is regulated by a mechanism that may involve the phosphorylation of a 47K protein by ATP. Triton-X-100 extract of brain membranes containing the catalytic and regulatory components of AC was found to be highly enriched in endogenous activity which phosphorylates the 54K band with Mn·GTP, but not with ATP. Finally, preincubation of membranes with GTP and divalent cations caused activation of AC which withstood sedimentation and washings. These findings provide the means for direct testing of the possibility that a 54K substrate of a GTP-utilizing protein kinase plays a role in AC regulation, and by extention--in neural receptor adaptation (Adv. Exptl. Med. Biol. 116:75, 1979 and Progress in Brain Res., 1982). Supported in part by grants DA02747 and MH35735.

156.4 CALCIUM/CALMODULIN-DEPENDENT PROTEIN PHOSPHORYLATION IN APLYSIA NEURONS. S.A. DeRiemer, L.K. Kaczmarek and P. Greengard. Dept. of Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06510.

A rise in intracellular cAMP triggers a long lasting afterdischarge in the Bag Cell neurons of Aplysia. Changes in the phosphorylation state of two specific Bag Cell proteins, BC I (M_r 33,000) and BC II (M_r 21,000), have been observed during an afterdischarge. These two proteins are also substrates for a cAMP-dependent protein kinase (cAMP-PK) in broken cell preparations (Jennings et al., J. Neurosci. 2(2):158-168, 1982). Since there is a large inward calcium component to the action potentials of the Bag Cell afterdischarge, and since calcium-dependent protein phosphorylation has been shown to mediate some of the second messenger actions of calcium in other systems, we have begun a study of calcium-dependent protein phosphorylation in Aplysia.

We have examined endogenous protein phosphorylation in homogenates of isolated Bag Cell clusters, as well as in homogenates of the remainder of the CNS of Aplysia, using sodium dodecyl sulfate polyacrylamide gel electrophoresis to analyze the pattern of phosphorylated substrates. Results with the two preparations were similar except in the case of the Bag Cell specific protein, BC II. In addition to the cAMP-PK previously described, we have found a protein kinase activity dependent on calcium plus calmodulin (Ca/CaM-PK). Three classes of endogenous substrates were observed: 1. Proteins that are substrates for cAMP-PK but not for Ca/CaM-PK such as BC I. 2. Proteins that are substrates for Ca/CaM-PK but not for cAMP-PK. The major substrate in this class is an M_r 51,000 protein which by peptide mapping resembles a Ca/CaM-PK substrate from mammalian brain. 3. Substrates for both cAMP-PK and Ca/CaM-PK (M_r 80,000 and the previously described Bag Cell specific BC II).

Ca/CaM-PK activity was inhibited by drugs which block other calmodulin dependent processes. The drugs tested, in decreasing order of potency, were R24571 > trifluoperazine > chlorpromazine > W7. The ID_{50} of trifluoperazine was 6 µM. The physiological effects of these drugs on the Bag Cell afterdischarge are under investigation.

These results suggest that protein phosphorylation may mediate some of the actions of calcium in Aplysia neurons in general and during the Bag Cell afterdischarge in particular.

156.5 CALCIUM-ACTIVATED POTASSIUM CONDUCTANCE IN INTERNALLY PERFUSED SNAIL NEURONS IS ENHANCED BY PROTEIN PHOSPHORYLATION. Irwin B. Levitan, Jacques E. de Peyer*, Armand B. Cachelin* and Harald Reuter*. Friedrich Miescher-Institut, Basel, Switzerland and Dept. of Pharmacology, Univ. of Berne, Switzerland.

Depolarizing voltage steps induce inward and outward currents in voltage clamped, internally perfused neurons from the snail Helix roseneri. Addition of 0.01 to 1 μM of the catalytic subunit of cyclic AMP-dependent protein kinase to the internal perfusing medium results in an increase in the net outward current, with no apparent effect on the inward current. In addition, the catalytic subunit causes an increase in the rate of activation of the outward current. DTNB-inactivated catalytic subunit (1 μM) is without effect, indicating that the change in outward current results from protein phosphorylation rather than simply from perfusion of protein per se. Decreasing the external calcium concentration from 10 to 1 mM eliminates the effect of catalytic subunit, suggesting that calcium plays an important role in this response. This suggestion is supported by the finding that the enhancement and increase in rate of activation of outward current can be mimicked by increasing the calcium concentration in the internal perfusing medium. Furthermore, when 10 mM EGTA is added to the internal perfusing medium to completely suppress the calcium-activated potassium conductance, there is no effect of catalytic subunit on the remaining component of outward current (the delayed rectifying current). The results are consistent with the hypothesis that cyclic AMP-dependent protein phosphorylation can regulate the calcium-activated potassium conductance in these cells.

156.6 INDEPENDENCE OF CHOLINERGIC- AND HISTAMINE-STIMULATED INCREASES IN PHOSPHATIDYLINOSITOL TURNOVER IN CLONED CELL LINES. Neri M. Cohen* and William L. Klein. Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

The character of the histamine-mediated increase in phosphatidylinositol (PI) turnover was investigated in neuroblastoma N1E-115 cloned cells. This study was greatly aided by the availability of a one-dimensional thin-layer chromatography (TLC) solvent system (acetone:butanol:acetic acid:water :: 5:5:1:1) (Cohen et al., J. Neurochem., in press) for the rapid and consistent separation of PI from other major phospholipids. Histamine stimulation caused as much as a 430% increase in the incorporation of 32P into PI, with the level of stimulation being dependent on the age and maturity of the cultures. Denser and more mature cells showed a significantly lower level of stimulation than immature cells. 10 -7 M. pyrilamine completely blocked the response to histamine stimulation and 10 -7 M. metiamide had no effect on the response, indicating that the histamine PI response is mediated by the H1 and not the H2 receptor. Removal of extracellular Ca++ by the addition of excess ethyleneglycoltetraacetic acid (EGTA) had no effect on the ability of histamine to stimulate the increased turnover of PI. The time course for increased incorporation of 32P into PI was similar to that observed previously for the cholinergic-mediated response, with stimulated rates of uptake significantly decreased by 30 minutes and no different from control rates by 40 minutes. Dual stimulation of both the cholinergic and histamine systems simultaneously produced an additive effect on the increased turnover of PI. Desensitization of the cholinergic-mediated stimulation of increased turnover had no effect on the ability of histamine to mediate a second stimulation of PI turnover. The notion of discrete functional units within the membrane, each containing a specific receptor and the machinery for the physiological reactions mediated by that receptor, is supported by these results.

156.7 TEMPERATURE DEPENDENT CONFORMERS OF CALMODULIN. P. Gangola* and H. C. Pant (SPON: H. Gainer). Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism. Rockville, MD 20852.

Conformational changes occur when calcium binds to calmodulin (CaM) which has been found to regulate a large number of fundamental cellular processes. We report here temperature induced conformational changes in calmodulin using the intrinsic tyrosine fluorescence. Calcium bound CaM undergoes a reversible conformational change in the temperature range 22-30°C. The transition temperature depends upon the concentration of calcium bound to CaM. In fully Ca^{2+}-bound CaM the transition occurs at slightly higher temperature than when the Ca^{2+} concentration is lower and the CaM is not fully bound. The apo-form of protein does not show this transition in the fluorescence intensity.

CaM has four binding sites or domains. Domains I and II contain no tyrosine residues while domains III and IV each have one tyrosine. A difference in the sequence of Ca^{2+} filling of these four sites is observed for the two temperature dependent conformers. For the low temperature conformer (which exists from 5-20°C), Ca^{2+} first fills one of the non-fluorescent domains (I or II); the next two sites to be filled are the fluorescent domains (III and IV), while the last site filled is the remaining, unfilled non-fluorescent site. For the conformer existing above 30°C, both of the non-fluorescent sites (I and II) are filled first followed by the fluorescent sites (III and IV). This temperature dependent transition is also affected by pH.

The CaM-Ca complex exists as two distinct conformers depending upon the temperature of the system with the calcium filling sequence being different for these two conformers. Furthermore, our results indicate that temperature induced conformational changes in CaM increase the Ca^{2+} binding affinity of one of the non-fluorescent sites (I or II).

156.8 [^{3}H]NITRENDIPINE BINDING IS REGULATED BY INORGANIC AND ORGANIC CALCIUM BLOCKERS: DIFFERENCES BETWEEN CENTRAL AND PERIPHERAL CALCIUM CHANNELS. K.M.M. Murphy, R. Gould* and S.H. Snyder Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Recent advances in the pharmacology of calcium and calcium blockers have allowed the identification of distinct sites of actions of various classes of inorganic and organic calcium antagonists. Lanthanum and cobalt are potent and selective inorganic calcium entry blockers. Nifedipine, verapamil and diltiazem are examples of three structurally different classes of organic calcium channel blockers.

[^{3}H]Nitrendipine labels high affinity sites in brain, myocardium, smooth muscle, and skeletal muscle which appear to represent the pharmacologically relevant site of action for the dihydropyridine calcium channel blockers. Thus in brain, heart and skeletal muscle, the potency of the various dihydropyridines at [^{3}H]nitrendipine sites parallels their physiologic potency. Other classes of calcium antagonists appear to interact allosterically with this site.

In brain membranes, [^{3}H]nitrendipine binding is absolutely dependent upon calcium ions. The ionic calcium agonists strontium or barium can replace calcium in this regard. Lanthanum, cobalt or other inorganic calcium blockers inhibit the calcium stimulation of [^{3}H]nitrendipine binding. These ionic interactions occur at some site distinct from the dihydropyridine binding site.

Interactions with other classes of calcium antagonists are apparent. For example, verapamil but not diltiazem, can regulate [^{3}H]nitrendipine binding. Verapamil's potent inhibition of [^{3}H]nitrendipine binding is non-competitive and sensitive to ionic regulation, suggesting a site of action separate from those of the dihydropyridine calcium blockers.

[^{3}H]Nitrendipine labeled calcium channels in peripheral tissue differ in the sensitivity to ionic regulation. Removal of endogenous cations by EDTA is less effective in lowering [^{3}H]nitrendipine binding in heart and skeletal muscle than in brain. In addition, complete restoration of those sites by addition of calcium ions, as seen in brain, is not observed in these peripheral tissues. However, the binding sites do appear sensitive to the inorganic calcium antagonists, lanthanum and cobalt. In addition, verapamil and D-600 regulate binding in a manner similar to their action in central nervous tissues.

Differential regulation of [^{3}H]nitrendipine binding in various tissues by distinct classes of calcium blockers may provide a basis for selective pharmacologic intervention at calcium channels in different tissues.

156.9 IN VITRO AUTORADIOGRAPHIC LOCALIZATION OF CALCIUM CHANNELS IN RAT BRAIN USING [^{3}H]NITRENDIPINE. R.J. Gould*, K.M.M. Murphy, and S.H. Snyder. Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Calcium entry into cells regulates a multiplicity of excitation-secretion coupling processes. Depolarization-induced calcium entry into nerve terminals through voltage-dependent channels may regulate neurotransmitter release.

The dihydropyridine calcium channel antagonist [^{3}H]nitrendipine labels sites in the brain and peripheral tissues which are related to the pharmacologically relevant site of action of these drugs. These sites are regulated differentially by the inorganic calcium agonists and antagonists, and interact allosterically with sites recognizing verapamil, a structurally different calcium channel blocker. In guinea pig and rat, there are high numbers of [^{3}H]nitrendipine binding sites in the brain, heart, and skeletal muscle with other tissues having lower levels.

Within the brain of both species, striking regional differences exist in the numbers of [^{3}H]nitrendipine sites, with the pattern of regional distribution similar for both species. The hippocampus shows the highest numbers of specific [^{3}H]nitrendipine binding sites. The striatum, cerebral cortex and olfactory bulb also demonstrate high levels while the cerebellum, thalamus and hypothalamus have approximately half the number of sites of these regions. The midbrain and brainstem show substantially reduced amounts of [^{3}H]nitrendipine labeled sites.

In vitro autoradiography has been employed to determine the localization of [^{3}H]nitrendipine binding sites at a finer anatomical resolution. The cerebral cortex, for example, demonstrates a diffuse distribution of [^{3}H]nitrendipine binding sites while the hippocampal formation shows localization to the stratum molecularis of the dentate gyrus and the stratum radiatum. Substantially lower levels are seen in the granular layer of the dentate gyrus and the pyramidal layer of the hippocampus. In the olfactory bulb, the [^{3}H]nitrendipine binding sites are clearly localized to the external plexiform layer with the glomeruli and mitral cell layers having markedly reduced numbers of sites.

The distinct regional distribution of [^{3}H]nitrendipine binding sites within the brain suggests the possibility of an endogenous neurohumour which may regulate calcium fluxes via nitrendipine binding sites. The identification of such a factor will be facilitated by in vitro [^{3}H]nitrendipine binding and a knowledge of the specific receptor localization.

156.10 THE INTERACTION OF CINNARIZINE AND RELATED ANALOGUES WITH RECEPTOR SITES FOR CALCIUM CHANNEL ANTAGONISTS. F.J. Ehlert*, W.R. Roeske* and H.I. Yamamura. (SPON: D.J. Jenden). Dept. of Pharmacol. Univ. of Arizona Health Sciences Center, Tucson, Arizona 85724.

The interaction of cinnarizine and related analogues with receptor sites for calcium channel antagonists was investigated in ligand-binding studies using the potent dihydropyridine, [^{3}H]nitrendipine. Initial studies indicated that [^{3}H]nitrendipine bound in a saturable manner to homogenates of the rat cerebral cortex, heart and longitudinal muscle of the ileum. The specific component of [^{3}H]nitrendipine binding was consistent with mass-action behavior and was characterized by a high affinity dissociation constant in the range of 0.1 - 0.3 nM. Several other potent dihydropyridines competitively inhibited the specific component of [^{3}H]nitrendipine binding with a potency in the 10^{-10} - 10^{-9} M range. Verapamil and its methoxy derivative, D600, also inhibited [^{3}H]nitrendipine binding but were somewhat less potent and caused an allosteric inhibition of binding. Cinnarizine, flunarizine and lidoflazine also inhibited [^{3}H]nitrendipine binding with IC_{50} values of approximately 10^{-6} M in both the heart and cerebral cortex of the rat. Analysis of the data suggested that the inhibition of [^{3}H]nitrendipine binding by cinnarizine was allosteric. Preliminary experiments suggest that cinnarizine, flunarizine and lidoflazine also cause a qualitatively similar inhibition of [^{3}H]nitrendipine binding in the longitudinal muscle of the rat ileum. The results of our binding experiments investigating several structural analogues of calcium channel antagonists suggest that [^{3}H]nitrendipine is a useful probe for characterizing binding sites for calcium channel antagonists, and perhaps, for detecting tissue differences in the nature of these sites.

156.11 CALCIUM ANTAGONIST BINDING AND CALCIUM UPTAKE INHIBITION IN A CLONAL CELL LINE. Lawrence Toll. Bio-Organic Chemistry Laboratory, Life Sciences Division, SRI International, Menlo Park, California 94025

The pharmacology of the voltage-dependent calcium channel has come under close scrutiny recently due to the labeling with tritium of the calcium antagonist nitrendipine. Using receptor binding techniques, several groups have determined binding characteristics of [^{3}H]nitrendipine and other dihydropyridines, as well as other classes of calcium antagonists. Binding has been studied in brain, heart, ileum and other organs. In all cases, receptor affinity correlates with pharmacological potencies in inhibiting smooth muscle contraction. I now report the binding of calcium antagonists and their inhibition of ^{45}Ca uptake in a phenochromacytoma clonal cell line.

The phenochromacytoma cell line, PC12, has been used as a model system for the study of storage and calcium-dependent release of acetylcholine and catecholamines. Properties of Na^+ and Ca^{++} fluxes have also been studied in this cell line. [^{3}H]-Nitrendipine binding to PC12 cell membranes is similar to binding in brain and other organs. Binding is saturable, with a K_D of about 1 nM. The receptor density is about 30 fmol per mg protein, or about 1,650 calcium channels per cell.

[^{3}H]Nitrendipine binding can be displaced by other dihydropyridine calcium antagonists with affinities between 1 and 5 nM. [^{3}H]Nitrendipine binding is also inhibited by compound D-600 (methoxyverapamil) which also is known to inhibit calcium uptake in smooth muscle and other tissue. The IC_{50} of D-600 is about 10 μM, however, maximal inhibition is not as great as with the dihydropyridine compounds.

Affinities of the calcium antagonists at the [^{3}H]nitrendipine binding site were compared with their abilities to inhibit the depolarization induced ^{45}Ca uptake into PC12 cells. Increasing potassium from 5 to 55 mM increases ^{45}Ca accumulation 5-fold. Uptake is rapid, being half maximal within 30 sec. Inhibition of potassium induced ^{45}Ca uptake by the calcium antagonists correlates very well with their inhibition of [^{3}H]nitrendipine binding. The dihydropyridine inhibitors have half-maximal inhibition in the range of 1-5 nM, while D-600 is about 5 μM. With 1.3 mM $CaCl_2$ in the incubation buffer, 1.5 nmol calcium is taken up per minute per mg protein. Assuming the nitrendipine binding sites equal the number of functioning calcium channels, about 50,000 calcium atoms pass through each channel per minute.

156.12 PHOTOACTIVATED CYCLIC NUCLEOTIDES PROBE THE KINETICS OF CALCIUM CHANNEL REGULATION IN HEART. Joel Nargeot*, Jeanne M. Nerbonne, Henry A. Lester, and Joachim Engels*. Division of Biology 156-29, California Institute of Technology, Pasadena, CA 91125.

The positive inotropic and chronotropic effects of beta-adrenergic agonists on heart arise predominantly from an enhanced slow inward current (this current is carried mainly by calcium ions). Binding of agonists to myocardial beta receptors causes an increase in intracellular cAMP which, in turn, is thought to mediate the slow inward current via a chain of events including protein phosphorylation and leading to an increase either in the number of functional calcium channels or of their elementary conductance. The effects of adrenaline are observed after a latency of 4-6 sec and require about 60 sec to reach completion in frog heart at 25°; little is known of the rates of the intermediary biochemical events. Furthermore, the negative inotropic effects of muscarinic agonists are based on a decrease in this calcium current, as well as on an increased potassium conductance. Among the postulated intracellular second messengers for the muscarinic response are decreased cAMP and increased cGMP.

To obtain more information on these events, we are exploiting photoactivatable cAMP and cGMP analogues. The ortho-nitrobenzyl esters of cAMP and cGMP cleave efficiently upon irradiation and therefore allow precise concentration jumps that are complete within at most 300 msec. We are studying the behavior of the slow inward current after such jumps. In voltage-clamped TTX-treated atrial trabeculae from bullfrog heart, flash-induced concentration jumps (1-10 μM) of intracellular cAMP increase the calcium current by at least twofold. The decrease in the slow inward current produced by 1 μM carbachol is completely overcome by cAMP jumps of ~10-20 μM. Furthermore, when this current has been attenuated by 0.1 μM carbachol, a single cAMP jump (~10 μM) results in a five to sixfold increase in the slow inward current. The effects are complete within 30 sec and proceed along a roughly exponential time course, with a time constant of 15-20 sec. Increases are detectable within 300 msec after the flash. Neither the slow inward current nor the muscarinic potassium conductance are affected by concentration jumps of cGMP (up to 100 μM). We conclude that the response to beta agonists is significantly limited in rate either by the activation of protein kinase or, more likely, by the rate of protein phosphorylation.

156.13 BARBITURATES DECREASE VOLTAGE-DEPENDENT CALCIUM CONDUCTANCE OF MOUSE NEURONS IN DISSOCIATED CELL CULTURE

R.L. Macdonald and M.A. Werz. Neurosciences Program and Dept. of Neurology, The University of Michigan, Ann Arbor, MI 48109.

Barbiturates decrease presynaptic release of neurotransmitter, synaptosomal calcium uptake and the duration of somatic calcium-dependent action potentials (CAPs) at anesthetic concentrations. To investigate the mechanism by which barbiturates decrease neuronal calcium entry, we studied barbiturate actions on CAPs and voltage-dependent inward calcium currents evoked in dorsal root ganglion (DRG) and spinal cord neurons grown in primary dissociated cell culture using standard intracellular recording and single electrode voltage clamp techniques. DRG neurons were used in the voltage clamp experiments since they are spherical and do not have the extensive dendritic arborization of spinal cord neurons.

DRG and spinal cord neuron somatic CAPs were decreased in duration by pentobarbital (PB)(100-500 μM) and phenobarbital (PhB)(500-2000μM), while the inactive barbiturate, barbituric acid (BA), was ineffective at 2 mM. CAP duration was decreased in the absence of an effect on resting membrane potential or conductance. PB and PhB also decreased CAP duration of DRG neurons following substantial blockade of potassium conductances by substitution of cesium (Cs) for potassium in the recording medium and by intracellular injections of Cs from recording micropipettes filled with 3 M CsCl or 4 M CsAc. CAPs recorded with Cs injection were much prolonged in duration (>500msec) and retained no after-hyperpolarization, suggesting that most potassium conductance was blocked. DRG neurons were voltage clamped in potassium-free medium containing Cs and using 3M CsCl recording micropipettes. Depolarizing voltage commands (20-80 mV) from a holding potential of -60 mV evoked net inward currents (I_I). Both PB and PhB but not BA decreased the magnitude of I_I. The calcium channel blocker, cadmium (Cd) (500 μM) also blocked I_I. PB did not affect leak current (determined in the presence of cadmium). When potassium conductances were only partially blocked by tetraethylammonium (5mM), both the early I_I and the late outward current were reduced by PB, suggesting that the barbiturates did not enhance calcium-activated potassium conductance.

Thus, it appears that barbiturates decrease calcium entry by decreasing voltage-dependent calcium conductance. It is likely that this mechanism underlies barbiturate presynaptic actions to decrease presynaptic calcium entry and neurotransmitter release.

156.14 CALCIUM ENTRY MAY INDUCE PROLONGED REFRACTORINESS IN THE BAG CELL NEURONS OF APLYSIA. L.K. Kaczmarek. Dept. of Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06510.

Following brief electrical stimulation the bag cell neurons of Aplysia generate a long lasting afterdischarge which, in vivo, serves to trigger egg laying behavior. At the end of their discharge these neurons enter a prolonged refractory period during which further electrical stimulation either fails to elicit afterdischarge or generates only short discharges. This period is also associated with the failure of action potentials which originate in bag cell neurites to invade the somata. Refractoriness endures for about 18-24 hours after which a full length afterdischarge may again be stimulated.

The hypothesis that calcium entry during an afterdischarge triggers the onset of the refractory period was suggested by ion substitution experiments (Kaczmarek et al., Brain Res., in press). In the present study this hypothesis has been further tested using the calcium ionophore Ro2-2985. Incubation of abdominal ganglia for 20 min in an artificial seawater medium in the presence of 5-50 μM Ro2-2985, followed by electrical stimulation of a pleuroabdominal connective, resulted either in a failure to generate afterdischarge or in afterdischarges that were significantly shorter than the control duration (30 min). The mean durations of afterdischarges, recorded with extracellular suction electrodes over the bag cell clusters, were 20.0, 14.0, 1.7, 2.7, and 0.0 min for ionophore concentrations of 1.0, 2.5, 5.0, 10.0, and 50.0 μM, respectively. Failure to generate afterdischarge was usually associated with the failure of action potentials to fully invade bag cell somata. These concentrations of ionophore were not toxic to the cells, since, following exposure to 50 μM Ro2-2985, vigorous afterdischarges could be elicited after extracellular addition of 90 mM TEA, a procedure that is also effective in overcoming the refractoriness that follows an afterdischarge. Recovery from exposure to the ionophore (5 μM) was tested in three ganglia, 20 hrs after washout of the ionophore. In all three cases, electrical stimulation triggered afterdischarges (mean duration 19.0 min). The ionophore (5 μM) was also tested in a calcium-free, TEA containing extracellular medium in which stimulation normally triggers brief (<1 min) bag cell afterdischarges which show no subsequent refractory period. No effects were observed on afterdischarges in this medium.

Brief exposure to Ro2-2985 therefore induces an electrical state in the bag cell neurons that is similar to the refractory state that follows afterdischarge in a calcium containing medium and supports the hypothesis that calcium entry during afterdischarge induces the subsequent refractoriness.

157.1 ADENOSINE INHIBITS EXCITATORY SYNAPTIC TRANSMISSION IN THE IN VITRO RAT HIPPOCAMPUS. W. R. Proctor and T. V. Dunwiddie. Dept. of Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262

Adenosine, adenine nucleotides, related purines such as inosine, and metabolically stable analogs of adenosine have been shown to reduce synaptic efficacy in the rat hippocampus in vitro (Dunwiddie and Hoffer, Br. J. Pharm. 69:59, 1980). We have compared the actions of adenosine on extracellularly recorded field EPSPs with its effects on intracellularly recorded potentials in this brain region.

Adenosine (5-100 uM) was found to reduce the amplitude of synaptic potentials elicited by stimulation of excitatory Schaffer collateral and commissural afferents to the CA1 region. Quantitative analysis of the dose-response curve for adenosine on extracellularly recorded EPSPs gave an EC_{50} value of 18 uM (95% confidence limits: 13-25 uM). Intracellular recording from hippocampal pyramidal neurons revealed parallel changes in synaptic potentials during superfusion of slices with adenosine. The decrease in intracellularly recorded EPSPs elicited by adenosine was quantitatively similar to the changes in extracellularly mediated potentials (EC_{50}=21 uM; 95% limits 14-31 uM). When these data were analyzed by means of a Hill plot, the slopes were not significantly different from 1. No significant changes in the resting membrane potential or resistance were found at adenosine concentrations which were sufficient to reduce the EPSP by 50%.

The relatively high potencies of two non-metabolizable analogs of adenosine (L-N^6-phenylisopropyl adenosine, L-PIA; N^6-cyclohexyladenosine, CHA; EC_{50} values less than 0.02 uM) would appear to suggest that these actions are mediated by what have been termed purinergic A_1 receptors. The rank order potencies of purinergic agonists (L-PIA > CHA > NECA > adenosine > ATP > inosine) also supports this classification. Theophylline (as well as other alkylxanthines) was shown to be a competitive inhibitor of the purinergic response when tested at concentrations between 200 uM and 5 mM. K_i values for theophylline estimated from dose-response curves for the various adenosine analogs tested ranged from 39-57 uM; this K_i value correlates well with K_d values previously reported for theophylline (obtained from ligand binding studies on the A_1 receptor).

Thus, a comparison of intracellular and extracellular responses demonstrates that the primary effect of adenosine on hippocampal electrophysiology is an inhibition of excitatory synaptic transmission; little if any change in somatic membrane properties is induced by low concentrations of this nucleoside.

157.2 ANTAGONISTIC INTERACTIONS BETWEEN ADENOSINE DERIVATIVES AND NOREPINEPHRINE ON BEATING RATE IN RAT ATRIA. M.K. Samet and C.O. Rutledge, Dept. Pharmacol. and Toxicol., School of Pharmacy, Univ. of Kansas, Lawrence, KS 66045.

Adenosine (Ado) and its derivatives can antagonize the rate increasing effect of exogenously administered norepinephrine (NE) in spontaneously beating rat atria (Fed. Proc. 41:1055, 1982). In order to further define this Ado interaction with NE, we have examined a number of Ado derivatives for their efficacy and potency in shifting the concentration-effect curve for NE-induced chronotropy. Since maximal response rate to NE may be a function of basal rate, experiments were performed utilizing carbachol to decrease basal beating rate. Carbachol exposure at 0.2 µM decreased spontaneous beating rate by 50 beats/min but did not change either the EC_{50} or the maximal response rate to NE. Reducing spontaneous beating rate by 170 beats/min with 0.7 µM carbachol produced a slight increase in the maximal response to NE while shifting the EC_{50} by approximately 20-fold. Therefore, all experiments were performed with Ado derivatives at concentrations which produced a maximal 50-60 beats/min depression in spontaneous rate. The A_1-Ado receptor agonist N^6-phenylisopropyladenosine (N^6-PIA) at a concentration of 10 nM was capable of increasing the EC_{50} for NE about 6-fold without altering the maximal change in beating rate. Adenine (100 µM) produced no change in the concentration-effect curve to NE, while inosine (100 µM) decreased the maximal response. Neither compound altered the spontaneous rate. The Ado analog 2'-deoxyadenosine did not change the EC_{50} to NE at either 10 or 100 µM, but produced a decrease in the maximal response rate (similar to 100 µM Ado), while suppressing spontaneous rate by 20 beats/min. The Ado nucleoside derivative S-adenosyl-L-homocysteine (SAH, 100 µM) did not decrease spontaneous rate nor alter the EC_{50} to NE. However, SAH did decrease the maximal response to NE. The apparent A_2-Ado receptor agonist 2',5'-dideoxyadenosine (100 µM) did not alter the EC_{50} to NE, but did decrease the maximal response without altering spontaneous rate. These data demonstrate that A_1-Ado receptors are involved in shifting the postsynaptic sensitivity of atria to NE without affecting the maximal response since only N^6-PIA was capable of shifting the EC_{50} to NE. Moreover, the A_2-Ado receptor agonist 2',5'-dideoxyadenosine decreased the maximal response without changing the EC_{50} for NE. Since adenine did not affect either the EC_{50} to NE nor the maximal response, an intact nucleoside is required for these effects. These data suggest that endogenous Ado may serve a neuromodulatory role in controlling both the potency and efficacy of endogenous NE in increasing atrial rate. 157.3 SIMILARITIES BETWEEN ADENOSINE RECEPTORS MEDIATING INHIBITION OF NOREPINEPHRINE RELEASE IN KIDNEY AND INHIBITION OF FIELD EPSPs IN HIPPOCAMPUS. B. Fredholm*, T. Dunwiddie and P. Hedqvist*. Depts. of Pharmacology and Physiology, Karolinska Institutet, Stockholm, Sweden and Dept. of Pharmacology, University of Colorado, Denver, CO 80262

Adenosine (ADO) influences sympathetic neurotransmission in the rabbit kidney by causing a prejunctional inhibition and a postjunctional enhancement (Hedqvist & Fredholm, N.S. Arch. Pharmacol. 293:217, 1976). It also inhibits field EPSPs and interictal spikes in the rat hippocampal slice preparation (Dunwiddie, Fredholm and Hoffer, N.S. Arch. Pharmacol. 316:326, 1981). We have further examined the pharmacological specificity of these two effects.

Rabbit kidneys with an intact nerve supply were perfused in vitro with a saline medium containing dextran. The nerve stimulation-induced release of tritium (6 Hz, 90 pulses) from the ^{3}H-NE labelled tissue was determined. ATP, ADP, AMP, and ADO were virtually equipotent in reducing tritium release, β,γ-methylene-ATP was less potent than ADO, and inosine and hypoxanthine were essentially inactive. As an antagonist of the ADO effect, 8-phenyl-theophylline was more potent than theophylline, which was more potent than caffeine (K_i: 0.15, 50, 125 µM respectively). The rank order potency of agonists and the antagonism by methylxanthines suggests the response is mediated by P_1 rather than P_2 purine receptors in terms of Burnstock's classification. The effect of ADO was enhanced in the presence of an adenosine deaminase inhibitor, and by two inhibitors of adenosine uptake.

Additional ADO analogs were used to provide evidence for other purine receptor classification schemes. The adenosine analog L-PIA was about 30 times more potent than ADO (IC_{50}: 0.05 and 2.0 µM respectively). Another adenosine analog NECA had an intermediate potency (0.2 µM) whereas SQ 22356 and 2-deoxy-ADO were almost inactive. This order of potency corresponds to an R- rather than P-type receptor (Londos, C. and Wolff, J. PNAS 77:2551, 1977).

The inhibitory effect of adenosine analogs on field EPSPs in rat hippocampal slices was studied as well. The EC_{50} values for two N^6-substituted analogs, L-PIA and cyclohexyl-ADO, were approximately 0.02 µM, while NECA was about 10-fold less potent. Theophylline was able to competitively antagonize the response to adenosine analogs; in these experiments, the K_i value for theophylline was found to be 39 µM when tested against ADO, and 57 µM versus L-PIA. These results suggest that the presynaptic receptors mediating inhibition of NE release in the kidney, and the receptors (possibly also presynaptic) mediating inhibition of field EPSPs in rat hippocampus are of the A_1 subtype.

157.4 CHARACTERISTICS OF THE ADENOSINE INHIBITED ADENYLATE CYCLASE (A_1 RECEPTOR) IN RAT AND MOUSE CEREBELLUM. W. J. Wojcik and N. H. Neff. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Adenosine has been found to interact with two different membrane bound receptors. Micromolar concentrations of adenosine and various analogs stimulate the low affinity A_2 receptor and activate adenylate cyclase activity, while nanomolar concentrations inhibit adenylate cyclase through the A_1 receptor. We report that L-phenylisopropyl adenosine (PIA) inhibited basal adenylate cyclase activity in a washed P_2 preparation from cerebellum of rat and mouse. The extent of inhibition was greatest in the cerebellum when compared to the hippocampus, frontal cortex and striatum of the rat. Further studies in the cerebellum indicated the inhibition of adenylate cyclase to be mediated through the A_1 receptor. Nanomolar concentrations of PIA (5 nM to 1 µM) inhibited the basal adenylate cyclase in a concentration dependent manner with the EC_{50} being 60-70 nM. In the presence of 1 µM PIA, a concentration which produces maximal inhibition, basal adenylate cyclase was reduced by 30-40%. We also observed that the adenosine receptor antagonist, isobutyl methylxanthine, 50 µM, competitively antagonized the PIA response by shifting the PIA dose response curve to the right.

In order to associate the A_1 receptor to a specific cell type in the cerebellum, we tested whether selected cerebellar lesions affected the PIA inhibition of adenylate cyclase. Climbing fibers were destroyed by a systemic administration of 3-acetylpyridine (75 mg/kg). Two weeks after this treatment, we tested the responsiveness of adenylate cyclase to PIA (5 nM to 1 µM). We obtained similar dose response curves for PIA in the control and 3-acetylpyridine treated rats. This indicated that the A_1 receptor was not associated with the cerebellar climbing fibers. The neurological mutant, 'Staggerer' mouse, was reported to have no apical dendrites on the Purkinje cells and fewer granule cells. One month after birth, the response of adenylate cyclase to PIA was investigated in the 'Staggerer' mouse cerebellum and in their heterozygous, wild-type control. The basal adenylate cyclase activities were the same for both groups. The EC_{50} for the two dose response curves were also similar. However, the maximal response to 1 µM PIA was different. In the cerebellum of the 'Staggerer' mouse, PIA inhibited basal adenylate cyclase activity by only 19%, while a 41% inhibition was observed in the control cerebellum. This difference in the extent of inhibition may indicate that the A_1 receptor is associated with the Purkinje cell dendrites and/or the granule cells in the cerebellum.

157.5 BARBITURATES INHIBIT ^{3}H-ADENOSINE UPTAKE AND ENHANCE ^{3}H-ADENOSINE RELEASE IN RODENT WHOLE BRAIN SYNAPTOSOMES. R. A. Gonzales* and S. W. Leslie. Dept of Pharmacology, Univ. of Texas Coll. of Pharmacy, Austin, Tx 78712 and Dept. of Pharmacology and Neurosciences Program, Univ. of Alabama in Birmingham, Birmingham, Al 35294

Adenosine has been attracting attention recently for its possible role in mediating inhibition of synaptic transmission in the CNS. We have investigated the effects of barbiturates on adenosine movements across the synaptic plasma membrane using rodent whole brain synaptosomes to test the hypothesis that some of the depressant actions of these drugs may be mediated through interference of an endogenous adenosine system. Adenosine uptake was studied using synaptosomes prepared from male Sprague Dawley rats and Swiss Webster mice by differential and Ficoll gradient centrifugation methods. After preincubation at 37°C, ^{3}H-adenosine was added to the synaptosomes in the presence of pentobarbital, methohexital, and 5-(2-cyclohexylideneethyl)-5-ethylbarbituric acid (CHEB) at varying concentrations and times. The uptake was halted by diluting the synaptosomes in isotonic buffer followed by rapid filtration through Whatman GF/B fiberglass filters. All three compounds significantly inhibited ^{3}H-adenosine uptake at anesthetic concentrations (100 µM-300 µM). Kinetic analysis of the inhibition by pentobarbital showed that it was noncompetitive. In addition, pentobarbital did not affect the distribution of adenosine metabolites in the synaptosomes. Release of adenosine was studied using the P_2 pellet from CD-1 mice. After loading with ^{3}H-adenosine, synaptosomes were filtered, washed, and then incubated with releasing medium which was changed every minute. 50 mM KCl added to the medium caused an enhancement of ^{3}H efflux mainly due to increased release of adenosine and inosine. This effect was abolished in the presence of 250 µM EGTA. 0.3 mM pentobarbital did not significantly alter total release of ^{3}H stimulated by 50 mM KCl, but it caused a 50% increase in ^{3}H-adenosine release. These results suggest some of the depressant effects of barbiturates may be due to a drug induced enhancement of adenosine levels in the synapse.

157.6 ADULT AND NEONATAL MONOAMINE LESIONS PRODUCE DIFFERING LOCOMOTOR RESPONSES TO CAFFEINE. L. Erinoff*, M. Basura*, and S.R. Snodgrass. Neurology Res., Childrens Hospital of Los Angeles, L.A., CA 90054.

Adult rats (270g) were given 20 mg/kg desmethylimipramine (DMI) followed by intraventricular injection of saline-ascorbate, 6-hydroxydopamine (6HDA) 250 ug/20ul, or 5,7-Dihydroxytryptamine (5,7DHT), 150ug/20ul. Three days later, the procedure was repeated except that the opposite ventricle was injected and the 5,7DHT injection was reduced to 75ug/10ul. Two weeks later, one hour recording of locomotor activity was begun using photocell cages. Locomotor activity of control, 6HDA, and 5,7DHT animals were similar, and all rats showed a similar inverted U-shaped dose response function for caffeine (5, 15, and 30 mg/kg). L-phenylisopropyl adenosine (PIA) in doses of 0.05, 0.1, and 0.2 mg/kg reduced the locomotion of all three groups. A dose of 5 mg/kg caffeine reversed the activity decreases associated with 0.1 mg/kg PIA but not 0.2mg/kg.

These data suggest that caffeine increases locomotor activity in adult-treated control, 6HDA, and 5,7 DHT rats by blockade of adenosine receptors. Stimulation of these receptors by low doses of the adenosine agonist l-PIA decreases locomotor activity.

A parallel experiment involved neonatal rats who received DMI followed by intraventricular 6HDA, 100ug/10ul, 5,7DHT, 50ug/10ul, or vehicle on days 3 and 6 postnatal. Rats with neonatal 5,7DHT showed an enduring decrease in locomotor activity. Caffeine (15 mg/kg) increased the activity of DHT rats to equal that of controls. One interpretation of these results is that DHT lesions change the sensitivity of adenosine receptors if made in neonatal rats but not adults.

157.7 AN ANIMAL MODEL FOR CNS CAFFEINE INTOLERANCE. Mitsutaka Nakamura John M. Carney and H. Dix Christensen, Univ. Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK 73190.

Caffeine sensitization produced by chronic L-N^6-Phenylisopropyladenosine (PIA) may be an animal model of CNS caffeine intolerance in humans. Six male Sprague Dawley rats were trained to respond under an alternating component schedule in which a 10 min Time Out period preceeded each of four 10 min differential reinforcement of low rates (DRL) 15 sec components. Cumulative dose-effect curves for caffeine (3.2-56 mg/kg) provided stimulation of responding and a reduction in reinforcement at relatively low doses in 4 of the 6 rats. No dose of caffeine produced stimulation in the other 2 rats. Caffeine caused a generalized decrease in DRL behavior at higher doses (32 and 56 mg/kg). L-PIA (0.01-0.178 mg/kg) only produced dose-related decreases in responding. Daily injection of 1.0 mg/kg L-PIA resulted in the development of caffeine sensitization to the behavioral stimulant effects of caffeine, with all six rats now showing stimulation. Chronic L-PIA injection resulted in a 10 fold increase in the maximum amount of DRL response stimulation. Other caffeine behavioral responses are not altered. In the process of developing PIA tolerance one would anticipate the alteration to be associated with the high affinity adenosine A_1 receptor, but there could be some disposition differences. In CNS caffeine intolerant humans, plasma kinetics, overt metabolism and cardiovascular responsiveness are within the ranges of non-smoking caffeine abstainers.

Cortical cups were implanted in these rats to investigate drug disposition by both superfusion and affusion. Simultaneous measurement of behavior and caffeine or PIA extraneuronal concentrations can be determined. In drug free animals both PIA and caffeine superfusate concentrations were about 5% of that in plasma. In the case of caffeine, affusate concentrations could approach those of cortex tissue homogenates. PIA, measured in the affusate, gave anticipated tissue concentration for behavioral response that are only slightly higher than that required in binding studies. The results from these studies gives a working hypothesis that CNS caffeine intolerance may be due to altered adenosine receptors. The PIA tolerant rat provides a model in which to study changes in adenosine receptor systems.

157.8 DISCRIMINATIVE PROPERTIES OF METHYLXANTHINES. F.A. Holloway and H.E. Modrow* Dept. Psychiatry and Behavioral Sciences, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190 U.S.A.

Recently we reported that rats trained to discriminate caffeine from saline in an appetitive operant task displayed generalization of the caffeine training cue to another xanthine, theophylline, but not to several other stimulants, including amphetamine, methylphenidate, or nicotine. We now assessed cross generalization among xanthines and examined blockade of the xanthine cue with 1-phenylisopropyl-adenosine (PIA) or a benzodiazepine, chlordiazepoxide. The latter drugs are of interest since caffeine has been shown to impair CNS binding of both PIA and diazepam.

In a two-lever operant task, male albino rats were trained to press one of the two levers for food pellets after saline injections and the other after injections of either 32 mg/kg caffeine or 56 mg/kg theophylline. Reinforcement was available on a variable ratio schedule (VR 10) for correct responses. Training sessions lasted 10 minutes and were preceded by a one-minute extinction period. After attainment of criterion performance ($\geq$ 70% accurancy on 8 consecutive days), generalization tests were given every 3-4 days. Each test consisted of a single 2 minute extinction period. Drugs were injected 20 minutes prior to test or training sessions. Both response rate and discrimination accuracy (% drug-lever response) were recorded.

Caffeine and theophylline trained rats showed generalization to the training drug and cross-generalization to each other. Strong generalization of the caffeine cue to paraxanthine (one of the major metabolites of caffeine in rats) was evident. Discrimination accurancy increased and reponse rate decreased with increases in dose. Little generalization of either xanthine cue to amphetamine was noted. Both the caffeine and theophylline cues were largely blocked by 5 or 10 mg/kg chlordiazepoxide but neither cue was significantly affected by 0.1 mg/kg PIA, a dose which markedly depressed response rate. These data suggest that the cue properties of xanthines may be based on their action at the putative benzodiazepine receptor. Nevertheless, the relationship among xanthines, benzodiazepines, and adenosine is clearly a complex one. For example, prior work has shown that the adenosine cue itself can be blocked by caffeine. We found no information on caffeine's possible antagonism of the benzodiadepine cue.

158.1 BRAIN MEMBRANE AFFINITY COLUMN: AN APPROACH FOR ENDOGENOUS BENZODIAZEPINE RECEPTOR LIGAND PURIFICATION. D. Urquhart and A. K. Sinha. Dept Physiology & Biophysics, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854

Our focus has been to characterize a ^{3}H-diazepam displacing activity present in the 105,000 x g supernatant of hamster brain (Br.Res.193:519(1980)). We have determined this material to be nondialyzable and < 20,000 daltons as indicated by ultrafiltration (Amicon). The stability of this substance to heating at 95° C for 60 min. is dependent upon the homogenization medium. It is thermostable in .32 M sucrose and thermolabile in 50 mM Tris HCl (pH = 7.4). Ammonium sulfate precipitates this material within 20-56% of saturation.

In an effort to purify this ^{3}H-diazepam binding inhibitor we have prepared an affinity column composed of 30,000 x g brain membrane. Celite forms the supportive matrix of this column. ^{3}H-diazepam binds to this column and can be displaced by an excess of cold. When a solution of 20 μM diazepam is applied to a column preloaded with 2 nM ^{3}H-diazepam, ∿ 50% of the radioactivity is eluted within 1.5 column volumes. This elution pattern contrasts to that obtained when buffer, (Tris HCl, pH 7.4), alone is the eluant. Buffer washes out ^{3}H-diazepam without a sharp peak of radioactivity. There is no indication that Celite itself specifically binds diazepam. As yet, the pharmacological specificity of such "diazepam displaceable" binding needs to be determined.

Brain membrane contains many different binding "sites". Therefore, to harvest a specific endogenous ligand one must choose a specific eluant. As a result, the eluting substance must be separated from the endogenous ligand. We plan to exploit the nondialyzable nature of this endogenous ligand and use its affinity for the receptor to purify it.

158.2 INHIBITION OF BENZODIAZEPINE RECEPTOR BINDING IN RAT BRAIN BY β-CARBOLINE 3-CARBOXAMIDES. R.A. Locock*, G.B. Baker, R.G. Micetich and R.T. Coutts*. Neurochem. Res. Unit, Univ. of Alberta, Edmonton, Canada, T6G 2G3.

A series of tetrahydro β-carboline 3-carboxamides have been synthesized by condensation of D- and L-tryptophan with formaldehyde, methyl ester formation and condensation with aliphatic amines. The corresponding aromatic β-carboline derivatives were synthesized by aromatization of methyl tetrahydro β-carboline 3-carboxylate and condensation with the appropriate amines. These amides are related structurally to ethyl β-carboline 3-carboxylate (β-CCE) which has a high affinity for benzodiazepine receptors (Braestrup et al., Proc. Natl. Acad. Sci., 77, 2288-2292, 1980).

The inhibition of specific ^{3}H-flunitrazepam binding to rat cortical P_2 synaptosomal suspensions prepared according to Klepner et al. (Pharmacol. Biochem. and Behav., 11, 457-462, 1979) was measured by a filtration assay. The P_2 synaptosomal membranes (0.5 mg protein/ml) in 0.1M tris citrate (pH 7.1) were incubated at 0°C for 1 hour with 1 nM ^{3}H-flunitrazepam and the compounds under test. Binding was terminated by rapid filtration under vacuum through Whatman GF/B filters. After washing twice with ice-cold buffer the radioactivity remaining on the filter was estimated by conventional liquid scintillation counting. Non-specific binding was estimated in the presence of 1 μM clonazepam.

IC_{50} values were calculated by log-probit analyses of five concentrations of the inhibitors in duplicate. The most potent compound was ethyl β-carboline 3-carboxamide with an IC_{50} value of 245.9 ± 10.5 nM/liter (n=5). Increasing the number of carbon atoms in the side chain decreased potency, e.g. n-butyl β-carboline 3-carboxamide gave a value of 715.3 nM/liter. In the tetrahydro β-carboline series the most potent compound was dimethyl tetrahydro β-carboline 3-carboxamide, IC_{50} = 64.8 ± 9.7 μM/liter. Again, increasing side chain length was accompanied by decreasing potency.

Although these amide derivatives are less potent inhibitors of benzodiazepine binding than β-CCE (IC_{50} = 3.5 nM, by this procedure), the β-carboline 3-carboxamides may be more effective in vivo since they may not be as rapidly metabolized as the β-carboline 3-carboxylate esters.

Supported by grants from Alberta Mental Health Research Fund and Medical Research Council of Canada.

158.3 ANXIOGENIC POTENTIAL OF β-CARBOLINE AND RELATED COMPOUNDS AS BIOASSAYED BY GENERALIZATION TO INTEROCEPTIVE DISCRIMINABLE STIMULI (IDS) PRODUCED BY PENTYLENETETRAZOL (PTZ). H. Lal, D. Bennett*, F. Elmesallamy* and T. Gherezghiher. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, Texas 76107.

The occurance of β-carboline in mammalian tissues and their ability to bind to the benzodiazepine receptors suggest that these compounds could be endogenous ligands for the benzodiazepine receptors. However, β-carbolines lack benzodiazepine-like pharmacological profile in vivo. It is therefore, possible that β-carbolines produce effects opposite to those of benzodiazepines in humans, i.e. induction of anxiety. To explore this possibility, we tested these compounds for generalization to the IDS produced by PTZ. These IDS are generalized only to drugs that are anxiogenic in man and are blocked by specific anxiolytic drugs (Lal and Shearman, Ann. Rev. Med. Chem. 15: 51, 1980). We trained food-deprived, male-hooded rats to discriminate PTZ-induced IDS from saline by selecting one lever after injection of PTZ and another lever after injection of saline on a fixed-ratio-of-ten schedule of food reinforcement. After the discrimination of PTZ-cue was reliably established, β-carbolines were tested. These rats selected PTZ-appropriate lever after injection of β-carboline, harmane or harmaline but not after injections of diazepam. PTZ, harmane and harmaline were equipotent. PTZ and harmane showed similar efficacy. Doses higher than those producing 50% efficacy could not be tested in cases of β-carboline and harmaline as those doses suppressed responding. Diazepam given along with the test drugs antagonized the IDS produced by PTZ and harmane. Diazepam combination with β-carboline and harmaline resulted in behavioral toxicity such that the discriminative responses were not emitted. Since drug discrimination is a form of animal behavior which closely parallels verbal reports of drug action in human, it is suggested that β-carbolines and related chemicals are anxiogenic pharmacological agents.

158.4 DIFFERENTIAL MODIFICATION OF GABA AND BENZODIAZEPINE BINDING SITES BY GROUP SELECTIVE REAGENTS. M.K. Ticku[1,2] and T.P. Burch[1]*. Dept. Pharmacology[1] and Psychiatry[2], Univ. Tex. Hlth. Sci. Ctr., San Antonio, TX 78284

The effect of group-selective reagents on the binding of [^{3}H]-benzodiazepines and its enhancement by muscimol was investigated in rat brain membranes. Diethyl pyrocarbonate (DEP) and diazotized sulfanilic acid produced a dose-related (0.1-10 mM) inactivation of [^{3}H]diazepam (1 nM), [^{3}H]flunitrazepam (0.3 nM) and [^{3}H]propyl-β-carboline-3-carboxylate (0.3 nM) to cortex, cerebellum and hippocampus. DEP and sulfanilic acid produced inactivation of 50% of the binding sites for the three ligands at 1-1.5 mM and 0.5-1.0 mM, respectively. Scatchard analysis revealed the DEP (1 mM) produced a decrease in the B_{max} (~40-60%) of these three radioligands in the three regions tested without altering the K_D. Partial inactivation of [^{3}H]diazepam binding by 1 mM DEP in cortex, cerebellum or hippocampus did not alter the ability of muscimol and pentobarbital to enhance [^{3}H]diazepam binding in any of these regions. The EC50 values for muscimol or pentobarbital were similar in control and DEP (1 mM) treated regions. In contrast, following the inactivation of [^{3}H]diazepam binding with sulfanilic acid, muscimol or pentobarbital were not able to enhance [^{3}H]diazepam binding. The effect of these two group-selective reagents on [^{3}H]GABA binding indicated that while DEP did not alter [^{3}H]GABA binding significantly, sulfanilic acid was a potent inhibitor of [^{3}H]GABA binding. Thus, while both DEP and sulfanilic acid inactivates the benzodiazepine binding sites, sulfanilic acid also eliminates [^{3}H]GABA binding and the enhancement of [^{3}H]diazepam binding by GABA agonists. These results further support the notion that benzodiazepines and GABA bind to two distinct sites.

158.5 PHOSPHORYLATION OF GABA-MODULIN IN RAT BRAIN CORTICAL SLICES, SYNAPTOSOMES, AND SYNAPTIC MEMBRANES. B.C. Wise*, A. Guidotti and E. Costa. (SPON: W. Mendelson). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

GABA-modulin (GM), a brain membrane bound protein of MW 16,000 that inhibits the binding of ^{3}H-GABA to its recognition site and inhibits the stimulation of ^{3}H-diazepam binding by GABA, has recently been purified to homogeneity and shown to be a substrate for cAMP-dependent protein kinase. In the present studies, GM was found to be present in a phosphorylated state in rat cortical synaptosomes and slices which had been incubated with inorganic ^{32}P. After the incubation, GM was extracted from the tissue preparations with 1 N acetic acid (80°C) followed by ammonium sulfate precipitation and reverse-phase HPLC. Liquid scintillation spectrometry of the HPLC fractions revealed a peak of radioactivity that corresponded to the GM protein peak. GM was also phosphorylated in crude cortical synaptic plasma membranes that were incubated with Ca^{2+}, calmodulin, phosphatidylserine, or cAMP. GM was extracted and phosphorylation quantitated using the same procedure as that for the intact tissue. Ca^{2+} caused a 2-fold increase in GM phosphorylation, while calmodulin (0.65 µM) and phosphatidylserine (25 µg/ml) in the presence of Ca^{2+} caused a further increase in GM phosphorylation by 5- and 2-fold, respectively. cAMP (50 µM) was less effective (1.5-fold increase) and cGMP (50 µM) was completely ineffective in supporting GM phosphorylation under the experimental conditions used (2 min incubation at 30°C). The incorporation of ^{32}P into the GM molecule was confirmed by SDS-polyacrylamide gel electrophoresis and liquid scintillation counting of slices cut from the gel. We are investigating whether the phosphorylation of this membrane bound protein is important in the regulation of the GABA-benzodiazepine receptor complex.

158.6 ACTION OF BETA-CARBOLINE IN FLUNITRAZEPAM-PHOTOLINKED CULTURES C.Y. Chan*, T.T. Gibbs*, and D.H. Farb* (SPON: D. Soifer). Dept. of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Brooklyn, NY 11203.

Benzodiazepines (BZDs) enhance GABA chemosensitivity and potentiate GABA-like synaptic activity in cell cultures of embryonic chick spinal cord. After UV-irradiation in the presence of 100 nM flunitrazepam (FNZM), both BZD binding and enhancement of GABA chemosensitivity were specifically reduced by 75%. The GABA response in the absence of BZD was unaltered, indicating that photoinactivation of the BZD site does not also inactivate the GABA receptor. About 25% of BZD binding sites were resistant to inactivation and presumably account for the residual enhancement of GABA action in inactivated cultures. All neurons studied exhibited some residual BZD sensitivity, indicating that inactivation-resistant sites are not limited to a neuronal subpopulation. There was no apparent change in BZD binding affinity or biphasic dissociation kinetics after inactivation of membranes, indicating that inactivation-sensitive and -resistant sites are otherwise similar. Recent studies have shown that β-carbolines compete with BZDs for CNS binding sites and elicit anxiety-related behavior effects. We have studied the effects of β-carboline carboxylate methyl ester (BCCM) upon the electrophysiological response to GABA in cell culture and the binding of ^{3}H-FNZM to CNS membranes before and after photoaffinity inactivation of benzodiazepine sites. Standard intracellular microelectrode techniques were used to measure membrane potential and conductance of embryonic chick spinal cord neurons in culture. Multiple pressure ejection pipets were used to apply drugs to individual neurons. BCCM had no effect when applied alone (5nM-1µM), but when applied prior to GABA, BCCM inhibited GABA-induced conductance changes in a dose-dependent manner, with maximal inhibition of about 45% and an EC_{50} of 5-10 nM. This is in good agreement with the IC_{50} of 10nM which we have found for competition of BCCM with ^{3}H-FNZM in membrane homogenates. In the presence of 1µM BCCM, the response to 17µM GABA was reduced by 47%, while the response to 100µM (saturating) GABA was reduced by 43%. Thus, BCCM appears to act as a partial noncompetitive antagonist of GABA action. Although BZD binding and enhancement of GABA chemosensitivity were reduced by 75% in photoinactivated cultures, inhibition of the GABA response by 1µM BCCM was unaltered (51% vs. 53% in control cultures). Thus, photoinactivation does not affect the inhibitory action of BCCM, indicating that the site of BCCM action is either distinct from the BZD site or included in the inactivation resistant fraction of BZD sites. 158.7 BENZODIAZEPINE RECEPTOR TURNOVER IN CELL CULTURE. L. A. Borden*, C. Y. Chan* and D. H. Farb* (SPON: D. A. Fischman). Dept. of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Brooklyn, NY 11203.

Saturable, high-affinity binding sites for benzodiazepines (BZDs) have been identified in homogenates of CNS tissue and in cell cultures prepared from brain or spinal cord. The level of brain BZD binding sites is regulated by convulsive activity like that observed in epilepsy and possibly by chronic exposure to BZD drugs. While neural activity appears to play a role in BZD-R regulation, it is totally unknown as to what control mechanisms and/or chemical signals might underlie such effects. As a first step, we have developed methods, both biochemical and electrophysiological, to monitor BZD-R turnover. When embryonic chick brain or spinal cord cell cultures were photolinked with flunitrazepam (FNZM), washed and scraped, the reversible binding of (^{3}H)FNZM to P_2 membranes was decreased to ca. 75% of control, non-irradiated cultures. Photolabeling of spinal cord cultures resulted in a 75% decrease in the maximum BZD potentiation of GABA chemosensitivity (α_{max}=% potentiation) demonstrating that photoaffinity binding labels the functional BZD-receptor (BZD-R). To study recovery in culture, receptors were photoblocked with unlabeled FNZM (100nM, 0°C, UV for 20 min); control dishes were kept in the dark. Cultures were washed and then scraped and homogenized either immediately, or after various times of incubation. Reversible binding of 5nM (^{3}H)FNZM, determined by filtration, increased with recovery time ($t_{1/2}$~8.5 hr). The electrophysiological response (α_{max}=441%, n=8) returned to control values (α_{max}=444%, n=14) by 24 hr after photoaffinity blockade (α_{max}=123%, n=11) showing that the recovery of functional BZD-R is being measured. Cycloheximide (20µg/ml) prevented the return of binding sites, suggesting that recovery is dependent on protein synthesis. To study receptor degradation, cultures were photolabeled with 5nM (^{3}H)FNZM for 20 min at 0°C (+ or - 1mM flurazepam). Cultures were washed and returned to the incubator for various periods of time, then scraped, homogenized and radioactivity in the pellet (30,000 x g, 20 min) was determined. Irreversibly bound radioactivity decreased with a $t_{1/2}$~6 hr. The radioactivity released into the growth media did not comigrate with authentic (^{3}H)FNZM in TLC (chloroform:acetone, 9:1), indicating that loss of bound radioactivity does not represent dissociation, a conclusion also supported by the blockade of recovery by cycloheximide. Further, greater than 90% of the specifically bound radioactivity remained associated with (^{3}H)FNZM photolabeled membranes after dialysis in 1% Triton (24 hr, 4°C). (Supported by NSF BNS-80-04871, NIH NS-18536, and a MDA fellowship to C.Y.C.)

158.8 PHARMACOLOGICAL AND PHYSICAL PROPERTIES OF TWO CENTRAL BENZODIAZEPINE (BZ) RECEPTORS. M. M. S. Lo and S. H. Snyder. Johns Hopkins Uni. Sch. of Med., Dept. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

Two pharmacologically distinct population of central BZ receptors are separated by their solubility to non-denaturing detergents. Extraction of native membranes with various detergent solubilizes only a distinct fraction of the BZ receptors (Lo, M.M.S. et al., Proc. Natl. Acad. Sci. USA, 79:680-684, 1982). The BZ receptors associated with the insoluble pellet is soluble in salt and detergent. The salt plus detergent soluble (SE) BZ receptors display pharmacological properties similar to Type I BZ receptors whereas the detergent soluble (DE) BZ receptors resemble Type II receptors.

Both physical forms are modulated by γ-aminobutyric acid (GABA). Anions stimulate BZ binding in the DE receptors whereas the SE receptors are not regulated by anions. Some divalent cations also regulate the DE BZ receptors but not the SE receptors.

Dissociation kinetics of the two soluble forms of BZ receptors are also different. Monophasic dissociation of [^{3}H]diazepam is observed with DE receptors at 0°C in the presence of 1,000 fold excess diazepam ($K_{-1} = 3.9 \times 10^{-3} s^{-1}$) which is decreased in the presence of chloride. On the other hand, dissociation of [^{3}H]diazepam is clearly biphasic in SE receptors.

Heat inactivation of the two soluble BZ receptors appear to be similar and consists of at least two exponential components. GABA protects both forms of BZ receptors (DE and SE) by reducing the rate of inactivation of the fast and slow phases. However, chloride ions only protects the fast phase of DE receptors. In contrast, calcium ions protects only the slow phase in DE receptors. Both anions and cations does not protect SE receptors from heat inactivation.

We have also characterized the physical properties of the two soluble BZ receptors. Chromatography in HPLC protein sieve columns shows that native DE receptors, labelled with [^{3}H]flunitrazepam, consists of two oligomeric forms with molecular weights about 250,000 and 60,000. In contrast, SE receptors exists only in the low molecular weight form. Separation by reverse phase HPLC shows that the soluble BZ receptors (DE and SE) consists of 3 major peaks which occurs with different stoichiometry in the two types of soluble receptors. This shows that the DE and SE BZ receptors exist in different oligomeric states and contain physically heterogeneous populations which are also different in their pharmacological and kinetic properties.

158.9 CENTRAL BENZODIAZEPINE (BZ) RECEPTORS: HETEROGENEITY AND COOPERATIVITY IN RECEPTOR SUB-POPULATIONS. R.R. Trifiletti*, M.M.S. Lo and S.H. Snyder. (SPON: V.B. Mountcastle). Johns Hopkins University School of Medicine, Depts. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

Kinetic properties of central BZ receptors from bovine brain have been studied in vitro in both the membrane and soluble state. The data are most consistent with the existence of at least two distinct receptor populations and cooperativity in some of the receptor populations.

Dissociation kinetics of [^{3}H]-flunitrazepam (FNZ) or [^{3}H]diazepam (DZ) is biphasic in membrane preparations whether initiated by drug displacement or infinite dilution (for cerebral cortex, k_{-1} = 1.4 x 10^{-3} sec^{-1} and 0.7 x 10^{-3} sec^{-1}, for fast and slow phases respectively). Considerable regional variation is apparent. Pre-incubation with methyl β-carboline 3-carboxylate (Ro-22-7497), selectively abolishes the fast phase of [^{3}H]-DZ or [^{3}H]-FNZ dissociation in a dose-dependent fashion. The ED_{50} (∿1 nM) for this effect is comparable to the K_d of Ro-22-7497 at Type I benzodiazepine receptors.

Analysis for cooperative effects, by comparing dissociation by infinite dilution into buffer or buffer containing various ligands, indicates that the fast phase of [^{3}H]-FNZ dissociation is sensitive to receptor occupation. Agonists such as FNZ or CL 218,872 (all 1 μM) accelerate the fast phase (k_{-1} = 1.9 x 10^{-3} sec^{-1}) while antagonists such as Ro-15-1788 or Ro-22-7497 (all 1 μM) slow this phase (k_{-1} = 0.9 x 10^{-3} sec^{-1}). By contrast, the slow phase of [^{3}H]-FNZ dissociation is unaffected by receptor occupation. Similar experiments with [^{3}H]-ethylβ-carboline 3-carboxylate (CCE), shows a biphasic dissociation curve at 1.0 nM by infinite dilution and prominent cooperative effects. These results suggests that at least some sub-populations of BZ receptors display cooperative interactions with both BZ and β-carbolines.

Differential solubilization [Lo et al., Proc. Natl. Acad. Sci. USA 79:680-4 (1982)] indicates that salt plus detergent soluble (SE) receptors displays biphasic dissociation kinetics of [^{3}H]-FNZ whereas dissociation from detergent soluble (DE) receptors is monophasic. Cooperative phenomena appear to be present only in the SE receptors. This may mean that cooperative phenomena are restricted to Type I receptors, known to be enriched in the SE fraction.

In summary, the kinetic data obtained suggests that the complex kinetic properties of central benzodiazepine receptors observed in the membrane state may be explicable in terms of distinct sub-populations of receptors of different kinetic properties. Cooperative interactions appear present in some of these sub-populations.

158.10 EFFECT OF GABA ON [^{3}H]-PROPYL BETA-CARBOLINE-3-CARBOXYLATE LABELLED BENZODIAZEPINE RECEPTOR SUBTYPES IN RAT BRAIN. K.W.Gee*, F.J.Ehlert* and H.I.Yamamura. (SPON: J.B.Angevine). Dept of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

The regulation of benzodiazepine(BZD) receptor subtypes(type I and type II) by GABA was studied by assessing the effect of GABA on flunitrazepam(FLU) inhibition of [^{3}H]-FLU and [^{3}H]-propyl beta-carboline-3-carboxylate([^{3}H]-PCC) binding in various brain regions. In the hippocampus, the type I BZD receptor(high affinity) labelled by a low concentration(0.04nM) of [^{3}H]-PCC at 0°C did not appear to be GABA regulated. This was based upon the observation that GABA(10^{-4}M) has no significant effect on FLU/[^{3}H]-PCC competition curves in the hippocampus. In contrast, when [^{3}H]-FLU(0.05nM) or a high concentration of [^{3}H]-PCC(0.5nM) was used to label both type I and type II(low affinity) receptors under similar conditions, GABA(10^{-4}M) caused a significant increase(1.7 fold) in the affinity of FLU as measured by FLU/[^{3}H]-FLU and FLU/[^{3}H]-PCC competition experiments. In cerebral cortex, GABA enhancement of FLU inhibition of [^{3}H]-PCC(0.04nM) binding was present but significantly less than the enhancement observed with [^{3}H]-FLU(0.05nM) or a high concentration of [^{3}H]-PCC(0.5nM). An effect of GABA on the potency of FLU was also observed in the cerebellum when either [^{3}H]-FLU or [^{3}H]-PCC was used as ligands. Dissociation kinetics of high(0.5nM) or low (0.04nM) concentrations of [^{3}H]-PCC in the hippocampus support the notion that 0.04nM [^{3}H]-PCC labels a single binding site whereas the high concentration of [^{3}H]-PCC labels both the high (type I) and low affinity(type II) sites. In the cerebral cortex, low concentrations of [^{3}H]-PCC predominantly labels the high affinity site with a small proportion of the low affinity site also being labelled. PCC/[^{3}H]-FLU competition curves in the cerebellum indicate PCC binds to a single BZD receptor site in this brain region. Overall, these findings suggest that GABA regulation may be predominantly associated with the type II BZD site found in the cerebral cortex and hippocampus. In addition, a regional difference in the way type I receptors are associated with GABA receptors may occur. Consequently, GABA regulation of BZD receptor affinity may be a determinant of BZD receptor heterogeneity. (Supported by USPHS grants MH-27257, MH-30626 & Program Project grant HL-20984. NRSA(NS-06923) from the NINCDS to K.W.Gee and RSDA, Type II(MH-00095) from the NIMH to H.I. Yamamura.)

158.11 INFLUENCE OF AGE ON β-CARBOLINE BINDING IN HIPPOCAMPAL SUBFIELDS R.H. Zobrist*, H.L. Komiskey and T.F. Murray. College of Pharmacy, Washington State University, Pullman, WA 99164-6510.

Studies indicate that aging in humans leads to increased sensitivity to the CNS depressant effects of the benzodiazepines(BZ). This increased sensitivity may be related to an increase in BZ binding in the hippocampus (Memo, et al., J. Pharm. Pharmacol. 33: 64, 1981). However, different areas of the hippocampus are known to vary in the type of neurons, neurotransmitter levels and functions (Jones and Smith, Prog. Neurobiol.,15:19, 1980). Therefore, subregions of the hippocampus were examined for an age-dependent alteration in 3H-propyl-β-carboline-3-carboxylate (3H-PCC) binding. 3H-PCC is believed to selectively label a BZ_1 receptor subclass (Braestrup and Nielsen, J. Neurochem., 37:333, 1981). Furthermore, a derivative of the β-carbolines may be related to a presumed endogenous ligand (Braestrup et al., Proc. Nat. Acad. Sci., 77:2288, 1980).

Male Sprague-Dawley rats were decapitated and the hippocampi removed. Tissue from 4 animals was pooled, homogenized in 50mM Tris-Cl buffer (pH 7.3) and centrifuged at 48,000 X g for 10 min. The pellet was resuspended and washed 3 times with ice-cold buffer. Aliquots of the final 1:25 w/v homogenate were then incubated in triplicat with 3H-PCC for 90 min. at 0-4°C. Incubation was terminated by vacuum filtration through Whatman GF/B filters and immediately washed with 3 X 3ml of ice-cold buffer. Binding in the presence of luM unlabeled ethyl-β-carboline-3-carboxylate was defined as nonspecific. Scatchard analysis of equilibrium binding experiments in hippocampal membranes over a 3H-PCC concentration range of 1pM to 12nM indicated a Kd=0.93nM and Bmax=798 fmol/mg protein. In addition, a second binding site of somewhat higher affinity was present.

The subregions of the hippocampus were examined for an age-dependent change in 3H-PCC binding. Young (3-4 months), mature (12-13 months), and old (28 plus months) male Fischer-344 rats were used. After decapitation the hippocampi were removed, subfields (regions CA1 and CA4/area dentata) were dissected out under a 20X dissecting microscope and stored at -80°C until used (within 24 hours of removal). Tissue from 3 animals was pooled and prepared for the binding assay as indicated above. A saturating concentration of 3H-PCC (6nM) was used to determine if the maximum number of 3H-PCC binding sites varied with age. A 12-20 percent reduction in specific 3H-PCC recognition sites was found in the subfields of the hippocampus of the old rats as compared to the corresponding areas of mature and young animals. These results indicate that aging may be associated with a reduction of BZ_1 receptors in specific regions of the hippocampus. (Supported by USPHS Grant AG 03327-01)

158.12 FOMINOBEN: A COMPOUND WITH PROMINENT BENZODIAZEPINE-LIKE ACTIVITY. S.A.Springfield*, B.Krespan*, F.Baldino, P.Skolnick*+ and H.M. Geller (SPON: W.J.Nicklas). Dept. of Pharmacology, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854, +NIMH, Washington, DC 20205.

Fominoben (3'-chloro-2'-(N-methyl-N-[(morpholino-carbonyl)-methyl]-aminomethyl)benzanilide-hydrochloride) is a novel therapeutic agent with both antitussive and respiratory stimulant properties. Recent communications have also reported that fominoben can displace ^{3}H diazepam binding from brain membranes. We have now conducted biochemical, behavioral, and electrophysiological experiments to characterize further the actions of this interesting agent. Initially, we examined the ability of fominoben to displace ^{3}H-diazepam from putative benzodiazepine receptors on washed rat cerebral cortical membranes, and replicated the earlier work showing an IC_{50} of 1 μM. We also examined the interaction of fominoben with BCCE in the presence and absence of 10 μM GABA. The IC_{50} of fominoben for displacement of BCCE in the absence of GABA was approximately 6 μM, whereas in the presence of 10 μM GABA the IC_{50} was reduced 38%. The findings would suggest that fominoben has benzodiazepine-like qualities.

Two series of experiments were designed to test this possibility in animals. Fominoben was first tested for its ability to antagonize seizures produced in CF1 mice by either pentylenetetrazol (PTZ, 50 mg/kg) or 3- mercaptoproprionic acid (3-MP, 75 mg/kg). Mice were given i.p. injections of 0.5-100 mg/kg fominoben 30 min prior to i.p. injection with either of the convulsants. We measured time to seizure following PTZ injection. Treatment with 50 mg/kg or 100 mg/kg of fominoben prolonged time to seizure beyond 15 min (the maximum measured). When the selective BDZ antagonist, RO 15-1788, was injected i.p. (5 or 10 mg/kg) 15 min prior to the injection of PTZ, the action of fominoben was blocked. Second, electrophysiological experiments were performed on rat cerebral cortical neurons in situ. Fominoben (1 mg/kg, i.v.) produced a rapid depression of neuronal activity in 2 of 5 cells tested. Additional administration of fominoben (1-2 mg/kg) resulted in a total inhibition of discharge in these 2 cells. In 2 cells fominoben (1 mg/kg) produced an increase in the rate of activity, whereas increasing the dosage above 1 mg/kg resulted in a dose-related decrease. The ability of RO 15-1788 to reverse the depressant action of fominoben was tested on these 2 cells. RO 15-1788 (10 mg/kg i.v.) reversed the depressant action of fominoben on both cells. On one, fominoben (8-16 mg/kg) was again injected after RO 15-1788 and the unit was once again depressed. In summary, the data from biochemical, behavioral and electrophysiological tests are consistent with fominoben being a benzodiazepine-like compound. (Supported by NIH grant NS 15468.)

158.13 COUPLING OF PUTATIVE CALCIUM CHANNELS WITH BRAIN BENZODIAZEPINE RECEPTORS. J.D. Hirsch and R.L. Kochman. Dept. Biol. Res., G.D. Searle & Co., Chicago, IL 60680.

Nickel ion has opposite effects on the specific binding of ^{3}H-diazepam (^{3}H-DZ) and ^{3}H-propylβ-carboline carboxylate (^{3}H-PrCC) to mouse brain benzodiazepine receptors, stimulating the former and inhibiting the latter. With ^{3}H-DZ, Ni^{2+} increased binding by increasing ligand affinity while versus ^{3}H-PrCC, binding affinity declined and the number of sites increased. Since these Ni^{2+} effects are not due to direct chloride channel or GABA receptor interactions and since Ni^{2+} is a calcium antagonist in other systems, we examined the possibility that the effects of this ion were through a Ca^{2+}-associated mechanism. 4-Aminopyridine, which increases Ca^{2+} transport, inhibited ^{3}H-DZ and ^{3}H-PrCC binding with IC_{50}'s of 1650 and 2000μM respectively. This drug competitively inhibited ^{3}H-DZ binding but was a noncompetitive inhibitor of ^{3}H-PrCC binding. 4-Aminopyridine did not displace ^{3}H-DZ from kidney membranes nor did it displace ^{3}H-muscimol from GABA receptors. Displacement of ^{3}H-DZ by 4-aminopyridine was blocked in a concentration-dependent fashion by Ca^{2+}, La^{3+} at 5mM, and Ni^{2+} at 5mM. In this case, Ca^{2+} and La^{3+} had little effect on basal ^{3}H-DZ binding, while Ni^{2+} stimulated binding. Ni^{2+} had no effect on ^{3}H-DZ binding in kidney membranes or on ^{3}H-muscimol binding in brain membranes. The Ni^{2+} stimulation of ^{3}H-DZ binding in brain (55% at 5mM) was decreased in a concentration-dependent fashion by Ca^{2+}; at 5 mM Ni^{2+} and 200 mM Ca^{2+} binding was the same as control values. However, Ca^{2+} could not reverse the Ni^{2+} inhibition of ^{3}H-PrCC binding. Like Ni^{2+}, the other Ca^{2+} antagonist cations, Mn^{2+}, Co^{2+}, and Cd^{2+} all stimulated ^{3}H-DZ binding and inhibited ^{3}H-PrCC binding. Basal binding of ^{3}H-DZ was stimulated 33% by 100μM GABA and 44% by 500μM pentobarbital. These indirect alterations in the benzodiazepine receptor also reduced the affinity of 4-aminopyridine by 20 to 40%. Photoaffinity inactivation of specific ^{3}H-DZ binding in brain membranes, which spared all of the specific ^{3}H-PrCC binding, also led to a marked decrease (2.3-fold) in the ability of 4-aminopyridine to displace the β-carboline. These results suggest that: (1) the effects of Ni^{2+} on ^{3}H-ligand binding to the brain benzodiazepine receptor appear to be mediated through a Ca^{2+}-associated mechanism; (2) this receptor along with the GABA receptor and the chloride channel seems to be coupled tightly to a putative Ca^{2+} channel; and (3) binding sites for ^{3}H-DZ and ^{3}H-PrCC, which may be subsets of the benzodiazepine receptor, are not associated with this Ca^{2+} channel in the same way.

159.1 ZINC AND GABA BINDING: FROM PATHOLOGY TO PHYSIOLOGY. M. Baraldi. Inst. of Pharmacology, Modena Univ., 41100 Modena, Italy.

We recently demonstrated a pathology of the GABAergic system in hepatic encephalopathy (HE) consequent to fulminant hepatic failure induced by Galactosamine-HCl in rats. The mild stage of HE is characterized by an increase in GABA receptors that are supersensitive to Bicuculline inhibition both in vitro and in vivo, while the severe stage showed a loss of low affinity binding sites. The concomitant decrease in GAD activity allowed us to infer the presence in HE of a denervation supersensitivity phenomenon. In this condition Benzodiazepine receptors are up regulated and supersensitive to GABA stimulation. Since in search of factors responsible of this changes in GABA receptor complex we found a decrease of zinc in brain tissues and a parallel increase in blood, we decided to study this heavy metal as a candidate modulator of GABA binding sites. We present now evidences that zinc is an important factor which can physiologically regulate the binding of GABA to its receptors. It is well known that in fresh synaptic membranes the binding of GABA is very low and that freezing, thawing and washing procedures result in an increase of GABA binding sites by removing endogenous inhibitory factors. Testing the levels of zinc during the above mentioned procedures in synaptic membranes we found a progressive decrease of this metal in the homogenates and a parallel increase in the washing supernatants. The addition of zinc to these membranes leads to a decrease of GABA binding sites at the levels found in fresh no washed membranes (zinc IC_{50} 10^{-5} M). Lineweaver-Burke plot indicates that zinc is a noncompetitive antagonist of GABA receptors. Using frozen, thawed, Triton X-100 treated and extensively washed membranes we got a further decrease in the zinc content of the homogenate which parallels the increase of low affinity binding sites and the unmasking of high affinity GABA receptors (Kd_1=250,Bmx_1=8.5;Kd_2=33, Bmx_2=2). By adding zinc to these membranes we found an inhibition of low affinity GABA binding sites and, with a lesser extent, of the high affinity GABA receptors (Kd_1=220,Bmx_1=4.5;Kd_2=35,Bmx_2= 1.6). It has been demonstrated that factors such as endogenous GABA and peripheral proteins (GABAmodulin) can modulate the GABA receptor unit, however the present findings seem to indicate that other factors can interfere in the regulation of the GABA receptor complex.

159.2 PIPECOLIC ACID- AND GABA SYSTEMS: SIMILARITIES AND DIFFERENCES. E. Giacobini, M.d.C. Gutierrez, H. Nishio* and Y. Nomura*. Lab. of Neuropsychopharmacology, Dept. of Biobehav. Sci., Univ. of Conn., Storrs, CT 06268.

Pipecolic acid (PA) can be synthesized in vitro and in vivo in mammalian brain as a product of lysine metabolism (cf. Giacobini, E., Cell. Mol. Biol., 26: 135, 1980).

Pipecolic acid and GABA mutually inhibit their uptake in mouse brain synaptosomes (Nomura, Y. et al., Neurochem. Res., 5:1163, 1980). However, GABA and nipecotic acid (a powerful non-competitive inhibitor of the uptake of GABA) produce a greater inhibition of synaptosomal uptake of ^{14}C-GABA than of ^{3}H-PA synaptosomal uptake. In addition, PA (10^{-4}M) significantly reduces the synaptosomal and glial uptake of ^{14}C-GABA in the mouse. Pipecolic acid (10^{-4}M) increases K^+-stimulated release of ^{3}H-GABA from rat brain slices, however, GABA (10^{-4}M) affects neither spontaneously nor high K^+ induced release of ^{3}H-PA from rat brain slices (Nomura, Y., Neurochem. Res., 6:391, 1981).

GABA (2.7 mM) and nipecotic acid (2.7 mM) inhibit (30% and 34% respectively) the uptake of ^{3}H-PA (.114 mM) in the mouse brain, following an injection of a double-labeled mixture into the carotid artery (Nishio, H. and Giacobini, E., Neurochem. Res., 6:835, (1981).

The binding of ^{3}H-PA and ^{3}H-GABA to mouse brain fractions and their mutual relation have been studied. Pipecolic acid (5 mM) does not displace ^{3}H-GABA (8 mM) from fresh and frozen membrane preparations.

Our results suggest that GABA and PA are transported and released from and bound to different systems in mouse brain, however, they do not rule out the possibility of a modulatory action of PA on GABA synapses.

Dr. Y. Nomura and Dr. H. Nishio's present address: Dept. of Pharmacology, Inst. of Pharmaceutical Sci., Hiroshima Univ., School of Med., Hiroshima, Japan.

159.3 GLYCINE AND GABA UPTAKE IN THE MUTANT MOUSE SPASTIC. W. Frost White and Allen H. Heller. Harvard Medical School and Children's Hospital Medical Center, Boston, MA. 02115.

The spastic mutation is a single autosomal recessive mutation that results in hyperexcitability and marked abnormalities in coordinated movement. Electromyographic abnormalities have also been observed, and suggest that these signs result from a defect in spinal cord mechanisms. No anatomical abnormalities have been observed in the CNS of spastic mice. Both the behavioral and electromyographic signs of the spastic mutation can be reproduced in normal mice given subconvulsive doses of strychnine, suggesting that these may be related to a defect in glycine-mediated inhibition in the spinal cord. Biochemical investigations of the postsynaptic glycine receptor, using ^{3}H-strychnine as a ligand, demonstrate at least an 80 % reduction in the binding to spastic spinal cord, brainstem, and midbrain when compared to littermate control animals. In contrast, binding studies for the GABA and benzodiazepine binding sites demonstrate more binding in the spastic spinal cord and brainstem compared to littermate controls. These results support the hypothesis of a defect in glycine-mediated inhibition in spastic animals. They also suggest that the glycine and GABA inhibitory systems interact to maintain inhibitory tone.

In this paper we report our results on the high affinity, Na^+-dependent uptake of glycine and GABA into crude synaptosomal preparations of spastic and littermate control spinal cord and brainstem. In these studies we find 40.4 ± 9.6 % more glycine uptake and 22.5 ± 13.0 % more GABA uptake in spastic than in control animals. Kinetic analyses indicate that these differences result from changes in Vmax and not from changes in Km.

These results indicate that the glycine uptake system is intact in spastic animals. The finding that both glycine and GABA uptake is greater in spastic animals further suggests an interaction in the regulation of the glycine and GABA inhibitory systems in the mammalian CNS. (Supported by NIH grants NS00623, NS11237, and the Children's Hospital Mental Retardation Center Core Grant HD0627.)

159.4 A STUDY OF ^{3}H-GABA UPTAKE BY DISSOCIATED HIPPOCAMPAL CELLS IN CULTURE. J.A. Davidenas* (SPON: C. Rivier). The Salk Institute, La Jolla, CA 92037.

GABA is an important inhibitory transmitter in the hippocampus. Immunycytochemical studies indicate that in vivo it is present in a variety of interneurons, including the so-called basket cells. It is known from physiological studies, that when GABA is iontophoresed onto the somata of hippocampal pyramidal cells in vivo and in vitro, it produces a long-lasting hyperpolarization.

I have examined autoradiographs of hippocampal cells maintained in culture in an effort to determine the number and types of cells which can be specifically labeled with ^{3}H-GABA in vitro. The cells from dissected hippocampi of 18 day rat fetuses were dissociated by mild trypsinization and subsequent trituration in the presence of DNAse. After a brief incubation in a medium supplemented with serum, the cultures were maintained for varying periods in a defined serum-free medium. Cell samples at each time point were preincubated with 1 mM β alanine for 15 minutes prior to incubation with the ^{3}H-GABA to reduce uptake by non-neuronal cells. At different culture ages (between 5 hr and 23 days) the cells were incubated for 30 minutes at 37° C with ^{3}H-GABA (5 x 10^{-8}M or 2 x 10^{-7}M, Spec. act. 28.2 Ci/mmol, New England Nuclear) plus 1 mM β alanine in a buffered salt solution. Immediately after this incubation, the cells were rinsed twice and fixed with a mixture of 1% paraformaldehyde and 1.5% glutaraldehyde, osmicated, dehydrated, and coated with Kodak NTB-2 emulsion. The autoradiographs were exposed for 5 days at 4° C and developed in D19.

The autoradiographs revealed three classes of neurons: (i) The majority of the cells (≈70%) were entirely unlabeled; this class presumably includes most of the hippocampal pyramidal cells. (ii) About 5% of the cells were very heavily labeled. In this morphological category the cells ranged from pyramidal-like neurons to simple bipolar or fusiform cells. (iii) About 25% of the cells were clearly labeled, but not nearly as densely as the preceeding. These cells similarly show considerable variability in form. The distribution of the three classes of cells seems to be established relatively soon after plating, and is maintained, essentially unchanged, from the 4th day in vitro; however, some labeled cells are seen within 12 hours of dissociation.

159.5 GAMMA-AMINO BUTYRIC ACID BINDING INHIBITION BY HUMAN URINE. J. B. Fiorito*, D. K. Phair*, and A. K. Sinha. Dept. Physiology & Biophysics, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854

Some GABA analogs have been suggested as probable uremic toxins. The inhibitory effect of these analogs on brain gabaergic synapses may explain the etiology of uremic coma. We have investigated the possibility that some normal urinary constituent, other than GABA, might bind to the GABA receptor sites of the brain membranes.

Hamster brain membrane (48,000 g) was frozen, thawed, Triton X-100 treated (37° incubation for 30 min) and washed three times. ^{3}H-GABA binding was performed with ∿ 600 µg membrane protein in the absence of sodium. Morning urine was used from 4 normal, healthy males aged 24-48 yrs. One microliter of urine added to 1 ml incubation volume decreases ^{3}H-GABA binding by 30%. Increasing urine volume to 5, 10, 50, 100 and 200 µl decreases ^{3}H-GABA binding to 40, 29, 10, 5 and 4% respectively. This inhibition is not diminished by removing urinary GABA by gabase treatment. An electrolyte solution simulating human urine was found not to inhibit ^{3}H-GABA binding. The urinary inhibitor is thermostable (boiling water bath for 30 min). The inhibitor is dialyzable (6000-8000 M.W. cut off) and also passes through 500 and 1000 M.W. cut off ultrafiltration membranes. Scatchard analysis reveals that the inhibition is competitive in nature. We have tested the effectiveness of three GABA analogs, present in normal urine, for GABA binding inhibition. Creatine and creatinine have low affinities for the GABA receptor (IC_{50} of 1.3 mM and 3 mM respectively) and guanidoacetic acid has a much higher affinity (IC_{50} = 460 nM).

159.6 Na^+-INDEPENDENT GABA BINDING IN CNS REAGGREGATE CULTURES. J. M. Wehner*, K. Kang* and J. R. Bloomer* (SPON: J. R. Sheppard). Departments of Lab. Med. and Path. and Med., University of Minnesota, Minneapolis, MN 55455.

CNS reaggregate cultures exhibit a variety of differentiated functions including myelination, spontaneous electrical activity and neurotransmitter synthesis and release. Honegger and Richelson (Brain Res. 162:89, 1978) demonstrated that the inhibitory neurotransmitter GABA was released in culture but little is known about the expression of GABA receptors in reaggregate cultures.

Na^+-independent GABA receptors were measured in whole mouse brain reaggregate cultures to determine whether postsynaptic receptors were expressed in culture. Whole brain reaggregate cultures were prepared by the mechanical dissociation method of Honegger and Richelson from timed pregnant Balb/c ByJ mice at 16-17 days in gestation. ^{3}H-GABA receptors were measured at various times in culture using the centrifugation method of Enna and Snyder (Mol. Pharmacol. 13:442, 1977). GABA (10^{-4}M) was used to assess nonspecific binding. Specific saturable Na^+-independent receptors were detectable at all times in culture tested (3-33 days). The average B_{max} was 2.45 ± 0.54 pmol/mg protein. Starting material obtained from 16-17 days gestational animals which underwent mechanical dissociation also had detectable specific binding prior to exposure to culture media. Thus GABA receptors are expressed in late gestational animals, survive the cell dissociation process, and retain their binding characteristics for at least 33 days in culture.

Scatchard analysis of binding data indicated a high affinity ^{3}H-GABA site with a K_d of 15 ± 2.5 nM, which was not altered as a function of time in culture. Solubilization with Triton X-100 detergent was not necessary to reveal this high affinity site. Competition experiments with the agonists muscimol and GABA yielded IC_{50}'s of 2 nM and 10 nM, respectively.

These results indicate that reaggregate cultures not only synthesize and release GABA but also express GABA postsynaptic receptors with characteristics similar to the high affinity GABA receptors of rodent brain. Reaggregates could provide a useful system to examine the effects of drugs or toxic agents on the gabanergic system.

159.7 [^{3}H]-GABA BINDING IN SUBCELLULAR FRACTIONS OF RAT BRAIN. L. Gronke and J.P. Hammerstad, Dept. of Neurology, Oregon Health Sciences Univ., Portland, OR 97201

Most often, pharmacological specificity and regional localization are used to equate ligand binding with neurotransmitter receptors, but subcellular binding patterns can also provide valuable correlations.

We have used analytical differential centrifugation according to the five fraction scheme of deDuve as adapted for brain by P. Lauduron (Int. Rev. Neurobiol. 20:251-281, 1977) to obtain the nuclear (N), heavy mitochondrial (M), light mitochondrial (L), microsomal (P) and supernatant (S) fractions from rat brain. Enzyme activities (lactate dehydrogenase, cytochrome oxidase, β-galactosidase, and Na-K ATPase) were used to monitor the composition of the fractions. Membranes prepared from the homogenate and from the N, M, L and P fractions were (1) dialyzed (without freezing) or (2) frozen/thawed and extensively washed. [^{3}H]-GABA binding was measured by a standard centrifugation assay.

There was no reliable specific [^{3}H]-GABA binding in the N fraction, 35-45% in M, 15% in L and 35-45% in P. Relative specific activity (% of total binding/% of total protein), however, was most enriched in the L and P fraction. Saturation binding experiments showed a single binding site in the L and P fraction but a more complex binding isotherm in the M fraction.

These results are consistent with a localization of the GABA receptor on non-synaptosomal plasma membrane which fragments and distributes mainly into the L and P fractions. The more complex binding in the M fraction (which contains the synaptosomes) could indicate an additional binding site.

159.8 MODULATION OF ^{3}H-GABA AND ^{3}H-MUSCIMOL BINDING BY Ca^{++}. M.G. Corda*, A. Guidotti and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Binding of ^{3}H-muscimol and ^{3}H-GABA was studied in frozen-thawed and repeatedly washed synaptic membranes from rat brain cortices incubated in 20 mM KPO_4 + 50 mM KCl pH 7.0 at 23°C in the presence and absence of Ca^{++}. The addition of Ca^{++} decreased ^{3}H-muscimol binding. The decrease was significant with 0.5 mM Ca^{++} and reached maximal value (about 40%) with 5 mM Ca^{++}. In contrast, the binding of ^{3}H-GABA was increased by Ca^{++}. It has been reported (Nature 290:149, 1981) that Ca^{++} interacts with GABA receptors by revealing a subclass of GABA binding sites ($GABA_B$ binding sites) which can be recognized by baclofen. Therefore the studies of the effect of Ca^{++} on ^{3}H-GABA and ^{3}H-muscimol binding were repeated in presence of $5x10^{-5}$M baclofen, a dose of drug which failed to modify both bindings "per se". Under these conditions Ca^{++} decreased ^{3}H-GABA and ^{3}H-muscimol binding to the same extent. This effect was temperature dependent and was abolished when the membranes were incubated at 0°C. Moreover the effect of Ca^{++} was partially reduced by pretreatment of the membranes with 0.1 mM $AgNO_3$ (Supavilai et al., Neuroch. Internat. 1982, in press) and was reversed by the addition of an excess of EGTA or by washing the membranes at the end of the incubation period. Ca^{++} was more potent than Ba^{++} and Mn^{++}, while Mg^{++} was ineffective at concentrations up to 5 mM. Scatchard plot analysis of ^{3}H-muscimol binding in presence and absence of Ca^{++} revealed that the decrease was due to a reduction in the apparent number of high and low affinity binding sites with no significant change in the apparent dissociation constants.

The inhibition of ^{3}H-muscimol binding by Ca^{++} was not potentiated by the addition of calmodulin (up to 50 µg/ml) and was still present after inhibition of phospholipase A_2 by 1 mM mepacrine or 1 mM tetracaine. Moreover, the effect of Ca^{++} was additive to that of purified GABA-modulin. These data indicate that Ca^{++} decreases the number of $GABA_A$ binding sites while it unveils $GABA_B$ binding sites. The mechanism of these opposite actions is presently under investigation.

159.9 GABA IN CSF AND PLASMA: IMPORTANCE OF CONJUGATED GABA. L. T. Kremzner*, L. J. Côté, J. M. Messing*, F. Kronenberg*, R. Mayeux*, and J. A. Downey* (SPON: J. W. Correll). Departments Rehabilitation Medicine and Neurology, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

GABA (γ-aminobutyric acid), a major inhibitory neurotransmitter, occurs at micromole/gram levels in brain and spinal cord and at picomole/ml. levels in the cerebrospinal fluid (CSF). To delineate the relationship of GABA (free and conjugated) in different physiological pools we determined GABA in human CSF and plasma using HPLC coupled with O-phthalaldehyde fluorescent measurements. CSF and blood were placed on ice immediately after collection and rapidly processed at 4°C. Free and conjugated GABA were extracted with perchloric acid (PCA); conjugated GABA was determined on the PCA extract after 6N HCl hydrolysis at 110°C for 24 hr. Using these procedures, free GABA in lumbar CSF, obtained from patients with neurological disorders, ranged from 50 to 500 pmoles/ml; ventricular fluid GABA levels are 10 to 20 fold greater. After acid hydrolysis, the GABA values increased to between 3,000 to 6,000 pmoles/ml, a 15 to 100 fold increase. The increase in CSF GABA could not be accounted for by the hydrolysis of homocarnosine (γ-aminobutyrylhistidine) indicating that other GABA conjugates are also present. Unconjugated (free) plasma GABA levels varied from 300 to 1500 pmoles/ml; conjugated GABA levels varied from 1,500 to 7,300 pmoles/ml. The origin of CSF GABA is presumed to be from the central nervous system (CNS), while the origin of plasma GABA is uncertain. Because of concentration and volume differences, total plasma GABA is up to 10 fold greater than total CSF GABA. Preliminary studies indicate that under circumstances of elevated unconjugated plasma GABA, there is a concomitant but lesser increase in conjugated GABA, suggesting a dynamic relationship between the two GABA forms. Studies are in progress to characterize the chemical nature of the GABA conjugates in CSF and plasma.

159.10 CROSS TOLERANCE TO THE ANTINOCICEPTIVE EFFECTS OF MORPHINE AND THIP, A GABA RECEPTOR AGONIST. T.H. Andree* and S.J. Enna, Depts. of Pharmacology and of Neurobiology and Anatomy, Univ. Texas Medical School, Houston, TX 77025.

THIP (4,5,6,7-tetrahydroisoxazolo(5,4-c)-pyridin-3-ol) is a direct acting GABA receptor agonist which has been shown to possess antinociceptive potential in laboratory animals and man. At a dose of 7.5 - 10 mg/kg (i.p.) in mice THIP produces maximal analgesia which can be antagonized by atropine but not by naloxone. These data suggested that THIP analgesia is not mediated through an action on the brain opiate system (J. Pharmacol. Exp. Therap. 220:482, 1982). To determine whether tolerance develops to the antinociceptive effect of THIP, mice were treated for five days (7.5 mg/kg, i.p., b.i.d.) and analgesia tested on the sixth day using both tail immersion and hot plate methods. In both cases the dose-response curves for THIP indicated a significant reduction in the potency of this compound in the chronically treated animals. Moreover, some tolerance to the analgesic effect of morphine was also noted in these animals. Additional experiments revealed that morphine-dependent mice were tolerant to the analgesic effects of both THIP and morphine. Preliminary data indicate no changes in brain receptor binding for either GABA or the cholinergic muscarinic systems in the THIP tolerant animals. These data suggest that the opiates and GABA agonists act through separate, but related, pathways to induce an analgesic response. Thus, THIP and related GABAmimetics may be useful substitutes for opiates in the treatment of pain.

159.11 GAMMA-AMINOBUTYRIC ACID ALTERS THE PO_2 DISTRIBUTION IN INTACT GERBIL BRAIN. E.K. Angelopoulos*, P.E. Coyer, & L.J. Bearden (SPON: G.V. Pegram). Dept. Neurology, Neurosciences Program, & Dept. Biomedical Engineering, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

Several findings have suggested a specific association of gamma-aminobutyric acid (GABA) with cerebral blood vessels. The enzymes for both the synthesis and degradation of GABA have been found in elevated concentrations around cerebral vessels. It has also been observed that elevated CSF concentrations of GABA occur in humans during pathological conditions such as migraine headache and cerebral anoxia. These increased levels correspond to the concentration of GABA which has been shown to effectively induce the relaxation of isolated cerebral arteries in vitro. Additional pharmacological studies have verified the presence of GABA receptors on the wall of cerebral arteries (Edvinsson & Krause, Brain Res. 173: 89-97, 1979; Krause, et al., Brain Res. 185: 51-57, 1980). Therefore, there is substantial in vitro evidence which suggests a role for GABA in the control of the cerebral circulation.

Using a PO_2 microelectrode and adjacent pressure microinjection pipette, unit activity (action potentials) and PO_2 were recorded from the brains of anesthetized gerbils (held at 37°C) before, during, and after GABA injection. Bipolar EEG was also monitored. Following microinjection of GABA, the time to reach the maximum response in PO_2 varied from 25-40 sec, but in each case there was an increase in the PO_2 above the control (resting) level. In some cases these responses lasted several minutes. Using phosphate buffer loaded micropipettes (pH=7.2) no increases in the brain PO_2 were observed in control experiments. The duration of the GABA-mediated increase in PO_2 lasted several minutes depending upon the concentration of injected GABA and the length of the injection pulse. A transient increase in PO_2 with GABA pressure microinjection followed by a temporary cessation of spontaneously-firing units was also observed. Return of neural activity occurred as the PO_2 continued to increase. These results suggest a possible vasodilatory effect of GABA on the cerebral circulation as well as an alteration of neuronal activity.

159.12 INTRACELLULAR ANALYSIS OF GABA-EVOKED RESPONSES OF FROG PRIMARY AFFERENT AXONS. A.L. Padjen and T. Hashiguchi, Dept. of Pharmacology & Therapeutics, McGill University, Montreal, PQ H3G 1Y6

Previous studies, using sucrose gap recording on dorsal roots in frog spinal cord, indicated the existence of two types of GABA responses on primary afferents: a bicuculline-sensitive depolarization and a bicuculline-resistant hyperpolarization (Bourne & Padjen, Neurosci. Abst. 6: 148, 1980). Present experiments were initiated to examine sensitivity to GABA of primary afferent axons using intrafiber recording (KCl filled microelectrodes) at the root entry of isolated hemisected frog spinal cord preparation, continuously perfused with Ringer at 10°C (Hashiguchi & Padjen, Neurosci. Abst. 7: 437, 1981). Successful recording was obtained from over 40 large myelinated axons (resting membrane potential >70 mV; conduction velocity >15 m/s). Perfusion with GABA (0.1 - 5 mM) in normal Ringer depolarized the majority of fibers with a prominent fading of response. In 5 fibers GABA caused a hyperpolarization (up to 6 mV), accompanied by disappearance of spontaneous activity, shortening of duration of primary afferent depolarization and no change or increase in effective resistance (Re). After blockade of synaptic transmission GABA depolarized all fibers (4 mV and 10 mV, for 0.2 and 1 mM, respectively; no difference between Mn and TTX blockade). These depolarizations were characterized by a fast rise and were accompanied by a net decrease in Re. Fading of the plateau was prominent with higher conc of GABA. The equilibrium potential, obtained by extrapolation, was -30 mV. The GABA analog kojic amine (KJA; 0.1 - 1 mM) caused a slowly developing depolarization without fading (amplitude comparable to GABA response), but was present in only 9 of 30 fibers tested. Baclofen (0.1 mM) caused a small (<2 mV) hyperpolarization (in 2/7 fibers) without any detectable change in Re or propagating action potential. Bicuculline (0.1 mM) reversibly antagonized depolarizing responses to GABA and KJA without direct effect on electrical properties of fibers. In one fiber, the depolarizing response to KJA was reversed by bicuculline to hyperpolarization. These results suggest that: 1) the GABA-evoked hyperpolarization recorded in normal Ringer is indirect resulting from inhibition of tonic and evoked interneuronal activity. 2) Direct hyperpolarizing responses to GABA, KJA and baclofen, seen in sucrose gap recording, may not be present in large myelinated fibers. 3) KJA may activate a separate bicuculline sensitive (possibly GABA-) receptor not present in all primary afferent fibers.

159.13 USE OF GABACULINE INDUCED GABA ACCUMULATION FOR AN INDEX OF RETINAL GABA SYNTHESIS. M. A. Proll* and W. W. Morgan. Dept. of Anatomy, The Univ. of Texas Health Science Center, San Antonio, TX 78284.

GABA is thought to be a major inhibitory neurotransmitter in the central nervous system, but, until recently, there was a limited number of techniques available for measuring GABA synthesis. With the advent of relatively specific GABA transaminase (GABA-T) inhibitors, GABA accumulation following the inhibition of the degradative enzyme GABA-T can be used as an index of GABA synthesis (Bernasconi, et al., J. Neurochem. 38: 57, 1982). We decided to see if this method could be used as an index of GABA synthesis in the rat retina. Gabaculine was injected intravitreally, and unless specified otherwise, all experiments were performed on male Sprague-Dawley rats under ordinary laboratory fluorescent lighting. GABA was measured by gas-liquid chromatography. The accumulation of GABA after gabaculine was both dosage- and time-dependent. Dosages of 0.05 µg, 0.10 µg and 0.25 µg of gabaculine per eye injected at 60 min prior to sacrifice all significantly increased retinal GABA content, but the increase measured with 0.05 µg was significantly less than the accumulation with the 2 higher dosages. The accumulation with 0.10 and 0.25 µg gabaculine/eye did not differ, thus the 0.10 µg/eye dosage was used in subsequent experiments. Next GABA was measured at 0, 30, 60 and 90 min after gabaculine treatment in both light- and dark-adapted rats. In the dark-adapted experiment, rats were dark-adapted for approximately 15 hours, and the experiment was then performed in a photographic darkroom with light provided by a photographic red safe light. In both groups, the linear increase in retinal GABA content over the 90 min treatment period was approximately 3 fold, and the rates of GABA accumulation in the dark- (0.054 µg GABA/min/retina) and light- (0.051 µg GABA/min/retina) adapted groups were similar. The GABA agonist muscimol (MUS) and the GABA antagonist bicuculline methiodide (BIC) significantly suppressed and facilitated, respectively, the gabaculine induced increase in GABA levels. All dosages of MUS (0.375, 1.5 and 3.0 nmoles/eye) significantly depressed gabaculine-induced GABA accumulation, and the effect was dosage-dependent. The antagonist BIC was able to partially block the inhibitory effect of MUS. Gabaculine-induced GABA accumulation appears to be a useful technique for measuring the rate of GABA synthesis in the retina. Supported by DA00755 and RSDA DA00083-06A1 to WWM.

159.14 FLURAZEPAM INHIBITS THE GABACULINE INDUCED INCREASE IN GABA CONTENT IN THE RETINA. S. L. Lane* and W. W. Morgan (SPON: A. Miller). Dept. of Anatomy, The Univ. of Texas Health Sci. Ctr. at San Antonio, TX 78284.

Benzodiazepines (BZ) in the CNS are believed to exert their action by potentiating GABAergic transmission. BZ receptors have also been demonstrated in the retina but their physiological significance remains to be elucidated. It has been recently shown in our laboratory that flurazepam (FLU), a water soluble BZ, exerts an inhibitory action on dopamine (DA) neuron activity although this does not appear to be mediated through the GABA system (Kamp and Morgan, Eur. J. Pharmacol. 77: 343, 1982). Therefore, the purpose of the present experiments was to determine if the BZ exert any influence on the retinal GABAergic neurons. In the brain, BZ have been shown to suppress GABA synthesis (Bernasconi, et al, J. Neurochem. 38: 57, 1982).

Adult male albino rats were given intravitreal injections of saline, gabaculine, a GABA-T inhibitor (.1 µg/eyeball), varying doses of FLU (0.125µmole, 0.25 µmole, 0.5 µmole or 1.0 µmole/retina), or varying doses of FLU plus the single dose of gabaculine. The animals were sacrificed one hour later. The administration of gabaculine alone resulted in a marked enhancement of GABA content over saline controls ($p<.01$). FLU alone had no effect on GABA content. However, when combined with gabaculine, FLU prevented the gabaculine induced increase in GABA content in a dose-dependent manner.

These results lend support to the hypothesis that the BZ may influence the GABA system via a negative feedback loop. FLU may act to potentiate GABA action at post-synaptic receptor sites. The post-synaptic interpretation of this potentiation would be that there was an increase in available GABA. This could trigger a long loop negative feedback system which would effectively inhibit further synthesis of GABA. Alternatively FLU could be potentiating an autoreceptor system wherein GABA feedback inhibits its own synthesis. Additional investigations are required to differentiate between these possibilities. Supported by DA00755 and RSDA DA00083-06A1 to WWM.

159.15 BACLOFEN: DEPRESSION OF NEURONAL FIRING IN THE HIPPOCAMPAL SLICE. Brian Ault* and J. Victor Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

In the rat hippocampal slice the anti-spastic drug, baclofen, preferentially depresses transmission at synapses made by axons of CA3 pyramidal cells. Bicuculline (BIC) cannot reverse this effect of baclofen. We have suggested that baclofen acts at a BIC-insensitive GABA receptor located on one type of glutamatergic/aspartergic synaptic terminal to depress the release of excitatory transmitter. In the present study, we examined whether, in addition, baclofen acts postsynaptically to reduce the firing of hippocampal neurons.

(±)Baclofen (20 µM) completely suppressed the synchronous firing of CA1 pyramidal cells in response to stimulation of stratum radiatum or stratum oriens and of CA3 pyramidal cells in response to stimulation of stratum radiatum. In contrast, the firing of CA3 pyramidal cells evoked by mossy fiber stimulation was unaffected and the firing of dentate granule cells evoked by perforant path or associational-commissural stimulation was reduced by only 43% and 21%, respectively. When tested on the population spike evoked by stimulation of the Schaffer collateral-commissural fibers in area CA1, (-)baclofen depressed the population spike with an IC_{50} of about 2 µM. (+)Baclofen was about two orders of magnitude less potent. Input-output curves, in which population spike amplitude was plotted against the amplitude of the corresponding Schaffer collateral-commissural extracellular EPSP, were unaffected by baclofen. In contrast, imidazole-4-acetic acid (IAA) and 3-aminopropanesulfonic acid (3-APS), which are thought to act largely at postsynaptic GABA receptors, reduced the slope of the input-output curve. The depressant effect of (-)baclofen on the population spike was little affected by 100 µM BIC, but depressions produced by 3-APS and IAA were readily antagonized. GABA-induced depressions were much less sensitive to BIC than those produced by the latter two analogues. These results are consistent with the effects of baclofen and other GABA agonists on extracellular EPSP's in the hippocampal slice and suggest that the baclofen-induced depression of synaptically-evoked firing can be explained by an interaction with presynaptic BIC-insensitive GABA receptors.

(-)Baclofen at submicromolar concentrations shortened the period of burst firing evoked in area CA1 by antidromic stimulation in the presence of BIC. This action appears to be postsynaptically mediated. These observations suggest that agonists at BIC-insensitive GABA receptors might be useful limbic anticonvulsants. (Supported by NIH grant NS 16064.)

159.16 RELEASE OF ENDOGENOUS, OF ENDOGENOUSLY FORMED LABELLED AND EXOGENOUS LABELLED GABA BY HIGH K^+ OR VERATRIDINE IN RAT HIPPOCAMPAL SLICES. J. C. Szerb. Department of Physiol. Biophysics, Dalhousie U., Halifax, N.S., Canada, B3H 4H7

To see how the release of GABA freshly formed from glutamate (glu) compares with that of endogenous (endo) unlabelled or exogenous (exo) labelled GABA, rat hippocampal slices were incubated for 30 min in 3 mM K^+ with 5 µCi/ml [3,4-^{3}H]l-glutamate and 0.5µ Ci/ml [U-^{14}C] GABA and were superfused first with 3 mM K^+ then for 36 min with either 50 mM K^+ or 50 µM veratridine (V) in the presence or absence of Ca^{2+}. Endo GABA was measured by HPLC which was also used to separate labelled GABA from labelled glu and labelled metabolites. Although 10 times less [^{14}C] GABA than [^{3}H] glu was present in the incubation fluid, slices contained twice as much [^{14}C] GABA than [^{3}H] GABA 15 min after labelling. During the following 48 min perfusion with 3 mM K^+ the content of [^{14}C] GABA but not that of [^{3}H] GABA declined. In the presence of Ca^{2+} 50 mM K^+ released [^{14}C] GABA with a higher specific activity (SA) than that in the slices while the SA of released [^{3}H] GABA was about equal to that in slices. Exposure for 36 min to V in the presence of Ca^{2+} caused an initial large release of both endo and labelled GABA followed by a rapid decline. The SA of [^{14}C] and [^{3}H] GABA released were the same as with 50 mM K^+. In the absence of Ca^{2+} release induced by 50 mM K^+ was much reduced but that evoked by V was increased. Depolarization with 50 mM K^+ in the presence of Ca^{2+} induced a synthesis of endo GABA in excess of release but V, in the presence or absence of Ca^{2+}, or 50 mM K^+, in the absence of Ca^{2+}, failed to induce excess GABA synthesis. Results suggest: (1) Exo labelled GABA is preferentially taken up into releasable stores while GABA synthesized from exo glu is distributed uniformly. (2) Considerable Ca^{2+}-independent release of GABA induced by V in the absence of a GABA-T inhibitor originates from neurons since GABA taken up by glia would have been metabolized. (3) An increase in extracellular K^+ in the presence of Ca^{2+} rather than depolarization per se may regulate GABA synthesis.

159.17 COMPOUND LY81067, A DIARYLTRIAZINE, AUGMENTS GABA-MEDIATED INHIBITION IN RAT HIPPOCAMPUS. B. S. Lamishaw*, W. B. Lacefield* and R. C. A. Frederickson. Lilly Research Labs., Eli Lilly and Company, Indianapolis, IN 46285.

Biochemical and electrophysiological evidence suggests some form of coupling between the action of γ-aminobutyric acid (GABA) and benzodiazepines (BZD). GABA enhances BZD binding to neuronal membranes and under certain conditions diazepam (DZ) increases GABA binding. A novel diaryltriazine compound, LY81067, has been found to enhance the binding of ^{3}H-flunitrazepam and ^{3}H-GABA to neuronal receptors, without itself binding to these receptors. We have utilized an electrophysiological model to distinguish GABA-like and BZD-like effects in order to characterize the properties of this and related compounds. Rats were anesthetized with urethane and recording and stimulating electrodes were placed in the CA1 area of hippocampus and contralateral hippocampus, respectively, using stereotaxic techniques. This allowed orthodromic activation of pyramidal cells in CA1 and recording of the resulting population spike. A paired-pulse paradigm was utilized in which the second population spike is reduced in amplitude due to GABA-mediated recurrent inhibition.

Bicuculline (0.1 mg/kg i.v.), but not strychnine (0.7 mg/kg i.v.), antagonized the recurrent inhibition of the second spike confirming mediation by GABA. GABA-like agents such as muscimol (5 mg/kg i.v.), THIP (5 mg/kg i.v.) and Progabide (10 mg/kg i.v.) reduced the amplitude of both population spikes. DZ (0.1 mg/kg i.v.) and LY81067 (0.5 mg/kg i.v.) preferentially inhibited the second spike. Doses ten times higher did not affect the first spike. Thus DZ and LY81067 appear to selectively potentiate GABA-mediated recurrent inhibition. Preliminary experiments suggested that β-carboline-3-carboxylic acid ethyl ester (6 mg/kg i.v.) antagonizes the effects of DZ and LY81067, but not that of muscimol. Thus LY81067 is unique in potentiating GABA action in a manner electrophysiologically similar to that of DZ, but without binding to either GABA or BZD receptors.

159.18 COMPOUND LY81067, A DIARYLTRIAZINE, ENHANCES BENZODIAZEPINE AND γ-AMINOBUTYRIC ACID BINDING TO RAT BRAIN RECEPTORS. Frank P. Bymaster*, William B. Lacefield* and David T. Wong. Lilly Res. Laboratories, Eli Lilly and Company, Indianapolis, IN 46285

Compound LY81067, enhanced the receptor binding of ^{3}H-flunitrazepam (^{3}H-FLU) and ^{3}H-γ-aminobutyric acid (^{3}H-GABA) in cerebral cortical membranes. Stimulation of 50 percent ^{3}H-ligand binding above control occurred at LY81067 concentrations (SC_{50}) of 700 and 250 nM, respectively. The maximal stimulation on binding of both ^{3}H-ligands was higher and the SC_{50} lower for LY80167 than the pyrazolopyridines, tracazolate, etazolate and cartazolate. The saturation binding of ^{3}H-FLU (0.2 to 10 nM) was increased at each concentration by LY81067; Scatchard analysis revealed that predominately the affinity constant (Kd) was decreased from 1.44±0.04 to 0.80±0.03nM and the number of binding sites was increased from 1247.4±21.7 to 1500.6±32.6 fmoles/mg protein. The Hill coefficient was 0.95±0.02 for control and 0.93±0.02 for LY81067-treated membranes. The saturation binding of ^{3}H-GABA (0.5-60nM) was increased at each concentration by LY81067; Scatchard analysis revealed that ^{3}H-GABA bound to 2 components of sites, both of which were stimulated by LY81067. The Kd for each component was decreased and the number of binding sites was increased. The binding of ^{3}H-GABA and ^{3}H-FLU to receptors from cerebral cortex, cerebellum, pons-medulla, hippocampus, corpus striatum, and midbrain were all enhanced by LY81067. The GABA antagonists, picrotoxin and bicuculline, partially antagonized the enhancement of ^{3}H-FLU binding by LY81067. Bicuculline at 10μM changed the SC_{50} of LY81067 from 470nM to 6000nM. The SC_{50} for LY81067 enhancement of ^{3}H-FLU binding was lowered from 6800 to 800nM by addition of chloride anion to a chloride-free medium, suggesting involvement with the chloride ionophore. Treatment of membranes with the detergent Triton x-100 decreased the ability of LY81067 to enhance the binding of either ligand; however, the specific binding of the ligands was not decreased by this treatment and GABA was able to enhance ^{3}H-FLU binding in these membranes. This suggests the solubilization of a component(s) which is required by LY81067 to stimulate binding and that this mechanism is different from that required for GABA-induced elevation of ^{3}H-FLU binding.

159.19 MUSCIMOL-SCOPOLAMINE INTERACTIONS IN THE RAT BRAIN: A STUDY WITH [14-C]2-DEOXY-D-GLUCOSE. P. Helén* and E. D. London. (SPON: G. A. Young) Lab. of Neurosci., Natl. Inst. on Aging, Gerontology Res. Ctr., Baltimore City Hosp., Balto., MD 21224.

The [14-C]2-deoxy-D-glucose ([14-C]DG) method of Sokoloff et al. (J. Neurochem. 28:897,1977) has been used to show that γ-aminobutyric acid (GABA) agonists (muscimol and 4,5,6,7-tetrahydroisoxazolo-[5,4-C-]-pyridin-3-ol, THIP) produce dose-dependent decreases in local cerebral glucose utilization (LCGU) of many brain regions (Palacios, J.M. et al., Eur. J. Pharmacol. 71:333, 1981). Because of evidence for cholinergic components in some actions of GABA-mimetic drugs, we extended our previous observations on GABAergic effects on LCGU, and assessed the cholinergic involvement in GABA-mimetic action by measuring LCGU in rats treated with muscimol in the presence or absence of scopolamine, a muscarinic antagonist.

250-350 g male Osborne-Mendel rats were used in this study. Four hr after surgical insertion of cannulae into the right femoral artery and vein, each rat was given one of the following treatments: saline (1 mg/kg, 30 min and 14 min before [14-C]DG), muscimol (4 mg/kg, 16 min after saline, 1 ml/kg, and 14 min before [14-C]DG), scopolamine (0.4 mg/kg, 30 min before [14-C]DG and 16 min before saline, 1 ml/kg), scopolamine (0.4 mg/kg, 30 min before [14-C]DG) + muscimol (4 mg/kg, 14 min before [14-C]DG). All injections were given i.v.. LCGU was determined as described by Sokoloff et al. (1977).

Muscimol significantly ($p \leq 0.05$) reduced LCGU in the following brain regions: medial geniculate body (35%), nucleus accumbens (26%), auditory cortex (48%), frontal cortex (52%), and thalamic nuclei [ventral (38%), ventromedial (37%), reticular (25%), reuniens (23%) posterior (39%) and parafascicular (26%)]. 0.4 mg/kg scopolamine did not antagonize the effects of muscimol in any brain region. Scopolamine alone reduced LCGU in the media geniculate body (23%), auditory cortex (28%) and frontal cortex (24%). LCGU reductions in response to scopolamine + muscimol were greater than after muscimol alone in the anterior thalamus (45% vs. 21%), periventricular nucleus of the thalamus (45% vs. 21%) and medial cortex (51% vs. 26%). In the following regions, where neither muscimol nor scopolamine decreased LCGU, significant decrements were seen after combined treatment with both drugs: olfactory bulb (49%), lateral habenula (19%) and dentate gyrus (26%).

These findings support the concept of GABAergic-cholinergic interactions in the rat brain and suggest that some GABA-mimetic effects can be enhanced by anticholinergic drugs. Further studies with extended dosage ranges of GABA-mimetic, cholinomimetic and cholinolytic drugs are required for a more complete eluciation of these interactions.

159.20 CHANGES IN 2DG BRAIN METABOLISM INDUCED BY DIRECT GABA AGONISTS. G.T. Golden, R.G. Fariello, G. Alexander* and R.J. Schwartzman. Medical Service, Neurology Section, VA Hospital and University of Texas Health Science Center at San Antonio, Texas 78284.

The direct GABA agonists muscimol (5-Aminomethyl-3-hydroxyisoxazole) and THIP (4,5,6,7 tetrahydroisoxazole (5, 4-C pyridin) 3-oL) have been proposed for clinical application in disease states demonstrating possible impaired GABA mediated inhibition (such as extrapyramidal dysfunctions, pain, psychosis, and seizures). We have examined patterns of metabolic activity in the brains of rats, using the quantitative 14C-2-deoxy-o-glucose technique, after a single i.v. administration of either muscimol (0.7 mg/kg) or THIP (10.0 mg/kg). Rats were anesthetized with ketamine HCl and N20. Cannulas were inserted in the femoral vein and artery. EEG leads were connected to the scalp and the animal was placed in a restrainer and allowed to recover. After recovery, a baseline EEG was recorded for 20 minutes. Ten to twenty minutes after administering a direct GABA agonist, a bolus of 14C 2DG (7.5 μci/100g) was injected via the femoral vein catheter. Arterial blood samples (0.15cc) were obtained at 15 sec intervals for the first minute, 2,4,6,10 minutes, and every 5 minutes for the remainder of the study (45 minutes after the initial bolus injection), for the determination of 14C concentration. Forty-five minutes after 2DG the animals were sacrificed, brains removed, frozen in liquid nitrogen, and cut in 20μ sections; these were placed on microscopic slides and exposed along with plastic 14C standards on Kodak SB-5 x-ray film for 14 days. The 14C concentration of each structure was computed from its optical density as compared to that of the standards. The local cerebral metabolic rate for glucose lCMRg was calculated quantitatively according to its method of Sokoloff (J Neurochem 28:897-916, 1977). The mean lCMRg from the experimental animals were compared to controls by 1 way ANOVA.

Immediately after injection of muscimol, the EEG showed paroxysmal bursts of 4-6 c/s; spike and wave lasting through the experiment. Sustained EEG changes occurred within 30 seconds after THIP, spikes, polyspikes and spike wave occurred bilaterally with a tendency to become rhythmic. 2DG analysis revealed a remarkable alteration of brain metabolic activity compared to control animals. Several neural areas in the experimented animals demonstrated similar patterns of metabolic activity. These include the lateral habenular nucleus, nucleus accumbens, medial septal nucleus, superior olivary complex and the inferior colliculus. All the aforementioned structures showed an increase in lCMRg after both THIP and muscimol. The only common neural area showing a decrease in lCMRg for both muscimol and THIP groups was the motor cortex. In addition, several neural areas showed changes in lCMRg specific to the particular GABA agonist administered.

159.21 POTENTIAL DIAGNOSTIC VALUE OF PLATELET GABA-TRANSAMINASE AND PLASMA GABA IN AFFECTIVE ILLNESS. B. Umberkoman-Wiita, W.H. Berrettini*, T.A. Hare and W.H. Vogel. Department of Pharmacology, Thomas Jefferson University, Philadelphia, Pennsylvania and Section on Psychogenetics, National Institute of Mental Health, Bethesda, Maryland.

Recent studies (Gerner and Hare, 1981; Gold et al., 1980) have demonstrated low CSF GABA in depressed patients. To determine whether the peripheral GABA system was affected in the same way, we measured plasma GABA and platelet GABA-transaminase activity in euthymic medication-free bipolar patients and in normal volunteers. The bipolar group (n = 9) showed significantly lower platelet GABA-transaminase activity ($p < .035$, two-tailed "t" test) and lower plasma GABA ($p < .02$). Additionally, twin studies revealed that both platelet GABA-transaminase activity ($r_i = .57$, $p = .035$) and plasma GABA levels ($r_i = .72$, $p = .007$) were concordant in monozygotic twin pairs (n = 9). We found no correlation between platelet GABA-T and plasma GABA, indicating that platelet GABA-T levels may not play a part in limiting circulating GABA levels. These studies suggest that plasma GABA and/or platelet GABA-transaminase may be genetic markers for vulnerability to affective illness.

159.22 GLYCINE, NEUROACTIVE AGENT EVALUATION. A. de la Sierra, O. González*, V. Santoni*, A. Reyes*, University of P. R., Cayey Campus 00634.

The effect of glycine & its carboxy-borane derivative on the force and rate of contraction of intestinal, cardiac and skeletal muscle of Bufo marinus was registered in a 564B Tektronic oscilloscope with memory storage from a force transducer. Central synaptic effects were also measured by registering force and rate of contraction as well as EMG of gastrocnemius contralateral to a site of sciatic stimulation. All observations were made during a 10 min. period after treatment with 1.0 mg of glycine, epinephrine and a.choline. The interactions of these drugs were also evaluated. Immediately after adding glycine to a 2.0 cm segment of small intestine submerged in 35 cc of aerated glucose-amphibian Ringer's, there was a relaxation of 500 mg of tension sustained for variable periods. Epinephrine caused a dramatic increase in tension of 1.25 grams when compared to only 375 mg from a.choline. Rate of contraction of smooth muscle was too slow and variable to quantitate. This effect was not inhibited by atropine. Alpha and Beta blockers are being evaluated in this respect. The effect of glycine on miocardium was similar to that of a.choline when applied over intact heart of decerebrated frog. Soon after glycine treatment there was a relaxation of 500 mg and a bradycardia of 30/min. responsible for an increased diastolic filling that periodically provoqued a violent Sterling contraction of 750 mg during sistolic ejection. The arrhytmia persisted for 6 min. Epinephrine had variable effects. The central synaptic results are inconclusive and the experimental design subject to re-evaluation. With the aid of the MNDO computer program (Univ. of Indiana), we are making theoretical evaluations of these results as they relate to conformational changes in glycine and their Boron derivatives, currently assayed.

159.23 TAURINE PRODUCES GABA-LIKE INHIBITION OF EVOKED POTENTIALS IN CAT SOMATOSENSORY CORTEX S. Brailowsky and R. T. Knight*, Clinical Neurophysiology Laboratory, U.C. Davis, V.A. Medical Center, Martinez, CA 94553.

The primary SEP in the cat consists of a surface positive followed by a surface negative deflection. Previous studies suggests that the positivity reflects depolarization of cell bodies of neurons in layer IV and that the aftergoing negativity reflects depolarization of corresponding apical dendrites. GABA has been shown to inhibit this aftergoing negativity of the primary SEP in the cat. Taurine produces GABA-like inhibition in several physiological systems. We investigated the effects of acute direct cortical application of low doses (1-100 ug/ul) of GABA and taurine on the cat primary SEP. Twenty animals were studied in acute preparation under barbiturate anesthesia with monitoring of core temperature and controlled expired carbon dioxide concentration. The cortical surface was maintained by warmed saline drip. Both GABA and taurine produced rapid, equivalent and reversible inhibition of the negativity of the primary SEP. Saline control and glutamate had no effect. We were unable to inhibit the taurine and GABA effects by pre-treatment with bicuculline or picrotoxin, even when these substances induced epileptogenic activity at the application site.

We conclude that even if taurine is not considered a true neurotransmitter, its physiological effects on superficial layers of the somatosensory cortex are indistinguishable from those of GABA.

160.1 CHARACTERIZATION OF VASOPRESSIN-STIMULATED ORNITHINE DECARBOXYLASE IN MOUSE BRAIN. R. Tintner, H.E. Gray, W.G. Luttge and A.J. Dunn. Dept. of Neuroscience, Univ. of Florida, Gainesville, FL 32610.

The polyamines are believed to modulate cellular responses to a number of hormones and neurosecreted agents. Ornithine decarboxylase (ODC) is the initial, and probably rate-limiting, enzyme in their biosynthesis. We earlier showed that intracerebroventricular (icv) injections of either lysine-vasopressin (LVP) or saline-increased ODC activity in adult mouse brain, but with different time courses. The effect of LVP, however, was much larger and dose-dependent (Tintner et al., Trans. Am. Soc. Neurochem., 12:150, 1981). The present studies extend the endocrine and enzymologic characterization of this effect.

Male CD-1 mice (25-32 gm) were used. All peptides were injected bilaterally icv in a total of 2 ul and animals sacrificed 3h after injection. ODC was assayed routinely by capture of $^{14}CO_2$ from 1-[^{14}C]-L-ornithine substrate. LVP, ACTH, PRO-LEU-GLY-NH_2 (PLG), desamino-8-arginine-vasopressin (DDAVP) or oxytocin injections increased brain ODC activity 206, 190, 160, 128 and 102% of saline control, respectively. Adrenalectomy prevented the increase in ODC activity by LVP relative to saline but not the smaller increase seen in injected relative to uninjected animals. High dose dexamethasone restored the former but suppressed the latter effect. The enzyme activity was localized exclusively to the cytosol fraction by the routine assay with added γ-acetylenic GABA (Dow-Merrell) and by assay of ^{14}C-putrescine from U-[^{14}C]-L-ornithine. Cytosol from LVP-injected adult and uninjected neonatal mouse brain was subjected to Sephacryl (S-300) gel filtration and ultracentrifugation on 10-30% glycerol linear gradients. The adult and neonate preparations behaved identically with the following hydrodynamic parameters: $S_{20,\omega}$ 3.8±.1 X 10^{-13} s^{-1}, Stokes' radius 38.5±1.6 X 10^{-8} cm, molecular weight 63±4 X 10^3 Daltons, f/f_o 1.5.

These data are discussed in relation to the known behavioral and biochemical effects of vasopressin and its analogs as well as the physical characteristics of ODC from other tissues.

160.2 MODULATORY EFFECTS OF CATECHOLAMINES AND VASOPRESSIN ON NEURONS IN THE LATERAL SEPTUM. J.E. Marchand and N. Hagino. Dept. of Anatomy, Univ. TX Health Sci. Ctr. at San Antonio, TX 78284

Neurons containing Dopamine (DA), norepinephrine (NE), and vasopressin are known to project to the lateral septum; furthermore, these neurotransmitters have been shown to be involved in functions controlled by the septal-hippocampal axis. In this study, we have used electrophysiological and iontophoretic techniques to examine the effects of these agents on responses of lateral septal neurons driven by stimulation of hippocampal efferents.

Field and extracellular unitary potentials were recorded (using glass pipette containing .2M NaAcetate and Pontamine Sky Blue) from neurons in the lateral septum of urethane anesthetized (1 g/Kg bwt) Sprague-Dawley albino rats. Stimulation of the fimbria-fornix, using bipolar stainless steel electrodes (250 µm o.d., 300 µm intertip distance) evoked two prominent negative field potentials in the lateral septum. The early negativity developed a peak amplitude at 4-6 msec, and latencies of unitary spikes driven by stimulation corresponded with the field negativity; units were activated at latencies of 4-7 msec and appeared to be monosynaptically driven, as determined by small latency shifts during decreased intensity of stimulation. The later polysynaptic negative field potential (peak amplitude 10-12 msec) with associated unitary spikes (9-13 msec latencies) was also activated by fimbria-fornix stimulation, and was particularly prominent in the ventral portion of the lateral septum. Further, it was found that decreasing the stimulus intensity increased the size of the late negative field, and caused an increased probability of firing of the septal unit at the late vs the early latency. DA, NE, and arginine-vasopressin (AVP) were iontophoresed upon these septal units, and it was found that each of these agents reduced the probability of the unit firing at the first latency, while increasing the probability of firing at the second latency. These data suggest that the function of these transmitters might be to enhance polysynaptic responses over monosynaptic responses. (Supported by NICHD-HD-10071.)

160.3 NEUROTENSIN INCREASES DOPAMINE TURNOVER IN RAT BRAIN. Avinoam Reches, Robert E. Burke, De-hua Jiang, H. Ryan Wagner, & Stanley Fahn, Dept. Neurology, College of Physicians & Surgeons, Columbia University, New York, NY 10032.

Neurotensin (NT) injected intracerebroventricularly (ICV) in rat increases dopamine (DA) turnover in the corpus striatum and nucleus accumbens. Significant increases in 3,4-dihydroxyphenylacetic acid (DOPAC) levels occurred within 15 min after injection with peak levels at 60 min for both brain regions. This effect of NT was dose-dependent; significant increases in DOPAC and homovanilllic acid (HVA) accumulation were obtained at 3 ug with maximal response at 100 ug. NT, like haloperidol, stimulated 3,4-dihydroxyphenylalanine (DOPA) accumulation in striatal neurons in the presence of DOPA decarboxylase inhibitor after injection of gamma-butyrolactone (GBL), an agent which selectively blocks the firing of dopaminergic neurons. NT (30 ug) had a similar stimulatory effect on DOPA levels in the accumbens while haloperidol (0.25 $mg \cdot kg^{-1}$) had an insignificant effect in this brain region. NT failed to block the inhibitory effect of apomorphine (0.5 $mg \cdot kg^{-1}$) on DOPA accumulation in both the striatum and accumbens after GBL injection while haloperidol (0.25 $mg \cdot kg^{-1}$) inhibited apomorphine effect in both regions. Unlike antipsychotic drugs, NT failed to displace ^{3}H-spiperone from DA receptors in either the corpus striatum or nucleus accumbens. The presence of NT in the binding assay did not alter the ability of DA to displace ^{3}H-spiperone in either brain region. These experiments suggest that NT increases DA turnover in the nigrostriatal and mesolimbic pathways. It is suggested that this effect is mediated, in part, through inhibition of presynaptic DA receptors in a mechanism which is different from the one through which the antipsychotics interact with the DA receptors.

This work was supported in part by NIH grant NS15959, the Peggl Engl Fellowship awarded to Dr. Reches by the Parkinson's Disease Foundation, and by a Fogarty Public Health International Research Fellowship (NIH TW02884) awarded to Dr. Reches. Dr. De-hua Jiang was the recipient of an H. Houston Merritt Fellowship from the Parkinson's Disease Foundation.

160.4 VASOPRESSIN AFFECTS DOPAMINE-SENSITIVE ADENYLATE CYCLASE IN RAT BRAIN. N.D. Courtney* and M.A. Raskind* (SPON: T. Kennedy). Geriatric Research, Education & Clinical Center, Veterans Administration Medical Center, Seattle, WA 98108.

Evidence indicates that behavioral effects of vasopressin result from its action at specific sites (receptors) in the brain (De Wied, D. The Neurosciences. Edited by F.D. Schnidt et al, MIT Press, 1974, pp. 653-666). Peptide hormones may bind to receptors and consequently activate adenylate cyclase or may modulate the effect of other neurotransmitters on the activity of adenylate cyclase. We examined the effect of vasopressin on adenylate cyclase activity in rat brain, addressing the questions: 1) Does vasopressin alter adenylate cyclase activity in brain homogenates? 2) Does vasopressin modulate dopamine stimulation of caudate adenylate cyclase? Dopamine was chosen on the basis of its well-characterized stimulation of adenylate cyclase in homogenates of caudate nucleus.

Male Wistar rats were sacrificed by decapitation. The brains were quickly removed and brain regions were dissected according to the guidelines of Glowinski and Iverson. Brain regions were homogenized in 2 mM Tris-2 mM EDTA and assayed immediately. The standard adenylate cyclase assay mixture (100 µl) contained 80 mM Tris-Maleate pH 7.4, 0.5 mM ^{32}P ATP (150-250 cpm/pmol), 2.0 mM $MgCl_2$, 1 mM isobutyl methyl xanthine, 0.6 mM EGTA, 0.5 ml tissue homogenate plus the samples to be tested. The reaction was carried out at 30°C. ^{32}P cyclic AMP formed was recovered by the method of Salomon et al (Saloman, Y. et al. Anal. Biochem. 58:541-548, 1974).

Vasopressin significantly enhanced dopamine activation of caudate adenylate cyclase. This vasopressin effect was concentration dependent. Maximal enhancement (62%) occurred with $1x10^{-4}$ M vasopressin. Over the concentration range of $1x10^{-4}$ to $1x10^{-6}$ M, vasopressin alone had no reliable effect on the activity of caudate adenylate cyclase under the conditions tested. Further, adenylate cyclase activity was not reliably altered with vasopressin in selected brain regions.

These results indicate that although vasopressin may not have a direct effect on adenylate cyclase activity, it can modulate the activation of adenylate cyclase by another neurotransmitter. This modulatory effect is compatible with that demonstrated for other neuropeptides.

160.5 NIGROSTRIATAL DOPAMINE TERMINALS BEAR NEUROTENSIN RECEPTORS BUT THE MESOLIMBIC DO NOT. R. Quirion, H.D. Everist and A. Pert. Biological Psychiatry Branch and Neuroscience Branch, NIMH, Bethesda, MD 20205.

Neurotensin has been shown to exert complex effects on dopamine neurotransmission. These effects appear to be mediated through dopaminergic cell body areas as well as their terminal fields. The purpose of this study was to ascertain the precise localization of neurotensin receptors in relation to mesolimbic and nigrostriatal dopamine neurons. Nigrostriatal dopaminergic projections were lesioned unilaterally by intranigral injections of 6-hydroxydopamine (9 µg). Mesolimbic dopaminergic projections were lesioned either unilaterally (7.5 µg 6-OHDA) or bilaterally (7.5 µg 6-OHDA per side) by injections of this neurotoxin into the A-10 catecholamine nuclei. One month later tha animals were killed and their brains removed. Serial 25µm sections were taken through the forebrain region encompassing the nucleus accumbens and caudate nucleus and the midbrain region encompassing the substantia nigra and ventral tegmental area. These sections were than exposed to [^{3}H]-neurotensin and processed for autoradiography using a tritium sensitive film. Computer optical density analysis was used to quantify the lesion effects.

There appeared to be considerable binding of [^{3}H]-neurotensin to the substantia nigra, especially the zona compacta. Neurotensin receptors appeared to increase in number along a caudal to rostral plane in the caudate nucleus. No differences were observed along the dorsal-ventral plane however. The nucleus accumbens appeared to contain 24% more neurotensin binding than the head of the caudate nucleus at the same level. Neurotensin binding was reduced significantly in the substantia nigra following 6-OHDA lesions, indicating that some neurotensin receptors are located on dopaminergic cell bodies or dendrites. Similar findings have been reported by Palacios and Kuhar (Nature, 294: 587, 1981). Neurotensin binding also decreased in the more medial A-10 regions following 6-OHDA injections. We also found a substantial decrease of neurotensin receptors in the caudate nucleus ipislateral to the nigral 6-OHDA lesions. Neurotensin binding in the dorsal half of the caudate was reduced 65% relative to the unlesioned side. Binding in the ventral aspect, however, was reduced only 37%. Interestingly, neither unilateral nor bilateral A-10 lesions were effective in reducing neurotensin binding in the nucleus accumbens. Neurotensin receptors appear to be localized on dopaminergic terminals in the nigrostriatal but not the mesolimbic pathway. Dopaminergic cell bodies giving rise to both of these pathways, on the other hand, are high in neurotensin receptors. The pharmacological effects of neurotensin on dopaminergic neurotransmission are probably mediated through all of these sites.

160.6 EFFECTS OF VASOACTIVE INTESTINAL POLYPEPTIDE AND OTHER VASOACTIVE AGENTS ON ADENYLATE CYCLASE IN RAT CEREBRAL MICROVESSELS. Minta Huang* and O.P. Rorstad, Dept. of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

The following observations by other workers suggest that vasoactive intestinal polypeptide (VIP) may play a role in regulating cerebral vascular tone: 1. Vasodilatation of cerebral vessels and in increase of cerebral blood flow by VIP, 2. Localization of VIP-like immunoreactivity in nerves innervating cerebral vessels. On the basis that cAMP probably is the second messenger responsible for vasodilatation caused by beta adrenergic agents, the present study examined the effects of VIP and other vasoactive agents on the activity of adenylate cyclase (AC) in isolated rat cerebral microvessels. Catecholamines, prostaglandin E_1 (PGE_1), prostaglandin E_2 (PGE_2) and 2-chloro-adenosine (2-Cl-Ad) stimulated rat microvessel AC in a similar manner as previously observed with guinea-pig microvessel AC (Huang and Drummond, Mol Pharmacol 16: 462, 1979). The order of relative potency of the catecholamines was isoproterenol (INE)>epinephrine (EPI)>norepinephrine (NE) (see table). Stimulation of AC by catecholamines was completely abolished by propranolol and unaffected by phentolamine. Histamine and dopamine at 0.1 mM had marginal stimulatory action. Serotonin had no effect at the same concentration. Activations by PGE_1, PGE_2 and 2-Cl-Ad were dose-related. Only VIP, out of 22 peptides (many of which are vasoactive) examined, stimulated AC activity. Stimulation by VIP required guanosine triphosphate and was unaffected by propranolol or phentolamine. The magnitude of the VIP response was 2-3 fold over the activity observed with guanosine triphosphate alone. The activity of AC in response to VIP tested in combination with INE, PGE_1 or 2-Cl-Ad approximated the sum of activities elicited by each agonist tested independently. The action of VIP was not mimicked by other peptides of the glucagon-secretin family. Somatostatin-14, which has an inhibitory action on stimulated AC activity in some model systems, somatostatin-28 and [D-Trp^8,D-Cys^{14}] somatostatin (a superactive analog) had no effect on the stimulatory action of VIP or PGE_1 on microvessel AC. In conclusion, this study suggests the existence of cerebral vascular receptors for VIP that are distinct from receptors for catecholamines, PGE_1, adenosine or other peptides of the glucagon-secretin family.

160.7 IMMUNOHISTOCHEMICAL LOCALIZATION OF GLUTAMATE DECARBOXYLASE AND MET-ENKEPHALIN-LIKE IMMUNOREACTIVITY IN THE SEPTAL COMPLEX OF THE RAT. D.L. Cheney, P. Panula*, A.V. Revuelta*, H.K. Thompson*, J.-Y. Wu and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032 and Baylor College of Medicine, Houston, Texas.

Previous biochemical and immunohistochemical studies have shown that met-enkephalin is found in the lateral septum, where enkephalin-immunoreactive fibers and terminals surround the cell bodies in a basket-like manner. However, few met-enkephalin immunoreactive cells have been found in this region and it has been suggested that the fibers might come from the hypothalamus or dorsal raphe nucleus. Antibodies against glutamate decarboxylase (GAD), the synthesizing enzyme of GABA, have been used to study the distribution of GABAergic neurons in different parts of the brain, but these studies have not included the septal region. In this study we report the distribution of met-enkephalin-like immunoreactivity (ME-LI) and GAD-like immunoreactivity in the septal complex of the rat. Brains of formalin-fixed normal and colchicine-treated rats were used. The peroxidase/antiperoxidase method was used to demonstrate immunoreactivity in fresh cryostat sections. Dilution of the specific antibodies was 1:1000 and incubation was carried out at 4° for 48 hours. Consecutive sections were incubated with non-immunized rabbit serum or met-enkephalin antiserum preabsorbed with met-enkephalin. These sections showed no reaction product. In normal rat brain, a dense network of met-enkephalin immunoreactive fibers and terminals surrounding the cells was seen in the intermediate part of the lateral septal nucleus. In colchicine injected animals, numerous met-enkephalin-immunoreactive cells were found in the dorsal, intermediate and ventral parts of the lateral septal nucleus. Fewer cells were found in the medial septal nucleus and in the nucleus of the diagonal band. Neurons exhibiting GAD-immunoreactivity were most numerous in the medial septal nucleus and in the nucleus of the diagonal band. These large cells extended posteriorly to the septo-fimbrial nucleus. The dorsal, intermediate and ventral portions of the lateral septal nucleus contained relatively few small GAD-positive cells, but in this area a dense network of GAD-positive fibers and terminals was observed. Thus, the GABAergic cell bodies in the septal complex are located in the same area where cholinergic septo-hippocampal neurons are found. Interactions between the GABAergic and cholinergic neurons in this area may explain the reduced turnover rate of acetylcholine in the hippocampus when GABA agonists are injected into the septal area. Contrary to what has been published it appears that the septal complex has a large number of met-enkephalin immunoreactive cell bodies and terminals. The possibility exists that enkephalin in the septum may be largely confined to septal interneurons.

161.1 TIME COURSE OF CAPSAICIN EFFECTS ON SUBSTANCE P-IMMUNOREACTIVE NERVES IN THE CARDIOVASCULAR SYSTEM. R.E. Papka, J.B. Furness* and M. Costa*. Dept. Anatomy, Univ. of Kentucky, Lexington, KY 40536 and Ctr. Neuroscience, Flinders Univ. South Australia 5042.

Capsaicin, the active agent in many chili peppers, releases and depletes substance P from primary sensory neurons. When administered to animals the effects of capsaicin are evident very quickly (within one to several minutes); these include lacrimation, activation of some nociceptors, bronchial constriction and vasodilatation. Since the effects of capsaicin are likely to result from release of substance P we examined, morphologically, the time course of the effects of capsaicin on substance P-immunoreactive nerves. Previous studies (Papka, R.E., et. al., Neurosci. Lett., 27: 47, 1981; Furness, J.B. et. al. Neurosci., 7: 447, 1982) indicated that guinea pig pericardium, atrioventricular valve, inferior vena cava, superior mesenteric artery and intestinal submucosa are model tissues for study because of their characteristic pattern and density of capsaicin-sensitive substance P-immunoreactive nerves. Guinea pigs were injected s.c. with capsaicin, 50 mg/kg, and sacrificed after 5,15,30, 60 minutes, 2,4,12 or 24 hours. Tissue was processed for immunohistochemistry of substance P (using whole mount preparations) and conventional electron microscopy.

In control preparations immunofluorescence in nerve trunks and fibers appeared bright and homogeneous. Within five minutes after injection of capsaicin changes were observable. The immunofluorescence began to appear less intense and less homogeneous (e.g. it appeared somewhat granular or "dusty"). Larger nerve trunks remained evident; however, there was a decrease in number of immunofluorescent fine single fibers. With increasing time after capsaicin treatment there was a trend toward progressive dimunition of the substance P-immunofluorescence, so that by 4 hours about 50% fewer nerve fibers were evident in the preparations and by 24 hours there was up to 95% fewer fibers. In those trunks that were evident, the intensity of immunofluorescence was markedly reduced and it appeared granular or "dusty". In animals treated for 2 hours or longer immunofluorescent swellings were commonly seen in nerve trunks. Electron microscopy revealed alterations in some nerve fibers within 5 minutes after capsaicin treatment. These include swelling of fibers, loss of internal morphology and disruption of mitochondrial morphology. In some fibers it appeared as though degenerative processes were in progress.

Capsaicin appears to have a quick onset of action with regard to its effects on the morphology of substance P-immunoreactive nerves. This action is progressive and by 24 hours depletion of substance P-immunoreactive material is nearly complete. Supported by Grant 1RO1HL22226 from NHLBI and PHS BRSG 2SO7RR05374-20.

161.2 ULTRASTRUCTURAL EFFECTS OF CAPSAICIN ON SUBSTANCE P TERMINALS IN THE SUBSTANTIA GELATINOSA. L.D. Wilkin, T.H. Williams. Dept. Anatomy, Univ. Iowa College Med., Iowa City, IA 52242.

Intrathecal or subcutaneous administration of capsaicin to experimental animals has been found to produce desensitization to noxious thermal and chemical stimuli. It has been hypothesized that capsaicin induced analgesia results from depletion of substance P (SP), a putative pain transmitter, from the terminals of primary afferent neurons in the spinal cord. In vivo and in vitro studies in which capsaicin was administered to spinal cord or spinal cord slices resulted in release and depletion of SP. However, other putative neurotransmitters have been identified in these areas and capsaicin has been shown to deplete somatostatin and cholecystokinin varicosities in the substantia gelatinosa. At the ultrastructural level, information is lacking regarding the effects of capsaicin on neurons containing SP.

Male guinea pigs (250-350g) received incremental subcutaneous injections of capsaicin totaling 125 mg over a 48 h period and were allowed to survive for 2 d or 8-10 d. Control animals received no treatment. All animals were anesthetized with Nembutal, ventilated with 95% O_2-5% CO_2, and perfused with a fixative solution of 4% paraformaldehyde-0.2% glutaraldehyde in phosphate buffer. Tissue blocks from the cervical spinal cord were sectioned with a vibratome and processed for SP immunocytochemistry according to the PAP method of Sternberger. Following immunostaining, tissues were postfixed in osmium tetroxide and embedded in epon for thin sectioning and electron microscopy.

At the light microscopic level, the normally dense SP immunoreactivity in layers I to III of the substantia gelantinosa appeared markedly reduced in both short- and long-term capsaicin treated animals. At the ultrastructural level, SP terminals were numerous in layers I to III of control animals, conforming to previous descriptions of small, unmyelinated fibers and C-type terminals. In 2d-survival animals, the contents of SP-immunoreactive axons and terminals in substantia gelatinosa were highly variable. While some of these profiles were intact, others appeared to be at various stages of disorganization with different degrees of depletion of SP-immunoreactive vesicles. In 8d animals, no intact SP-immunoreactive terminals were found; only disorganized SP-immunoreactive terminals devoid of vesicles were present. The axolemma was intact in most SP-immunoreactive elements. "Classical" degeneration of SP-immunoreactive processes was not seen.

Supported in part by Grant #NS11650 to T.H.W.

161.3 POTASSIUM EVOKED RELEASE OF CHOLECYSTOKININ FROM FRONTAL CORTEX AND HYPOTHALAMUS OF LEAN AND GENETICALLY OBESE RATS. P. Micevych, T. Yaksh*, V.L.W. Go* and J. Finkelstein. Depts. of Neurosurgery and Gastroenterology, Mayo Foundation, Rochester, MN 55905, and Program in Human Anatomy, Northeastern Ohio Univ. College of Med., Rootstown, OH 44272.

Recent evidence has implicated cholecystokinin (CCK) as a centrally acting satiety factor. We examined the tissue levels of CCK in the hypothalamus and frontal cortex of the genetically obese (fa/fa; wt = 450-500 g) Zucker rat and found that they were not different from age-matched lean (Fa/-; wt = 200-270 g) littermates. We then examined the release of CCK from frontal cortical and hypothalamic fragments in vitro. Rats of either sex, 9-14 weeks old were decapitated and the hypothalamus or frontal cortex was dissected out. Hypothalamic or cortical fragments were superfused with oxygenated KRB containing D-glucose and bacitracin (a protease inhibitor). The depolarizing stimulus was 50 mM K+. Five 10-min samples were collected, lyophilized and then reconstituted to 1/3 their original volume for RIA. The magnitude of release (basal or evoked) of CCK from frontal cortices obtained from fa/fa and Fa/- rats did not vary.

		Frontal Cortex	Hypothalamus
Tissue Levels[1]	Obese	26.7 ± 3.5	24.3 ± 5.7
	Lean	23.9 ± 4.1	27.6 ± 5.2
Release[2]	Obese	2.7 ± 4.1	2.1 ± 0.19
	Lean	2.6 ± 3.5	1.15 ± 0.16

[1]Values are mean of 5 trials ± SEM in pMole equivalents CCK-8/mg wet weight tissues.

[2]Mean of 9 trials ± SEM in fMole equivalents CCK-8/mg/10 min.

However, hypothalamic fragments from obese rats were observed to release significantly greater amounts of CCK, in response to K+, than their age-matched lean littermates. The basal release levels from obese and lean rats were the same (0.3 ± 0.09 fMoles/mg tissue/10 min). Sephadex G-50 chromatography demonstrated that the immunoreactive CCK was isographic with authentic sulfated CCK-8. These studies, and the recent work demonstrating that the levels of CCK-8 binding sites are lower in the hypothalami of obese rats than in lean rats (Finkelstein et al, Endocrine Soc. Abs., 1982) may imply a genetic lesion in these obese animals which involves a decreased receptor population in hypothalamus and an elevated release of CCK in the hypothalamus, a CNS area implicated in satiety. 161.4 IMMUNOHISTOCHEMICAL AND RADIOIMMUNOASSAY STUDIES OF SUBSTANCE P IN THE DORSAL HORN FOLLOWING GANGLIONECTOMY. A. Stroink*, P. Micevych, V.L.W. Go* and T.L. Yaksh* (SPON: F.W.L. Kerr). Depts. of Neurosurgical Research and Gastroenterology, Mayo Foundation, Rochester, MN 55905.

Deafferentation of the cat lumbosacral dorsal horn by unilateral ganglionectomy L2-S3 produces a depletion of substance P (sP) immunoreactivity as demonstrated by the peroxidase-antiperoxidase technique of Sternberger. This depletion is most marked at 11 days postlesion as compared to the nonlesioned side. This was followed by a partial recovery of sP in the substantia gelatinosa at 14 days; and by one month the restoration of sP in the dorsal horn was indistinguishable from the unlesioned side. Met-enkephalin (M-ENK) immunoreactivity remained unchanged by ganglionectomy. We have attempted to correlate these qualitative immunohistochemical results, thought to be suggestive of sprouting, with quantitative radioimmunoassay (RIA) analysis. Unilateral ganglionectomies L2-S3 were performed on cats (2.5-4 kg) which were allowed to survive 7, 11 and 21 days postsurgery and then sacrificed under deep pentobarbital anesthesia. Spinal cord tissue was then removed at the midpoint of the surgical lesion (L4-L7) and separated into four quadrants (left and right, ventral and dorsal) and immediately frozen. RIA was performed on this tissue as well as comparable spinal cord tissue in unlesioned cats. The control levels of sP and M-ENK in the dorsal horns of unoperated cats (ng/gm) are given below:

	Right Dorsal Horn	Left Dorsal Horn
sP	197.7	187.2
M-ENK	44.7	41.3

Compared to the intact dorsal horn, a 35% depletion of sP immunoreactivity is observed at 7 days postlesion, 29% depletion of sP at 11 days, and 70% depletion of sP at 21 days. At no time following unilateral ganglionectomy were levels of M-ENK immunoreactivity altered as compared to the controls. There was no significant change in the levels of sP immunoreactivity in the ventral horns in any of these animals. RIA does not appear to confirm the immunohistochemical evidence for the recovery of sP immunoreactivity following ganglionectomy. The reasons for this discrepancy are yet unclear but may question our understanding of sprouting in the dorsal horn postdeafferentation. (Supported by funds from the Mayo Foundation and AM 07198-06.)

161.5 DISTRIBUTION OF ENKEPHALIN, SUBSTANCE P AND SEROTONIN LIKE IMMUNOREACTIVITY IN THE INTERPEDUNCULAR NUCLEUS OF THE CAT. S.E. Kapadia* and N.C. de Lanerolle. Depts. of Anatomy and Neurosurgery, Yale Univ. Sch. of Medicine, New Haven, CT 06510.

The aim of this investigation was to define the distribution of methionine-enkephalin (ENK), substance P (SP) and serotonin (5-HT) like immunoreactivity within the interpeduncular nucleus (IPN). Consecutive vibratome transverse serial sections (65 um) obtained in the cranio-caudal axis of the midbrain were processed using the indirect antibody peroxidase-antiperoxidase immunocytochemical technique, and examined by both light and electron microscopy (EM). The IPN can be subdivided by the cross sectional arrangement of blood vessels within it. Two rows of dorsoventrally aligned large blood vessels are located bilaterally and two similarly aligned rows of smaller vessels are present medial to the large vessels, dividing the IPN into a paired outer lateral region, a paired intermediate region and an unpaired median region. Each region is further divided into a dorsal, middle and ventral zone. ENK-like immunoreactivity was seen in some cell bodies and fibers within the paired lateral and intermediate regions throughout the length of the IPN. About the middle of the IPN in the cranio-caudal axis was a distinct cluster of ENK cell bodies and fibers in the dorso-intermediate zone. SP containing perikarya and fibers were seen mainly in the rostral IPN with maximal concentrations in the unpaired median region, specifically in the ventromedian and central zones. By contrast, 5-HT labeled structures were principally located in the caudal IPN. Both cell bodies and fibers were distributed throughout the lateral and intermediate regions extending into the dorsomedian and ventromedian zones. Thus the 5-HT immunoreactive structures form a girdle inside the IPN around its periphery. In the dorsomedian zone were predominantly 5-HT cell bodies, whereas in other regions a mixture of cell bodies and fiber-like processes were seen. EM revealed distinct differences in cell size, morphology of cellular organells and synaptic organization of the different neurochemical systems examined. Of particular interest was the clear demonstration of axo-dendritic contacts in which both the terminal and dendrite were immunoreactive for SP. (Supported by Yale Fluid Research Funds).

161.6 CONTRIBUTION OF BULBOSPINAL AND INTRASPINAL PATHWAYS TO SUBSTANCE P-LIKE IMMUNOREACTIVITY IN THE THORACIC SPINAL CORD. J.F. McKelvy B.M. Davis, J.E. Krause and J.B. Cabot, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, N.Y. 11794.

Substance P-like immunoreactivity (SPLI) is found throughout the thoracic spinal grey, and is particularly dense in laminae I and II of the dorsal horn and in the neuropil surrounding sympathetic preganglionic neurons (SPN's). Since both the brainstem and the spinal cord contain SP positive cells which might give rise to such terminations, the relative contribution of bulbospinal and spinal-spinal pathways to SP content in the thoracic spinal cord was assessed using a highly specific and sensitive radioimmunoassay.

White Carneaux pigeons (15) were used. In 6 birds the thoracic spinal cord was totally transected at the junction between T2 and T3. After a 7 day survival time the birds were decapitated. T1, T2, T3 and T4 were removed, frozen separately on dry ice and microdissected into three regions: dorsal horn (DH), ventral horn (VH) and the intermediate spinal grey (containing the SPN's). Unoperated control birds (6) were processed in parallel. Three additional birds received mid-cervical hemisections. After 14 days these birds were decapitated, and the T1 spinal segment was removed and frozen. T1 was microdissected in the transverse plane into right and left DH and VH, and right and left intermediate laminae. SP was acid extracted (cold 2M HOAc) from tissue and acid soluble protein in each sample was determined using Lowry's assay. The results are expressed in SP/region (e.g.SP/T1 DH) and SP/ug acid soluble protein.

In general results were similar whether the amount of SP was expressed per region or per ug protein. Significant depletion was seen in the DH and VH in all segments sampled, rostral and caudal to the thoracic transection. Depletion in the DH was 30-50% (ANOVA, $p<.05$) and 30-40% in the VH ($p<.05$). No significant depletion was seen in intermediate laminae rostral to the transection. Caudal to the transection, however, the amount of SP was decreased by as much as 37% ($p<.05$). No significant differences in SP content could be detected between the two halves of the spinal grey in cervical hemisected birds. Indeed, the total amount of SP calculated by combining samples from both sides of the spinal cord, was indistinguishable from levels found in controls.

The lack of significant SP depletion following cervical hemisection suggests that bulbospinal SP input to avian DH, VH, and SPN's must be minor. In contrast, the presence of significant SP inputs via intraspinal circuits can be inferred from the observations following total transection of mid-thoracic spinal cord. (Supported by HL24103 and BNS 7921781.)

161.7 SUBSTANCE P PATHWAYS TO SYMPATHETIC PREGANGLIONIC NEURONS: EVIDENCE FOR MAJOR SPINAL-SPINAL CIRCUITRY. B.M. Davis and J.B. Cabot, Dept. Neurobiology and Behavior, S.U.N.Y. at Stony Brook, Stony Brook, NY 11794.

Substance P (SP) immunoreactivity has been localized to the sympathetic preganglionic neuropil at the light microscopic level in several vertebrates including the cat, rat, and pigeon. Moreover EM immunohistochemistry has revealed SP staining in terminals containing dense core vesicles in the rat sympathetic preganglionic neuropil (Holet and Elde,1981). We report here the results of experiments designed to locate the cells of origin of the SP projection(s) to avian sympathetic preganglionic neurons (SPN's).

White Carneaux pigeons (Columba livia) were used. Lesions were placed so as to isolate the thoracic spinal cord from regions of the nervous system known to contain SP cells. After a 7 or 14 day survival time, birds were perfused and spinal cord segments sectioned and stained for SP or 5-HT-like immunoreactivity. In an additional 3 animals injections of tritiated amino acids were made in dorsal root ganglia and the appropriate segments of thoracic spinal cord were processed for autoradiography.

Pigeons in which 3,5 or 6 sequential dorsal rhizotomies (C14-T5) were performed showed no obvious depletion of SP staining in the SPN neuropil. Conversely, SP staining was markedly reduced in the dorsal horns ipsilateral to the rhizotomies. The autoradiographic results confirmed that primary sensory afferents terminated in dorsal and ventral horns but no projection to SPN's could be detected.

High cervical hemisections also had no effect on the SP staining. In these cases, adjacent sections were stained for 5-HT-like immunoreactivity.(The cells giving rise to 5-HT terminals in the spinal cord are located exclusively in the brainstem.) Unlike the SP staining, 5-HT staining was greatly attenuated in the dorsal and ventral horns, and in the SPN neuropil ipsilateral to the hemisection.

Minor SP depletion was observed in all regions of the spinal grey, rostral and caudal to a mid-thoracic spinal transection. Depletion was confined to the segments adjacent to the transection, with normal levels of SP staining present in the remainder of the spinal cord. Substantial depletion of SP within the SPN neuropil was observed only when thoracic spinal cord was totally isolated from ascending and descending axons by two ipsilateral thoracic hemisections or two total thoracic transections.

Currently, we are repeating these experiments using a highly specific and sensitive radioimmunoassay for SP(1-2pg).The results to date confirm the major conclusion of the above experiments: The majority of SP terminations within the SPN neuropil have their cells of origin in the spinal grey.(Supported by HL24103)

161.8 REGIONAL BRAIN DISTRIBUTION OF NEUROTENSIN-LIKE IMMUNOREACTIVITY IN THE WOODCHUCK (MARMOTA MONAX). G. Bissette*, D. Luttinger, C.B. Nemeroff, V.M. Miller and A.J. Prange, Jr. (SPON: P.T. Loosen). Biol. Sci. Res. Ctr., Dept. Psychiat. and the Neurobiology Program, University of North Carolina School of Medicine, Chapel Hill, NC 27514 and School of Life and Health Sciences, University of Delaware, Newark, DE 19711.

Neurotensin (NT) is a tridecapeptide (pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Lle-Leu-OH) that is heterogeneously distributed in the central nervous system (CNS) of the rat, guinea pig, rabbit, cow, monkey and man. When administered directly into the CNS, NT produces a variety of effects including hypothermia, analgesia and muscle relaxation (see Trends in Neurosciences 3: 212-215, 1980 for review). Our group has previously reported that centrally administered NT produces a potent hypothermic response in the rat, mouse, gerbil, hamster, guinea pig and monkey (Pharmacol. Biochem. Behav. 11: 473-477, 1979). This effect was not observed in the woodchuck, even after the administration of large doses (100 µg) of the peptide. In view of this finding, we sought to determine whether NT is present in the brain of the woodchuck and if so, whether the CNS distribution of the peptide is similar to that observed in other mammals. Adult woodchucks (3 male, 5 female) were killed and their brains rapidly removed, dissected and frozen on dry ice. The samples were homogenized in approximately 10 volumes of 1N HCl and NT was measured by radioimmunoassay (Manberg et al., J. Neurochem., in press) using an antiserum directed towards the mid-portion of the NT molecule. The sensitivity of the assay was 20 pg per tube. Protein concentration was determined with the Folin reagent and the data obtained expressed as pg NT per mg protein. The highest concentration of NT was found in the hypothalamus. The following brain regions contained substantial quantities of immunoreactive NT (expressed in decreasing concentrations): septum, amygdala, caudate-putamen, ventral tegmentum, cingulate cortex, and olfactory tubercle. The pituitary contained no detectable NT. The CNS distribution of NT in the woodchuck is similar to that observed in the rat, monkey and man.

161.9 PREFERENTIAL IMMUNOHISTOCHEMICAL LOCALIZATION OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN THE SACRAL SPINAL CORD OF THE CAT. C. N. Honda. Neurobiology Curriculum and Department of Physiology, Univ. of North Carolina, Chapel Hill, NC 27514.

The distribution of neuronal processes containing VIP-like immunoreactivity was compared with that of substance P (SP)-, somatostatin (SS)-, and cholecystokinin-8 (CCK)-like immunoreactivities in vibratome sections of lumbar, sacral, and coccygeal segments (L4-Co4) of the cat spinal cord. The peroxidase-anti-peroxidase (PAP) technique was used after permeabilization with ethanol.

VIP-containing fibers were visualized in some sacral dorsal rootlets, their spinal entry zones, and often in the dorsolateral funiculus. Lissauer's tract (LT) was intensely labelled in sacral segments, but the proportion of LT occupied by VIP fibers progressively decreased rostrally and caudally until only small bundles persisted at L4 and Co4. Forming a thin shell around the dorsal horn, collaterals, apparently originating from LT, projected either medially or laterally through lamina I. Laterally, many axons terminated in lamina V, and some in lateral laminae VI and VII. Others projected further to medial V and the posterior commissure. Medially, VIP axons descended through lamina I along the lateral edge of the dorsal funiculus to expand into terminal fields in the dorsal commissure and medial lamina V. VIP fibers and terminals were also present in the gray matter surrounding the central canal. The spinal distribution of VIP fibers and terminals was most dense in the sacral segments.

This distribution of VIP-containing fibers is remarkably similar to that of pelvic nerve visceral afferents (Morgan et al. J. Comp. Neurol. 201:415,1981), both in their segmental distribution patterns within the gray matter, and in their localization to the sacral cord. SP-, SS-, and CCK-containing fibers and terminals exhibited segmental localizations within the gray matter similar to pelvic nerve afferents and VIP fibers, with the exception that SS was well localized to the inner portions of lamina II and the outer parts of III. The density of SP-, SS-, and CCK-containing fibers was constant at all levels examined (L4-Co4). In contrast, the distribution of VIP-containing fibers, much like the pelvic nerve afferents, was mostly confined to the sacral segments.

Thus, while SP-, SS-, and CCK-containing fibers may contribute to the population of sacral visceral afferents, they appear also to be common to afferent systems in other segments. It is suggested that VIP-containing fibers are preferentially associated with the spinal distribution of an afferent system, such as the pelvic visceral nerves, which is localized to the sacral spinal cord.

Supported by USPHS Grants NS 10321 and NS 07166.

161.10 VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN PRIMARY AFFERENT PROJECTIONS TO THE SACRAL SPINAL CORD OF THE CAT. M.Kawatani*, I. Lowe, C.Morgan, I.Nadelhaft, S.Erdman* and W.C.deGroat. Depts. of Pharmacol. and Neurosurg., Univ. Pitt. and V.A. Hosp., Pitt., PA

HRP studies have shown that sacral afferent neurons innervating the urogenital organs and colon via the pelvic nerve send axons centrally into Lissauer's Tract (LT) and collaterals into Lamina I laterally and medially around the dorsal horn (DH). The lateral collateral pathway (LCP) projects into the sacral parasympathetic nucleus (SPN). In the present study we have used immunohistochemical (IHC) techniques to examine the relationship of VIP to these visceral afferent pathways since VIP has been proposed as a transmitter in primary afferent neurons and in addition is very abundant in nerve fibers in the pelvic organs.

The distribution of VIP in lumbosacral and coccygeal segments was determined with IHC techniques Tissue was obtained from normal adult cats as well as cats in which sacral ventral and/or dorsal roots were transected on one side 4-5 weeks prior to sacrifice. In sacral segments VIP terminals were concentrated in LT and lamina I in the area of the LCP. In longitudinal sections VIP in this region exhibited a periodic organization in which clusters of terminals occurred at fairly regular intervals (210-250 μ) along the length of the cord. Pelvic visceral afferents had a similar periodicity. A few VIP axons projected from lateral lamina I through the dorsal band of the SPN in lamina V to end in the region of the dorsal commissure and central canal. Few VIP fibers were noted in the lateral band of the SPN. Small numbers of VIP axons projected medially from LT into lamina I and along the medial side of the DH into the dorsal commissure. VIP axons were noted in the region of the central canal in sacral segments. The L7 and Cxl segments exhibited fewer VIP axons in LT, lamina 1 & X, whereas other lumbar and coccygeal segments were virtually devoid of VIP. VIP fibers were markedly reduced in LT and laminae I & V ipsilateral to where sacral dorsal and ventral roots were transected. A slight reduction in VIP fibers was also noted following transection of the ventral roots. VIP around the central canal was not changed following deafferentation.

These experiments have shown that in lumbosacral and coccygeal segments of the cat spinal cord VIP is contained largely in afferents entering the cord at the sacral level. Since the distribution of VIP axons in LT, lamina I & V closely parallel the distribution of previously demonstrated visceral primary afferent projections, it is tempting to speculate that VIP is contained in part in visceral afferents. Further support for this proposal has been obtained in preliminary studies in which dye tracing was combined with IHC. In these experiments it was shown that some sacral dorsal root ganglion cells labelled by true blue applied to the pelvic nerve also contained VIP.

161.11 AN INVESTIGATION OF NEURONS DISPLAYING CHOLECYSTOKININ-LIKE IMMUNOREACTIVITY IN THE CEREBRAL CORTEX OF THE MONKEY AND RAT. S.H.C. Hendry, K.L. Valentino, E.G. Jones and M.C. Beinfeld. James L. O'Leary Division of Experimental Neurology and Neurological Surgery and McDonnell Center for The Study of Higher Brain Function, Washington University School of Medicine, and Department of Pharmacology, St. Louis University, St. Louis, MO

Light and electron microscopic immunocytochemistry was used to examine the neurons of the monkey and rat cerebral cortex that display cholecystokinin-like (CCK) immunoreactivity. In both species the CCK positive cells form a very small percentage of the total population of cortical neurons. The somata of the immunocytochemically stained neurons are present in all layers but are concentrated superficially, in layers I-III. CCK positive neurons are all non-pyramidal neurons with somata among the smallest found in neocortex. Most give rise to 2-4 long, radially ascending and descending processes, which branch at relatively few points and can extend through much of the thickness of the cortex. Labeled punctate structures that possibly correspond to CCK positive axon terminals are located in several layers and are most densely distributed in layer VI.

Ultrastructurally, CCK positive neurons resemble typical non-pyramidal cells of previous descriptive studies. They receive both symmetric and asymmetric synapses on their somata and dendrites. The numbers of axosomatic and axodendritic synapses on different CCK positive neurons are found to vary. CCK positive terminals form asymmetric synapses onto several different neuronal processes including the somata of unlabeled non-pyramidal cells and the shafts of dendrites. Within CCK positive terminals, reaction product is present diffusely in the cytoplasm and could not be localized to any distinct population of synaptic vesicles.

Supported by NIH Grant Number NS10526.

161.12 CHOLECYSTOKININ-OCTAPEPTIDE-IMMUNOREACTIVITY (CCK-8-LI) IN NEURONS IN DISSOCIATED CULTURES OF RAT CEREBRAL CORTEX. John Delfs, Eugene Straus, Zhu Chun-Han*, and Marc Dichter. Division of Neuroscience, Children's Hosp.Med. Center, Boston, MA 02215 and Dept. of Medicine, Montifiore Hosp., Bronx, N.Y.

The carboxy-terminal octapeptide of cholecystokinin (CCK-8) has been demonstrated by radioimmunoassay to exist in high concentrations in mammalian cerebral cortex (Muller et al., 1977; Rehfeld, 1978) and immunohistochemical studies in vivo suggest a localization to a neuronal population (Straus et al., 1977; Larsson and Rehfeld, 1979).

Dissociated cultures of cerebral cortex were prepared from 15-16 day fetal rats as previously described (Dichter, 1978; Delfs et al., 1980). A well-characterized radioimmunoassay was used to determine the presence of CCK-8-LI at time intervals from plating to 35 days in culture. Both the cells and the media contained insignificant amounts of CCK-8-LI at plating, but demonstrated a time-dependent increase in the amount of CCK-8-LI.

For immunohistochemical staining, cultures grown on glass cover slips were fixed in 4% paraformaldehyde followed by 0.4% Triton-X-100. After preincubation with non-immune goat serum, the culture was incubated with a rabbit antibody prepared against a CCK-8 conjugate (Immunonuclear Corp.) at concentrations from 1:100 to 1:400, followed by a goat anti-rabbit gammaglobulin (Cappell) and were studied under a Zeiss combination phase-fluorescence microscope. Staining was considered specific when eliminated by preincubation with an excess of synthetic CCK-8 (sulfated, Peninsula Labs).

Neurons containing CCK-8-LI were predominately of two categories. The most prominent staining was seen in widely ramifying processes, with brightly staining swellings in close anatomical relation to other neuronal perikarya and dendrites. These processes may arise from large, multipolar neurons, better seen after pretreatment of the cultures with colchicine 100uM for 46 hours prior to fixation. Staining for CCK-8-LI was also seen in very small neurons of both stellate and bipolar morphology, which were often in intimate anatomical proximity to much larger non-CCK neurons.

These results indicate that CCK-8 is synthesized by several different morphologic subtypes neurons in these cultures and this system may be valuable for further studies on the synthesis and role of CCK-8 in cerebral cortex.

161.13 THE DEVELOPMENT AND DISTRIBUTION OF CHOLECYSTOKININ AND AVIAN PANCREATIC POLYPEPTIDE IMMUNOREACTIVE NEURONS IN THE RAT VISUAL CORTEX. J.K. McDonald, J.G. Parnavelas, and A.N. Karamanlidis. Depts. of Physiology and Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

Using immunocytochemistry, we have examined the development of cholecystokinin-like (CCK-IMR) and avian pancreatic polypeptide-like (APP-IMR) immunoreactivity in the rat visual cortex. Sprague-Dawley albino rats of both sexes at several postnatal ages, as well as adults, were perfused with fixative containing 4% paraformaldehyde, 0.1M D,L-lysine and 0.01M Na periodate in 0.1M phosphate buffer. 35 µm coronal sections were cut and processed for fluorescence and PAP immunocytochemistry. CCK and APP antisera were generously provided by G. Rosenquist and J. Kimmel. Preabsorption of each antiserum with the appropriate antigen prevented labeling.

In the adult visual cortex, CCK-IMR neurons were located in all cortical layers but were concentrated primarily in layers II & III. Labeled multipolar and bitufted nonpyramidal neurons were observed, the majority resembling bitufted neurons described in Golgi preparations (Feldman & Peters, 1978). Of particular interest was the presence of labeled neurons in layer I which correspond to the persisting horizonal cells and vertical cells described by Bradford et al. (1977). Immature CCK-IMR cells were first observed on the third postnatal day. They matured gradually and increased in frequency during the next few days and by day 8, bitufted and multipolar neurons were identified in all cortical layers, particularly layers II & III. Labeled cells and their processes mature dramatically during the second postnatal week and only slight changes were noted after this time.

APP-IMR neurons in the adult were fairly evenly distributed in layers II to VI but appeared more frequently in layers V & VI. Labeled cells included multipolar, bitufted and bipolar forms of non-pyramidal neurons. A very small number of pyramidal cells were also identified in layers V & VI. An interesting feature of some bitufted neurons and layer VI multipolar neurons with horizontally oriented dendrites was their resemblance to somatostatin IMR cells reported in the rat visual cortex (McDonald et al., 1982). A small number of immature APP-IMR neurons were present in the subplate region on the first postnatal day. These cells mature gradually during the first two weeks of postnatal life. At the end of this time, APP-IMR neurons appeared similar in morphology to their adult counterparts. These results indicate that various peptide-containing immunoreactive neurons in the rat visual cortex display distinctive morphologies, distributions and rates of development. (Supported by NIH Grants EY02964 and EY03783).

161.14 LOCALIZATION AND CHARACTERIZATION OF GLUCAGON-LIKE IMMUNOREACTIVITY IN THE RETINA. N. Brecha, M. Cilluffo* and T. Yamada*. Center for Ulcer Research and Education, VA Wadsworth Medical Center, Jules Stein Eye Institute, Brain Research Institute and UCLA School of Medicine, Los Angeles, CA 90073.

Previous studies localizing glucagon-like immunoreactivity in the central nervous system including the retina have suggested that glucagon-like immunoreactivity is of the non-pancreatic type. We have extended these studies in retina to further characterize the morphology and biochemistry of retinal glucagon-like immunoreactivity. Pigeon retinas were fixed in paraformaldehyde/lysine/periodate solution, washed, and processed according to standard immunohistochemical protocols. Using antisera raised against porcine pancreatic glucagon (N211 provided by N Track, and G-VI) at least 3 distinct populations of amacrine cells were identified. In central retina the majority of immunoreactive cells had a small somatic diameter and gave rise to primary processes which arborized in lamina 1 of the inner plexiform layer (IPL). Some of these processes contributed secondary processes which arborized in lamina 3 and perhaps lamina 5 of the IPL. A second population of medium- to large-sized immunoreactive cells located in ventral retinal regions gave rise to single thick primary processes which coursed in lamina 1 of the IPL for a short distance before ramifying into many fine secondary processes. These processes ramified in laminae 1, 3 and 5 of the IPL. One of these processes, present in lamina 1 of the IPL was followed to the ora serrata where it joined a fascicle of glucagon-containing fibers. A third population of immunoreactive cells was present in the peripheral retina. These cells had medium-sized somata and gave rise to two or three primary processes which ramified primarily within lamina 1 of the IPL, some of these processes also extended to the ora serrata. No staining was observed in sections incubated with antisera preabsorbed with 10 µM synthetic glucagon. Acid-ethanol extracts of retinal tissues were radioimmunoassayed using antiserum 30K which is specific for the COOH-terminus of glucagon. Retinal GLI was 10.0±1.2 pmol/g wet weight (mean±SE) as compared to 2737±185 pmol/g in the pancreas and undetectable quantities in the brain. Retinal GLI chromatographed on Sephadex G-50 as a smaller molecule (K_d 0.85) than did pancreatic GLI (K_d 0.70) which co-eluted with porcine pancreatic glucagon.

Our studies demonstrate that 1) GLI is localized in pigeon retina to at least 3 distinct types of amacrine cells, and 2) retinal GLI is of the pancreatic type although it may be somewhat smaller in size.

161.15 COEXISTENCE AND RELEASE OF PANCREATIC POLYPEPTIDE FROM NORADRENERGIC SUPERIOR CERVICAL GANGLIA NEURONS. J. A. Olschowka and D. M. Jacobowitz. Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

Pancreatic polypeptide (PP) is a 36 amino acid peptide recently found in neuronal cells in the periphery and the brain. Its neurophysiological signficance is unknown. However, PP-like immunoreactivity has been demonstrated to coexist with catecholamine-containing cells of the rat hindbrain and periphery. This study examines the coexistence of PP in noradrenergic (NA) neurons of the rat superior cervical ganglia (SCG) and the release of PP from these neurons.

Using the indirect immunofluroescent technique, bovine PP-like immunoreactive fibers and cell bodies were observed in the SCG only after increasing the intraganglionic content of PP by either: 1. direct application of colchicine on the SCG (75 µg in 25 µl saline), 2. vinblastine treatment (3 mg/kg, iv) or 3. ligating the pre- or postganglionic nerves. The SCG was observed to contain a dense intraganglionic plexus of PP-like immunoreactive fibers and 30-50% of all SCG neurons contained PP. Thick PP-containing fiber bundles were observed at both the pre- and postganglionic poles of the SCG. Moderate numbers of PP-fibers were observed both entering and leaving the SCG through the preganglionic nerve, while large numbers of fibers left with the postganglionic nerves. These postganglionic PP-fibers could be observed innervating the vasculature of the eye and salivary gland and disappeared after lesion of the nerve. 6-OHDA treatment (2 x 50 mg/kg, ip), which selectively destroys NA fibers, also resulted in a loss of these fibers.

Prior studies have shown that NA is released from varicose terminals during high nerve impulse activity. To determine if PP is co-released with NA during stimulation, the right cervical sympathetic trunk was separated from the vagus, ligated, severed and supramaximally stimulated for 20 or 40 min (5 V, 20 pps, 10 msec duration). The left sympathetic trunk was severed as control. A few animals were pretreated with reserpine (5 mg/kg, iv) 5 hr prior to stimulation. Immediately after stimulation, the animals were perfused and processed for immunohistochemistry. On the stimulated side, the PP-fibers of the eye and salivary gland were virtually depleted of their PP content as compared to control. The presence of reserpine, while totally depleting NA, did not influence the control side or enhance the reduction of PP on the stimulated side. These results suggest that PP coexists with a proportion of SCG catecholamine cells and that it is co-released with NA during stimulation.

161.16 IMMUNOREACTIVE ANGIOTENSIN II IN THE BRAIN OF THE DOCA-SALT HYPERTENSIVE RAT. J.A. Weyhenmeyer. College of Medicine and Department of Anatomical Sciences, University of Illinois, Urbana, IL 61801.

Angiotensin II (AII) has been proposed to play an important role in the neural control of blood pressure, drinking behavior, naturesis, and hormone release. Although the origin of brain AII has remained controversial, this laboratory and others have demonstrated the presence of immunoreactive AII in cell bodies and fiber profiles in the rat and primate CNS. Recently, we reported that there was a significant increase in the distribution of AII in the brain of the spontaneously hypertensive rat (SHR) compared to its normotensive control, the Wistar Kyoto rat (Hypertension, 1982). The purpose of this investigation was to determine whether the distribution of AII in the brain and brainstem of the DOCA-salt hypertensive rat was similar to that observed in the genetically predisposed SHR.

Ten-week-old male Sprague Dawley rats were given weekly injections of DOCA (30 mg Percorten pivalate/kg body weight) and their drinking water was substituted with a 1% NaCl solution. Rats were monitored for blood pressure by non-invasive techniques, and only those animals with a systolic pressure above 160 mmHg were considered acceptable for experimental studies. AII was localized by the unlabeled antibody enzyme method of Sternberger. Briefly, rat brains were fixed in buffered picric acid-paraformaldehyde, vibratome sectioned, and incubated in Triton x-100 to enhance antibody penetration. The sections were incubated with rabbit anti-AII, followed by goat anti-rabbit IgG and rabbit peroxidase anti-peroxidase. Staining was completely eliminated by the substitution of primary antiserum preabsorbed with excess AII or when preimmune serum was substituted for the primary antiserum.

Immunoreactive AII was widely distributed in fiber profiles of the brain and brainstem of the DOCA-salt hypertensive rat. Many of these nerve fibers contained densely stained varicosities along the length of the profiles. Dense concentrations of AII containing fibers were localized in structures immediately surrounding the lateral, third and fourth ventricles, which is consistent with observations in the SHR. Positively stained fiber profiles were also observed in structures that have been implicated in the neural control of blood pressure, including the locus coeruleus and nucleus tractus soitarius. In contrast to the AII fiber pattern in the brains of the SHR, relatively few fibers containing AII have been localized in the preoptic area or thalamus of the DOCA-salt hypertensive rat.

This work was supported by Grant HL27757 from the National Heart, Lung and Blood Institute.

161.17 ANGIOTENSIN II-LIKE IMMUNOREACTIVITY IN THE CENTRAL NUCLEUS OF THE RAT AMYGDALA. M.D. Cassell, T.S. Gray, D. Ganten and T.H. Williams. Univ. of Iowa, Iowa City, IA 52242.

The immunohistochemical localization of angiotensin II-like immunoreactivity (AII) in the CNS and its demonstrated physiological effects on neurons suggest that angiotensin II could act as a neurotransmitter. The central nucleus of the amygdala (CNA) contains several other neuropeptides, each with a highly specific pattern of distribution of cell bodies and terminals. AII has been identified in the amygdala and, with a view to analyzing the relationships to other peptide systems, we have determined the precise distribution of AII in the CNA at both the LM and EM level using a modified Sternberger-PAP immunocytochemical method. Anti-AII was generated in rabbits. Immunoadsorption of the antibody with synthetic val^5 AII, but not angiotensin I, lys-vasopressin or neurotensin, abolished immunostaining.

At the mid-rostrocaudal level, a large number of AII terminals were distributed over the lateral and intermediate parts of the CNA. This distribution is quite distinct from the distributions of substance P, VIP, somatostatin, CCK, neurotensin and m-enkephalin immunoreactive terminals. AII-terminals outlined cell bodies and dendrites, particularly in the intermediate CNA. These rings and clusters of terminals made definitive identification of AII cells in the CNA very difficult. The high density of AII terminals was continued into the rostral CNA but was distinct from the anterior amygdaloid area which had few AII terminals. AII-fibers were seen traveling in the adjacent substantia innominata but lesioning of this area produced only a slight reduction in AII terminal density in the CNA. Caudally, AII terminals were present throughout the CNA and fibers could be seen passing into the stria terminalis. A small number of AII terminals were observed in the medial, cortical, basomedial and basolateral nuclei, but not in the lateral nucleus.

Ultrastructurally, AII was observed in terminals, dendrites and cell bodies. In perikarya and dendrites, the reaction product was distributed in the cytosol against mitochondria and rough ER, and in a few large vesicles. In terminals, reaction product was associated with the surface of round, clear vesicles. Large, dense cored vesicles were also observed. AII terminals were observed making asymmetrical axo-dentritic and axosomatic synaptic contacts with non-AII neurons. AII-terminals were observed making symmetrical axosomatic, but not axodendritic, contacts with AII-perikarya.

161.18 EGG-LAYING HORMONE, LEUCINE-ENKEPHALIN AND SEROTONIN IMMUNOREACTIVITY IN THE ABDOMINAL GANGLION OF APLYSIA: A LIGHT MICROSCOPIC STUDY. W.E. Hopkins*#†, L.S. Stone*#, B.S. Rothman#, A.I. Basbaum#§, and E. Mayeri#† (SPON: E. Glazer). Depts. of #Physiology and §Anatomy, Univ. of Calif., San Francisco, CA 94143 and †Dept. of Basic Sciences, Calif. Coll. Podiatric Medicine, San Francisco, CA 94115.

Immunoreactive egg-laying hormone (IR-ELH), leucine-enkephalin (IR-ENK), and serotonin (IR-5HT) cells and processes were studied in the abdominal ganglion of the marine mollusk Aplysia californica with emphasis on the anatomical relationships of immunoreactive fibers to the bag cells. The bag cells consist of two clusters of about 400 neuroendocrine cells each that synthesize and secrete ELH and other neuroactive peptides. Confirming the results of Chiu and Strumwasser (J. Neurosci. 1:812, 1981), only the bag cell somata (BCS) and their fibers labeled for ELH. Their fibers branched profusely in the sheath and septa surrounding the ganglionic neurons, including neurons known to respond to bag cell activation. This provides a morphological substrate for ELH-mediated transmission from the bag cells to these target neurons.

IR-5HT processes were extensively branched in the sheath surrounding the BCS, while the BCS themselves were devoid of labeling. Large IR-5HT fibers apparently arising from the head ganglia coursed down the connectives and divided into several fine branches, which terminated among the BCS. IR-5HT fibers with beaded varicosities were found in a delicate array which enveloped individual bag cell somata. Since application of 5HT inhibits bag cell activity (Kaczmarek et al., PNAS 75:5200, 1978), this anatomical evidence suggests that serotonergic neurons directly inhibit the bag cells.

Branched IR-ENK processes were found in the sheath overlying the BCS, and were discernibly more numerous over the left cluster than the right one. These fibers appear to arise caudally, as only sparse enkephalin imunoreactivity was found rostrally in the connectives. There was no IR-ENK in bag cell somata, and few IR-ENK processes seen among the somata. The numerous IR-ENK ramifications in regions containing dense arborizations of bag cell processes suggest an axo-axonic relationship, although ultrastructural studies would be necessary to establish this.

IR-ENK and IR-5HT were not confined to the bag cell region. Numerous neurons and processes containing either IR-ENK or IR-5HT were observed in other parts of the ganglion. It should be possible to identify some of the neurons with combined immunocytochemical and electrophysiological techniques.

161.19 BIOSYNTHESIS AND RELEASE OF MET-ENKEPHALIN IN TELEOST RETINA. Y. Y. T. Su. Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030

The presence of enkephalin-like immunoreactive molecules and opiate-binding receptors in the retinas of several species has been reported. Recently, Djamgoz et al. (Nature, 292, 620, 1981) have demonstrated that enkephalin served as a presynaptic inhibitor to GABA containing amacrine cells in the goldfish retina. In this report a recent studies on the synthesis and release of enkephalin in goldfish and catfish retina will be presented.

The isolated fish retina was incubated in 0.2 ml of oxygenated Ringer's solution containing 40 μCi of ^{3}H-methionine and peptidase inhibitor for 30 min. The tissue was rinsed 3 times in large volumes of Ringer's solution containing peptidase inhibitor and incubated in the same unlabeled solution for another hour. The labeled tissue was homogenized in ice-cold 2 N acetic acid, boiled in a water bath for 3 min and centrifuged at 40,000 x g for 45 min. The labeled met-enkephalin presented in the supernatant was identified by immunoassay, thin layer chromatography and high performance liquid chromatography. All three methods showed that labeled enkephalin was synthesized in the tissue. A binding studies of the partially purified labeled enkephalin to mouse brain membrane preparations showed a saturable specific binding curve and this curve was completely suppresed by naloxone. All these studies demonstrated that labeled enkephalin was synthesized in the retina.

In order to study the release of enkephalin, the labeled tissues were incubated in high K^+ (60 mM) Ringer's solution, followed by several washings with normal Ringer's solution (all solutions containing peptidase inhibitor). The solutions were concentrated and assayed for enkephalin. The released enkephalin represented 8 to 10% of total enkephalin synthesized in the tissue. The release of enkephalin was completely suppresed by 5 mM Co^{+2}. This may indicate that the release is calcium dependent.

161.20 IMMUNOREACTIVE RANATENSIN IN RAT BRAIN. T. L. O'Donohue, J. J. Pisano*, T. W. Moody, J. A. Olschowka and D. M. Jacobowitz. Lab. of Clinical Sci., NIMH; Lab. of Chemistry, NHLBI, NIGMS, NIH, Bethesda, MD 20205; Dept. of Biochemistry, George Washington University, Washington, D.C.

Ranatensin is an undecapeptide amide related in structure to bombesin and GRP-peptides which are thought to be localized in mammalian brain. Using an antisera that recognizes neither bombesin nor GRP, we have identified a ranatensin-immunoreactive peptide in brain. The peptide elutes identically to ranatensin on Sephadex G-25 chromatography but can be resolved from ranatensin into three immunoreactive peaks using reversed phase HPLC. Interestingly, one peak, but not the other two, is recognized by an antibody that specifically recognizes bombesin but not ranatensin. This peak therefore has both ranatensin and bombesin antigenic determinants but is identical to neither.

The ranatensin has been visualized in neuronal processes by immunocytochemistry in certain regions throughout the brain and the distribution determined by RIA. The distribution was quite different from that described for bombesin. Highest concentrations of ranatensin immunoreactive neurons were noted in the septum, ventral hippocampus, hypothalamus and brainstem. Terminal neuronal fields were observed in the nucleus of the tractus diagonalis, nucleus interstitialis stria terminalis, medial preoptic nucleus, median forebrain bundle, nucleus amygdala medialis, interpeduncular nucleus, nucleus parabrachialis dorsalis, nucleus tractus solitarius and the lateral reticular nucleus. The widespread distribution of the ranatensin-like neuronal processes suggests a possible role in a variety of CNS functions.

161.21 ONTOGENY OF SUBSTANCE P AND ENKEPHALIN IN THE AVIAN CILIARY GANGLION AS STUDIED BY COMBINED HPLC AND RIA. Jeffrey D. White, James E. Krause, Harvey J. Karten and Jeffrey F. McKelvy. Depts of Neurobiology and Behavior and Psychiatry, SUNY at Stony Brook, NY 11794.

The avian ciliary ganglion (CG) has proven an excellent model system for the study of cholinoceptive and cholinergic neuronal function. Recently, the co-occurrence of Substance P-like and Leu^5-enkephalin-like immunoreactivity in terminals of pre-ganglionic neurons has been described (Erichsen et al., Nature 295: 407, 1982). The present study was undertaken to determine the chemical nature of the immunoreactivities and to measure their levels during embryogenesis.

Initially, acid extracts from 20 stage 45 chick CG were subjected to High Performance Liquid Chromatographic (HPLC) analysis combined with RIA for Substance P (SP). An isocratic HPLC system was employed which separates SP, SP sulfoxide, SP free acid and SP_{5-11}. A highly specific and sensitive C-terminally directed antiserum was used in the RIA. After HPLC, a peak of immunoreactivity corresponding to the elution volume of SP was observed. For developmental studies, CG were dissected from chick embryos at stages 32, 35, 37, 40, 45, 7 days post-hatching and adult. During embryogenesis, the level of SP (per ganglion) was constant from stages 32-37 (9 pg./ganglion) and increased thereafter. By 7 days post-hatch, the level of SP had increased 4 fold to a level of 36 pg./ganglion.

Similarly, acid extracts from 20 stage 45 ganglia were subjected to gradient HPLC elution analysis which separates Met^5- and Leu^5-enkephalin, dynorphin, ß-endorphin and the amino terminal fragments of enkephalin (ENK). RIA of these HPLC fractions for Leu^5-ENK demonstrated immunoreactivity that co-eluted with Leu^5-ENK. Preliminary studies of Leu^5-ENK ontogeny indicate a peak of immunoreactivity at stages 37-40, consistent with the immunohistochemical observations of Davis, Erichsen and Karten (Soc. Neurosci. Abstr., Vol. 7, p. 400, 1981).

As a consequence of these biochemical data, studies examining the physiological role of SP and ENK in the ciliary ganglion are warranted.

161.22 THE PRESENCE OF ANGIOTENSIN II-LIKE PEPTIDE IN CULTURED BRAIN CELLS. J.M. Kenny* and J.A. Weyhenmeyer (SPON: M. Holzwarth). College of Medicine and Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

Angiotensin II (AII)-like immunoreactivity has been localized in the brains of many species including rat, monkey and human. The proposed physiological roles of the octapeptide at the level of the brain include pressor and dipsogenic responses, and the release of ADH and ACTH. Weyhenmeyer et al. have supported the existence of endogenous brain angiotensin II by demonstrating the presence of AII-like immunoreactivity in primary cultures of fetal rat brain neurons (Neurosci. Letters, 16:41,1980). Fishman et al. (Science, 214:921,1981) have shown the presence of all the components of the renin-angiotensin system in the NG108-15 neuroblastoma x glioma hybrid cells. The aim of this research was to show the de novo synthesis of AII in the NG108-15 cells and primary cultures of fetal rat brain.

For the primary cultures, brains were removed from 20 day old rat fetuses, dissociated with trypsin, and plated at $2.8x10^6$ cells/35mm Falcon plate. Primary cultures were grown for days 1,2 and 3 in Dulbecco's modified Eagle's medium with 10% fetal calf serum, 100U penicillin G, 100ug streptomycin, and 0.25ug fungizone. Cells were changed to serum-free DME supplemented with 5ug/ml of insulin and transferrin, $2x10^{-8}$M progesterone, $1x10^{-4}$M putrescine, $3x10^{-8}$M selenium, 10mg/ml L-glutamine, and the same concentrations of antibiotics. Supplemented DME was used on days 3,5 and 7 and cells were taken for experiments on day 8. NG108-15 cells were grown in DME with 12.5% horse serum and 2.5% fetal calf serum with the same antibiotic concentrations as the primary cultures for 3 days, then incubated in serum-free DME containing only antibiotics, and taken for experiments on day 4, cell density averaging $4.9x10^6$ cells/35mm plate.

On the day of the experiment, cells were incubated with 5uCi/plate ^3H proline at 37°C in an atmosphere of 10% CO_2 for 30 minutes or 1,2,3 or 4 hours. The cells were then digested and aliquots of the digest were incubated in triplicate in dilutions of 1:1, 1:10 and 1:50 with anti-AII and buffer for 36 hours at 4°C. The antibody showed 7.1% cross reactivity at 50% displacement with AI. The antigen-antibody complex was precipitated with dextran and charcoal and centrifugation and counted in a scintillation counter. Upon comparison with a standard curve developed for the RIA, preliminary evidence indicates the presence of pg levels of AII-like peptide per mg of protein in the cellular digest.

This research was supported by Grant HL27757 from the National Heart,Lung and Blood Institute to J.A.W.

162.1 MU, KAPPA, AND OTHER OPIOID COMPOUNDS IN MOUSE TASTE AVERSION EXPERIMENTS. Peggy J. K. Dobry, CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Administration of a novel drug after a novel-tasting substance can lead to decreased ingestion of the substance when it is offered later. This "taste aversion" can be conditioned in animals both by drugs which humans self-administer and by drugs which humans avoid, and even by drugs which animals self-administer intravenously.

On Day 1, water-deprived CF-1 female mice were offered 5% sucrose solution for exactly 15 minutes. Immediately, mice were injected subcutaneously with saline or drug. On Day 2, the procedure was repeated. For the next 24 hours, mice had free access to water. On Day 4, in the Test Session, water-deprived mice were offered sucrose solution for 10 minutes (in addition, water was available in the Test Session, but its consumption was not measured). Groups were compared statistically by the Mann-Whitney U test (one-tailed test for drug-induced decreases in fluid consumption). Note that the Test Session occurred 48 hours after the last drug injection.

Agonists and antagonists of the mu receptor cause powerful dose-related taste aversions. The mg/kg dose causing 50% suppression of drinking is: morphine sulfate, 3.9; methadone, 2.3; pentazocine (lactate), 5.4; butorphanol tartrate, 15; cyclazocine, 1.6. Similar results were obtained for the enkephalin analog FK-33824 (0.24).

Primarily-kappa opioids did not cause taste aversion; bremazocine (0.3-3 mg/kg), ketocyclazocine (1-10 mg/kg), ethylketocyclazocine methanesulfonate (3-30 mg/kg), U-50,488H (3-30 mg/kg).

The sigma agonist SKF-10047 caused a dose-related taste aversion with 50% suppression at 6.6 mg/kg.

Naloxone hydrochloride did not cause taste aversion at 1 and 3 mg/kg, which are effective narcotic-antagonist doses.

Nalorphine hydrochloride is a special case, since 1 and 3 mg/kg caused a significant increase in fluid consumption. This increase was seen even with 5 days between the final nalorphine injection and the Test Session -- 4 of these days with water ad libitum. Hence, it is highly unlikely that the increased drinking is due to some non-specific dehydration. Increased drinking was not seen in rats in a similar test.

The differences in taste aversion predict that kappa agonists will have entirely different subjective effects from those of mu, sigma, or delta agonists.

162.2 MORPHINE MICROINJECTED INTO NUCLEUS RETICULARIS PARAGIGANTOCELLULARIS REDUCES ACTIVITY OF NEURONS IN NUCLEUS RAPHE MAGNUS. Mary M. Heinricher and J. Peter Rosenfeld. Depts. of Psychology and Neurobiology & Physiology, Cresap Neuroscience Laboratory, Northwestern University, Evanston, Ill. 60201.

Although microinjection of morphine into, or electrical stimulation of the nucleus reticularis paragigantocellularis (PGC) results in behaviorally-defined analgesia, the neural substrate of this effect has yet to be determined. It has been suggested that the analgesia is mediated through the nucleus raphe magnus (NRM) (Azami, et al., J. Physiol., 306: 16-17P, 1980). The present experiment was designed to investigate the effect of PGC morphine microinjections on unit activity in NRM.

Rats were anesthetized with urethane (1.2 g/kg) and a 25 gauge guide cannula implanted above PGC. NRM unit activity was recorded using a glass micropipette. The firing rate of NRM units ranged from 1 to 44 Hz. The great majority of units responded to noxious pinch. After a unit was isolated, morphine sulfate (1 µg in 0.5 µL) was infused into PGC through a 31 gauge injector cannula over the course of 4 minutes. Only 1 cell was used per animal.

The predominant effect of PGC morphine microinjections was suppression of spontaneous activity. Over half of the units showed a reduction of firing rate of at least 25%, while most of the remaining cells showed a less pronounced suppression. This effect was antagonised by systemic naloxone (1 mg/kg) in 66% of the cases in which it was attempted. Only one cell showed a substantial increase (71%) in firing rate after PGC morphine, and this effect was not reversed by naloxone. These results suggest that the analgesic effect of PGC morphine microinjections is not mediated by an increase in descending inhibition from NRM.

162.3 HALOPERIDOL CATALEPSY IS ANTAGONIZED BY A HIGH DOSE OF MORPHINE IN THE C57BL/6J MOUSE. K. E. Stevens and G. A. Mickley. Department of Behavioral Sciences and Leadership, USAF Academy, CO 80840.

In the rat, and in most other species, a sufficiently large dose of morphine produces hypokinesia and catatonia. Similar behaviors can be observed after an injection of a dopamine receptor blocking agent (e.g., haloperidol). These and a variety of biochemical observations have led many to suggest that morphine might also produce some of its behavioral effects by inhibiting dopamine receptor activity as well (H. Lal, Life Sci. 17, 483-496, 1975). The data reported here highlight some behavioral differences evoked by haloperidol and morphine in the C57BL/6J mouse and support the hypothesis that there may be different mechanisms which mediate the behavioral changes produced by the drugs (H. Lal, et.al., Life Sci. 17, 29-34, 1975).

Pre-drug baseline measures of catalepsy and spontaneous locomotor activity were recorded from 60 male C57BL/6J mice. Some of these animals received a first injection of 2 mg/kg haloperidol. The catalepsy and hypokinesia produced by the haloperidol was later challenged with either a 30 or 60 mg/kg injection of morphine. Control animals received either saline or haloperidol as their first injection then either morphine or saline as a challenge. Post-drug catalepsy measures were taken 75 minutes after the first injection and then 60 minutes after the second injection. Spontaneous locomotion was also recorded after administration of each of the drugs.

C57BL/6J mice exhibited quite different behavioral responses to the two drugs. Haloperidol produced catalepsy and hypokinesia in these mice. However, when morphine was administered (after a control saline injection) it produced a stereotypic locomotor hyperactivity and no catalepsy. When morphine was given as a challenge to haloperidol's behavioral effects it effectively countered the catalepsy ($p < .05$, Kruskal-Wallis). Interestingly, however, morphine did not significantly increase the locomotion of these mice ($p > .05$, Kruskal-Wallis).

Although opiate actions may be in some way, related to the inactivity of dopamine receptors, morphine's reversal of haloperidol catalepsy suggests that perhaps the neurochemical actions of morphine and haloperidol are not identical in this mouse. In additon, since morphine did not reverse the hypokinesia of haloperidol-treated mice, but did counter the catalepsy, it may be the case that the neurochemical substrates of these two behaviors are, in some ways, different.

This research was supported by Defense Nuclear Agency.

162.4 REINSTATEMENT OF HEROIN-REINFORCED RESPONDING IN THE RAT BY CENTRAL IMPLANTS OF MORPHINE IN THE VENTRAL TEGMENTAL AREA. J. Stewart. Dept. of Psychology, Concordia Univ., Montreal, Canada H3G 1M8.

Non-contingent intravenous 'priming' injections of heroin or morphine reinstate heroin-reinforced responding after a period of extinction in rats trained to self-administer 100 µg/kg/infusion intravenously. Rats similarly trained were implanted with intracerebral cannulae directed at either the ventral tegmental area (VTA), the caudate nucleus (CN), or the periventricular grey (PVG). Each rat had cannulae placed at two of these sites. Following extinction of lever-pressing for heroin, crystalline morphine HCl applied via a 28-guage stainless steel tube into the VTA reinstated heroin-reinforced responding for up to 3 hours in spite of continued extinction conditions. No effect of morphine was seen at the other two sites. Pretreatment i.p. with 2 mg/kg naltrexone HCl 30 min prior to testing blocked the effect of the morphine implant in the VTA. These data add support to the view that the positive incentive properties of heroin and morphine are mediated via the mesolimbic dopamine system.

162.5 FAILURE TO BLOCK THE OPIATE EFFECTS OF ETONITAZINE WITH NALTREXONE IN RATS. M.R. Lynch, J. H. Porter* and D. N. Johnson. Dept. of Psychology, Va. Commonwealth Univ., Richmond, VA 23284.

Naltrexone blockade of the opiate effects of oral etonitazine was attempted in a choice situation with .01 mg/ml quinine in order to equate drug and placebo solutions on the basis of palatability. Ten male albino rats were provided with 5 μg/ml etonitazine HCl solutions and the quinine for 24 hrs. each day, with bottle positions counterbalanced over days to control for position preferences. Naltrexone was administered i.p., once per day, in a dose of 3 mg/kg. After six days access to the drug and placebo solutions, 3 of ten animals began showing precipitated withdrawal following antagonist injections. This number increased to 6 rats on day seven and these rats continued to show precipitated withdrawal over the remaining 4 days of naltrexone administration. Intakes of the etonitazine solution ranged from negligible amounts to as much as 115 mls, representing μg/kg/day doses of 28 to 825 over the last three days of choice-testing. Rats exhibiting withdrawal drank 412 to 825 μg/kg/day. Analgesic testing to examine cross-tolerance to 5 mg/kg morphine was conducted 24 and 48 hrs. after the last naltrexone injection, with animals remaining on choice tests over these 48 hrs. After antagonist action had disipated (48 hrs.), a significant difference in post-morphine tail flick latency was noted between animals consuming low doses of drug ($\bar{X}$ = 167 μg/kg/day) and those five with the highest intake ($\bar{X}$ = 614). While no spontaneous withdrawal symptoms were noted over six days following removal of choice-test solutions, daily water intake dropped to approximately one-half of previous fluid consumption and gradually recovered over the six days. Body weights also dropped over the first 96 hrs. of this abstinence period and then recovered. These six days were followed by 12 more days of continued choice-testing, but with daily injections of saline only. Repeated cross-tolerance testing was conducted after 12 days of this testing, with identical results to the 48 hr. test conducted after daily naltrexone injections. Water intakes over six more days of abstinence, showed a similar decrease and recovery as in the previous opiate-free period, and body weights dropped from a mean of 450g to 410g over the first 24 hours and then gradually recovered. The results indicated a failure to block opiate effects of orally ingested etonitazine, when intake exceeds 350 μg/kg/day.

162.6 SUBCUTANEOUS INFUSION OF MORPHINE BY OSMOTIC MINIPUMP: TOLERANCE AND DEPENDENCE WITHOUT ANALGESIA. D.H. Malin, K.E. Peek*, K. Freeman*, W.R. Mills* and L.S. Neal*. Univ. of Houston at Clear Lake City, Houston, TX 77058.

Infusion of opiates via osmotic minipumps offers certain advantages in comparison with pellet implantation: steady, precise infusion rate and ease of removal. Previous authors (Wei and Loh, 1976; Simmons, et al., 1978; Lange, et al., 1979) have produced morphine tolerance or dependence in the rat through osmotic minipumps connected to intraventricular cannulas. We now report that tolerance and dependence can be achieved by the much simpler procedure of s.c. minipump implantation.

Subjects were female Sprague-Dawley rats ($\bar{x}$ = 275 g). Alzet osmotic minipumps (model # 2001) were filled with a 50 mg/ml morphine sulfate solution or with distilled water alone. Minipumps were inserted s.c. through a 2-cm incision in the scapular region of rats under light anesthesia. The incision was closed by 2 skin clips. This procedure required less than 3 minutes. It has been demonstrated (Theeuwes and Yum, 1976) that the minipump delivers 1 μl/hr continuously for at least 7 days. Thus, each rat received only .014 mg/kg/hr. Not surprisingly, this minute dose failed to produce analgesia on the tail-flick test. In fact, morphine-infused animals showed significantly lower flick latencies than water-infused controls at intervals ranging from 12 hours to 6 days post-implantation.

Nevertheless, rats demonstrated considerable tolerance to morphine after 7 days of infusion. Four morphine-infused rats showed significantly less increase of tail-flick latency in response to 4 mg/kg s.c. morphine as compared with water-infused controls.

In addition, rats demonstrated morphine dependence following 7 days of infusion, as evidenced by naloxone-precipitated abstinence symptoms. In response to 2 mg/kg s.c., 4 morphine-infused rats showed significantly more writhes, wet-dog shakes, dyspnea, and teeth-chattering as compared to 4 water-infused animals. Another experiment demonstrated spontaneous withdrawal. Morphine and water pumps were removed from rats under light anesthesia 7 days after implantation. Five rats formerly implanted with morphine pumps showed significantly more abstinence-like symptoms (wet-dog shakes, head shakes, scratches, dyspnea) than 5 animals formerly implanted with water pumps. This difference persisted for 3 days after pump removal.

Dependence formation by morphine infusion could not be accounted for by change in brain tissue endorphin levels. RIA for Met-enkephalin revealed 632 ± 22 ng/g (mean ± SEM) in 5 rats infused with morphine for 7 days and 638 ± 77 in rats infused with distilled water for 7 days. RIA for beta-endorphin revealed 189 ± 9 ng/g in morphine-infused brains and 193 ± 11 in water-infused brains. These differences were not significant.

162.7 INTRACEREBRAL INJECTION OF NALOXONE IN THE REGION OF THE NUCLEUS TRACTUS SOLITARIUS: EFFECT ON EEG CHANGES INDUCED BY SYSTEMIC MORPHINE M. Kelly,* J.D. Bronzino, N. Oley, C. Cordova,* and P.J. Morgane (SPON: K. Morest). Trinity College, Hartford, Connecticut, 06106.

Recent evidence has indicated that the nucleus of the solitary tract and area postrema (NTS/AP) region of the dorsomedial medulla plays a role in pain suppression. For example, the region of NTS/AP has been found to be rich in opiate receptors and to be involved in pain modulation when stimulated with noradrenlin. We recently reported that microinjections of morphine in the region of the NTS/AP produced analgesia using the traditional tail-flick test (Brain Research, 236:511-515, 1982) and the EEG and behavioral effect of systemic administration of morphine (EEG Clin. Neurophysiol., 53:14-26, 1982). In the present study we set out to determine whether microinjections of naloxone, an opiate antagonist, applied directly into the region of the NTS will prevent the EEG effects of subsequent systemic injection of morphine. Male Sprague-Dawley retired breeder rats had microinjections (0.1 μl) of Naloxone at various doses (i.e., 1 μg, and 2.5 μg) or Ringer's solution directly injected into the region of the NTS via a 28 gauge cannula system. Five minutes following the intracerebral injection of naloxone, the animal was given an injection of 30 mg/kg morphine sulphate i.p. Intracerebral injection of naloxone into the region of the NTS was effective in significantly decreasing the EEG synchronizing effect of systemic administration of morphine. These microinjections had a major impact upon the percent of animals reaching High Voltage Low Frequency (HVLF) activity and the amount of time spent in HVLF activity. In our earlier work (Society of Neuroscience p.450, 1981), we showed that 30 and 10 μg injections of naloxone into the region of the NTS produced significant changes in the EEG synchrony (HVLF) that normally follow a morphine injection. These early results, however, failed to show a clear differentiation between animals whose cannula were within the NTS and those slightly out of this region. With doses of 2.5 and 1.0 μg a definite histological specificity emerges. At 1.0 μg of naloxone, for example, the control placement outside NTS produced results similar to those obtained with sham and Ringer's control while the placements in the NTS resemble the effects produced by higher doses of naloxone in the NTS. These results indicate that the primary effect of naloxone into the region of the NTS is upon morphine-induced EEG synchronization and suggests that the region of the NTS is involved in this morphine-induced EEG effect. (Supported by NIH Grant GM 27226-01).

162.8 DISRUPTION OF MATERNAL BEHAVIOR AFTER SYSTEMIC OR CENTRAL ADMINISTRATION OF MORPHINE IN RATS. B. S. Rubin*, C. T. Grimm* and R. S. Bridges. Lab. of Human Reprod. and Reprod. Biol., Harvard Medical School, Boston, MA 02115.

Opiate immunoreactivity in the hypothalamus as well as pain thresholds change during pregnancy and lactation in rats. In the present study we examined the possibility that opiates may be involved in regulating maternal responsiveness. In experiment #1 the effects of systemic treatment with morphine (M) and the opiate antagonist naloxone (N) on the onset and maintenance of maternal behavior were measured. Twenty-five primigravid rats had their pregnancies terminated by ovariectomy plus hysterectomy (OH) on day 17 of gestation. After surgery subjects were injected with M (5mg/kg), M plus N (0.5mg/kg) or saline (S). Animals were thereafter injected with these substances daily from 0900-1000 h. Behavioral testing was initiated 1 hr after injections beginning 24 hr after OH. Pup-oriented and nest building responses were scored each day during a 1 hr test. M treatment significantly disrupted the onset of maternal behavior, whereas concurrent administration of N to M-treated rats prevented the disruptive effects of M alone. Latencies to show full maternal behavior to foster young were 5.0 days for M, 0.4 days for S and 0.5 days for M plus N rats. M treatment alone also diminished the quality of maternal responsiveness in a T-maze test, but did not reduce activity levels in an open field test. In experiment #2 we attempted to localize morphine's disruptive action in the CNS by applying M directly to the medial preoptic area (MPOA), an area involved in the mediation of maternal behavior, or the ventromedial nucleus (VMN) of the hypothalamus. M-filled cannulae were lowered into the brains of 26 ovx, estradiol-primed, pup-induced maternal virgins. Subjects were tested for maternal responsiveness both after M-filled and after blank cannulae were lowered into place. Eleven of 13 females with M-filled cannulae in the MPOA showed a dramatic disruption of maternal responsiveness during the 1 hr test session; however, these same 11 subjects exhibited a normal maternal response when blank cannulae were lowered into the same sites. In contrast, only 3 of 13 females exhibited some deficit in maternal behavior after M-filled cannulae were placed in the VMN, and the deficit was less severe. The results of activity tests revealed that direct application of M to the MPOA did not alter activity levels, whereas M application to the VMN suppressed open field activity. In summary, these data indicate that morphine can act centrally to modulate the expression of maternal behavior and thereby suggest a possible role for endogenous opiates in the mediation of maternal responsiveness. 162.9 OPIOID MODULATION OF STIMULATION-INDUCED FEEDING: COMPARISON OF CENTRALLY AND PERIPHERALLY ACTIVE COMPOUNDS. K. D. Carr, K. A. Bonnet and E. J. Simon. Departments of Psychiatry and Pharmacology, New York University School of Medicine, New York, NY 10016.

Recent evidence indicates that the endogenous opioids are involved in the regulation of food intake. Several laboratories have reported that naloxone, the opiate antagonist, suppresses eating in food-deprived animals. While opioid peptides and opiate receptors are indeed located in regions of the CNS that are involved in mechanisms of hunger, taste and reinforcement, they are also located in peripheral tissues such as the gastrointestinal tract, adrenal medulla and pancreas where opioid activity could affect feeding. The purpose of the present study was to discriminate between peripheral and central opioid activity in the acute regulation of feeding behavior. Frequency threshold for feeding induced by electrical stimulation of the lateral hypothalamus was examined in rats after administration of opioid agonist and antagonist compounds that show differential penetrability of the blood-brain barrier. There is evidence that, unlike naloxone and morphine, quarternary naloxone and the agonist loperamide do not cross the blood-brain barrier. We therefore determined stimulation-induced feeding threshold prior to and 20 min after subcutaneous injection of each of these four compounds.

Naloxone elevated stimulation-induced feeding threshold in a dose-related manner (0.2 - 5.0 mg/kg) while quarternary naloxone (2.0 - 10.0 mg/kg) did not. Progressive increases in naloxone's threshold-elevating action over the course of a session suggest an effect on post-ingestive events, possibly a reduction in the reinforcement of consummatory behavior. Morphine sulfate reduced stimulation-induced feeding threshold at low doses (e.g. 1.25 mg/kg) but elevated threshold at higher doses (2.5, 5.0 mg/kg). Loperamide either had no effect (0.0625, 0.125 mg/kg) or elevated threshold (0.25 mg/kg). The threshold-elevating effect of loperamide was blocked by pretreatment with quarternary naloxone.

These results indicate that the anorectic action of naloxone is due to blockade of receptors in the CNS and that central opioid activity may play a role in the reinforcement of consummatory behavior. The suppressive effect of peripheral opioid activity on feeding may be due to the inhibition of gastrointestinal motility.

162.10 LIMBIC ACETYLCHOLINE TURNOVER RATES CORRELATED WITH MORPHINE-SEEKING BEHAVIOR, J.E. Smith, C. Co* and J.D. Lane. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Opiate self-administration is maintained by the reinforcing properties of these drugs. Acetylcholine releasing neurons may be involved in these reinforcement processes since disruption of cholinergic neuronal activity with atropine attenuates intravenous morphine self-administration (Davis and Smith, Life Sci. 16, 237, 1975). This study was initiated to directly assess the involvement of cholinergic neurons in opiate reinforcement. The turnover rates of acetylcholine (ACh-TO) were measured in the frontal cortex (FC), pyriform cortex (PC), caudate nucleus (CN), diagonal band (DB) and hippocampus (Hipp) of rats intravenously self-administering morphine (I) and in yoked-morphine infused (II) and yoked-vehicle infused (III) littermates. Fourteen litters of three (conditions I-III) male F-344 rats were implanted with chronic jugular catheters and two littermates in each group made physically dependent upon morphine with hourly infusions. One of the dependent rats was then allowed to self-administer morphine (10 mg/kg) by lever pressing. The other two littermates in each group received simultaneous yoked infusions. After stable baselines of self-administration were obtained, an average interinjection interval was calculated for each self-administering animal. At 5 min (N=7 litters) and 10 min (N=7 litters) prior to a predicted self-infusion, 0.5 mCi of [^{3}H]-choline were injected through the jugular catheter and the litter sacrificed by immersion in liquid nitrogen at the predicted self-administration time. The brains were removed at -20°C and the areas of interest dissected from serial coronal sections at -20°C. Content and turnover rates were determined with modifications of previously described procedures (Shea and Aprison, Anal. Biochm. 35, 136, 1969; Fiegenson and Saelens. Biochem Pharmacol. 18, 1479, 1969). Passive morphine infusion (comparing Group II and III) resulted in a decrease in ACh-TO in the CN and significant increases in the DB and Hipp. Morphine self-administration (comparing groups I and II) resulted in significant increases in ACH-TO in the FC and decreases in the PC, CN and Hipp. The changes in ACh-TO in the FC, CN and Hipp in the self-administering rats are consistent with the proposed involvement of a FC-CN and a Hipp loop in opiate reinforcement [suggested by prior investigations of the turnover rates of biogenic amine and amino acid neurotransmitters in self-administering rats (Smith et al, Nature 287, 152, 1980; Pharmac. Biochem. Behav. 16, 509, 1982)]. (Supported in part by USPHS Grant No. DA-01999-04).

162.11 DIFFERENTIAL RESPONSIVITY TO MORPHINE IN MONOSODIUM GLUTAMATE TREATED RATS. N. Nicotera, D. Badillo-Martinez, P. Butler*, A.L. Kirchgessner*, V. Sikorszky* and R.J. Bodnar. Dept. of Psychology, Queens College, C.U.N.Y., Flushing, NY 11367.

The medial-basal hypothalamus appears to be involved in pain perception given its concentration of brain B-endorphin and ACTH cells as well as the observed deficits in morphine analgesia following its destruction by neonatal treatment with monosodium glutamate (MSG). However, this brain area may mediate through opioids other behavioral responses as well. Therefore, MSG-induced changes in opiate analgesia must be understood in terms of selective or general behavioral deficits. To this end, neonatal rats received either a high dose (HMSG: 2g/kg on days 2 & 4; 4g/kg on days 6, 8 & 10), a low dose (LMSG: 1 g/kg on days 2 & 4; 2g/kg on days 6, 8 & 10) or a saline vehicle (SAL). Beginning at 80 days of age, flinch-jump and hot plate thresholds were measured following a dose range of morphine. While HMSG rats displayed increased jump thresholds following the 2.5 mg/kg morphine dose, they exhibited an attenuated analgesia following 5 and 10 mg/kg doses. Conversely, HMSG rats showed significantly longer hot-plate latencies following the 10 mg/kg morphine dose with analgesia persisting over time. Hypoactivity induced by the 10 mg/kg morphine dose failed to dissociate across groups, but hyperactivity following the 2.5 mg/kg dose was present in SAL and LMSG, but not in HMSG, rats.

Flinch-jump thresholds, hot-plate latencies, body temperature and body weight were measured every fourth day following daily morphine (15 mg/kg) injections over 14 days. Maximal morphine analgesia on jump thresholds occurred on day 1 for SAL rats, on days 1 and 5 for LMSG rats and on day 5 for HMSG rats. Gender-specific effects were also apparent on this measure with males exhibiting more pronounced differences across groups. By contrast, repeated morphine injections altered hot-plate latencies and hyperthermia similarly across groups. The chronic morphine injections resulted in more marked weight loss in HMSG rats. Therefore, the analgesic and locomotor changes noted in HMSG rats following acute morphine appear to be dependent upon dose, pain test and gender. Moreover, HMSG rats appear to display a delayed maximal analgesic response following repeated morphine injections with pain test and gender as critical variables. These data indicate that MSG-induced loss of the B-endorphin/ACTH system, as well as other pertinent hypothalamic neuromodulators, produce pronounced, yet selective, effects upon an animal's analgesic, locomotor and weight control responses following acute or chronic opiate administration. Supported by NIH GRSG 5-S05-RR-07064.

162.12 EFFECTS OF KAINIC ACID LESIONS OF THE NUCLEUS ACCUMBENS ON RESPONDING MAINTAINED BY A CONCURRENT FOOD, WATER AND MORPHINE SCHEDULE, S.I. Dworkin, G.F. Guerin, J.D. Lane, D.R. Cherek and J.E. Smith, Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Results from several studies suggest that operant behavior maintained by different reinforcers may share specific neuronal systems that mediate reinforcement processes. The nucleus accumbens has been shown to support both intracranial self-stimulation and opiate self-administration,while lesions decrease responding maintained by cocaine self-administration. This study assessed the effects of lesions of the nucleus accumbens on concurrent food, water and morphine reinforcement.

Male Fisher F-344 rats were trained to lever press on separate retractable levers on a non-reversable choice schedule involving food and water presentation. The subjects were implanted with bilateral intracranial injection cannulae into the nucleus accumbens and with a jugular catheter. The three reinforcers were each available with 24-hour access on FR 10 schedules with a 100 sec limited hold contengency and each reinforcement or elapsed limited hold was followed by a 30 sec time out. Chemical lesions of the nucleus accumbens were then produced by bilateral microinjections of kainic acid while control animals received microinjections of saline.

Comparable rates and temporal patterns of responding were maintained by the three reinforcers. Between 7 and 20 morphine infusions were delivered each day. The number of food and water presentation was 10 to 15 fold larger. Most of the food and water was taken during the subject's dark cycle (between 5 am to 5 pm). Morphine infusions were more evenly distributed over 24 hours. Kainic acid lesions of the nucleus accumbens resulted in an initial decrease in responding maintained by all three reinforcers. The total number of food and water presentations subsequently increased to values observed before the lesion while morphine infusions decreased to about 50 percent. Food and water presentations were distributed during both light and dark cycles. However, morphine infusions were no longer evenly distributed over the 24-hour period.

The effects of extinction were studied with pre-lesion subjects to further assess the behavioral effects of the lesions. Changing the food schedule to extinction resulted in large increases in morphine intake with a concomitant decrease in water intake while extinction of responding maintained by morphine decreased food and water responding. The effects of the lesion on responding maintained by the three reinforcers were not similar to the effects of extinction. (Supported in part by USPHS Grant DA-01999-04).

162.13 REVERSAL OF MORPHINE (M)-INDUCED CATALEPSY IN RATS BY QUATERNARY NARCOTIC ANTAGONISTS. D.R. Brown, M.J. Robertson*, L.I. Goldberg* Dept. Pharmacology, University of Chicago, Chicago, IL 60637

The pure narcotic antagonists, naloxone (Nx) and naltrexone (Ntx), are useful pharmacological tools in opiate research; however, their value in determining sites of opiate action is precluded by their rapid diffusion across the blood-brain barrier. Their quaternary derivatives, naloxone methobromide (NxMeBr) and naltrexone methobromide (NtxMeBr) may be less permeable to the blood-brain barrier due to their limited lipid solubility. We evaluated the abilities of NxMeBr and NtxMeBr as well as Nx and Ntx, given peripherally, to reverse M-induced catalepsy in rats; this opiate-induced rigid immobility is presumably mediated at CNS sites. Moreover, the action of NtxMeBr was assessed after intracerebroventricular (i.cv.) administration. Male Sprague-Dawley rats (300-350 g) were given M (20 mg/kg, base; s.c.) and tested for catalepsy at 30 min intervals from 30-240 min after injection. Two groups of rats received random doses of Nx and NxMeBr or Ntx and NtxMeBr, respectively, and saline administered s.c. 40 min following M. A third group of rats with chronic cannulae implanted in the right cerebral ventricle were injected with random doses of NtxMeBr (0.1-1.0 µg/5 µl) or saline (5 µl), i.cv. 70 min after M administration. Duration of catalepsy was determined by placing animals' forepaws over a horizontal bar 10.5 cm high; catalepsy was measured with a 300 sec cutoff time. Rats given saline after M injection remained fully cataleptic for over 120 min. The peripheral dose of each drug necessary to shorten catalepsy duration to 150 sec (ED_{50}) appears below at 60, 90, and 120 min after M administration:

	ED_{50}* (mg/kg)		
	60	90	120
Nx	0.0007	0.018	0.017
NxMeBr	1.06	1.36	1.27
Ntx	0.007	0.008	0.002
NtxMeBr	20.9	10.8	2.4

*Based on least squares regression of means; n = 5-9 animals/point

NtxMeBr had an ED_{50}=0.001 mg/kg at 90 min post-M when administered i.cv. These results indicate that 1) NxMeBr may penetrate the blood-brain barrier but is less potent than Nx; 2) NtxMeBr, given s.c. is initially impermeable to the CNS although its potency increases with time suggesting either slow diffusion into the brain or the formation of active, lipophilic metabolites; 3) NtxMeBr, given i.cv. is 21,000-fold more potent in reversing catalepsy than it is upon s.c. injection. Thus, NtxMeBr may be useful in defining sites of opiate action and in therapeutically blocking undesirable peripheral effects of opiate analgesics.

162.14 NALOXONE INCREASES SOCIAL NEED. L. Normansell*, S. Siviy* K. White* and J. Panksepp Dept. of Psych., Bowling Green State Univ., Bowling Green, OH 43403

In past work we have demonstrated that brain opioids inhibit emotions resulting from social separation while blockade of opiate receptors increases separation distress. Accordingly, the brain opioid theory of social affect predicts that opiate receptor blocking agents should increase social motivation. However, we have repeatedly observed naloxone (1-10 mg/kg) to reduce social play in young rats. This observation could be deemed inconsistent with the above theory, but it is the expected outcome from the perspective that an essential condition for vigorous play is a state of social comfort. To further determine whether naloxone does in fact increase social motivation, young rats were tested in a variety of discrete situations with social rewards.

Opioid blockade (naloxone 1 mg/kg) increased the tendency of 15-20 day old rats deprived of both food and home overnight to choose home rather than food reward. Similarly, 10-13 day old rat pups treated with naloxone (10 mg/kg) ran from clean bedding to dirty home bedding twice as fast as controls, while 16 day old animals given a choice between dirty home bedding on one side of a test chamber and their anesthetized mother on the other, latched a nipple in a third of the time following naloxone (1 mg/kg) compared to saline. However, juvenile rats (25-40 days of age), tested for play motivation in a spatial learning situation (U-maze), seemed socially timid following naloxone, exhibiting slow entry into the play chamber (average latency: naloxone (1 mg/kg)--4.3 sec, saline--1.9 sec). During 9 days of extinction testing, naloxone treated animals also ran much slower than control or morphine treated ones (mean running speed for last eight days of extinction: saline--22.6 sec; morphine (1 mg/kg)--11.7 sec; naloxone--81.3 sec) and made fewer correct responses (saline--57%, morphine--65%, naloxone--20% correct).

Taken together, these results affirm that naloxone increases social need. Accordingly, the reduction of play following naloxone may be due to a reduced ability of an animal to elaborate a brain state of social comfort which normally promotes energetic and competitive social interactions.

162.15 PHARMACOLOGICAL SEPARATION OF AGGRESSION FROM OTHER SYMPTOMS OF MORPHINE WITHDRAWAL. K.M. Kantak and K.A. Miczek. Dept. Psych., Tufts Univ., Medford, MA 02155.

Withdrawal from morphine engenders a characteristic behavioral syndrome. Naloxone administration readily precipitates this syndrome. Heightened aggressive behavior has also been associated with morphine withdrawal. The following experiments were conducted to determine the mechanisms which might mediate the aggressive and other symptoms of morphine withdrawal. Initially, morphine withdrawal aggression was investigated in mice with or without fighting experience. 75mg morphine or placebo pellets were implanted in resident mice who showed attack and threat behavior toward intruder animals. In a second group non-experienced resident mice were given morphine or placebo pellets. Parellel experiments were performed in intruder animals who showed defensive and escape behaviors. After tolerance to morphine was established, naloxone HCl (1 or 10 mg/kg, i.p.) was administered, and withdrawal, including changes in aggression, was evaluated immediately post-injection. In other animals, the pellets were removed and behavioral measures were taken 48 hrs later. Morphine withdrawal aggression was observed following morphine pellet removal in non-experienced animals. An increase in biting attacks was observed in both resident and intruder mice. In contrast, naloxone decreased attack in non-experienced and experienced resident mice and increased escapes and vocalizations in non-experienced and experienced intruder mice. These effects of naloxone were observed in both morphine and placebo treated mice. The anti-aggressive action of naloxone might not be related to withdrawal from the µ-opiate receptor while the aggression enhancing action of morphine pellet removal might be. Since µ-opiate receptors may influence catecholamine functioning, a second series of experiments was conducted in which non-experienced residents were withdrawn from morphine by pellet removal and tested for aggression against intruders 48 hr later with various doses of apomorphine HCl (0.01-1.0 mg/kg, i.p.) and clonidine HCl (0.1 and 0.25 mg/kg, s.c.). At doses of apomorphine which primarily act on presynaptic dopamine receptors (0.01, 0.03 and 0.1 mg/kg) morphine withdrawal aggression and jumping behavior were not affected. Hyperthermia was produced by 0.01 and 0.03 mg/kg. With 1.0 mg/kg of apomorphine, which primarily acts on post-synaptic dopamine receptor, morphine withdrawal aggression and jumping were suppressed. This was accompanied by hypothermia. Clonidine a presynaptic α-noradrenergic agonist, also suppressed attacks at 0.1 and 0.25 mg/kg, but caused an increase in withdrawal jumping. A slight hypothermia at both clonidine doses was measured. This suggests that morphine withdrawal aggression can be viewed independently from other morphine withdrawal symptoms.

162.16 DISCRIMINATIVE AND REINFORCING STIMULUS PROPERTIES OF STEREOISOMERS OF CYCLAZOCINE. Barbara Lord Slifer*, Robert L. Balster* and W.D. Rodes* (SPON: M.J. Kallman). Pharmacology Department, Medical College of Virginia, Richmond, VA 23298/

Cyclazocine (C), a benzomorphan with sigma-receptor agonist activity has been shown to be similar to the prototype sigma agonist N-allylnormetazocine (NANM) and the dissociative anesthetic phencyclidine (PCP). For example: C, NANM and PCP all produce psychotomimetic effects in humans (Domino & Luby, 1981; Keats & Telford, 1964) and result in a similar profile of effects in the chronic spinal dog (Gilbert & Martin, 1976; Vaupel & Jasinski, 1979). Recent binding studies with C in rat brain (Zukin & Zukin, 1981) have shown multiple sites with displacement at a low affinity site by PCP and NANM but not naloxone or morphine. In spite of such demonstrated similarities, certain differences still exist. While PCP is an effective reinforcer in maintaining self-administration behavior, the psychotomimetic benzomorphans are not self-administered by animals. Recent evidence has indicated that the (+)-isomer of NANM is more specific than the (-)-isomer for producing the PCP-like discriminative- and reinforcing-stimulus effects of this compound (Brady et al., 1981; Slifer and Balster, 1982), and similar isomeric separation of discriminative stimulus effects of C have been shown in squirrel monkeys in previous research in this laboratory. We report here on the discriminiative stimulus effects in rats and the self-administration by rhesus monkeys of the racemic mixture and the pure stereoisomers of cyclazocine.

Rats were trained on a PCP-SALINE 2-lever discrimination task for food pellets on a FR-32 schedule of reinforcement. Training was done on a double alternation schedule and test sessions consisted of 2-min extinction periods during which various doses of PCP, (±)-C and the pure (+)- and (-)-isomers of C were tested. PCP (0.3 - 3.0 mg/kg) and (+)-C (1.0 - 30.0 mg/kg) produced dose-related drug-lever appropriate responding. Neither the (-)-isomer (0.03 - 1.0 mg/kg) nor (±)-C (0.1 - 3.0 mg/kg) resulted in over 40% PCP-lever responding at doses which markedly suppressed response rates. Rhesus monkeys were trained to self-administer (SA) i.v. cocaine (50 µg/kg/inj) by lever pressing on a FR-10 schedule of reinforcement. Doses of cyclazocine ((±), (+), (-)) or saline were substituted for cocaine for 4 consecutive daily sessions. Substitution of the racemate (0.1 - 3.0 µg/kg/inj) or (-)-C (0.03-3.0 µg/kg/inj) did not result in responding above saline levels at any dose tested while the (+)-isomer maintained rates of self-administration which were well above saline SA rates at the 10.0 µg/kg/inj dose in all monkeys tested. It appears that the PCP-like stimulus properties of cyclazocine, like NANM, are revealed in the (+)-isomer in both rats and monkeys. (Supported by grants DA-01442 and DA-05193).

163.1 SODIUM HUNGER AND THE VOLUNTARY INTAKE OF ETHANOL. L. A. Grupp. Dept. of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

A number of reports, both recent and in the recent past, point to the involvement of sodium in choice and voluntary consumption of ethanol. Iida (Jap. J. Pharmacol., 6:87, 1957) showed that daily i.p. injections of saline or of the aldosterone analog, desoxycorticosterone acetate (DOCA), increased the voluntary intake of an otherwise rejected (15% v/v) ethanol solution. Interestingly, DOCA has been used in the treatment of Delerium Tremens (Smith, J.J., Quart. J. Stud. Alc., 11:190, 1950) and it has been noted (ibid) that the Addisonian crisis is similar biochemically and clinically to Delirium Tremens. In keeping with this theme, the present experiment investigated the effect of sodium hunger on the voluntary intake of ethanol.

Four different groups of female Wistar rats maintained on a nutritionally adequate (basal) diet were offered a choice between distilled water and either 3%, 6%, 12% v/v ethanol solutions or distilled water every third day (Phase I). Only ethanol (3 groups) or distilled water (1 group) was available on intervening days. When consumption had stabilized the animals were first switched to a low sodium (L.S.) diet (Phase II) and then to an L.S. diet in combination with a brief regimen (4 injections) of the diuretic furosemide (60 mg/kg). In the final phase the animals were returned to the basal diet. Control groups were treated identically except that they were maintained on the basal diet throughout.

For those animals which preferred ethanol while on the basal diet (3% and 6% groups), the L.S. diet in combination with the diuretic, but not the L.S. diet alone, produced a decrease in the preference for ethanol, a decrease in the absolute amount of ethanol consumed and a concomitant increase in water intake. Reintroduction of the basal diet in the final phase lead to a recovery of the ethanol consumption. None of the control groups showed similar changes.

These findings indicate that sodium hunger is a condition incompatible with the ingestion of appreciable quantities of ethanol. To what extent this effect is directly related to the electrolyte imbalance or secondary to a change in metabolic state, taste sensitivity or some other factor or combination of factors, remains to be explored.

163.2 EFFECT OF AMPHETAMINE ON ETHANOL DRINKING IN RATS. P.M. Duncan. Psychology Dept., Old Dominion Univ., Norfolk, VA 23508.

The effect of chronic amphetamine (amph) treatment on rats' voluntary drinking of ethanol solution (ES) has apparently not been reported previously. Exp 1 examined this effect at 2 doses of d-amph (.8 and 4.0 mg/kg) in 18 male Long-Evans rats which had access to both H_2O and 5% ES during an 8-day baseline (BL) period. Three groups (n=6) each then received 8 daily injections of saline, low or high amph doses. Mean ethanol preference relative to H_2O (EP) in the high-dose grp dropped progressively on inj days 1-8 from a .78 BL to .30 on day 8. Low-dose grp mean EP gradually decreased from a BL of .72 to .31 on day 8, with the most pronounced decline occurring on days 5-8. Saline grp mean EP remained stable near its .88 BL. ANOVA revealed sig. diff. ($p < .05$) between each drug grp and the saline grp, but not between the 2 drug grps. In Exp 2, the effect of 10 daily amph inj (1.5 mg/kg) on subsequent EP in 8 rats not allowed concurrent access to (but previously familiarized with) ES was examined. Three other grps (n=8 each) included one given saline inj and no ES access for 10 days, and 2 grps given daily saline or amph inj concurrent with continued (post BL) access to H_2O and ES. All 4 grps had access to both ES and H_2O on days 11-16 during which daily amph or saline treatments continued as on days 1-10. A drop in EP, first seen on day 5 and persisting near a mean of .25 through day 16 (sig. diff., $p < .05$), emerged only in the grp receiving both amph inj and continued ES access on days 1-10. Mean EP for the saline-constant access grp remained near the BL level of .60. When the "delayed ES access" grps were again given ES-H_2O choice on day 11, both amph and saline-inj grps maintained high (at least .50), similar mean EPs on days 11-16. Since the decline in EP produced by daily amph injection emerged only (or became greater) after several days off such treatment, and did not occur at all if rats were familiarized with amph effects while not drinking ES, the results are consistent with the interpretation that ES intake potentiates and/or prolongs aversive amph effects and thus produces a conditioned taste aversion (CTA) for ES which eventually causes the decreased EP. Potentiation of amph effects by ethanol (injected IP) has been observed for amph-stereotyped behavior (Todzy, et al., Psychopharm 59: 143, 1978) and for amph-produced CTA to flavored liquid in a conventional CTA paradigm (Duncan, EPA convention, 1982). Pre-exposure to amph has been shown to reduce its effectiveness as a US for production of CTA (Cappell, et al., Psychopharm 43: 157, 1975). Although post-ingestional potentiation of amph effects by orally consumed ethanol has not been directly demonstrated, potentiation could logically occur and result in the decreased ES intake seen here.

163.3 EFFECTS OF ETHANOL 4 G/KG BODY WEIGHT IN RATS OF DIFFERENT AGES. E. M. Burns, T. W. Kruckeberg* and P. K. Gaetano*. Dept. of Nurs. Science, University of Illinois Medical Center, Chicago, IL 60612

The purpose of this research was to determine whether or not ethanol 4 g/kg body weight daily throughout the brain growth spurt would affect body temperature and if so, therefore confound neurochemical and/or morphological findings. Sprague-Dawley timed-gestation rats were obtained from the Holtzman Company (Madison, WI). On the day after birth, animals were weighed, pooled, and 8 pups randomly assigned per dam. Subsequently, animals were given ethanol 4 g/kg body weight (in two 2 g/kg doses three hours apart) daily from day 27 through 37 postconception (approximately day 6-16 postnatally). Age-matched isocaloric milk "pair-fed" controls and "handled controls (handled in the same manner as treated pups, including intubation without the administration of any substance) were included in this study. Ethanol solution (20% W/V, prepared from 95% alcohol USP) or the isocaloric equivalent of milk was administered via a metal intragastric tube.

Mean blood ethanol concentrations (BEC) at the peak level (45 minutes after the second 2 g/kg dose) was found to be 264.90 ± 68.27 mg% (N = 71). Body temperature was measured using a mini thermistor probe and telethermometer (Yellow Springs) prior to treatment or handling, at 45, 105 and 180 minutes after the first 2 g dose of ethanol, and at 60 and 180 minutes after the second 2 g dose of ethanol on days 27, 30, 34, and 37 postconception. Body temperature in ethanol-treated animals did not differ from that in the two groups of controls, which did not differ from each other.

Body temperature was measured similarly in additional animals on day 43 postconception (the day after weaning). In these animals, body temperature was significantly lower in the ethanol-treated as compared with controls at one time period only (105 minutes after the first 2 g dose). In ethanol-treated adult rats body temperature was significantly lower from 105 minutes after the first 2 g/kg dose throughout the remainder of the observation period (405 minutes) as compared with body temperature prior to ethanol treatment.

Additional controls were used to investigate the temporal pattern of the ontogeny of thermoregulation in the Sprague-Dawley rat. By day 41 postconception thermoregulation in developing rats approached that of adults.

Since no effect of ethanol 4 g/kg body weight occurred on any day throughout the brain growth spurt on body temperature, changes observed in synaptic neurochemistry and morphology are not due to the effect of ethanol on body temperature.

163.4 MEMORY FACILITATION BY POST-TRAINING ETHANOL: STRAIN DIFFERENCES. R.L. Alkana, D.A. Finn* and R.D. Malcolm*. Institute for Toxicology, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

In contrast to the typical impairment induced by pre-training ethanol administration, recent studies demonstrate that immediate post-training injection of ethanol (0.75 - 4.5 g/kg) facilitates retention performance on a single trial passive avoidance task in C57 and Swiss Webster mice. The present study extended this investigation to a third mouse strain with a documented difference in central nervous system sensitivity to ethanol. Age-matched, drug-naive, male C57 BL/6J, Swiss Webster (Sim) and BALB/cJ mice were housed 4-5 per cage on a 12 hour light-dark cycle (0700 on) for two weeks before experimentation. After 4 days of pre-handling and saline injections (0.1 ml) to reduce stress, the mice were trained between 1500 and 1830 hours on a one-trial passive avoidance task according to a counterbalanced design using footshocks of 0.10 mA (Swiss Webster), 0.15 mA (C57) and 0.20 mA (BALB). Footshock levels were selected on the basis of pilot studies to produce approximately equivalent retention times in saline treated controls. Immediately after training, mice were injected i.p. with 3.0 g/kg ethanol (16% w/v) or an equivalent volume of normal saline. Retention was tested in the non-ethanol state one week after training. Retention was operationally defined as the difference between test session and training session latencies to leave the lighted start box and reach a point 8 cm into the darkened end of the two-compartment alley. Immediate post-training injection of ethanol significantly increased retention latencies in C57 and Swiss Webster mice compared to their respective saline injected controls ($p < 0.05$, Mann Whitney U), but did not significantly alter retention latencies in BALB mice. These strain differences in response to ethanol could reflect underlying differences in brain sensitivity to ethanol, hormonal or neurotransmitter responses or other factors which may prove useful in understanding ethanol's effects on learning and memory (Supported by NIAAA, ADAMHA Research Grant AA-04600).

163.5 EFFECT OF ETHANOL ON SPONTANEOUS MOTOR ACTIVITY (SMA) IN ALCOHOL-PREFERRING AND -NONPREFERRING RATS. Marshall B. Waller, William J. McBride, Lawrence Lumeng* and Ting-Kai Li*, VA Medical Center, Regenstrief Institute and Depts. of Psych., Biochem. and Medicine, Indiana Univ. School of Medicine, Indianapolis, IN 46223.

Low doses of ethanol (EtOH) reportedly are excitatory and potentiate behaviors such as SMA in several strains of mice and rats. To examine whether behavioral arousal is a correlate of EtOH preference the effects of low doses of EtOH on SMA were studied in the selectively bred preferring (P) and -nonpreferring (NP) lines of rats and in the Maudsley Reactive (MR/N) strain for which behavioral arousal has been reported (Kochar and Erickson, Alcoholism 6: 147, 1982). Alcohol naive male and female animals were given food and water ad libitum except during the test sessions. Food was removed 24 hr. before testing. After the intraperitoneal injection of saline or EtOH (0.0625 to 1.5 g EtOH/kg), SMA was monitored every 3 minutes for 30 minutes post-injection in an electronic activity monitor. Each EtOH dose was compared to saline (the paired t-test) for evaluation of statistical differences in activity. Female P rats showed an increase in SMA after the injection of 0.0625 and 0.125 g EtOH/kg while doses of 0.0625 to 0.5 g EtOH/kg increased SMA in P males. However, MR/N females exhibited increased SMA only at the 0.25 g EtOH/kg dose and MR/N males were more active after doses of 0.125 and 0.25 g EtOH/kg. In all cases, the maximum change in activity occurred within 9 min. post-injection. In sharp contrast, doses of 0.0625 to 0.5 g EtOH/kg failed to induce stimulation of SMA in either male or female NP rats. Doses of 1.0 or 1.5 g EtOH/kg consistently depressed SMA in all three strains of rats. Six minutes after the intraperitoneal injection of P female and MR/N male rats with 0.125 g EtOH/kg, cerebral blood EtOH concentrations were 15 and 12 mg%, respectively. Brain EtOH content was 21 and 16 mg/g, respectively. The intraperitoneal administration of 1.5 g EtOH/kg into P and MR/N animals elevated cerebral blood EtOH concentrations to 223 and 214 mg%, respectively and brain EtOH content was 286 and 269 mg/g, respectively 6 min. post-injection. These data suggest that P rats are more sensitive to stimulation by low doses of EtOH than either the MR/N or NP lines and that the CNS pharmacologic effects of low doses of EtOH may be an important variable in governing EtOH drinking behavior. The drinking scores, determined by free-choice drinking of 10% EtOH vs. water after SMA testing, for the P, MR/N and NP animals in this study were 6.6 ± .2, 3.3 ± .5 and 0.9 ± .3 g EtOH/kg/day. Therefore, the evidence is consistent with a positive relationship between EtOH preference and EtOH-induced locomotor stimulation. (Supported by Grants AA-03243 and MH-00203).

163.6 THE RELATIONSHIP BETWEEN CENTRAL AND PERIPHERAL ACETALDEHYDE OXIDIZING CAPACITY AND VOLUNTARY ETHANOL CONSUMPTION IN THE RAT. S. M. Socaransky*, C. M. G. Aragon*, F. Rogan*, Z. Amit, and Z. W. Brown. Center for Research on Drug Dependence, Dept. of Psychology, Concordia University, Montreal, Quebec, Canada, H3G 1M8.

The relationship between voluntary ethanol consumption and cerebral and hepatic aldehyde oxidizing capacity was investigated in the male Wistar rat. A significant correlation was observed between voluntary ethanol intake and levels of brain aldehyde dehydrogenase (ALDH) activity. Within the same animals there was no correlation between levels of hepatic ALDH activity and voluntary ethanol consumption. Levels of cerebral ALDH activity did not differ between ethanol exposed and control animals. Higher levels of hepatic ALDH activity were observed in ethanol exposed than in controls animals indicating possible induction or protection of the enzyme in the liver in response to ethanol. As a significant correlation existed between voluntary ethanol consumption and cerebral ALDH activity levels it is argued that brain ALDH activity may be integrated into the regulation of voluntary ethanol consumption. Preliminary investigations of cerebral ethanol oxidizing capacity and its relation to voluntary ethanol consumption also indicate a possible relationship between brain catalase activity and voluntary ethanol intake.

163.7 SUBCELLULAR DISTRIBUTION OF 3H-LEUCINE IN BRAINS OF ETHANOL TOLERANT VS. NONTOLERANT RATS AFTER PERIPHERAL ADMINISTRATION. D.D. Walczak* and H. Kalant* (SPON: P. A. Stewart). Dept. Pharmacol., University of Toronto, Toronto, Ontario M5S 1A8.

Rats were placed on a chronic treatment regimen known to produce tolerance to ethanol. Tolerance was assessed by a method developed in our laboratory in which rats were trained to cross a suspended dowel to obtain a food reward. Ethanol produced dose-dependent decrements in ability to obtain the reward, and tolerance developed to this effect. Duration of exposure was limited to six weeks to limit the development of chronic toxicity and metabolic tolerance. Ethanol or isocaloric sucrose was administered by daily gavage beginning at 3.0 g/kg/day. Doses were increased by 0.5 g/kg/day twice a week until 5.0 g/kg/day was reached. Doses were increased by 0.5 g/kg/day at weekly intervals thereafter until the level of 6.0 g/kg/day was reached. Tolerance development was measured at two-week intervals by constructing log dose-response curves using the selected behavioral test. Effects of 6 and 12 weeks treatment on the pharmacokinetics of ethanol and 3H-leucine were determined. After six weeks of treatment the animals were assigned to one of four experimental groups: Ethanol tolerant receiving ethanol (ET+E), ethanol tolerant receiving sucrose (ET+S), Sucrose controls receiving ethanol (SC+E), and Sucrose control receiving sucrose (SC+S). All animals were fitted with indwelling jugular cannulas 24 hr prior to receiving a test dose of either ethanol 3.5 g/kg or isocaloric sucrose, followed 30 min later by three i.v. injections of 3H-leucine, 0.5 mCi, spaced 30 min apart. Sixty min after the last i.v. injection the animals were sacrificed by decapitation and then subjected to subcellular fractionation according to the five-fraction scheme of deDuve et al. (Biochem. J. 60: 604-617, 1955). All fractions were analyzed for protein content and radioisotope concentrations. Groups ET E and ET S showed slight decreases in the protein content of whole homogenate and light mitochondrial fraction, and increased protein content in the 100 x g pellet and supernatant. Both ET groups showed increased incorporation of 3H-leucine into the heavy and light mitochondrial fractions, with the increases being significant in the light mitochondrial fractions. Ethanol withdrawn (WT S) subjects showed the highest degree of incorporation in these fractions. The fractions showing these changes have been subjected to electrophoresis on SDS-polyacrylamide gels to determine the specificity of labeling of individual protein bands. This data suggests that an increased turnover of light mitochondrial components is occurring in the ethanol-tolerant animals that is not observed in either sucrose control group.

163.8 TEMPORAL CHANGES IN PLASMA LEVELS AND METABOLISM OF KETONE BODIES BY LIVER AND BRAIN OF C57BL/6J MICE AFTER ETHANOL AND/OR STARVATION. R. A. Schreiber and Y.-Y. Yeh*. Dept. of Biochem., UTCHS, Memphis, TN 38163 and Dept. of Nutrition and Metabolism, The St. Jude Children's Research Hosp., Memphis, TN 38101.

Two experiments were performed, on the hypothesis that the liver may metabolize ethanol (ETOH) to β-hydroxybutyrate (BOHB) and acetoacetate (AcAc), which may then be utilized by the brain. In Experiment I, levels of plasma BOHB and AcAc were determined for up to 31 hr. after either an injection of 5 g/kg of 20% ETOH, or after starvation, or both. Untreated control levels were .322 mM BOHB and .049 mM AcAc, ± .054 and .010 (SEM), respectively. No sex differences were found. Starvation elevated BOHB levels starting at 7 hr., and were significantly elevated (.922 mM) by 10 hrs. BOHB levels peaked (2.5 mM) at about 24 hr., then appeared to decrease to 1.8 mM at 31 hr. The AcAc/BOHB ratio began to fall from .225 ± .074, attaining a nadir of .046 at 15 hr.; due to the rise in BOHB levels. ETOH enhanced BOHB levels which peaked at 10 hr. (1.42 mM) and returned to control levels by 15 hr., while ETOH plus starvation caused an increase to 1.22 mM BOHB by 7 hr., and to 1.88 mM by 31 hr. The AcAc/BOHB ratio had fallen to .108 by 7 hr. and .058 by 10 hr., where it remained, approximately, to 31 hr.

Other mice were then given 5 g/kg ETOH ± starvation (Gps. E, or E + S) and were sacrificed for metabolic studies at times of ETOH-elevated ketone bodies (10 hr.), or starvation-elevated ketone bodies (24 hr.). Liver homogenates were incubated with 1-^{14}C palmitate; hepatic capacities for incorporation into CO_2 and ketone bodies were determined. Brain homogenates were incubated with 3-^{14}C AcAc; incorporation into CO_2 and fatty acids was determined. In controls, male livers utilize more palmitate for energy (423.6 vs 120.9 nmol/g/30 min), and female brains incorporate more AcAc than males (171.8 vs 358.7 nmol/g/2 hr.). There were no sex differences among experimental groups. Neither E nor E + S affected the capacity for CO_2 production from palmitate in liver or from AcAc in brain at 10 hr. At 24 hr., starvation led to an elevated capacity for liver utilization of palmitate. The capacity for AcAc synthesis was increased 70% at 10 hr. in both Gps. At 24 hr., the synthetic capacity was doubled in Gp. E + S, and had returned to control levels in Gp. E. In the brain, the capacity for fatty acid synthesis was 90% higher in Gp. E + S, and 70% higher in Gp. E at 10 hr; both had returned to control levels by 24 hr.

Taken together, the two experiments show that ETOH increases ketone body levels by accelerating hepatic ketogenesis. Since plasma BOHB levels determine brain utilization rates (Hawkins et al., Biochem. J., 122:13, 1971), ETOH could provide a potential source of ketone bodies for brain synthesis of lipids and for energy.

163.9 ALCOHOL AND THE AUDITORY BRAINSTEM RESPONSE: DOSE EFFECTS. Julia A. Lee,* Robert F. Berman, Donald W. Nielsen, and Eugene P. Schoener. Psychology Dept., Wayne State University, Otological Research Laboratories, Henry Ford Hospital, and Pharmacology Dept., Wayne State University School of Medicine, Detroit, MI 48202.

Ethyl alcohol is one of the few pharmacological agents to alter the auditory brainstem response (ABR), a series of 6-7 waves within the first 10 msec following an auditory stimulus. Chu, Squires, and Starr (Arch. Neurol.,35:596, 1978) demonstrated that an acute dose of alcohol (2-3 g/kg) produced slowing of the ABR waves. They administered only one dose of alcohol and measured the ABR at a single time point (45-60 min) following alcohol. The present study was undertaken to confirm and extend their results by administering a range of alcohol doses and recording the ABR over a longer time period.

Four adult male Long Evans rats were surgically prepared according to a recently developed procedure for ABR recording in unanesthetized, unrestrained rats (Lee, Abbott, Berman, and Nielsen, Neurosci. Abstr., 7:51, 1981). With this procedure the speaker-ear distance is held constant by attaching a miniature speaker to the rat's skull. Ethanol doses of 0.5, 2.5, and 5.0 g/kg, po were administered at intervals of at least 7 days. Sessions began with a 30-60 min baseline period followed by drug administration. ABR recording was continued for 2-3 hrs.

Slowing of the ABR waves with a moderate (2.5 g/kg) and a high (5.0 g/kg) alcohol dose was observed for all subjects. With the higher dose, wave slowing typically started sooner, lasted longer, and was more pronounced. A most interesting result was noted with the moderate alcohol dose. For two subjects, there was a biphasic effect characterized by an initial decrease in wave latencies followed by an increase (wave slowing). The wave slowing started 45 min after alcohol. With the 0.5 g/kg alcohol dose an early excitatory effect was seen for one subject. No other definitive ABR latency changes were noted at this lowest dose. These findings indicate that the ABR is sensitive to excitatory as well as depressive effects of acute alcohol doses. The excitatory effects observed would appear to correspond to the rising phase of blood alcohol levels.

Jones, Stockard, and Weidner (Electroenceph. clin. Neurophysiol., 49:23, 1980) found that when temperature was held constant, ABR wave slowing in response to acute alcohol did not occur. They suggested that alcohol's action upon the ABR reflects an indirect effect of alcohol-induced temperature change. Therefore, the relation of brain temperature to the present dose-dependent effects is now being investigated.

163.10 A GENETIC ANALYSIS OF ETHANOL RESPONSIVITY IN MICE. B.C. Dudek, M.E. Abbott* and T.J. Phillips*. Dept. Psychology, SUNY-Albany, Albany, NY 12222.

The selective breeding program of McClearn and Kakihana (Behav. Genet. 3:409, 1973) produced two lines of mice which dramatically differ in response to sedative-hypnotic properties of ethanol (ETOH). In our experiments, LS mice lose the righting reflex for over 100 min in response to a 3.8 g/kg dose of ETOH while the SS mice are similarly impaired for less than 30 min. A mendelian genetic analysis of this selected phenotype demonstrated an additive genetic system with no maternal effects, minimal interlocus interaction and no dominance. Biometrical genetic analysis computed the heritability of the character at.19 and estimated the number of genes controlling the character to be at least 13. The correlation between genotype means of the loss of righting reflex duration and blood ETOH levels at righting was .98, domonstrating that the genetic effect is almost completely due to tissue (neural) sensitivity to the drug and not dispositional factors. Male mice were somewhat more sensitive than females but this difference was small relative to the genetic effect. The depressant drugs tertiary-butanol and acetaldehyde produced longer loss of righting reflex in LS than in SS mice. Intermediate inheritance was present in the t-butanol experiment, but dominance to the LS genotype was found for acetaldehyde. Pentobarbital produced longer loss of righting reflex in SS mice, thus demonstrating the specificity of the selection program for alcohols and alcohol metabolites rather than sedative -hypnotics generally.

The stimulant properties of low ETOH and t-butanol doses were assessed with a measurement of their effects on locomotor activity. Both alcohols produced considerable activation in SS mice but very little in LS mice. F1 and F2 mice showed sub-hypnotic ETOH dose response curves intermediate to the two parentals. It is likely that some or all of the 13 or more genes differentiated by the selective breeding for the hypnotic dose sensitivity phenotype also predispose the differential stimulant properties of sub-hypnotic doses in the two lines. The number of loci involved in the difference between the two lines suggests that the ongoing work into the neural mechanisms underlying the ETOH sensitivity phenotype should find several biochemical and perhaps anatomical systems to be responsible.

163.11 DOPAMINERGIC INTERACTIONS OF ETHANOL WITH NEUROTENSIN, β-ENDORPHIN AND BOMBESIN, G. D. Frye, E. Widerlov, R. A. Mueller, and G. R. Breese. Center for Alcohol Studies, University of North Carolina, Chapel Hill, N.C. 27514

Neurotensin (NT), bombesin (BOM) and β-endorphin (β-END) are neurobiologically active peptides which have been identified endogenously in many areas of the mammalian brain. Changes in behavior, neurochemistry and neurophysiology following their central administration suggests that these peptides and others may represent a new class of neuronal transmitter or modulator. Recently it has been shown that the central administration of NT, β-END and BOM can alter the actions of CNS active drugs. For example, we have found that ethanol-induced impairment of the aerial righting in mice is potentiated by intracisternal (IC) injection of these peptides (Frye, et al. Peptides 2, Suppl.1, 99, 1981). The mechanism of this interaction is not clear, but could involve brain dopamine (DA) systems. Ethanol has been widely reported to alter DA metabolism in brain and recently, NT, β-END and BOM also have been shown to act on this transmitter. Ethanol (2.25 g/kg i.p.) as a 10% (w/v) solution or saline was given 15 minutes prior to IC injection of NT (60 µg), BOM (45 µg), β-END (20 µg) or saline (25 µl) to unanesthetized rats. The animals were sacrificed 45 min after the IC injection. The concentrations of DA, DOPAC, and HVA, were determined in striata, olfactory tubercles and nuclei accumbens using high performance liquid chromatography. Ethanol alone consistently did not change DA, DOPAC or HVA concentrations in any of the three brain areas studies. In general, NT, β-END and BOM increased DOPAC concentrations in all brain areas except in the tubercles where NT had no effect and the stratum where BOM caused a decrease. HVA concentrations were also increased in the stratum and tubercles by NT and β-END, but only in the tubercles by BOM. Ethanol failed to alter changes in DA metabolites caused by the peptides alone. These results do not support the hypothesis that the potentiation of ethanol-induced depression by NT, BOM, β-END is due to a synergistic effect on DA mechanisms. (Supported by USPHS AA-02334 and HO-03110).

163.12 INTERACTIVE EFFECTS OF ANDROGEN AND ALCOHOL ON AGGRESSION IN MICE. Joseph F. DeBold and Klaus A. Miczek. Department of Psychology, Tufts University, Medford, MA 02155.

Both alcohol and androgen may substanitally modulate aggressive behavior in male mice and other species. In addition, alcohol administration alters androgen secretion through direct actions on the testes and by affecting gonadotropin secretion. It has been suggested that at least some of the effects of alcohol on aggression are mediated by the effects of alcohol on androgen levels. If this hypothesis is correct, then animals with very low androgen levels or artificially controlled androgen levels should show much less alteration in aggressive behavior after alcohol. We compared the behavioral response to alcohol in male and female mice and in castrated mice implanted with constant release capsules of testosterone.

Male and female CFW mice were housed in pairs. Within a few weeks these resident mice will repeatedly attack an unfamiliar intruder mouse placed into their home cage. In the first experiment two separate groups of resident male (n=20) mice were given 0, 0.1, 0.3, 1.0, 1.7 or 3.0 g/kg of ethanol p.o. Fifteen minutes later their attack and threat behavior toward a same-sex intruder mouse was measured. These doses had little effect on the time spent walking and rearing by the male residents but the 3.0 g/kg dose of alcohol significantly suppressed aggression. However, in females 0.1g/kg significantly enhanced aggression although 3.0g/kg reduced attack and locomotion. Male (n=11) and female (n=7) mice were also tested for the response to 3.0g/kg ethanol 5, 15, 30, 60 or 120 minutes after administration. In this time course study suppression of aggression lasted through the 120 min test in females, while males were beginning to recover to normal attack rates by 120 min. Another group of male mice (n=15) were castrated and implanted with 7.5mm silastic capsules of testosterone, which released constant high levels of androgen. These animals when given the same doses of alcohol as the intact males showed a shifted dose response curve. Doses of 1.0 and 1.7g/kg significantly increased aggression; 5.6g/kg ethanol was required to inhibit aggression. Blood alcohol levels were somewhat lower in males than females after the higher doses of alcohol but this difference was small and did not appear to be related to the biphasic action on aggression.

The results from these experiments demonstrate that the effects of alcohol on aggressive behavior are different in mice with high, normal and low levels of androgen. However, it does not appear that the effect of alcohol on aggression requires changes in androgen levels or that normal male levels of testosterone are necessary for this response to alcohol.

163.13 IMPAIRMENT OF CALCIUM-MEDIATED INHIBITION WITH CHRONIC ETHANOL TREATMENT MEASURED INTRACELLULARLY. D. Durand and P.L. Carlen. Depts. of Biomedical Engineering & Phsyiology, University of Toronto, Addiction Research Foundation and Playfair Neuroscience Unit, Toronto, Canada.

Chronic ingestion of ethanol has been shown to produce psychological, behavioral and morphological damage in animal models of ethanol induced brain damage. Although specific areas like the hippocampus have for example shown to be particularly affected very few studies have been aimed at the study of pathophysiology of this organic brain syndrome. Recently, however, extracellular in-vivo recordings in the hippocampus of animals fed ethanol in liquid diets for 5 months revealed significant impairment of inhibitory mechanisms. These results were however confounded by the presence of anesthetics. We have been able to confirm the depression of inhibition from chronic ethanol treatment by both extracellular and intracellular recording in-vitro and have studied the possible mechanisms.

For 5 months, male Sprague Dawley rats were provided ad-libitum but measured access to a liquid diet containing 35% of its calories as ethanol while a control group received isocaloric amounts of the same diet with ethanol replaced by maltrox-dextrins. One set of animals was withdrawn for 2 months and an in-vitro extracellular study was performed while another set was withdrawn for 3 weeks and intracellular recordings were obtained in-vitro.

Inhibition was measured extracellularly in the CA1 cell layer using an antidromic conditioning pulse followed by an orthodromic test pulse (stratum radiatum) at various delays. The inhibition in the ethanol fed animal was significantly decreased at a delay of 20 ms ($p<.05$ 2 tailed t-test). Intracellular recordings from 125 granule cells revealed that inhibitory post-synaptic potentials (IPSPs) were significantly reduced in ethanol-fed animals compared to their control while the resting potential, action potential, EPSP and rheobase currents were not affected. The after-hyperpolarization (AHP) following spike trains from depolarizing current pulses were also significantly reduced in ethanol animals. Identical results were obtained in a total of 24 CA1 cells from the same animal group. Therefore the two main inhibitory potentials (IPSP and AHP) are both depressed confirming the extracellular results.

Recent evidence points to a calcium-mediated potassium conductance as responsible for both the AHP and the late phase of the IPSP. This data therefore suggests that calcium mechanisms may be impaired by chronic ethanol treatment.

163.14 PHYSIOLOGICAL MEASURES OF ETHANOL WITHDRAWAL IN LONG-SLEEP AND SHORT-SLEEP MICE. D. M. Gilliam and A. C. Collins*. Inst. for Behavioral Genetics, Univ. of Colorado, Boulder, CO 80309.

In order to assess dependence liability in the long-sleep (LS) and short-sleep (SS) mice, selectively bred for a difference in acute ethanol sensitivity, different groups of mice were administered an ethanol or a pair-fed control diet for either 7 or 14 days. Physiological measures of withdrawal were then obtained during a 24-hr period that began immediately after termination of treatment by noting changes in rectal temperature (T), pulmonary ventilation (PV), heart rate (HR), and acoustic startle response (ASR). Withdrawal effects observed following the 7-day ethanol treatment were less severe and occurred more quickly after treatment terminated than did those observed following the 14-day treatment period. SS mice consumed more ethanol (g/kg/day) than LS mice under both treatment conditions. Withdrawal severity following the 7-day treatment did not differ between the SS and LS mice; however, effects observed following the 14-day treatment were more severe in the SS than in the LS mice. Peak withdrawal was characterized by a general depression in T, PV, and HR, but the time course of the effect differed among measures. ASR was depressed throughout most of the withdrawal period.

Concurrent measurement of several physiological processes during ethanol withdrawal, rather than use of only a single measure, may better indicate variations in neural and systemic functioning.

163.15 ACUTE ETHANOL EFFECTS ON PURKINJE NEURON SPONTANEOUS ACTIVITY IN THE IN VITRO CEREBELLUM OF ETHANOL TOLERANT LONG AND SHORT SLEEP MICE. A.S. Basile* and T.V. Dunwiddie (SPON: D. Taylor). Dept. of Pharmacology, Univ. Colorado Health Sci. Center, Denver, Co. 80220.

Ethanol-induced changes in spontaneous activity of Purkinje neurons were compared in cerebellar slices from ethanol tolerant and naive LS and SS mice. The LS and SS mice are selectively bred to show high and low sensitivity to the soporific effects of ethanol. LS and SS mice were made behaviorally tolerant to ethanol with daily i.p. injections of 4.5 or 5.0 g/kg ethanol,respectively, for 5 consecutive days. On the 6th day, the mice were sacrificed and parasagittal slices were prepared from the cerebellar vermis. Slices were normally perfused with a modified Ringer's solution containing 1mM Ca^{2+}, 3.9 mM Mg^{2+}, 4.5 mM K^{+} and 0.001% H_2O_2, saturated with 95% O_2/5% CO_2. This medium eliminates almost all synaptic transmission in the slice. Extracellular recordings were made from spontaneously firing single Purkinje neurons. Ethanol was added to the perfusion medium in concentrations of 25-500 mM and drug-induced depressions in Purkinje cell spontaneous activity were quantified. The EC_{50} values for these depressions in firing rate were determined by Hill plots to be 75±8 mM and 327±29 mM in non-tolerant LS and SS mice, respectively. However, while repeated ethanol administration decreased the sensitivity of Purkinje cells in LS mice (EC_{50}=131±29 mM), the SS mice showed an increased sensitivity (EC_{50}=216±29 mM). These shifts in dose response curves between tolerant and non-tolerant mice are significantly different at the $p<0.05$ level, as indicated by the lack of overlap in the EC_{50} 95% confidence levels (horizontal bars, below). In conclusion, differential electrophysiological responsiveness to ethanol in tolerant LS and SS mouse lines is maintained in the in vitro cerebellum, and repeated ethanol treatments can induce significant shifts in Purkinje cell sensitivity to ethanol. 163.16 FETAL EXPOSURE TO ETHANOL POTENTIATES OPIOID STRESS ANALGESIA IN ADULT RATS. L.R. Nelson, J.W. Lewis, J.C. Liebeskind, B.J. Branch*, and A.N. Taylor. Departments of Psychology and Anatomy and Lab. of Neuroendocrinology, Brain Research Institute, UCLA and Brentwood VA Medical Center, Los Angeles, CA 90024.

Taylor et al. (Pharmac. Biochem. & Behav., 1982) have demonstrated that rats exposed to ethanol in utero display an enhanced release of corticosterone as adults in response to certain stressors, such as cardiac puncture or noise and shake, but not others, such as fasting or cold stress. In the present study, we investigated a behavioral response, analgesia, to another type of stress, inescapable footshock. Lewis et al. (Science, 1980) described two forms of stress analgesia elicited by different parameters of footshock delivery; one form is opioid mediated, and the other appears not to be.

Subjects were female offspring of Sprague-Dawley dams fed either a 5% w/v ethanol-containing casein-supplemented liquid diet (BioServ) ad lib, pairfed an isocaloric liquid diet without ethanol, or given lab chow and water ad lib from gestation day 8 to birth. At birth, all pups were cross fostered to normal dams who had food and water available ad lib. At approximately 150 days of age, rats were tested for stress analgesia. Prior to footshock, baseline pain sensitivity was measured with the tail-flick test. Rats were then exposed to either prolonged/intermittent (2.5 mA, 1 sec on per 5 sec for 10 min) or brief/continuous (2.5 mA, for 2 min) footshock stress that produce opioid and non-opioid analgesia, respectively. After footshock termination, tail-flick latencies were recorded at 1 minute intervals for the first 9 minutes, and at 2 minute intervals from 9 through 15 minutes. All animals received both forms of footshock in a counterbalanced order separated by 1 week.

Rats prenatally exposed to ethanol (n=16), were significantly ($p < .05$) more analgesic after the prolonged/intermittent (opioid) footshock than offspring of pairfed (n=11) or normal (n=8) dams. Rats in all three groups showed similar analgesia following brief/continuous footshock.

These results are congruent with the results of Taylor et al. (1982), and add prolonged/intermittent inescapable footshock to the list of those stressors to which rats prenatally exposed to ethanol are more sensitive in adulthood. In addition, these results suggest that prenatal ethanol exposure produces long-term effects on the functioning of endogenous opioid-mediated analgesia systems. 163.17 DEGENERATIVE CHANGES OBSERVED IN THE SCIATIC NERVE OF RATS. AN EXPERIMENTAL MODEL OF ALCOHOLIC NEUROPATHY. J.P. Machado-Salas, G. Espinosa*, J. Espinosa* and P. García. Lab. Neuromorfología. UIICSE. ENEP Iztacala. UNAM. P.O. Box 314. Tlalnepantla 54030 Edo. de Mexico. MEXICO.

Even though the association of alcoholism and peripheral neuropathy in humans was established by Lettsom, two hundred years ago, it is until fairly recently that most of classical works have been done. Many unsolved facts are claiming for a more experimental approach. On this regard, the study of primary effects of ethanol on peripheral nerves, without involvement of dietary factors, deserves special mention.

We have raised, under similar environmental conditions, two groups of Wistar rats: control and experimental. The latter, were allowed to drink from a 20% (v/v) ethanol solution for up to 24 months. Both groups were fed with balanced rat food, ad libitum. Their daily in take of liquids was recorded every day, and their change in weight, every other day. In this regard, there was not a significative ponderal difference between groups. Also, there were not clinical signs of dietary defficiences. Smaller groups of 6 to 8 rats, were sacrificed every 4 months, and their sciatic nerves processed for light and electron microscopic studies. Hematoxilyn & Eosin, Guillery's, luxol fast-blue and Bodian's methods were used for the former.

The sciatic nerves of long-term alcoholized rats showed: a) Irregular contours of the myelin sheaths and axones, b) Fragmentation of axones, c) vacuolization of myelin sheat and or axones, d) changes in diameter and trajectory of the same axon. On the other hand, the E/M showed: a)Round, patch-like areas in the myelin sheat, wich depicted abnormally separated interlameller spaces, b) Distorted, degenerated axones, loaded with dark bodies, fragmented tubules and degenerated mitochondria, c) Axoplasmic vacuoles filled with few, widely separated tubules and small, dark mitochondrion. The presence of abundant collagen was evident, as well as rather abundant fibres and mononuclear cells and capillaries among fibres.

These findings are very similar to those described in human alcoholic patients, therefore, we conclude that the chronic administration of ethanol, in well-fed rats, producessevere pathological changes in the peripherical nervous system. Therefore, we propose this model as an experimental paradigm of alcoholic neuropathy.

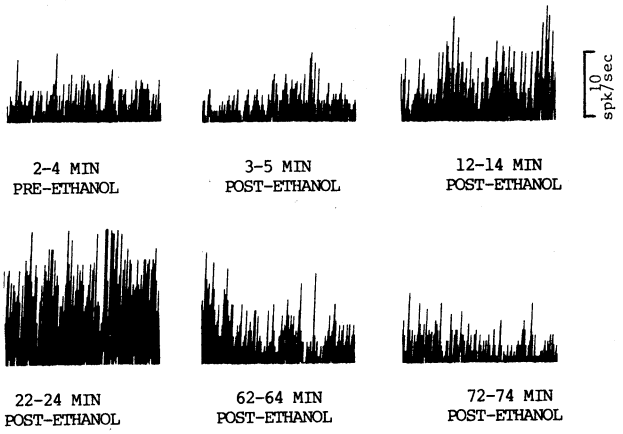
163.PO ELECTROPHYSIOLOGICAL EFFECTS OF ACUTE ETHANOL ON OLIVO-CEREBELLAR NEUROTRANSMISSION. Joseph Rogers, G.R. Siggins, G. Aston-Jones, L.Y. Koda, and F.E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

Ethanol, given in a single, acute IP dose under chloral hydrate anesthesia, increases climbing fiber-mediated bursts in cerebellar Purkinje cells. Climbing fibers originate in the inferior olivary nucleus (ION) of the brainstem. When spontaneous single unit, multiple unit, or field potential electrical activity is recorded in the ION before and after acute IP ethanol (2 g/kg), increased activity is consistently observed. A typical example is shown in the ratemeter records below. ION electrode placements were histologically (by lesion) and/or physiologically (by stimulation of contralateral hindpaw) verified in all cases.



Taken together with our cerebellar recordings, these data suggest that altered Purkinje unit firing after ethanol is secondary to activation of ION firing. Deranged firing of the ION may provide one of several mechanisms for the well-known, socially-catastrophic effects of ethanol on motor performance.

164.1 GOLD THIOGLUCOSE LESION FORMATION: NEURAL SPECIFICITY.
Danley F. Brown* (SPON: D.D. Rigamonti). Div. of Combat Casualty Care, Letterman Army Inst. of Research, San Francisco, CA 94129

A single intraperitoneal injection of gold thioglucose (GTG) will cause a bilateral lesion in the ventromedial hypothalamus (VMH). This pathological phenomenon produces a sustained hyperphagia and obesity, presumably by destroying VMH glucosensitive neurons controlling feeding behavior. Recently, controversy has developed concerning the specificity of GTG-induced necrosis in the VMH. Since the hypothalamus does not possess a strong blood-brain barrier, it is postulated that GTG-induced VMH necrosis is brought about by a breakdown in the endothelium of the area microvasculature. The resulting ischemia leads to brain cell death and lesion formation. This idea of a nonspecific GTG-induced lesion in the hypothalamus is attractive, but inconsistent with other evidence. For instance, although other circumventricular organs, in addition to the VMH, apparently can be damaged by a GTG challenge, the median eminence is always spared. This observation is important, since the blood-brain barrier permeability of the median eminence is similar to that of other hypothalamic regions apparently affected by GTG. Recent work also suggests that linkages may be present among the circumventricular organs in the hypothalamus, thus accounting for extra-VMH damage. Using a small dose of GTG (100 mg/kg), Debons et al (J. Pathol. 129:73, 1979) have clearly shown morphologically that initial GTG damage in the VMH is perivascular. Dissolution of neural structures and edema were apparent adjacent to intact undamaged capillaries. In this study we chose to further investigate the initial process of GTG lesion formation in the VMH at the ultrastructural level in mice. Two doses of GTG were utilized, 300 and 800 mg/kg. Depending on the GTG dose, initial VMH destruction appeared between 4-6 hours after the GTG challenge. This damage was manifested by apparent extracellular edema and distention of the neuropil. Although GTG-induced necrosis appeared to commence adjacent to capillaries, occasionally the regional edema and dilated extracellular areas were not confined to the pericapillary space. By 12 hours, the animals treated with 800 mg/kg GTG exhibited extensive cellular destruction. Mice challenged with 300 mg/kg GTG showed similar results, but to a lesser degree. Complete dissolution of the cytoplasmic matrix was evident; nuclei were pycnotic, mitochondria were swollen, and synaptic figures were disrupted. Our results strongly support the idea that GTG lesion formation is a substrate-specific toxin for the neural cellular matrix in the VMH. The data also lend credence to the hypothesis of the existence of a glucoreceptor participating in feeding behavior.

164.2 DIFFERENCES IN CELL BODY CROSS-SECTIONAL AREAS OF NEURONS IN OBESE AND LEAN MICE. G.A.Oltmans and P.E. Meyers* (SPON: P.C. Tang). Departments of Pharmacology and Anatomy, The Chicago Medical School, N. Chicago, IL 60064.

In many respects the obesity syndrome of the obob mouse resembles that of the rat with lesions of the ventromedial hypothalamus (VMH). Consequently, it has been proposed that the syndrome in the obob mouse may in part result from a hypothalamic defect. Recently, Bereiter and Jeanrenaud (Br. Res. 165:249-260, 1979) reported decreased cell body sizes in several brain regions, including the VMH, in the obob mouse. In the current study we have repeated this work on VMH cell size in animals younger and older than those studied by Bereiter and Jeanrenaud in order to determine if this is a constant condition in the obob.

Frozen sections from 6 week and 12 month old obob mice and their age-matched lean littermate controls were cut at 25 μ and stained with thionin. The VMH was divided into 4 quadrants, dorsomedial (DM), ventromedial (VM), dorsolateral (DL), and ventrolateral (VL). Photomicrographs of these quadrants were taken from both left and right sides resulting in 8 positive transparencies per animal. Transparencies were projected onto poster paper and 25 cells/transparency were drawn for a total of 200 cells/animal. Only those cells with a focused nucleolus were analyzed. Total magnification was 4,000 x. Error in reproduction and measurement of cells from slide to paper was measured at less than 3%. Measurements were made with a polar planimeter.

In 6 week old obob mice the cell sizes were significantly smaller in the DM and VL aspects of the VMH nucleus when compared to lean controls. In contrast, at 12 months of age there were no significant differences between obob and lean mice in cell body sizes in any of the regions analyzed, and, if anything, there was a tendency for the cell size to be slightly larger in the obob mice. A comparison of the 6 week and 12 month old animals indicates that cell size remained about the same in obob mice at the different ages, but that cell size decreased in the older lean mice.

164.3 FRAGMENTED INGESTIVE PATTERNS FOLLOWING SEPTAL LESIONS IN RATS
J. C. Mitchell, F. W. Flynn*, L. A. Evey* and T.L. Steele Psychology Dept. Kansas State University, Manhattan, KS 66506

In a first experiment, feeding on a balanced liquid diet and drinking patterns were measured in groups of rats with septal damage and in unoperated controls. Measurements were made with drinkometers for one hr following 24 hr deprivation periods and were recorded on a multichannel event recorder. Feeding measures included: total food and water intake, number and size of meals or feeding bouts, and number and duration of intrameal intervals. Septal rats did not differ from controls in total food or water intake. When a meal was defined as the consumption of at least .5 gm food separated by greater than 1.0 min septals were found to consume many small meals whereas controls generally ate one large meal. However, when a meal was defined as the consumption of at least .5 gm followed by an interval greater than 10 min, (a commonly used definition, e.g. LeMagnen & Davos, 1980) no differences in meal size were found, with both septals and control animals generally consuming one meal.

In order to account for these findings, this study was replicated using the same feeding and drinking measures and the animals behavior was monitored and recorded using a television camera. The incidence of grooming and exploratory behavior was also recorded on the event recorder showing feeding and drinking. The feeding and drinking patterns observed in this study were similar to those of the first study. The septal rats spent much greater amounts of time grooming and exploring the cage and slept rarely. Normals showed the typical satiety sequence of eating followed by grooming, and then by sleep. The eating of the septal rats was constantly interrupted by bouts of grooming, exploring or drinking with no orderly behavioral sequence. Thus, the septal animal appeared to exhibit the "fragmented behavior" described by Rowland (1977) in animals with lateral hypothalamic lesions. It is not yet clear as to whether it is more appropriate to describe animals with septal lesions as having fragmented behavioral patterns or as animals who eat small meals.

164.4 INGESTIVE RESPONSES TO HOMEOSTATIC CHALLENGES IN RATS WITH ABLATIONS OF ANTEROLATERAL NEOCORTEX. S.W. Kiefer, C.V. Grijalva, M.W. Gunion*, P.H. Cooper, and D. Novin. Dept. of Psychol. and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Ablations of the anterolateral neocortex (Braun, JCPP, 89:507, 1975) or prefrontal neocortex (Kolb & Nonneman, JCPP, 88:806, 1975) in rats induce a syndrome of feeding deficits and sequential stages of recovery similar, but shorter, than that after lateral hypothalamic (LH) lesions. In the present study, it was determined whether rats with anterolateral neocortex ablations would also show the particular deficits following homeostatic challenges that have been demonstrated in LH lesion rats.

Male Sprague-Dawley rats were placed into four groups: Group AC (n=19) was given anterolateral neocortex ablations; Group BWC (n=19) was a body weight control group; Group CC (n=15) was given control ablations of dorsal-posterior neocortex; Group N (n=20) was the normal control group. Following postoperative recovery the rats were tested for food and water consumption in a series of homeostatic challenges: glucoprivation induced by 2DG (125, 250, and 500 mg/kg) and insulin (4, 8, and 16 U/kg), food consumption in the absence of water and following food deprivation, water consumption in the absence of food and following water deprivation, and water consumption following ip hypertonic (5 ml of 1.0 M NaCl ip) saline injections. Both short term (1-3 h) and long term (3-24 h) consumption measures were taken.

Groups CC, BWC, and N showed similar dose response increases in food and water consumption following 2DG administration. Group AC increased water consumption in a dose-dependent manner but ate significantly less than controls with the 500 mg dose. With the insulin injections, all groups showed a significant increase in food and water consumption and there were no group differences. Likewise, there were no group differences in the amount of food consumed following periods of food deprivation (8, 12, or 24 h), the amount of water consumed following 24 hr water deprivation, or the amount of water consumed following hypertonic saline injections. Rats in Group AC were prandial drinkers because these rats consumed significantly less water in the absence of food (12 and 24 hr food deprivation periods).

The present results indicate that, on the whole, rats with anterolateral neocortex ablations respond normally to glucoprivic challenges although their response to high doses of 2DG may be impaired. Additionally, rats with ablations of anterolateral neocortex display prandial drinking, something characteristic of LH rats.

164.5 DOES CORTICOFUGAL FIBER DAMAGE CONTRIBUTE TO THE LICKING AND EATING ABNORMALITIES OF DECORTICATE AND LATERAL HYPOTHALAMIC LESIONED RATS. I.Q. Whishaw and B. Kolb. Dept. of Psychology, Univ. of Lethbridge, Lethbridge, Alberta Canada, T1K 3M4.

Rats that receive bilateral lateral hypothalamic (LH) lesions are initially aphagic and adipsic but recover eating and drinking in well described stages. Decorticated (DC) rats are aphagic and adipsic but do not actively or passively reject food as do LH rats. Their recovery is characterized by an increase in motor efficiency and they typically require training before they spontaneously drink. Are the deficits in these animals related? We measured tongue extension during licking and cookie mash eating speed in DC and LH rats. DC rats were unable to extend their tongue more than 2 mm even after prolonged recovery, and were unable to eat 2 g of food in less than 60 sec. LH rats were initially as impaired, but over 30 days tongue extension improved to 75% of a normal 13 mm, and eating speed increased to 12 sec, vs 3 sec for control rats.

The deficits in tongue use and in eating speed were then demonstrated in a disconnection paradigm involving unilateral LH damage and contralateral neocortex removal. The abnormalities were as severe in these rats as was found in DC rats. This experiment suggested that a corticofugal system common to the cortex and LH could underlie the impairments. Varying the lesion location in the cortex and brainstem showed that the cortical source of the impairments was centered in the orbital frontal motor cortex with lesser contributions from surrounding neocortex. The brainstem source was located in the far lateral hypothalamus, from the level of the anterior ventromedial nucleus to the level of the substantia nigra. Corticofugal fibers involved in the control of head musculature have their origin in the lateral frontal cortex, and project in the cerebral peduncles adjacent to, or in, this area of the LH.

So yes, the correlation between effective lesion locations for producing tongue and eating abnormalities and the projection of corticofugal fibers is sufficiently close to suggest that these motor fibers are importantly involved in the aphagia and adipsia of LH and DC rats. Currently, studies are directed toward distinguishing corticofugal fiber damage-induced impairments from impairments that follow dopamine depletion and sensory system damage.

164.6 BODY WEIGHT REGULATORY CONSEQUENCES OF SUBCUTANEOUS INFUSION OF QUININE IN THE RAT. John P. Heybach* & Peter C. Boyle* (SPON: H. N. Sapru) Central Research Department, General Foods Corp., White Plains, NY 10625.

Adult male rats (S.D.; 345-365g) were allowed either ad libitum (AL; n = 8) access to powdered chow or were restricted to 60% (R; n = 8) of ad libitum intake for 7 days. On day 7 four rats from each group were implanted subcutaneously with Alzet minipumps containing quinine HCl (Q: 350µg/µl in absolute ethanol) while the remaining four rats in each group were implanted with pumps containing only vehicle (V). Vehicle or drug solutions were delivered at a rate of 2µl/hour. Following surgery, all rats were allowed ad libitum access to powdered chow for seven days. Food intake, corrected for spillage, and body weight were recorded daily. The R rats lost weight over the seven days preceding pump implantation. The AL-Q rats became hypophagic and lost weight during Q infusion with body weights stabilizing on days 14-15. Vehicle infusion had no effect. The R-Q rats became hyperphagic and gained weight during the Q infusion with body weight stabilizing on days 14-15 at the same level as that for the AL-Q rats. These results indicate that quinine's effect on body weight is not dependent upon its presence in food. Furthermore, quinine results in the attainment of an altered body weight maintenance level that is achieved by either decreases or increases in food intake depending upon the relationship of existing body weight to the new Q-induced level. We conclude that Q reduces the level around which body weight is actively regulated presumably by a pharmacologic mode of action.

164.7 MAINTENANCE AND DEFENSE OF ALTERED BODY WEIGHT LEVEL DURING CHRONIC INGESTION OF A QUININE ADULTERATED DIET. Peter C. Boyle* & John P. Heybach* (SPON: M. LEVITT) Central Research Department, General Foods Corp., White Plains, NY 10625.

In an attempt to assess the influence of chronic ingestion of quinine on body weight regulation, separate groups of adult male rats (S.D.; 350-370g) were allowed ad libitum access to either powdered chow (C) or chow adulterated with 0.4% (w/w) quinine sulfate (Q) for 28 days. On days 28-42 one group of rats from each dietary condition (n = 10/grp) was restricted to 60% of the daily food intake of its respective ad libitum control, followed on days 42-54 by unrestricted access to their respective diets. Food intake, corrected for spillage, and body weight was recorded daily throughout. Rats ingesting Q were initially hypophagic and lost weight. Food intake gradually recovered, but body weight remained at a reduced and constant percentage of C weight. During the restriction and refeeding periods both Q and C rats lost and subsequently regained equivalent amounts of weight. The Q and C rats showed a relative hyperphagia on the first refeeding day following food restriction, although this was more pronounced in the C group. From day 7 on the Q and C rats displayed similar changes in the gross efficiency of food utilization under ad libitum, restricted and refeeding conditions. These results indicate that following the acute phase (days 0-7) of hypophagia and weight loss, Q rats gain weight at the same rate and respond to a food restriction and refeeding manipulation in a fashion similar to C eating rats. We conclude that quinine ingestion does not compromise the animals' ability to respond to regulatory challenges but rather reduces the level at which body weight is regulated.

164.8 THE LATERAL HYPOTHALAMIC SYNDROME: IMPORTANCE OF THE ANSA LENTICULARIS IN AFFECTING THE ORIENTATION PHASE OF FEEDING BEHAVIOR. W. J. Kuenzel* (SPON: J. Barrett). Dept. of Poultry Sci., Univ. of Maryland, College Park, MD 20742.

The lateral hypothalamic syndrome, as originally proposed by Teitelbaum and Epstein (Psychol. Rev. 69:74, 1962) has been a useful model for documenting feeding and drinking deficits and stages of recovery following bilateral hypothalamic lesions. A controversy has arisen in the avian literature regarding the length of time required to recover from feeding deficits following bilateral lesions directed to various sites in the prosencephalon. The most extensive studies documented to date suggest that aphagia and deficits in grasping and mandibulation can persist for weeks following bilateral destruction of quinto-frontal structures in pigeons (Zeigler, H. P., Adv. Study Beh., Vol. 7:286, 1976). In contrast, bilateral lesions produced in several hypothalamic and thalamic sites effected transient aphagia in the chick (Kuenzel, W. J., Physiol. Behav. 28:237, 1982).

In an attempt to resolve the issue, feeding and drinking behavior of the adult fowl were first observed. A repeatable feeding sequence was recognized in all hens. It could be conveniently partitioned into 5 distinct phases which were later used to define a lateral hypothalamic syndrome for this species following several placements of bilateral lesions within the diencephalon. The 5 phases include (1) Arousal and food recognition, (2) Orientation (positioning of the body and head toward specific food particles), (3) Grasping (rapid opening and closing of the bill tip about a food particle), (4) Mandibulation (movement of feed particles from bill tip toward back of mouth), and, (5) Swallowing.

Several hens were lesioned throughout the diencephalon and mesencephalon. Food and water intake, feeding behavior and feeding efficiency were monitored before and after surgery. Similar to a previous study with chicks, adult hens showed transient aphagia (1-5 days) following lesions to the quinto-frontal tract and ansa lenticularis. However, the diet fed in both studies was mash. When a whole-grain diet such as wheat was alternated with the mash diet every 4-5 days, aphagia was scored up to 15 days with the whole grain diet compared to 0-3 days with the latter. Observing feeding behavior before and after surgery suggested that bilateral lesions to the ansa lenticularis resulted in orientation deficits. More persistent aphagia was produced on whole grain diets when two or more deficits in the feeding sequence were disrupted, particulary a combination of orientation and grasping deficits. The texture of the diet greatly affected the extent of aphagia. (Study conducted during tenure of a Fulbright-Hays Fellowship to Britain, Poultry Research Center, Scotland.)

164.9 GASTRIC AFFERENT INPUTS TO THE MESENCEPHALON AND HYPOTHALAMUS. I. Zarco de Coronado, F. C. Barone and M. J. Wayner. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210

Male hooded rats were anesthesized with urethane and prepared for hypothalamic and mesencephalic single neuron recording. A gastric balloon or catheter was positioned in the stomach and the stomach was filled while simultaneously monitoring mesencephalic central gray (CG) or lateral hypothalamic (LH) neuronal activity. In order to evaluate pressure associated effects, balloons having different elastic properties were utilized for stomach distension. Those balloons requiring the highest pressures for filling (> 100 Hg) significantly changed the discharge frequency of LH and CG neurons when filled from 0-10 ml. Usually, lowering the temperature of water used to fill the gastric balloon increased the change in discharge frequency. Neural responses were eliminated by spinal cord transections but were unaffected by bilateral cutting of the cervical vagus nerves. The filling of more elastic balloons (50-80 mm Hg) in the stomach was not as effective in altering neural activity, and an increase in filling velocity (from 0.4 ml/sec up to 1 ml/sec) was required before changes in neural activity were observed. The responses observed during control experiments in which balloons were filled in the intraperitoneal cavity and the esophagus were not correlated with gastric distension responses. In other experiments infusions of solutions were made directly into the stomach, thus producing a more natural gastric distension ($\sim$ 30 mm Hg). Although even at higher filling velocities few central neurons were affected, distension responses observed under these conditions could be eliminated by bilateral transection of the vagus nerves. Also, the effects of gastric infusions using different solutions on neural activity were evaluated. When the effects of distension were controlled, some neurons appeared to be sensitive to osmotic changes in the stomach. In other experiments, animals were prepared for gastric stimulation and simultaneous recordings of electrocardiographic (EKG) and cortical electroencephalographic (EEG) activity and blood pressure were made. For the various balloon types or filling temperatures, gastric stimulation always resulted in a similar increase in blood pressure. No significant effects on EKG and EEG were observed. These results illustrate that both spinal and vagal afferents are important in the mediation of different types of gastric stimulation to LH and CG neurons. In addition, some neurons are sensitive to changes in gastric osmolality. These effects are probably important in mesencephalic and hypothalamic mechanisms controlling ingestion and autonomic nervous activity.

164.10 EFFECTS OF BILATERAL NUCLEUS ACCUMBENS DAMAGE ON SCHEDULE INDUCED AND SCHEDULE DEPENDENT BEHAVIORS. D. L. Armstrong,* M. J. Wayner, F. C. Barone, B. B. Falk,* P. A. McGrattan* and S. M. Jones.* Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210.

Small electrolytic lesions in the nucleus accumbens produce deficits in schedule induced drinking. Male rats were reduced to 80% of ad lib feeding body weight and were trained to press a lever for 45 mg food pellets on a FI-1 min schedule. When schedule dependent lever pressing and schedule induced licking and drinking stabilized during 30 min daily test sessions animals were anesthesized with Equi-Thesin and prepared for surgery. Each animal received two bilateral lesions in the accumbens that damaged both the medial and lateral portions of the nucleus. Lesions were produced by passing 1 mA anodal current for 15 sec through insulated tungsten wire. Control animals received identical treatment except that no current was passed through the electrodes. Animals were also examined weekly for open-field activity and performance on sensorimotor tests. Following surgery the animals with lesions showed decreased lever pressing, licking, and water consumption for a 3 week period and then recovered to pre-surgery baseline levels of responding. Control animals were not affected. Home cage food and water consumption remained stable in both conditions. Results indicate that damage to the nucleus accumbens disrupts lever pressing and schedule induced drinking 3-4 weeks, then these behaviors appear to return to normal values. There were no observable effects on home cage ingestion. These results partially support the findings of Robbins and Koob (Nature 285: 409-419, 1980) who report that 6OHDA infusion into the accumbens-septi impairs development of schedule induced drinking.

164.11 CNS SITES OF NALOXONE INDUCED HYPODIPSIA: A MAPPING STUDY. D. A. Czech[1], E. A. Stein[2], M. J. Blake[2]* and O. O. Yang[2]*. Depts. of Psychology[1] and Biology[2], Marquette Univ., Milwaukee, WI 53233

Recent studies have indicated that narcotic antagonists can suppress appetitive behaviors in rodents. Both food and water intake is significantly reduced following systemic injections of either naloxone or naltrexone, with water intake generally agreed to be more sensitive. These observations have been interpreted to implicate an endogenous opiate system in some aspect of appetitive behavior - perhaps the reinforcing qualities of the stimuli. While this drinking effect has been shown to be quite robust and CNS mediation strongly indicated, relatively little is known about specific CNS mechanisms and/or sites of drug action. We report here an initial mapping study of CNS nuclei involved in naloxone suppression of drinking behavior in the rat.

Male, Holtzman rats were implanted with bilateral guide cannula aimed at the preoptic area, lateral hypothalamus, lateral ventricle or nucleus accumbens. Following a 1 week recovery period, rats were placed on a 23 hour water deprivation schedule with one hour water access given daily between 1100-1300 hours. On test days, 33 gauge injection needles were inserted into the guides and 0.5 μl of either naloxone or saline was injected bilaterally over 30 seconds. Rats were returned to the test cages immediately and allowed to drink water for 1 hour. No food was available during this test period. Water consumption was measured at 5, 10, 15, 30 and 60 minutes post injection. Naloxone doses employed were 12.5, 25 and 50 μg. Each rat was tested at each dose (plus saline) in an incomplete Latin Square design with test days separated by 3-4 days. All loci were confirmed histologically.

ANOVAs were performed with significance level set at $p<.05$. At 15 minutes post injection, fluid intake for the 50 μg dose was significantly less in the POA and LH groups when compared to corpus callosum and cortex control sites. However, at 30 minutes, the NAS as well as the LH and POA groups differed significantly from controls. Again, no significant changes were seen at the two lower doses. At 60 minutes post injection, only the POA group was still consuming significantly less fluid. Again, the 50 μg dose was solely effective. Animals with LV cannulae never showed significant decreases in drinking at any dose used, nor did we observe any latency to first drink in any group.

These results implicate a central enlorphinergic mechanism regulating or otherwise influencing fluid intake behavior. Further, these sites are not necessarily within readily diffusable distance from the ventricles. It is clear that additional CNS sites be examined to further delineate the possible circuitry mediating this behavior. Supported by NIDA grant DA02234 to EAS.

164.12 GENETIC INFLUENCES ON INGESTIVE BEHAVIOR OF MICE WITH SEPTAL LESIONS. C. R. Goodlett,* P. J. Donovick, and R. G. Burright.* Department of Psychology, State University of New York at Binghamton, Binghamton, NY 13901.

Septal lesions in rats are reported to result in motivational changes, including increased intake of saccharin, and ad lib hyperdipsia with associated overdrinking following a hypovolemic challenge. However, the effectiveness of septal lesions in producing hyperdipsia in rats were unpredictable, and not explained on the basis of histological analysis. Changes in ingestive behavior have been less extensively studied in mice, though inbred strains are known to differ in their acceptance of saccharin (Fuller, 1974). Thus, we examined the effects of septal lesions in the genetically diverse Heterogeneous (HET) stock, as well as in the C57BL/6J, DBA/2J and AKR/J inbred strains, on feeding and drinking, and on the response to each of the following challenges: (1) saccharin acceptance; (2) cellular dehydration; (3) hypovolemia; and, (4) 24 hours of food deprivation.

Unlike rats, the groups of HET mice given septal lesions showed no evidence of ad lib hyperdipsia, not differing from surgical controls in their daily water intake. The lesioned mice also did not differ from controls in drinking elicited by saccharin, hypovolemia or cellular dehydration. However, during the 24 hour food deprivation, the septals drank significantly more water, and lost less bodyweight than did the controls. In further contrast to rats, HET mice with septal lesions increased their food consumption postoperatively to almost 20% more than control levels; this hyperphagia lasted the entire 50 day experimental period. Despite their increased food intake, the mice with septal lesions lost bodyweight after surgery, and maintained their bodyweight at about 90% of control levels. Only during the food deprivation, when septals drank more than controls, did the two groups have equal mean bodyweights.

Preliminary results from the inbred strains indicate that C57s drink more saccharin than DBAs and AKRs, as previously found. Septal lesions result in a large elevations of saccharin intake only in the DBAs, less elevations in the C57s, and no change in the AKRs. The hyperphagia and weight loss seen in the HETs was also found in all three inbred strains. These results emphasize the importance of genotype in the effects of limbic damage.

164.13 LONG TERM CHANGES IN NEURAL LOBES OF RATS WITH LESIONS OF THE PERIVENTRICULAR TISSUE SURROUNDING THE PREOPTIC RECESS (AV3V). J. R. Carithers and A. K. Johnson. Dept. of Veterinary Anatomy, Iowa State Univ., Ames, IA 50011 and Dept. of Psychology, Univ. of Iowa, Iowa City, IA 52242.

Rats with lesions in the AV3V region undergo acute adipsia and do not develop an appropriate antidiuretic response to the dehydration which results from their failure to drink. We have observed fine structural evidence that unreleased neurosecretory material is accumulated in neural lobes of lesioned rats during this acute phase. If the rats are maintained experimentally through this period, they resume drinking and become capable of excreting a concentrated urine in response to water deprivation. However, their drinking responses to treatment with angiotensin II or hypertonic saline are chronically impaired, and they exhibit chronic hypernatremia and hyperosmolality. Therefore, we have examined the effects of five days of water deprivation on the fine structure of neural lobes of rats which have received AV3V lesions or sham operations five weeks earlier.

In rats with sham lesions, five days of water deprivation led to depletion of neurosecretory granules and increased amounts of fine tubular smooth endoplasmic reticulum in axon terminals. In neural lobes of lesioned rats, there were more axons which contained accumulations of dense bodies, lamellated bodies and images suggestive of crinophagy and reorganization than were present in controls. Lesioned rats also had many axons which were filled with closely packed masses of neurosecretory granules, and these axons were usually ensheathed by attenuated processes of pituicytes. Such closely packed masses of neurosecretory granules were rare or absent in controls. After five days of water deprivation, changes which were qualitatively similar to those of control rats, but which involved fewer axons, were observed in neural lobes of lesioned animals. Axons which were packed with granules or appeared to be undergoing reorganizational changes were very noticeable after the reduction in neurosecretory material in water-deprived rats, but the number of such axons did not appear to have changed.

It appears that five weeks after AV3V lesions there are still axons which do not release their contents in response to appropriate stimuli for hormone release.

164.14 DRINKING DEFICITS IN RATS AFTER LESIONS OF THE AV3V AREA. T. W. Gardiner* and E. M. Stricker (SPON: A. R. Caggiula). Dept. of Psych., Univ. of Pittsburgh, Pittsburgh, PA 15260.

In confirmation of previous observations (Buggy and Johnson, Am. J. Physiol., 233:R44, 1977), we find that ablation of the anteroventral wall of the third cerebral ventricle (AV3V region) abolishes the drinking response of rats to injection of hypertonic saline; nevertheless, most rats drink significant amounts within 10-12 hr after hypovolemia is produced by sc injection of polyethylene glycol (PEG) solution. However, further investigation of these phenomena indicates that these animals have not lost their capacity to respond to osmoregulatory stimuli, nor are their responses during hypovolemia unimpaired. In one series of experiments, caffeine (12.5 mg/kg, ip) injected together with 2 M NaCl (2 ml, sc) was found to restore drinking ($M \pm SD = 11.5 \pm 6.3$ ml/2 hr) in 8 of 10 lesioned animals that had failed to drink after injection of hypertonic saline alone. Caffeine alone was ineffective in eliciting drinking in either lesioned or control rats. Urine measurements indicated that the enhanced drinking was not secondary to an induced diuresis; in fact, drinking often preceded urine excretion by 30-60 min. In another series of experiments, 15 lesioned rats which had failed to drink following NaCl treatment were injected with 30% PEG (5 ml, sc). Four of these rats failed to drink during the subsequent 12 hrs. Among the 11 rats which did drink, 7 began drinking only after the light period ended (8 hr after the PEG treatment). Furthermore, this late, nocturnal drinking may not have been elicited by the hypovolemia, since most lesioned rats drank comparable amounts during a baseline period of food deprivation, when PEG was not given.

These findings parallel the results of recent investigations involving rats with lesions of the subfornical organ in which caffeine treatment was shown to restore drinking after PEG injection (Hosutt et al., J. Comp. Physiol. Psychol., 95:104, 1980). Collectively, they suggest that the drinking deficits that animals have after damage to these adjacent brain areas may not reflect disruptions specific to osmoregulatory or hypovolemic thirst but may instead be of a more general nature.

On the other hand, when 5 rats with AV3V lesions were tested for their feeding responses to 2-deoxyglucose (500 mg/kg, ip), food intake was found to be increased ($M \pm SD = 4.1 \pm 2.0$ g above baseline, 5 hr test) to an extent comparable to that observed in control animals. This preliminary finding suggests that the deficits of lesioned animals may be limited to drinking behaviors rather than including motivated ingestive behaviors in general.

164.15 EFFECTS OF HEPATIC PORTAL INFUSIONS ON HYPOTHALAMIC NEURONAL ACTIVITY. W.-H. Tsai, F. C. Barone and M. J. Wayner. Brain Research Lab., Syracuse Univ., 601 University Ave., Syracuse, NY 13210.

Male rats were anesthesized with urethane and prepared for hypothalamic neuronal recording and peripheral vascular infusions. The mesenteric vein beside the descending colon was cannulated so that infusions only altered the portal circulation. The femoral vein was also cannulated so that infusions could enter the general circulation. Different solutions that were infused by both routes included: water; 0.15 M NaCl; 2.5 M NaCl; 1.7 M NaCl; 0.8 M NaCl; 5.0 M glucose and 5.0 M sucrose. Single neurons located in the lateral preoptic area (LPA) and lateral hypothalamus (LH) were studied. Neural activity was monitored continuously and the effects of 0.1 ml vascular infusions delivered at 0.04 ml/sec were determined. Responses were categorized according to changes in neuronal activity associated with the infusion of solutions via the two venous routes. Neurons that exhibited significant changes in discharge frequency when NaCl but not sucrose or glucose was infused were considered to be receiving inputs from sodium receptors. If NaCl effects were observed only via the mesenteric route, the cells were considered to be receiving inputs from hepatic sodium receptors. The majority of neurons that were effected by venous infusions were of this type. In some cases, NaCl concentration-response relationships for neurons could be established during mesenteric infusions. Other types of effects were observed and included neural responses associated with osmolality and pressure changes. In some cases, these effects were observed only via the mesenteric route, and cells were considered to be receiving inputs from hepatic osmo- and possibly baroreceptors. Very few neurons that were affected by venous infusions were of this type. Spinal cord and vagus nerve transections were made in order to determine the afferent pathways involved in the observed effects. In other experiments, animals were prepared for venous infusions and simultaneous recordings of electrocardiographic (EKG) and cortical electroencephalographic (EEG) activity and blood pressure were made. NaCl infusions by either mesenteric or femoral routes resulted in a short lasting desynchronization of EEG and a much longer lasting increase in blood pressure. These results indicate that synaptic input originating from sodium receptors associated with the hepatic circulation does modulate the activity of hypothalamic neurons and that these receptors probably participate in the regulation of drinking behavior by this mechanism.

164.16 **AMPHIBIAN FEEDING RESPONSES AS RELATED TO TEMPORAL AND REGIONAL CHANGES IN AMINO ACID PATTERNS OF THE CENTRAL NERVOUS SYSTEM.** **Claude F. Baxter, Jim W. Dole*, Ken H. Tachiki*, Betty B. Rose* and Roger A. Baldwin*. Neurochemistry Labs, VA Medical Center, Sepulveda, CA 91343, Dept. of Psychiatry, UCLA Sch. of Med. 90024 and Dept. of Biol., Calif. State Univ. at Northridge, CA 91330.**

Prey-seeking behavior and cerebral amino acid levels are altered during adaptation of the toad Bufo boreas to an altered osmotic environment. This amphibian seeks prey using both visual and olfactory cues. Changes in amino acid patterns and glucose in the olfactory bulbs, optic lobes, cerebral hemispheres and blood of toads in a hyperosmotic saline environment (HOE) have been studied and correlated with changes in feeding behavior.

Laboratory-adapted toads, feeding actively on mealworms, were used. They were exposed to HOE (410 ± 20 mOs) for from 2 to 28 days. Blood plasma osmolality equilibrated with environmental osmolality within hours after exposure to HOE. The qualitative changes in levels of most amino acids were similar for the three brain areas tested, but the % changes differed substantially for different brain areas. The time of peak levels for non-essential brain amino acids ranged from 4 to 8 days of HOE.

When toads in HOE, feeding on mealworms (F) were compared with toads that did not feed (NF), significant biochemical differences between F and NF were observed. The initial elevation of blood glucose, in response to HOE, was more rapid in toads that became NF. Some putative neurotransmitter amino acids were significantly higher in specific brain areas of NF as compared to the same brain areas in F, irrespective of time in HOE: i.e., glutamate in the cerebral hemisphere ($p < .025$), glycine in optic lobe ($p < .025$) and aspartate and glutamate in olfactory bulb ($p < .025$ and $p < .005$, respectively). Whereas most non-essential amino acids in brain tissues were higher in NF than in F, the reverse was true for many essential amino acids.

Amino acid levels in some areas of brain appeared to be correlated with aspects of feeding behavior. Strike accuracy (the number of successful strikes at prey, expressed as a % of total strikes) was correlated with critical levels of several amino acids in specific brain areas. For example, a 50% reduction of strike accuracy appeared correlated with phenylalanine increases of approximately 0.01 µmol/g in olfactory bulb, optic lobe and cerebral hemisphere. This represents only 6.3, 8.5 and 15% of the peak increases of this amino acid observed in brains of toads kept for 6 days in HOE. These results suggest that small regional changes in neurotransmitters or their precursors may be linked to changes in feeding behavior. 164.17 DISTURBANCE IN WATER REGULATION IN PSYCHIATRIC PATIENTS.
W.B. Lawson, C.N. Karson, J.E. Kleinman, K.F. Berman, L.B. Bigelow and R.J. Wyatt* (SPON: C. Duncan-Johnson). Adult Psychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032 and National Institute of Health, Building 31, Room 4C-35, Bethesda, Maryland 20205.

Disturbances in water regulation have long been noted in psychiatric patients. Such a disturbance is manifested by polydipsia, and secondary peripheral consequences including polyuria, hypertension, and hyponatremia which may lead to seizures and death. In order to assess the prevalence of this disorder, urine output was measured in psychiatric inpatients admitted to our research ward over the past three years. Urine volume was found to be a reliable and quantifiable measure of water intake in these patients.

Results: Twenty-four hour urine volumes were measured in 58 chronic psychiatric male and female patients, 51 of whom were diagnosed as schizophrenic by RDC and DSM III. These patients, when they were at least six weeks medication free (MF), excreted significantly more urine than 29 normal controls (mean = 2345.48 ml, SE = 371.86 vs. mean = 1303.14 ml, SE = 116.85; Analysis of variance: F = 5.51, p .006, post hoc testing by LSD = p .04). This was also found to be the case when they were on neuroleptic medication (MP), usually haloperidol .4 mg/kg, at least six weeks (mean = 2935.87 ml, SE = 380.99, LSD = p .002). Twenty patients who participated in both the MF and the MP treatments excreted significantly more while on medication (mean = 2742.35 ml, SE = 551.88 vs. mean = 3720.60 ml, SE = 690.26, t = 2.12, p .04).

Conclusion: Disturbance in water regulation in psychiatric patients is more common then is generally thought, and may be exacerbated by antipsychotic medication. The possibility of a relationship between mental illness and the biochemistry of central thirst mechanisms will be discussed. For example dopaminergic and endogenous opiate systems have been implicated in the etiology of schizophrenia and the regulation of thirst.

165.1 EFFECTS OF PIMOZIDE ON SACCHARIN AND SUCROSE CONSUMPTION. D. Sandberg*, M. Vaillancourt*, R. Wise and J. Stewart (SPON: F. Ervin). Dept. of Psychology, Concordia Univ., Montreal, Canada H3G 1M8.

The role of dopamine in mediating the rewarding property of sweet solutions was evaluated by comparing the effects of pimozide, a dopamine receptor blocker, on the consumption of sodium saccharin and sucrose solutions.

In the first experiment, nondeprived male rats were given six, eight-hour test sessions, separated by at least two days, during which they were offered a choice between water and one of six sodium saccharin solutions (.009%, .028%, .083%, .25%, .75%, and 2.5%; w/v). The order of presentation of the saccharin solutions was random and the specific concentrations were chosen so as to yield a biphasic relationship between saccharin concentration and intake. Separate groups were injected intraperitoneally with either .5 or 1.0 mg/kg pimozide or the tartaric acid vehicle four hours prior to the test. Up to a point, intake of the saccharin solution increased with elevations in the solution concentration. Further increases in the solution concentration resulted in decreased intake. Although the mean values for saccharin intake of the two pimozide groups were consistently below those of the control group, group differences did not achieve statistical significance.

In the second experiment, the effects of pimozide on consumption of sucrose solutions were assessed. The procedure was identical to that used in Experiment 1 with the exception that a series of six sucrose solutions (.68%, 1.71%, 3.42%, 6.81%, 17.1%, 34.2%; w/v) replaced the six saccharin solutions. Concentrations of the solutions were chosen to produce an inverted-U function similar to that observed when saccharin was used as the test solution in Experiment 1. Control group animals consumed 2.5 times more of the optimal sucrose solution than had previously been observed with the most preferred concentration of saccharin. Pimozide suppressed intake of sucrose in a dose-dependent fashion but only at those concentrations that comprised the ascending limb of the inverted-U function. These findings are discussed in relation to both reward- and performance-deficit hypotheses of pimozide action. Some similarities between the effects produced by pimozide and cholecystokinin on consummatory behavior are also discussed.

165.2 ESTRUS AND DIESTRUS HORMONAL CONDITIONS INFLUENCE THE FEEDING RESPONSE TO 2-DEOXY-D-GLUCOSE. Lois J. McDermott and Denise E. Jorgensen.* Biopsychology Lab. University of Colorado, Colorado Springs, CO 80933.

The food intake of female albino rats was measured 4 hours following injections of 2-deoxy-d-glucose (2DG) (250 or 450 mg/kg, i.p.) or isotonic saline (which constituted a baseline for comparison). Females with cycling ovaries (NORM, n=18) were tested with 2DG the mornings of estrus (EST) and diestrus (DIEST). Ovariectomized (OVX, n=18) females were tested the day following injections of estradiol benzoate (20.0 µg/rat, s.c.) and progesterone (2.5 mg/rat, s.c.) (EST-H) or sesame oil (DIEST-O). These treatments were employed as models of the hormonal conditions of EST and DIEST, respectively. Prior to injections of 2DG or saline vaginal smears were examined to confirm the hormonal condition of the NORM and OVX groups. Daily food intake of half of the OVX group (OVX-R, n=9) was restricted to keep the body weight of these animals similar to the NORM group the remaining subjects of the OVX group (OVX-AL, n=9) were allowed ad libitum access to food and exhibited significantly elevated body weights relative to the NORM and OVX-R groups. Subjects were tested 3 times with each dose of 2DG or saline under both hormonal conditions with at least 4 days between tests.

Injections of 2DG produced a significant increase in food intake relative to baseline in the NORM and OVX groups during both the EST/EST-H and DIEST/DIEST-O conditions (NORM/OVX, respectively). The response to 2DG of OVX groups during DIEST-O was significantly larger than that obtained during EST-H. (A difference in response to 2DG during EST and DIEST conditions in the NORM group was observed but did not achieve customary levels of significance.) Although baseline intake for both NORM and OVX groups was suppressed during EST/EST-H relative to DIEST/DIEST-O, this difference was not sufficient to account for the magnitude of the difference that was observed in the response to 2DG during the different hormonal conditions.

The magnitude of the feeding response to 2DG relative to baseline was not only a function of the hormonal conditions during testing (EST-H vs. DIEST-O) but was also a function of some concomitant of the body weight of the animal. The OVX-AL group exhibited both a larger response to 2DG relative to baseline as well as greater body weight than the NORM group. Further the difference between the response to 2DG under the EST/EST-H vs. DIEST/DIEST-O conditions was larger for OVX females than NORM females as was the body weight of the OVX group.

This research was supported in part from a grant from CRCW-UCCS.

165.3 DISSOCIATION OF FOOD INTAKE AND PLASMA BETA-ENDORPHIN IN TUMOR-BEARING RATS AND IN DEXAMETHASONE-TREATED RATS FOLLOWING 2-DEOXY-GLUCOSE. G. K. W. Yim, M. T. Lowy*, J. M. Davis*, D. R. Lamb* and P. V. Malven. Dept. Pharmacol./Toxicol., Physical Educ., Animal Sci., Purdue Univ., W. Laf., IN 47907.

Food intake (FI) following administration of 2-deoxyglucose (2-DG) is known to be decreased in normal rats injected with dexamethasone (DEX) and in Sprague-Dawley rats bearing hindlimb implants of the Walker-256 carcinosarcoma (tumor-bearing rats; TBR). Since these TBR are known to have enlarged adrenal glands and elevated glucocorticoid levels, they may be comparable to DEX-treated normal rats in that both may experience glucocorticoid-induced inhibition of pituitary beta-endorphin (β-EP) release. Our previous work showed that plasma β-EP was increased during various hyperphagic states (i.e. nocturnal hyperphagia and daytime hyperphagia induced by food deprivation, acute exercise or 2-DG treatment). The present study examined the relationship between basal and 2-DG induced levels of plasma β-EP and FI in normal DEX-treated rats and in TBR. β-EP was quantified in silicic acid extracts of rat plasma using radioimmunoassay procedures described previously. Elevated concentrations of plasma β-EP were observed following 2-DG in agreement with earlier results, and DEX pretreatment (400 µg/kg and 200 µg/kg at 24 and 2 hr prior to sampling) blocked the 2-DG induced elevation (509 ± 16 vs 176 ± 14 pg/ml). However, DEX did not reduce FI during the 1 hr following 2-DG (3.0 ± .3 vs 3.2 ± .3 gm). In TBR, plasma β-EP did not fluctuate between day and night as in controls. Daytime injection of 2-DG raised plasma β-EP in TBR (555 ± 59 pg/ml) to the same concentration as in non-tumor controls (509 ± 16 pg/ml). However, FI following 2-DG was reduced by 35% in TBR as compared to non-tumor controls.

In summary, DEX decreased plasma β-EP in non-tumor rats without affecting 2-DG induced eating during the first hour. Untreated and 2-DG treated TBR were anorexic but their plasma concentrations of β-EP were not deficient. These results illustrate two situations where plasma β-EP and FI could be experimentally dissociated. (Supported in part by ACS grant CH 194, NIH grant TG GM07095, PHS grant DA-2661, and a Purdue Research Foundation fellowship.)

165.4 OPPOSITE EFFECTS OF YOHIMBINE AND CLONIDINE ON THE FOOD INTAKE OF GENETICALLY OBESE (obob) MICE. M. Beales*, M.F. Callahan, and G. A. Oltmans. Dept. of Pharmacology, Chicago Med. School, N. Chicago, IL 60064.

The obesity syndrome of the genetically obese mouse, obob, is characterized by behavioral, physiological, and hormonal abnormalities. Several CNS abnormalities have also been identified, including increased hypothalamic (HT) norepinephrine (NE) levels, increased number of HT alpha-adrenergic receptors, and decreased HT NE release. Since application of NE agents to the HT can modify feeding, it is possible that defects in endogenous NE systems could result in hyperphagia. Previous work has indicated that amphetamine, which activates central catecholamine systems, reduces food intake in obob mice. In the current study we examined the effects of the alpha-2 receptor agonist clonidine and the alpha-2 receptor blocker yohimbine on food intake in obob and lean mice.

All animals were adapted to a 6-hour feeding schedule until a stable baseline food intake was established (about 3 weeks). Thirty minutes before food was presented animals were injected with yohimbine, clonidine, or vehicle and placed in individual cages. Food intake was measured after 1, 3, and 6 hours of food access. Relatively low doses of both drugs were used in an attempt to affect primarily alpha-2 receptors. Both drugs had their greatest effects on food intake during the first hour of food access. Yohimbine (1 to 3 mg/kg) produced a dose-dependent decrease in the food intake of obob mice (see table). Higher doses (4 to 5 mg/kg) were required to decrease the food intake of lean mice. A low dose of clonidine (100 µg/kg) increased the food intake of obob mice (140% of control). Higher doses of clonidine (200 to 500 µg/kg) produced a dose dependent decrease in the 3 hour food intake of both lean and obob mice.

Effect of Yohimbine on 1 Hr. Food Intake in obob and Lean Mice

Food Intake[a]	Yohimbine Dose (mg/kg)				
	1	2	3	4.6	5.0
lean	90	79	80	72*	59*
obob	92	75*	59*	--	--

[a]Food intake is expressed as a % of the vehicle treated lean or obob control.

*Differs significantly from vehicle treated controls, $p < .05$.

These results suggest that obob mice may be more sensitive than their lean littermates to the effects of alpha-2 adrenergic drugs on food intake (eg., anorexia or hyperphagia). This may reflect an abnormality in the presynaptic alpha-receptors of the obob mutant, and such an abnormality might result in decreased NE release. The failure to release adequate amounts of NE may result in failure to limit food intake to caloric requirements. (Supported by NS 15600).

165.5 CHOLECYSTOKININ:EFFECTS OF DURATION AND DOSE ON FEEDING BEHAVIOR, INSULIN AND GLUCOSE IN RHESUS MONKEYS. Bonnie L. Metzger* and Barbara C. Hansen*. (SPON:P.Coyle). Dept. of Physiology, University of Michigan, Ann Arbor, MI 48109.

Exogenous cholecystokinin (CCK-8) produces feeding cessation in human and non-human animals. In these studies, we examined the dose response and time course of intravenous (IV) synthetic CCK-8 on eating behavior and associated post-absorptive insulin and glucose responses to a mixed meal in male monkeys following an overnight fast. Four monkeys (Macaca mulatta) weighing 6-9 kg were fitted with IV cannulae. Saline controls were used and doses randomized. A minimum of 16 hours separated experiments. Feeding behavior was measured by the size and length of each meal, the length of subsequent inter-meal intervals (IMI), number of meals and total daily kcal intake. Plasma insulin (IRI) and glucose were monitored for 120 min following feeding start. In experiment 1, CCK-8 IV infusions were initiated at the start of voluntary feeding and continued for 6 min at a rate of 15, 30, 60 or 120ng/kg/min. Rapid suppression of feeding occurred within 2.5 min,however, the effective dose varied across monkeys ranging from 30 to 120ng/kg/min. Each CCK-8 enhanced feeding interruption lasted <20 min. Because the effects of the 6 min infusion were of short duration, experiment 2 was designed to test the effect of continuous infusions. Using doses approximating anticipated physiological levels (2,4 or 8ng/kg/min), infusions were started 30 min prior to and continued through the animal's usual 8 hour feeding period. Only the 8ng/kg/min dose consistently reduced total daily intake ($p<.0001$). The decrease in intake was the function of diminished kcal consumption during the 1st ($p<.001$) and 2nd ($p<.05$) daily meal. There was no CCK-8 enhanced delay in the onset of subsequent meals. The minimal effective dose ranged from 4ng/kg/min (n=2) to no response during 8ng/kg/min in 1 animal. Across all experiments only CCK-8 doses >15ng/kg/min delayed both IRI and glucose rises following the meal relative to saline controls ($p<.05$). We conclude that IV exogenous CCK-8 reduces usual meal size and length with maximal effects in the early part of the feeding period. The large dose (>30ng/kg/min) CCK-8 satiety effect is extremely rapid and brief suggesting that this effect is not dependent upon associated stomach distention or the passing of nutrients into the duodenum. Further, the response delays of IRI and glucose induced by CCK-8 do not correlate with feeding interruptions and imply that neither IRI nor glucose alterations mediate CCK-8 enhanced satiety.

165.6 THE EFFECT OF CHRONIC MORPHINE ADMINISTRATION ON MACRONUTRIENT SELECTION IN THE RAT. R. Ottaviani* and A. Riley*. (SPON: C. F. Tyner). Psychopharmacology Laboratory, The American University, Washington, D.C. 20016.

Recently, Marks-Kaufman and Kanarek (Pharmac. Biochem. Behav. 12:427-430, 1980), reported that the acute administration of morphine sulfate selectively affected the rat's intake of a range of macronutrients. For example, morphine suppressed the consumption of carbohydrates and proteins throughout a six hour test. While fat consumption was also initially suppressed by morphine, by the end of the six hour sampling period, fat intake was elevated above control values.

Because morphine also produces marked catatonia at high doses (Riley, Ortuno, Hoffman, Siemon, & Heft, Neurosci. Abst. 6:783, 1980), it is quite possible that the initial suppression of feeding of all macronutrients reflects this interfering behavioral suppression. The subsequent inverse in fat intake, in turn, may reflect a simple compensation for lost calories and not a direct stimulating effect of fat intake by morphine. If the delayed fat intake is compensatory, as tolerance develops to the morphine-induced catatonia, there should be no initial suppression of fat intake and similarly no compensatory increase. The following experiment examined the effects of chronic morphine exposure on macronutrient selection in the rat.

Following a distilled water injection baseline period of seven days, during which time the macronutrient intake of fats, carbohydrates and proteins was assessed for six hours each day, rats were injected with morphine sulfate or distilled water for 21 consecutive days and monitored daily for macronutrient selection. While both groups consumed approximately 5.5 g of food during baseline, morphine significantly suppressed overall food consumption over the 21 days of injections. In addition to affecting total intake differentially, morphine selectively affected macronutrient selection upon acute and chronic administration. Throughout injections, the percentage of fat intake for morphine-injected rats (75%) was significantly higher than that for control subjects (41%), i.e., morphine-injected rats substantially preferred fats to carbohydrates (or proteins). This difference was evident even on Day 21 when catatonia had functionally dissipated and when controls and drugged animals showed no initial differential suppression of fat intake following injections.

These data suggest that morphine selectively alters macronutrient selection in the rat with this effect due to a direct action of morphine on feeding not to a compensatory intake.

165.7 EFFECTS OF CENTRAL INJECTIONS OF NEUROTRANSMITTERS AND DRUGS ON FREELY-FEEDING RATS, J. Grinker, C. Marinescu* and S.F. Leibowitz. Rockefeller University, New York, New York 10021.

Meal pattern analysis allows the evaluation of neurotransmitter and drug effects on spontaneously feeding animals. The feeding changes induced by central injections of norepinephrine (NE), amphetamine (Amph) - a releaser of NE and dopamine, and chlorpromazine (CPZ) - a dopamine receptor antagonist, were compared.

Rats were chronically implanted with 23 gauge cannulae aimed at the perifornical hypothalamus or the paraventricular nucleus. Adult male Sprague Dawley rats (n=6) received paraventricular nucleus injections of NE (20nmoles) or vehicle (normal saline-NS). Injections of both NE or NS were administered for five days at 10 A.M. in a counterbalanced design. Additional groups received perifornical hypothalamic injections of Amph (150nmoles) or vehicle in the A.M. or CPZ (100nmoles) or vehicle in the P.M. Injections were administered for each substance and for vehicle control for at least five days. Rats were maintained on a diet of 80% lab chow and 20% dextrose and a 12/12 light-dark cycle. Meals were defined as minimum feeding bout of 10 licks with an intermeal interval of 15 minutes. Meal pattern data were collected on a PDP 8 computer connected to solid food lickometers (Strohmayer and Grinker, Physiol. Behav. 24:789, 1980).

The two drugs produced different behavioral profiles. Amph decreased the duration, size and latency of the first meal and increased the rate of a subsequent meal. CPZ increased the duration, rate, and size of the first meal and also lengthened the intermeal intervals. In contrast, NE increased the size and duration of the first meal as well as the rate of eating but failed to have sustained effects on meal frequency.

Ritter and Epstein (Proc. Nat. Acad. Sci., 72:(9) 3740, 1975) have also reported that hypothalamic injections of NE in the freely-feeding rat increased meal size but did not change meal frequency. We now report that Amph and CPZ have opposite effects on the microstructure of feeding. These data suggest that meal analysis can provide important information about drug and metabolic interactions in the control of normal feeding. (Supported in part by NIH 22879 and AM 27980).

165.8 BRAIN SEROTONIN AND TRYPTOPHAN IN GENETICALLY OBESE AND DIABETIC MICE. Joan F. Lorden and Joanne P. Steves.* Department of Psychology, University of Alabama in Birmingham, Birmingham, AL 35294.

Obese (ob/ob) and diabetes (db/db) mice display syndromes characterized by obesity, hyperglycemia and hyperinsulinemia. The primary cause of the syndrome has not been identified for either mutant; however, assays of central monoamines have revealed elevated levels of hypothalamic norepinephrine in both cases (Lorden et al., Brain Res., 1975, 96, 390-4) suggesting the possibility of a central nervous system defect. Recent studies (Garthwaite et al., Endo., 1979, 105, 1178-82) have also indicated that 4-5 mo old ob/ob mice have elevated levels of central serotonin (5HT), a proposed mediator of satiety. Since the elevated insulin levels of the db/db mouse might be expected to have a similar effect on 5HT in that mutant, we assayed the brains of 7 wk old, female, ob/ob (C57BL/6J-ob) and db/db (C57BL/KsJ-db) mice and lean controls for 5HT and tryptophan (TRP) using a fluorometric technique. The mice were fed ad lib and food was removed two hours before sacrifice. Both the ob/ob and db/db mice were significantly obese and hyperglycemic at sacrifice. In the ob/ob mice, TRP and 5HT levels were elevated in the brainstem and telencephalon. No significant differences in 5HT levels could be found in the db/db mice, although TRP was greatly reduced. This may indicate a decreased rate of 5HT turnover in diabetes mice.

In a second experiment ob/ob, db/db and lean control mice from each background strain were fasted overnight. Ninety to 120 min prior to sacrifice, the mice were given oral infusions (.3cc) of either water or 2M glucose. Fasted ob/ob mice were hyperglycemic and hyperinsulinemic in comparison with lean controls and the glucose meal increased blood glucose and plasma insulin in both groups. However, increases in 5HT and TRP levels were seen only in the ob/ob mice. In the fasted db/db mice, TRP levels were lower than those of lean (db/m) controls; however, 5HT levels did not differ. As in the ob/ob mice, a glucose meal had a greater effect on TRP and 5HT levels in db/db mice than in lean controls. The differential effect of glucose in mutant and normal mice is most likely due to increased insulin release by the mutants. The results suggest some basic differences in the neurochemistry of these mutants, despite similarities in the syndromes. The significance of these differences for the obese and diabetes syndromes remains to be assessed; however, widespread disturbances in central monoaminergic systems may be important factors in the endocrinological disorders seen in these mice. (Supported by NINCDS grant NS 14755).

165.9 FOOD DEPRIVATION, NALOXONE AND PLAY. S. Siviy*, G. Davies* N. Najam* J. Rossi III* and J. Panksepp (SPON: Z.M. Nagy). Dept. of Psych., Bowling Green State Univ., Bowling Green, OH 43403

It is well established that naloxone reduces both feeding and social play in rats. In analyzing the interactions between feeding and play in young Long-Evans rats, we observed that 24 hrs of food deprivation reduces social play by 57%. The ability of hunger to reduce play is promptly reversed by a single meal. Accordingly, play may be used as a sensitive behavioral indicator of normal satiety processes. For instance, if a pharmacological substance reduces food intake by inducing normal satiety, it should also cause hungry animals to play more. The ability of satiety to invigorate social play could serve as a highly stringent criterion for specification of normal satiety factors in the body. Since the reduced feeding following naloxone has been suggested to reflect normal satiety, we evaluated the ability of the drug to reverse deprivation-induced reduction in play. Rather than restoring play, naloxone (1 mg/kg) further reduced it. To further clarify how naloxone modulates food and social motivation in a single situation, young rats (14-16 days old) were allowed to choose between dirty home bedding on one side of a test chamber and their anesthetized mother upon clean bedding at the other end, latency to begin suckling being measured. Rather than slowing suckling latency, as would be predicted by a satiety hypothesis, naloxone-treated animals latched onto a nipple in less than half the time of control animals (44 vs 136 sec for naloxone and saline pups, respectively), suggesting naloxone had amplified an internal state of social need. Also, in preweanling rats, naloxone did not reduce food intake (as measured by weight gain following one hour of suckling) Indeed, young rats treated chronically with naloxone (3-26 days of age, 5 mg/kg, three times a day) grew faster than controls.

These data suggest that appetite reduction evoked by opiate receptor blockade may be similar to anorexia induced by social separation. Furthermore, the ability of food deprivation to reduce play, provides a compelling behavioral end-point for evaluating the normality of food intake reductions induced by drugs and hormones.

165.10 NALMETRENE DECREASES FOOD AND WATER INTAKE AND BODY WEIGHT GAIN IN ZUCKER OBESE AND LEAN RATS. C.L. McLaughlin, C.A. Baile and R.R. Tuttle*. Sch. Vet. Med., Univ. of Penn., Kennett Sq., PA 19348 and Key Pharmaceuticals, Inc., Miami, FL 33169.

Opiates may play a role in the control of food intake since administration of opiates increase, while administration of opiate antagonists decrease food intake. There is evidence that obese rats and mice have increased concentrations of opiates and are more sensitive than normal-weight rats and mice to the effects of opiate antagonists on food intake. In these experiments food and water intake, body weight gain and feeding behavior responses to a new opiate antagonist, nalmetrene (NM) were measured in Zucker obese and lean rats. In experiment 1, male Zucker obese (548±6 g) and lean (415±10 g) rats were administered 0, .03, .06 or .125 mg/kg NM twice daily for 1 wk (n=5 obese and 5 lean per treatment). Average daily ad libitum food intakes were decreased relative to pretreatment intakes by all treatments in lean (Δ=.7±.5, .3±.6 and -.1±.4 vs 3.6±1.1 g, $p<.01$, ANOVA) but not obese rats. Weight gains were less in treated than control lean rats (0±.2 vs .9±.2 g/day, non-paired-t=2.59, $p<.01$), but water intakes were not affected in obese or lean rats. In experiment 2, Zucker obese (477±6 g) and lean (387±9 g) rats were administered 0, .125 or .25 mg/kg NM twice daily for 21 days (n=3 males and 3 females per phenotype per treatment). Only in obese rats was food intake decreased by .125 mg/kg NM the first 2 wks (Δ=-3.0±1.1 vs .5±1.0 g, ANOVA, $p<.05$) and rate of weight gain was decreased by .125 and .25 mg/kg NM the first wk (1.2±.7 and 1.5±.3 vs 3.3±.7 g/day, $p<.05$, ANOVA). Daily food and water intakes and rate of body weight gain were not different from control after 3 wks of NM treatment, indicating development of tolerance. In experiment 3, feeding behavior response to 7-day administration of 0 or 1 mg/kg NM was measured. Ten male Zucker obese rats (326±14 g) were treated at the onset of the dark portion of the 12-hr light-dark cycle and allowed to bar press for food for 14 hrs. Compared with the pretreatment wk NM decreased 14-hr food intakes (28.0± 1.2 vs 31.3±1.6 g, t=3.27, $p<.01$) by decreasing average meal size (3.2±.3 vs 3.7±.3 g, t=3.64, $p<.003$); however, the effects occurred only in the first 3.5 hrs since feeding behavior 3.5-14 hrs was not affected. The decrease in food intake 3.5 hrs after treatment was similar on the first and last days (9.6±.9 vs 7.8±1.0 g) indicating lack of development of tolerance after 7 days. Average daily weight gains and water intakes were also decreased (3.2±.3 vs 4.5±.4 g, t=3.13, $p<.006$ and 37±2 vs 47±3 ml, t=3.59, $p<.01$), although the decrease in water intake was proportional to the decrease in food intake. Thus, chronic administration of the new opiate antagonist NM can decrease food intake and body weight gain in Zucker obese and lean rats and the effect is primarily on average meal size.

165.11 ABDOMINAL VAGOTOMY REDUCES THE DIPSOGENIC BUT NOT THE ANOREXIC ACTION OF SYSTEMIC SEROTONIN IN RATS. K. J. Simansky, K. A. Bourbonais*, and G. P. Smith. Dept. Psychiatry, Cornell Univ. Medical College, White Plains, NY 10605

Systemic administration of serotonin inhibits food intake (Pollock & Rowland, Pharmacol.Biochem.Beh., 1981, 15, 179) and produces drinking (Kikta et al, Pharmacol.Biochem.Beh., 1981, 14, 889) in rats. We determined the effects of abdominal vagotomy on the anorexic and dipsogenic actions of six doses of serotonin (.25-5.6 mg/kg sc) injected 12 min before a liquid milk diet was provided to male rats deprived for 17h of milk but not water. Serotonin reduced 30 min food intake in the controls (n = 6) in a dose-dependent manner. Vagotomy (n = 5) did not significantly alter the inhibition of food intake by these doses of serotonin. For example, the apparent threshold dose of 0.5 mg per kg reduced food intake by 30 ± 8% in controls and 46 ± 13% in vagotomized rats. In comparison, cholecystokinin octapeptide (4 mcg/kg ip) failed to inhibit feeding in these vagotomized rats (-14 ± 14%) while decreasing food intake by 56 ± 9% in the laparotomized controls. This effect of vagotomy on cholecystokinin-induced satiety replicates our earlier work (Science, 1981, 213, 1036) and, furthermore, suggests that the normal anorexic effect of serotonin after vagotomy was not an artifact of the different baselines for 30 min food intake (14.4 ± 1.5 ml, controls vs. 6.2 ± .4 ml, vagotomy; $p < .01$).

In contrast to the above, vagotomized rats drank less than controls ($p < .05$) during the 60 min after presentation of food. For example, controls drank 6.8 ± .9 ml after 2.0 mg/kg serotonin while vagotomized rats drank 2.6 ± .9 ml ($p < .05$). The baselines did not differ (3.1 ± .3, controls; 2.8 ± .7, vagotomy). When food was not provided under these conditions, controls drank 8.3 ± 1.5 ml during the 132 min after injection and vagotomized rats drank 3.8 ± .6 ml ($p < .01$).

These results demonstrate that the dipsogenic, but not the anorexic, action of systemic serotonin is mediated, in part, by the abdominal vagus nerve in the rat.

165.12 EFFECTS OF IMIDAZOLE-4-ACETIC ACID (IMA) AND CHLORDIAZEPOXIDE (CDP) ON DRINKING BEHAVIOR OF THIRSTY RATS. I. P. Day* AND B. BEER. Dept. CNS Research, Medical Research Division of Amer. Cyanamid, Lederle Laboratories, Pearl River, NY 10965

IMA, a metabolite of histamine, is a pharmacologically active agent. Its presence in the brain suggests a role in the functioning of the central nervous system. Based on opposite effects of IMA and CDP on conditioned emotional responses in rats, it was proposed that IMA has a causal relationship in the production of anxiety states (Clody, et al. 80th Annual Convention, APA, 825, 1972). CDP, as well as other benzodiazepines, disinhibits behavior suppressed by a variety of stimuli. Benzodiazepines increase both regular drinking and feeding behavior and drinking of unknown or adulterated solutions (Poschel, B., Psychopharmacologia 19:193, 1971).

We examined the interaction of IMA and CDP in drinking behavior in rats. Naive rats were deprived of water for 48 hours and placed in single cages the day before the experimental session. Drugs were administered intraperitoneally at a volume of 0.1 ml/100g. Graduated Richter tubes containing tap water or quinine solution were presented immediately after treatment or 30 minutes after treatment.

IMA decreased drinking of tap water in a dose-dependent manner. The lowest dose causing a significant effect was 30 mg/kg i.p. Maximum suppression of drinking was observed when the drinking tubes were presented immediately after the injection of IMA. CDP at 4, 8 and 12 mg/kg i.p., injected 30 minutes prior to IMA had either no effect or enhanced the IMA-induced suppression of drinking. The interaction of IMA and CDP was examined in an aversive paradigm where a quinine-adulterated solution was presented to water-deprived rats. Drinking behavior was decreased with increasing concentration of quinine. CDP increased both drinking of tap water and water adulterated with quinine. IMA treatment caused further suppression of drinking of quinine solution in a dose-dependent manner. CDP at 4 and 8 mg/kg i.p. administered 30 minutes prior to IMA had no effect on IMA-induced suppression of drinking behavior.

The mechanism of IMA-induced suppression of drinking behavior in rats is not clear. This effect is not antagonized by CDP. Both compounds, IMA and CDP, decrease motor activity and cause ataxia. Ataxia by itself does not decrease drinking behavior, as seen with CDP. The ED_{50} for ataxia, measured in a rod-walking test in rats, was 7 mg/kg p.o., which is about the same as the dose significantly increasing drinking. The ataxic ED_{50} of IMA was 97 mg/kg i.p. and the doses suppressing drinking behavior used in this experiment were 30 and 60 mg/kg i.p. IMA and CDP at the doses used in this study both decreased motor activity in rats by about 30% in comparison with controls.

165.13 BRAIN MONOAMINE CHANGES ASSOCIATED WITH BURN-INDUCED ANOREXIA. Y. Berlatzky*, W. T. Chance, F. van Lammeren* and J. E. Fischer* (SPON: A. Mathieu). Department of Surgery, University of Cincinnati Medical Center, Cincinnati, Ohio 45267.

Burn trauma induces a hypermetabolic state, the degree of which is directly related to the severity of the burn. Although this hypermetabolism has been related to increased catecholamine activity, no direct measurement of brain levels of norepinephrine (NE) or dopamine (DA) have been reported in a appropriate animal burn model. In preliminary studies we observed that a 30% surface burn in guinea pigs resulted in significant anorexia in addition to hypermetabolism as well as increased whole brain levels of DA and the serotonin (5-HT) metabolite, 5-hydroxyindoleacetic acid (5-HIAA). Therefore, we investigated monoamine changes in 10 brain areas of burned (B, n = 10), pair-fed (PF, n = 9) and freely-feeding (FF, n = 8) guinea pigs. Burn trauma was induced in anesthetized guinea pigs by a 30 sec open flame (kerosene-soaked gauze applied to the shaved back). Burned and FF animals were provided food (30% casein) and water ad lib. Each animal of the PF group was allowed water ad lib. and had access only to the amount of food consumed during the preceeding day by the B group. Although body weights decreased daily following the burn, food intake rebounded 3 days afterward and then significantly declined to less than 60% of control values. Burned and FF animals were sacrificed on day 6, with the PF animals being decapitated on day 7. Brains were rapidly dissected into 10 areas and frozen in liquid N_2. Amino acids were measured in plasma, while brain regions were homogenized in formic acid-acetone for quantification of monoamines by HPLC. Threonine, valine, cysteine, leucine, tyrosine (Tyr), phenylalanine, ornithine, lysine, arginine and 3-methylhistidine were elevated in B animals' plasma, while glutamate and glycine were decreased. Thus far, 4 of the 10 areas have been analyzed for monoamine changes. Tryptophan (Tryp), Tyr, and 5-HT were significantly increased in the hypothalamus of B and PF animals, while 5-HIAA was elevated only in the B group. In the septal area, Tryp, Tyr and DA were elevated in B and PF animals, while the DA metabolite, 3-methoxytyramine (3-MT) was increased in PF as compared to B animals. The amygdala exhibited increased Tryp and Tyr and decreased homovanillic acid (HVA) in B and PF animals, while 3-MT was decreased in B as compared to PF guinea pigs. Within the mesencephalon, Tryp was elevated in B and PF animals, 5-HIAA, dihydroxyphenylacetic acid and NE were increased in B animals, while HVA was decreased in PF guinea pigs. These data suggest that hypothalamic serotonergic systems and dopaminergic systems in the amygdala and septal areas may be important in the mediation of burn anorexia, since B and PF groups exhibited divergent responses in monoamine metabolites in these areas.

165.14 NORMALIZATION OF BRAIN INDOLEAMINES IN ANORECTIC TUMOR-BEARING RATS BY FORCED ENTERAL FEEDING. F. van Lammeren*, W. T. Chance, H. I. Karlberg* and J. E. Fischer* (SPON: M. von Meyenfeldt). Dept. Surgery, Univ. Cincinnati Med. Ctr., Cincinnati, OH 45267.

We have previously reported (Am. J. Surg. 143: 133, 1982) that rats bearing Walker (W) 256 carcinosarcomas exhibit increased brain levels of the serotonin (5-HT) precursor, tryptophan (Tryp), and metabolite, 5-hydroxyindoleacetic acid (5-HIAA) immediately prior to the onset of anorexia. In order to better investigate the relationship of nutrition to CNS monoamines in TB rats, the effects of supraoptimal enteral feeding of rats bearing W 256 tumors was studied. Tumors were induced in 13 immature, female, Sprague-Dawley rats by the im. injection (0.1 ml) of 5 X 10^4 W 256 cells. Similar rats were divided into pair-fed (PF, n = 8) and freely-feeding (FF, n = 8) control groups. Five days later, one group of TB (n = 6) rats was begun on enteral force feeding (40% solution of modified tube-feeding diet, ICN, Cleveland, OH) by gastric tube at 125% of the daily ad lib. (AL) intake of the FF group. Significant anorexia was observed in the AL-TB rats (n = 7) by day 6, with the rats being sacrificed on days 9 and 10 (PF). Brains were frozen in liquid N_2 prior to their homogenization in formic acid-acetone for quantification of monoamines by HPLC. Although plasma albumin levels were decreased in both groups of TB rats, the enteral feeding significantly restored concentrations towards normal. Plasma total Tryp was significantly decreased in both TB and PF groups, while free Tryp was significantly increased in both TB groups. Levels of brain Tryp were reduced in the enterally-fed TB rats as compared to all other groups. The AL-TB group exhibited significantly increased brain 5-HIAA, which was normalized by enteral feeding. Although norepinephrine was significantly decreased in AL-TB and PF groups, the enteral feeding also normalized this effect, suggesting a nutritional etiology. Levels of dopamine (DA) and dihydroxyphenylacetic acid were not changed across these groups. Other DA metabolites, however, were differentially affected. Thus, 3-methoxytyramine (3-MT), was significantly decreased in both TB groups and increased in PF rats, while concentrations of homovanillic acid (HVA) were significantly elevated in both TB groups and in the PF group. These results suggest that aberrations in DA metabolism may be more important in the mediation of cancer anorexia than the previously-reported indoleamine changes. Thus, 3-MT concentrations were differentially affected by the tumor and PF treatments. The absence of reversal of changes in both 3-MT and HVA by the enteral feeding schedule suggests that alterations in brain concentrations of these DA metabolites are not due to the effects of under nutrition.

165.15 HYPERPHAGIA FOLLOWING INTRAHYPOTHALAMIC MICROINFUSIONS OF 5,7-DIHYDROXYTRYPTAMINE: EVIDENCE FOR A POTENTIAL SEROTONERGIC MEDIATION OF ESTROGENIC INFLUENCES UPON FEEDING. D. J. Steel*, R. J. Waldbillig* (SPON: Vernon J. Odom) Department of Psychology, University of Florida, Gainesville, Florida 32611

Recently this laboratory has presented evidence indicating that in female rats, anatomically restricted and neurochemically selective depletions of forebrain serotonin result in a high-fat diet-contingent hyperphagia and obesity (Waldbillig, Bartness and Stanley, JCPP 95: 391, 1981). Although this earlier study did not attempt to relate food intake to estrous cycle stage, an inspection of the raw data had suggested a failure of serotonin-depleted rats to show the reductions in food intake typically attributed to the estrous stage of the cycle. The purpose of the present study was to directly examine the effects of forebrain serotonin depletions on estrous cycle related variations in food intake.

Two groups of 10 Long-Evans female rats, matched with regard to body weight, received intraperitoneal injections of desmethylimipramine (25 mg/kg) 60 minutes prior to intrahypothalamic microinfusions (4.0 ul bilaterally) of either isotonic saline (control group) or 5, 7-dihydroxytryptamine (5, 7-DHT - 3.0 ug/ul) in the vicinity of the ventromedial nucleus (VMN).

Compared to controls, the 5, 7-DHT treated animals exhibited a stable long-lasting high fat diet contingent hyperphagia and obesity. An analysis of variations in food intake across 51 days of daily vaginal smearing (to determine estrous cycle stage) revealed that animals receiving 5, 7-DHT were significantly (t (19) = 4.00, $p < .01$) hyperphagic with respect to controls during the estrous stage of the cycle. However, during the diestrous stage of the cycle 5, 7-DHT animals were normophagic (t (19) = 1.63, $p > .05$). These data are taken to indicate that the serotonin depletion-induced hyperphagia reported here and in our earlier work is the result of depleted animals failing to show the typical "estrogen-induced-anorexia." Further work is needed, however, to evaluate the possibility that the so-called "estrogen-induced anorexia" is the result of estrogen activating a serotonergic circuit that is inhibitory with respect to feeding.

166.1 AN ETHOLOGICAL ANALYSIS OF MATING IN NAVANAX INERMIS (MOLLUSCA; OPISTHOBRANCHIA).

J.L. Leonard* and K. Lukowiak* (SPON: G. Mpitsos). Department of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta T2N 1N4.

As the first stage of a neuroethological study of sexual behavior in Navanax, we have developed an ethogram and described the events involved in courtship and copulation.

Navanax is a simultaneous hermaphrodite, which normally copulates in pairs with one animal assuming the male and the other the female sexual role. Copulations occur in bouts with the members of a pair exchanging sexual roles with each copulation. Bouts of as many as 6 copulations with strict alternation of sexual roles have been observed. The alternation of sexual roles is accompanied by changes between behaviorally identifiable "male" and "female" states.

At least eight different action patterns are involved in courtship and copulation in Navanax. Two action patterns are "female" and six "male". Courtship (= pre-copulatory) behavior is initiated by the male who turns onto and follows the mucous trail of a conspecific. After catching up with the "female", he explores her caudal lobes and posterior parapodia with his head. She responds by spreading her parapodia, exposing the common genital aperture. Copulation last an average of 42 min and is terminated after the "female" turns and begins to show male courtship behavior toward the "male".

The "female" action patterns are "Spread-tail Up" and "ALF's (anterior lateral folds of head) Pointed". Both are strongly influenced by "motivational" factors. The "male" and "female" behavioral states are not mutually exclusive. In animals which have been isolated for several days it is not uncommon for an individual to begin courtship of a conspecific and fail to achieve intromission because it has stopped exploring the partner's parapodia and assumed the female copulatory posture. Spread-tail up may be elicited by very gentle mechanical stimulation of the caudal lobes and posterior parapodia, and/or by exposure to conspecific mucous. Isolated animals often spend long periods of time with spread parapodia and ALF's Pointed.

Sexual behavior in Navanax is complex involving several action patterns which are influenced by both specific stimuli and by "motivational" factors related to to different behavioral states. This system should prove useful in understanding the physiological mechanisms underlying complex behavior.

166.2 THE SEROTONERGIC METACEREBRAL CELLS MAY CONTROL BEHAVIORAL STATE IN PLEUROBRANCHAEA, R.A. Palovcik and J. L. Ram. Wayne State University, Detroit, Michigan 48202.

Serotonergic metacerebral cells (MCC's) have been presumed to specifically modulate feeding behavior in gastropods. An alternative function for the MCC's in Pleurobranchaea is that they mediate transitions from the still state to more alert states. Injection of intact animals with serotonin (10^{-7} moles/kg) enhanced behavioral state but never produced feeding. Comparison between recording from MCC's during different behavioral states were significant only when the still state was compared to other states (alert, moving, proboscis, or radula). Activation of the feeding motor program via stomatogastric nerve stimulation only moderately excited the MCC's. Highest rates of MCC firing were produced by aversive body wall nerve stimulation which suppressed the feeding rhythm. Since it has previously shown that feeding is more easily elicited under higher behavioral states (Lee and Palovcik 1976, Behav. Biol. 16, 251-266), MCC activation may subserve a more general arousal in Pleurobranchaea.

166.3 MOTION OF A FLOW-FIELD IS THE OPTIMAL STIMULUS FOR THE LANDING RESPONSE OF THE BLOWFLY, CALLIPHORA. H. Eckert University of Marburg, Zoology, P.O.Box 1929, D-3550 Marburg, FRG

The landing response (LR) of flies was elicited by moving grated patterns. The number of LR (upward throw of both foreleg tibiae) elicited by 20 stimulus repetitions was taken as response strength. The strength of the reaction depends sinusoidally on the direction of motion. The preference direction, (i.e. the direction of motion eliciting maximally strong responses), vary with the eye region stimulated: they are arranged radially with an origin in the direction of flight. If the influence of binocular interactions is eliminated (by painting one eye with black paint) then the preference directions follow the axes of the compound eye differing from the preference directions determined in 'binocular' flies. Only by binocular computation is the radial distribution of preference directions achieved: e.g. the vertical preference direction in the binocular region of the eye is based on horizontal (or oblique) preference directions determined in 'monocular' flies. Thus, nature has found a way to achieve changing preference directions (radial distribution) based on a homogeneous distribution of elementary movement detectors which are arranged along the horizontal axis of this compound eye. The figure shows the arrangement of preference directions (black arrows) together with inhibitory directions of movement (open arrows) in a scheme of the hexagonal facet array of both eyes. The central white patch denotes the direction of flight.

166.4 CORRELATED CINEMATOGRAPHIC AND ELECTROMYOGRAPHIC ANALYSIS OF BEHAVIOR IN THE LAMPREY. Galen Eaholtz*, Joseph Ayers and Gail A. Carpenter. Marine Science Institute and Departments of Biology and Mathematics, Northeastern University, Boston, MA 02115.

We have developed a technique which allows direct comparison of behavior and electrophysiological recordings in freely behaving lampreys. Specimens are implanted with recording leads (0.001 in stainless steel) in one or several segmental myotomes and released into photographic trays for electromyographic recording. Both aquatic behaviors (swimming, burrowing, aversive withdrawal) can be intitiated in this environment, by applying appropriate releasers, as well as crawling by reducing the water level. A signal common to both an 8mm film and the electrophysiological recording is provided by a small lamp in the field of the motion picture. The lamp is illuminated by irregular pulses triggered by a hand held switch and the voltage powering the lamp is recorded on FM tape with the electromyograms. The shape of the lamprey's body and the status of the lamp (on or off) is digitized with a magnetic tablet for each frame of the motion picture. The digitized motion pictures are then analyzed on a frame-by-frame basis by computer algorithms (Soc. Neurosci. Abs. 6:466) which extract the locus (position) and curvature of axial flexions from the digitized images of the lamprey's body shape. A plot of the locus of axial flexions versus time (movie frame number) reveals linear conduction of flexion waves down the body. If the abscissa of the locus versus time plot is adjusted to the chart recording time base, the electromyographic recording (electrical activity at constant locus) can be directly related to the behavior by aligning light status pulses from the film with the lamp voltage voltage pulses recorded with the electromyogram.

We are currently applying this technique to determine the motor programs which underly different lamprey behaviors as well as to assess the neuronal basis of behavioral deficiencies (Soc. Neurosci. Abs. 7:681) observed in specimens recovering from complete transection of the spinal cord.

166.5 SPINAL CONDITIONING: CIRCUIT ANALYSES. R.C. Durkovic. Dept. Physiol., Upstate Medical Center, Syracuse, NY 13210

In studies of a simplified neural model of learning, paired stimuli are delivered to the hind limb of the spinal cat in a classical conditioning paradigm. As a result flexion reflexes undergo changes that exhibit the characteristics of classically conditioned responses, the majority of such data being obtained by recording from ankle flexors [e.g. JCPP 84:88(1973), Physiol. Behav. 14:297 (1975)]. The present study was conducted:

(A) to compare simultaneous reflex alterations during conditioning in physiological flexor muscles of the knee [semitendinosis (ST)], ankle [tibialis anterior (TA)], and toes [extensor digitorum longus (EDL)], and

(B) to examine the changes in the Aα conditioned stimulus (CS) spinal circuitry of these muscles during the course of conditioned reflex facilitation induced by CS activation of Aα and Aδ cutaneous fibers.

The CS was electrical stimulation of the saphenous nerve (10/s for 1.5 s) at an intensity supramaximal for Aα and Aδ fibers. Random intertrial intervals averaged 3 min. Probe CS alone trials which activated Aα fibers but were subthreshold for Aδ fibers were delivered before and intermittently during acquisition. The unconditioned stimulus (US) was a 30/s, 0.5 sec train of stimuli to the superficial peroneal nerve at an intensity that activated all Aα and Aδ cutaneous fibers. For conditioning animals the US was delivered during the last 0.5 sec of the CS train. For sensitization control animals the US followed the CS by at least 30 sec. Flexion reflex responses to the CS and US were measured by tension transducers attached to the distal tendon of each muscle.

During conditioning reflex responses to the Aαδ CS increased rapidly in ST and TA compared to preacquisition levels. In control animals responses to the CS declined. In contrast, reflex changes in EDL were small and did not exhibit the patterns displayed by ST and TA. Nor did the US excite EDL as it did ST and TA.

During conditioning, probe Aα CS inputs indicated that the Aα circuitry is not usually involved in the conditioned reflex facilitation seen in ST and TA. These studies suggest that the spinal circuitry involved in spinal conditioning is specific for each motoneuron pool requiring excitatory inputs from both CS and US and involving pathways activated by Aδ cutaneous fibers.

166.6 CLASSICAL CONDITIONING OF LYMNAEA STAGNALIS, T. Audesirk, J. Alexander*, G. Audesirk. Div. of Biol. Sci., Univ. of Missouri, Columbia, Mo. 65211.

The pond snail Lymnaea stagnalis is capable of rapid acquisition of a learned association between food (a sucrose-casein mixture: UCS) and a non-food chemostimulus (amyl acetate: CS). The training procedure consists of adding the CS to the water housing the snails, followed 15 sec later by the UCS. Snails then remain in the presence of both stimuli for the next two minutes. Fifteen CS - UCS pairings result in a significantly greater number of feeding movements to the CS by the experimental group than by their random controls. The elevated response persists for at least three weeks, and can be restored by brief (3 pairing) retraining. We found that both learning and expression of the learned response (rasping to the CS) are dependent on motivation which, in turn, is age-dependent.

Learning in Lymnaea shows several parallels with mammalian learning. For example, massed training is less effective than spaced training, especially when retention of the response is compared. Backward conditioning (presenting the CS 15 sec after the UCS) is less effective than forward conditioning, although both procedures result in learning. One striking finding is that the surroundings in which the snails were raised influenced their subsequent ability to be classically conditioned. Snails raised in "enriched" environments (including gravel, algae, and other snail species) acquire the conditioned response more readily than those raised under "impoverished" (bare tank) conditions, although both were fed the same high protein diet.

The neural circuitry underlying feeding in Lymnaea is known in some detail (e.g. Benjamin and Rose, TINS, 1980) making this gastropod a promising system for the study of neuronal changes underlying a learned modification of feeding.

166.7 NEURAL CORRELATES OF CONDITIONED CLAW CLOSING IN CRAYFISH. W. Stern-Tomlinson and G.L. Gerstein, Dept. Physiology, Univ. Pa. Sch. of Med., Philadelphia, PA 19104

In the following study, we examined various spike train parameters in order to determine their candidacy as neural codes for closing behavior. Crayfish were operantly conditioned to maintain the dactyl within a certain angular range, using a training paradigm involving an aversive stimulus (shock to the tail). The task was closing from a more open position. In some cases, appropriate tactile stimulation was given during the period of training. This period was followed by a test period in which claw position was monitored, in order to assess the duration of the trained behavior. It was determined from control data on the duration of tactile stimulus effects that, for the most part, tactile stimulation did not greatly affect test period performance.

The neural basis for closing behavior was then investigated by recording, during behavior, from proprioceptive (PD) neurons and from the synergist motor neurons slow closer excitor (SCE) and opener inhibitor (OI).

(1)Firing of PD neurons was sometimes periodic; this periodic driving of SCE and OI influenced firing of SCE and OI, but did not affect behavior in any obvious way. Therefore, such spike patterning is neither destructive of behavior, nor is it a relevant coding parameter.

(2)In different individuals closing behavior was achieved by alternate strategies, involving increases in the firing rate of SCE alone, or of both SCE and OI. Therefore, increased SCE firing appears obligatory. The behavioral significance of the alternate strategies is not known.

(3)SCE and OI have a greater than random probability of firing within about 100ms of one another. Quantitative changes in coincident firing did not correlate consistently with changes in dactyl position. However, the normalized amount of coincident firing increased with increase in SCE or OI firing rate.

167.1 ELECTRIC ORGAN DISCHARGE PATTERNS IN THE SKATE (RAJIDAE) AND THEIR RELATION TO BEHAVIOR, B. Bratton* and J. Ayers (SPON: John Neumeyer). Biology Department and Marine Science Institute, Northeastern University, Nahant, Mass. 01908.

A quantitative analysis of the electric organ discharge (EOD) patterns in the Little Skate (Raja erinacea) and the Winter Skate (R. ocellata) was undertaken to characterize such properties as pulse duration, frequency, train duration, amplitude and pattern. These EOD properties were also correlated with the animal's behavior.

It was found that the skate's discharge has a characteristic pulse duration depending on the species under investigation. The pulse duration for R. erinacea averages 68 msec. while a sibling species, R. ocellata, has a pulse duration averaging 189 msec. Other properties described in this study have shown that R. erinacea has a characteristic discharge frequency of 2 to 7 pulses per second. The skate can discharge the electric organ at the low rate of 2 to 3 pulses per second for periods of a few seconds to several minutes.

The pulse amplitude varies in a way similar to the frequency. It ranges from a maximum of 1.5 volts to a minimum of 0.1 volt. This variation takes place during most of the discharge trains observed.

To test the idea that a skate will respond to the electrical discharge of another skate, the animals were subjected to artificially produced pulses from a stimulator. Experiments in which a stimulus is similar in pulse duration, amplitude and frequency, proved to be ineffective in evoking a response from the skates. The skate would discharge to a d.c. stimulus if the polarity was positive but would not respond to a negative stimulus at "make". Only when the negative stimulus was turned off would the skate discharge.

It was demonstrated that the releasing stimuli for discharge was physical contact with another skate. Skates isolated from other animals rarely discharge whereas groups of skates are found to discharge regularly. In some approach behaviors, two skates may respond to each other with interacting EOD displays.

The specific occurence of the EOD with ongoing behaviors suggests a possible role in communication. This proposed function for the EOD in Rajidae is based on the occurrence of the EOD when skates come into contact with each other and the lack of the EOD display during other individually isolated behaviors.

167.2 SIGNIFICANCE OF ELECTRORECEPTOR TUNING IN THE RECOGNITION OF SPECIES SPECIFIC SIGNALS IN MORMYRID ELECTRIC FISH. C. D. Hopkins and A. H. Bass Section of Neurobiology and Behavior; Cornell University; Ithaca, New York. 14850.

Knollenorgan electroreceptors are the putative electric communication sensors of Mormyrid electric fishes. They are electrically tuned to frequencies most prevalent in the power spectrum of the species-specific electric organ discharge (EOD), which is spike like. Tuning is very broad (Q10's range from 0.1 to 0.9) to match the broad spectral bandwidth of the EOD.

Field work on the Mormyrids of the Ivindo River of Gabon (West Africa) has shown that there are two classes of Knollenorgan receptors in most species of Mormyrids. Low frequency organs are located on the lateral and ventral sides of the head, and respond most sensitively to stimuli between 500 and 1500 Hz; high frequency organs are located on the dorsal surface of the head, and over the rest of the body, and are tuned one octave higher.

Knollenorgans respond to natural stimuli (EODs from other individuals) by generating spikes which are phase locked to the EOD waveform. Knollenorgans respond to outside-negative to outside-positive going voltage transitions. Inversion of the stimulus polarity causes a shift to a different phase of the stimulus waveform.

Low frequency organs respond to gradual transitions in the waveform, preferentially, while high freqency receptors respond to more rapid transitions. When presented with a complex waveform like an EOD, low and high frequency receptors fire spikes at different, yet characteristic latencies. Each species-typical EOD from the field site evokes a unique temporal pattern of spikes.

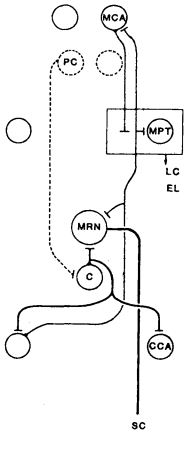
It is likely that the difference between low and high frequency receptors arose to increase the complexity of temporal sampling of species specific EODs, and hence reduce ambiguity in species recognition.

167.3 CENTRAL PATHWAYS OF THE ELECTRIC ORGAN DISCHARGE COMMAND IN MORMYRID FISH. C.Bell, S.Libouban*, T.Szabo*. C.N.R.S., Lab. Physiol. Nerv., Dept. 3, Gif-sur-Yvette, 91120, France.

The motoneurons to the mormyrid electric organ are driven by a descending volley from a medullary relay nucleus (MRN). The MRN does not itself initiate the electric organ discharge (EOD) but is driven by another center (Aljure, 1964). One goal of the present study was to identify this center anatomically. A second goal was to establish the pathways responsible for the corollary discharges of the EOD command in the electrosensory lobe (EL), where electroreceptors terminate.

The species Gnathonemus petersii was used. Electrical activity preceding the EOD was recorded extracellularly using pipettes filled with HRP in saline. After locating a structure with such activity, HRP was injected by iontophoresis.

A group of smaller cells is found immediately beneath the large cells of the MRN. The smaller cells are suggested as the origin of the EOD command and are thus provisionally referred to as the command nucleus (C). Axons of C terminate densely in MRN. Axons of C also project to a caudal bulbar nucleus, the caudal command associated nucleus (CCA). A mesencephalic nucleus, provisionally referred to as the pre command nucleus (PC),



appears to have a strong projection to C. The connection from PC to C is the only one in the diagram not yet confirmed with both retro- and anterograde transport. The axons of the cells in CCA ascend and cross the midline. They send collaterals to MRN and to the medial paratrigeminal nucleus (MPT), before terminating in a small mesencephalic command associated nucleus (MCA). The latter nucleus was studied by Aljure (1964) and Szabo (1979). The axons of the MCA descend to a region medial to MPT, where cells projecting to the electrosensory lobe (EL) are located. The EL may also be reached via MPT which projects to lobus caudalis (LC), a source of afferents to EL.

The cells of MRN appear to project only to the spinal cord (SC). The cells of C appear to project only to MRN and to CCA. Thus if C is indeed the origin of the EOD command, then the corollary discharges must be transmitted by way of the CCA.

167.4 HOW TO TALK TO A COCKROACH: BEHAVIORAL DISCRIMINATION AMONG ACOUSTICALLY DISTINCT SOUND SIGNALS IN *GROMPHADORHINA PORTENTOSA*. M.C. Nelson and R.K. Potter*. Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

Close-range sound communication figures prominently in the courtship of *G.portentosa*, the giant Madagascar hissing cockroach. Several acoustical features distinguish courtship sounds from other social and non-social sound signals; the two features that most reliably sort sounds by context are relative amplitude or sound level (SL) and the temporal pattern of amplitude modulation (AM). (All sounds are broadband and frequency does not vary with context.) We carried out experiments to determine whether these features are behaviorally relevant to the recipients of sound signals, and if so, which features of courtship sound are important in promoting female receptivity and hence successful courtship.

The mating success of muted males, unable to vocalize, is only 1/10th that of vocalizing males; playback of recorded courtship hisses restores normal mating success (Nelson & Fraser, Behav Ecol & Sociobiol 6,'80). We compared disturbance hisses (high SL, abrupt onset) with courtship hisses (low SL, slow onset w/ rapid AM). By shifting the amplitude of recorded signals during playback we were able to compare the importance of AM vs SL features. Thus, animals in 4 playback groups heard one of 4 signals at the appropriate moments during courtship: CN, Courtship at Normal SL (62 dB); DN, Disturbance at Normal SL (80 dB); CH, Courtship at High SL (80 dB); or DL, Disturbance at Low SL (62 dB). Control groups could vocalize normally, or were muted but heard no playback signal. We scored female receptivity and mating success, and measured latency and frequency of several distinctive courtship displays for single males paired with trios of virgin females, to gauge the normality of interactions in different groups.

We conclude that females need both AM and SL cues for receptive behavior. 1) Courtship AM is not a sufficient cue: CH, like DN, is ineffective in eliciting receptivity (see Table). 2) Low SL is not a sufficient cue: DL is less effective than CN in eliciting receptivity. Only a signal that combines low SL and the appropriate AM pattern (i.e. CN) is adequate to elicit normal receptive behavior from females, who thus appear to be analysing the signals emitted by males in both the amplitude and temporal domains.

Group	courtship AM	courtship SL	♀recep-tivity	mating success
CN	yes	yes	+++	+++
DL	no	yes	+	++
CH	yes	no	-	---
DN	no	no	---	---

167.5 INFERIOR LARYNGEAL NERVES CONTROL ULTRASONIC COURTSHIP VOCALIZATIONS IN MALE RODENTS. A. A. Nunez, S. M. Pomerantz and N. J. Bean*. Dept. of Psychol. & Neuroscience Program, Michigan State Univ., East Lansing, MI 48824.

Adult male rodents of *different species* produce ultrasounds as part of their precopulatory behavior. The temporal patterning and the frequency of the ultrasounds are species-specific; however in all cases they seem to facilitate copulations. In the present study we investigated the peripheral neural mechanisms involved in the production of ultrasounds in males of two species of myomorph rodents.

In house mice (Mus musculus) of the Swiss Webster strain, bilateral or unilateral cuts of the inferior laryngeal nerve (inferior cuts) abolished the production of 70 kHz ultrasounds in a large proportion of the animals (100% after bilateral cuts; 70% after unilateral cuts). Some recovery of function was evident *after* 2 weeks in animals with unilateral cuts. Bilateral cuts of the superior laryngeal nerve (superior cuts) or sham surgery did not reduce the proportion of animals that emitted 70 kHz ultrasounds during tests with adult females.

In deer mice (Peromyscus maniculatus), superior cuts or sham surgery did not prevent the production of 35 kHz ultrasounds during courtship behavior. On the other hand, only 14% of the males receiving unilateral inferior cuts produced ultrasounds on behavioral tests conducted 1 week after surgery. Males with unilateral inferior cuts recovered the ability to produce 35 kHz ultrasounds 3-4 weeks after surgery. This recovery of function was reversed by transections of the contralateral inferior laryngeal nerve.

The present results confirm that the inferior laryngeal nerves innervating the larynx are responsible for the motor output involved in ultrasound production. Previous work with rats has shown that the inferior laryngeal nerves originate in the nucleus ambiguus. Preliminary data from HRP studies suggest a similar pattern of laryngeal innervation in house mice and deer mice.

All the surgical procedures for the present study were done following the guidelines recommended by the NIH.

167.6 BILATERAL INTERACTIONS WITHIN THE VOCAL CONTROL PATHWAY OF BIRDS. K.R. Manogue*, J.A. Paton and F. Nottebohm (SPON: J. Cohen). The Rockefeller University, New York 10021.

Bilateral interactions between the right and left sides of the song control pathway of three avian species, the budgerigar (Melopsittacus undulatus), the zebra finch (Poephila guttata) and the canary (Serinus canarius) were compared using microstimulation and recording in anesthetized preparations. These birds were chosen in order to compare the physiological properties of each vocal control system with several anatomical and functional features known to differ among these species. Central and peripheral control of song in both oscine species is dominated by one side of the nervous system, although the lateralization in zebra finches is less marked than that of canaries. It is not yet known whether control of vocalization in budgerigars is centrally lateralized, but no peripheral laterality is present in a related parrot. The vocal control pathway of budgerigars has robust bilateral distributions both centrally and peripherally, while the canary (and we assume the zebra finch) have strictly ipsilateral connections between the principal efferent stations of the song control pathway. Stimulation of the highest of these efferent stations, the neostriatal nucleus hyperstriatum ventrale pars caudale (HVc), caused a constant-latency increase in neural activity of the tracheosyringeal (ts) nerves. These nerves supply the avian organ of voice, the syrinx. Unilateral stimulation of HVc in budgerigars caused equal responses in both right and left ts nerves (11-16 ms latency). In zebra finches and canaries, much larger responses were evoked in the ipsilateral ts nerve than in the contralateral ts nerve, as Arnold found when recording from syringeal muscle (Amer. Sci. (1980) 68, 165-173). The crossed responses in the oscines occured 3-5 ms later and at a higher threshold than the ipsilateral response. Also, the contralateral response could only be demonstrated with rates of stimulation exceeding 35/s. Simultaneous bilateral stimulation of HVc in budgerigars gives a greater than linear summation of responses on each ts nerve, evidence for convergence of ipsi- and contralateral inputs onto the same set of motor neurons. The bilateral distribution of excitation within the song control pathway of budgerigars should lead to coactivation of bilaterally paired muscles on each side of the syrinx. This type of interaction should ensure that the two sides of the parrot syrinx operate in a unitary, or single-voiced fashion. In contrast, the two sides of the song control pathway in the oscines are almost completely isolated from each other, and are thus free to act independently. This type of organization lends itself to the simultaneous production of unrelated sound elements by the two independent sound sources present in the songbird's two-voiced syrinx.

167.7 THE ROLE OF PERIPHERAL FEEDBACK IN THE MAINTENANCE OF VOCAL PATTERNS BY ZEBRA FINCHES. S. W. Bottjer & A. P. Arnold. Dept. of Psychology, UCLA, Los Angeles, CA 90024

Auditory feedback is essential for song learning in young zebra finches (Poephila guttata), but not for maintenance of song in adult birds (Price, '79, J. Comp. Physiol. Psychol., 93: 260). The latter result suggests that adult vocal behavior is either (a) dependent on feedback from the vocal organ (syrinx), or (b) not dependent on any source of peripheral feedback, but is instead controlled by a central motor program. We report preliminary results of an experiment designed to test the first possibility.

In zebra finches, afferent fibers originating in the syrinx leave via a branch of the hypoglossal nerve, and join the main trunk of the vagus to enter the brainstem dorsally (Bottjer & Arnold, '81, Soc. Neurosci. Abstr., 7: 270). It is possible to section hypoglossal afferent fibers, while leaving hypoglossal efferents intact, at the point where hypoglossal afferents join the vagus. The results presented herein represent our initial findings concerning the maintenance of stable song patterns in deafened adult zebra finches which have undergone section of either the left or right hypoglossal afferents. (Usually afferent and efferent fibers of the descending branch of the vagus are sectioned along with hypoglossal afferents; control experiments indicate that unilateral section of the descending vagus in deaf birds has no effect on vocal behavior.)

The song patterns of eight adult zebra finches were recorded; the birds then underwent bilateral removal of the cochleae and their song patterns were recorded again. Following this deafening operation, hypoglossal afferent fibers were sectioned on either the right (N = 4) or left (N = 4) side (hypoglossal efferents were left intact). Section of hypoglossal afferents on the left side disrupted the form of individual song notes in 1 out of 4 birds; section of afferents on the right side caused similar disruption in 2 out of 4 birds. (The overall tempo and structure of song were not affected in any case.) Interestingly, birds whose song was disrupted by unilateral section of afferent fibers tended to exhibit some minor changes in song as a result of deafening. All birds in which song was disrupted showed at least partial improvement as a function of time following the operation (8 to 19 days). This improvement was even observed in one additional bird following subsequent section of the intact, contralateral hypoglossal afferents. These preliminary results indicate that stereotyped vocal patterns produced by adult birds can persist in the absence of auditory feedback as well as feedback from the vocal organ.

Supported by NSF grant BNS 80-06798 and USPHS grant MH 15345.

167.8 ANATOMICAL MAPPING OF THE CHICK MIDBRAIN CALL AREA: THREE-DIMENSIONAL THRESHOLD TOPOGRAPHY OF EVOKED VOCALIZATIONS. C. K. Bluhm* and R. E. Phillips. Lab. of Behavioral Physiology, 495 An Sci Vet Med Bldg., Univ. of Minnesota, St. Paul, MN 55108.

The primary objective of this study is to localize in greater detail the neural control areas of the avian midbrain which are most directly involved with electrically stimulated call production in anesthetized 1-3 day-old chicks (Gallus domesticus). After electrode placement, data collection, and histology were completed, we used computer-assisted data analysis to generate graphs of the three-dimensional threshold topography of evoked vocalizations for each planar section of the chick brain. These plots were then superimposed on an atlas of brain nuclei to delineate regions of the brain controlling low threshold calling.

The results of this study show that the chick midbrain contains a region localized in the nucleus intercollicularis (ICo) and nucleus mesencephalicus lateralis, pars ventralis (MLv) and linked to the archistriatum in the forebrain by the tractus occipito mesencephalicus (OM) pathway. The four midbrain call regions most important for low threshold calling are the (1) ICo, (2)MLv, (3) OM, and (4) the posterior commissure. Lowest threshold calls (10-30 μA) coincided with the anterior ICo and MLv, but the MLv was of greater importance as a continuous low threshold call area. Ventral to the ICo-MLv, a broad band of call sites occurs laterally. This band corresponds to MLv output fibers and is distributed caudally through the lateral reticular formation dorsal to the isthmic nuclei. This bundle exits the midbrain in a ventrolateral position and converges on the lateral pontine nucleus in the medulla. The thresholds for calling in the OM were always higher (40-60 μA) than those elicited from the MLv. The medial OM area and the lateral ICo-MLv call area were initially separate, but the two areas merged caudally. This suggests that the OM is an important input to the MLv call area.

Low thresholds for calling occurred throughout the anatomically diffuse MLv, but were lowest near the borders of the ICo and OM. The ICo, which has been previously implicated as the major midbrain call area, actually appears to have input going through it to the lowest threshold call area in the MLv. The ICo-MLv border had low threshold call sites, but the majority of these lay in the MLv.

In conclusion, the results of this study demonstrate that the control of call production in newly hatched chicks is similar to that of adult chickens. Moreover, our results demonstrate the applicability of computer graphics for use in analyzing large sets of neurophysiological data. By mapping this information on planar sections of a brain atlas, we can correlate neuroanatomical structures with specific behavior patterns.

167.9 RESPIRATORY GATING OF ACTIVITY IN THE AVIAN VOCAL CONTROL PATHWAY. J.A. Paton, K.R. Manogue*. The Rockefeller University, New York, NY 10021.

Vocalizations in birds are produced by air flowing past the membranes of the syrinx. The nature of the sounds produced depends on the characteristics of air flow and membrane position, which are controlled by the respiratory and vocal control systems of the central nervous system. In birds, the vocal control pathway contains a neostriatal nucleus, HVc; an archistriatal nucleus, RA; and a medullary motor nucleus, nXIIts, which innervates the muscles of the syrinx via the tracheosyringeal nerve.

To search for sites of interaction between the systems controlling respiration and vocalization, we electrically stimulated individual nuclei within the vocal control pathway and recorded respiratory phase and neural activity within the tracheosyringeal nerve. Experiments were done in budgerigars (Melopsittacus undulatus), zebra finches (Poephila guttata), or canaries (Serinus canaria) lightly anesthetized with Chloropent. Nuclei were stimulated with trains of 0.3 ms cathodal, constant current pulses (2-100ua) from 1 Mohm tungsten microelectrodes. Whole nerve responses were recorded from the ipsilateral tracheosyringeal nerve with a pair of hook electrodes covered with oil. Respiration was monitored with a thermistor placed in the path of tracheal air flow, such that the temperature of the thermistor increased during expiration.

In budgerigars, stimulation of HVc, RA, or nXIIts produced stimulus- locked potentials on the tracheosyringeal nerve. In each case stimulation recruited more activity during expiration than during inspiration, a phenomenon we refer to as respiratory gating. This gating seems to be a function of the excitability of the tracheosyringeal motor neurons, because the size of antidromically evoked potentials in nXIIts were also greater during expiration. The source and mechanism of this respiratory input to nXIIts remains to be determined. Respiratory gating was also found in zebra finches and canaries, both oscine songbirds.

As a result of respiratory gating, song related control of the syrinx is most effective during expiration when vocalizations normally occur. In effect then respiratory gating coordinates shared control of the same set of motor neurons during two different behaviors: breathing - an ongoing, automatic, medullary motor behavior - and singing - a complex, voluntary, learned behavior which is controlled by telencephalic nuclei.

Supported by NSF Grant BNS 79 24602, and USPHS Fellowship 1F32 MH08231.

167.10 ONTOGENY AND SEXUAL DIMORPHISM OF THE SONIC MOTOR NUCLEUS IN THE OYSTER TOADFISH. M. L. Fine, D. Economos*, J. R. McClung and R. Radtke*. Dept. of Biology and Physiology, Virginia Commonwealth Univ., Richmond, Va. 23284 and Pacific Gamefish Foundation, Honolulu, HI 96825.

Male oyster toadfish, Opsanus tau, produce a courtship boatwhistle call and have a larger sound-producing organ than females, who do not boatwhistle. Since number of neurons has been shown to increase postnatally in fishes, we considered ontogeny in our examination of the sonic motor nucleus (SMN) in the toadfish, a teleost known to live for about 12 years. Our purpose was to investigate the possibility of sexual dimorphism in ontogeny of the SMN. Fish were aged by counting annual rings on saccular otoliths and ranged from 1 to 11 years of age.

Compared to mammals in which brain growth is generally completed in early life, the toadfish brain retains a potential for increase in mass, cell number and cell size into later life. Brain weight increases for the life of the toadfish though this increase decelerates with increasing fish weight. Neuron number, ranging from 760 to 2888 in the SMN, increases rapidly to about 3 years, more slowly to about 8 years, and then levels off. There are no sexual differences in regressions of brain weight and SMN neuron number against fish size or age. Neuronal soma size in the SMN ranges from 9 to 35μm in average diameter and 67 to 916μm^2 in area. This increase in size can be observed for at least 7 years. Males have larger neurons than females. However, males can be separated into populations with large and small soma sizes. Neuron size is not different between females and males with small somas. Neurons in males with large somas are significantly larger than neurons in females and neurons in males with small somas ($p < .0001$). Such male dimorphism is reminiscent of other behavioral and morphological dimorphisms, which have led to characterization of males into territorial and satellite forms in certain mating systems.

Supported by NSF Undergraduate Research Program and Va. Commonwealth Univ. biomedical grant-in-aid.

167.11 THE SEXUAL DIFFERENTIATION OF SOCIAL PLAY IN NORWAY RAT PUPS IS MEDIATED BY THE ANDROGEN RECEPTOR SYSTEM. M.J. Meaney*, J. Stewart, M.Y. McGinnis* and B.S. McEwen (SPON: Philip A. Femano). The Rockefeller University, New York, NY and Dept. of Psychology, Concordia University, Montreal, Canada.

Social play among juvenile Norway rats is sexually dimorphic; males engage in more play fighting than do females. The play fighting of juvenile females can be masculinized by neonatal exposure to either testosterone (T) or 5α-dihydrotestosterone, but not by estradiol. The neonatal castration of males results in female levels of play-fighting (Meaney and Stewart, Horm. Behav. 15: 197, 1981). Previous work (Goy, Recent Adv. Primatology, 1: 449, 1978) has shown that 5α- dihydrotestosterone, administered prenatally, also masculinizes social play in female rhesus monkeys. These findings suggest that in the Norway rat and the rhesus monkey androgens, interacting with the androgen receptor exert an organizational influence on social play.

We have further examined this hypothesis by studying the play-fighting of juvenile Tfm rat pups. Rats bearing the X-linked Tfm mutation are known to be insensitive to androgens and show a marked deficiency of androgen receptors. We found that prepubertal Tfm males play-fought no more frequently than did female pups, and that both groups engaged in significantly less play fighting than did normal male pups. In a second study, we found that male pups treated with the anti-androgen Flutamide (in Silastic capsules) during the neonatal period (days 1 to 10 of life) engaged in less play-fighting than did control males. Moreover, Flutamide-treated males, like the Tfm males, engaged in play-fighting at rates that were statistically indistinguishable from those of female pups.

In subsequent work we have been examining the androgen receptor system in the limbic brain of neonatal rats using a nuclear exchange assay and (^{3}H)R1881 as a ligand (Soc. Neurosci. Abst., this meeting). In one such study, we found that a Flutamide treatment that was comparable to that used to block the masculinization of social play dramatically reduced the nuclear translocation of the androgen receptor in various brain regions of T-primed pups. Taken together with previous data, the findings strongly suggest that the sexual differentiation of social play in juvenile rats is mediated by the activation of the androgen receptor during the neonatal period. In considering this finding it is important to note that social play is sexually dimorphic in a broad range of species and that is especially so in primates, including humans.

167.12 CHEMOSENSORY CONTROL OF SPAWNING MECHANISMS IN GOLDFISH. Leo S. Demski, Joseph G. Dulka*, School of Biological Sciences, Univ. of Kentucky, Lexington, KY and R. Glenn Northcutt, Division of Biological Sciences, University of Michigan, Ann Arbor, MI.

Sperm release (SR) has been evoked in immobilized, lightly anesthetized goldfish by electrical stimulation of the olfactory tract (OT) using both suction and metal-hook electrodes. Thresholds were below 20 μA in 5 animals. Cutting or applying xylocaine to the OT proximal to the electrode blocked the responses, the latter being reversible. Responses can still be evoked with the contralateral OT severed and the ipsilateral lateral bundle of the OT (LOT) cut. Indeed, stimulation of the medial bundle (MOT) alone produces low threshold responses. The results suggest that chemosensory information carried in the MOT may influence SR mechanisms and perhaps other sexual motor pathways. Three functional systems are represented in the teleost OT: 1) afferents from the cells in the olfactory bulb; 2) fibers originating from neurons in the brain and ending on cells in the olfactory bulbs and 3) fibers of ganglion cells located on the surface of the olfactory nerves i.e. the terminal nerve (TN). Initially, we assumed that the SR resulted from either othodromic activation of afferent fibers and consequent excitation of their central targets or, less likely, antidromic activation of the efferent OT fibers and subsequent excitation of central areas via activated collaterals. However, recent studies suggest that activation of the TN system may be the most likely cause of the SR responses. Münz et al. (Cell and Tis. Res. 222:313) have demonstrated that the TN in sunfish projects to forebrain regions related to SR as well as the retina and that the system contains LHRH. Northcutt (unpublished) has demonstrated similar anatomical connections for the TN of goldfish, including evidence that dendrites of the cells extend into the olfactory epithelium. In goldfish TN fibers are located only in the MOT. To test the liklihood that the TN modulates SR in goldfish, we carried out the following experiments. Stimulation of the optic nerve at currents below 50 μA resulted in evoked SR. Control experiments (as above) and stimulation of other nearby nerves indicate that current spread to other structures was not involved. We theorize that the SR is triggered by antidromic activation of the TN fibers efferent to the retina with subsequent excitation of central SR areas via excited collaterals. Preliminary observations indicate that μl quantities of LHRH injected into the ventricle near the preoptic area (100 μg/ml) can trigger sustained and powerful SR activity. The pharmacological specificity of the response is yet to be determined. At this point, our data strongly suggest that activation of TN fibers in the MOT is responsible for triggering SR.

167.13 CENTRAL CONTROL OF EATING IN THE PIGEON: A SENSORIMOTOR CHAIN FROM GRAIN THROUGH BRAIN. J.M.Wild and H.P.Zeigler, Dept. of Behavioural Biology, R.S.B.S., Australian National Univ. and Biopsychology Program, Hunter College, City Univ. of New York.

The neural control of feeding in the pigeon involves contributions from afferent and efferent components of the avian trigeminal system. We have now identified structures which link the trigeminal sensory and motor systems, completing a sensorimotor circuit mediating grasping, pecking and feeding in the pigeon.

Somatosensory input from the oral region is conveyed to the telencephalon of birds by a group of trigeminal lemniscal ("quinto frontal") structures, including the principal trigeminal sensory nucleus (PrV), the quintofrontal tract (QFT) and its terminal field, the nucleus basalis (NB) of the telencephalon. Efferent pathways for oromotor activity include the cranial nerve motor nuclei of the trigeminal and facial nerves (V/VII) and premotor neurons located in the lateral (parvocellular) reticular formation (Rpc). These premotor neurons receive a descending projection from the telencephalon via the occipitomesencephalic tract (OMT), which originates in the anterior and intermediate archistriatum (Arch).

To complete a trigeminal sensorimotor circuit connecting the afferent and efferent components of the pigeon's feeding system it is necessary to identify the structure(s) linking NB with Arch. We have used a combination of orthograde and retrograde markers to identify the projection of NB and to determine the connections between its terminal field and that portion of Arch from which OMT originates.

Injections of ^{3}H proline into NB labeled a terminal field in the neostriatum caudale, internal to the ventricle and dorsal to Arch, within a region designated by Karten as the regio trigeminalis telencephali (rTT). Injections of HRP into this region retrogradely labeled cells in NB. Injections of HRP or tritiated amino acids into rTT produced dense labeling of a spherical terminal field within Arch. HRP injections into this Arch region retrogradely labeled cells within rTT, as well as anterogradely labeling OMT, which has previously been shown to project upon Rpc. We have previously demonstrated that HRP injections into this reticular region retrogradely label cells within the anterior and intermediate Arch and produce anterograde labeling of V/VII.

Our experiments demonstrate that these intratelencephalic structures (rTT, Arch) link the trigeminal sensory and motor systems in the pigeon. The identification of a trigeminal sensory telencephalic-trigeminal motor circuit adds feeding to the limited number of *vertebrate* behaviors for which such circuits are being delineated. 167.14 GRASPING IN THE PIGEON: FINAL COMMON PATH MECHANISMS. Bradley G. Klein and H. Philip Zeigler, Biopsychology Program, Hunter College, CUNY, N.Y.,N.Y. 10021 and Dept. of Ornithology, American Museum of Natural History, N.Y.,N.Y. 10024

Considered as an effector organ, the beak of birds functions in pecking, grasping and manipulation analogously to the hand of primates. Behavioral studies of pecking have shown that grasping involves an adjustment of gape size which takes place during head descent, is linearly related to seed size and is completed prior to tactual contact of the beak with the seed. We have used photographic, surgical & behavioral procedures to provide a quantitative description of the pigeon's grasping response, identify the motoneurons mediating this response and clarify their contribution to the control of grasping.

The topography of pecking & grasping were examined using high speed (400 fps) cinematography. A single frame camera,triggered by the pecking response, provided data on gape size at the point of maximal opening prior to grasping. A variety of seed sizes were used to derive gape size functions. The motor nerves to beak opener muscles were identified by dissection and their contribution to the control of gape was examined using a 2 stage denervation procedure. In the first stage the facial (VII) nerve branches innervating the opener muscle of the lower beak (M. depressor mandibulae) were sectioned. In the second stage section of the trigeminal (V) innervation of the opener muscle of the upper beak (M. protractor quadrati) was added. The effect of these procedures upon grasping topography was compared with those produced by sham surgery.

Behavioral studies show that production of gape involves both opener muscles. Smaller gapes involve only the upper beak (maxilla). Larger gape sizes are produced by jointly activating both beak openers. Section of N. depressor mandibulae abolishes opening of the mandible & produced a significant reduction in gape. Subsequent section of N. protractor quadrati removes the contribution of the maxilla & no significant gape was evident.

These data indicate that N. depressor mandibulae & N. protractor quadrati constitute the final common path for beak opening during grasping. The cell bodies of these motoneurons lie in the V/VII motor nuclear complex and our previous HRP studies show that they receive monosynaptic inputs from sensory (proprioceptive) neurons in N. Mesencephalic V & interneurons in the Lateral Reticular Formation & disynaptic inputs from the telencephalon. The identification of final common path neurons for opening-grasping will facilitate the use of this response as a neurobehavioral marker for studies of sensorimotor and motivational processes.

167.15 EVOLUTION OF FLIGHTLESSNESS: NEUROBEHAVIORAL EFFECTS. R. R. Provine. Dept. of Psych., Univ. Md. Baltimore Co., Catonsville, MD 21228.

The consequences of the evolution of flightlessness on the neurobehavioral process of the wing-motor system were evaluated by searching for drop-evoked and spontaneous wing-flapping in flightless emus and penguins. The commun emu (Dromaius novaehollandiae) was selected because its tiny wings provide no flight related function. Emus evolved from flighted forms by the Pleistocene. Humboldt (Spheniscus humboldti) and Black-footed (Spheniscus demersus) penguins were also tested. Extant penguins are flightless in air but evolved from flying ancestors as early as the Eocene. Although penguins lost their capacity for aerial flight, they are masterful flyers through the denser medium of water. Their drop-evoked wing-flapping performance was compared with that of the common puffin (Fratercula artica) and murre (Uria aalge) that are capable of both submarine and aerial flight. The results of the comparative analysis should indicate if a behavior and its neural mechanisms are conserved over millions of years of evolutionary history when they serve no apparent function. The present comparative analysis of the effect of flightlessness on emus and penguins over millenia contrasts with the typical deprivation experiment that examines the effect of a short interval of movement restriction during the lifetime of the individual (Provine, R.R., Behav. Neur. Biol., 27:233, 1979; Dev. Psychobiol., 14:279 and 481, 1981).

Emus performed neither drop-evoked nor spontaneous wing-flapping. Penguins produced no drop-evoked wing-flapping but performed powerful wing-movement during submarine "flight." In contrast, puffins and murres that are capable of both aerial and submarine flight performed spontaneous and drop-evoked wing-flapping. Drop-evoked and spontaneous wing-flapping of the emu and drop-evoked wing-flapping of the penguin were lost during evolutionary history.

167.16 MOTILITY PATTERNS IN THE OPOSSUM DURING DEVELOPMENT. Richard W. Bunch, C.H. Narayanan, and Y. Narayanan*. Dept. of Anat., LSU Sch. of Med., New Orleans, LA 70119-2799.

The relationship of early fetal behavior and progressive differentiation of the developing nervous system has been under investigation in our laboratory. In this study, both quantitative and qualitative recordings of motility in the opossum were made beginning with prenatal stages and followed through to 42 days postnatally. Recordings of time spent in activity as well as responses to cutaneous stimulation were conducted with emphasis on changes of motility patterns with age. Wild opossums were bred in captivity. Laparotomies were performed on pregnant opossums and the uterine horns placed in Tyrode solution (35^{o}C, pH 7.0). The embryos were exposed within a specially constructed observation chamber (Bunch, et al., 1980) for subsequent observation and recordings of behavior. Pouch young were similarly exposed while inside the pouch. Activity was recorded with an Esterline Angus polygraph. Behavior was categorized into local (eg. isolated forelimb activity), partial (eg. forelimb and head), and total (eg. head, forelimb and trunk) motility patterns. Responses to cutaneous stimulation were recorded using a pressure graduated esthesiometer. Results of this study indicate that spontaneous motility begins at 12½ days post conception in the form of sudden bursts of activity comprised of head extension and forelimb abduction. Within 24 hrs, this motility transforms into a total pattern of integrated activity involving crawling movements of the forelimbs and synchronous rotation of the head and trunk in a cephalocaudal sequence. The total percent activity increased steadily throughout the observation period. Total activity is the most prevalent type of behavior until approximately 24 days after birth. Partial activity comes into the picture and shows an increase in frequency from here on. Partial and local motility patterns begin to increase after 32 days postnatally while total motility patterns show a decrease. Responses to cutaneous stimulation appear first in the perioral region at birth and in the forepaws 10-12 days later. These responses are at first of the total pattern type and later become more localized in nature. All 3 categories of motility were observed at every stage of development. By birth, the opossum has formed a predictable motility pattern in striking contrast to motility patterns of the chick or rat fetus at comparable stages of development. The changes in frequencies of the different categories of activity in the developing opossum may reflect different degrees of summation or recruitment of neuronal activity.

168.1 PRENATAL AND POSTNATAL UNDERNUTRITION AND THE EFFECTS OF BRAIN DAMAGE. Marc D. Schrode*, C. Robert Almli, Stanley Finger, and Peter J. Morgane. Washington University School of Medicine, St. Louis, Mo. 63110 and Worcester Foundation for Experimental Biology, Shrewsbury, Ma. 01545.

The topic of in utero undernutrition has only recently begun to receive research attention. In utero undernutrition may be one of the major factors contributing to premature birth, and thus, small-for-gestation-age and small-for-date infants. Postnatal undernutrition in rats results in retarded (or altered) body weight, eye-opening, behavioral development, and nervous system development. Prenatal undernutrition might be expected to have similar or more severe effects. The present study is the first program determining the relations between pre- and postnatal undernutrition, neural development, and the effects of brain damage sustained early in life. Research has shown that lateral hypothalamic (LH) destruction sustained by rats younger than 6 days of age is associated with continued growth and life, whereas LH destruction sustained by rats 6 days of age and older is associated with body weight loss and death. The present study determines if undernutrition alters the time-course of LH-lesion-induced deficits in developing rats.

Prior to breeding, during gestation, and postnatally, dams and litters were maintained on normal (25% casein) or low-protein (6% casein) isocaloric (4.3 kcal/g) diets. The 6% and 25% pups sustained LH destruction at 10 days of age. At this age, 6% pups had body weights that approximated those of the 25% pups at birth.

Following LH destruction at 10 days of age, 25% rats ceased suckling, lost body weight, and died by 5 days postlesion. The 6% rats also ceased suckling, lost body weight, and they died by 3 days postlesion. Another difference was that the 6% rats died in response to smaller and less-well placed damage. However, 6% and 25% rats were similar for % daily body weight lost (from postlesion), % body weight lost at death (from prelesion), and % of control body weight through the day of death.

Undernutrition, and the potential for delayed neural development, did not protect the 6% rats from the effects of LH damage. In fact, the undernutrition may have exacerbated the brain damage effects. Brain damage (e.g. intraventricular hemorrhage) so common to premature human infants may be more devastating due to pre- and postnatal nutritional status. (Supported by BSRG grant S07RR05389 and NICHD grant HD06364)

168.2 EFFECTS OF FOOD RESTRICTION DURING LACTATION ON POSTNATAL DEVELOPMENT OF RAT CEREBELLAR CORTEX. A. Feria-Velasco, A.R. del Angel* and G. Tapia-Arizmendi*. Div. Developmental Biology. Unidad de Investigación Biomed. Occidente. I.M.S.S. Guadalajara, Jal. MEXICO.

Malnutrition at various stages of development has been reported to bring about a wide variety of changes in the central nervous system. In the present work, the effects of food restriction during lactation on the postnatal development of cerebellar cortex were studied in 169 male and female rats. A method described by Wiggins was used to impose food restriction during lactation. Four pups of each offspring of 8 were separated from their mothers 1 hr the day of birth, 2 hours the 2nd day, 3 hours the 3rd, and one more hour consecutively per day until the pups were separated 12 hrs the 12th day. The following days until weaning (21st day) the pups were separated from their mothers for 8 hrs per day, and after weaning the food was taken out the cages for 8 hrs at night and determinations were done at birth, 5, 10, 15, 20, 25 and 30th days in both, the control and experimental groups. Weights of body and cerebellum were recorded, and DNA, RNA and proteins were measured. Representative animals from each group were fixed by intracardial perfusion and sections from vermis and cerebellar hemisphere were postfixed and embedded in Epon 812. On 1 μm-thick sections, thickness of cerebellar cortex, external granular layer and molecular layer were measured and recorded.

Body and cerebellar weights showed statistically significant differences in the restricted animals in the order of 30-40%, and 16%, respectively. Cerebellar DNA and RNA contents in the restricted groups were 30% lower than in the normal animals at 5 and 10 days, and 12-18% at 30 days of age. A significant delay in disappearance of the external granular layer of cerebellar cortex was observed in the restricted pups, being more conspicuous in vermis than in cerebellar hemisphere. No significant differences were found in thickness of molecular layer when both groups of animals were compared and similar results were obtained in the total thickness of cerebellar cortex.

168.3 AMPHETAMINE ISOMERS FAIL TO DECREASE HYPERACTIVITY IN THE NEONATAL 6-HYDROXYDOPAMINE MODEL. J.T. Concannon and M.D. Schechter, Program in Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

In an attempt to replicate the findings of Shaywitz et al. (Nature 261:153, 1976) reporting that amphetamine decreases hyperactivity in developing 6-hydroxydopamine (6-OHDA)-treated rats, we utilized intracisternal injections of 6-OHDA or its vehicle, and measured activity during development using a time-sampling procedure. At 5 days of age, rat pups were pretreated with intraperitoneal desmethylimipramine and then were randomly assigned to either 6-OHDA or vehicle treatment using a littermate control design. Behavioral activity was measured at 15, 20, 25 and 30 days of age, using a repeated-measures design, after an intraperitoneal injection of either saline or graded doses of either d-amphetamine (0.125, 0.25, 0.50, 1.00 or 2.00 mg/kg) or l-amphetamine (0.25, 0.50, 1.00, 2.00 or 4.00 mg/kg). In vehicle and 6-OHDA-treated pups injected with saline, activity increased from moderately low levels at 15 days of age to moderately high levels at 25 days of age. Furthermore, 6-OHDA-treated pups injected with saline were hyperactive at 20 days of age. At 25 days of age, activity in both saline-injected groups was equal and, thereafter, declined to levels typical for adults. Administration of increasing doses of the amphetamine isomers generally increased activity in both vehicle- and 6-OHDA-treated rats at all ages and d-amphetamine was more potent than l-amphetamine in this respect. Perhaps most importantly, no dose of either amphetamine isomer decreased activity at 20 days of age in the 6-OHDA-treated hyperactive pups. Whole-brain dopamine (DA), assayed at 35 days of age, was significantly depleted (56%), whereas whole-brain norepinephrine (NE) was not significantly depleted (9%). Furthermore, the 6-OHDA treatment did not lead to decreased body weight at a time when hyperactivity was detected. Hence, no convincing evidence was found for a "paradoxical calming" effect of amphetamine in DA-depleted hyperactive rat pups, confirming the findings of other recent reports (Thieme et al., Psychopharmacology, 67: 165, 1980; Pappas et al., Psychopharmacology, 70:41, 1980). Since clinically-useful drugs do not reduce hyperactivity in this model, these results suggest that the neonatal 6-OHDA-treated rat does not appear to represent an accurate model for the pre-clinical investigation of human hyperkinesis.
(Supported by NIMH grant #33636)

168.4 NEONATAL FEBRILE SEIZURES ALTER ADULT HIPPOCAMPUS MORPHOLOGY AND BENZODIAZEPINE BINDING. J. E. Franck,* J. Chisholm,* and C. K. Kellogg. Dept. Neurosurgery, Univ. of Wash., Seattle, WA (JEF), Dept. of Pharmacology and Dept. of Psychology, Univ. of Rochester, Rochester, NY.

Febrile seizures in children are common and are thought to increase the risk of adult partial seizures or temporal lobe epilepsy. Despite this association there is a puacity of experimental work on the neurologic sequelae of this type of convulsion. We have found that a single neonatal febrile seizure (NFS) induces selective morphologic and benzodiazepine (BDZ) binding changes in the hippocampus of adult rats.

A febrile seizure was induced on postnatal day 15. Control pups were removed from the dam for a comparable time period. At twenty days of age there was a proliferation of reactive astrocytes restricted to the hippocampus (Cajal and Holzer methods). This reaction disappeared by 60 days. At 20 and 60 days hippocampal cells appear normal in Nissl stained material. There was no evidence of ongoing neuronal degeneration at any age studied (Fink-Heimer method). By 90 days, however, neurons in the CA3 and CA2 regions of the hippocampus were grossly shrunken and basophilic and were bounded by an increased extraneuronal space. These observations suggest a neuronal loss of water, with condensation of the cytoplasm. This reaction was not seen in other subfields nor was it seen in other brain regions or in control animals.

The BDZ binding site and its putative endogenous ligand may play a role in seizures, hence BDZ binding was measured as an initial attempt to characterize the nature of the hippocampal alterations following NFS. Binding was determined by displacement analysis of ^{3}H flunitrazepam with CL 218-872, a non-BDZ anti-seizure agent which, unlike the BDZs, displays high affinity for a specific subpopulation of BDZ sites. A NFS produced a significant decrease in the IC_{50} (418 $\pm$ 28 nM vs 624 $\pm$ 62 nM) and the Hill coefficient (.570 $\pm$ .018 vs 694 $\pm$ .041) in the hippocampus at 90 days but not at earlier ages. Cortex and cerebellum were unchanged. The Bmax remained constant following NFS indicating that the number of binding sites is unchanged but a greater proportion are of the high affinity type. An increase in high affinity BDZ sites in the hippocampus following NFS suggests that the morphologic changes have functional implications.

A single NFS produces changes specific to hippocampus. The subfields involved are similar to those most sensitive to epileptic insult in humans and which have been shown to be involved in seizure genesis in hippocampus in experimental work. The present data indicate that febrile seizures during development are not a benign event and require intensive study.

168.5 SENSORI-NEURAL DEGENERATION IN THE COCHLEA OF YOUNG (DEAF) SHAKER-1 MUTANT MICE. A. Shnerson*, R. Pujol*, T. R. Van De Water* and M. Lenoir* (SPON: R. D. Ginzberg). Lab. Develop. Otobiology, Albert Einstein College of Medicine, New York, New York 10461 and Laboratoire de Neurobiologie de l'Audition, Montpellier, France.

The study of mutant mice with genetic anomalies of the inner ear can provide insights into the processes which act to form a normal inner ear. Further definition of the nature and course of postnatal changes in the sensory and neural components of the inner ears of shaker-1 mice was, therefore, undertaken. The cochleas of 3-, 6-, 10-, 12-, 18-, and 30-day-old mice, homozygous for the shaker-1 gene (sh-1/sh-1), were examined using transmission electron microscopy. Relative to observations in the normal mouse (Shnerson, A., Devigne, C. and Pujol, R., Dev. Brain Res., 2:77, 1982), the present findings indicate retarded development coupled with progressive degeneration of early onset in Corti's organ, its nerve supply, and the cells of the spiral ganglion. Especially noteworthy are the following: Both outer hair cells and spiral ganglion cells of 3-day-old mice were already abnormal. Spiral ganglion neurons were especially loosely ensheathed by glial cells and were in direct contact with nerve fibers. Outer hair cells contained vacuoles and lysosomes. By 6 days of age inner hair cells were similarly affected. Most of the afferent nerve supply of the organ of Corti had degenerated by Day 18. The behavior of efferents within Corti's organ was complex. Efferents arrived late (Day 12) at the outer hair cells, were few in number, formed only immature synapses with these cells, and subsequently degenerated. In contrast, the efferent nerve supply of the inner hair cells appeared normal.

The selective degeneration of efferents to outer hair cells is viewed as being consistent with the hypothesis that there are two, independent, efferent systems which innervate the two types of cochlear sensory hair cells. The simultaneous occurrence of organ of Corti and spiral ganglion cell anomalies suggests that the shaker-1 mouse may be a useful model animal through which to gain insights into the role of sensori-neural interactions in the phenotypic expression of genetic inner ear defects.

Supported by grants from INSERM (81-6022) and DGRST (81-0799) to R. Pujol and by funds from NIH-NINCDS (NS08365) to T. R. Van De Water.

168.6 HYPOMYELINATION AND RECOVERY OF THE MYELIN DEFICIT IN FEMALES HETEROZYGOUS FOR THE JIMPY GENE. J. Rosenfeld, V.L. Friedrich Jr. Laboratory of Neuromorphology, Univ. of Connecticut U-154, Storrs, Connecticut 06268.

Jimpy is a sex linked murine mutation producing a severe hypomyelination throughout the central nervous system in affected hemizygous males. Consistent with Lyon's hypothesis, the effect of X chromosome inactivation has been observed in females heterozygous for the jimpy gene. The result of such X chromosome inactivation is a mosaic pattern of myelin distribution and gliosis, observed thus far only in the optic nerve (Skoff et al.). The process of X chromosome inactivation should, however, affect all brain regions. We wondered whether the amount of myelin in the heterozygote might be reduced in regions which do not exhibit visible 'patching' of myelin.

In this study we used point hit counting of electron micrographs from the anterior commisure to determine the amount of myelin in females heterozygous for jimpy ($X^{Jp}X^{+}$) and in controls ($X^{+}X^{+}$) at 43 and 201 days after birth. A 20% decrease in the amount of myelin was observed in the younger jimpy heterozygote compared to the same age control.

We found no difference in myelin content between the older jimpy heterozygote and its control. In control animals the amount of myelin was the same at the two ages. By contrast, the amount of myelin in the older heterozygote was increased substantially over the value for the young heterozygote.

In the light microscope, we could find no evidence of unmyelinated patches in the anterior commisure or in other fiber tracts of the brain and spinal cord. However, a similar reduction in the amount of myelin at the young age and a subsequent increase at the older age may be occuring in other areas. We observed an increase in myelin content of the jimpy heterozygote with age. This may reflect a compensatory recovery of myelination. The jimpy heterozygote might be a suitable model for the study of the regulation of myelination and remyelination in the central nervous system. We are presently expanding the study to include other brain regions and younger animals.

168.7 HYPOXIA AND PYRAMIDAL CELL SPINE FORMATION AND DENDRITIC ARBORIZATION: A QUANTITATIVE GOLGI STUDY. M.C. Yu*; D. Spero* and F. Hackett*. (SPON: N. Ingoglia). Dept. of Anatomy, New Jersey Medical School, Newark, New Jersey 07103.

A study was made to determine the effect of hypoxia on the development of dendritic spine and dendrite arborization of the pyramidal cells of the rat parietal cerebral cortex. New-born Sprague-Dawley rats were culled into 8 pups per dam. On postnatal day 5, they were placed into an hypoxic chamber and exposed to a low oxygen environment (10% O_2; 90% N_2) for 7 consecutive days. During the period of hypoxia, the pups were removed from the chamber twice daily at 9:00 AM and 4:00 PM for supplemental feedings with an enriched liquid diet, in order to minimize the factor of undernutrition as a result of possible decreased milk production by the dams. For control, another group of rats, also culled to 8 pups per litter, were exposed to normal ambient air and nursed by their dams. On postnatal day 12, one week after the hypoxic exposure, all the rats were taken out of the chamber. One group of rats was killed immediately while the other groups were cross-fostered by other, normal lactating dams, and killed at postnatal days 17, 22, 40 and 80, respectively. The rats were perfused intracardially with 10% phosphate-buffered formalin. The brain was removed to be processed by the rapid Golgi method, and serial sections were cut at 80 microns. Dendritic spines on the apical dendrite of pyramidal cells at Layers III and V were assessed quantitatively at successive increments of 50, 100, 150 and 200 um from the cell body. Apical and basal dendrites were also enumerated at similar intervals of distance from the cell body. At day 12, the number of spines of the control group was consistently greater than the hypoxic group. At day 17, however, the number of spines of the hypoxic group was found to slightly exceed the control. Thereafter, the spines of the hypoxic group were equal to the control at postnatal days 22, 40 and 80 respectively. These data suggested that spine formation was retarded during the period of hypoxia, but substantial recovery occurred after the removal of the hypoxic stress. The alteration in spine number will be correlated with the altered pattern of dendritic arborization.

168.8 PRENATAL L-DOPA TREATMENT DIFFERENTIALLY AFFECTS ADULT COPULATORY BEHAVIOR. C. Marschall and L.G. Clemens. Michigan State University, East Lansing, MI. 48824

Dopaminergic neurotransmission in the brain may facilitate masculine copulatory behavior in adult male rats. Sexual behavior in castrated (Malmnas, Pharmacol.Biochem. Behav.4:521, 1976) or sexually sluggish males (Tagliamonte,et al, Pharmacol. Biochem. Behav.2:257, 1974) is increased following systemic treatment with L-DOPA. The role of CNS dopamine in the mediation of feminine sexual behavior is not clear.

Maturation of the dopaminergic system in the CNS begins early in ontogeny (Coyle and Henry, J. Neurochem 21:61, 1974). Thus the prenatal period is a particularly sensitive period in which manipulation of neurotransmitter levels may alter normal development with possible long-term effects on function.

Pregnant Long-Evans rats were injected i.p. with L-DOPA (30 or 60 mg/kg saline) daily on prenatal days 10-21. Controls received saline alone. At birth litters were adjusted to 5 males, 5 females. Animals were weaned on day 25 postnatally. Female offspring were ovariectomized between 60-70 days of age and tested first for the display of lordotic behavior following estrogen-progesterone priming.Masculine copulatory behavior was assessed weekly following treatment with 250 ug testosterone propionate daily. Male offspring were castrated and tested for the display of copulatory behavior following treatment with 100 ug testosterone propionate daily. The potential to display feminine copulatory behavior was tested following estrogen-progesterone priming.

Body weights of offspring at weaning did not differ among the treatment groups. Mount frequency was significantly elevated by the 4th week of testing in L-DOPA treated female offspring.The per cent of L-DOPA treated females displaying mounting behavior was also higher when compared with controls (100% vs 61%).Mount frequency of females displaying mounting behavior was also significantly higher in the L-DOPA offspring(60mg L-DOPA, 18 $\pm$ 2.6: saline, 9 $\pm$ 0.3).Parameters of masculine copulatory behavior in male offspring were altered inconsistently.

Lordotic behavior was not affected by L-DOPA treatment in female offspring, nor was a consistent effect in male offspring observed.

Thus manipulation of CNS neurotransmitter levels prenatally may have consequences evidenced in behavioral differences in adulthood.

168.9 MODEL PHENYLKETONURIA: BENEFITS OF A NEW THERAPEUTIC APPROACH. J. A. Beel*, L. J. Fisher*, L. S. Stodieck*, and M. W. Luttges, Department of Aerospace Engineering Sciences, University of Colorado, Boulder, CO 80309.

Recent studies (Luttges and Gerren, 1979) have shown that postnatal administration of α-methyl phenylalanine induces behavorial deficits in adult mice. Such deficits are characteristic of other animal models of phenylketonuria. Reductions in brain myelin proteins and changes in electrical recovery cycles were also observed. Based upon the hypothesis (Hughes and Johnson, 1978) that reduced brain protein synthesis produced by excess phenylalanine was the basis for phenylketonuria-like effects, studies of therapeutic reversal were attempted. Treatment with a mixture of large, neutral amino acids followed daily α-methyl phenylalanine treatments. Examinations of brain protein synthesis indicated restored levels of postnatal brain metabolism when the appropriate mixture of amino acids was administered. The restoration of synthesis levels was correlated with two additional observations: (1) electrophoretic and autoradiographic similarities in proteins isolated from various subcellular fractions and (2) variations in levels of ^{35}S-methionine uptake into intracellular pools. Following α-methyl phenylalanine treatment, those mice receiving a mixture of amino acids also exhibited normal daily increases in body weight. When tested behaviorally as adult mice, those mice which received amino acid therapy exhibited performance which differed significantly from the performance of mice which did not receive therapy. The treated mice also differed from control mice which received neither α-methyl phenylalanine nor therapy. These studies suggest that hyperphenylalaninaemia models of phenylketonuria depend upon imbalances in brain concentrations of large, neutral amino acids. Such imbalances are currently treated by lowering phenylalanine levels but may be approached by increasing the levels of other large, neutral amino acids. The latter approach, used here, appears to provide therapeutic benefits in the absence of dietary limitations common to the usual treatment of phenylketonuria.

168.10 BIOCHEMICAL CHANGES IN RATS WITH EXPERIMENTALLY INDUCED PHENYLKETONURIA (PKU). H. K. Berry, R. E. Butcher*, and P. G. Ruehlman*. Children's Hospital Research Foundation, Cincinnati, OH 45229.

Direct and indirect changes during early stages of brain development contribute to the pathogenic pattern in phenylketonuria (PKU).

We previously developed an animal model of PKU characterized by behavioral deficits persisting beyond the period of exposure to PKU-inducing diet. We used the model to examine biochemical changes at different stages of development. PKU was induced in pregnant rats by combined feeding of p-chlorophenylalanine, (PCPA), an inhibitor of phenylalanine hydroxylase, together with a slight excess of phenylalanine (PHE) in the diet. Fetuses were delivered by cesarian section at 22 days gestation. Brain weights of PKU fetuses were significantly lower than fetuses whose dams were pair-fed with PCPA or PHE alone. Maternal brain weights were unaffected.

Protein, DNA, cholesterol, cell number and cell size were lower in brains from fetal PKU animals than from any of the control fetuses. Cholesterol was the only maternal structural component which was lower in PKU dams than in control dams.

Reductions in brain serotonin were seen in both PKU and PCPA animals and, thus, were not attributable to the presence of excess PHE.

Brain PHE was elevated in PKU animals as expected; glycine was also elevated in PKU brains compared to controls. Valine, isoleucine, leucine, methionine and tryptophan were reduced in brains of PKU animals. These amino acids were fed to PKU rats to see if the deleterious effect of excess PHE could be overcome by supplying one or more essential amino acids. A supplement of valine, isoleucine, and leucine, fed to pregnant rats along with the PKU-inducing diet, resulted in fetal brain weights similar to those of pair-fed animals. Tryptophan and methionine feeding had no effect on fetal brain weights. PHE content of PKU fetal brains was reduced though there was no effect on plasma PHE levels. Supplementing the diet of PKU animals with valine, isoleucine, and leucine inhibited transport of PHE into brain and prevented the PKU-induced deficit in fetal brain weights. The data supported the hypothesis that brain protein synthesis was limited by lack of certain essential amino acids.

168.11 ION FLUCTUATIONS DURING NORMAL AND ABNORMAL BRAIN DEVELOPMENT - X-RAY MICROANALYSIS OF VENTRICULAR CONTENTS, TRANSPORTING EPITHELIA AND DEVELOPING NEURONS IN THE RAT. J.G. Chamberlain*+, R. Wróblewski* and Lars Edström* (SPON: M. Diamond). Cell Biology Section, Wenner Gren Institute and Karolinska Institute - Neurology, Stockholm, Sweden.++

Ultrastructural studies are not always reliable predictors of functional correlates. We report here important new data on electron probe x-ray microanalysis of developing brain cells and cerebrospinal fluid, demonstrating early regional and age differences with compartmentalization and electrolyte variability.

Embryonic and fetal brains from days 12-21 of pregnancy and one-day postnatal were quench frozen in liquid Freon 22 cooled with nitrogen (-180°), sectioned (14-16 μm) in the cold (-30°), and processed for x-ray analysis on carbon plates (JEOL 100C with Kevex). For comparison, brains of day 14 and 19 fetuses from mothers injected with niacin antagonist, 6-Aminonicotinamide (6-AN) (8 mg./Kg. b. wt. i. p.) on day 13 were similarly processed. Gelatin-embedded electrolyte standards allowed relative peak intensity (Rx) conversions to mM./Kg. dry wt. for cellular compartments. These and other data will be presented.

Relative concentrations of Na+ and Cl- differed in the cells of the cerebral cortex, ependyma, choroid plexus and cerebrospinal fluid (CSF) crystals. During cerebral development, Na+ and Cl- concentrations appeared to be correlated (ratio=1.0), while potassium was more related to phosphorus intensity (ratio=1.7). Sulphur was low in all compartments (R_S=1.0) and was considered as an internal control. K+ was inversely related to Na+/Cl- fluctuations within the choroid plexus epithelia. Sharp phase changes appeared in elemental composition at specific growth stages, e.g., days 14 and 19. The R_{Cl-} was highest (+23) in the ventricular crystals where its pattern followed most closesly that of K+. Na+ was also elevated in the ventricles early in development (i.e., day 12-13). When compared to controls, brain tissue and CSF crystals from 6-AN treated animals showed inverse changes in Na+, Cl- and K+ 2-24 hours after injection; five days later there still were differences (e.g., K+).

The relationship between the compartments of the early developing rat brain appear to continuously change, perhaps due to various growth processes reaching their respective peak and falling away at different times. The cerebral cortex, ependyma, choroid plexus and CSF appear to manifest individual ionic balances (e.g., Cl-) and marked cellular asynchrony early in embryogenesis (e.g., days 12-14). These balances are rapidly and markedly altered in prehydrocephalic young (6-AN treated).

168.12 AGE-DEPENDENT SUSCEPTIBILITY TO MICROWAVE HYPERTHERMIA INDUCED "FEBRILE" CONVULSIONS. D. L. Hjeresen, A. W. Guy* and J. Diaz. Dept. of Psychology, Univ. of Washington., Seattle, WA 98195.

Convulsions associated with fevers occur in an estimated 2 to 5% of children between 6 mo and 6 yrs of age. The neural mechanisms and clinical treatment of febrile convulsions are currently a matter of considerable debate. Previous animal models, based on raising ambient temperature or using electroconvulsive shock, have done little to resolve this issue. Rather, it seems likely that the stress induced by these methods, occuring at a critical period in brain development, could account for the deleterious effects on brain growth and behavior reported.

We have previously reported that when 13 and 17 day old rat pups are subjected to microwave (MW) hyperthermia convulsions can be induced. Further, we noted no deleterious effects of these convulsions on brain growth or behavioral performance. We also noted that pups tested at 17 days were less susceptible to convulsions than those tested at 13 days. This parallels the clinical observation that children beyond 6 yrs are no longer susceptible to febrile convulsions and suggests that a critical period exists in humans and rats for the induction of febrile convulsions. We test this hypothesis with the MW hyperthermia model developed in our laboratory.

Twelve litters of Long-Evans rats were culled to 8 pups each on Day 4 post-partum. One pup from each litter was assigned to each of the 8 exposure conditions: Exposed to MW energy (SAR=.378 W/kg per mW/cm^2 of input power) or sham exposed on Days 11, 13, 15, or 17. These days were selected since they represent the period of rapid brain growth in rats most comparable to the risk period for febrile convulsions in humans. Post-exposure behavior was scored on a 4 point scale with 4 representing severe clonic-tonic convulsions.

The results indicate a decreasing sensitivity to convulsions with increasing age. The mean (± SEM) behavioral ratings among pups exposed at 11, 13, 15, or 17 days were 3.17 ± 0.28, 2.54 ± 0.29, 1.67 ± 0.39 and 1.12 ± 0.13 respectively, indicating considerable convulsive behavior at 11 days, less so at 13 days and nearly normal behavior at 15 and 17 days, compared to controls. Activity measures, whole brain, cerebellar and brain stem weights and Day 21 body mass did not differ between groups either on the basis of exposure group or severity of convulsion. Analysis of additional behavioral parameters and neural biochemistry assays is in progress.

It is apparent from these initial results that humans and rats share a decreasing susceptibility to febrile convulsions during comparable periods of brain development. Further, it again demonstrates that MW hyperthermia promises to be a powerful research tool in the area of febrile convulsions.

169.1 SAFETY MARGIN OF NEUROMUSCULAR TRANSMISSION IN RAT EXTRAOCULAR MUSCLE. Yong I. Kim*, Daniel S. Zahm*, Humphrey H. Liu* and T. R. Johns. Dept. of Neurology and Div. of Biomedical Engineering, University of Virginia School of Medicine, Charlottesville, VA 22908.

Ocular symptoms such as ptosis and diplopia are present at onset in more than 65% of patients with myasthenia gravis (MG) and in approximately 10% of these patients the disease remains confined to extraocular muscles. Ocular myasthenia gravis may simply be a mild form of generalized MG, reflecting low titers of anti-acetylcholine receptor antibodies, or it could result from a different pathogenesis.

In an attempt to understand more about the disease process, we have examined the safety margin of neuromuscular transmission at singly innervated extraocular myoneural junctions (80-90% of the extraocular muscle fibers are singly innervated) and compared it with that in forelimb muscle of normal rats. In addition, rats with experimental autoimmune myasthenia gravis (EAMG) were also examined.

Using conventional intracellular recording and an on-line microcomputer system, experiments were performed on superior oblique extraocular muscle (EOM) and forelimb flexor digitorum longus (FDL) muscle in female Lewis rats.

In EOM of normal rats the amplitude of miniature end-plate potentials (MEPPs) was approximately twice the value recorded in FDL. This increase could be attributed to smaller EOM fiber diameter. MEPP frequency in the two muscles was not significantly different. MEPP and end-plate potential (EPP) waveforms were also similar in EOM and FDL. Impulse-evoked EPPs of EOM, measured in the presence of 0.6 µg/ml d-tubocurarine (dTC), were 36% smaller than the EPPs of FDL. Direct quantal content analysis, performed in the presence of 10 mM Mg^{++}, demonstrated that the mean number of ACh quanta released per nerve impulse is about 2 to 5 in EOM and about 10 in FDL.

The postjunctional sensitivity to dTC was measured as percent reduction in MEPP amplitude produced by low concentrations of dTC and was similar in the two muscles. When the MEPP amplitudes were measured in both EOM and FDL of the receptor-immunized EAMG rats, approximately the same percent reductions from control values were recorded in each muscle.

These results indicate that the rat extraocular muscle has a reduced safety margin of neuromuscular transmission which is likely due to a decrease in the number of ACh quanta released from motor nerve terminals and probably involves no postsynaptic factor. We suggest that this reduced safety margin should be demonstrable in human EOM and it is partially responsible for the early appearance of ocular symptoms in MG patients. (Supported in part by a center grant from the Muscular Dystrophy Association of America)

169.2 SINGLE FIBER ELECTROMYOGRAPHIC STUDIES IN MULTIPLE SCLEROSIS, J.K.Baruah* and B.O. Khatri*, (Spon: M.P. McQuillen) Department of Neurology, The Medical College of Wisconsin, 9200 W. Wisconsin Avenue, Milwaukee, WI 53226.

Forty percent (McAlpine et al, Multiple Sclerosis, 1st ed., Livingston 1955) of patients with multiple sclerosis (MS) complain of weakness in extremeties, often present as tiredness and fatiguibility. The later significantly get worse on physical exertion. In large majority of these patients, the weakness is secondary to demyelination of corticospinal tract. However, in some the clinical dysfunction of corticospinal tract is lacking, but they still may complain of tiredness or fatigue. The possibility that this complaint might be secondary to defective neuromuscular transmission was addressed with single fiber electromyography (SFEMG) in addition to routine EMG in a group of patients with chronic progressive MS. Twenty-one patients (M = 10, F - 11) were selected for this study and all of them had significant degree of weakness in the extremeties. The routine peripheral nerve conduction, needle EMG and repeatitive stimulation (ulnar nerve at 3HZ) studies were normal in all patients. The SFEMG studies of extensive digitorum brevis muscle at multiple sites revealed prolongation of jitter values in 15/21 patients. The range of mean consecutive jitter difference in these patients was 56 - 285 µsec (normal 22 - 52 µsec). Blocking of second potentials was detected in 8/15 patients with abnormal jitter values. Serum anti-acetylcholine receptor antibody was not detected in any patient. These findings suggest that in many patients with MS, who complains of fatigue, neuromuscular transmission may be defective. The mechanism of this effect is not known. Studies are underway to ascertain whether the defect is repaired as the symtom improves.

169.3 QUANTUM CONTENT OF END-PLATE POTENTIALS IN EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS. Humphrey H. Liu*, Yong I. Kim* and T.R. Johns (SPON: G.R. Hanna). Dept. of Neurology and Div. of Biomedical Engineering, University of Virginia School of Medicine, Charlottesville, VA 22908.

Myasthenia gravis (MG) is a disease of the neuromuscular junction caused by an immune response which results in the production of autoantibodies against acetylcholine receptors (AChRs). The disease is characterized by a reduction in the number of functional AChRs, leading to a postsynaptic impairment of neuromuscular transmission. A recent study of intercostal muscle biopsies from patients with MG (Cull-Candy et al., J. Physiol. 299:621-638,1980) indicates, however, that presynaptic changes also occur at the myasthenic neuromuscular junction. The mean number of transmitter quanta (m) released from MG motor nerve terminals is significantly greater than normal, especially when $[Ca^{++}]_o$ is low. We studied the transmitter release process in rats with experimental autoimmune myasthenia gravis (EAMG) in order to determine whether a similar increase in m is demonstrable.

EAMG was induced in female Lewis rats by immunization with purified Torpedo AChR protein suspended in Freund's complete adjuvant. Age-matched control rats received saline and adjuvant. Intracellular recordings were made in vitro on flexor digitorum longus muscles 45 to 189 days after the initial immunization. In the presence of 3 mM $[Mg^{++}]_o$, mean quantal content was estimated at three different values of $[Ca^{++}]_o$, 0.25, 0.4 and 0.6 mM. At each end-plate both direct and indirect variance methods were used to calculate m and 10 to 15 end-plates were sampled in each muscle. All biopotentials and quantal release parameters were analyzed on-line using a microcomputer system.

In the range of $[Ca^{++}]_o$ studied, the mean values of m in EAMG were found to be 25 to 50% greater than normal. We found a linear relationship between log m and log $[Ca^{++}]_o$ which showed a slope of 3.2 in EAMG and 3.3 in normal muscle. The increase in evoked transmitter release, however, was not found in all receptor-immunized animals studied; a wide variation appears between different animals. The increased quantal transmitter release was also found to vary as a function of disease duration. Animals sacrificed after a prolonged period since initial immunization seemed to show a larger increase in m.

These results demonstrate a presynaptic change in the transmitter release process associated with the development of EAMG in rats. Although the mean quantal content in EAMG does not seem to increase to the extent described in human MG, such a presynaptic change is an important factor to consider in determining the overall severity of neuromuscular blockade. (Supported in part by a center grant from the Muscular Dystrophy Association of America)

169.4 IMPAIRED NEUROMUSCULAR TRANSMISSION IN STREPTOZOTOCIN INDUCED DIABETES. G.A. Ruskan* and A.B. Drakontides Dept. of Anatomy, New York Medical College, Valhalla, NY 10595.

The manifestations and consequences of diabetic peripheral neuropathies have been well documented. Although morphological studies have implicated the motor nerve terminal as a prime site of lesion, few studies have examined neuromuscular transmission in the diabetic state.

The in vitro phrenic nerve hemidiaphragm preparation from 3 and 6 month streptozotocin (STZ) diabetic rats (50 mg/kg IV) rats, and age matched controls, were used to evaluate neuromuscular function. Parameters studied were: 1) indirect isometric twitch tension 2) post-tetanic potentiation (PTP) following nerve stimulation at frequencies of 10-100 HZ 3) fatique time following continuous stimulation of nerve at 10 HZ 4) potentiating effects of edrophonium. The data were compiled from 300-400 gm diabetic rats of 3 and 6 month duration with mean blood glucose values of 401 ± 10 gm/dl and compared to age matched controls of the same weights (blood glucose 105 ± 2 mg/dl).

Indirect twitch tension in both diabetic groups was not significantly different from controls. PTP could be elicited at all frequencies tested; however, the magnitude of potentiation was reduced, the greater reduction being evident in 6 month diabetic preparations (3 month 28%, 6 month 53% decreased PTP). This decrease is not attributable to a dysfunction of muscle contractile mechanisms, since direct stimulation of diabetic diaphragms elicited the same magnitude of response as seen in control preparations. PTP in rat diaphragm primarily reflects a neurogenic post-tetanic repetition of slow muscle nerve fibers, and this decrease in PTP suggests a loss of functional capabilities of these nerve fibers. Both diabetic groups fatiqued more rapidly than controls (control 151 ± 7 sec, 3 month 87 ± 6 sec., 6 month 104 ± 9 sec.). While this decrease might reflect a metabolic deficiency, an alternative explanation might be impairment of neural transmission. Degenerating motor nerve terminals have been demonstrated in human diabetes and animal models which would support this contention. In addition a reduction in cholinesterase activity is evident. In the presence of 10^{-5} and 10^{-6} g/ml concentrations of edrophonium, single indirect tiwtch responses were significantly enhanced in 3 month diabetics (32%, 45% respectively). This effect probably reflects the diminished cholinesterase activity which increased the concentration of ACh available at the neuromuscular junction.

These studies suggest that the neuromuscular junction is an initial site affected in STZ induced diabetes. Moreover, deficits of neuromuscular transmission are evident under conditions equivalent to a moderate degree of sustained hyperglycemia.

169.PO THE USE OF COMPREHENSIVE NERVE CONDUCTION STUDIES TO DELINEATE NERVE ROOT COMPROMISE NON-INVASIVELY AND ITS ADVANTAGES OVER CONVENTIONAL NEEDLE ELECTROMYOGRAPHY. R.A. Cyrulnik*(SPON:D. Becker)
Lab for Diagnostic Non-Invasive Analysis, Huntington Beach, CA92647

Using bipolar surface stimulation and recording techniques, late F-wave and H-wave responses were measured together with orthodromic sensory nerve conduction latencies and amplitudes in the distribution of cervical and lumbosacral nerve root innervations of patients presenting with clinical signs of radiculopathy. Distal peripheral nerve conduction velocities were determined in each case to rule out peripheral neuropathy as a contributing factor to clinical or electrodiagnostic findings. Absolute latency values (upper limit 32.0 msec. in cervical region, 54.5 msec. in lumbosacral region) were used as criteria for normality as well as relative comparison with conduction in adjacent roots (upper limit 2.0 msec.) for F-wave determinations, as well as for H-wave evaluation (upper limit of normal 32.0 msec., bilateral difference under 2.0 msec.). Standard absolute criteria were used for the various sensory nerve conduction values. The results showed excellent correlation with the clinical findings as well as conventional needle electromyography with the following advantages: (1)Significantly greater patient acceptance due to marked reduction of the pain of the procedure; (2)Significantly earlier detection of pathology because axonal degeneration is not a prerequisite for abnormal conduction; (3)Enhanced sensitivity since myelin sheath compression alone will alter conduction; (4)Availability of data regarding sensory abnormalities not detectable by conventional intramuscular EMG; (5)Detection of double crush syndromes since distal conduction data must be measured; (6)Improved correlation with the clinical course of the patient associated with rapid response of conduction changes to resolution of nerve root compression; (7)Direct determination of conduction in the roots themselves rather than by inference from spontaneous muscular activity. This technique has proven a valuable adjunct to needle electromyography both as a screening procedure as well as in those cases where conventional EMG alone cannot provide sufficient data to delineate all of the clinical findings. It can also be used in those situations where the patient cannot tolerate the pain of needle electromyography or are in such muscular spasm and/or unable to relax as to render the detection of spontaneous muscular activity impossible on needle EMG, as well as where the risk of infection from an invasive procedure contraindicates needle EMG. The above advantages make this technique an attractive alternative to needle electromyography in early screening of radiculopathy as a non-invasive form of EMG. Examples will be given.

170 SYMPOSIUM

ALZHEIMER'S DISEASE AND THE CHOLINERGIC INNERVATION OF NEOCORTEX BY THE NUCLEUS BASALIS. M-M. Mesulam, Beth Israel Hospital and Harvard University (Chairman); J. Axelrod, NIH-NIMH; K. Krnjevic, McGill University; M.J. Kuhar, John Hopkins University; P. Davies*, Albert Einstein Medical College, Bronx, N.Y.; J.T. Coyle, Johns Hopkins University; D.L. Price*, Johns Hopkins University.

Mammalian neocortex contains presynaptic cholinergic elements as well as neurons that respond to cholinergic agonists. A major portion of the cholinergic innervation in neocortex arises from neurons located in the nucleus basalis of Meynert. This cholinergic corticopetal pathway appears to be selectively involved in Alzheimer's Disease.

In this symposium, J. Axelrod will provide introductory remarks. K. Krnjevic will discuss the physiology of neocortical cholinergic transmission. M.J. Kuhar will describe the distribution and pharmacological identity of cholinergic receptors in neocortex. P. Davies will provide evidence for a selective loss of neocortical presynaptic cholinergic markers in Alzheimer's Disease. M-M. Mesulam will provide histochemical evidence to show that the nucleus basalis of Meynert is a major source for the cholinergic innervation of neocortex. It will also be shown that different parts of the nucleus basalis project to different portions of the cortical mantle. J.T. Coyle will show that there is pharmacological evidence for corticopetal cholinergic innervation originating in the nucleus basalis. D.L. Price will show that the nucleus basalis is preferentially involved in Alzheimer's Disease.

The identification of this cholinergic pathway as a site of special predilection provides a basis for further research on the phenomenology, etiology and treatment of Alzheimer's Disease.

171 SYMPOSIUM. SINGLE CHANNEL RECORDING. Charles F. Stevens, Yale (Chairman); Vincent E. Dionne*, UCSD; Steven Siegelbaum*, Columbia; Gary Yellen*, Yale; Harunori Ohmori*, UCLA; David Tank*, Cornell.

During the past year, the Neher patch recording method has been applied to a variety of new systems, and has provided insights into neuronal function at the level of single channels. Talks at this symposium will focus on some of the recent advances made with this method, and highlight some of its advantages.

The acetylcholine receptor remains the best studied channel protein, but the most widely used approach, fluctuation analysis, has not provided information about states preceding the open one. Statistical analysis of single channel currents yields inferences about pre-opening steps (Dionne).

5-HT produces, through a cAMP dependent protein phosphorylation step, a decrease in molluscan potassium currents. The mechanism of this modulatory effect has been investigated at the level of individual potassium channels (Siegelbaum).

Potassium currents play a central role in regulating neuronal electrical activity. Single channel analysis reveals unexpected complexities in the behavior of channels responsible for these currents (Yellen).

GH cells, from a pituitary derived cell line, depend on calcium currents for the regulation of secretion. The function of the channels linking excitation to secretion has been analyzed for these cells (Ohmori).

Planar bilayers have typically been used in attempts to reconstitute channels for elecrophysiological study. Torpedo chloride channels have been reconstituted in lipisomes and studied by the Neher method, thereby offering an advantageous alternative to the usual planar bilayer approach (Tank).

172 SYMPOSIUM. SEX HORMONES AND NEURAL DEVELOPMENT: IMPLICATIONS FOR THE GENESIS OF SEXUAL DIFFERENTIATION. C.D. Toran-Allerand, Columbia Univ. Coll. of Physicians and Surgeons (Chairman); W.T. Greenough, Univ. of Illinois; D.B. Kelley, Columbia Univ.; A.P. Arnold, Univ. of California, Los Angeles.

In many vertebrates sex differences in various neural structures and of numerous neuroendocrine and behavioral responses results from exposure of the CNS to endogenous sex steroids during restricted developmental periods. The cellular mechanisms involved appear to represent a complex interaction of hormonal and non-hormonal factors, the relative contributions of each varying among species. This symposium will consider the broad range of structural dimorphisms which are found in a wide variety of species and the in vivo and in vitro approaches which have been used to try to characterize and analyze the hormonal and non-hormonal contributions to the ontogeny of sexual differentiation. Greenough will review and compare the various morphological differences which have been described in the brain of various mammals; their relationship to the postulated existence of sexually dimorphic interneuronal connectivity patterns and the possible mechanisms involved in their origin. Kelley will consider the hormonal and non-hormonal factors in the differentiation of the sexually dimorphic laryngeal motoneurons of the frog, Xenopus laevis, focusing on the apparent differences in the developmental mechanisms controlling neuronal number (non-hormonal) and those controlling neuronal size (hormonal). Arnold will discuss the androgen-dependent sexually dimorphic neuromuscular systems of the bird and rat, emphasizing the different types of developmental processes influenced by androgen; the existence of distinct critical periods for each effect and the possible mechanisms involved. Toran-Allerand will consider the cellular expression of the steroidal effects in cultures of the developing CNS as one approach to elucidating the morphogenetic basis for the observed sexual dimorphism of the adult.

173 WORKSHOP

SPRINGING INTO ACTION: MECHANISM AND FUNCTION OF SPRING-LIKE PROPERTIES OF NEUROMUSCULAR SYSTEMS. J.C. Houk (Chairman, Northwestern Univ. Med. Sch.), J.A. Hoffer (NIH), W.Z. Rymer (Northwestern Univ. Med. Sch.), N. Hogan (MIT), R.B. Stein (Univ. of Alberta), T.A. McMahon (Harvard Univ.).

An analogy between the musculature and mechanical springs is a common theme of several recent developments in the field of motor control. This workshop was organized to evaluate origins of spring-like properties and to discuss their functional significance in normal motor control. Houk will introduce the topic by contrasting the intrinsic mechanical stiffness of skeletal muscle with the stiffness present when spinal reflexes are operative. The former derives largely from the elasticity of cross bridges whereas the latter is an emergent property dependent on neural feedback. Hoffer will review data showing that reflexes compensate for variations in intrinsic stiffness which result from stretch or from alterations in initial conditions. Variations in reflex gain are apparent from these data, but they may represent fixed nonlinearities rather than actions of a stiffness control system. Hoffer supports the notion of stiffness regulation, though not that of stiffness control. Rymer will explore potential mechanisms for stiffness regulation by comparing motor unit and muscle receptor activity with observed indices of reflex action. He will suggest that recruitment contributes more compensation than does rate modulation and that nonlinear feedback from primary spindle receptors is the major source of compensation for stretch-induced failures in stiffness. Data will be presented showing that force feedback contributions to stiffness regulation are not prominent in reduced animal preparations. Hogan will discuss the role of viscoelasticity (dynamic stiffness) in controlling voluntary limb trajectories. Data obtained for trajectory tracking by monkey subjects will be compared with optimal models, and questions of control strategy and central programs versus peripheral feedback will be addressed. Stein will bring us back to the issue of reflex gain modulation and its potential for stiffness control. In support of the latter concept he will describe stiffness measurements obtained from locomoting mesencephalic cats and results obtained in human subjects during tasks contrasting rigid positional control with compliant force control. McMahon will relate the concepts and results presented by previous speakers to walking and running performance in man. Spring models will be used to analyze running on a circular path, in enhanced gravity and on a compliant surface. The role of elastic storage in locomotion will also be evaluated.

174.1 BEHAVIORAL AND PHYSIOLOGICAL CHARACTERIZATION OF NON-NARCOTIC ANALGESIA PRODUCED BY CHOLINERGIC MICROINJECTION IN THE PARA-BRACHIAL REGION OF THE CAT. Y. Katayama*, S. M. Carlton*, D. P. Becker and R. L. Hayes (SPON: W. I. Rosenblum). Div. of Neurosurgery, Virginia Commonwealth Univ. Richmond, VA 23298.

Two guide tubes (26 gauge) were chronically implanted bilaterally through the cerebellum of 20 cats. After recovery from surgery, awake, unanesthetized cats were loosely restrained in canvas bags. Carbachol (0.3-0.6 µg in 0.15-0.3 µl of 0.9% saline, bilaterally, pH 7.4) was microinjected at 4 day intervals through 33 gauge cannulae into various brain stem loci. Four behavioral tests qualified nociceptive responses: tail withdrawal from noxious heat, applications of calibrated pinch to the extremities, subcutaneous injections of formalin and brief applications of alligator clips to the extremities. Additional tests examined other sensory and motor abilities, including studies of righting and placing reflexes, startle responses and locomotion. Over 50 sites were studied. Analgesic sites (n=20) were distributed around the dorsolateral half of the brachium conjunctivum (BC) from the marginal nucleus of BC, caudally, to the parabrachial reticular formation, rostrally. Some medial sites in this region produced analgesia associated with reduced spontaneous activity. The majority of analgesic animals showed marked suppression of all nociceptive behaviors in the absence of any evidence of motor or other sensory disturbances. Microinjection of 0.6 µg carbachol bilaterally produced suppression of the tail-flick reflex comparable to that produced by morphine (2.0 mg/kg, s.c.). Atropine either microinjected (1.0 µg in 0.5 µl, bilat., n=4) or systemically administered (0.5 mg/kg, i.v., n=8) after microinjection of carbachol significantly antagonized carbachol analgesia. Mecamylamine had no effect on carbachol analgesia either when microinjected (0.3 µg in 0.2 µl, bilat., n=4) or systemically administered (0.5 mg/kg, i.v., n=4) after carbachol microinjection. Naloxone (2.0 mg/kg) administered either before carbachol microinjection (i.p., n=4) or after carbachol analgesia (i.v., n=4) had no effect. No analgesia was produced by morphine microinjection (25 µg in 0.5 µl, bilat., n=4) into the same sites associated with carbachol analgesia.

These data suggest that: (1) supraspinal sites in the cat parabrachial region can selectively modulate the integration of nociceptive responses at the level of the spinal cord, (2) activity at these sites is influenced by muscarinic cholinergic rather than opiate mechanisms. Supported by NIH Grant #NS12587.

174.2 EVIDENCE FOR THE INVOLVEMENT OF HISTAMINE IN STRESS ANALGESIA. G.W. Terman*, J.W. Lewis, and J.C. Liebeskind, Department of Psychology, University of California, Los Angeles, CA. 90024.

In the past decade, much evidence has accumulated in support of the existence in the brain of a system whose natural function is to decrease the perception of pain. Numerous observations that stress can reduce pain responsiveness have suggested that stress may be a natural trigger for activating this system. Stress-induced analgesia, however, does not appear to be a unitary phenomenon. We have found that by varying the temporal parameters of footshock stress, opioid mediated and nonopioid mediated analgesia can be differentially produced (Lewis et al., 1980). Although several chemical mediators for the opioid form of stress analgesia have been suggested, the neurochemistry of the nonopioid form is less well understood. In this regard, we have recently reported that nonopioid stress analgesia, while resistant to serotonin, norepinephrine, and dopamine receptor antagonists and depletors, is attenuated by the histamine H_1 receptor antagonist, diphenhydramine (Terman et al., 1982). The present study was undertaken in an attempt to extend these results suggesting a role for histamine in stress analgesia.

Twenty male Sprague-Dawley rats were randomly divided into two groups. One group was injected with saline (i.p.), the other with α-fluoromethylhistidine (αFMH) (100 mg/kg, i.p.). αFMH is an irreversible inhibitor of L-histidine decarboxylase and has been seen to disrupt histamine synthesis in the rat liver (Kollonitsch et al., 1978) and the mouse brain (Garbarg et al., 1980). In mice, this disruption is particularly effective in depleting the rapidly turning over neuronal stores of histamine. Eight hours after drug or saline injection, each animal was tested for baseline pain responsiveness using the tail-flick test. Rats were then subjected to footshock stress according to the parameters known to produce nonopioid analgesia (3 min, 2.5 mA, 60 Hz sine waves on continuously). Recording of tail-flick latencies began one min after stress and continued at one min intervals for 12 min. Animals given αFMH, while not differing significantly from controls on baseline tail-flick latencies, were significantly less analgesic than controls after footshock ($p < .05$). These results support our previous findings suggesting that histamine plays a significant role in mediating the nonopioid form of stress-induced analgesia. (We thank Merck, Sharp, and Dohme for the generous gift of α-fluoromethylhistidine. Supported by NIH grant NS07628. G.W.T. was supported by training grant MH15795.)

174.3 CROSS-TOLERANCE BETWEEN OPIOID MEDIATED STIMULATION-PRODUCED AND STRESS-INDUCED ANALGESIA. E.R. Penner*, G.W. Terman*, and J.C. Liebeskind. Dept. of Psychology, University of California, Los Angeles, CA. 90024. (SPON: D.B. Lindsley)

Cross-tolerance experiments have proven to be a useful tool for demonstrating separate activation of a common neurochemical pathway. For example, analgesia produced by electrical stimulation of the midbrain periaqueductal gray matter has been found to manifest tolerance and cross-tolerance with morphine analgesia (Mayer and Hayes, 1975). This finding suggested that stimulation-produced analgesia (SPA) involves activation of the same endogenous pain-inhibitory system as that activated by morphine. More recently, stress has been suggested as a natural activator of this system. Numerous stressors have been reported to produce analgesia. We have demonstrated that naloxone-sensitive (opioid) and -insensitive (nonopioid) stress analgesia can be differentially produced by varying the temporal parameters of the footshock stress administered (Lewis et al., 1980). Moreover, the opioid but not the nonopioid form of stress analgesia shows tolerance and cross-tolerance with morphine (Lewis et al., 1981). Like stress analgesia, SPA has also been found to be mediated by both opioid and nonopioid mechanisms depending on the specific location of the stimulation site (Cannon et al., in press). Stimulation sites in ventral PAG cause naloxone-sensitive SPA, whereas sites in dorsal PAG cause naloxone-insensitive SPA. In this study we investigated whether the opioid forms of SPA and stress analgesia are mediated via the same pain inhibitory system, by testing for cross-tolerance between them.

Twenty-four male Sprague-Dawley rats were implanted with quadrupolar stimulating electrodes, with bipolar electrode sites in dorsal and ventral PAG. One week after surgery animals were tested for dorsal and ventral baseline SPA current thresholds, then divided randomly into two groups. For the following 14 days one group received footshock daily using parameters known to produce opioid analgesia (2.5 mA, 1 sec pulse/5 sec; 60 Hz sine waves for 20 min); the other group served as non-shocked controls. On the 15th day animals were again tested for dorsal and ventral SPA thresholds. In non-shocked animals baseline threshold values were not found to differ from final threshold values at either dorsal or ventral electrode sites. Shocked animals, however, while not showing any differences between baseline and final SPA thresholds for dorsal placements, did have final ventral thresholds that were significantly increased above baseline ($p < .01$). The present findings support the view that the opioid forms of SPA and stress analgesia are mediated by a common opioid pathway. (Supported by NIH grant NS07628. G.W.T. was supported by training grant MH15795.)

174.4 THE EFFECT ON NOCICEPTION IN RATS OF DIRECT APPLICATION OF SUBSTANCE P AND 5-HYDROXYTRYPTAMINE INTO THE NUCLEUS RAPHE MAGNUS. DONALD E. WILLIAMS. DEPARTMENT OF PSYCHOLOGY, UNIVERSITY OF GEORGIA, ATHENS, GEORGIA 30609.

The nucleus raphe magnus (NRM) contains serotonergic neurons which project to the spinal cord dorsal horn via the dorsolateral funiculus where they inhibit pain-conducting neurons. The NRM receives a projection from the periaqueductal gray (PAG), and NRM neurons are activated by electrical stimulation or morphine microinjections in the PAG.

Although PAG stimulation elicits responses from NRM neurons, little is known about the neurotransmitters that mediate these responses. Serotonergic projections from various brainstem nuclei to NRM have been described, however the effects of serotonin (5-HT) on NRM neurons is unknown. Substance P (SP) has been found in PAG cell bodies and in axon terminals within NRM. SP and 5-HT coexist in NRM neurons and autoreceptive, reuptake, and storage mechanisms for SP and 5-HT have been suggested. Single cell recordings have shown SP to excite NRM neurons. Thus, SP and 5-HT have been implicated as two possible modulatory transmitters in NRM-mediated analgesia. This hypothesis was tested using a tail flick response to heat following injection of SP or 5-HT into the rat NRM.

Since all NRM sites have been shown upon stimulation to suppress tail flick responses equally well, all injections were made through cannulae guides implanted in the dorsal NRM. Each injection was performed manually over 30sec. using a microsyringe and injector fitted to the cannula guide. 27 male rats (9/group) were tested for tail flick latency before (baseline), and 25 (T25) and 60 (T60) minutes after NRM injections of SP (2.5µg/0.5µl), 5-HT (10.0µg/0.5µl), or vehicle (saline; 0.5µl). 9 non-operated control subjects were tested similarly.

At baseline, there were no differences between groups. At T25, 5-HT subjects displayed longer latency scores ($p<0.01$). SP T25 and 5-HT T60 subjects approached showing significantly longer latencies ($p<0.10$). 3 additional subjects received a higher SP dose (5.0µg/0.5µl) and were tested without significant results.

The results suggest that SP at the given doses does not produce significant analgesia when applied directly to NRM, questioning its role as an important transmitter in NRM-mediated analgesia Rather, SP may act as a neuromodulator within NRM. The data also suggest that 5-HT may be important in endogenous analgesia by exerting an excitatory effect on NRM neurons; an effect similar to its hypothesized action on enkephalinergic interneurons in the spinal cord dorsal horn. The data in general are in accord with previous conclusions that serotonergic afferent NRM projections may subserve the descending pain control system and thus deserve further study.

174.5 MONOAMINES AS MEDIATORS OF THE ANALGESIC ACTION OF BACLOFEN. J.Sawynok, Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

Baclofen, an antispastic agent, can produce analgesia by actions at both spinal and supraspinal sites. Baclofen is similar to morphine in that it is effective administered into the periaqueductal grey while analgesia resulting from systemic injection is reduced by spinal cord section. Descending monoaminergic pathways are implicated in the analgesic action of morphine. In the present study, the role of monoamines in the analgesic action of baclofen was investigated.

Analgesia was evaluataed using the tail flick and hot plate tests and male Sprague Dawley rats (150-250g). Both reserpine (5 mg/kg, 18 hrs pretreatment) and α-methyl-p-tyrosine (250 mg/kg, 18 hrs pretreatment), which deplete brain catecholamine content, markedly potentiated the analgesic action of baclofen (10 mg/kg) administered intraperitoneally at all time intervals during the 3 hr observation period. The receptor antagonists phentolamine (5 mg/kg) and haloperidol (0.5 mg/kg) produced a similar potentiation. Reserpine, phentolamine and haloperidol alone were without significant effect on reaction latency, while α-methyl-p-tyrosine produced a slight but significant increase in tail flick latency. Agents interfering with serotonergic function by depletion (p-chlorophenylalanine, 300 mg/kg, 48 hrs pretreatment) or receptor antagonism (methysergide, 5-10 mg/kg) did not consistently alter the analgesic action of baclofen. When baclofen was administerd intrathecally (0.5 µg), reserpine and α-methyl-p-tyrosine did not potentiate analgesia for one hour following injection, but did to a mild degree at later time intervals. In these experiments, it is likely that baclofen initially was localized to the spinal cord but subsequently spread to supraspinal sites.

These results indicate that a decrease in catecholaminergic function enhances the analgesic action of baclofen, probably by an action at supraspinal sites. Serotonin does not appear to be critical for the expression of analgesia.

174.6 LATERAL HYPOTHALAMIC REWARD SITES YIELDING POSITIVE AND NEGATIVE STIMULATION-BOUND FEEDING RESPECTIVELY ATTENUATE AND POTENTIATE AVERSION. P. E. Simson* and E. E. Coons* (SPON: L. Brown). Dept. of Psychology, New York University, New York 10003.

In rats electrical stimulation of the lateral hypothalamus (LH) at reward sites which also elicited stimulation-bound feeding decreased lever pressing for 3-second interruptions of otherwise continuous trains of pulses to the pain-implicated nucleus reticularis gigantocellularis (NGC). This ameliorative effect occurred at currents both above and below those necessary to support classical self-stimulation and increased in magnitude with increases in current over a considerable microamperage range. By contrast, electrical stimulation at LH reward sites which did not elicit stimulation-bound feeding increased lever pressing to escape NGC stimulation. This potentiation of escape also occurred at currents both above and below those necessary to support self-stimulation and increased with increases in LH current amplitude. Thus, currents supporting self-stimulation behavior can have opposite effects on NGC-escape depending on whether or not there is also elicitable from the LH site an appetitive motivational state. These findings amplify previous reports from our laboratory (Carr, K. D. and Coons, E. E., Science 215, 1516, 1982) that the LH aversion-ameliorative mechanism is directly dependent on motivational rather than reward mechanisms activated by the LH stimulation. The existence of aversion-ameliorative mechanisms associated only with reward sites yielding feeding has implications for the observation that an escape component in self-stimulation behavior (reward-escape) is not associated with such sites as it is with others.

174.7 MEDIAL FOREBRAIN BUNDLE LESIONS IN THE RAT: THE EFFECTS OF STRAIN AND SHOCK PARAMETERS ON FOOTSHOCK SENSITIVITY. C. E. Lints and N. Mogharreban*. Dept. of Psychology, Northern Illinois Univ., DeKalb, IL 60115.

Bilateral medial forebrain bundle (MFB) lesions have been reported to produce an increased sensitivity to footshock in rats that has been interpreted as hyperalgesia and been related to the forebrain serotonin (5-HT) depletion produced by these same lesions. After difficulty replicating the effect in this laboratory, it was shown to be sensitive to the shock parameters used in testing (Lints, Nenja and Miller, Neurosci. Abstr., 5: 613, 1979). To examine the possibility that the strain of rat is also important, this experiment was designed to compare the effects of various shock parameters on footshock sensitivity in two different strains of rats with MFB lesions.

Sham-operated and MFB-lesioned rats of both the Holtzman Sprague-Dawley (Albino-MFB) and Long Evans (Hooded-MFB) strains were retested for footshock sensitivity using the flinch-jump technique, a custom-made shocker, and 3 different shock durations (.05, .1 and .2 sec). The animals were then tested with a Coulbourn (Model E13-33) shocker using the .1 sec shock duration. Both shockers were constant current devices that delivered ac current to the grids of the test chambers, and the rats were always retested in the same chambers. Following behavioral testing the forebrains were assayed for 5-HT and norepinephrine (NE) levels and the brainstems were used for histological verification of the locus and extent of the lesions.

The lesions were well-localized, and produced comparable forebrain 5-HT and NE depletions. With the custom shocker the Albino-MFB rats showed significantly lower flinch and jump thresholds than their controls with all 3 shock durations. The Hooded-MFB rats had lower flinch thresholds than their controls only with the .05 sec duration shocks, and lower jump thresholds only with the .1 sec duration shocks. With the .1 sec shocks the Hooded-Controls had significantly lower jump thresholds than the Albino-Controls. When retested with the Coulbourn shocker, the Albino-MFB rats were not different from their controls with respect to either flinch or jump thresholds and the Hooded-MFB rats showed significantly elevated flinch and jump thresholds. The shocker effect was replicated for both strains of rats in a separate experiment. The results of these experiments are discussed in terms of the differential sensitivity of the two strains of rats to footshock and the relationship of this measure of footshock sensitivity to pain sensitivity.

174.8 ENDOGENOUS ANTINOCICEPTION IN THE PREGNANT RAT. June L. Dahl†, Stephen T. Tiffany* and Timothy B. Baker*. Departments of Pharmacology† and Psychology, University of Wisconsin - Madison, Madison, WI 53706.

Although there is considerable evidence for endogenous mechanisms of pain inhibition, the physiological and psychological factors which control their activation have not been clearly elucidated. It has been shown that a variety of stressors produce analgesia in experimental animals. Gintzler has reported (Science 210, 193, 1980) that response to painful stimuli is reduced during pregnancy and parturition in the rat. We have initiated a series of experiments designed to define the neurochemical basis of the altered pain response during pregnancy. Sprague Dawley rats, with ad lib food and water, were individually housed and maintained on a 12-hour, light-dark cycle. In two initial studies, pregnant and nonpregnant rats did not differ in antinociception assessed by the tail flick procedure. This finding was substantiated in a third study in which measurements were made from the 5th day of gestation until one day after parturition. Data were analyzed by analysis of variance with the Greenhouse-Geisser correction for repeated measures. Across test days, a repeated measures analysis of variance revealed no significant differences in tail flick latencies between the pregnant and nonpregnant groups. Neither were there any significant interactions between pregnancy and other parameters, e.g., test day, time of test, p's > 0.05. However, when antinociception was assessed by an automated flinch/jump procedure, there was an overall group difference between pregnant and nonpregnant animals, $F(1,17) = 13.35$, $p < 0.01$. There was also a significant interaction between pregnancy and shock level such that group differences were greater at the higher shock levels $F(4,68) = 4.69$, $p < 0.01$, a finding typical of opiate induced analgesias. At one day postpartum, groups did not differ in flinch/jump response. Our flinch/jump data, and the absence of differences with the tail flick measure, indicate that the ability to demonstrate antinociception accompanying pregnancy is dependent on the nature of the analgesia assessment procedure. We are currently conducting studies designed to reveal whether pregnancy-induced antinociception is naloxone reversible and whether it is associated with changes in levels of brain opiate peptides as determined by radioimmunoassay. Supported in part by funds provided by the Research Committee of the Medical School (JLD) and by NIDA grant RO1DA02729-02 (TBB).

174.9 POTENTIATION OF COLD SWIM STRESS ANALGESIA BY DIAZEPAM. Donald S. Leitner and Dennis D. Kelly Dept. of Psychiatry, Columbia Univ. and NYS Psychiatric Institute, New York, New York.

Acute exposure to a stressor can elevate pain thresholds for a period that outlasts the exposure. Stress appears to be a necessary, if not sufficient, condition for inducing analgesia. Thus, physiological manipulations known to alter the experience of stress should modulate the analgesia prompted by an effective analgesic stressor. Diazepam, a minor tranquilizer, releases behavior suppressed by punishment and attentuates a number of stress-related, aversively controlled behaviors, such as pain-induced fighting and avoidance. We examined whether it might similarly attenuate the prolonged analgesia induced by a forced swim in cold water. In fact, it had the opposite effect.

In Exp I 11 rats were exposed to six conditions. In the first two, the rats were injected IP with 2mg/kg diazepam (DZP) either (1) 30 mins before, or (2) immediately following, a 3.5-min swim in 2°C water; flinch-jump testing occurred 30 mins following the swim. In two no-stress conditions the rats received similar DZP injections either (3) 30 mins or (4) 60 mins before testing. In two drug-free baseline conditions the subjects were exposed (5) to a cold-water swim 30 mins before testing or (6) to flinch-jump testing alone. Each rat was exposed to all six conditions in a Latin square sequence. DZP administered either before or after a swim significantly increased the amount of stress analgesia (conditions 1 and 2 vs 5). Yet, DZP by itself had no affect upon thresholds at the same post-injection intervals (3 and 4 vs 6). Thus DZP potentiates stress-induced analgesia without affecting normal pain thresholds and does not have to be present during exposure to the stressor to enhance subsequent analgesia.

Because the benzodiazepines have both anxiolytic and sedative properties and because the latter, but not the former, habituate with chronic dosage, the effects of long-term DZP administration were examined in Exp II. Ten naive rats were injected daily with 2 mg/kg DZP for 20 days. They were then exposed to conditions 1, 4, 5 and 6 as in Exp I. The results in the chronically dosed, DZP tolerant, animals were the same as in the acutely dosed rats.

Exp III examined the effects of DZP upon thermoregulation. Ten chronically dosed rats and nine DZP-naive rats were exposed to four conditions: DZP plus swim 30 mins later; DZP alone; vehicle plus swim; vehicle alone. Core temperatures were monitored before and 15, 30, 45, 60 and 90 mins postinjection. In both chronic and acute dosage, DZP was correlated with a larger temperature drop and a more prolonged course of recovery. Hence DZP may potentiate cold-water swim stress analgesia by altering the subject's experience of, or recovery from, the stressor, rather than by affecting the analgesic process triggered by exposure to stress.

174.10 CHARACTERIZATION OF STRESS-RELATED RESPONSES IN THE MONOSODIUM GLUTAMATE TREATED RAT. D. Badillo-Martinez, N. Nicotera, P. Butler, A.L. Kirchgessner, E. Sperber, and R.J. Bodnar. Dept. of Psychology, Queens College, C.U.N.Y., Flushing, NY 11367.

Medial-basal hypothalamic damage following neonatal administration of monosodium glutamate (MSG) produces analgesic deficits, suggesting that this brain region may be part of an intrinsic pain-inhibitory system. Alternatively, such destruction may interfere with the processing of the stressful consequences of a given stimulus condition. To distinguish between these competing hypotheses, neonatal rats received either a high dose (HMSG: 2 g/kg on days 2 & 4: 4 g/kg on days 6, 8 & 10), a low dose (LMSG: 1 g/kg on days 2 & 4; 2 g/kg on days 6, 8 & 10) or a saline vehicle (SAL). Beginning at 80 days of age, flinch-jump thresholds, thermoregulatory and activity levels were determined following a 2°C swim for 3.5 min (CWS). Pain thresholds, hyperphagia and activity levels were also determined following selected doses of 2-deoxy-D-glucose (2DG). While all groups displayed significant CWS analgesia, the HMSG group showed significantly attenuated effects. Moreover, the HMSG group displayed initial 2DG analgesia at lower doses, but the magnitude of 2DG analgesia across doses was greater in SAL rats. While pre-swim thermoregulation was similar across groups, CWS hypothermia was more pronounced in SAL and LMSG groups (12-14°C) than in HMSG rats (8°C). Furthermore, hypothermia persisted over 1 h in SAL and LMSG rats, but only 0.5 h in HMSG rats, indicating that CWS analgesic deficits of HMSG rats co-vary with its inability to thermoregulate properly following stress. Since CWS induced hypoactivity similarly across groups, this measure failed to co-vary with hypothermic and analgesic deficits. Hyperphagia occurred from 1-5 h after 2DG (650 mg/kg) in SAL rats, but was delayed in LMSG (hours 3-5) and HMSG (hour 5) rats. Hyperphagia was delayed following a 1200 mg/kg 2DG dose in SAL and LMSG rats and absent in HMSG rats, indicating further co-variance between analgesic and hyperphagic deficits. 2DG hypoactivity failed to dissociate the groups. These data suggest that the analgesic deficits following HMSG may be due to an inability to process normally the stressful consequences following exposure to a given stimulus and then subsequently dispay compensatory responses elicited by those stressful consequences. Supported by NIH GRSG 5-S05-RR-07064.

174.11 THE EFFECTS OF ADRENALECTOMY AND DEXAMETHASONE ON THE ANTIOCICEPTIVE EFFECTS OF PHYSOSTIGMINE USING THE RAT TAIL FLICK TEST. J.A. Romano, J.M. King. US Army Medical Research Institute for Chemical Defense, Aberdeen Proving Ground, MD 21010.

Physostigmine, a cholinesterase inhibitor, has been shown to produce antinociceptive responses on the tail flick, flinch jump, hot plate, and tail pinch tests. Certain authors have considered these effects to be mediated by the pituitary-adrenal axis, implying parallels between physostigmine-and stress-produced antinociception. Stress produced analgesia has been shown to be potentiated by adrenalectomy (Pharmacol. Biochem. Behav., 1982, 16:403) and attenuated by dexamethasone (Trans. Amer. Soc. Neurochem, 1981, 12:89). The present study addressed the hypotheses that physostigmine antinociception may be potentiated by adrenalectomy and attenuated by dexamethasone pretreatment.

Seventy adult male Sprague Dawley rats weighing between 225 and 370g were treated on the rat tail flick test (TF). An automated TF apparatus was used with a stimulus temperature of 69.1°C at focal point. Cutoff time for TF latencies was 15 seconds. Animals were tested on two occasions five days apart. Three pre-and three post drug trials were used on each occasion. In a first experiment sham operated animals who received 0.32mg/kg physostigmine salicylate (i.p.) showed elevation of TF post-drug scores on Day 1 followed by no elevation of post-drug TF scores Day 6. On the other hand adrenalectomized animals receiving 0.32mg/kg physostigmine showed statistically significant elevations in post-drug latencies even on Day 6, the second occasion of TF testing.

In a second experiment 0.65mg/kg physostigmine was given to intact animals on two occasions five days apart. These animals also received the synthetic glucocorticoid dexamethasone sodium phosphate (500µg/kg i.p. on Days 4 and 5 and 200µg/kg on Day 6 two hours prior to injection of physostigmine) or saline-control injections. In dexamethasone-treated animals the antinociceptive effect of 0.65mg/kg physostigmine on Day 6 was reduced to nearly one-half of Day 1 effect. On the other hand control animals receiving saline injections in place of dexamethasone did not manifest any reduction of the physostigmine antinociceptive effect. The elevation of the antinociceptive effects of physostigmine by adrenalectomy and the reduction of such effects following dexamethasone suggests that these effects may be mediated through hypothalamic-pituitary-adrenal mechanisms.

174.12 REGIONAL AND LATERAL SPECIFICITY OF BLOOD AND URINE FACTORS INHIBITING FLEXOR WITHDRAWAL REFLEXES IN UNANESTHETIZED RABBITS. A.E.U. Edisen, Y.K. Liu,* W. McMunn,* J. Salinas,* D. Quick,* B. Chandler,* L. Trevino* and R. Wayne*. Div. AH&LS, Univ. of Texas at San Antonio, Texas 78285.

Unanesthetized New Zealand albino rabbits, lightly restrained and in the prone position, were given electroacupuncture stimulation through needle electrodes in acupuncture points Bladder 49 (in the hip region) and Stomach 36 (motor point of the Tibialis Anterior muscle) in one hind limb. Stimulation by biphasic pulses, 0.3 msec. in duration, 2-4 Hz, and ranging from 1.5 to 10 Volts, for 45 to 90 minutes produced a region of insensitivity to pin pricks on the dorsal and lateral surface of the thigh, ipsilateral to the side of stimulation. This analgesic effect was confined to the dorsal and lateral thigh, sometimes extending to upper calf, but not to the ankle, plantar surface of the foot, back, sides or forelimbs. The animals were then sacrificed, blood drained into beakers containing heparin or citrate solution, centrifuged for 5 min. at 2500 rpm at 0°C to prepare plasma. Whole blood was allowed to clot to prepare serum and urine was expressed from the bladders of these donor animals. Unanesthetized naive rabbits with brisk active flexor withdrawal responses of both hind limbs were used as recipients for intravenous infusion of plasma, serum or urine through the marginal ear vein. Doses of these substances ranged from 3-10 ml/Kg and were well tolerated at the temperatures used, 0°C, 10°C, 20°C and 37°C. The pH of urine was 8.5. Analgesia, as indicated by decrease and eventual loss of flexor reflexes to strong pin pricks, appeared in the dorsal and lateral thigh region, sometimes in the upper calf, but not in other regions, within 15 to 75 minutes after infusion and was confined to the same side of the body, left or right, as that of the donor animal. In some recipients, a similar region of analgesia appeared 1.5 to 2 hours later in the contralateral limb. Analgesia persisted up to 2.5 days, and in one case, up to 5 days. These results indicate that substances produced by peripheral nerve stimulation, acupuncture, possess regional and lateral specificity of inhibitory action on flexor reflexes elicited by mechanical stimulation.

174.13 PAIN SENSITIVITY AND PLASMA ENDOCRINE LEVELS IN MAN FOLLOWING LONG-DISTANCE RUNNING: EFFECTS OF NALOXONE. M. Glusman, M.N. Janal*, E.W.D. Colt* and W.C. Clark. Dept. of Psychiatry, Columbia Univ. and NYS Psychiatric Inst., New York, NY 10032

Twelve long-distance runners (mean weekly mileage = 39.85) served as subjects in an investigation of stress-induced analgesia in man and its response to naloxone. Subjects were tested, in a randomly assigned counterbalanced order, on the ischemic pain test for a maximum of 15 min, the cold pressor test for a maximum of 3 min, and a thermal heat test with stimulus intensities of 0, 40, 60, 330, 350, 380 and 400 mcal/sec/sq cm and 3 sec duration. Responses to each of the three tests used an appropriate category rating scale of subjective intensity ranging from nothing to severe pain. Blood was drawn for determination of plasma levels of beta-endorphin (BE) like immunoreactive material, i.e. beta-endorphin and beta-LPH, human growth hormone (HGH), ACTH and prolactin (PRL). Each of these procedures was undertaken before and after a 6 mile run completed in approximately 35 min. Subjects participated on two occasions in a double-blind, counterbalanced design: on one day they received two intravenous injections of 0.8 mg naloxone at 15 min intervals following the run; on the other day, two equal volume injections of normal saline.

Results: Sensory decision theory analysis of the thermal test data showed decreased discriminability, P(A), following the saline control run ($p < .05$), a result consistent with an analgesic effect. This response was partially attenuated by naloxone. Response bias, B, was unaffected. The cold-pressor and ischemic pain tests suggested decreased sensitivity to pain following the saline run, but the results did not reach statistical significance. Naloxone tended to produce divergent results on the post-run cold-pressor and ischemic pain tests, enhancing pain sensitivity in the former and decreasing it in the latter; but again the results did not attain statistical significance.

Plasma levels of HGH, PRL, ACTH and BE were substantially increased by the 6 mile run. HGH was increased 15-fold over the resting level, PRL 5-fold, ACTH 3-fold and BE 2-fold.

The results suggest that long-distance running produces stress-induced analgesia in man. The effect of naloxone was not clear-cut, varying with the pain test used.

175.1 STIMULATION INDUCED INGESTION IN NEONATAL RATS, Timothy H. Moran*, Gary J. Schwartz* and Elliott M. Blass. Department of Psychology, Johns Hopkins University, Baltimore, Maryland 21218.

Three, 6, 10 and 15-day-old rat pups received 500msec pulse trains of electrical stimulation to the medial forebrain bundle (MFB) at the level of the lateral hypothalamus in the presence of milk. Pups receiving stimulation ingested more milk than littermate controls during the half hour test at 3, 6, and 10 days of age. Day 15 pups did not show this response to stimulation. Stimulated pups were more active than controls through Day 10 and exhibited mouthing, licking, gaping, stretch and even lordosis responses at younger ages. Pups' responses to stimulation became more directed to ingestion with increasing age. The responses to stimulation in the presence of milk were compared to those in an environment without goal objects. Milk augments the activation of stimulation, increasing the incidence of all behaviors in 3-day-old pups, and channels the behavior of older pups into ingestion. Behaviors incompatible with ingestion such as lordosis are selectively inhibited in responses to stimulation in the presence of milk in Day 10 pups. These results suggest a high degree of behavioral organization in neonatal rats that becomes more goal directed with age.

175.2 LONGTERM RETENTION OF CLASSICALLY CONDITIONED RESPONDING IN NEONATAL RATS. Ingrid B. Johanson and W. G. Hall. NC Div. of Mental Health Research Section, Raleigh, NC 27611.

Deprived infant rats as young as 1 day of age respond to oral milk infusions with an impressive behavioral activation, characterized by mouthing, probing, and vigorous locomotion. Components of this behavioral activation can come to be elicited by a neutral odor cue that has been repeatedly paired with milk infusions. The purpose of the present study was to assess long-term retention of such classically-conditioned responding.

Litters of 1-, 3-, and 6-day-old rats were removed from their mothers 24 hr before training. From each litter (n = 9-10 at each age), 3 pups were given 15 pairings of cedar odor with milk (C/M;10 sec of cedar with a milk infusion the last 5 sec; 4 min ITI); 3 pups received milk infusions prior to cedar exposure (M/C); and 3 received cedar exposure only (C). Thus each litter consisted of 3 triplets (C/M, M/C, and C), and each triplet was assessed for retention at 1 of 3 retention intervals. Ten min after training, pups were given 5 10-sec exposures to cedar odor, 2 min apart. During these "CS only" trials, activity, mouthing and probing were scored in the minute following each odor exposure. Pups were then returned to their mother and were left undisturbed until they were deprived 24 hr prior to testing for retention (5 "CS only" trials). For 1-day-olds, retention was tested 1, 2, or 3 days following training; for 3- and 6-day-olds, retention was tested 3, 6, or 9 days later.

Pups conditioned at 1 day of age mouthed and probed more than controls 1 day following training, although there was no evidence of retention 2 or 3 days after training. However, pups (n = 7) that were tested 1 day after training and again at 3 days showed conditioned activity and mouthing 3 days after training. That is, exposure to the CS 1 day after training maintained the effects of training for up to 3 days.

Pups that were trained at older ages retained the effects of conditioning for even longer periods of time. Pups conditioned at 3 days of age were more active and mouthed and probed more than controls 3 days after training, and they probed more than controls 6 days later. There was no evidence of retention 9 days after training. Similarly, pups trained at 6 days of age retained both conditioned mouthing and probing for up to 6 days, and retained conditioned mouthing up to 9 days after the original training. The pattern of responding that occurred in tests of retention was in general typical of the pup's age at retention testing, rather than its age at training.

In summary, these findings indicate substantial long-term retention of a brief appetitive learning experience that occurred in the first few days after birth.

175.3 DIETARY COMPONENT SELECTION BY GENETICALLY OBESE AND LEAN ZUCKER RATS: THE EFFECT OF ADRENALECTOMY. T.W. Castonguay* and J.S. Stern* (Spon: V. Mendel). Nutrition Department and Food Intake Laboratory, Univ. Ca., Davis, Davis, CA 95616.

Adult obese Zucker rats typically eat more than their lean littermates. Although several theories have been proposed to account for this hyperphagia, little is known about how obese rats control the quality of the foods they ingest. Yukimura and Bray (Endocrin. Res. Commun. 5:189-198, 1978) have shown that adrenalectomy can limit overeating and weight gain of the obese rat. The purpose of the present experiment was to determine if adrenalectomy would alter selection patterns of 10 week old obese and lean Zucker rats when they were provided with three macronutrient sources: a protein source, a carbohydrate source and a fat source.

After a seven day baseline period, half of the obese and lean female rats were given bilateral adrenalectomies under Metofane anaesthesia. The remaining half were given sham adrenalectomies. All four groups of rats were then allowed to select their own diets for an additional nine days.

During the baseline period, obese rats ate 20% more calories per day than lean rats. After adrenalectomy, lean adrenalectomized rats and both sham groups did not alter either caloric intake or dietary selection patterns. By contrast, caloric intake of obese adrenalectomized rats was reduced to 50% of its preoperative level. Although there was a tendency for the obese rats to reduce the intake of all three food sources, only the reduction in dietary fat was statistically significant. The obese sham-group selected 28% (5.0g) of their calories as carbohydrate, 30% (5.2g) as protein and 43% (3.3g) as fat. Obese adrenalectomized rats composed diets that were 28% (4.5g) carbohydrate, 34% (4.3g) protein and 38% (1.7g) fat. These differences in percentage dietary composition were not statistically significant. The obese sham-group selected a diet that was significantly higher in fat than the diet selected by the lean adrenalectomized group.

The results from this study suggest that the reduction in the intake of a composite diet may be an adaptation that is more specifically focused on the intake of one dietary fraction, i.e. dietary fat. These results are consistent with the suggestion that beta endorphin may be selectively increasing dietary fat intake in the obese rat, and that an adrenalectomy-induced rise in ACTH may have reduced endorphin activity, and thereby reduced fat intake of the obese rat.

175.4 COMPETITION BETWEEN FOOD AND BRAIN STIMULATION REWARD: A TEST OF THE REWARD HYPOTHESIS. R.A. Frank. Dept. of Psychology, Univ. of Cincinnati, Cincinnati, OH 45221.

It has been demonstrated that food intake can be dramatically reduced in some rats when brain stimulation reward (BSR) and food are placed in competition during short daily periods. This phenomenon, referred to as self-deprivation, can be observed despite food deprivation severe enough to be life threatening. Two hypotheses have been proposed as explanations for self-deprivation. According to the hunger reduction hypothesis, BSR reduces hunger and thereby decreases food intake. The reward hypothesis of self-deprivation explains reductions in food intake as the result of the greater reward value of BSR as compared to food. Although there have been several convincing demonstrations that BSR does not reduce hunger (e.g., Stutz & Rossi, Physiol. Psychol., 6:204, 1978), no direct test of the reward hypothesis has been attempted.

In order to generate data for a test of the reward hypothesis, rats were implanted with two bipolar stimulating electrodes aimed bilaterally at the ventral tegmental area. Self-deprivation tests were subsequently run for each electrode (left and right) at 40 and 60 uA. Once self-deprivation data had been collected for each electrode and current intensity, animals were given the choice between different pairs of electrode/current combinations in order to determine preferences among the combinations used in the self-deprivation test. According to the reward hypothesis, the electrode/intensity combination that is most preferred should produce the greatest self-deprivation while the least preferred combination should produce the least self-deprivation. Therefore, across all combinations of electrodes and intensities, increasing preferences should be associated with increasing self-deprivation.

The findings provide strong support for the reward hypothesis of self-deprivation. Eighty-eight percent of the predictions of preference that could be made on the basis of the self-deprivation data proved to be correct. Quantitative analyses of the data indicated that the degree of self-deprivation found for a particular electrode/current combination was a good predictor of percent choices for that same combination during a preference test.

175.5 COMPARISON OF TWO METHODS OF ESTIMATING THRESHOLDS OF INTRACRANIAL SELF-STIMULATION. G. Fouriezos and E. Nawiesniak*. BSR Lab., School of Psychology, University of Ottawa, Ottawa, Ontario. K1N 6N5.

Two methods for rapid determination of brain self-stimulation 'thresholds' were compared. The auto-titration method rewards lever-pressing with trains of lateral hypothalamic stimulation that progressively decrease in pulse frequency. Rats may restore the original frequency by depressing a second lever and the point at which they reset is deemed to be the auto-titration 'threshold' (AT). The second method offers the same descending sequence but resets are under timer control; the frequency at which rats cease to earn the stimulation is taken as the timed 'threshold' (TT). Five rats in a within-subjects design were tested in both paradigms. Both AT and TT were stable over time but AT's were consistently higher, indicating that resets were made at values that rats continued to self-administer. Doubling the frequencies in the sequence caused AT's to rise whereas TT's remained anchored at control levels. Changing only the initial frequency by 1 or 2 steps above and below the usual starting value caused AT's to rise and fall respectively whereas TT's were unaffected by this challenge. These results show that resetting behavior in autotitration does not occur at an absolute frequency but instead occurs at some value relative to the level of stimulation available immediately following a reset. The timed method was free of this problem. Both paradigms were tested for their ability to detect amphetamine's threshold-lowering effect. Rats reset at frequencies that were 90, 95, and 102% of control levels following 0.5 mg/kg ip of d-amphetamine sulfate in three tests separated by two days each. The timed method yielded 'threshold' estimates that were 68, 68, and 71% of control performance in identical tests. Together, these experiments demonstrated that the autotitration method does not measure thresholds nor does it properly detect a drug-induced change in self-stimulation threshold. A simple modification of existing implementations of autotitration, that of removing control over resets from the rats' paws, rectifies the problems.

175.6 PULSE INTENSITY versus PULSE FREQUENCY MANIPULATIONS IN BRAIN STIMULATION STUDIES. E. Miliaressis, P. P. Rompré* and A. Durivage*. Ecole de Psychologie, Université d'Ottawa, Ottawa, Canada, K1N 6N5.

Self-stimulation, exploratory activity and circling were elicited in the rat by electrical stimulation (0.1 msec in duration cathodal pulses) of the median forebrain bundle and raphe region respectively.

In order to maintain a constant behavioral output, increments in pulse intensity (I) were compensated for by increments in pulse period (P). The large majority of I/P curves were found to fit power functions with index of determination superior to 0.95 and exponents ranging from 1.4 to 0.1.

Subsequent testing with the use of moveable electrodes showed that the value of the exponent depends on the position of the electrode towards the behaviorally-relevant structure. In general, electrodes located outside the target structure generate exponents superior to 1. With electrodes within the structure, the value of the exponent may vary from 1.0 to 0.1 depending on the particular shape and dimension of the structure. In addition, alteration of the stimulated field by electrolytic lesions was found to reverse the value of the exponent from <1 to >1.

A geometric model which accounts satisfactorily for most of the I/P data was proposed. Non-geometric factors were also examined. It was found that factors such as the activation of behaviorally irrelevant elements may play an important role in the determination of the shape of I/P functions.

175.7 TEMPORAL INTEGRATION IN SELF-STIMULATION: A PARADOX L. D. Sax and C. R. Gallistel. Lab. of Psychology, Univ. of Pennsylvania, Philadelphia, PA 19104.

We present new findings regarding the temporal integrating characteristics of the substrate underlying self-stimulation in the rat, using a paradigm in which we determine the strength of stimulation required to produce a given level of reward, as a function of the interval separating two short bursts of stimulation. The findings are inconsistent with the leaky-integrator model of postsynaptic temporal integration suggested by Gallistel (J. Comp. Phys. Psych., 92:977, 1978) to explain his data on the strength of stimulation required at different train durations. They are also inconsistent with the adaptation model of Deutsch et al. (Beh. Bio., 29:359, 1980). The data favor a model in which a supra-threshold component of the reward signal is integrated perfectly (without leakage over time) to produce a given level of reinforcement. The linearly increasing charge-duration function (Huston et al., Beh. Bio., 7:383, 1972; and Gallistel, 1978) is also explained by this model. However, the model cannot explain the manner in which the charge-duration function changes as one varies the criterial performance used to derive it. The resolution of this paradox may deepen our understanding of the kind of process by which the transient neural signal generated by the stimulation is converted to an enduring reinforcement effect.

175.8 BRAIN STIMULATION REWARD IN THE LATERAL HYPOTHALAMIC MEDIAL FOREBRAIN BUNDLE: MAPPING OF BOUNDARIES AND HOMOGENEITY. A. Gratton and R. A. Wise. Center for Research on Drug Dependence, Department of Psychology, Concordia University, Montreal, Canada H3G 1M8.

It is well established that electrical stimulation of the lateral hypothalamic medial forebrain bundle is strongly rewarding to the rat. The present study was designed to determine the boundaries and relative sensitivity of the reward substrate in different portions of this region, using a moveable electrode to test multiple sites in vertical penetrations within each animal. Twenty-four male Sprague-Dawley rats were implanted with moveable monopolar stainless steel electrodes (1). Lateral coordinates varied from 0.5 to 3.2 mm from the midline and anterior coordinates were fixed at -0.8 mm from the Bregma (incisor bar elevated 5.0 mm above the interaural line). Rate-intensity determinations of brain stimulation reward were made at 0.25 mm intervals throughout the dorsal-ventral extent of the bundle.

Reward sites were found to extend from the ventral portion of the zona incerta to the base of the brain and from the fornix to the medial edge of the internal capsule. Although more medial placements also supported self-stimulation, this stimulation also produced signs of aversion. Stimulation within and near the internal capsule produced forced movements. The dorsal boundary of the positive region was abrupt; small electrode movements here produced major changes in reward threshold while similar movements had only minor consequences at more ventral sites. Threshold generally increased, though only slightly, as electrodes were lowered to the base of the brain. Within the boundaries of the system changes in stimulation current produced reasonably linear changes in response rate within the range of stimulation intensities from 10-50 μa (sine wave current). There was no systematic difference between medial and lateral thresholds. The MFB substrate for BSR can thus be characterized as dispersed throughout the entire cross-sectional area of the MFB, with relatively homogeneous distribution, but having a slightly lower sensitivity (reflecting, most likely, a slightly lower fiber density) in the more ventral portions of the bundle.

175.9 FASTER ACQUISITION OF MEDIAL PREFRONTAL CORTEX SELF-STIMULATION FOLLOWING PRE-TRAINING STIMULATION OF THE DORSAL PONTINE AREA. A. Robertson*, A. Laferriere* and P.M. Milner*.(SPON: K.Franklin). Dept. of Psychology, McGill University, Montreal, Quebec, Canada, H3A 1B1.

Intracranial self-stimulation (SS) of the medial prefrontal cortex (MC) in rats is acquired slowly, over a period of days. It has been demonstrated that prior non-contingent stimulation of the MC for several days dramatically shortens the number of days it later takes animals to start self-stimulating (Corbett et al., Physiol. Behav., 28, 531: 1982). These data suggest that stimulation-produced reward in the MC develops as a result of repeated exposure to the stimulation.

We have been examining whether we can get the same facilitatory effect of pre-training non-contingent stimulation on acquisition of SS of the MC by giving pre-training stimulation to other points in the brain anatomically related to the MC. In the present experiment, we examined the role of the dorsal pontine area and caudal midbrain (DT). Two groups of rats, each similarly implanted with a MC electrode, were used. One group (n=13) received pre-training stimulation through ipsilateral DT electrodes for nine days, 20 min/day, delivered at a rate of one 0.5 sec train of sine wave stimulation (30-40 uA RMS) every 64 sec. The electrodes were aimed at the area of the mesencephalic and motor nuclei of the trigeminal. The second (control) group (n=11) were treated identically, but did not receive pre-training stimulation. Following this phase, the speed of acquisition of SS of the MC was measured. Each rat was placed for 20 min/day in a box equipped with a response lever delivering 0.5 sec trains of sine wave stimulation (40 μA). No shaping procedures were used. The dependent variable was the no. of days it took a rat to reach a minimum of 100 responses/20 min. Control rats took an average of 6.1 (± S.E.M. .97) days to reach criterion. In contrast, rats which received pre-training stimulation of the DT took only 3.3 ±.89 days ($U = 27.5$, $p < .01$).

Interestingly, the DT group showed the same speed of acquisition as a group of animals (run in a previous expt.) which received pre-training stimulation through electrodes implanted into the sulcal part of the prefrontal cortex (Robertson et al, Physiol. Behav., 28, 1982, in press). Both of these groups took only slightly longer to reach criterion than rats who received pre-training stimulation of the MC itself. Similar pre-training stimulation delivered to the lateral hypothalamic and ventral tegmental areas has been shown to be without effect. Taken together, these data suggest that certain elements within the dorsal pontine area and the sulcal cortex form parts, perhaps interdependent parts, of a neural system involved in the development of the SS and the MC.

175.10 FRONTAL CORTEX SELF-STIMULATION: EVIDENCE FOR INDEPENDENT SUBSTRATES WITHIN AREAS 32 AND 24. L.R. Silva,* J.A. Vogel* and D. Corbett.* Dept. of Psych. and Soc. Rel., Harvard Univ. Cambridge, MA. 02138

Intracranial self-stimulation (ICSS) mapping studies have shown positive sites extending from the rostral medial cortex (area 32) into the cingulate cortex (area 24). It is not known whether the ICSS from these two regions of cortex has similar properties or whether it is mediated by a common neural system. Recently, it has been shown (Corbett et al., Physiol. & Behav., 1982, in press) that the ICSS from area 32 depends upon a system of corticocortical fibers that run laterally towards the sulcal cortices. In view of these findings, it seemed possible that ICSS along the medial cortex might also depend upon a corticocortical pathway, such as the cingulate bundle.

To test this hypothesis we first mapped the medial cortex for ICSS and determined the refractory periods associated with ICSS at different cortical sites. In a second experiment we looked for evidence of functional connectivity between sites in area 32 and 24 as determined by the collision technique (Shizgal et al., J.C.P.P., 94:227, 1980).

The 20 rats used in experiment 1 were implanted with monopolar stimulating electrodes aimed along the medial cortex. Each rat was trained to press a lever for a 500 msec train of 0.1 msec cathodal pulses delivered at 100 Hz. Following response stabilization, rate-intensity data were collected.

Three rats were used in the refractory period and collision experiments. Each rat was implanted with an electrode in area 32 and another electrode in area 24. Pulse pairs were delivered at various C-T intervals to each electrode. Similar pulse pairs were used in the collision tests except that the C pulse was delivered to one electrode while the T pulse was delivered to the other electrode. In both experiments, pulse effectiveness ratios were determined.

ICSS was obtained from area 32 well into the cingulate cortex (area 24). The rate-intensity curves at sites in these areas were similar; low rates with little change in response to increments in current intensity. Refractory periods were similar at ICSS sites in these regions as well, ranging from 4.0-6.3 msec. Finally, there was no evidence for collision between sites in area 32 and 24.

These findings suggest that the systems subserving ICSS within the medial cortex (areas 24 & 32) are similar but independent. Thus, if the output pathways at medial cortical ICSS sites travel within the cingulate bundle, they do so only for relatively short distances.

175.11 PARADOXICAL REINFORCING PROPERTIES OF APOMORPHINE: EFFECTS OF NUCLEUS ACCUMBENS AND AREA POSTREMA LESIONS. N.R. Swerdlow*, D. van der Kooy and G.F. Koob, Behav. Neurobiol. Lab, Salk Institute, San Diego, CA 92138 and Neurobiol. Res. Group, Dept. of Anatomy, Univ. of Toronto, Toronto, Canada M5S 1A8

Many psychoactive drugs have paradoxical reinforcing properties, producing positive reinforcing effects in some paradigms and aversive effects in others. A major step in unravelling these paradoxical properties would be the determination of different brain sites where the drugs act to produce their aversive as opposed to positive reinforcing effects. The present experiment tested the hypothesis that the area postrema is the substrate for apomorphine's aversive effects and the nucleus accumbens dopamine system is the important site of action for the drug's positive reinforcing effects. Apomorphine (.01-10.0 mg/kg, subcutaneously) paradoxically produced both dose-dependent aversive and positive reinforcing effects, as measured in conditioned taste aversion and place preference paradigms, respectively. The conditioned taste aversions produced by apomorphine were not modified in rats with bilateral 6-hydroxydopamine (6-OHDA) lesions of the nucleus accumbens (producing 92% depletion of dopamine in the nucleus accumbens) nor in rats with thermal lesions of the area postrema. Both types of lesions were behaviorally verified as effective in other paradigms; the 6-OHDA lesions potentiated the facilitatory effects of apomorphine on locomotor activity in photocell cages and the area postrema lesions attenuated the conditioned taste aversions to a novel flavor paired with scopolamine methyl nitrate (1.0 mg/kg, intraperitoneally). However, 6-OHDA lesions of the nucleus accumbens did clearly potentiate the conditioned place preferences induced by apomorphine. These results suggest that both the positive reinforcing and locomotor effects of apomorphine may partially result from activation of post-synaptic dopamine receptors in the nucleus accumbens. Moreover, the dissociation of apomorphine's aversive and positive reinforcing properties revealed by the 6-OHDA lesions may provide the first step in attempts to pinpoint the different brain sites of action where apomorphine produces its opposite motivational effects.

175.12 THERMOREGULATORY BEHAVIORS IN THE RAT AFTER REPEATED EXPOSURES TO HEAT A B Frol Dept of Psychology, Univ of Minnesota, Minneapolis, Mn 55455

Repeated exposures to a hot environment have been found to influence metabolism, sweating, cardiovascular and other autonomic systems in a variety of species. The relative importance of behavior in thermoregulation suggests heat acclimation may also influence heat loss behaviors. In a warm environment rats increase the frequency of grooming, rearing, extension, and activity. These behaviors and brain temperature were observed in rats during repeated short duration exposures to heat followed by a recovery period in a cooler environment.

Adult, male, Long-Evans, hooded rats were placed in cylindrical cages in an environmental chamber. A re-entrant polyethylene tube (PE 10) was implanted in the lateral preoptic nucleus to allow measurement of brain temperature. A testing session consisted of three consecutive periods: a 40 minute adaptation period, a 60 minute stress period, and a 30 minute recovery period. The ambient temperature during all three periods at a neutral exposure was 25°C. During a hot exposure the adaptation period was 25°C, rapidly raised to 40°C during the stress period, and slowly lowered to 25°C during the recovery period. The acclimation phase of the experiment had twenty test sessions, each session given on separate days. Experimental animals received ten hot and ten neutral exposures roughly alternating, whereas control animals received twenty neutral exposures. The testing phase consisted of two sessions at a neutral exposure followed by two sessions at a hot exposure for all animals. Grooming, rearing and extension were time sampled every twenty seconds and recorded. Activity measured by closure of microswitches under the cage and brain temperature measured by a thermocouple were recorded every other minute. Observation began in the last fifteen minutes of adaptation and continued to the end of the test session. The temporal patterning of heat loss behaviors and changes during the acclimation and test phases of the experiment were examined.

175.13 FEAR IN PREFRONTAL RATS. R. R. Holson* (SPON: G. Clark). Dept. of Psychology, University of Washington, Seattle, WA 98195.

Prefrontal lobotomy was long justified by the lowering of chronic anxiety, worry and even pain produced by surgical damage to human prefrontal cortex. Yet no animal model has to date produced incontrovertibly similar results; hence the effects of prefrontal cortical damage upon fear in rats is of considerable interest.

Adult (110 days mean age) male hooded rats were given multiple electrolytic lesions (tungsten electrodes, 2.5 mA DC, 15 secs per placement) in mesial frontal cortex (MFC). Histological verification confirmed that lesions were centered on area 32, with overlying cortex receiving minimal damage. Preliminary analysis of the wet weight of lesioned brains, as compared to sham-lesioned littermate controls, revealed a non-significant drop of 1.5% in MFC whole brain weight. Following fixation in formol-saline, both sets of brains were dissected, and no significant differences were noted in weight of cerebellum, hippocampus, neocortex outside of frontal poles, or brain remnant.

MFC rats were compared to shams on 5 tasks. Each task had two versions, differing in the degree to which subjects would be expected to perceive them as stressful or frightening. Tasks were: 1. HOARDING. (low aversion - covered runways; high aversion - exposed runways). 2. ONE-WAY AVOIDANCE. (low aversion - go from light to dark; high aversion - go from dark to light). 3. EMERGENCE. (from an enclosed box into an exposed corridor. High aversion - prior foot-shock in room; low aversion - no prior foot-shock). 4. BURROWING. (low aversion - burrow to escape open field; high aversion - exposure to open field in order to burrow). 5. OPEN FIELD ACTIVITY. (low aversion - prior handling; high aversion - no handling). On each task, MFC rats differed significantly from controls under high aversion (less hoarding and burrowing, fewer emergences, increased one-way avoidance errors, enhanced activity), but were not different from control under conditions of lower aversion.

It is concluded that one effect of MFC lesions in rats is to enhance reactivity to aversive/frightening situations, and that this effect may account for some of the classic MFC deficits, including hoarding problems and the avoidance deficit. It is premature to speculate on how this enhanced timidity in MFC rats is related to the reduced anxiety seen in lobotomized humans.

175.14 DOPAMINE IN THE NUCLEUS ACCUMBENS MODULATES CLASSICALLY CONDITIONED DEFENSIVE RESPONSES IN THE CAT. W. Jeffrey Wilson and S. Stefan Soltysik. Mental Retardation Research Center and Dept. of Psychology (W.J.W.), University of California, Los Angeles, CA 90024.

Adult cats, trained to criterion in a classical conditioning paradigm in which a tactile stimulus was paired with a 3.0 mA electric shock to the foot, received injections of dopamine (DA) (20, 80, & 320 µg), haloperidol (.5, 1, & 2 µg), or isotonic saline in 1 µl quantities into the nucleus accumbens via bilaterally implanted cannulae. Compared to sessions in which saline was injected, injection of dopamine reduced by 50% the magnitude of the conditioned leg flexion, without affecting the size of the unconditioned flexion. This effect was apparent for all doses of dopamine. Baseline and conditioned heart rate and respiration rate responses were not significantly affected by dopamine. Respiration amplitude, which consistently decreases during presentation of the CS, was also unaffected by DA, as was the probability of a conditioned vocalization.

Haloperidol (1 µg) had no effect on conditioned or unconditioned flexions or vocalizations, nor did it affect conditioned changes in respiration amplitude. However, this dose of haloperidol did cause an increase in respiration rate late in the CS-US period, and a decrease in heart rate for the same period.

The same doses of DA and haloperidol were tested for their effects on locomotor activity in these same subjects. Neither drug affected locomotor activity in an open field, as measured by number of grids crossed per 5 min interval for 30 min.

The fact that DA had its greatest effect on the conditioned motor response supports the contention that dopaminergic input to the nucleus accumbens is involved in the control of motor activity. That only the conditioned responses, and not the unconditioned responses or locomotor activity, were affected is consistent with the hypothesis that the accumbens might link motivation and motor control (Mogenson, et al., 1980; Stevens, et al., 1974). These results, coupled with those of previous experiments in our laboratory in which electrical stimulation of the accumbens had an inhibitory effect on the same motor responses, suggest that dopaminergic afferents to the accumbens from the ventral tegmental area exert a direct or indirect inhibitory influence on the connections within the accumbens between the emotive and motor systems.

175.15 CAFFEINE: EFFECTS ON HUMAN AGGRESSIVE BEHAVIOR. J.L. Steinberg, D.R. Cherek and J.E. Smith. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Aggressive behavior in human subjects was elicited in a laboratory setting and the effects of placebo and 1, 2, and 4 mg/kg doses of caffeine on that behavior were investigated. Subjects were given the option of pressing three response devices. Pressing button A was maintained by a fixed-ratio 100 schedule of monetary reinforcement, consisting of increments of ten cents indicated on a counter and paid to the subject after the session. We defined as aggressive, pressing button B or switch C which ostensibly delivered aversive stimuli by subtracting ten cents from or delivery of a one-second blast of white noise to another "person". Aggressive behavior, i.e., responding on button B or switch C, was elicited by subtracting money from the research subject which was attributed to another "person". The subtractions of money from the research subject took place automatically at random time points throughout the session. Compared to to the placebo condition, aggressive monetary-subtraction responses (button B) decreased in all subjects following the administration of caffeine. The highest dose of caffeine (4 mg/kg) resulted in the greatest reduction in aggressive monetary-subtraction responses. In general, caffeine resulted in similar suppression of aggression noise-delivery responses (switch C) and increased the number of non-aggressive monetary reinforced responses (push button A). The increase in non-aggressive responding following caffeine, indicates that the suppression of aggressive responding was not due to a non-selective generalized depressant action. These findings with caffeine should not be generalized to situations involving coffee-drinking or drinking other caffeinated beverages because of the presence of substances other than caffeine which might have psychoactive effect.

175.16 CORTICAL LOCALIZATION FOR CONTROL OF AFFECT IN HUMANS. R. G. Robinson, K. L. Kubos*, L. B. Starr* and T. R. Price*. Dept. of Psychiatry and Behavioral Sciences, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205, and Dept. of Neurology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Brain-behavior relationships have traditionally developed along two lines. One view described by Lashley emphasizes the importance of the amount of brain tissue removed in producing behavioral change. This is the mass action theory. The second view is based on the topographical localization of behavior, i.e., behaviors such as language expression, aggression or motor control of the contralateral limb are controlled by a specific cortical area. Mood or affect, however, has not been localized by using either one of these concepts. We have looked for relationships between location of brain injury and mood in patients with single focal CT scan verified lesions of either the left (N=28) or right (N=20) hemisphere in right-handed acute stroke patients without any prior risk factors for psychiatric disorder. Based on analyses of CT scan,patients were divided into anterior and posterior groups in each hemisphere. Patients with left anterior lesions (N=10), were the most depressed group (greater mean scores p<.01) and 60% had major affectve disorder by Research Diagnostic Criteria. Within this group there was a strong correlation (r= -.92) between the severity of depression and the proximity of the lesion to the frontal pole (confirming our earlier findings, Ann. Neurol., 9:447, 1980). Fifty percent of patients with left posterior lesions (N=8) had minor depressions. Patients with right posterior strokes (N=6) were significantly more depressed than patients with right anterior lesions (N=6) (p<.05). Two thirds of patients with right anterior lesions were unduly cheerful but apathetic and indifferent. Correlation between depression score and distance of the lesion from the frontal pole (r=.72) went in the opposite direction from that found in the left hemisphere (i.e., lesions farthest from frontal pole were the most depressed). The finding that depression occurs with left hemisphere lesions and right hemisphere lesions is associated with apathy and indifference confirm the findings of previous investigators (e.g., Gainoti, Cortex, 8:41, 1972). However, the intrahemisphere differences (i.e., depression occurs with left anterior and right posterior lesions and apathy occurs with right anterior lesions) suggests that cortical control of affect may be distributed in a graded fashion across the cortex. This kind of localization has not been described for brain-behavior relationships before. This kind of behavioral localization may be based on the anatomy of the noradrenergic pathways and the fact that anterior lesions produce more disruption of these pathways than posterior lesions (Morrison et al., Science, 205:313, 1979).

176.1 CORTICAL VOLUME ASYMMETRY AND BEHAVIOR IN THE ALBINO RAT. G.F. Sherman* and A.M. Galaburda. Department of Neurology, Beth Israel Hospital and Harvard Medical School, Boston, Ma.

The rat has a functionally asymmetrical brain which can be influenced by early experience (Denenberg et al., Sci., 1978, 201, 1150-1152; Sherman et al., Br. Res., 1980, 192, 61-67). In addition, thickness measurements of certain cortical areas have revealed anatomical asymmetries (Diamond et al., Exp. Neurol., 1981, 71, 261-268). However, the relationship between functional and anatomical asymmetry is unknown. In the present study we investigated this relationship and attempted to make a more accurate assessment of the size of specific architectonic areas.

17 brains were obtained from male and female Purdue-Wistar rats handled in infancy and raised in enriched environments or non-handled and raised in standard lab cages. The volumes of the total isocortex, the somatosensory region, the motor region, and the primary visual area on each side were measured. The architectonic zones were determined by well specified criteria (Galaburda and Sherman, Anat. Rec., 1982, 202, 60A) and their total volume measurements calculated from whole brain serial sections.

The total isocortex on the right side of the brain was significantly larger by 1.1% than the left side (t=3.03, p< .01). This was primarily caused by asymmetry present in males. Overall, 8 brains were symmetrical in total isocortex, while 8 of the remaining 9 brains had larger right hemispheres. The asymmetry in favor of the right hemisphere was negatively correlated (r=-.610, p< .01) with total activity in the open field. Since higher activity in the open field reflects lower emotional reactivity, it appears that a larger right hemisphere is associated with a higher level of emotionality.

In both the visual area and somatosensory zones 11 brains had larger areas on the right side, 5 had larger areas on the left, and 1 brain was symmetrical. Although intriguing this distribution is not significantly different from chance and additional brains are being examined. The motor cortex did not show a consistent asymmetry, although in nonhandled animals an asymmetry in favor of the right hemisphere was positively correlated (r=.608, p< .05) with total rightward turning in the open field.

Further analysis of the data revealed that the somatosensory region made up a greater proportion of the total cortex in handled than in nonhandled animals (t=2.66, p< .02). This did not seem to be due to an absolute difference in total or somatosensory cortex, but to the relationship between the two.

176.2 ROLE OF STIMULUS POSITIONS IN INTEROCULAR TRANSFER OF LEARNING IN PIGEONS. S.Watanabe Dept. of Psychology, Keio Univ.,Mita,Minato-Ku,Tokyo,Japan

Pigeon shows good interocular transfer of both successive and simultaneous discriminations in operant chamber with the pecking key. On the other hand, jumping stand experiments failed to obtain interocular transfer of learning in the pigeon(Graves & Goodale,1977). Such difference might be caused by difference of training apparatus. However, pigeons did not show transfer of spatial conditional discrimination(Green et al,1978) neither sequential order of pecking(Zeier,1976) in the operant chambers. Stevens and Kirsh(1980) also reported a failure interocular transfer of responding trained on FR schedule when pigeons had not received enough motor training with the tested eye.

In the present experiment pigeons were trained on monocular color discrimination in an operant chamber. Two different frontal panels were used. One had a single pecking key on which color stimuli were presented. The other had a pecking key which was illuminated by a white light and a stimulus key on which color stimuli were presented. The stimulus key located 7 cm above the pecking key. One group of pigeons was trained with the single key panel and the other group was trained with the two-key panel. The training procedure was discrete trial training with the positive reinforcement. After the bird learned the discrimination with one eye,retraining with the other eye was given.

When the stimuli were presented on the pecking key (the single key panel),the pigeons maintained their discriminative behavior with the naive eye. That is, they showed almost complete interocular transfer of learning. On the other hand,when the stimuli were presented on the separated key(the two-key panel) the birds failed to transfer their discriminative behavior from one eye to the other eye.

These results suggests that spatial relation of discriminanda(stimuli) and operandum(pecking key) has an important role in interocular transfer of learning in pigeons.

176.3 DOES THE RELATIONSHIP BETWEEN RESPONSE AND REINFORCER INFLUENCE INTEROCULAR TRANSFER IN CHICKS? Karen E. Gaston,* Thomas Altaffer,* & Jenee Todd* (SPON: C. G. Reiness). Pitzer College, Claremont, CA 91711.

Previous work demonstrated that a monocularly-acquired pattern discrimination does not transfer from trained to untrained eye in chicks key-pecking for heat (Gaston, K. E.: Brain Res., 171:339, 1979). This finding is in contrast to reports of interocular transfer for many other tasks in chicks and, especially, to reports that similar pattern discriminations show good transfer in pigeons. The present experiment is the first of a series designed to examine several methodological differences between the pigeon and chick pattern discrimination studies, in an effort to identify factors which determine the occurrence and the extent of interocular transfer in chicks.

In the typical pigeon experiment, a response to the correct stimulus is reinforced by food, whereas in the earlier chick study a correct peck was rewarded by heat. This may be considered an unnatural or non-adaptive association for birds, in that pecking is not normally related to keeping warm as it is to obtaining food. If the adaptive significance of a learning situation influences the extent of interhemispheric communication, then chicks would be more likely to show interocular transfer of the pattern discrimination if they were pecking to obtain food rather than heat.

To test this prediction, 16 5-20 day old domestic chicks were trained monocularly to perform a simultaneous two-choice visual pattern discrimination (+, Δ or Δ, +) for food reward and were tested first with the other eye for interocular transfer and then again with the first eye for monocular retention of the discrimination. The chicks required somewhat fewer trials and errors to reach the 90% criterion with the second eye than with the first (mean trials = 300 & 193.97; mean errors = 99.12 & 65.25), but these savings were not statistically significant. In contrast, the chicks had excellent retention of the discrimination, as evidenced by large and significant savings on both trials (mean = 101.24) and errors (mean = 14.86) when retested with the first eye. There was some indication that chicks trained first with the right eye required fewer trials and errors to reach criterion during acquisition, but demonstrated less savings on both measures during the interocular transfer test, than chicks trained first with the left eye. These possible differences are presently being examined more fully with additional chicks.

The lack of significant interocular transfer observed here in chicks pecking for food is very similar to the earlier pattern of results obtained using heat reinforcement. This suggests that the relationship between response and reinforcer cannot alone account for the previous failure of interocular transfer.

176.4 CIRCULAR CORTICAL KNIFE CUTS INDUCE ASYMMETRICAL BEHAVIOR IN THE RAT. K.L. Kubos*, G.D. Pearlson and R.G. Robinson. (SPON: S.Lukas) Dept. of Psychiatry and Behavioral Sciences, Johns Hopkins Sch. of Med., Baltimore, MD 21205

Previous studies have shown that NE right cortical lesions (Robinson, R.G. and Stitt, T.G., Brain Res. 213:395, 1981) or focal lesions of right cortical cell bodies (Kubos, K.L. et al., Brain Res., in press) cause spontaneous hyperactivity. In an effort to determine the specific contribution of cortical fibers of passage to the asymmetry phenomenon the following experiment was performed.

300 g. male Sprague Dawley rats were housed in running wheel cages for at least 3 weeks prior to surgery. Preoperative spontaneous baseline activity was established during the final week preceeding surgery. Under chloral hydrate anesthesia a fronto-parietal craniotomy was performed, and a 2 mm diameter cut extending to the internal capsule was stereotaxically made with a rotating micro-knife. Identical unilateral lesions were made in either the left or right lateral cortex. Daily activity was then monitored for the next 30 days. Left-lesioned animals demonstrated an initial 30% decrease in activity followed by a gradual return to preoperative baseline level. Right-lesioned rats, on the other hand, demonstrated an initial increase in activity which peaked at 120% above preoperative baseline levels at day 18 and subsequently fell to 80% by day 30. Both left and right lesioned groups were statistically different from controls as well as from each other.

176.5 BINOCULAR DEPTH PERCEPTION IN CATS FOLLOWING NEONATAL SECTION OF THE CORPUS CALLOSUM. Brian Timney[1], Andrea Elberger[2] and Leslie Vandewater*[1]. [1]Department of Psychology, University of Western Ontario, London, Canada and Departments of Anatomy and Neurobiology, University of Texas Medical School, Houston, Texas.

Recently we reported that neonatal section of the optic chiasm in kittens leads to a relatively minor impairment of binocular depth perception (Timney & Lansdown Soc. Neurosci. Abs. 1981, 7, 674). The results indicated that an indirect pathway, presumably through the corpus callosum, was sufficient to mediate this ability. The present study was designed to establish whether the corpus callosum was necessary for the maintenance of good stereoacuity.

Three kittens underwent section of the posterior half of the corpus callosum within two weeks of birth and a fourth kitten was given a sham operation. The surgery was carried out at the University of Texas then the kittens were shipped to Ontario for testing. The Ontario investigators did not know the experimental condition to which each animal had been assigned, except for an additional kitten which served as a normal control.

Binocular and monocular depth discrimination thresholds were measured using the jumping stand technique, in which the cats were trained to jump from a platform towards the closer of two surfaces placed beneath them. Thresholds were calculated as the smallest separation that could be discriminated with 70% accuracy.

All three of the callosum-sectioned kittens performed indistinguishably from normals. Binocular depth thresholds (approx. 6 min/arc disparity) were much better than monocular, suggesting that the animals had retained their ability to use uniquely binocular cues to depth. In order to determine whether the excellent performance was due to some form of development compensation, the corpus callosum of the normal kitten was sectioned (by F. Lepore, Université de Montréal) at the age of 4½ months. There was no difference between pre- and post-operative thresholds, suggesting that an alternative pathway was subserving the discrimination. However, section of the optic chiasm in the callosum-sectioned cats, which eliminated the possibility of binocular convergence for these animals, led to dramatic deterioration of performance.

The results, in conjunction with those obtained previously, suggest that either the optic chiasm or the corpus callosum provide pathways sufficient to maintain stereoscopic vision, but neither structure seems to be necessary.

176.6 LOCALIZATION OF INTERHEMISPHERIC VISUAL CONNECTIONS IN MACAQUES. C. R. Hamilton, S. B. Tieman, B. A. Vermeire and R. L. Meyer. Division of Biology, Caltech, Pasadena, CA 91125.

The main purpose of these experiments is to establish with reasonable accuracy the location in the cerebral commissures of fibers connecting different regions of visual cortex. If a significant separation of connections from various cortical areas exists, then it is possible to prepare and behaviorally test monkeys with intact interhemispheric connections restricted to a subset of visual areas. A knowledge of the kinds of visual information that can still be transferred between the hemispheres would allow inferences to be drawn about the functions of the visual areas that remained interconnected. A second point of the experiments is to determine the major heterotopic targets of commissural projections from various regions of visual cortex.

Tritiated proline and discrete lesions were placed in several regions of visual cortex in 12 macaques and after one week survival the brains were processed by standard autoradiographic or reduced silver methods. The visual regions studied included the 17/18 border, MT, V4, and IT cortex. The localization of fibers in the splenium of the corpus callosum was quite discrete. Furthermore, there was a continuous progression of fibers in the splenium from postero-ventral to antero-dorsal that corresponded with the cortical order 17/18, V4, MT. Essentially all fibers leaving IT cortex passed through the anterior commissure. All the regions investigated sent fibers to homotopic regions of the opposite hemisphere; these projections usually were patchy. Heterotopic projections were best seen with the proline injections. They were most striking for injections in and around V4 and MT and projected predominantly to contralateral areas "downstream" from the injection site. Overall, these results encourage the continued behavioral study of interhemispheric transfer in monkeys with commissural connections restricted to selected subsets of visual areas.

176.7 TILT AFTEREFFECTS IN MONKEYS. B. A. Vermeire and C. R. Hamilton. Division of Biology, Caltech, Pasadena, CA 91125.

The tilt aftereffect, the illusion that a vertical line appears tilted after prolonged viewing of an oblique grating, has been extensively studied with human subjects. Recent interest in this illusion has centered on the suggestion that interocular transfer of the aftereffect depends on the integrity of binocular neurons in the visual cortex. This is inferred from the finding that strabismic and amblyopic animals lack binocular neurons in the visual cortex and that people with similar disabilities usually fail to show the expected interocular transfer of the tilt aftereffect. A more direct assessment of the dependence of interocular transfer on binocular neurons and of the visual areas involved in this aftereffect could be made if tilt aftereffects were measurable in experimental animals.

Four monkeys (M. mulatta) were tested for tilt aftereffects using a modified method of constant stimuli. All monkeys had their optic chiasm sectioned so that the magnitude of the aftereffects, if present, would serve as a baseline for subsequent studies of interocular transfer in partially split-brain monkeys. The monkeys were trained to gaze at a high contrast vertical square wave grating projected on a screen. When the grating occasionally dimmed, the monkeys pushed the screen to initiate presentation of a test line oriented (in $1\frac{1}{4}^{\circ}$ steps) between 0° and $\pm 7\frac{1}{2}^{\circ}$. The monkeys were rewarded for pushing again if the line was vertical and for not pushing if the line was tilted. To produce aftereffects, the grating was tilted $\pm 10^{\circ}$. Each monkey, tested binocularly, showed reliable aftereffects of about 1° on each of eight separate sessions. Human subjects using the same apparatus showed aftereffects of about 1.5°; the somewhat smaller aftereffects of the monkeys probably reflect less complete adaptation associated with viewing the grating about 80% of the time. We are now testing partially split-brain monkeys for interocular transfer of these aftereffects. These monkeys have cortical binocularity restricted to the vertical midline of the visual field and to a subset of visual areas.

Supported by PHS grant MH 35323.

176.8 INTERHEMISPHERIC MNEMONIC TRANSFER IN MACACA NEMESTRINA. Robert W. Doty, John A. Gallant* and Jeffrey D. Lewine*. Center for Brain Research, University of Rochester Medical Center, Rochester, New York 14642.

Monkeys with optic chiasm transected via a transsphenoidal approach are trained to identify with one eye and hemisphere photographic "slides", unique for each trial, viewed 10 sec previously by the other. The monkey wears a light-weight mask equipped with shutters to provide selected monocular input. When performance is consistently correct for 90% of the 50-100 daily trials, either the entire corpus callosum (CC) is transected, leaving the anterior commissure (AC); or the AC and rostral CC are cut, leaving only 4-5 mm of the splenium. One each of such cases has now been tested, for >5600 trials each, and performance is indistinguishable. For the first two trials, given 60 days postoperatively, requiring use of AC only, the monkey appeared completely baffled, but then gradually accommodated, failing to respond to only ten of the first 50 trials, and achieving 94% correct for the 40 choices which it did make. Even this slight hesitancy was absent from the postoperative session in the animal performing interhemispheric transfer for the first time with only splenium remaining. Performance with color photographs of complex objects or scenes is distinctly better (85-95% correct) than with pure, objectless color (80-85% correct); but no consistent difference has been found between hemispheres (for intrahemispheric comparison, i.e., same eye) or for direction of transfer.

The intention had been to test also with abstract geometric patterns, using 2-6 stroke Japanese Kanji. The monkeys, however, were unable to attain preoperative performance consistently above chance despite 2200 and 2900 trials of training, even at 0.5-4 sec delay intervals. Since non-Japanese human subjects achieve 100% correct at 10-sec delays without the slightest difficulty, an interesting difference between human and macaque visual mnemonic organization is perhaps manifest here. That the monkeys' difficulty is not attributable to mere absence of color in the Kanji stimuli was shown by their postoperative ability to achieve interhemispheric identification with almost equal facility for two series of the same objects, one in "black and white" (85% correct) versus color (90% correct).

Using a "list" procedure in which response must be withheld upon a second presentation of any "slide" among the 280 viewed in a given session, one monkey with AC and chiasm cut (all CC intact) maintains a 74% correct interhemispheric identification at a mean delay of 26 sec (range 10-50 sec). There is a suggestion of left hemisphere superiority at the longer intervals.

The main conclusion to date is that for interhemispheric identification of color or complex objects after 10-sec delays the AC and CC offer essentially equivalent pathways.

177.1 SENSORY REACTIVITY, HABITUATION, AND ASSOCIATIVE LEARNING IN DECEREBRATE HUMAN INFANTS. G. G. Berntson, A. E. Ronca* and D. S. Tuber*. Lab. Comp. Physiol. Psychol., Ohio State Univ., Columbus, OH. 43212.

Human infants with extensive damage to, or total loss of, the cerebral hemispheres were tested for sensory reactivity, habituation, and associative learning in a conditioned expectancy paradigm employing heart rate measures of the orienting response. Two stimuli were repeatedly presented to the subjects in close temporal contiguity. Interspersed within these conditioning trials were occasional test trials in which the first stimulus was presented and the second stimulus withheld. In 3 of the 6 subjects, cardiac orienting responses (generally decelerator) on the initial trials indicated that the sensory stimuli were functionally processed. Within a few trials, however, these cardiac orienting responses appreciably declined, reflecting the normal process of habituation. A reinstatement of the cardiac orienting response was seen on test trials, in which the first stimulus was presented and the second stimulus withheld. This finding indicates that a stimulus-stimulus association had also been formed. In these cases, the orienting response was seen to the omission of a stimulus, an omission which could be detected only to the extent that a conditioned expectancy or stimulus association had been established.

In three additional infants, no evidence of associative learning was seen. In each case, however, there was minimal reactivity to the sensory stimuli, and when present, this minimal reactivity was not subject to habituation. CAT scans failed to reveal clear differences in the functional level of decerebration in those subjects who showed habituation and associative learning and those who did not. Thus, the autonomic indices employed appear to reflect the functional integrity of the remaining neuraxial levels, rather than the absolute level of decerebration. The present results document the cognitive processes of habituation and associative learning in the virtual absence of the cerebral hemispheres. These findings are in keeping with a growing body of literature detailing the extensive functional capacities of lower levels of the neuraxis. Moreover, the results suggest a method for the evaluation of cognitive processes in severely brain damaged or otherwise impaired infants and children. These studies are currently being extended to a broad population of mentally retarded and developmentally delayed infants and children.

177.2 A BRIEF SCALE FOR RATING BEHAVORIAL DEFICITS IN DEMENTIA James A. Haycox, M.D.

To evaluate and follow the progression of dementia in a Dementia Day Treatment Program, a brief and robust scale for measuring both cognitive and behavioral deficits was needed.

Good scales already existed for measuring cognitive deficits. A scale which can be administered in less than ten minutes has now been developed for rating the relevant behavorial deficits based on observation of precise forms of behavioral deterioration. Eight categories of behavior are rated: (1) language competence, (2) social interaction, (3) attention, (4) spatial orientation, (5) motor performance, (6) bowel and bladder control, (7) eating and nutrition, (8) and dressing-grooming competence. A score of zero in any category signifies full function while six indicates terminal disability. The minimum total score (0) indicates healthy-mindedness and the maximum score is 48. Para-professional raters achieved reproducibility ($r=0.9$) after a minimum of training and high correlation ($r=0.8$) with clinical judgements of patients' status done independently. We have evaluated and followed over 300 patients at risk for dementia. Analysis of our follow-up data demonstrates correlations with autopsy findings, contrasts the findings in several diseases causing dementia and illustrates the progression of dementia when treated in day care and when not treated.

177.3 VERBAL LEARNING AND REMOTE MEMORY FUNCTIONS IN ALZHEIMER-TYPE DEMENTIA. B.A. Thompkins-Ober*, B. Koss, R.P. Friedland, T.F. Budinger*, E. Ganz*, and D.C. Delis*. Dept. Neurology, University of California, Davis, V.A.M.C., Martinez, CA 94553 and Donner Laboratory, University of California, Berkeley.

Eight patients, clinically diagnosed as exhibiting Alzheimer-type dementia participated in a multidisciplinary study including neuropsychological evaluation, x-ray computerized tomography (CT), and positron emission tomography (PET) with 18-fluorodeoxyglucose. The patients (aged 55-75) were classified as either moderately or severely demented based on their Mattis Dementia Scale score. The performances of these two subgroups of four patients each were compared on both verbal learning and remote memory tasks. A Buschke selective reminding procedure was used to evaluate verbal learning abilities. After an initial presentation of the list of words, alternating study and recall trials were administered with presentation on the study trials of only items missed on the previous recall trial. The severe dements recalled fewer total items at the end of learning. However, the proportion of items recalled from long-term store (recalled at least once without representation) out of the total number of items recalled from both long-term and short-term store (without representation) was actually greater for the severe dements. This suggests differential learning strategies between the two groups. The moderate dements are more likely to repeat back the represented words on each trial in order to maximize recall, and therefore are distracted from encoding items into long-term store. In contrast, the severe dements seldom repeat back any of the represented words and instead focus exclusively on a few words from the list, increasing the probability of encoding these words into long-term store. Twenty minute delayed recall of the list showed greater memory loss of previously learned words for the severe dements.

Albert's remote events recall questionnaire yielded a measure of remote verbal memory. The moderate dements recalled many more events and their performance benefited more compared to severe dements when multiple choices were given for each question. This is indicative of a remote memory impairment which for moderate dements, but not for severe dements, can be overcome by the elimination of retrieval requirements.

These memory data will be discussed in relation to cerebral structural and metabolic abnormalities in these patients as documented by x-ray CT and PET.

177.4 COGNITIVE DEFICITS IN MULTIPLE SCLEROSIS. L.M. Nelson*, D.S. Thompson*, R.H. Heaton*, J.S. Burks*, S.H. Walker*. (SPON: L. Minier) Rocky Mountain Multiple Sclerosis Center, Dept. of Neurology, University of Colorado Med. Sch., Denver, CO 80262.

Prior studies of possible cognitive impairment in MS have not accounted for disease activity or made a distinction between clinical subtypes, [i.e. relapsing/remitting (R/R) and chronic/progressive (C/P) MS]. One-hundred consecutive patients with clinically definite MS (57 R/R tested in remission, 43 C/P) and 150 normal controls of similar age and education were given an expanded Halstead-Reitan Battery (HRB) measuring a broad range of cognitive and sensory/motor abilities. Group comparisons were made using analysis of covariance with adjustment for age and duration of disease.

The total MS group was not different from controls on the information and vocabulary subtests of the WAIS, suggesting comparable premorbid intellectual functioning in the MS group.

On the expanded HRB, the C/P group had several mean cognitive scores in the impaired range even on tests which require little or no motor ability (i.e. Category Test, Story and Figure Memory). The strongest differences between controls and C/P patients (as reflected by the size of F-ratios) were obtained with tests requiring complex problem-solving, concept formation, and sequencing. The R/R group tested in remission was not significantly different from the control population on any individual non-motor test. The profile of cognitive deficits among R/R patients was of a very mild nature, and showed no consistent pattern. Data will be presented examining the effects of acute exacerbations and life stressors on cognitive functioning.

The degree of cognitive impairment was related to duration of disease, but not to number of recorded disease exacerbations. The comparison of medicated versus nonmedicated subgroups revealed no significant differences on tests of cognitive abilities, indicating that the increased incidence of cognitive deficits among C/P patients was not due to medication effects.

Blind clinical ratings revealed that 57% of R/R and 74% of C/P patients had impaired cognitive functioning. For the purely cognitive tests of the HRB, a 60% concordance was noted with a clinical mental status exam in predicting cognitive impairment.

The neuropsychological profile is a necessary supplement to the clinical history and mental status exam in determining the presence or absence of cognitive involvement.

177.5 PRESENCE AS A NEW MODE OF HUMAN ATTENTION, Vinod D. Deshmukh, 3600 Rustic Lane, Jacksonville, Fla 32217

It is proposed that human attention has two fundamentally different modes. The commonly recognized human attention is called 'Mnemic' and the 'New' mode of human attention is called Presence. The word Mnemic means of or related to memory. In Mnemic mode of human attention there is focussing or directing of partial attention to a particular object in the environment. There are habitual cognitive and emotional responses based on memory that constantly interfere during the mnemic mode of human attention. This also creates the observer-observed duality and experience of personal time and change. It creates sustains and adds to the self image. It always limits perceptivity attentional energy, intelligence and feeling of goodness or natural happiness.

The 'New' mode on the other hand is evernew. It is not contaminated by the past memories. It is complete participant attention to the present-now and here. It is free of any habitual cognitive or emotional responses. It is free of self image with no interference with the present human activity. There is no divison as 'I' and the 'rest' or not-I. There is no projection into the future based on the past. It implies tremendous frictionless, conflictless attentional energy, intelligence and a feeling of self-freedom and natural goodness. Since it is completely one with the present-the what is; it is named as the state of Presence.

An hourglass model of observer and the observed is presented to explain the functoning of mnemic and new modes of participant attention. This model and above modes of attention also help to understand and to resolve the problem of Brain-Mind duality in Neuro Sciences.

177.6 THE PROCESSING OF EXPECTED AND UNEXPECTED EVENTS DURING CONDITIONING AND ATTENTION. S. Grossberg, Center for Adaptive Systems, Dept. of Math., Boston Univ., Boston, MA 02215.

Recent models of Pavlovian and instrumental conditioning can be unified to yield a theory wherein many conditioning, cognitive, motivational, psychophysiological, and pharmacological data can be synthesized and predicted(1). Some recent formal models contain internal paradoxes that restrict their predictive power. These paradoxes can be traced to an inadequate formulation of how mechanisms of short term memory and long term memory work together to control the shifting balance between the processing of expected and unexpected events. Once this formulation is strengthened, a unified processing framework is suggested wherein attentional and orienting subsystems coexist in a complementary relationship which controls the adaptive self-organization of internal representations in response to expected and unexpected events. Using this framework, conditioning and attentional constructs can be more directly validated by interdisciplinary paradigms in which seemingly disparate phenomena can be shown to share similar physiological and pharmacological mechanisms. A model of cholinergic-catecholaminergic interactions suggests how drive, reinforcer, and arousal inputs regulate motivational baseline, hysteresis, and rebound with the hippocampus as a final common path. Extinction, conditioned emotional responses, conditioned avoidance responses, secondary conditioning, and inverted U effects also occur. A similar design in sensory and cognitive representations suggests how short term memory reset and attentional resonance occur, and are related to evoked potentials like N200, P300, and CNV. Competitive feedback properties such as pattern matching, contrast enhancement, and normalization of short term memory patterns make possible the hypothesis testing procedures that search for and define new internal representations in response to unexpected events. Long term memory traces regulate adaptive filtering, expectancy learning, conditioned reinforcer learning, incentive motivational learning, and habit learning. When these mechanisms act together, conditioning phenomena like overshadowing, unblocking, latent inhibition, overexpectation, and behavioral contrast emerge.

177.7 MUSICAL THOUGHT DISCLOSES A HIGHLY STABLE PSYCHOBIOLOGIC CLOCK, M.Clynes, B.McMahon* and N.Nettheim* NSW State Conservatorium of Music, Sydney 2000 Australia.

Musical thought has the ability to activate psychobiologic clocks with a long term stability of 1 part in 500 or better[1]. The existence of such clocks presents a theoretical challenge. The unexpected findings also suggest that under proper experimental conditions such a psychobiologic clock could become a sensitive vehicle for the study of highly specific neurohormonal or drug influences and function.

This stability has been demonstrated through:

1. Performances over a number of years of major portions of several minutes duration of musical compositions by single performers as well as by ensembles (including string quartet). Pieces with a regular motoric pattern show greatest stability. For slow pieces stability tends to be less.

2. In experiments involving repeated tapping to silently thought music (each tap period measured to 0.00001 sec.) mean tapping-rate of groups of 1000 taps can be stable to within 1 part in 500 when a musician taps to the beat of a specific known allegro musical theme (e.g.Mozart K467 1st Movt.) thought silently and repeatedly. It was found in a series of experimental runs involving 4000 taps each that under these conditions the stability of the mean tapping rate increases with the number of taps whose duration is being averaged; over a range of groups of 1 to 1000 taps, the standard deviation decreases from 4% for single taps to less than 0.3% for groups of 1000 taps (only a factor of 2 less than the theoretical limit for the signal/noise improvement if the period consisted of a constant plus random noise.)

Other experiments comparing performances thought in real time with actual performances consistently show the thought performance to be slower by several per cent; as tested in 400 performances of professional musicians. (Clynes, in press).

These findings indicate that musical thought can activate highly stable psychobiologic clocks whose stability within the above limits is not affected by inner and outer environmental factors encountered by these musicians under normal working conditions.

177.8 INFORMATION PROCESSING (BASIC DIFFERENCES BETWEEN THE CENTRAL NERVOUS SYSTEM (CNS) AND THE COMPUTER) C.Torda. Res.Dpt.,N.Y.Center PA Train.(Curr.Addr.P.O.B.4866,Stanford Univ.,Calif.,94305).

With the development of artificial intelligence the problem of differences in information processing by the CNS and the computer emerged.Computers exceed human performance by speed, accuracy, consistency and near-perfect logical relationship between input and output. Since computers were created by human skill and intelligence one may expect the performance of the CNS to exceed that of the computer.This problem has been addressed in the current study. The various logic systems employed by the different programming techniques, symbol formation, coding, transmission of the coded information,memory storage and retrieval by the CNS and the computer have been compared.The known CNS mechanisms have been analyzed from the point of view of stimulus detection, transformation of exo- and endogenous energy forms into the form the CNS is able to utilize,the complex and multiple prevalently parallel coding(including their biophysical and biochemical regulation) and the central mechanisms for abstraction,integration,symbol formation,organization, regulation,etc.Through continuously changing oscillatory processes spontaneous interplay of excitatory and inhibitory circuits maintain a near-threshold state in absence of incoming stimuli.This selfgenerated local activity is selfregulated(mainly through the interplay of the glutamate-GABA cycle). Thus local processes may affect the nature of the newly generated codes. Every CNS output results from the interplay of several excitatory and inhibitory processes. By prevalence of one or the other putative neurotransmitter the different states of consciousness exert systemic regulation of stimulus sensitivity of the various networks.Order and some consistency is maintained by organizer, regulatory and decision systems,to name a few:the pace-maker neurons, the left and right hemispheres,time-keeping systems,the cyrcadian rhythms,the viscero-autonomic(VA)system,etc.Each VA process creates not only emotions,but also one nonspecific systemic inhibitory circuit through which nearly all other network activity is affected.The CNS processes are constantly affected by plasticity, the cognitive past and current physiological conditions.CNS memory is complex, multiple,distributed.The content constantly changes with performance and is subject to the quantum mechanical laws for submolecular systems.Any input into the CNS generates several output types,following various goals including preservation of survival of the organism.The final output is selected only partly by the input,and mainly by a decision system.This seems to contribute to the occasionally questionable logic of the CNS response.Human logic thus may appear erratic because human insight into the CNS processes is defective.We lack insight into the nature of the submolecular processes of the CNS, thus many processes appear as automatic and escape our conscious perception, including a potentially existing superior perfect logic system.

177.9 A COMPUTER MODEL FOR LEARNING PROCESSES AND THE ROLE OF CEREBRAL COMMISSURES, P.A.Anninos and P.Argyrakis*. Dept. of physics, University of Crete, Iraklion Crete, Greece.

Artificial neural nets constructed of discrete populations of neurons have been studied through computer simulation (Anninos,P,Kyb. 11,5,1972) in order to verify the potential role played by the great cerebral commissure as was pointed out by R.Sperry (Neurosc. vol 1 714,1967) in his experimental studies.

In our first theoretical study we consider the simulated intact brain consisting of two neural nets constructed with the same statistical parameters ($K^{\pm}$, ϑ, $\mu^{\pm}$, h), but different microscopic structures (Anninos, P.Kybern. 11, 5,1972), and with their interconnections ($\mu_{12}^{\pm}$ and $\mu_{21}^{\pm}$) corresponding to the intact corpus callosum. In addition, to each neural net or simulated hemisphere we consider a steady input with connections to both neural nets in order to simulate a process such as for example the incoming inputs to the two hemispheres from the two eyes. For the range of parameters used we found that these nets may respond in specific manner to specific stimuli, and furthermore whatever memory was transfered to one net was also transfered to the other. (In these studies the response of the system is monitored by the rise of cyclic activity, as descibed elsewhere (Anninos, P. Kyb. 11,5,1972). However, this behavior changed when the two nets were seperated. When the inter-connections were eliminated the response to each net was different for the same stimulus, so that the brain response to a given situation depended upon which net received the triggering stimulus. The situation changes after learning takes place, in which case the response of both nets was the same. (Learning was considered according to the synaptic facilitation rules, Papadopoulos et al, J.Theor. Biol, 80, 505, 1979).

The above findings verify the experimental observations of Sperry's work that the split brain behaves as if it were indeed two separate brains each performing concurrently and simultaneously diametrically opposite tasks.

177.PO Acquired Neurological Stuttering: Report of Two Cases. W. J. Nowack and R. E. Stone*. Departments of Neurology and Otorhinolaryngology (Speech Pathology), Indiana University School of Medicine, Indianapolis, IN 46223

The value of dysphasic disorders in localizing underlying neurological lesions has repeatedly been demonstrated clinicopathologically. There is debate in the literature about whether a less-frequent speech disorder, stuttering acquired in adulthood is associated with a specific central nervous system lesion. In fact, there have been those who have argued that stuttering acquired in adulthood is primarily a hysterical, psychogenic disorder. We have seen two cases at the Indiana University Medical Center which might help clarify the issue.

Case I: A 30 year old white female with no past history of speech disorder suddenly developed stuttering associated with the occurrence of new domestic difficulties. Her electroencephalogram, which had demonstrated left temporal sharp wave activity without spread to the right side at past times when she had had no speech disorder, now showed bitemporal sharp wave discharges. A course of speech therapy designed to improve airflow proved to assist the patient in retraining the motor mechanisms of speech production and to be anxiolytic to the patient. Following resolution of her domestic difficulties, her stuttering disappeared.

Case II: A 55 year old female, who had experienced a left hemispheric stroke, which did not produce stuttering, developed stuttering after a second right hemisphere stroke. Much less tissue was destroyed in the non-dominant (right) hemisphere than in the dominant (left) hemisphere, as demonstrated by CT scan of the head. Following some domestic difficulties, her stuttering worsened markedly. A similar program of anxiolytic speech therapy was begun. Her stuttering was decreased markedly and her communicative ability increased significantly, although some stuttering was still present.

Both cases suggest that stuttering is associated with bihemispheral disease with the greater pathological change in the dominant hemisphere. The two cases further suggest that the patient's emotional state can interact with the organically caused speech deficit to render the stuttering worse. These observations resolve some of the apparent contradictions in previous reports. Speech therapy which is primarily anxiolytic but which does not correct the underlying neuropathology can prove useful in the management of patients with stuttering acquired in adult life.

178.1 FUNCTIONAL RECOVERY OF BEHAVIOR IN ANIMALS FOLLOWING BRAIN TRANSPLANTS, H. Koopowitz, L. Davies*, and C. L. Keenan*. Developmental and Cell Biology, Univ. of Calif., Irvine 92717.

Brains transplanted from one individual flatworm (Notoplana acticola) into the body of a different decerebrate individual establish anatomical connections, within 24 hr, with the peripheral nervous system of the acceptor worm. Recovery of behavior occurs in these preparations as does recovery of function in identified neurones of the brain. Partial reappearance of simple behaviors appears 48 to 72 hr following the transplant and total recovery appears within the first 10 days. Simple behaviors include ditaxic walking, righting and avoidance turning. Usually the behaviors reappeared in the sequence above. More complex behavior such food capture recovers erratically. Some individuals recover within a few days but others require 20 days to recover this behavior. Of 60 transplants attempted, 42 reestablished all four behavior patterns. Even when the donor brain was rotated, functional connections were reestablished. Donor brains were placed in one of four possible orientations: normal, anterior-posterior reversed, dorsoventral inverted, and anterior-posterior reversed with dorsoventral inversion. All experiments were run double blind and all animals were tested for behavioral recovery each day. There were five trials for each behavior tested. Although 15 transplants were performed for each group, there was differential survival. Data is either expressed as means or as individual performances. The latter case was used if recovery was erratic. All animals were fixed and examined histologically to confirm the orientation of the donor brain. Intracellular investigations of vibration responder interneurones were performed in worms which had accepted anterior-posterior reversed brains, 20 days after surgery. These cells had reestablished connections with peripheral sensory neurones. Lucifer fills of these cells indicated that they were able to grow to appropriate regions in the peripheral plexus although this required complex routes.

178.2 INPUT PROPERTIES OF CLOSER MUSCLE FIBERS IN DIMORPHIC CLAWS OF SNAPPING SHRIMP. DeForest Mellon, Jr. and L. David Smith. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22903

Transformation of claw type in snapping shrimps (Alpheus) is accompanied by an increase in claw closer muscle volume due to specific, renewed growth of individual, pre-existing adult muscle fibers. During transformation, fibers in the closer muscle of the original pincer claw continuously increase their diameter until, in the fully transformed snapper claw, the fibers are four to five times as broad as in their original form. Furthermore, excitatory junction potentials (ejp's) in closer muscle fibers of transformed claws are as large or larger than those exhibited by homologous fibers in non-transformed pincer claws. In theory, during growth fiber input resistance, R_0, varies inversely with the muscle fiber diameter, d, such that $R_0 \sim d^{-3/2}$ as long as sarcoplasmic resistivity, R_i and specific membrane resistance, R_m, remain constant. This relationship holds strictly during growth of identified superficial flexor muscles in the crayfish abdomen. We wished to know whether the input resistance of pincer and snapper closer muscles in snapping shrimps is determined by the theoretical relationship with fiber diameter and, if so, the mechanisms employed during transformation to maintain adequate excitatory synaptic potential amplitude as the target muscle fiber volume enlarges and electrical resistance falls. We used separate microelectrodes to pass current into claw muscle fibers and to record resultant membrane potential charges. Our results show that the mean input resistance of 44 snapper closer fiber was 32 Kohms and that for 25 pincer closer fibers was 151 Kohms, suggesting the input resistance of closer fiber does fall during transformation. The relationship between d and R_0 in these fibers is close to theory. The data from 25 closer fibers, the majority from paired pincer and snapper claws, are best fit by a power function, in which $R_0 \sim d^{-1.59}$. The input resistances of fibers from the two types of claw lie along a continuum, in which size is the obvious independent variable. The possibility that either R_i or R_m also show a consistent relationship with fiber size was examined. Both of these parameters vary widely in muscles of the two claw types, but neither is consistently dependent upon muscle fiber size. We conclude that during pincer-to-snapper claw transformation, R_0 of closer muscle fiber increases as a consequence of geometrical factors alone. Since ejp's of snapper closer muscle fiber are larger than corresponding activity in pincer claws, excitatory synaptic currents must increase during transformation. Statistical studies are now underway to determine the nature of this change in synaptic current and its cellular basis.

178.3 EMBRYONIC ORIGINS OF THE GIANT FIBER SYSTEM IN CRICKETS. G.A. Jacobs and R.K. Murphey, SUNYA, Albany, N.Y. 12222

We have examined the embryonic origin of a class of mechanosensory interneurons (INs) to learn more about the development of this system and provide a framework within which to study segmentally homologous neurons within and across species. These bilaterally symmetric INs are located in the terminal ganglion, which is composed of fused embryonic ganglia 7-11. The fusion process tends to distort the positions of cell somata and commissures, so we stained INs throughout this embryonic period to insure a correct interpretation of their segmental origins.

In embryos the IN somata are confined to three distinct clusters in each ganglion. Neurons within a cluster cross the midline in the same commissure and project rostrally in either a ventromedial tract (VMT) or a dorsolateral tract (DLT). Somata of neurons in cluster 1 are located in the anterior dosolateral quadrant of their embryonic ganglion, cross the midline in the anterior commissure (AC) and project anterior in the VMT. Cluster 2 somata lie ventromedially, their neurites cross the midline in the AC and project anteriorly in the DLT. Cell bodies of neurons in cluster 3 occupy the posterior dorsolateral quadrant of their ganglion cross dorsally in the posterior commissure and travel rostrally in the DLT. This pattern of clusters is repeated for ganglia 7-10; ganglion 11 however, contains only a single cluster of neurons. These resemble cluster 1 neurons, their neurites form a single commissure and project anterior in the VMT. Ganglion 11 appears reduced to an "anterior half" ganglion as compared to the others.

We can now use this information from embryos to devise a classification scheme for many previously identified neurons. Each neuron is given a segment number followed by a cluster number which reflects its embryonic origin. For example: neurons 7-1, 8-1(MGI),and 9-1(LGI), belong to cluster 1 in their respective ganglia, cross in the AC and have axons in the VMT. Neuron 11-1 was originally described by Levine and Murphey (1980) as a 10th segment neuron, our results show that it comes from the 11th segment. This numbering scheme incorporates without change cricket neurons 9-2,10-2,9-3,10-3 of Mendenhall and Murphey (1974). These studies also allow us to identify segmentally homologous neurons, for example, the positional IN described by Sakaguchi and Murphey (1981) is located in cluster 2 in the 7th ganglion and we have identified its segmental homologues in ganglia 8-10. We are now in a position to study the receptive field properties of these homologous neurons to determine how segmental position affects synaptic connectivity.

178.4 EMBRYONIC DEVELOPMENT OF THE GRASSHOPPER'S CERCAL SENSORY SYSTEM: ORIGIN OF SENSORY NEURONS AND THE FORMATION OF THE CERCAL NERVE. Marty Shankland and David Bentley. Depts. of Molecular Biology and Zoology, University of California, Berkeley, Ca. 94720.

Antibodies against horseradish peroxidase display high-affinity binding to some unknown antigen(s) found in insect neurons (Jan & Jan, Soc. Neurosci. Abstr. 7:3, 1981). In grasshopper embryos differentiating neurons begin to express this antigen around the stage of growth cone formation, and we have used direct immunofluorescence to follow the development of the peripheral nervous system in the cercus. Antibody staining shows that the first cercal neurons differentiate at 45% of embryonic life. These cells migrate from the epidermis into the lumen, where they form apical dendrites and send afferent axons toward the CNS. Eventually these cells become associated into two scolopidial organs, one located at the tip of the cercus and one at the base. The two goups of axons grow separately along the ventral body wall toward the CNS, and converge onto a pair of more proximal neurons, where they fuse to form a single afferent nerve. These proximal neurons--the Midway Cells--differentiate at 35% of embryogenesis at a point halfway between the cercal bud and the CNS, and are the first peripheral neurons to take part in the construction of the cercal nerve.

Between 50 and 65% the antigen appears in a large number of sensory neurons located in the cercal epidermis. These epidermal neurons send afferent axons into the lumen, where they fasciculate onto the nerve already established by the scolopidial organ at the tip. Anti-peroxidase faintly stains two other cells, the trichogen and tormogen cells, which are associated with each epidermal neuron. These two cells will respectively form the shaft and socket of a hair receptor innervated by the neuronal dendrite. While the sensory neuron undergoes morphological differentiation coincident with the appearance of the antigen, we found that the trichogen and tormogen cells do not form the sensory hair until one molt later in development. During the intervening time the epidermis secretes an embryonic cuticle which is without sensory hairs. The dendrites of the sensory neurons form specialized contacts with this cuticle, and when the cuticle pulls free from the epidermis at 70% the dendrites remain attached and lengthen to span the gap. At 80% the trichogen cell extends a process into the space beneath the old cuticle to form the hair shaft around the dendrite, and at 85% a new, postembryonic cuticle is secreted over both hair and socket. The old cuticle plus that portion of the dendrite not encased within the hair shaft are shed at hatching. Thus, during grasshopper embryogenesis epidermal sensory neurons appear one molt prior to the formation of their sensilla.

178.5 CHOLINE ACETYLTRANSFERASE-DEFICIENT MUTANTS OF THE NEMATODE C. ELEGANS: EFFECTS ON NEUROMUSCULAR JUNCTIONS. J. B. Rand*, O. J. Bashor*, L. F. Cavalier*, and R. L. Russell* (SPON: I. Hanin). Dept. of Biological Sciences, Univ. of Pittsburgh, Pittsburgh, PA 15260.

We have obtained 5 independent allelic mutations in the gene cha-1, which we believe to be the structural gene for choline acetyltransferase (ChAT). Four of these alleles (b401, p1152, p1154, and p1156) are relatively severe, and strains containing them share the same spectrum of phenotypes: greatly reduced ChAT activity (0.4-2.0% of wild-type), slow growth, small size, uncoordinated movement, and resistance to cholinesterase inhibitors (carbamates and organophosphates). The fifth allele, p503, is relatively mild; strains homozygous for p503 have 8-10% the normal ChAT level and are behaviorally and developmentally normal. The residual ChAT activity in strains homozygous for p503 has altered K_m's and salt sensitivity; these results together with the strict gene dosage observed with animals heterozygous for any of the alleles support our contention that cha-1 is the structural gene for ChAT (or a subunit of ChAT). Animals homozygous for any of the severe cha-1 alleles have acetylcholine levels decreased about 50%, which, although significant, are not nearly as profound as the decrease in ChAT activity.

Since the nervous system of C. elegans is simple (350 neurons total) and invariant, and since all the synaptic interactions have now been mapped, it is possible to examine known, identifiable putative cholinergic neurons in both wild-type and mutant animals. Therefore, we investigated the effects of genetic reductions in acetylcholine synthesis on the formation of (cholinergic) NMJ's and on neuronal circuitry in general through serial-section electron microscopic reconstruction of the nerve cords of wild-type and cha-1 animals. Series of 200-1000 sections (72.5 nm/section) were analyzed; all the motor neurons in both the ventral and dorsal nerve cords were identified and traced, and all their neuromuscular output was catalogued. The appearance, structure, and circuitry of the motor neurons from the cha-1 strains were normal. However, we observed a reproducible 30-35% decrease in the frequency of cholinergic NMJ's in cha-1 animals (.60-.66 NMJ's/µm in cha-1 vs .94-.99 NMJ's/µm in wild-type). We do not know if this reduced neuromuscular output is sufficient to account for the uncoordinated behavior of these mutants, but we have also observed alterations in the synapse patterns of ventral nerve cord interneurons in cha-1 animals, and the exact circuitry in these mutants is being ascertained.

Supported by a grant from the Muscular Dystrophy Association.

178.6 Genetic Studies of Sensory Neuron Projection Patterns in Drosophila melanogaster. S. H. Green. Division of Biology 216-76, Caltech, Pasadena, CA 91125.

The projections of genetically produced ectopic thoracic sensilla into the brain of D. melanogaster were studied by cobalt and HRP filling. These were compared with the normal projections of these sensilla into the ventral ganglion as well as the projections into the brain of the local sensilla that normally occupy the new locations of the ectopic neurons. The ectopic sensilla studied were the tarsal and tibial bristles of antennal legs produced by the genotype Antp Df(3)sbd /Pc ss and dorsal thoracic and wing margin bristles produced by the mutation ey . The mutations cause these sensilla to appear on the head by replacing or being added to sensilla that are normally present.

The normal antenna's projection has also been described by Stocker, R. and Lawrence, P. (Dev. Biol. 82, 224-237, 1981). It consists of a bilateral olfactory lobe (OL) component organized into glomeruli, and a mainly ipsilateral component in the posterior deutocerebrum and SEG which can be further subdivided into 3 major branches. The head macrochaetes all arborize in an identical manner in the subesophageal ganglion (SEG). The routes they take to the SEG, however, vary according to their positions on the head. The arborization is L-shaped with an ipsilateral, longitudinally oriented branch and a medially directed branch that crosses the midline. One branch of the non-OL antennal component precisely matches the head bristle projection.

The antennal leg projection is identical to the antennal for the non-OL component but in the OL the axons arborize randomly, are not organized into glomeruli, have few contralateral branches and have adventitious projections into the protocerebrum and SEG. Some of these latter are consistent from fly to fly. Mechanosensory fibers alone can make up the entire projection.

Thoracic and wing bristles on the head and eye project in the brain and optic lobes. In the brain they often reach the SEG but ramify irregularly. Similarly, their branching in the optic lobes is irregular and unlike that of retinular or intrinsic axons.

I conclude that the ability of ectopic axons to be guided by local pathways or branch in local neuropil is not like that of local neurons and depends on the modality or type of ectopic sensilla that is being studied. In general only the initial projection of the ectopic sensilla is like the local sensilla. The projections of ectopic sensilla into "foreign" neuropil bears no resemblance to their normal projections.

WITHDRAWN

179.2 CELL BIRTHDAYS IN THE SYMPATHOADRENAL SYSTEM: RELATION TO SURVIVAL AND DIFFERENTIATION IN DISSOCIATED CELL CULTURE.
P. Claude, L.E. Lillien*, I. Parada* and S.K. Presto*.
Wisconsin Regional Primate Research Center and Neuroscience Training Program, University of Wisconsin-Madison 53706.

In order to use neurons and adrenal chromaffin cells in vitro as models for differentiation in vivo, it would be useful to know whether the cells that survive in culture are representative of the donor population or whether they represent a subpopulation with special properties. This is a concern in situations in which a small proportion of the donor cells survive in culture. In this experiment we asked whether there was a selection in vitro on the basis of the developmental age of the cells . We used 3H-thymidine (3HT) labeling to compare the proportion of labeled neurons or chromaffin cells in dissociated cell cultures with the proportion of labeled cells in the donor tissues. Female rats at different stages of pregnancy (from E15 through E20; gestation is 21 days) received a single intraperitoneal injection of 3HT. When litters were born, cultures of dissociated cells were prepared from the superior cervical ganglia (SCG) and the adrenal medullae of some of the pups. After 5 days of growth in vitro in the presence of nerve growth factor, cultures were fixed, air dried, and coated with Kodak NTB-2 emulsion. SCG and adrenal medullary tissues from newborn littermates were also prepared for autoradiography. Chromaffin cells in 1 µm Epon sections of adrenal glands and neurons in sections of the SCG were identified by morphological criteria and the proportion of labeled cells was determined. In the adrenal cultures, chromaffin cells were identified on the basis of catecholamine histofluorescence and the proportion with neurites was noted.

The proportion of labeled neurons in the SCG in vivo was maximal following injections on E15 (23%) and declined progressively to 4% following injections on E20. In culture we observed a similar pattern of decline in the proportion of neurons labeled between E15 (34%) and E20 (0.7%), with a trend toward the preferential survival in culture of older neurons, i.e., those born before E18. The pattern of chromaffin cell labeling was quite different. In the adrenal in vivo 9% of the chromaffin cells were labeled following injections on E15 and the proportion of labeled cells rose to 19% following injections on E20. Preliminary analysis of chromaffin cell cultures suggests that, as in the case of cultured sympathetic neurons, there was some preferential survival of older chromaffin cells. However, there did not appear to be a large bias, based on developmental age, in the selection of neurons or chromaffin cells that survived in culture.

179.3 EXPRESSION OF NEURONAL TRAITS IN CULTURED NEURAL CREST.
J. Girdlestone and J.A. Weston (SPON: G. Ciment). Dept. of Biology, Univ. of Oregon, Eugene, OR, 97403.

Neural crest cells give rise to a number of derivatives including the neurons and glia of the PNS. To characterise the pattern of differentiation of these neurons we have examined the appearance of several neuronal markers in cultured neural crest populations. One such marker, the monoclonal Ab E/C8, which binds to neurons of the PNS and CNS, reveals the presence of a small sub-population of antigen-positive cells in primary neural crest cultures. These labelled cells are generally found in spherical aggregates, but antigen-positive cells with fine processes are also seen amongst the monolayer of non-neuronal cells, mostly melanocytes, which constitutes most of the culture. Catecholamine-fluorescent cells are also detected in crest cultures and a double-labelling procedure is being developed to determine if these constitute a sub-population of the cells containing the E/C8 antigen. With the availability of such specific markers we hope to assess the relative roles of environmental and intrinsic factors in the process of differentiation.

179.4 INTRACELLULAR MIGRATION OF MONOCYTES THROUGH THE CHOROID PLEXUS AS POTENTIAL EPIPLEXUS (KOLMER) CELLS IN THE MONKEY.
R. G. Clark. Dept. Anatomy and Cell Biology, Univ. Miami, Sch. of Med., Miami, FL 33101.

It is well known that a unique population of macrophages adheres to the surface of the choroidal epithelium. First called Kolmer cells, they now are usually referred to as epiplexus cells. Phagocytic in nature they have elongated processes which interdigitate with the microvillus processes and cilia of the choroid plexus epithelial cells. It has been suggested that these cells are hematogenous in origin and pass from the connective tissue core to cross between epithelial cells to reach the ventricular surface. The present study provides the first evidence that the macrophages pass through the epithelium but that the migration occurs by an intracellular rather than an extracellular route.

Six normal rhesus monkeys (2-4 kg) were studied. The animals were sacrificed with an overdose of sodium pentobarbital and perfused through the heart with 6 liters of a solution containing 1% paraformaldehyde and 1% glutaraldehyde in 0.075 M cacodylate buffer. Small portions of choroid plexus from all ventricles were removed and processed for electron microscopic evaluation.

The most significant finding was the presence of monocytic, macrophage-like cells which appeared to be passing through the choroid plexus. At times they were observed in the intercellular space between adjacent epithelial cells but the zonula occludens was always intact and appeared to block any further migration. Generally, the macrophages were contained within the choroidal cells causing the latter to bulge prominently into the ventricular lumen. The epithelial cells were so engorged by the monocytes that their nuclei were indented and cytoplasmic organelles greatly compressed. The macrophages did not appear to be phagocytizing the epithelial cells. Structurally the macrophages looked similar to the epiplexus cells but lacked the long cytoplasmic processes.

180.1 EARLY DESCENDING NEURONS OF THE XENOPUS TAIL SPINAL CORD. R.H. Nordlander. Depts. Anatomy and Oral Biology, Case Western Reserve University, Cleveland, OH 44106.

Fiber tract development in the amphibian spinal cord begins with the ingrowth of axons into small spaces between adjacent neuroepithelial cells (Nordlander and Singer, Exp. Neurol., 75:221, 1982). Each fascicle at first consists of one or a few axons to which others are added. The rostrocaudal developmental gradient, which allows this sequence to be observed within individual specimens over a range of stages, and the simplicity of the tail spinal cord makes it especially suitable for the study of pathfinding in the vertebrate central nervous system.

The purpose of this study was to identify the earliest descending axons of the tail spinal cord and to describe the cell classes to which they belong. Horseradish peroxidase (HRP) was applied to the spinal cord of Xenopus (stages 30 to 39) at a level previously shown to receive the first descending axons. Specimens were incubated for 10 min. to 48 hr. before fixation, reacted with the method of Hanker, et al. (Histochem. J., 9:789, 1977), embedded in plastic and sectioned in transverse and horizontal planes. HRP traveled retrogradely along axons of the two earliest axonal bundles, one dorsolateral (DLF) and one ventrolateral (VLF), to fill cells located rostral to the application site. Among these cells several types can be clearly distinguished on the basis of position and morphology.

Rohon-Beard cells are the most commonly labeled cells at the earliest stages examined. These cells, which are part of the primary sensory system, occupy a dorsal position and send ascending and descending axons in the DLF in addition to a peripheral axon.

Primary motor cells are smaller neurons appearing in the ventrolateral mantle layer. Each of these cells sends a short process rostrally and a longer axon caudally in the VLF. The descending process exits the cord via a ventral root at a more caudal level. Dendrites spread radially into the lateral marginal layer.

The most prominant and earliest interneurons to appear are the dorsolateral cells which are located directly lateral to the Rohon-Beard cells. Each of these cells sends a stout process circumferentially along the lateral border of the cord, later to be displaced medially as the marginal layer expands. Dendrites extend laterally from the process before it divides to send ascending and descending processes into the VLF. At successive stages the proportions of labeled interneurons increases and at least three types are observed at stage 39.

- The morphologic development of these cells was followed by comparison of specimens incubated for progressively longer periods.

Supported by NINCDS Program Project Grant NS-15731, Marcus Singer, program director.

180.2 INNERVATION OF CHICK WINGS WITH A SPLIT LOWER ARM: AN EVIDENCE FOR ACTIVE NERVE-MUSCLE RECOGNITION. M. Neset, C. Muniak* and C. Edwards. Neurobiology Research Center, SUNY Albany, Albany, N.Y. 12222.

Experiments were designed to acquire more information about the development of pattern formation. Innervation was studied in 12 day embryonic chick wings, having two lower arms in "parallel", both originating from the elbow. The grafts were performed according to Saunders and Gasseling (1968, In: Fleishmajer and Billingham, R.E. (Eds.) Epithelial-Mesenchymal Interactions).

The two flexor carpi ulnaris muscles (f.c.u.) of the grafted limb were always innervated, and the cell bodies of the neurons were in the specific area for f.c.u.-neurons in the cord, as determined by the retrograde HRP-technique. There are at least three possible explanations for this result. The innervation could be due to an increase in the number of neurons innervating the duplicated lower arm, i.e. a decrease in cell death. However, the numbers of motor neurons on the experimental and control side are similar, and this seems to exclude a role for cell death. Alternatively, branching of the neurons prior to entering the muscles may be present, with both muscles innervated by the same nerve fibers, keeping the number of motor neurons constant. However, the results of direct stimulation of the nerve trunks at the spinal root and close to the muscle showed no evidence of branching. Therefore, it is likely that the f.c.u.-muscles are innervated by separate groups of neurons, and that each fiber innervates more muscle fibers than normally.

The present findings taken together with earlier results of proximo-distal grafted limbs (Muniak & Neset, 1981, Soc. Neurosci. 7:464; Neset & Edwards, 1981, Soc. Neurosci. 7:465), show that a specific group of neurons innervates the f.c.u.-muscles whether these are in "parallel" or in "series", and that the total number of motor neurons is not affected by these types of grafts.

180.3 MONOCLONAL ANTIBODIES TO CEREBELLAR AFFERENT INPUTS, Richard Hawkes*, Evelyn Niday, Gerda Huber* and Andrew Matus. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

There are two afferent pathways to the mammalian cerebellum, the climbing fibers which terminate on the Purkinje cell dendrites and the mossy fibers which synapse with granule cell dendrites. We have produced a library of monoclonal antibodies (mab) which recognize diverse components of the rat cerebellum. Among these are two classes which are apparently specific for one or other afferent system. On SDS-gel immunoblots the first class, exemplified by mab 12D5, recognizes a single polypeptide band of apparent molecular weight 270,000. Immunocytochemistry reveals that staining of the cerebellum is confined to the granular layer, primarily to the synaptic glomeruli. Similar studies of neonatal tissue suggest that the staining locus is the mossy fiber system. Consistent with this hypothesis, we have identified antigen-positive cell bodies and processes in the pons, a major source of mossy fibers. The second group, exemplified by mab 6A1, recognizes several distinct polypeptide bands on gel blots. The immunocytochemical staining with 6A1 is confined to the molecular layer where it is distributed as patches along the margins of the Purkinje cell dendrites, consistent with the size and distribution of climbing fiber synapses.

180.4 HISTOGENESIS OF THE RAT SUBSTANTIA NIGRA: ISTHMIC ORIGIN OF ITS NEURONS. R. Marchand. Centre de recherche en Neurobiologie, Hôpital de l'Enfant-Jésus, 1401, 18e Rue, Québec, Qué. G1J 1Z4.

This study provides new data on the time of origin, the site of generation and the route of migration of the young neurons of the substantia nigra of the rat during embryogenesis. The neurons of the substantia nigra are generated on day 12, 13, 14 or 15 of gestation. They settle following a light spatiotemporal rostrocaudal gradient from day 12 to day 15. The neurons of the substantia nigra are generated at two different points of the basal plate at the level of the fovea isthmi (meso-isthmic junction) and migrate in radial pattern as two definite streams toward the ventral mesencephalon. Then the two streams of cells move rostralwards along the surface towards their final site. The median stream of cells originate in the medial basal plate along the unpaired floor plate of the isthmus rhombencephali. The median stream of cells clearly contributes to the formation of the substantia nigra, pars compacta, the area of Tsai and to the nucleus linearis caudalis. The ventrolateral stream of cells originates at the same level although more laterally along the basal plate. It contributes cells to the lateral and ventral areas of the susbtantia nigra.

The main findings of this work are the disclosure that the neurons of the substantia nigra are generated in the region of the isthmus rhombencephali and that its cells do not migrate between existing cells of the mesencephalic tegmentum as claimed previously but first migrate ventralwards in a radial pattern and then rostrally towards their definite site. All the cell groups of the basal mesencephalon and the midline structures of the caudal mesencephalon are apparently derived from the region of the isthmus rhombencephali.

180.5 CHANGES IN CENTRAL CANAL AREA IN YOUNG RATS FOLLOWING EXPOSURE TO X-RAYS. S. A. Gilmore, T. J. Sims and J. E. Leiting*. Depts. of Anatomy and Pathology, Univ. Arkansas Med. Sciences, Little Rock, AR 72205.

A population of cells having nuclei resembling those in the lateral walls of the central canal form a well-defined cluster situated just ventral to the central canal area. This ventrally situated cell cluster is extremely sensitive to ionizing radiation (Soc. Neurosci. Abst., 7:467, 1981). By 6 hours post-irradiation (P-I) many nuclei in this cluster are pyknotic, and by 24 hours this cluster essentially disappears. Further light and electron microscopic studies have been in progress to analyze the changes occurring in this area following exposure to x-rays.

A beam of soft x-rays (4000R) was directed to a 5mm length of lumbosacral spinal cord in 3-day-old rats. For light microscopy the rats were perfused-fixed at intervals from 6 hours to 10 days P-I. The spinal cords were embedded in JB4, and a variety of stains was used. Normal 3-day-old rats and rats killed at 18 and 24 hours P-I were used for ultrastructural studies. These animals were perfused with a modified Karnovsky's fixative, and both thick and thin sections were prepared in the usual fashion.

Ultrastructurally the cells in the ventral cluster in the normal 3-day-old rat resembled glioblasts, probably astrocytes. The nuclei were generally ovoid, with moderate amounts of condensed chromatin around the nuclear envelope. The cytoplasm was of medium density and contained microfilaments. Extensions of this cytoplasm surrounded small bundles of axons. The perikaryal membranes had no synapses or junctional complexes.

The ventral cluster, which had virtually disappeared by 24 hours P-I, was not reconstituted by 10 days P-I. During this interval, the cellular organization in the irradiated animals changed from a pseudostratified to a simple arrangement in the lateral walls of the canal, suggesting that a cell loss had occurred. Cell counts showed that the walls of the canal in the irradiated rats contained approximately 40% fewer cells than in the controls. Pyknosis was not a prominent feature of the lateral walls light microscopically. However, degenerative changes were observed ultrastructurally in the laterally situated ependymal cells. These data indicate that the cells in these areas (ventral cluster vs. lateral wall) are differentially sensitive to effects of ionizing radiation.

180.6 IS NEURAL MATURATION SIMILAR IN PRECOCIAL AND ALTRICIAL MURIDS? P. C. Brunjes. Dept. of Psychology, University of Virginia, Charlottesville, Va. 22901.

Offspring of Acomys cahirinus (the "spiny mouse") are born after a 38 day gestation period with open and functional ears and eyes and sophisticated locomotor capabilities. Would an animal with such divergent development exhibit ontogenetic patterns similar to those found in more commonly studied altricial murids such as the laboratory mouse and rat? The long gestation period of Acomys suggests that rates of maturation in altricial and precocial pups are the same with birth occurring at some arbitrary timepoint. To test this notion, we examined olfactory bulb growth in 0, 10, 20, and 60 day postpartum Acomys pups. The bulb was chosen because its clear lamination and pattern of late maturation facilitated examination. The following measures were employed: 1) changes in main olfactory bulb laminar volume (glomerular, G; external plexiform, E; mitral, M; and combined internal plexiform, inner granule and ventricular, I), 2) accessory olfactory bulb volume and 3) mean glomerular size. Tissue from four animals per age was examined and all measurements made with an Apple II based computer system. Significant age-related increases were found in all measures except for the mitral layer. Most increases were found between Day 0 and Day 10 (percentage increase was 73 for G, 156 for E, 50 for M, 72 for I, 81 for the accessory olfactory bulb and 80 for glomerular size) indicating that large amounts of postnatal maturation do occur in the precocial brain. Hinds and Hinds (J. Comp. Neur., 169:20, 1976) report that mice of the conceptual age examined here (postnatal days 18-28) also exhibit increases in bulbar volume, with most occurring in the external plexiform layer. However, mice evidenced only a 40% increase, compared to the 156% change found in Acomys. Thus, compared to their altricial cousins, Acomys exhibit considerably more neural growth at late gestational ages. Our results suggest that brain development is not similar in altricial and precocial murids; Acomys undergoes more neural development than predicted by data from altricial pups, and that neural maturation is delayed in Acomys in relation to the development of other systems. Perhaps neural growth and differentiation are withheld until after parturition to allow newborns to adapt to a complex world.

180.7 A SIGNIFICANT FRACTION OF THE ADULT NUMBER OF MATURE CEREBELLAR PURKINJE CELLS FIRST APPEARS BETWEEN POSTNATAL DAYS 16 AND 30 IN THE MOUSE. T.J. Diglio* and K. Herrup, Dept. of Human Genetics, Yale Medical School, New Haven, CT 06510

The achievement of the adult number of most large neuronal cell types is generally assumed to occur early in development. One obvious corollary to this view is that it should be possible to quantitatively account for all members of a given cell type at all stages following their ventricular genesis (and subsequent period of cell death, if any). We report here that rigorous quantitative analysis of cerebellar Purkinje cells does not bear out this prediction. Specifically, we find a 40% increase in Purkinje cell number occurs in the mouse between postnatal days 16 (P16) and P30.

Two to four C57BL/6J mice were analyzed at each of eight postnatal ages ranging from P10 to P180. All animals were perfused with half strength Karnovsky's fixative and processed identically. Serial wax sections of cerebellar halves from each animal were assembled, stained and, in 12 to 15 sections from each series, all Purkinje cells with a clearly visible nucleus were counted (5000 to 7500 cells per animal). Correcting our raw counts by the method of Hendry, with slight modifications, we find the number of Purkinje cells remains constant from P10 to P16 (51,000 cells per half cerebellum) then increases over the ensuing two weeks to reach adult levels (74,000 cells) by P30. Several additional observations lend perspective to these findings. First, Caddy and Biscoe (Proc. Roy. Soc. Lond. 287, 167) made nearly identical observations in C3H mice but dismissed their finding as artifact. Second, cells of the facial nucleus in the same animals used for the Purkinje cell counts described above do not have a period of cell number increase during postnatal life. Lastly, the number of medium-to-large neurons (MLNs) in the staggerer mutant also show no postnatal increase in cell number. Since the staggerer mutation is known to block Purkinje cell development at early stages, this finding suggests that the 40% increase in the wild-type is part of the normal sequence of developmental events.

Although the source of the late Purkinje cells remains unknown, preliminary analysis of animals injected embryonically with ^{3}H-thymidine and examined autoradiographically at several postnatal ages demonstrated that these cells do not arise by late development of immature cells present in the Purkinje cell layer at P10. Whatever their source, the occurence of this late addition of a large fraction of major neuronal cell type suggests a new chapter must be added to the story of CNS develoment.

180.8 TRANSIENT VISUALIZATION OF β-ENDORPHIN-CONTAINING NEURONS IN THE RAT BRAINSTEM DURING PERINATAL DEVELOPMENT. G. Baetge, W.J. Shoemaker, A. Bayon, R. Azad, and F.E. Bloom. The Salk Institute, La Jolla, CA 92037.

We have previously described the development of the opioid peptides, β-endorphin and enkephalin, in diencephalic and telencephalic structures of the rat. At embryonic day 16 (ED-16) β-endorphin is detectable in both brain and pituitary. Using permeation chromatography followed by radioimmunoassay (RIA), only a small amount of high molecular weight material (β-LPH or 31K protein) is present in the whole brain at this early stage of development (Bayon et al., Soc.Neurosci.Abstr.5:523, 1979). We now describe further details of this system using both immunocytochemical staining and high performance gel permeation chromatography on the brain stem. Using anti-serum specific for β-endorphin and the indirect 2-Step immunoperoxidase technique, we see stained perikarya and processes in the dorsal medulla oblongata coincident with nucleus commissuralis. The staining could be blocked by pretreatment with authentic β-endorphin and was observed from late fetal stages to post-natal days 17 or 19. The β-endorphin-positive cells are dispersed throughout an arc from the midline dorsal to the central canal which extends to the dorso-lateral edge of the vagus nucleus. Their distribution is similar to the dopamine-β-hydroxylase-positive staining cells of the A_2 catecholamine group, but the two groups have different morphological shape and appear to be separate. The perikarya of the β-endorphin-positive neurons are ovoid in shape with processes extending from either one or both poles. The longitudinal axis of the cells and the stained processes orient along the arc-shaped zone of immunoreactive cells. We are currently utilizing HPLC gel-permeation chromatography to resolve the different molecular weight components in this and other regions of embryonic, newborn and post-natal animals. Preliminary results indicate that the β-endorphin has the size of authentic β-endorphin with no high M.W. β-endorphin I.R. It is not yet clear whether the loss of β-endorphin positive perikarya in the brain-stem group after postnatal day 19 results from "programmed cell death", a switch to production of another neurotransmitter or simply loss of peptide stores to a level below detection. 180.9 GOLGI ANALYSIS OF NEURON DIFFERENTIATION IN THE PRESUMPTIVE DORSAL HORN OF THE E12 MOUSE EMBRYO. L. E. Wentworth. Dept. of Anat., Med. Ctr., Sch. of Med., San Francisco, CA 94143

During embryonic day 12 (E12, where EO = day vaginal plug observed) the presumptive dorsal funiculus reaches approximately 2/3 across the top of the dorsal cord and the ventricular layer comprises less than ½ the width of the dorsal cord. In addition to commissural cells and ipsilateral association cells, which began differentiating on E9 and have been described previously (Wentworth and Yee, Anat. Rec., 193:717-718, 1979), a variety of neuron types are differentiating in the alar plate region at this time.

Transversly oriented fusiform cells are seen which border the dorsal extent of the presumptive dorsal horn. Unlike ventral horn motoneurons, commissural and ipsilateral association neurons which go through a unipolar stage followed by a bipolar stage with the first dendrite growing from the pole opposite the axon, most of these cells go from a unipolar stage to a multipolar stage by branching first at the axonal pole and later at the opposite pole. These cells probably represent the marginal cells of lamina I in the adult.

Elongated pyriform cells oriented dorsoventrally are located in the mid intermediate region of the alar plate at this time. The axon is directed dorsally in some of these cells and ventrally and/or toward the lateral funiculus in others. A few cells are seen in the mid intermediate region which resemble early pyramidal cells. They are also oriented dorsoventrally and have an apical dendrite , basal dendrites and a descending axon. Some cells in the dorsal intermediate region have a tangential orientation with an axon directed dorsally and dendrites directed laterally toward the dorsolateral funiculus.

Multipolar cells are seen in the dorsolateral intermediate region which have extensive dendritic networks branching into the dorsolateral funiculus. These cells may be similar to some cells described in lamina IV of the adult (Brown, Organization in the Spinal Cord, Springer-Verlag, 1981).

The axon of many cells of the dorsal cord ramifies, sometimes extensively. Occasionally a cell is seen to have an axon which bifurcates and enters both the presumptive dorsal funiculus and the dorsolateral funiculus. Only a limited number of very early stages of neuron differentiation in the alar plate have been seen to date with the rapid Golgi method. We are now serially reconstructing thin sections in order to obtain a more complete picture of the differentiation of these cell types.

180.10 SEXUALLY DIMORPHIC DENDRITIC ORGANIZATION IN THE PREOPTIC AREA OF THE NEONATAL RAT. P. E. Meyers* and J. H. Gordon (SPON: C. M. Combs). Departments of Anatomy and Pharmacology, The Chicago Medical School, N. Chicago, IL 60064.

The dorsomedial portion of the medial preoptic area has been described as being sexually dimorphic. The current study examines normal development of sexually dimorphic dendritic organization in the rat pup within this area.

Six millimeter square blocks of tissue were removed from pups at 2, 4, and 6 days of age. Blocks were prepared by the Golgi-Cox method, embedded in celloidin, and cut at 70u. Camera lucida drawings of well-impregnated neurons were obtained from the dorsomedial medial preoptic area. Neurons were analyzed with a grid composed of concentric rings divided into equal octants. Rings were in radial increments of 10.5 um. Octants were numbered from 1 to 8 in a clockwise direction starting from 12 o'clock. At this time, data from the 6 day rats (2 male and 2 female) is the most complete. Data was taken as ring crossings per octant of each sex. For this preliminary analysis, crossings per octant are expressed as percentages of total crossings.

Sex	Total crossings	Octants (crossings/total crossings)							
		1	2	3	4	5	6	7	8
Female (20 cells)	378	31	12	8	7	20	10	2	10
Male	297	25	6	8	18	15	10	6	13

Females showed a strong preference for octant 2, differing from males by 52%. Females showed a minor preference for octants 1 and 5. Dendrites from females tend to orient from dorsolateral to ventromedial. Males showed strong preferences for octants 4 and 7, differing from females by 61% and 66.6% respectively. Males showed a minor preference for octant 8. Dendrites of males tend to orient from mediodorsal to ventrolateral. The younger animals showed similar trends.

Supported in part by NIH-BRSG #RR-05366.

180.11 THE DEVELOPMENT OF MEISSNER'S CORPUSCLES IN PRIMATE DIGITAL SKIN. W. E. Renehan* and B. L. Munger* (SPON: W. Graham). Dept. of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA 17033.

The development of Meissner's corpuscles has been studied in digital skin of fetal, newborn and adult rhesus monkeys (Macaca mulatta). Specimens were taken from 14 cm (measured crown-rump), 15 cm, 16 cm, 17 cm, 18 cm, and 19 cm fetal monkeys, covering the period of 3-6 months of gestation, and from newborn and adult animals. Serial paraffin sections were stained with ammoniacal silver, and tissue for electron microscopy was prepared using conventional methods.

Early in the third month of gestation, developing Meissner corpuscles were represented by a close association of one to five thinly myelinated and unmyelinated axons with the dermal capillary loop, high in the dermal papilla. As development proceeded, the vascular elements assumed a position lower in the papilla. Each axon branched into a number of smaller diameter fibers, oriented vertically with respect to the dermal papilla. In 15 and 16 cm fetuses, the axons pierced the basal lamina of the epidermis at the top of the papilla, and penetrated into the stratum basal and stratum spinosum. The portions of these axons in the apex of the dermal papilla were associated with a cluster of presumptive lamellar cells. These lamellar cells were indistinguishable from the Schwann cells associated with the afferent axons. During the fifth and sixth months of gestation the basal lamina of the epidermis was discontinuous in the region of the apex of the dermal papilla, allowing cell contact between lamellar and epidermal cells. In the neonatal period the basal lamina was again continuous.

In the perinatal fetus, the axons supplying the maturing corpuscles were no longer present in the epidermis. Instead, the thin unmyelinated branches of the parent axons changed their orientation, and assumed a position parallel to the skin surface. At the same time, the cytoplasmic processes of the lamellar cells occupied the spaces between the horizontal terminal portions of the afferent axons. The corpuscle was surrounded by a perineurial capsule continuous with the perineurial sheath of the nerve bundle. The capsule, however, was discontinuous at the apex of the dermal papilla. Axon terminations were enlarged, filled with numerous vesicles, mitochondria, neurofilaments, and membranous elements.

During the first month of life, an increase in the number of lamellae caused the Meissner corpuscle to achieve maturity.

(Supported in part by USPHS HD-11216.)

181.1 REDUCTION OF NATURALLY-OCCURRING CELL DEATH IN THE THORACO-LUMBAR AND SACRAL PREGANGLIONIC CELL COLUMN OF THE CHICK EMBRYO FOLLOWING BLOCKADE OF GANGLIONIC TRANSMISSION. J.L. Maderdrut* and R.W. Oppenheim (SPON: W.E. Hall). Neuroembryology Lab., Dorothea Dix Hospital, Raleigh, N.C. 27611.

The thoraco-lumbar (sympathetic) and sacral (parasympathetic) preganglionic cell column (column of Terni, CT) is formed by the secondary migration of motoneurons from the common motor column (CMC) in the ventrolateral spinal cord to a mediodorsal position between Stage 25-26 (day 4.5-5) and Stage 34 (day 8). Nerve fibers from perikarya in the cervical and thoraco-lumbar CMC were detected in the primary sympathetic chain by Stage 25. There was a significant loss of motoneurons in the thoraco-lumbar and sacral CT between Stages 34 and 36 (day 10). Pyknotic (degenerating) cells were seen in both the thoraco-lumbar and sacral CT during the period of naturally-occurring motoneuron loss. A massive degeneration of neurons occurred in the cervical CMC between Stages 24 and 26.

Either presynaptic (hemicholinium-3, HC-3) or postsynaptic (pempidine) blockade of ganglionic transmission spanning the period of naturally-occurring cell death reduced both the loss of motoneurons and the number of pyknotic cells in the thoraco-lumbar and sacral CT. Ganglionic blockade had no apparent effect on the volume of the thoraco-lumbar sympathetic ganglia at Stage 36. Blockade of ganglionic transmission between days 10 and 15 (Stage 41) decreased the volume of the thoraco-lumbar sympathetic ganglia but had no effect on the number of visceromotor neurons in the corresponding CT. Numberous small pyknotic profiles (presumably, oligodendrocytes) were scattered through both the gray and white matter of the spinal cord following treatment with HC-3. Blockade of ganglionic transmission between days 3 (Stage 18) and 8 had no effect on either the massive cell death in the cervical CMC or the secondary migration of thoraco-lumbar and sacral visceromotor neurons. The three drug regimens had no effect on the nuclear diameter of either thoraco-lumbar or sacral visceromotor neurons.

Both competitive (curare) and depolarizing (decamethonium) neuromuscular blockade between days 5-6 and 10 reduced naturally-occurring cell death in the thoracic medial (somatic) motor column but had no effect on cell death in the thoracic CT (cf. R.W. Oppenheim and J.L. Maderdrut, Proc. Soc. Neurosci., 1981, 7, 291). Postsynaptic blockade of ganglionic transmission had no effect on cell death in either the thoracic medial motor column or the lumbar lateral (somatic) motor column.

181.2 SURVIVAL OF LATERAL MOTOR COLUMN NEURONS IN EXPLANT CULTURES: TARGET AND SUBSTRATUM INFLUENCES. E. D. Pollack. Inst. Study Develop. Disabil., University of Illinois, Chicago, IL 60608.

Growth and survival of nerve fibers from developing tadpole spinal cord cultures have been demonstrated to be dependent on the presence of mesenchymal limb target tissue and the nature of the substratum (Pollack, Neurosci. Lett.,'80; Pollack et al., J. Comp. Neurol.,'81; Muhlach and Pollack, Dev. Brain Res.,'82). Increased survival of nerve fibers from cord explants has assumed the increased survival of lateral motor column (LMC) neurons. This is now confirmed for the LMC cells of spinal cord explants from young frog tadpoles cultured in the presence of limb mesenchyme and on the alternative substrata of collagen or polylysine. Stage V (Taylor-Kollros stages) tadpole lumbosacral spinal cord explants were cultured for 21 days on either re-constituted rat tail collagen (COL) or on poly-DL-lysine (PLYS) in the presence or absence of stage V mesenchymal hindlimb and then serially sectioned and stained. Control cord explants grown alone on PLYS exhibited an average LMC cell count 10 times that of explants on collagen. On both substrata, the LMC cell count was increased significantly when limb explants were present. However, the increases were more dramatic on collagen since very few LMC cells survive in cord cultures on collagen that lack target tissue. These findings are consonant with previous results on nerve fiber outgrowth.

The preliminary results suggest that both a target-based influence and the nature of the substratum may act interdependently to regulate neuronal survival in vitro. On collagen the limb target seems to mimic the survival effects from PLYS alone, while the addition of limb to cord cultures on PLYS enhances even further the survival of the LMC neurons. Increased numbers of cells are attributable to survival rather than proliferation since mitotic index and DNA differences are of insignificant magnitude. The present morphological observations correlate well with biochemical indices for tadpole spinal cord explants under similar conditions (Muhlach and Pollack, Neurosci. Abstr.,'82). Aside from neuronal counts, it appeared that the distribution of necrotic cells within the explants was a consistent feature. Only infrequently were such cells located within the LMC when limb had been present or in the ventricular zone, but were otherwise evenly distributed throughout the intermediate zone. These results offer further evidence in support of the hypothesis that the mesenchymal limb target serves as a source of a motor neuron survival (and growth) factor, while the attachment substratum acts in concert with it to favor the factor-promoted activities of the neuron.

(Supported by NIH grant NS 13814.)

181.3 TARGET DEPENDENCY OF CEREBELLAR GRANULE CELLS ON PURKINJE CELLS. QUANTITATIVE ANALYSIS OF LURCHER CHIMERIC MICE. R. WETTS & K. HERRUP, (SPON: E.L. Giller, Jr.). Dept. of Human Genetics, Yale Univ. Sch. Med., New Haven CT 06510.

Lurcher heterozygous mice (+/Lc) suffer a loss of 100% of the cerebellar Purkinje cells (PCs) and 90% of the granule cells (GCs) between the second and fifth postnatal weeks. To determine which neurons are directly or indirectly affected by the Lc gene, aggregation chimeras were constructed. The nervous systems of chimeric mice develop by the intermixing of mutant and wild type cells. In lurcher chimeras, the numbers of PCs and GCs are intermediate between +/Lc and wild-type mice. Previous work has shown that the Lc gene acts intrinsically on the PCs to cause their death, whereas the degeneration of the GCs is a secondary event.

Since the PCs (the only known direct site of Lc gene action) begin to degenerate during the period of synaptogenesis, it seems likely that the GCs die because they are unable to form synapses with their major post-synaptic partner. To investigate this theory further, we determined the numbers of GCs and PCs in 2 +/Lc, 4 wild-type and 3 lurcher chimeric mice. Since each of the 4 wild-type mice was a different inbred strain, the number of PCs was different in each. The numbers of GCs also differed such that there was a positive correlation with the numbers of PCs. When GC number is plotted as a function of PC number, the 4 points of the wild-type mice fall on a line that intercepts the y axis at zero GCs. This suggests that the number of GCs in a given animal is regulated by the number of PCs, possibly because the survival of the GCs is dependent on the formation of synapses with the PCs. Further, there appears to be little plasticity in this system; each PC can only support a specific number of GCs (about 180). The GC vs PC graph for the 3 chimeras also forms a straight line. This line has the same slope as the wild-type line, which lends some support to the above model. However, the y-intercept of this chimera line is 6.5 million. We assume that during the first week of synaptogenesis, the lurcher chimeras have a normal complement of PCs (just as +/Lc mice do), and this may partially explain the extra 6.5 million GCs. The reason this excess is greater than 1.5 million (the number of GCs in +/Lc mice) is unknown. It may indicate some plasticity in the chimeric environment affecting the interaction of GCs with PCs. Thus, the cerebellar GCs are similar to other neurons for which survival is dependent on the post-synaptic target. Supported by NIH grants HD07149, HD 12213 and NS 18381 and by the March of Dimes Birth Defects Fund.

181.4 THE SHORT AND LONG-TERM EFFECTS OF MOSSY FIBER - DEAFFERENTATION OF THE LATERAL CEREBELLAR CORTEX OF THE RAT. W.A. Anderson* and B.A. Flumerfelt (SPON: J.A. Kiernan). Department of Anatomy, University of Western Ontario, London, Canada.

Electrolytic lesions made within the basilar pontine gray resulted in the degeneration of nearly the entire population of mossy fiber rosettes within the ansiform lobule. These degenerating varicosities represented two distinct populations with respect to their time course of degeneration. The majority of the rosettes, simple and complex dispersed types, underwent a slow course of electron-dense degeneration. As a result, most glomeruli contained debris from degenerating mossy fiber varicosities during the first 57 days. A second, small population of mossy fiber rosettes of the simple clustered variety, however, underwent a rapid course of electron-dense degeneration by the 5th day. Since electrolytic lesions of the basilar pontine gray also included the nucleus reticularis tegmenti pontis, this center could represent the source of the simple clustered variety of mossy fiber rosette. All glomeruli were denervated by 80 days following pontine lesions.

Animals deafferentated of their mossy fiber input as adults were allowed to survive for a period of 57-120 days and subsequently examined following Golgi impregnation or processing for electron microscopy. The primary response to mossy fiber - deafferentation was the transneuronal degeneration of the granule cell system. Morphological evidence is provided which suggests that the mossy fiber varicosities may play an important role in the fragmentation and the removal of the granule cell digitiform dendrite. Image analysis of Golgi impregnated Purkinje cells has indicated significant losses in both smooth branch and spiny branchlet numbers following the loss of mossy fibers. Ultrastructural evidence for transneuronal degeneration which supports the quantitative findings is provided. The transneuronal degeneration of both the molecular layer interneurons and the Purkinje cells following mossy fiber - deafferentation, however, is secondary to the transneuronal loss of the granule cell system. Although a loss of dendritic spines occurred along the terminal branchlets following mossy fiber - deafferentation, many of the existing spines underwent marked changes in form. The present findings suggest that denervated Purkinje cell dendritic spines elongate to acquire a new synaptic input. (Supported by the MRC of Canada)

181.5 AGE-RELATED ULTRASTRUCTURAL CHANGES IN SYNAPTIC DEGENERATION IN OLFACTORY CORTEX: A BASIS FOR PLASTICITY. R.A.E. Bakay* and L.E. Westrum. Depts. of Neurological Surgery and Biological Structure, Univ. of Washington, Seattle, WA 98195.

The age dependent capacity of the olfactory cortex to reorganize and the form that this reorganization takes following deafferentation may be related to the comparative degenerative response of the synaptic structures at the various stages of synaptic maturation. The different patterns of these degenerative responses are being studied electron microscopically in rats receiving ipsilateral olfactory bulb ablation at birth, 3, 6, 9, and 13 days of age. Survivals include acute (12-36 hrs), subacute (3-7 days), intermediate (10-14 days), and chronic (up to 30 days) times. Acutely degenerating axon terminals in layer I are predominantly watery and flocculent in character in the 1-6 day old operants and are removed with minimal glial response subacutely from their postsynaptic contacts. No evidence of degeneration is observed at chronic survival times. This immature pattern of degeneration and possible competitive reinnervation is similar to that observed in newborn rats with the same lesion (Westrum, Anat. Embryol., 160, 1980). Electron-dense degeneration of synaptic terminals is observed first in the 6 day old operants subacutely, then becomes the predominant form in the 9 day old operants, and is the exclusive pattern in the 13 day old operants. The dense degenerating material increases in amount after the 6 day old operants with the 13 day old operants exhibiting a mature adult pattern of persisting degeneration (Westrum, Z. Zellforsch., 98, 1969). There is a marked glial phagocytic response in the 9 day old operants that increases with age. Growth cones and other processes invaginate dense terminals and possibly reestablish new contacts. Postsynaptic degeneration rarely seen in the 6 day old operants is common in the 9 day old operants, and is extensive in the 13 day old operants. This parallels neuronal death presumably from transynaptic degeneration in layer II which is again rare in the 6 day old operants and increases to an adult pattern in the 13 day old operants. The results show dramatic differences in the form of terminal degeneration between 3 and 13 operants coupled with increased glial activity, greater numbers of persisting dense degenerated terminals, and onset of neuronal death. All elements of the adult patterns of degeneration are present in the 6 day old operants to a minor degree and in the 9 day old operants this becomes the predominant pattern. It might then be predicted that these would represent critical ages at which major changes occur in the potential plasticity of the olfactory cortex. (Supported by N.I.H. 181.6 EARLY RESPONSES OF CAT RETINA TO VISUAL CORTEX ABLATION AT BIRTH. Helen E. Pearson, Bert Payne and Timothy J. Cunningham. Depts. of Anatomy and Physiology/Biochemistry. The Medical College of Pennsylvania, Philadelphia, PA 19129.

Some neurons in the central nervous system of young mammals are especially vulnerable to target removal after lesions while others which survive often have a remarkable capacity to reorganize their projections. We have investigated these phenomena in the retina of infant cats following visual cortex lesions; such lesions remove most of the lateral geniculate nucleus, a major target for optic axons. As a result, there is both ganglion cell death, more marked in the periphery than in central retina, (Pearson et al. 1981) and reorganization of retinofugal pathways (Labar, et al. 1981). Normal retinae and retinae from kittens with all cortical visual areas ablated bilaterally at birth (day 1) were compared in the light and electron microscope. The animals were perfused on postnatal days 2-5. Whole mounts were prepared and four blocks of retina were taken along the vertical meridian from periphery to center. Every 50th semithin section was collected through the blocks from the left eye and stained with toluidine blue. Blocks from the right eye were trimmed for thin sectioning. We examined peripheral retina for evidence of both naturally occurring and lesion-induced cell death. We examined central retina, where ganglion cells are more likely to survive the lesion, for fine structural changes. In peripheral retina of normal kittens, late stages of cellular degeneration are found in both the ganglion cell layer and the inner nuclear layer. The appearance of these profiles in normals suggests that naturally occurring neuron death is a feature of postnatal development of the cat's retina. In central retina of normal kittens, fine structural observations indicate that ganglion cells accumulate cisternae of rough endoplasmic reticulum (RER) and polysomes from postnatal day 2 to day 5. By day 3, Nissl-like bodies are apparent in the cytoplasm of some cells. In operated animals, degenerating cells appear also in the ganglion cell and inner nuclear layers. Preliminary counts from peripheral retina of 2 and 3 day-old kittens show an increased surface areal density of degenerating profiles in both layers of the operated animals. In the central retina of operated animals, ganglion cells contain some cisternae of RER but often have large areas of cytoplasm occupied by monosomes. The cytoplasmic changes are seen clearly 72 hrs after the lesion and are similar to the reaction shown by neurons during regenerative sprouting. The results suggest that after visual cortex ablation retinal ganglion cells respond rapidly. Some die, but others reorganize their intracytoplasmic organelles possibly to support modified growth of the subcortical visual pathways.

181.7 RETINAL GROWTH AND NEURONAL DEATH IN THE DEVELOPMENT OF ADULT DIFFERENTIAL GANGLION CELL DENSITY. D.R. Sengelaub and B.L. Finlay. Department of Psychology, Cornell University, Ithaca, N.Y. 14853

At maturity the hamster retina contains approximately 80,000 ganglion cells. These ganglion cells are distributed unevenly across the retinal surface with a central elevation in density of 2:1 over peripheral areas. To understand how this central specialization develops, we have studied the distribution of cells in the ganglion cell layer through the first 10 postnatal days with light microscopy.

On the day of birth, cell counts in horizontal sections through the retina found the linear density of cells in the ganglion cell layer to be essentially uniform across the retinal surface ($\bar{x}$ central= 78.1 cells per 100u; $\bar{x}$ peripheral= 82.9 cells per 100u; central-peripheral ratio= .94). By postnatal day 10 this distribution approaches the adult pattern ($\bar{x}$ central= 34.4 cells per 100u; $\bar{x}$ peripheral= 24.6 cells per 100u; central-peripheral ratio= 1.4). By postnatal day 10 there is a 226% decrease in the central cell density and a 336% decrease peripherally. Since glia are added to the retinal ganglion layer during this early postnatal period, these postnatal day 10 cell densities underestimate the actual decrement in neuron density. During the first 10 postnatal days the retinal cross-sectional length increases by 260% and this growth is responsible for part of the decrease in density. However, considering the glial addition, growth alone is unlikely to account for the density changes centrally and cannot account for those seen in the periphery.

The hamster retinal ganglion cell layer shows a substantial amount of cell death during this same period and cell death rates in the periphery of the retina are 25% higher than those found centrally. We suggest that this differential cell death can account for the additional decrease in the peripheral cell density.

181.8 INCREASED EARLY INNERVATION OF THE SUPERIOR COLLICULUS DOES NOT RESULT IN INCREASED CELL SURVIVAL. Kenneth C. Wikler* and Barbara L. Finlay. Department of Psychology, Cornell University, Ithaca, N.Y. 14853

Following partial unilateral lesions of the superior colliculus in neonatal hamsters, neuroanatomical and electrophysiological investigations have demonstrated that the entire retina projects in an orderly fashion to the remaining tectal area in the adult. This tectal fragment could thus be hyperinnervated by the retina in early development. Since our prior studies have shown that substantial cell death occurs in the superior colliculus in this period, this preparation provides a model to test if increased afferent innervation can decrease the amount of early cell loss in a target structure.

Lesions of the caudal half of the right tectum were made on the day of birth in neonatal hamsters. Reductions of the surface area of the residual superficial gray layer of the superior colliculus ranged from 48% to 79% of normal surface area. The numbers of degenerating cells, recognized by their pyknotic appearance in light microscopy, were expressed as a fraction of the number of normal-appearing cells. These ratios were then compared between the normal and early-ablation sides. Assessments of ratios were made for postnatal days 4-8, the period of maximal early cell death in the hamster superior colliculus. No differences in either the time course or the amount of early cell loss were found (mean ratio for normal side =4.22 degenerating cells per 1000 normal cells; mean ratio for the early ablation side= 3.93 degenerating cells per 1000 normal cells; F=0.21,ns).

These results suggest that increased afferent innervation does not sustain more neurons in a target population, and that in normal development, targets are saturated with afferents that must compete for terminal space.

181.9 INDUCED CHANGES IN THE LATERALITY OF THE CENTRIFUGAL PROJECTION TO THE AVIAN RETINA. Dennis D.M. O'Leary and W. Maxwell Cowan. The Salk Institute, and The Clayton Foundation for Research-California Division, La Jolla, CA 92037.

In normal post-hatched chicks the nucleus of origin of centrifugal fibers to the retina, the isthmo-optic nucleus (ION), contains about 10,000 neurons, all of which send their axons to the contralateral eye. In addition there are approximately 1,500 cells that lie outside the boundaries of the ION, which can be retrogradely labeled by injections of various marker substances into the eye. Of these "ectopic ION neurons", all but a small percentage (≈ 2%) project to the contralateral eye. Early in the development of the nucleus (around the 12th day of incubation - E12) the ION and ectopic neurons also project predominantly to the contralateral eye; the exception being that in addition to the small percentage of the ectopic neurons which project to the ipsilateral eye about 1% of the ION cells also project ipsilaterally. These ipsilaterally projecting ION neurons can no longer be labeled after E17. However, if one optic vesicle or optic cup is removed between stages 10 and 17 (of the Hamburger and Hamilton series) and wheat germ agglutinin-conjugated HRP (WGA-HRP) is injected into the surviving eye on E12 in many of the cases essentially all of the cells in the ION of both sides are labeled. In chicks from which an optic cup was removed on or after stage 13 and WGA-HRP is injected into the other eye on day E18, the ION on the contralateral side appears heavily labeled, but that on the opposite side has virtually disappeared. Counts of the number of labeled cells in the contralateral ION indicate that in these cases often only 50% of the normal number of ION neurons survive. This suggests that during the period when axons from the ipsilateral ION were present in the surviving retina (between sometime late on the 9th day, when they first reach the retina, and some time after day 12) they compete with the axons from the contralateral ION, either for available synaptic sites or more probably for a trophic agent provided in limited quantities by the retina, and although their parent cells subsequently degenerate, during the period of the competition they jeopardize the survival of about half of the population of ION neurons on the contralateral side. Interestingly, if the eye removal is done at stage 12 or earlier a substantial number of ION and ectopic ION neurons (up to 3,400) persist on the ipsilateral side and can be retrogradely labeled by an intraocular injection of WGA-HRP at E18. On the contralateral side in these cases there are again only about 50% of the normal number of ION and ectopic ION neurons. It is noteworthy that in all of these cases in which a significant percentage of the ipsilateral ION neurons survive anterograde labeling has revealed the presence of a substantial ipsilateral retino-tectal projection.

181.10 THE EFFECTS OF PROTEIN DEPRIVATION ON THE NUCLEUS LOCUS COERULEUS: A MORPHOMETRIC GOLGI STUDY IN RATS OF THREE AGE GROUPS. S. Diaz-Cintra*, L.Cintra*, T.Kemper* and P.J.Morgane. (Spon: W.McFarland). Worcester Foundation for Expt. Biology, Shrewsbury, MA 01545.

In our continuing morphometric Golgi studies of the monoamine nuclei of the brainstem we have examined the effects of an 8% protein diet, instituted prenatally, on the three cell types we previously characterized in the nucleus locus coeruleus (Brain Res., in press). In control rats fed a 25% protein diet all cell types (ovoid, fusiform and multipolar) in the locus coeruleus showed significantly decreased dendritic spine densities on both primary and secondary dendrites between 30 and 90 days of age. All three cell types then showed a significant increase in spines between 90 and 220 days. In protein malnourished animals we previously found that the nucleus raphe dorsalis shows a significant dendritic spine incrementation between 30 and 90 and between 90 and 220 days (Brain Res. 221: 243-255, 1981) thus indicating that this nucleus responds to malnutrition by continuing to add dendritic spines across the 3 age groups studied. The three cell types in the locus coeruleus in animals fed a low protein (8%) diet show a significant decrease in primary and secondary dendritic spines between 30 and 90 days followed by a highly significant increase in spines between 90 and 220 days with the highest increase in dendritic spines during this period occurring in the multipolar and ovoid cells. Thus, locus coeruleus cells respond to malnutrition with an initial slight decrease in dendritic spines between 30 and 90 days followed by a highly significant increase between 90 and 220 days of age. It is apparent from these studies that the nucleus raphe dorsalis and locus coeruleus each respond to malnutrition insult with an increased synaptic input with the course of spine development in locus coeruleus in the period 90-220 days of age being in the same general direction as that of the raphe dorsalis cells, i.e., toward a higher dendritic spine density. Protein malnutrition thus appears to markedly affect the monoamine nuclei of the brainstem. Further, the response of these cells to malnutrition is in the direction of keeping and/or adding new dendritic spines in coping with such a stress. (Supported by NFH Grant HD-06364, NICHD)

181.11 SEGMENTAL SELECTIVITY OF SYNAPSE ELIMINATION IN RAT SOLEUS MUSCLE. Wesley J. Thompson. Dept. of Zoology, Univ. of Texas, Austin, TX 78712

I have examined the segmental selectivity present in the elimination of synapses from rat soleus muscle by comparing the extent of synapse loss by soleus motor neurons in each of the two spinal nerves (L4 and L5) supplying the muscle. For this purpose, motor unit sizes were measured by stimulating single soleus motor axons teased from the L4 and L5 ventral roots and comparing the size of the twitch or tetanic contraction evoked to that obtained by direct stimulation of the muscle. Intracellular recordings of epp's in muscle fibers while stimulating single L4 or L5 soleus motor neurons showed this tension measurement procedure gave a reasonable estimate of the percentage of the muscle innervated by a motor axon. I found that L4 and L5 motor units were, on average, about the same size at 6 days post-natal and that units in both nerves underwent an average four-fold reduction in size during subsequent synapse elimination. Thus, individual L4 and L5 motor neurons lose approximately the same numbers of synapses. However, the whole L4 spinal nerve was found to lose synaptic contact with more muscle fibers than the whole L5 nerve, as shown by both tension recordings and intracellular recordings of epp's. This apparent disproportionate loss by the L4 spinal nerve was shown to be explained by the smaller number of soleus motor neurons present in L4 compared with L5. These results were obtained from three different Wistar rat stocks. Therefore, in contrast to reports by others (Miyata and Yoshioka, J. Physiol. 309: 631; O'Brien, J. Physiol. 317: 89P), I find that synapse elimination in rat soleus shows no marked segmental disproportion. Rather, as initially shown by Brown et al. (J. Physiol. 261: 387), synapse elimination results in the generation of motor units of approximately the same size by favoring the loss of synapses by the larger motor units, irrespective of spinal origin of motor neurons.

181.12 THE REGULATION OF SYNAPTIC POSITION, SIZE, AND STRENGTH IN ANURAN SKELETAL MUSCLE. Bruce Nudell* and Alan D. Grinnell. (SPON: A. Cangiano). Jerry Lewis Neuromuscular Res. Center, UCLA, Los Angeles, CA 90024.

In an attempt to discern the rules governing synaptic size and the competitive interactions among endplates on multiply innervated muscle fibers, we have examined the physiology, morphology, and position of endplates on identified fibers in the Xenopus laevis pectoralis muscle. This work has revealed that:

1) The percentage of fibers with one endplate declines in large muscles; and within the same muscle, singly-innervated fibers are smaller than dually-innervated fibers.
2) Single junctions tend to be stronger than junctions on dually-innervated fibers.
3) Single junctions are typically located near the middle of their fibers, while the endplates on dually-innervated fibers are located toward either end, and are usually separated by at least 20% of the total fiber length.
4) Junctions on the same dually-innervated fiber tend to be more similar in length than do junctions on different fibers of the same input resistance. There is no corresponding tendency for greater similarity in physiological strength of paired junctions, which frequently show large differences in EPP amplitude.
5) The total terminal length on dually-innervated fibers of equivalent input resistance is inversely correlated with the mean release/length and total release of both junctions. There is no apparent correlation between the distance separating endplates and their strength or length.

The data provide support for a model of synaptic regulation similar to that proposed by Jansen and his colleagues (Jansen, J. K.S., Thompson, W., & Kuffler, D.P., Prog. Brain Res. 48: 3-18, 1978) in which nerve terminals are attracted, grow and are maintained in proportion to the amount of a substance supplied by muscle fibers. Our findings suggest that such a substance is produced or distributed uniformly throughout each fiber in amounts proportional to the fiber size and inversely proportional to the total transmitter output of all junctions innervating the fiber or the level of muscle fiber activity they evoke. A form of competitive interaction between the terminals which helps to determine synaptic spacing may involve local depletion of this substance.

181.13 SYNAPSE REPRESSION IN CULTURE. M.C. Fishman, A.E. Schaffner and P.G. Nelson. Lab. Dev. Neurobiol., N.I.H., Bethesda, MD 20205.

Selective reduction in polyneuronal innervation is characteristic of the developing neuromuscular junction. It seemed possible that the use of cell culture might provide an opportunity to evaluate this phenomenon at the molecular level. We have studied the cholinergic synapses between ciliary ganglion neurons and myotubes in culture, and the effects of spinal cord neurons upon these synapses.

The ciliary ganglion of 8-day chick embryos was explanted onto chick myotubes plated 2 weeks previously. By 3 days after plating the ciliary ganglion had extended a halo of neurites. Synaptic connections were assessed by intracellular recording from myotubes while stimulating the ganglion extracellularly through a 5-10μm tip micropipette filled with 0.9% NaCl. Recordings were obtained from all muscle cells within one field diameter (~500μm) of the ganglion (4-10 muscle cells per plate). There was no clear correlation between the degree of obvious morphological neurite-myotube contact and presence of synaptic connections. Under control conditions between 80 and 100% of myotubes evidenced synaptic input from the ciliary ganglion. This degree of innervation remained stable over four days (days 3 to 6 after plating).

In other plates we added dissociated spinal cord cells from 6-day embryos 1 week prior to adding the ciliary ganglion. We enhanced this spinal cord population for motoneurons by dissociating only the ventral half of the cord. The concomitant presence of these ventral spinal cord cells only slightly reduced the number of myotubes manifesting connections to the ciliary ganglion at the time of first evaluation. Thus, 82% of myotubes exhibited epsp's 3 days after plating of the ciliary ganglion in the presence of spinal cord cells, while 96% of myotubes tested in control plates were connected. Over the ensuing days there was a progressive decrement in the ciliary ganglion-myotube synapses, with 64% of myotubes connected at day 4, 62% at day 5, and 17% at day 6. Experiments in which similar numbers of dissociated cells were added from the dorsal spinal cord or from the dorsal root ganglion showed that these cell populations did not cause a reduction in ciliary ganglion-myotube synapses over the same time period. The medium alone, previously conditioned by spinal cord cells and myotubes, also did not cause a reduction in synapses, suggesting that the synapse repression was not due to removal of critical synapse stabilization factors from the medium by the spinal cord cells.

Thus, synapse repression can take place in culture, even without the intricate connections and full heterogeneity of cell populations found *in vivo*.

181.14 DENDRITIC SPINES IN LOCUS COERULEUS AND NUCLEUS RAPHE DORSALIS DEVELOP OUT-OF-PHASE IN RATS OF THREE AGE GROUPS. Peter J. Morgane, Tom Kemper*, Leon Cintra* and Sophia Diaz-Cintra* (Spon: A. Dren) Worcester Found. for Expt. Biol., Shrewsbury, MA 01545.

We have carried out morphometric Golgi studies on the three cell types (ovoid, multipolar and fusiform) which we identified in the nucleus raphe dorsalis (Brain Res. 207: 1-16, 1981) and nucleus locus coeruleus (Brain Res., in press). Between 30 to 90 and 90 to 220 days of age dentritic spines on both primary and secondary dendrites of all three cell types in each nucleus showed exact out-of-phase development between the two nuclei. However, all three cell types within each nucleus were precisely in phase with each other with respect to their dendritic spines. All three cell types in the nucleus raphe dorsalis between 30 and 90 days showed a significant increase in dendritic spines on primary and secondary dendrites (16% increase on fusiform cells; 24% increase on multipolar cells; 15% increase on ovoid cells). The locus coeruleus during this period showed a significant decrease in spines on primary and secondary dendrites (21% decrease on fusiform cells; 16% decrease on multipolar cells; 39% decrease on ovoid cells). Between 90 and 220 days of age all three cell types in the locus coeruleus showed a significant increase in dendritic spines (50% on fusiform cells; 18% on multipolar cells; 67% on ovoid cells). In the nucleus raphe dorsalis there was a significant decrease in dendritic spines on two of the three cell types (9% decrease on fusiform cells; 19% decrease on multipolar cells), the exception being a non-significant decrease in primary dendritic spines in the ovoid cells (decrease of 9%). This out-of-phase development of dendritic spines between locus coeruleus and dorsal raphe may have important functional implications in a wide variety of behaviors via their widespread projection systems and are thought to be reciprocally inhibitory.

182.1 THE DORSAL MOTOR NUCLEUS AND NUCLEUS AMBIGUUS IN THE CAT AND MONKEY: LIGHT AND ELECTRON MICROSCOPIC STUDIES FOLLOWING HRP INJECTIONS INTO THE VAGUS NERVE. J.H. McLean and D.A. Hopkins. Dept. of Anatomy, Faculty of Medicine, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

A recent study in the cat has shown that the dorsal motor nucleus of the vagus nerve (DMV) may contain three neuronal types with differing projections (McLean and Hopkins, J. Comp. Neurol., 1982). The nucleus ambiguus (NA) also has a variety of cell types but its fine structure has not been studied with respect to efferent projections. In the present study the fine structure and projections of the DMV in the Cynomolgus monkey have been compared to those in the cat and the NA has been studied in both the cat and monkey after injections of horseradish peroxidase (HRP) into the cervical vagus nerve. The brain stems were processed for light and electron microscopy using standard procedures and tetramethylbenzidine and diaminobenzidine were used as chromogens for HRP histochemistry.

After HRP injections in the vagus nerve, retrogradely labeled cells were present ipsilaterally in the DMV, NA, intermediate zones and occasionally in the medial solitary nucleus. In the monkey DMV, medium-sized neurons measuring 26 x 18 µm with abundant cytoplasm and an oval nucleus with few indentations were labeled. Small neurons measuring 12 x 9 µm with scanty cytoplasm and an invaginated nucleus were not labeled and accounted for 12-18% of the DMV neurons. In this respect, the monkey DMV resembles that in the cat. At the electron microscopic level, axosomatic synapses were observed on both types of neurons. Most terminals were 1-2 µm in diameter. Approximately 70% of the terminals that synapsed on medium-sized neurons contained round vesicles and made symmetric (RS) or asymmetric (RA) contact with the plasmalemma while 30% contained pleomorphic vesicles and made symmetric (PS) contact. On small neurons, over 90% of the synapses were of the RA or RS type.

In both species, the NA contained labeled neurons dispersed among unlabeled neurons. Many labeled neurons were large (45 x 35 µm) but the majority averaged 30 x 20 µm. These neurons were round or spindle-shaped with an oval or indented nucleus and an abundant cytoplasm. Smaller labeled neurons (24 x 18 µm) with an invaginated nucleus were more common in the rostral NA. Axosomatic synapses were observed on the plasmalemma of almost all labeled neuronal profiles. Generally, the terminals were 1-2 µm in diameter. Approximately 50% of the terminals formed RA or RS type synapses while the remainder were PS type.

These results provide a basis for further ultrastructural studies on the connectivity and structural organization of the cells of orgin of the vagus nerve in the cat and monkey. Supported by the MRC of Canada.

182.2 STAPEDIUS AND TENSOR TYMPANI MOTONEURONS IN THE CAT. M. Shaw and R. Baker. Dept. Physiol. and Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016

The numbers and locations of motoneurons to the middle ear muscles, stapedius and tensor tympani, were determined using retrograde transport of horseradish peroxidase (HRP). Stapedius motoneurons lay outside the traditionally recognized facial nucleus in several distinct locations: 1) in the interface between the facial nucleus and the superior olive: 2) in a thin scattered lamina of somewhat smaller cells spread dorsal to the facial nucleus; and 3) in a cluster located ventro-medial to the rostral third of the facial nucleus. Smaller numbers of cells also lay dorsal to the superior olive or scattered in the reticular formation, medial to the descending loop of the facial nerve. All projections were ipsilateral.

Tensor tympani motoneurons also lay outside the traditionally recognized trigeminal motor nucleus, in an area 200µm ventral to it. At the medial edge they formed a closely packed group, but at the lateral edge the cells trailed ventrally, medial to the trigeminal motor root. They extended beneath the full rostro-caudal length of the trigeminal motor nucleus. Filled cells were also found in the inferior salivatory nucleus, probably from spread to the lesser superficial petrosal nerve which clings to the muscle epimysium in the cat. Some HRP filled cells were also found in the trochlear, oculomotor and mesencephalic nuclei. The labeling of these cells could not be explained by spread of HRP through the Eustachian tube and into the orbit. First, the trochlear projection was entirely ipsilateral. Second, neurons to tensor veli palatini and the pterygoids were not labeled, as would have been expected. Labeled trochlear neurons were seen in every case in which the whole muscle was injected and may represent a small direct innervation of the tensor tympani or surrounding structure. HRP filled axons could be seen crossing the pontine midline, but their source could not be ascertained.

The mean number of motoneurons was 696 for tensor tympani and 668 for stapedius, yielding innervation ratios of 1:5.7 and 1:2.6, respectively. These values place stapedius and tensor tympani among the most finely innervated muscles known.

Thus, the motor pool for a cranial muscle need not be organized as a distinct subnucleus of the major motor nucleus of its branchial arch. These findings also raise intriguing questions about the development of specific innervation either to or from motor pools as widely scattered as stapedius and tensor tympani. Supported by NIH #EY0504, Fight-For-Sight, NYC #F-346 and USPHS #NS13742.

182.3 EXCITATORY ACTION OF CYCLOBENZAPRINE IN LOCUS COERULEUS (LC) AND SUB-COERULEUS (SC). N. Penington* and R. J. Reiffenstein. Dept. of Pharmacology, Univ. of Alberta, Edmonton, AB, Canada T6G 2H7

Opposite mechanisms of action for the tricyclic, central skeletal muscle relaxant cyclobenzaprine (CBZ) have been advanced. Depression of spontaneous and evoked firing of LC neurons has been reported by Barnes and co-workers (1980, 1981) who proposed that blockade of norepinephrine (NE) uptake enhanced recurrent inhibition of LC. Commissiong et al. (1981) reported CBZ increased LC firing and turnover of NE in ventral spinal cord, and loss of the relaxant effect of CBZ after LC destruction. They proposed that CBZ blocked α_2-adrenoceptors on LC neurons. We have attempted to investigate these differences by systemic and local drug administration in urethane-anesthetised (1.2-1.5 G/KG i.p.) 150-250 G male Sprague-Dawley rats. Only data from histologically identified recording sites (after staining with Pontamine Sky Blue ejected from the electrode) are reported; most were in SC and ventral LC. CBZ (0.25-0.5 mG/KG, i.v.) greatly increased LC/SC neuron firing in 35 of 38 animals. After CBZ, noxious stimulation still induced vigorous LC/SC firing, but normal rebound decreases in firing (post-stimulus suppression, PSS) were seldom seen. Low doses (0.25 mG/KG, i.v.) of yohimbine (YOH) produced the same effect in all 11 trials. Also, clonidine (CLON)(10-75 µG/KG, i.v.) reduced spontaneous firing and the firing in response to CBZ or noxious stimulation. Since all drugs used alter blood pressure (BP), and BP is known to affect LC firing (Persson and Svensson, 1981), this relationship was studied in 12 animals. We observed LC/SC firing and BP were inversely related. Spontaneous changes in LC/SC firing were mirrored by BP changes. CLON-induced inhibition of, and PSS of, LC/SC firing were paralleled by increases in BP, while the vasodepresssor effects of CBZ and YOH coincided with increased firing. Indirect drug effects via BP were avoided by applying NE, CLON, CBZ and YOH iontophoretically. Both CBZ and YOH (5-30 nA) potentiated the response to noxious stimulation, increasing the duration of the LC/SC firing (blockade of PSS), and sometimes also increasing the maximal rate. Induction of firing in the absence of stimulation was generally not seen. Very high doses of YOH (>80 nA) and CBZ (>150 nA) suppressed the maximal firing rate and the (extracellular) spike height. NE and CLON inhibited LC firing, consistant with previous observations. We conclude that a direct effect of i.v. CBZ on LC cannot be shown, but the iontophoretic results are consistant with an α_2-antagonist action of CBZ on LC neurons. The absence of direct stimulation in response to local CBZ suggests that the effects are due to potentiation of physiologically evoked LC stimulation by suppression of recurrent inhibition. Supported by U. of A. MR & GR Funds (R.J.R.). N.P. holds an AHFMR studentship.

182.4 AT LEAST 25 DISTINCT BRAINSTEM NUCLEI PROJECT TO THE FOREBRAIN ALONG THE MEDIAL FOREBRAIN BUNDLE (MFB). Robert P. Vertes. Dept. Physiol., Wayne State Univ. Sch. Med., Detroit, MI 48201

In previous reports we found that the discharge of a large percentage of neurons in the medial pontine reticular formation (PRF) was highly correlated with hippocampal theta and that electrical stimulation in this same PRF region was very effective in eliciting a theta rhythm in the hippocampus (J. Neurophysiol. 42:214, 1979 and 46:1140, 1981). It was also shown that a synchronizing system could be traced from PRF through the midbrain in the ventrolateral tegmentum to the diencephalon where it appeared to join the MFB. In the present study HRP injections were made at several levels of the MFB to evaluate the contribution of PRF fibers to the MFB. Small WGA-HRP injections (.25-.50 ug of conjugate) were made in 30 rats and brains were reacted using the TMB procedure of de Olmos et al. (J. Comp. Neurol. 181:23, 1978). Unexpectedly, few HRP reactive cells were found in the PRF following MFB injections. We did observe, however, that a substantial number of PRF cells were labelled when caudal MFB injections encroached upon the supramammillary nucleus (SUM). Further, we have found that SUM is very heavily labelled following HRP injections in both the MFB and the medial septum. These results suggest that the SUM may be an important link between the PRF and the septum in the generation of hippocampal theta.

Although few cells within the medial RF were labelled following HRP injections within the MFB, at least 25 other nuclei in the brainstem were found to contribute fibers to the MFB. These nuclei were the following (from caudal to rostral): A1 (directly above the lateral reticular nucleus); A2 (mainly within the nucleus of the solitary tract); a group of cells on the dorsolateral border of the MLF at the level of the rostral pole of the inferior olive; nucleus gigantocellularis, pars ventralis; raphe magnus; nucleus incertus (on the midline within the central gray at the level of locus coeruleus - LC); dorsal lateral tegmental nucleus of Castaldi (DLT) (between incertus and LC within the central gray - CG); locus coeruleus; nucleus subcoeruleus; raphe pontis; dorsal and ventral parabrachial nucleus; Kolliker-Fuse nucleus; A7 (lateral pontine tegmentum, medial to lateral lemniscus); median raphe; dorsal raphe; rostral and caudal linearis nuclei; retrorubral nucleus (RR) (midbrain tegmentum posterior to red nucleus); ventral tegmental area (VTA); medial part of substantia nigra (SN) pars compacta; peripeduncular nucleus (dorsolateral to SN, pars lateralis); nucleus of Darkschewitsch (ND); a distinct cell group in the midbrain CG dorsal and lateral to ND; and supramammillary nucleus. The median and dorsal raphe, the linear nuclei, VTA, SUM, RR and DLT were heavily labelled. These results suggest that the influence of the brainstem on the forebrain is substantial.

182.5 CYTOARCHITECTURE OF THE PRIMATE PERIAQUEDUCTAL GRAY, NUCLEUS MEDIALIS. L.K. Laemle, UMDNJ- New Jersey Medical School, Newark, N.J. 07103.

The discovery by Reynolds (1969) of the role of the midbrain periaqueductal gray matter in stimulus produced analgesia has renewed interest in the cytoarchitecture and fiber connections of this region. At the present time, data concerning the morphological substrate in this complex, multifunctional area is contradictory. Controversey persists concerning (1) whether data support subdivision of the PAG into discrete nuclei or regions (2) identification of cell populations and their distributions. Regardless of the answers to the above questions, Nissl and Golgi studies in the cat, rat, and monkey, and studies of fiber connections (Mantyh, 1981, 1982), suggest that the cytoarchitecture and organization of the PAG is similar among species. Much of the nociceptive activity appears to be centered in the region identified by Hamilton (1973) as the nucleus medialis (PAGM).

The present report is based upon Nissl, Golgi, and counterstained Golgi preparations of the PAGM in the squirrel monkey, macaque, baboon, and human. Parameters evaluated include cell density and perikaryal size, shape, and orientation. In Golgi preparations additional neuronal characteristics such as axonal origin and trajectory, and the number of primary dendrites, their branching patterns, and spine populations were also studied.

In Nissl preparations, the PAGM is clearly delineated from the remainder of the PAG by the low packing density of its cells. Both Nissl and Golgi preparations indicate that morphologically the primate PAGM is comprised of a heterogeneous population of neurons as judged either by size, or by perikaryal shape and orientation. Three classes of cells are distinguishable based upon perikaryal diameter: small (less than 15uD), medium sized (15u-25uD), and large (greater than 25uD). Using perikaryal shape and orientation as the criteria, neurons can be classified as fusiform (vertical and horizontal), triangular (pyramidal and inverted pyramidal), or stellate. All cell populations described by Laemle (1979) in the human PAGL are present in the PAGM, however, there appears to be a greater proportion of triangular perikarya in the PAGM. Large triangular perikarya (greater than 30uD) which are demonstrated here have not been reported previously. Dendritic arborizations of PAGM neurons are extensive, often spanning the entire PAGM and continuing into the PAGL, or extending through the subependymal zone where they occasionally appear to make contact with the aqueduct. (Supported by GRS funds from UMDNJ-New Jersey Medical School).

182.6 CREST SYNAPSE STRUCTURE AND LOCATION WITHIN THE INTERPEDUNCULAR NUCLEUS OF THE NEAR-TERM RHESUS MONKEY FETUS. N. J. Lenn and V. Wong. Depts. of Neurol. and Pediat., and Clinical Neuroscience Research Center, Univ. of VA, Charlottesville 22908; and Carnegie Labs. of Embryol., Univ. of CA, Davis 95616.

In a previous study, it was found that the neurons of rhesus fetus interpeduncular nucleus (IPN) were generated between E36 and E42 (term = E165). IPN was recognizible on E45. Dendritic branching increased between E81 and P8, suggesting that synaptogenesis would be a feature of this interval. Particular interest in the paired habenular afferent synapses, the crest synapses, is based on their location in particular subnuclei and their consisting of one afferent from each habenula in the rat. In the rhesus, crest synapses have been noted as early as E148, and may yet be found earlier. In the present study, the detailed distribution of crest synapses was mapped at two levels of the nucleus at E162. By this age crest synapses are numerous and of mature fine structure. The more rostral level studied was in the center of IPN, and the more caudal level near its caudal extent. Perfusion fixation followed immediately after delivery by hysterotomy. One % paraformaldehyde-1.25% glutaraldehyde was delivered via the heart. A second solution with twice these concentrations followed. The location of each crest synapse was plotted on photographs on the sections.

Crest synapses were indistinguishable from those of rat. They consisted of two processes containing 40-60 nm synaptic vesicles. These formed asymmetrical contacts, occasionally en passant on opposite sides of markedly narrowed dendritic processes. At the more caudal level, they were concentrated in two intermediolaterally placed zones which curved medially to merge with one another ventrocaudally. These zones were recognizible with rather sharp borders except medially, due to darkly staining fibers. Fibers leaving these areas crossed the central portion of IPN as narrow bundles which separated pallisades of neuronal perikarya. At the more rostral level, there were fewer crest synapses present, but they were similarly located in two intermediolateral zones.

The striking similarities of these findings to those of rat IPN suggest that other features such as neurotransmitter specificity, left-right pairing of afferents at crest synapses, developmental mechanisms which normally produce this pattern, and possibly alterations in synaptogenesis after early unilateral lesions of the habenula, are likely to withstand extrapolation from rat to monkey. Supported by grants HD NS 08658 and RR000169 to the California Regional Primate Center.

182.7 NUCLEAR ORGANIZATION OF THE RAT'S LATERAL THALAMUS. T. Takahashi* (SPON: F. Scalia). Dept. of Anatomy and Cell Biology, S.U.N.Y. Downstate Med. Ctr., Brooklyn, NY 11203.

The lateral thalamus relays visual information from the superficial laminae of the superior colliculus (sc) and the nuclei of the pretectum to the cortical territories adjacent to the striate area. The nuclear organization of this area of the rat has never been precisely determined despite the fact that the rat is often used in behavioral and physiological studies of vision. Analysis of cytoarchitecture and hodology undertaken presently indicates that the lateral thalamus of the rat consists of eight nuclei.

The cytoarchitecture of the lateral thalamus was studied using Nissl-stained, coronal sections of normal brains. To study the innervation of the lateral thalamus, a small injection of ^{3}H-leucine (10-160 nl, 25-50 μCi/μl) was placed in Area 4,17,18, or 18a (of Krieg, J. Comp. Neur., 84:221,1946) or in the sc of female hooded rats (n=34). The brains of these rats were then processed according to the protocol for autoradiography of Cowan et al. (Brain Res., 37:21, 1972). The sizes and positions of the injections were such that virtually all of the areal dimension of Area 17, Area 18 and the superficial layers of the sc was involved.

A study of the cytoarchitecture revealed seven cellular fields which were termed nucleus suprageniculatus (sg), nucleus lateralis posterior pars caudomedialis (lpcm), nucleus lateralis posterior pars lateralis (lpl), nucleus lateralis posterior pars rostromedialis (lprm), intramedullary area, (ima), nucleus lateralis dorsale pars ventrolateralis (ldvl) and nucleus lateralis dorsale pars dorsomedialis (lddm). Analysis of connectivity showed that lpl is further divisible into rostral (lplr) and caudal (lplc) sectors. Therefore, there are eight nuclei in total. Nucleus sg, the most caudal element of the lateral thalamus, is composed of medium to large, fusiform and multipolar neurons. It contains the entire terminal field of the superficial layers of the ipsilateral sc. Nucleus lpcm, found rostrolateral to sg, is loosely packed with large multipolar cells and contains the entire terminal field of the superficial layers of the sc of both sides. Nucleus lpl, a long cellular territory found lateral to lpcm, extends from the caudal pole of the dorsal lateral geniculate (lgd) to the caudal pole of ldvl and contains round cells which are smaller and more densely packed than those of lpcm. Its caudal portion (lplc) contains the entire terminal field of the ipsilateral sc while its rostral portion (lplr) contains that of Area 17. Area 18 projects to lplr and Area 18a projects to both lplr and lplc. The intramedullary area, which occupies the fibrous zone lateral to lpl and medial to lgd, contains round and fusiform neurons and is innervated by Area 18a. Nucleus lprm, situated medial to lpl, is characterized by round neurons which are frequently found in clusters. It contains the entire terminal field of Area 17 and it receives inputs from Area 18 and 18a as well. Nucleus ldvl is evenly packed with moderately large, polygonal cells and contains the entire terminal field of Area 17 and 18. It also receives inputs from Area 18a. Finally, lddm, tightly packed with small round cells, and lying medial to ldvl, receives inputs from Area 4.

182.8 RESPONSE PROPERTIES OF AN INTERNEURON MODEL. D. J. Surmeier* and R. J. Weinberg (SPON: A. L. Towe). Dept. of Physiology and Biophysics, University of Washington, Seattle, Wash., 98195.

As part of a study of the response properties of cells in cat cuneate nucleus, we have developed a neuronal model to assess the possible role of various intrinsic properties of the neuron and of its afferent input in generating spike trains. Most previous neuronal models have assumed that synaptic events preceding the last spike can be ignored in the computation of membrane potential. Thus, immediately following a spike, the membrane potential is restored to its original resting level, and all ongoing synaptic events are eliminated ("membrane resetting"). This "resetting" assumption is not warranted in cells electrically dominated by their dendrites, unless the dendrites support a regenerative action potential. In our model, therefore, the membrane potential following a spike returns to that level which would be predicted by the ongoing synaptic activity without a spike, although the spike threshold is transiently increased.

The responses of this model to various random and deterministic inputs have been studied on a digital computer. We have confirmed the observation of Segundo, et al. (Kybernetik 5, 157-171) that non-resetting models readily produce high-frequency bursts, a property characteristic of neurons in the cuneate nucleus. The cross-correlogram of resetting models has been reported to be similar to the time derivative of the EPSP (Knox, Biophys. J. 14, 567-582). In our model, however, the cross-correlogram is closer in shape and time course to the EPSP itself.

We are now performing a quantitative study of the influence of several "afferent" (e.g., afferent input statistics, EPSP amplitude, and synaptic noise level) and intrinsic "cell" variables (e.g., membrane time constant, degree of post-spike refractoriness, recurrent IPSP's) upon the interspike interval histogram, joint interval distribution, auto- and cross-correlograms, and the power spectrum and cross-spectrum.

182.9 A COMPUTER SYSTEM FOR SEMI-AUTOMATIC CELL RECOGNITION IN NEUROANATOMIC STUDIES. D.S. Schlusselberg, W.K. Smith, B.G. Culter and D.J. Woodward. Department of Cell Biology, University of Texas Health Science Center, Dallas, TX 75235.

A common task in neuroanatomical research is the identification of specifically stained cells in sections of brain tissue examined with a light microscope. Positions of these cells are commonly plotted in relation to cytoarchitectonic boundaries and brain landmarks, and then displayed as sequences of serial sections. A computer data acquistion system has been developed to store this anatomical information in disk files, allowing quantification and viewing of cell distributions in a three-dimensional form. The most time consuming aspect of the current version of this system is the manual entry of cell positions, especially in studies where large volumes of tissue are involved. We report here that significant progress has been made toward developing a general set of strategies for automating the visual recognition process by the use of a high speed graphics processor which analyzes digitized video images obtained from a light microscope.

A host computer controls stepper motors on a light microscope stage to scan a user-defined region of a given section. This region is divided into scanning squares which are sequentially digitized into a video frame buffer and analyzed by a high speed microprogrammable graphics processor. The cell recognition program scans the digitized image for shades above or below a certain intensity threshold, and subsequently identifies the region bounded by pixels outside the threshold shade range. If the area of this region is within a window of user-defined values the region is accepted as a cell, and its center, area and optical density are stored in local memory. A cross appears in the video image over regions selected as cells. The algorithm counts objects in a 512 by 512 pixel array in about one-third of a second, allowing program values and microscope lighting to be adjusted interactively to achieve the optimal accuracy of cell recognition. After selection of these parameters the user can add or delete cells, and then signal the program to store the list of cell descriptions obtained from a single field scan. Cell locations are stored as biological coordinates defined by a zero point and axis for each section. Cells whose centroids are near scan box boundaries are identified and flagged so that they are only counted once in subsequent scanning fields. The initial version of the system is being applied to the analysis of pigmented dopamine cells in human brainstems, and HRP-filled projection cells in rat thalamus and cortex. The raster graphics hardware employed for image analysis can also be used to create three-dimensional views of cell distributions. 183.1 STANDARDIZATION OF ^{3}H-TISSUE IMAGES WITH DIFFERENT ISOTOPIC STANDARDS, T.W. Lysz, A.W. Toga and W.A. Geary II. Dept. of Pharmacol. and Neurol., Washington Univ. Sch. of Med., St. Louis, MO 63110.

Quantitative autoradiography requires the ability to standardize the optical density (OD) of an image to a known concentration of radioactivity in tissue. Until recently, ^{3}H-images have been standardized using ^{14}C-standard plastics. We have compared the standardization of ^{3}H-images using ^{3}H- and ^{14}C-plastic standards.

Tissue ^{3}H-images were produced by injecting 6 rats with variable doses of ^{3}H-2-deoxyglucose (100-1000 µCi). After 1 hour, brains were rapidly perfused, fixed, and hemisected. One half brain was dissected into thalamus, striatum, and frontal cortex. The other half brain was frozen, mounted, and processed for film autoradiography. Dissected tissues were homogenized and treated with 1N NaOH for 2 hours at 80°C. Triplicate samples were neutralized and counted by liquid scintillation spectroscopy. Sections for autoradiography were cut at 20 µm at -20°C and exposed for 12 days against LKB Ultrofilm at room temperature. ^{3}H-containing plastic was made by adding variable amounts of ^{3}H to 1 ml of liquid methacrylate monomer and subsequent mixing with 2 grams of methacrylate polymer. After a 12 day exposure, a tissue OD vs tissue nCi/mg curve was generated with a digital mini-computer using a program for the best fit polynomial regression by the method of least squares. ^{3}H- and ^{14}C-plastics were calibrated by interpolation.

To examine the relationship between exposure time and resultant OD, calibrated ^{3}H- and ^{14}C-plastic standards were exposed against LKB Ultrofilm for 7, 12, and 20 days. Both isotopes produced lower optical density with shorter exposure time and increased OD with longer exposure time. However, the effects of variable time of exposure was not the same for the two isotopes. For a tissue radioactivity of 5 nCi/mg, calibrated ^{3}H-plastic displayed ODs of 0.34, 0.40, and 0.68 for 7, 12, and 20 days, respectively. ^{14}C-standard plastic calibrated at 5 nCi/mg produced 0.13, 0.40, and 1.05 ODs for the three exposure times. Equivalent ODs for ^{3}H- and ^{14}C-plastics at 12 days result from the original 12 day calibration exposure. The results show a lack of covariation between ^{3}H- and ^{14}C-generated images with changing exposure times. Thus, the use of ^{14}C-isotope to standardize ^{3}H-tissue images requires either strict adherence to a single exposure time or the generation of multiple calibration curves for different exposure times. The use of ^{3}H-plastic for ^{3}H-tissue images circumvents this problem.

183.2 QUANTITATIVE AUTORADIOGRAPHY OF OPIATE BINDING SITES IN RAT CNS. W.A. Geary II and G.F. Wooten, Depts. of Pharmacol. and Neurol., Washington Univ. Sch. of Med., St. Louis, MO 63110

We have employed quantitative autoradiography of radioligand binding in fresh frozen brain sections (Sci. 214, 1981) to describe opiate binding sites in the rat CNS. This abstract describes the method and characterizes the pharmacology of ^{3}H-naloxone (45 Ci/mmole) and ^{3}H-etorphine (35 Ci/mmole) binding to brain sections.

Rats were sacrificed by decapitation and brains were rapidly removed, frozen, and prepared for frozen sectioning. Serial 20µm sections at the level of the striatum were cut coronally and stored at -35°C until needed. For experimentation, sections were dried at 20°C and preincubated for 5 minutes in iced PBS (pH 7.4). After preincubation to remove endogenous ligands, sections were incubated in PBS buffer containing radioligand for 30 minutes at 20°C (total binding). Preliminary experiments showed equilibrium conditions at 30 minutes. Nonspecific binding was determined by incubating matched adjacent sections in buffer containing radioligand plus excess (200 nM Naloxone-HCl or 150 nM Etorphine-HCl) unlabeled drug. After incubation to equilibrium, sections were rapidly rinsed (3-5 sec) twice in iced buffer and once in iced deionized H_2O. After air drying at 20°C, sections were co-exposed with radioactive plastic standards for 12 days to LKB Ultrofilm. For initial saturation studies, sections were also solubilized and counted by liquid scintillation spectroscopy.

Analysis of solubilized brain sections showed saturable binding for both ^{3}H-naloxone and ^{3}H-etorphine. Scatchard analysis revealed K_D = 1.42 nM and B_{max} = 38.2 fmoles/section for the antagonist and K_D = 1.03 nM and B_{max} = 75.1 fmoles/section for the agonist.

Quantitative densitometry yielded Scatchard analyses in close agreement with scintillation spectroscopy: K_D = 1.55 nM and B_{max} = 27.2 fmoles/mg tissue wet weight for ^{3}H-naloxone and K_D = 1.47 nM and B_{max} = 71.1 fmoles/mg tissue wet weight for ^{3}H-etorphine for the striatum.

Pharmacological specificity was determined by competition experiments using 2.0 nM ^{3}H-naloxone and several opiate drugs. Stereospecificity was demonstrated by a levorphanol IC_{50} of 5.5 nM while dextrophan showed an IC_{50} >1000 nM. The rank order potency for competition with 2.0 nM ^{3}H-naloxone was as follows: etorphine (IC_{50} = 0.9 nM) > naloxone (IC_{50} = 4.0 nM) > levorphanol (IC_{50} = 5.5 nM) > morphine (IC_{50} = 125 nM) > dextrorphan (IC_{50} = 1000 nM). The distribution of binding sites was in agreement with published descriptions of opiate binding sites in the rat CNS. The use of quantitative autoradiography will facilitate the regional characterization of opiate binding sites.

183.3 QUANTITATIVE AUTORADIOGRAPHY OF ^{3}H-SPIPERONE BINDING SITES IN THE RAT STRIATUM. G.F. Wooten, W.A. Geary II and M.B. Ferrari*. Depts. of Pharmacol. and Neurol., Washington Univ. Sch. Med., St. Louis, MO 63110.

Some of the biochemical properties of ^{3}H-spiperone binding to rat striatum were studied by quantitative in vitro autoradiography (Eur. J. Pharmacol. 72:421-422, 1981 and Neurosci. Letters 25:101-105, 1981).

Following decapitation, brains were rapidly removed, frozen in liquid freon, and mounted on brass chucks. Serial 20 µ sections were taken in the coronal plane through the striatum and stored at -35°C for up to 10 days. Prior to binding studies the sections were thawed to 20°C and preincubated for 5 min. in iced PBS (pH 7.4). Because preliminary studies showed that equilibrium was reached in approximately 20 minutes at room temperature, incubations were carried out for 30 minutes. Nonspecific binding was determined by incubating adjacent sections in buffer containing radioligand plus d-butaclamol 1 µM (l-butaclamol 1 µM had no effect on binding). Following incubation for 30 minutes at room temperature, sections were rinsed for five seconds x2 in iced PBS and once in iced deionized water. After drying at room temperature, sections were exposed along with plastic standards to LKB Ultrofilm for 12 days. After development, the film was analyzed densitometrically with a Leitz MPV Microdot variable aperture microdensitometer.

There was no effect of tissue thickness between 5 and 40 µ on the autoradiographic images. Saturation curves for ^{3}H-spiperone, when subjected to Scatchard analysis, revealed a Kd = 0.45 nM and a Bm = 48 fmoles/mg tissue in the striatum. Striatal binding was stereospecific as the IC_{50} for d-butaclamol was approximately 8 nM while the IC_{50} for l-butaclamol was 10 µM (^{3}H-spiperone concentration was 1 nM). The pharmacologic specificity of ^{3}H-spiperone binding was characterized by competition experiments for binding against ^{3}H-spiperone 1 nM. The following IC_{50}'s were determined: fluphenazine < 0.1 nM, spiperone 0.8 nM, haloperidol 15 nM, apomorphine 0.2 µM, dopamine 20 µM, and serotonin 110 µM.

In studies of regional ^{3}H-spiperone binding by quantitative autoradiography, there was a highly significant ($P < 0.001$) correlation between regional in vitro binding and the regional cerebral distribution of ^{3}H-spiperone determined autoradiographically 2 hours after an intravenous injection of ^{3}H-spiperone in vivo.

The use of quantitative in vitro autoradiography will greatly facilitate the biochemical characterization of regionally distinct drug and neurotransmitter binding sites.

183.4 BENZODIAZEPINE RECEPTORS: AUTORADIOGRAPHIC LOCALIZATION IN RAT AND HUMAN AMYGDALA. D.L. Niehoff and M.J. Kuhar. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205

Electroencephalographic, evoked potential and behavioral studies have implicated the amygdaloid nucleus as an important site of action of benzodiazepine (BZ) drugs. Within this structure, the lateral, basal, and central nuclei, and the anterior rather than the posterior aspect have been demonstrated to be responsive to BZ's by means of studies involving lesions of these nuclei or direct application of BZs. As expected, light microscopic autoradiography (LM-ARG) has demonstrated a high density of BZ receptors in the amygdala. The triazolopyridazine drugs (TPZ's), typified by CL218,872, appear to differentiate two subtypes of BZ receptors, Type 1 (TPZ-preferring) and Type 2 (TPZ non- preferring). In this study, we have utilized a LM-ARG technique involving CL218,872 (Young et al., J. Pharmacol. Exp. Ther. 216:825, 1981) to localize multiple BZ receptors in rat and human amygdala and to correlate these results with previous data on BZ effects on this structure.

Multiple BZ receptors in 8 micron rat or human slide-mounted tissue sections encompassing the entire rostral-caudal extent of the amygdala were labeled according to Young et al., 1981. Autoradiograms were generated by the apposition of emulsion-coated coverslips.

In the rat, the highest density of BZ receptors was found in the lateral nucleus, and the lowest in the central nucleus. Both anterior and poterior cortical nucleus and the more caudal portions of the basolateral and basomedial nuclei also contained high levels of receptors. At all levels, the majority of the receptors appeared to be of the Type 2 subtype, except in the anterior aspect of the lateral nucleus and the most anterior portion of the anterior cortical nucleus. Thus, these results can be correlated with previous results suggesting the importance of the lateral nucleus and the anterior aspect of the amygdala in the action of BZ's.

Because the human brain has been shown to differ from that of the rat in both the gross distribution of BZ receptors and the degree of heterogeneity in several regions, the distribution of multiple BZ receptors in human amygdala will be compared to that in the rat. Species differences may have implications for the development of animal models for human anxiety. An attempt will be made to identify specific neuronal circuits that are likely to be affected by BZ administration.

Supported by grants DA00266, MH00053, and grants from Hoffman-La Roche, American Cyanamid and the McKnight Foundation.

183.5 AUTORADIOGRAPHIC STUDIES ON GABA$_A$ RECEPTOR SITES IN THE RAT BRAIN. S. Kito, E. Itoga*, Y. Nakamura* and T. Kishida*. Third Dept. of Int. Med. Hiroshima Univ. School of Med., Hiroshima, Japan 734.

γ-Amino butyric acid (GABA) receptor sites are widely distributed in the mammalian central nervous system. Recently, GABA receptor sites were classified into GABA$_A$ sites and GABA$_B$ sites according to bicuculline sensitivity, i.e. GABA$_A$ sites were bicucullin sensitive and revealed a high affinity for muscimol whereas GABA$_B$ sites were bicucullin insensitive and had a high affinity for baclofen (Bowery 1980). We investigated GABA$_A$ receptor sites in the rat cerebellum through biochemical binding experiments using cryostat sections. We also observed autoradiographic distribution of GABA$_A$ sites in the rat brain with use of ^{3}H-GABA as a ligand. Wistar strain male rats were used for the experiments. The cerebellum was obtained by decapitation and 10 um frozen sections were made by cryostat. The sections were stored at -20°C and used within a week. For the binding assay, slides were preincubated in 50 mM Tris HCl buffer containing 2 mM CaCl$_2$ (pH 7.4) for 20 min at 20°C. Then the slides were incubated with various concentrations of ^{3}H-GABA and 50 uM baclofen (to suppress the ^{3}H-GABA binding to GABA$_B$ receptor sites) with or without 0.2 mM GABA. After the incubation, the slides were rinsed in the same redioactive-free buffer and the tissues were wiped away with Whatman filter paper, placed in a scintillation vial and disolved with 1 ml Soluene. Twelve hours later, the scintillation fluid was added to the samples and counted. Scatchard analysis of specific ^{3}H-GABA binding to GABA$_A$ sites in cerebellar cryostat sections indicated the presence of saturable binding with two components. Namely, one component with the Kd value of 9.8 nM and the Bmax of 274 fmol/2 sections and another component with the Kd value of 0.16nM and the Bmax of 55 fmol/2 sections were determined. The Kd value obtained from kinetic experiments was 13 nM. As the next step, we tried to observe distributions of these high and low components of GABA$_A$ receptor sites in the rat brain autoradiographically. Incubation of cryostat sections with 0.2 nM and 10 nM ^{3}H-GABA with 50 uM baclofen followed preincubation. The slides were rinsed, air dried, carbon coated and coated with nuclear track emulsion. After 8 week exposure, the slides were developed and stained with toluidine blue. The distribution pattern of both components of the GABA$_A$ receptor site was similar to that of ^{3}H-muscimol binding sites in the cerebellam. However,in the striatum and substantia nigra, binding sites of the low affinity component were more mumerous than in other regions of the brain. These distributions were visualized and quantified by the Texture Analyzing System.

183.6 IMPLICATIONS OF TRANS-SYNAPTIC DEGENERATION FOR RECEPTOR BINDING STUDIES IN THE RAT STRIATUM. T. Hattori, P. Weinreich* and P. Seeman (SPON: J.I. Nagy). Dept. Anat. and Pharmacol., Med. Sci. Bldg., Univ. Toronto, Toronto, Ont. Canada

The decrease of the number of striatal dopamine receptors after decortication has been interpreted to indicate that these receptors are contained on terminals of the corticostriatal projection and are therefore presynaptic. However, in view of the total absence of classical axo-axonic synaptic contacts between two boutons in this brain area, other interpretations should be investigated. We now suggest that trans-synaptic degeneration of striatal dendritic spines which receive synaptic inputs from both the corticostriatal and nigrostriatal projections may explain the loss of receptor binding. Two days after decortication, ^{3}H-spiperone radioceptor assays revealed approximately a 15% decrease in binding, although this value was not significant due to the large variability between animals. Maximal and uniform reduction in binding occurred at 5 days postlesion (45% decrease) with no further change apparent up to 19 days postlesion. Two and three days postlesion, degenerating dendritic spines that were postsynaptic to degenerating boutons were often observed. This evidence ranged from examples of a degenerating bouton in synaptic contact with a normal appearing spine (both of which were totally engulfed by astrocytes) to the most advanced stage where both the terminal and postsynaptic spine showed dark type degeneration. At 3 days postlesion, out of 750 cases of degeneration, about 33% were in the final stage. The present data clearly indicate that trans-synaptic degeneration occurs in the striatum. Therefore, it cannot be concluded that a decrease in the number of receptors after cortical lesions necessarily indicates that these receptors are localized on the presynaptic terminals. It is equally possible that this reflects a loss of receptors that were located on dendritic spines that underwent trans-synaptic degeneration.

183.7 D-LSD BINDING IN MOUSE BRAIN: DIFFERENCES BETWEEN IN VIVO AND IN VITRO LOCALIZATION. B.J.Ebersole*, S.Maayani, R.Weiśbach and H.Weinstein*. Department of Pharmacology, Mount Sinai School of Medicine of CUNY, New York, NY, 10029.

Establishing a relationship between binding of [^{3}H]-d-lysergic acid diethylamide([^{3}H]LSD) and its pharmacology requires consideration of dynamic mechanisms that may modulate interactions of the drug with the binding sites. Such mechanisms may cause differences between the characteristics of LSD binding measured in equilibrium in vitro and non-equilibrium in vivo experiments. Using radioautographic localization and high affinity binding to mouse brain membranes, we found differences between the localization of [^{3}H]LSD in vitro and following in vivo administration of the drug. Mice injected i.v. with 100nmol [^{3}H]LSD/kg, with or without coinjection of 5µmol/kg unlabeled LSD, were killed 15 min later,when brain drug levels are maximal. Brains were dissected, homogenized, filtered, and rinsed with cold buffer. [^{3}H] bound to membranes was unchanged LSD. [^{3}H]LSD conc. in all regions was ca. 12nmol/kg tissue. In animals receiving excess LSD, bound [^{3}H]LSD in cerebellum was not reduced; bound [^{3}H]LSD in both cortex and hippocampus was reduced to cerebellar levels."Specific" binding was thus defined for each animal as binding in excess of cerebellar levels.

	Total bound	"Specific" bound	Levels are
CTX	4.5 + 0.6	3.6 + 0.5	expressed as nmol
HIP	1.8 + 0.2	0.9 + 0.2	[^{3}H]LSD/kg tissue,
CER	0.9 + 0.2	-------	mean+SEM, n=6

Specific binding in HIP is significantly less than in CTX. In contrast, specific [^{3}H]LSD binding in vitro (defined in the absence and presence of 1 uM LSD) was similar in CTX and HIP with half-maximal saturation at 5nM and B_{max}=200 fmol/mg protein. The in vivo/in vitro difference in the ratio of HIP:CTX specific binding was confirmed by radioautographic studies of brain slices exposed to [^{3}H]LSD under in vivo(as above) or in vitro(6nM [^{3}H]LSD) conditions. Labeling in CTX was similar under both conditions,with a dense band seen in both layers III-IV of CTX and anterior cingulate gyrus. This band was designated "specific" labeling as it was not apparent in competiton experiments with unlabeled LSD (1uM in vitro,5µmol/kg injection in vivo). In contrast, marked differences were seen in HIP. In vitro, specific label was seen in all areas except CA2 and CA3. In vivo, the slight label--seen in CA1, CA2, CA3, and CA4, but not in dentate gyrus--was not affected by co-injection of excess LSD, indicating a lack of specific binding. Ongoing studies aim to determine if the observed differences are due to effects of endogenous modulators or neurotransmitters, or to time and/or region-dependent modes of interaction of the drug, as determined by pharmacokinetic or pharmacodynamic characteristics. [Supported by USPHS Grants DA-01875 and DA-00060,and Predoctoral Training Grant GM07163(B.J.E.)]

183.8 REGIONAL DIFFERENCES OF 2-BROMO D-LSD AND D-LSD INTERACTION WITH 5-HT AND LSD BINDING SITES. S. G. Beck, S. Maayani, H. Weinstein*, and J. P. Green. Department of Pharmacology, Mount Sinai School of Medicine of CUNY, New York, NY 10029.

LSD (d-lysergic acid diethylamide) produces hallucinations in man, but its 2-bromo derivative (BOL) does not. However, other physiological and mental effects are elicited by both drugs, but BOL is 20-100 fold less potent. Delineation of pharmacological mechanisms responsible for such differences between related drugs should help to elucidate the mode of action of LSD in brain. We used high affinity binding methods and radioautographic localization to compare the interaction of LSD and BOL with specific binding sites in various regions of rat brain. Competition of LSD and BOL for binding sites in P_2 membrane preparations from female rat cortex (CX) or hippocampus (HIP) was studied with several concentrations of [^{3}H]LSD or [^{3}H]5-HT. [^{3}H]LSD was used at 2 and 6nM and [^{3}H]5-HT was used at 0.5, 2 and 6nM, concentrations chosen to occupy 50-80% of available sites. Non-specific binding was defined with 10^{-6}M unlabeled LSD. In CX, BOL and LSD appeared equipotent at both [^{3}H]LSD concentrations with Hill coeffs. near unity. However, BOL appeared four fold less potent than LSD at all [^{3}H]5-HT concentrations. Competition by BOL deviated from simple competitive behavior at the higher concentrations but not at 0.5nM. Hill coeffs. for competitions with the increasing concentrations of [^{3}H]5-HT were 0.93, 0.86, and 0.64 respectively. In contrast, Hill coeffs. for competition by LSD deviated from unity (0.82) only with 6nM [^{3}H]5-HT. Differrences between LSD and BOL were greatest in HIP where BOL was four fold less potent than LSD at both concentrations of [^{3}H]LSD. Hill coeffs. for both LSD and BOL were unity. These results are consistent with the hypothesis that BOL and LSD interact with at least two populations of serotonin binding sites labeled by both [^{3}H]LSD and [^{3}H]5-HT. The difference in the affinity of BOL for these populations is much greater than that of LSD. That such differences between BOL and LSD were more apparent in HIP than in CX is consistent with previous findings of a regional heterogeneity in the distribution of multiple serotonin sites. In CX the sizes of the populations appear equal, whereas in HIP one population predominates. This regional difference between BOL and LSD was confirmed by results from in vitro radioautography experiments with [^{3}H]LSD and [^{3}H]5-HT. Consistent with results from high affinity binding in homogenates, BOL (10^{-6}M), like LSD, eliminated the binding by [^{3}H]LSD in CX, but did not eliminate the labeling of HIP by [^{3}H]LSD or [^{3}H]5-HT. This pattern of selective regional competition for sites labeled by [^{3}H]LSD and [^{3}H]5-HT is identical to the one observed in our radioautography studies with the neuroleptic spiroperidol. (Supported by USPHS Grants DA-01875, DA-00060 and DA-07135)

183.9 CHARACTERIZATION OF MULTIPLE [^{3}H]5-HYDROXYTRYPTAMINE BINDING SITES IN RAT SPINAL CORD TISSUE, P.J. Monroe & D.J. Smith, Dept. of Pharmacology/Toxicology & Anesthesiology, W.V.U. Medical Center, Morgantown, West Virginia 26506.

Multiple serotonin (5HT) binding sites apparently exist in several areas of the central nervous system (Snyder & Goodman, J. Neurochem. 35: 5, 1980). For example, Peroutka & Snyder (Mol. Pharmacol. 16: 687, 1979) reported two sites in the rat frontal cortex, one of which ($5HT_1$) has a high affinity for ^{3}H-5HT while the other binds ^{3}H-spiperone preferentially. In the present study the existence of a similar multiple 5-HT binding site system was studied in tissue from the rat spinal cord.

A membrane fraction was prepared from spinal cord tissue by the method of Peroutka & Snyder (see reference). Binding assays for ^{3}H-5HT were carried out with these membranes at 37°C for 20 min. using 800 µl of tissue suspension (20 mg tissue/tube), 100 µl of ^{3}H-5HT and 100 µl of drug. After the incubation, the tissue was collected on Whatman GF/B filters and radioactivity analyzed in Dimilume after a 5 hr extraction (spec./total binding=35-40%). Binding assays using ^{3}H-spiperone as the radioligand were also performed. Some assays were conducted with each radioligand in frontal cortex tissue for comparison to the spinal cord data.

The results indicated that multiple 5-HT binding sites exist in the spinal cord. A curvilinear Scatchard plot results from saturation studies with [^{3}H] 5-HT. Two apparent sites are resolved with dissociation constants of 6.7 & 33.0 nM for the high and low affinity sites, respectively. Additional support for the existence of multiple 5HT binding sites comes from the analysis of the displacement of 30 nM ^{3}H-5HT by the unlabeled ligand, where Hill coefficients (n_H) were significantly less than unity (0.32). Similarly, Hill plot analysis indicates that unlabeled spiperone interacts at these multiple 5HT sites (n_H=0.50). However, specific ^{3}H-spiperone binding, which can be demonstrated in the frontal cortex is absent in the spinal cord. None of the specifically bound ^{3}H-5HT was found to be associated with the 5HT uptake carrier since fluoxetine, an inhibitor of 5HT uptake, does not alter binding characteristics.

The high affinity spinal cord site is apparently analogous to the high affinity $5HT_1$ binding site located in the frontal cortex. A dissociation constant similar to that for the high affinity spinal cord site can be calculated from saturation studies using frontal cortex tissue (K_D=4.4 nM), and in both tissues, spiperone displays nearly equal potency (IC50 value against 2 nM ^{3}H-5HT in frontal cortex, 3µM, and spinal cord, 6 µM). However, the low affinity site in the spinal cord is not analogous to the $5HT_2$ site in frontal cortex that preferentially binds ^{3}H-spiperone.

183.10 NEUROTENSIN RECEPTORS AND OPIATE RECEPTORS IN THE FOREBRAIN OF THE RHESUS MONKEY: AUTORADIOGRAPHIC LOCALIZATION. Miles Herkenham, Steven P. Wise, Remi Quirion, and Candace B. Pert. Laboratory of Neurophysiology and Biological Psychiatry Branch, NIMH, Bethesda, Maryland 20205.

Previous studies have emphasized the similarities between mu-opiate and neurotensin receptor distributions. Accordingly, these receptors were visualized autoradiographically in slide-mounted sections through the forebrain of a rhesus monkey. The ligands used to label the receptors were [^{3}H]naloxone (NAL) and [^{3}H]neurotensin (NT), respectively (see Herkenham and Pert, J. Neurosci., in press; Young and Kuhar, Brain Res., 1981, 206: 273).

Cerebral cortex. The patterns of NT and NAL binding in the cerebral cortex are stikingly similar. In general, deep cortical layers (layers V and VI) show the highest levels of binding. This distribution suggests that the output elements of cortex may be most subject to neurotensinergic and opiatergic modulation. For both receptors, cortical fields in proximity to the allocortex are receptor-dense while the classical visual, somatosensory and motor fields are receptor-sparse. Thus, both of these receptors are preferentially distributed in limbic cortex, specifically the cingulate, entorhinal, parasubicular, insular, prostriate, orbital frontal, and medial frontal cortex. While we note the marked enrichment of opiate receptors in the limbic cortex relative to the sensory and motor fields, this disparity is even greater for NT receptors.

Striatum. NT and NAL strongly contrast in their binding to the striatum. NAL binding to striatal opiate receptors is distributed densely and heterogeneously in the ventromedial striatum and displays a gradient of decreasing density towards the dorsolateral striatum. NT has low and homogeneous binding levels in the caudate and putamen and moderate binding in the lateral portions of accumbens nucleus. Thus, the striatal binding patterns indicate a significant exception to the general correspondence of opiate and NT receptors.

Conclusions. The di- and telencephalic structures most heavily labeled by NAL include most of the amygdala, many parts of thalamus and hypothalamus, the septal nuclei, the ventromedial striatum, and the basal nucleus of Meynert. Of these, only the basal nucleus is heavily labeled by both NT and NAL. By contrast, NT most heavily labels the endopiriform nucleus, parasubiculum, CA_4 hippocampus, and the limbic iso- and juxtallocortex. Hence, most of the NT receptor-dense regions are within cortex, and more specifically, limbic cortex. In view of their more limited localization to limbic forebrain structures, NT receptors may have a more circumscribed role in brain function than do opiate receptors.

183.11 RADIOHISTOCHEMICAL LOCALIZATION OF OPIATE RECEPTORS IN RAT BRAIN: THE BENZOMORPHAN BINDING SITE. F. Valdes*, B. Crain, K. Chang, and J. McNamara (SPON: R. Dasheiff). Departments of Medicine, Pathology, and Pharmacology, Duke University Medical Center and The Wellcome Research Laboratories, Research Triangle Park, Durham, NC 27705.

Recent biochemical investigations discovered the presence of a subpopulation of opiate receptor binding sites with high affinity for several benzomorphan drugs (PNAS 78:4141, 1981). These sites exhibit high affinity for opiate receptor antagonists (e.g. diprenorphine) and low affinity for both mu (e.g. morphiceptin) and delta (e.g. [D-Ala^2, D-Leu^5] enkephalin) agonists. These sites have therefore been termed benzomorphan binding (BB) sites. Elucidating the functional significance of these binding sites will be facilitated by understanding their anatomic distribution. We therefore analyzed the distribution of BB sites with the in vitro radiohistochemical method of Young and Kuhar.

Thin (10 micron) frozen sections of rat brain were thaw mounted on gelatin coated slides. To promote removal of endogenous opioids, the sections were preincubated in 50 mM Tris Cl buffer pH 7.7 containing 50 µM GTP and 100 mM NaCl. The sections were then incubated at 25° C for 40 min. in 170 mM Tris Cl buffer ph 7.7 containing 2 nM [^{3}H] diprenorphine (DPN) under four different conditions: 1) [^{3}H] DPN alone (labelled mu, delta and BB sites); 2) with added 10^{-5} M morphiceptin (labelled delta and BB sites); 3) with added 10^{-5} M morphiceptin + 2 X 10^{-7} M [D-Ala^2, D-Leu^5] enkephalin (labelled BB sites); or 4) with added 2 X 10^{-6} M DPN (nonspecific). The sections were rinsed, dried, and apposed to either emulsion (Kodak NTB2) coated coverslips or tritium sensitive film (LKB ultrofilm [^{3}H]).

The BB sites were preferentially enriched in gray matter compared to white matter. BB sites were found in the following areas (density ranging from the highest to the lowest): amygdala = hypothalamus > cortex = caudate > thalamus = hippocampal formation. Areas particularly enriched were the habenula, the most dorsal medial portion of caudate, and the interstitial nucleus of the stria terminalis. These findings should provide a framework for pursuing sites at which the various pharmacologic actions of the benzomorphans are mediated.

183.12 CHARACTERIZATION OF THE AFFINITY PURIFIED GLYCINE RECEPTOR OF RAT SPINAL CORD. F. Pfeiffer*, D. Graham* and H. Betz* (SPON: ENA). Max-Planck-Institute for Psychiatry, Department of Neurochemistry, 8033 Martinsried, Federal Republic of Germany.

Glycine is a major inhibitory neurotransmitter in mammalian spinal cord. The hyperpolarizing action of this amino acid can be selectively antagonized by the alkaloid strychnine, the latter being a highly specific ligand for the glycine receptor. Recently, this receptor has been solubilized from rat spinal cord membranes using the non-ionic detergent Triton X-100 (Pfeiffer and Betz, Brain Res. 226: 273, 1981).

The glycine receptor was purified 1950-fold by affinity chromatography on aminostrychnine-agarose and wheat germ agglutinin-Sepharose. Polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate and mercaptoethanol revealed three glycine receptor associated polypeptides of molecular weight 48,000, 58,000 and 93,000. Using our previously published photoaffinity-labeling procedure (Graham et al., Biochem. Biophys. Res. Comm. 102:1330, 1981), ^{3}H-strychnine was incorporated irreversibly into the 48,000-dalton polypeptide. The dissociation constant of ^{3}H-strychnine binding to the purified glycine receptor was 9.3 nM. The glycine receptor agonists glycine, ß-alanine and taurine inhibited the binding of ^{3}H-strychnine. Gel filtration and sedimentation in sucrose/H_2O and sucrose/D_2O gradients gave a Stokes radius of 7.7 nM, a partial specific volume of 0.78 ml/g and a sedimentation coefficient of 8.2 S for the purified glycine receptor. From these data, a molecular weight of 246,000 was calculated for the glycine receptor protein.

183.13 DOPAMINE RECEPTOR TURNOVER AFTER VIPOXIN BLOCKADE. Jonathan E. Freedman and Solomon H. Snyder. Johns Hopkins University School of Medicine, Depts. of Neuroscience, Pharmacology and Psychiatry, Baltimore, MD 21205.

Vipoxin is a small, basic protein, molecular weight 13,000, which we have purified to apparent homogeneity from Russell's viper venom. Vipoxin inhibits ^{3}H-ligand binding to alpha-adrenergic, dopaminergic, and serotonergic receptors. The inhibition of binding is highly selective and potent, and essentially irreversible (J. Biol. Chem. 256, 13172).

We have studied effects on dopamine receptors after stereotaxic injection of vipoxin into the corpus striatum of pentobarbital-anesthetized rats. Vipoxin reduces ^{3}H-spiroperidol binding to dopamine receptors in striatum homogenates, with 5 µg of vipoxin inducing a 50% reduction in binding 5 hr after injection. The reduction in binding reflects a decrease in the number of receptor sites rather than a change in binding affinity. The rats also display rotational stereotopy ipsilateral to the injection site. Vipoxin does not reduce ligand binding in brain regions other than the region injected. ^{3}H-Spiroperidol binding sites begin to reappear within 24 hr after injection, and return to control values at around 2 days. The kinetics of reappearance can be described by receptor synthesis at the rate of approximately 40 fmol/mg protein-hr and receptor degradation with a rate constant of 0.06 hr^{-1}, corresponding to a receptor half-life of approximately 12 hr.

Because vipoxin also acts at alpha-adrenergic and serotonin receptors, this technique can also be applied to these receptors in other brain regions. Furthermore it is possible to determine the relative effects on receptor synthesis and receptor degradation giving rise to such changes in receptor number as the supersensitivity of dopamine receptors after chronic neuroleptic treatment or nigrostriatal lesion.

183.14 [^{3}H]N-ACETYLSEROTONIN LABELS SEROTONERGIC RECEPTORS IN RAT FRONTAL CORTEX. L. P. Niles, G. M. Brown and R.K. Mishra* Department of Neurosciences, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5

In attempting to determine how the pineal gland influences brain and endocrine function in mammals we have examined binding of the putative pineal hormone N-acetylserotonin in CNS tissues. Using tritiated N-acetylserotonin ([^{3}H]NAS), saturable, high affinity binding was found in human, rat and calf brain membranes. In fresh rat brain membranes, suspended in 50mM tris Hcℓ, pH 7.4, [^{3}H]NAS binding was monophasic with dissociation constant (K_D) values ranging from 3 - 7 nM and a binding site concentration (Bmax) of 230 - 400 fmol/mg protein. Frozen membranes displayed biphasic scatchard plots with a high affinity binding component similar to that in fresh tissue and a second population of low affinity, high capacity binding sites.

TABLE 1

	Ic_{50}(nM)	nH
NAS	10.89	1.09
5-HT	19.59	1.21
5-Methoxytryptamine	432	0.82
N-acetyltryptamine	$>10^6$	
Quipazine	190	0.49
Methysergide	83	0.86
Mianserine	106	1.01
Ketanserine	118	0.98
Cyproheptadine	5348	0.64
Spiperone	157	0.64

Pharmacological characterization of [^{3}H]NAS binding indicates that the 5-hydroxyl group is necessary for high affinity binding. Thus, among the tryptamines examined, N-acetylserotonin (NAS) and serotonin (5-HT) were the most potent inhibitors of [^{3}H]NAS binding. 5-Methoxytryptamine shows about a 30-fold decrease in affinity, while N-acetyltryptamine, which lacks a C-5 substituent, has negligible effects on binding. The 5-HT agonist, quipazine, and various antagonists exhibited moderate binding affinity. The specific 5-HT_2 antagonist, ketanserine, and spiperone, which reportedly binds to 5-HT_2 sites in the rat frontal cortex, also inhibited binding. These findings suggest that [^{3}H]NAS labels both 5-HT_1 and 5-HT_2 sites in the rat frontal cortex and that the biological effects of NAS may involve interaction at central serotonergic receptors.

183.15 EFFECT OF CHRONIC TREATMENT WITH OVARIAN STEROIDS ON NEUROTRANSMITTER RECEPTORS IN THE RAT BRAIN. A. Biegon*, L. Snyder, and B.S. McEwen. The Rockefeller University, New York, NY 10021.

During the human menstrual cycle or pregnancy in humans and rodents, the brain is exposed to gradually changing and elevated levels of ovarian steroids lasting 2-3 weeks or longer. In order to study the consequences of such hormonal states for neurotransmitter chemistry, we chose to measure the effects of 2-week treatments with estradiol (E_2) and progesterone (P), separately and in combination, on beta and alpha adrenergic and serotonergic receptor levels in rat cerebral cortex. Ovariectomized rats received subcutaneous Silastic implants containing 10% E_2 in cholesterol; pure P; both E_2 and P; or empty capsules. The resulting levels of E_2 approximate proestrous afternoon levels and midpregnancy. Rats were killed two weeks later and cerebral cortex from 5-6 rats was pooled and frozen for subsequent assay of membrane binding of $5HT_1$ (^{3}H 5HT), $5HT_2$ (^{3}H spiperone); beta (^{3}H dihydroalprenolol); $alpha_1$ (^{3}H prazosin) receptors in washed membrane preparations. The experiment was repeated 5-6 times. We found that chronic E_2, P and E_2 plus P significantly reduces $5HT_1$ receptor density (Bmax values in fmoles/mg protein: Control, 864; E_2, 786; P, 732; E_2 plus P, 711; $p < .02$ for all groups compared to control by paired t-test). No significant change in Kd was found. $5HT_2$ receptors increased in density following E_2 (Bmax in fmoles/mg protein: Control, 447; E_2, 581, $p < .01$, paired t-test). A smaller, but still significant increase appears after P alone: Bmax=508 ($p < .05$). E_2 plus P results in no change in $5HT_2$ binding: Bmax=450. $Alpha_1$ adrenergic receptors were unaffected by E_2, P or E_2 plus P treatment. Beta adrenergic receptor density was decreased by chronic E_2, as has been shown previously with a higher level of E_2 (Wagner et al., Brain Res. 71:147, 1979), whereas P had no effect (Bmax in fmoles/mg protein: Control, 608; E_2, 437; P, 513; E_2 plus P, 460, $p < .05$ for paired t-test vs control for E_2 and E_2 plus P, but not for P alone). We conclude that ovarian steroids can modify selectively the densities of serotonergic and adrenergic receptor subtypes. The reduction of $5HT_1$ receptors may be the result of a direct steroid interaction with the membrane (cf., Biegon and McEwen, J. Neurosci. 2:199, 1982). The reduction in beta receptors might be the result of chronic stimulation of norepinephrine release (cf., Wagner et al., cited above). Regardless of mechanism, receptor modulation by steroid hormones may play a role in the affective and behavioral correlates of menstruation and the postpartum period.

184.1 STRESS INDUCED MODULATION OF HIPPOCAMPAL SYNAPTIC CHOLINERGIC MECHANISMS. Varda H. Gilad, Louis Shenkman, Jose M. Rabey[1] and Gad M. Gilad. Isotope Department, Weizmann Institute of Science, Rehovot, and [1]Ichilov Hospt., Tel-Aviv Univ., Israel.

We have recently demonstrated that inbred Wistar-Kyoto (WKY) rats, which are behaviorally more reactive to stress than Brown-Norway (BN) rats, also have higher choline acetyltransferase (CAT) activity in the septum and hippocampus. And, this is parallelled by a comparable strain difference in acetylcholinesterase staining intensity in the hippocampus. The present study sought to determine whether strain differences also exist in the dynamic regulation of synaptic choline uptake and acetylcholine (ACh) release in the hippocampus after stress. [^{3}H]-choline uptake as measured in synaptosomal preparations (P_2 fractions) was 30% higher in WKY rats, directly correlated to their higher CAT activity. After immobilization stress for 2h, choline uptake was reduced to a similar extent (20 to 30%) in both strains. This reduction in precursor uptake was accompanied by increased ACh release after stress. Release of ACh in control unhandled rats was comparable in both strains. But ACh release after acute stress was 50% higher in WKY than in BN rats. Maximum muscarinic cholinergic binding capacity (Bmax) as assessed by measuring the specific binding of the ligand [^{3}H]-quinuclidinyl benzilate was higher in BN rats (BN:2.216, WKY:1.592pmol/mg protein). The dissociation constant (Kd) however was similar in both strains (BN:5.9×10^{-10}, WKY:6.3×10^{-10}). Binding capacity was not changed after stress. We conclude: 1) Choline uptake in the hippocampus is directly related to CAT activity; 2) After stress,increased ACh release is accompanied by a compensatory reduction in choline uptake; 3) Muscarinic cholinergic binding is inversely related to ACh release after stress, and 4) Reduction in choline uptake may be a hallmark of cholinergic synapses during adaptation to increased neuronal activity.

184.2 A SODIUM DEPENDENT HIGH AFFINITY CHOLINE UPTAKE SYSTEM UNASSOCIATED WITH ACETYLCHOLINE SYNTHESIS. M. Ivy*, R. Sukumar and J.G. Townsel. Department of Physiology and Biophysics, University of Illinois Medical Center, Chicago, IL 60612.

Low and high affinity choline uptake systems have been demonstrated in neuronal tissues of vertebrates and invertebrates. The low affinity system has been found in diverse tissues and cell types. The high affinity choline uptake system (HACUS), on the other hand, is thought to be restricted in distribution to cholinergic neurons and terminals [Kuhar, M.J. and Murrin, L.C., J. Neurochem. 30: 15-21, 1978]. The HACUS is Na^+ dependent and has been shown to contribute significantly to the synthesis of acetylcholine (ACh) [Yamamura, H.I. and Snyder, S.H., J. Neurochem. 21: 1355-1374, 1973]. In this study we have characterized a sodium dependent HACUS which is exclusive of ACh biosynthesis.

The cardiac ganglion which regulates the neurogenic heart of the horseshoe crab Limulus polyphemus was incubated in Chao's physiological salt solution containing 2 µM [^{3}H] choline at room temperature (25 ± 2°C). The ganglion readily accumulated radioactivity. The rate of uptake was 0.04 p.moles/min/mg tissue. A tissue/medium (T/M) ratio of greater than 7:1 was obtained after 90 min. of incubation in 0.01 µM [^{3}H] choline. The uptake of [^{3}H] choline showed saturation kinetics and was dependent on the presence of sodium ions. Analysis revealed the presence of two kinetically distinct uptake processes for choline - a high affinity uptake system with a Km of 7.92 µM and Vmax of 0.68 p.moles/mg/min and a low affinity uptake system with a Km of 92.37 µM and a Vmax of 9.07 p.moles/mg/min respectively. Neither uptake system was greatly influenced by the absence of calcium and potassium ions in the incubation medium. However, the high affinity choline uptake system was sensitive to some metabolic inhibitors and was significantly blocked by hemicholinium - 3 (HC-3). A comparative study of the [^{3}H] choline uptake products in several neuronal tissues of Limulus including the cardiac ganglion was done. A considerable portion of the label taken up was incorporated into [^{3}H] ACh in the corpora pedunculata (81%), the circumoesophageal ring (57%), and in the abdominal ganglia (47%). In the cardiac ganglion the prevalent product (84%) of the extractable radioactivity taken up co-electrophoresed with phosphorylcholine. [^{3}H] ACh was not detected in extracts of the cardiac ganglion following tissue incubation in either 2 or 5 µM [^{3}H] choline. The ACh synthesizing enzyme, choline acetyltransferase (E.C.2.3.1.6) was also undetected in extracts of the cardiac ganglion. These results suggest that the Na^+ dependent HACUS is not restricted to cholinergic functions.

(Supported by NIH Grant HL 24140)

184.3 THE EFFECTS OF ANTICONVULSANT DRUGS ON HIGH AFFINITY CHOLINE UPTAKE, J.A. Miller* and J.A. Richter. Departments of Pharmacology and Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The sedative-hypnotic barbiturate, pentobarbital, when administered in vivo inhibits sodium dependent high affinity choline uptake (HACU) in vitro. Recent studies from this laboratory have suggested, however, that the inhibition of HACU is not correlated with the hypnotic effect (Richter, J.A., et al., J. Neurochem., in press, 1982). We have looked at some other barbiturates and other anticonvulsant drugs to see if there is a relationship between anticonvulsant activity and the inhibition of HACU. In these experiments drugs were administered i.p. to male ICR-Swiss mice and the animals were decapitated at a later time. The hippocampi were removed and HACU was measured in a synaptosomal preparation of this tissue by the method of Simon et al. (Simon, J.R. et al., J. Neurochem. 26: 909, 1976).

The anticonvulsant barbiturates, phenobarbital and barbital, inhibited HACU at doses that did not cause a loss of righting reflex. This further supports the suggestion that the effect of barbiturates on HACU is independent of the hypnotic effect. The brain level of phenobarbital did correlate with the degree of inhibition of HACU. Barbituric acid (which lacks hypnotic or anticonvulsant activity) had no effect on HACU in doses up to 400 mg/kg, supporting the view that the effect of barbiturates is not a nonspecific effect. The benzodiazepine, chlordiazepoxide, also inhibited HACU but at relatively high doses (>18 mg/kg). The anticonvulsant diphenylhydantoin had no inhibitory effect on HACU in doses up to 80 mg/kg when the animals were killed 30 min. postinjection. Thus it appears that the effect of inhibiting HACU may not be common to all anticonvulsant drugs.

In order to characterize further the relationship between anticonvulsant activity of a drug and its ability to depress HACU we plan to correlate the potencies of the drugs as anticonvulsants and as inhibitors of HACU. We also hope to examine interactions of the anticonvulsants with convulsants (e.g., pentylenetetrazole) which can themselves stimulate HACU. It may be that some anticonvulsants may have no effect on HACU unless it is already elevated. (Supported by DA-00796).

184.4 EFFECT OF EXOGENOUS ATP ON $\Delta\Psi$ AND ΔpH IN ISOLATED, CHOLINERGIC SYNAPTIC VESICLES. J.Suszkiw and M. O'Leary Dept. Physiology, Univ. of Cincinnati Medical School Cincinnati, OH 45267

Highly purified (>1500 nmol ATP/mg protein) synaptic vesicles, isolated from the electromotor nerve terminals of Torpedo marmorata, were incubated (30 min,15°) in media consisting of 187.5 mM KSCN,37.5 mM NaCl, 137 mM Lys.Cl,3 mM $MgCl_2$, 0.1 mM $CaCl_2$, 75 mM sucrose and 5 mM HEPES buffer,pH 7.2.

$\Delta\Psi$ and ΔpH were estimated from the distribution of [^{3}H] Ch and [^{14}C]methylamine, respectively, as previously described (J. Suszkiw, in Cholinergic Mechanisms, G. Pepeu and H. Ladinsky, eds. p. 313, Plenum Press, 1981).

In the absence of exogenous ATP, the Ch_{in}/Ch_{out} ratio was 7.7, in agreement with previously determined distribution of [^{3}H]MTPP. Addition of 3 mM ATP to the incubation medium doubled the Ch_{in}/Ch_{out} ratio to 15, indicating hyperpolarization of vesicles from approx. -50 to -68 mV. The effect of exogenous ATP on vesicle membrane potential was observed only in synaptic vesicles that had been previously exposed to Na^+; it was not seen in vesicles that had been isolated in Na^+-free media, and was abolished at 0°. These results provide first demonstration that the vesicle-associated Mg^{+2}-ATPase (1.8 µmol ATP hydrolyzed/30 min./mg protein) may be involved in an electrogenic dissipation of ΔNa^+ (in>out) imposed across vesicle membrane.

The vesicles also accumulate [^{14}C]methylamine. In the absence of ATP the $[^{14}C]MA_{in}/[^{14}C]MA_{out}$ ratio was ∿4; this ratio increased only slightly in the presence of 3mM ATP ($[^{14}C]MA_{in}/[^{14}C]MA_{out}$=5). The corresponding, calculated ΔpHs are 0.6 and 0.7 units, acidic interior. These results indicate that, unlike the Mg^{+2}-ATPase in the catecholaminergic vesicles, the vesicular ATPase does not appear to be involved in the generation of a substantial electrochemical proton gradient in cholinergic synaptic vesicles.

184.5 CHOLINE EXPOSURE AUGMENTS SUBSEQUENT LOW-AFFINITY CHOLINE ACCUMULATION OF CULTURED HUMAN SKIN FIBROBLASTS. Robert Rybczynski* and Donald Kay Riker, (SPON: W.F. Riker, Jr.) Depts. of Human Genetics and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

In 1981 we reported high-affinity choline accumulation in cultured human skin fibroblasts, defined by an apparent K_T of 3-5μM, hemicholinium-3 sensitivity, and Na^+-dependence (Riker et al, J Neurochem 36:746). We had explored choline concentrations between 0.125-6μM to minimize contributions of low-affinity systems. Extension of this range has now demonstrated both "high" and "low" -affinity components. Further, we report a selective effect of choline, present during the growth phase, on subsequent choline-accumulation kinetics.

Human skin fibroblasts from one of 8 donor lines were plated in 60mm plates in DMEM/5% fetal-calf serum and grown to confluency (7-9 days). Choline, if added, was introduced 24 hrs after plating (final conc.=2mM). All plates were refed 48 hrs before assay. Just prior to assay cells were preincubated (x2) and washed (x4) to remove exogenous choline. Temperature-dependent ^{3}H-choline accumulation was assessed during a 4-min incubation (37° vs. 1°) at choline concentrations of 0.25-35μM. Incubation was stopped with 1° buffer washes (x3), and intracellular tritium counted after lysing cells in 0.6N NaOH.

We constructed Scatchard plots (v vs. v/s) and used Rosenthal's graphic method (Anal Biochem 20:525, 1967) to derive two K_T's and V_{max}'s from curved plots. Plots were curvilinear 60% and linear 40% of the time. Curved plots yielded K_T's of 0.6±0.1SEM and 56±8μM and V_{max}'s of 14.3±1.5SEM and 473±56 pmoles/mg pro/4 min (N=9). These K_T's are similar to those of synaptosomes. Linear plots gave intermediate values (K_T=23.2±6.0; V_{max}= 351±49; N=6). Theoretical argument demonstrates that linear results can be explained by low-affinity "masking" of the high-affinity component. Given the resolution of Scatchard-Rosenthal methods, we conclude that two classes of choline transport, though not always visible, exist in cultured fibroblasts.

By exposing cells to 2mM choline during their growth phase the low-affinity V_{max} increased 327% (473±56 to 2020±116) pmoles/mg pro/4 min), while its affinity decreased 139% (K_T: 56 to 134±62μM). In contrast, the carrier-mediated, high-affinity process did not react to this treatment. At choline concentrations estimated in the extracellular space (4-16μM) such a change would produce an 86-105% increase in the rate of low-affinity choline transport. Thus, previous exposure to choline has the potential to augment its subsequent accumulation by the low-affinity process only.--Supported by the Dystonia Medical Research Foundation, Beverly Hills, CA.

184.6 REGIONAL AND SUBCELLULAR DISTRIBUTION OF ACETYLCHOLINESTERASE ISOENZYMES IN RAT BRAIN. D.M. Maxwell*, D.E. Lenz*, I.J. Dembure* and C.A. Broomfield* (SPON: B. Hackley, Jr.). US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010.

Recently, we reported that rat cerebral acetylcholinesterase (AChE) exists in four molecular forms distinguished by differences in their pI values and in vivo rates of inhibition by soman, an irreversible inhibitor of AChE (Biochem. Pharmacol., 30:1369, 1981). Since AChE exists in close association with several subcellular components of both muscarinic and nicotinic cholinoreceptors, we undertook to determine whether distribution of these four AChE isoenzymes was related to cholinoreceptor environment or subcellular distribution. The ratio of muscarinic to nicotinic cholinoreceptors in several regions of rat brain were measured using ^{3}H-QNB and ^{125}I-a-bungarotoxin, respectively. The ratio of muscarinic to nicotinic cholinoreceptors in the rat brain regions were: caudate, 67:1, cerebral cortex, 22:1, hippocampus, 15:1, cerebellum, 15:1, midbrain, 9:1, and brain stem, 6:1. In spite of these regional differences in the population of cholinoreceptors associated with the AChE enzyme, there was no significant difference in the relative amount of the four isoenzymes in these regions. Since muscarinic cholinoreceptors predominate in the rat brain we also examined the isoenzyme pattern of AChE from electric eel, which contains purely nicotinic cholinoreceptors, and found the same isoenzyme pattern as that observed in each of the rat brain regions. Thus, association with different cholinoreceptor environments does not appear to influence the isoenzyme pattern of AChE. However, differences in the isoenzyme pattern were observed in rat brain AChE from different subcellular locations. Synaptosomal AChE was enriched in isoenzymes with high pI values when compared to microsomal AChE. This observation may explain why AChE isoenzymes with high pI values are inhibited in vivo more rapidly by soman than AChE isoenzymes with low pI values.

184.7 HALOTHANE ACTION ON ACETYLCHOLINE SYNETHESIS IN RAT BRAIN SYNAPTOSOMES, G.V.W. Johnson and C.R. Hartzell*. Research Department, The Alfred I. duPont Institute of the Nemours Foundation, Wilmington, DE 19899.

Cholinergic nerve terminals require choline and acetyl-CoA as precursors for acetylcholine synthesis. Choline is actively transported into the axonic terminals, while acetyl-CoA is produced directly from pyruvate by the action of pyruvate dehydrogenase (PDH) in the mitochondria. As a part of the overall study of neurotransmitter synthesis and the effects of inhalation anaesthetics, we report the effects of halothane on acetyl-CoA levels and choline acetyltransferase and PDH activities in the synaptosomes. Synaptosomes were isolated from rat cerebra, purified by centrifugation through a discontinuous Ficoll gradient and maintained in an isosmotic salt solution. Acetyl-CoA levels were measured using a radioisotopic technique. [^{14}C(U)]-oxaloacetate and citrate synthase were added to the sample and the amount of [^{14}C(U)]-citrate formed was determined (Pande & Caramancion, Anal. Biochem. 112:30, 1981). Initial concentrations of acetyl-CoA were found to be 19.5 ± 2.4 pmol/mg protein. During the first 10 minutes of incubation the acetyl-CoA levels in both control and 3% halothane-exposed synaptosomes dropped significantly to 4.5 ± 1.1 pmol/mg protein and 9.7 ± 1.7 pmol/mg protein, respectively. During the remaining 30 minutes of incubation synaptosomal acetyl-CoA levels remained elevated in the presence of 3% halothane when compared to untreated controls ($P<0.1$).

When measuring PDH activity, synaptosomes were pretreated with 0.2% digitonin to make the plasma membranes "leaky". Oxidative pyruvate metabolism was then measured using gas flow radiorespirometric techniques with (1-^{14}C)-pyruvic acid. Three percent halothane depressed PDH activity by 24%.

Choline acetyl-transferase (ChAT) was not significantly affected by halothane, nor did it change over the period of incubation. Control values for ChAT in the synaptosomes was determined to be 0.41 U/mg protein, while in the presence of 3% halothane synaptosomal ChAT activity was 0.43 U/mg protein.

Our interest is the action of halothane on acetylcholine synthesis. We demonstrated previously that halothane competitively inhibits choline uptake and depresses pyruvate metabolism. We have now shown that the depression of pyruvate metabolism is due in part to the decreased PDH activity. The observed increase of acetyl-CoA levels could be due to the decreased availability of choline. An alternate explanation includes the inhibition of NADH CoQ reductase by halothane. This effect would increase the reducing equivalents within the mitochondria thus inhibiting the citric acid cycle metabolism of acetyl-CoA. ChAT was unaffected by halothane, but this is not unexpected since it is probably a soluble enzyme.

185.1 DIETARY ASCORBIC ACID (AA): EFFECTS ON ETHANOL CONSUMPTION AND LIGAND BINDING IN GUINEA PIGS. Z.S. Dolinsky, S.L. Margoles* and E.G. Shaskan, Department of Psychiatry, University of Connecticut Health Center, Farmington, CT 06032.

Alcoholics have been shown to be deficient in AA. It is assumed that this deficiency is a result of poor nutrition concomitant with ethanol ingestion, but it is possible that low AA plays an etiological role in the development of alcoholism. Ethanol's effects are associated with changes in membrane fluidity. AA plays an important role in lipid peroxidation and has been demonstrated to attenuate the effects of ethanol.

The present study examined the influence of AA and a stressor upon ethanol consumption in adult male Hartley guinea pigs. Animals were given a two bottle choice of 10% ethanol or water, and fluid intake was measured daily for three weeks. After baseline measures, during which animals received AA supplemented chow, subjects were divided into two groups: A+ (Purina chow supplemented with 1g/kg AA) or A- (chow with no added AA). These two groups were further divided into a stress (2.5 min., 10°C. swim during the final nine days of fluid measurement) and non-stress group. Following the last day of testing, animals were sacrificed and AA levels were recorded in half brain and spleen. Since spiroperidol binding and MAO activity are membrane related phenomena, with AA and ethanol associations, these variables were also measured in corpus striatum and spleen.

The A- group was characterized by marked decreases in both spleen and brain AA relative to the A+ group. In addition, stress tended to raise the AA levels in the A+ group. There was an initial indication of an increase in ethanol consumption in the A- group relative to the A+ group: however, this increase was small and temporary. Stress in general, tended to decrease ethanol consumption. There was a positive correlation between ^{3}H-spiroperidol binding and MAO activity (tryptamine, 100μM) in the striatum of the A+ group. This was not seen in the A- group, or in spleens from either group.

Since AA deficiency only affected ethanol intake transiently, its role in mediating ethanol intake in guinea pigs is not clear. In this model system, however, the absence of a positive correlation between MAO activity and ^{3}H-spiroperidol binding in the A- group suggests that AA deficiency, secondary to ethanol intake, may alter membrane associated phenomena. This finding calls attention to the potential role which AA may play in mediating ethanol's influence on membrane function.

185.2 EFFECTS OF ETHANOL ON RAT HYPOTHALAMIC LHRH RELEASE. A STUDY UTILIZING RIA AND IMMUNOCYTOCHEMISTRY. W.L. Dees*, N.H. McArthur, P.G. Harms*, and K.L. Farr*. Dept. of Veterinary Anatomy and Dept. of Animal Science, Texas A&M Univ., College Station, TX 77843.

To further understand the mechanism of action by which ethanol (ETOH) decreases plasma luteinizing hormone (LH) levels, the effects of multiple I.P. injections of ETOH (1.0-1.5 g/kg) or saline on hypothalamic luteinizing hormone releasing hormone (LHRH) and plasma LH were evaluated in intact and castrate male rats. After injections every 4 hours for 2 days or every 6 hours for 8 days, animals were killed and their tissues processed. Some animals were decapitated, brains removed, and blocks containing the hypothalamus (with median eminence, ME) were subjected to acetic acid extraction of LHRH, and the hormone quantitated via RIA. Brains from other groups of animals were removed following cardiac perfusion of 10% phosphate buffered formalin. Blocks containing the hypothalamus with ME were post fixed in Bouin's solution and processed for immunocytochemistry (ICC) using a specific antiserum to LHRH and the peroxidase-antiperoxidase technique. The RIA data showed that in all rats studied, hypothalamic LHRH was inversely correlated with plasma LH. In response to castration, both saline and ETOH treated rats showed a decrease in hypothalamic LHRH content with a concomitant increase in plasma LH; however, the ETOH treated animals retained significantly greater concentrations of LHRH, and showed significantly lower plasma LH levels when compared to saline treated controls. Likewise, ETOH treated intact animals showed significant increases in LHRH content, with LH levels remaining significantly lower than the saline treated intact controls. Values were considered significant if $P < 0.05$. Differences visualized immunocytochemically between saline or ETOH treated intact and castrated rats were consistent with the data which we obtained using RIA. Thus, these data using the complementary techniques of RIA and ICC support the hypothesis that ETOH diminishes or possibly inhibits hypothalamic LHRH release, and hence provides an explanation for depressed plasma LH levels observed in ETOH treated intact and castrated rats.

185.3 INTRACELLULAR MEASUREMENT OF ETHANOL EFFECTS ON RAT LOCUS COERULEUS NEURONS IN A BRAIN SLICE PREPARATION. S.A. Shefner, T.H. Chiu* and E.G. Anderson. Depts. Pharmacol. and Physiol. Biophys., Univ. of Illinois College of Medicine, Chicago, IL 60680.

In vivo experiments using extracellular recording have shown that ethanol (ETOH) inhibits the firing of rat locus coeruleus (LC) neurons (Pohorecky, L.A. and Brick, J., Brain Res. 131:174, 1977). Intracellular recordings were made from rat LC neurons in a brain slice preparation during bath application of known concentrations of ETOH (10-60 mM), the concentration range found in brain during mild ETOH intoxication to sedation. Coronal slices (300μ) of rat pons containing the LC were cut on a vibratome and mounted totally submerged by artifical CSF in a small recording chamber (0.3 ml) kept at 37°C. Glass microelectrodes filled with 2 M KCl (60-100 MΩ) were used for recording.

Of 32 LC neurons (from 28 preparations) 44% were spontaneously active with firing frequencies ranging from 0.5 to 13 Hz. Bath application of ETOH (10-60 mM) inhibited the spontaneous firing in 7 of 8 neurons tested. This effect was dose-dependent both in terms of the extent of inhibition and the latency of the inhibitory effect. ETOH (10-60 mM) also caused changes in resting potential and input resistance (as measured by constant current hyperpolarizing pulses) in 15 of 16 cells. Three types of effects were noted: 1) membrane hyperpolarization (3-30 mV; n=5), 2) membrane depolarization (6-20 mV; n=5). (These effects were associated with a decrease or no change in input resistance.) 3) Biphasic responses (small transient initial depolarizations of 1-6 mV and variable changes in input resistance, followed by a prolonged hyperpolarization associated with a clear decrease in input resistance; n=5). In addition, ETOH (30 mM) was found to potentiate the effect of bath application of γ-aminobutyric acid (GABA; 0.5, 1 mM) on LC neurons (n=7). ETOH caused up to a 4-fold increase in GABA-induced depolarizations and up to a 2-fold increase in the GABA-induced reduction in input resistance.

It is possible that ETOH-induced inhibition of firing and changes in membrane potential and resistance may also be explained in terms of a GABA-mimetic effect or potentiation of tonic GABA-ergic input onto these cells. In fact, GABA (1 mM) completely inhibits spontaneous activity in LC cells (n=5). The variable membrane potential effects seen with ETOH are similar to the effects seen with GABA (n=21), in that, with KCl-filled recording electrodes GABA hyperpolarizes about 1/3 of LC neurons tested and depolarizes the remaining 2/3. This is presumably due to Cl^- leakage into the cell affecting the Cl^- equilibrium potential. GABA responses, however, are always associated with a decrease in input resistance whereas the initial transient depolarization seen with ETOH can be associated with an increase in input resistance. Secondly, GABA and ETOH applied to the same neuron do not always cause similar effects on membrane potential. These data suggest that ETOH effects on membrane potential and resistance can not be explained purely by a GABA-mimetic action, or potentiation of a tonic GABA-ergic input onto LC neurons. (Support: SAS, NIAA 7374; THC, NIAAA 2696).

185.4 CHANGES IN GAMMA-HYDROXYBUTYRIC ACID CONTENT IN THE LIVER AND BRAIN OF ETHANOL DEPENDENT RATS. F. Poldrugo* and O. C. Snead, Department of Pharmacology, Pediatrics and The Neuroscience Program, University of Alabama in Birmingham School of Medicine, Birmingham, Alabama 35233.

γ-hydroxybutyric acid (GHB) is a metabolite of γ-aminobutyric acid (GABA) and occurs naturally in brain. This compound has a number of diverse neurophysiologic and neuropharmacologic properties (Snead, Life Sci. 201, 1935, 1977). A marked increase of GHB in liver and brain has been reported to occur with single high dose administration of ethanol (Roth, Biochem. Pharmacol. 19:3013, 1970). However, there are no data concerning the effect of ethanol on liver and brain GHB. The object of these experiments was to examine the liver and brain content of GHB in an animal model of ethanol dependence.

Rats were allowed free access to a liquid diet containing either ethanol or isocaloric sucrose. After 1, 2, 4, 6, and 10 hours and in the morning of the first, second, fourth, sixth, and tenth day, the animals were decapitated and the GHB content of liver and brain determined by electron capture gas liquid chromatography. Blood ethanol was determined concomitantly by head space chromatography.

The GHB content of liver increased within the first hour of initiation of ethanol administration. This increase was significant (27.4 vs. 17.8 mM/gm. tissue; $p<.05$) in animals in which the blood ethanol level was greater than 60 mg/100 ml at the moment of sacrifice. At 8 a.m. of the first, second, fourth and tenth day of ethanol tolerance, the GHB liver content was still higher than control (17.9 vs. 5.7 mM/gm tissue $p<.01$).

While there were striking changes in the ethanol addicted animals in terms of liver concentration of GHB, there was very little change in concentration of GHB in brain in alcoholic rats. These data suggest that different mechanisms may be operative in GHB metabolism in the periphery vs. that in brain in ethanol dependent rats.

185.5 EFFECTS OF ACUTE ETHANOL TREATMENT ON RAT BRAIN OPIATE-PEPTIDE SYSTEMS. Scott N. Deyo, Joseph Rogers, William J. Shoemaker, Steven J. Henriksen, and Floyd E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute La Jolla, CA 92037.

Studies in our laboratory indicated a possible involvement of endogenous opioid systems in the acute effects of low doses of ethanol (ETOH). In a behavioral paradigm, naloxone reversed an ETOH-induced increase in the rate of punished responding (Koob et al., Subst.Alc.Act.Mis.1:447, 1980). ETOH also produces changes in hippocampal electrographic activity similar to that observed with low icv doses of β-endorphin (Henriksen et al., PNAS 75:5221, 1978). Subsequently, we have studied the neurochemical effects of ETOH on central opiate-peptide systems in the rat. An initial experiment demonstrated that ETOH induced a decrease in hypothalamic leu-enkephalin immunoreactivity (leu-enk-IR) two hours after administration. The effect on the leu-enk-IR was directly related to the blood ethanol concentration; however, there was no effect of ETOH on hypothalamic β-endorphin content. The following studies were, therefore, conducted with in vitro ETOH treatment (20, 40 and 100 mM) on the release of leu-enk-IR from rat globus pallidus slices. The lowest concentration (20mM) failed to produce a significant effect on leu-enk-IR release, but 40 mM ETOH produced a significant ($p<.025$; ∿ 30%) increase in K^+-stimulated, Ca^{+2}-dependent leu-enk-IR release. 100 mM ETOH produced an elevation of non-stimulated Ca^{+2}-dependent release of the peptide, and an inhibition of K^+-stimulated, Ca^{+2}-dependent leu-enk$_{IR}$ release. We observed a similar effect of the highest concentrations of ETOH on dopamine release from striatal synaptosomes. Interestingly, the effects of both concentrations of ETOH disappeared when ETOH was removed from the release buffers indicating these effects to be rapidly reversible.

Binding studies examining the effects of acute, in vitro ETOH on [^{3}H]-[D-Ala^2, D-Leu^5]-enkephalin (DADLE) saturation curves demonstrated no effect on the binding constants for DADLE in either the absence or presence of 10^{-4}M 5'-guanylyl imidodiphosphate, a stable GTP analog.

In conclusion our studies support the idea that ETOH in low to moderate (intoxicating) concentrations might act to increase the activity of enkephalin systems by increasing the rate of release of the peptide. (Supported by Grants NIDA 01785, NIAAA 03504 and NIAAA 07273.)

185.6 EFFECTS OF CHRONIC ETHANOL TREATMENT ON THE COUPLING OF CNS MUSCARINIC RECEPTORS AND PHOSPHOLIPID METABOLISM OF C57/BL MICE. Thomas L. Smith. Dept of Pharmacol., University of Arizona and Veterans Administration Medical Center., Tucson, Az. 85723

The disposition of CNS acetylcholine is known to be affected by both acute and chronic ethanol (E) administration. The purpose of the present work was to determine the effects of E treatment on CNS muscarinic receptors and their linkage to phospholipid metabolism. Adult male C57/BL6 mice were given a liquid diet containing 7% E (v/v) for eight days. This treatment has been previously demonstrated to produce functional tolerance and physical dependence. Chronic E treatment resulted in a significant increase (15%) in maximal specific binding of the muscarinic antagonist, ^{3}H-QNB, to isolated cholinergically enriched synaptosomes. No change in K_D was observed. These results are in agreement with a previous report (Life Sci 25:2173, 1979). In synaptosomes of untreated mice, muscarinic receptor activation by carbamylcholine enhances the in vitro incorporation of ^{32}P into phosphatidylinositol (PhI) and phosphatidic acid (PhA) by two fold. Chronic E treatment did not result in a corresponding increase in basal or carbamylcholine stimulated ^{32}P incorporation into these lipids. E given in vitro (300mM) reduced basal incorporation of ^{32}P into PhI and PhA of controls by c.a. 20%, while reducing carbamylcholine stimulated labeling of PhA by more than 30%. Synaptosomes from mice chronically treated with E were more resistant to the inhibitory effects of in vitro E on muscarinic enhanced PhA labeling. These results suggest that increased muscarinic receptor density after Chronic E treatment does not necessarily elicit a supersensitive muscarinic response. (supported by Veterans Administration Alcohol Research Grant).

185.7 ETHANOL AND K+ CONDUCTANCE: ENHANCEMENT OF THE AFTERHYPERPOLARIZATIONS (AHPs) FOLLOWING ACTION POTENTIALS OR DEPOLARIZATIONS EVOKED WITH AMINO ACIDS AND EFFECTS OF K+ AND Na+ CHANNEL BLOCKERS. P.L. Carlen, N. Gurevich*, E. Puil. Addiction Research Foundation Clinical Institute, Departments of Medicine, Physiology, Institute of Medical Science and Playfair Neuroscience Unit, Toronto Western Hospital, University of Toronto, and Departments of Anaesthesia and Pharmacology, Faculty of Medicine, University of British Columbia, Vancouver, B.C., Canada.

The AHPs following glutamate-evoked depolarizations of spinal and hippocampal neurons have been attributed to an electrogenic Na+-pump. A Ca^{2+}-activated K^+-conductance (Ca-gK) has been shown to be responsible for the slow AHPs which follow spikes in both types of neurons, and recently has been suggested to account for the AHP which follows the depolarization of hippocampal CA1 neurons with glutamate. We have attempted to resolve these conflicting explanations by examining the effects of low Ca-conditions (0 Ca^{2+} and 2.4 mM Mn^{2+}) and of ethanol (10mM), which increases Ca-gK following the post-spike AHP, probably by raising intracellular free Ca++. Ethanol also augments post-amino acid AHPs of hippocampal neurons in in vitro slices of guinea pig brain. The depolarizations elicited with aspartate or glutamate applied extracellularly by pressure ejection usually were not associated with large changes in membrane conductance (G_m); G_m tended to decrease with aspartate and increase with glutamate. Recovery from glutamate-depolarization was characterized by a conspicuous increase in G_m. Perfusion with low (Ca^{2+})-solution did not prevent the emergence of AHPs following such depolarizations in most cases, but completely blocked the post-spike slow AHPs and synaptic transmission. AHPs which followed aspartate- or glutamate-depolarizations were sometimes reduced by low (Ca^2) perfusion. Ethanol increased the amplitude and duration of AHPs following depolarizations evoked with the amino acids in either normal- or low-(Ca^{2+})-perfusion. These data suggest that (1) both a Ca-gK and an electrogenic Na-pump may be responsible for the AHPs following depolarizations evoked with aspartate or glutamate, and (2) ethanol increases both types of AHPs possibly through raising intracellular free Ca^{2+} thereby activating a gK. Indeed, the movement of Ca^{2+} into neurons may not be requisite for the activation of a K^+-conductance in the case of post-amino acid AHPs.

The following Na+ and K+ channel blockers were used in an attempt to block ethanol effects: perfused TTX, intracellularly injected QX222 (a local anaesthetic) and intracellularly injected cesium. Ethanol-induced increase of hyperpolarization, conductance increase and post-spike longlasting AHP all persisted.

185.8 ALCOHOL PRODUCES ACUTE AND CHRONIC CHANGES IN NEURAL ALPHA-ADRENERGIC RECEPTORS. Michael E. Charness*, Adrienne S. Gordon and Ivan Diamond. Dept. of Neurology, Univ. of California, San Francisco, CA 94143.

Alcohol produces many effects on neural cell membranes. We have investigated the consequences of this interaction on neuroreceptors in NG108-15, a murine neuroblastoma x glioma hybrid cell line. Opiate (ORB) and alpha-adrenergic receptor binding (ARB) in whole cells was assayed by rapid filtration using ^{3}H-met-enkephalinamide and ^{3}H-Rauwolscine respectively. ETOH added acutely to cells decreased ARB by 40% in 100 mM and 90% in 600 mM ETOH. ORB decreased 20% in 100 mM and 70% in 600 mM ETOH. In order to search for tolerance to ETOH, cells were grown 4-6 days in the presence (chronic) or absence of 200 mM ETOH. ARB increased 2.6 + 0.6 fold in chronic ETOH cells compared to controls. ORB increased less consistently. Acute addition of ETOH to cells grown chronically in alcohol had less effect on ARB than in control cells. ORB sensitivity to ETOH was unaffected by chronic ETOH. Thus, while acute ETOH strikingly reduced ARB in NG108-15, chronic ETOH produced compensatory increases in ARB with tolerance to the acute effects of ETOH. This model system will be of value in studying the development of alcohol tolerance in neural cells.

185.9 MICROCOMPUTER-ASSISTED OPEN FIELD OBSERVATIONS OF ADULT MALE RATS TREATED WITH ETHANOL ON POSTNATAL DAYS 1-8. T.Sonderegger, S. Berney-Key*, J. Ritchie*, V. Tumblin*,J. Flowers*, and E. Zimmermann. Dept. of Psychol., U. Nebraska-Lincoln, Lincoln, NE. 68588:Dept. Anat., BRI, UCLA, Los Angeles,CA.90024

Few studies have examined effects of ethanol upon the postnatal rat although the central nervous system is still developing during this period. In the study reported here, known quantites of ethanol were administered directly to rat pups by intragastric intubation. Ethanol was in a 30% Sustagen (Mead Johnson) vehicle to counteract malnutrition effects. (This administration procedure has been shown to produce high levels of blood alcohol as long as four hours later.)

Eight litters of Charles Rivers CD albino rats were adjusted to litter sizes of 10 on Day 1 and pups randomly assigned to treatment groups: ethanol (E), Sustagen (S) or handled (H). Tapered doses, increasing to 4 g/kg on Days 4 and 5, were given twice daily to E pups; S pups received comparable volumes of isocaloric (sucrose) Sustagen and H pups were handled. On Day 4, E pups ceased to gain weight; one H pup of each sex from each litter was removed and placed with a nonlactating female until bodyweights matched littermate E animals. These animals were designated as Pair Underfed (PU) controls. Five other litters were used as unhandled (U) controls. Animals were weaned on Day 21 and housed in same-sexed pairs. Only data from male animals are reported.

Mortality was low (4/80). Both E and PU animals had lower body weights on Day 8 but otherwise group mean body weights did not differ (through Day 150). On Day 120, approximately, open field measures (5-min trials on 4 days during the dark cycle) were recorded directly on two microcomputers using programs for real time observations. These programs permitted timing of onset of events, summation of event times, frequency records of specific behaviors, records of episode sequences, and summation of episode times. Computer obtained activity data correlated well with similar data obtained by traditional methods.

E animals were less active (total squares entered) than other groups ($p<.05$) and exhibited longer start latencies ($p<.03$) than other groups. Activity levels of all groups decreased over days ($p<.01$). Various computer-timed and summated measures also discriminated among some groups. Computer-assisted recording procedures provide a finer focus on the subtle behavioral differences produced by treatment of the developing rat with relatively low doses of ethanol early in life and may prove valuable in assessments of effects of drug exposure in the developing organism.

185.10 EFFECT OF MICROINJECTION OF ETHANOL ON TRIGEMINAL MOTONEURONS IN THE CHRONIC CAT. A. Baranyi* and M.H. Chase. Depts. of Physiology and Anatomy and the Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024.

Systemically injected ethanol has been shown to exert a variety of different neuronal effects which depend upon the dose administered and the response recorded. It depresses somatic reflexes of the spinal cord but facilitates spinal GABA-ergic and cholinergic synapses. Neither the influence of the animals' behavioral states nor that of anesthetic agents have been controlled for in these investigations; in addition, the specific responses that were examined have not been studied in isolation from the indirect effects elicited by the systemic route of administration. Accordingly, to attend to these problems we applied ethanol juxta- and intracellularly while recording from trigeminal motoneurons in chronic cats during the behavioral states of sleep and wakefulness. Five chronic cats were implanted with electrodes to monitor EMG, EEG and EOG activity and to stimulate the mesencephalic Vth nucleus (Mes V) and masseter nerve. Chronic intracellular paradigms (Chase et al., J. Neurophysiol., 44:349-358, 1980) were used to record 26 motoneurons during wakefulness, quiet sleep and active sleep. Ethanol (50-150 picoliters of 0.5-2.5M solutions) was injected into and next to the recorded cell by pressure via a combined multibarrel electrode. Extracellular ethanol injection in 17 neurons induced the following qualitatively different dose-dependent responses. (1) Small doses of 0.5-1M ethanol induced a reversible decrease in firing activity (for 1-2 minutes) and a 10-30% reduction in the orthodromic and antidromic spike amplitude. The peak latency of Mes V EPSPs increased, while their amplitudes and decay time were attenuated. No changes in membrane potential or resistance were observed. (2) Increased doses (1-2M) caused, in addition, membrane hyperpolarization of 3-8 mV preceded by a short depolarizing phase. The membrane resistance decreased during hyperpolarization and the synaptic and action potentials were suppressed. (3) Large doses of ethanol (2.5M) induced a transient excitation which ended in a depolarizing block of neuronal activity. Intracellular injection of 2.5M ethanol in 9 neurons caused a reversible (for 0.5-1 minute) depolarization together with an attenuation in the spike and EPSP amplitude. The cellular effect of microinjected ethanol on trigeminal motoneurons was found to be state-independent. We conclude that ethanol induces a relatively specific inhibition of Na-activation which was characteristic of all doses and which was revealed with both juxta- and intracellular routes of injection. On the other hand, the hyperpolarizing action of ethanol is likely due to different mechanisms, possibly those involving changes in membrane receptor activity.

185.11 ETHANOL INCREASES THE FIRING RATE OF DOPAMINERGIC NEURONS G.P. Mereu* and G.L. Gessa*, Institute of Pharmacology, University of Cagliari, 09100 Cagliari, Italy.

The effect of the acute administration of ethanol on the electrical activity of dopaminergic neurons in the substantia nigra, pars compacta (SN-DA neurons) was studied in unanesthetized paralyzed rats using the microelectrode single unit recording technique. Ethanol, injected via femoral vein in doses from 0.1 to 8.0 g/kg, produced a biphasic effect. In doses ranging from 0.5 to 2.0 g/kg, it produced a dose-related increase (from 25 to 90%) in the firing rate, an effect which began approximately 30 to 60 sec after treatment and persisted for 10 to 120 min (in proportion to the dose). During ethanol stimulation, the firing pattern was characterized by a progressive increase in long "trains" discharge with decreased amplitude and increased duration of the action potential. On the contrary, high doses of ethanol (over 3.5 g/kg) inhibited the dopaminergic activity until the complete suppression of cell discharge at doses of about 6.0 g/kg. Gradual recovery from inhibition began 5 to 30 min after treatment in proportion to the ethanol dose. The stimulant effect of ethanol was readily reversed by the subsequent injection of apomorphine (20 ug/kg), while the inhibitory response to high doses was not antagonized by haloperidol in doses up to 1.0 mg/kg. Neither response was modified by intravenous naloxone up to a dose of 5 mg/kg. Our findings support the hypothesis that the alterations of dopaminergic activity might play an important role in ethanol intoxication.

186.1 PARTIAL PURIFICATION AND CHARACTERIZATION OF DOPAMINE RECEPTORS FROM RAT STRIATUM. J.Y. Lew* and M. Goldstein. Department of Psychiatry, New York Univ. Med. Center, New York, N.Y. 10016.

The present study was undertaken to purify and to characterize soluble dopamine (DA) receptors from rat striatal membranes. The DA receptors were solubilized by using the detergent CHAPS (Lew, J.Y. and Goldstein, M., Eur. J. Pharmacol., 72:403, 1981). The membrane-bound DA receptor was solubilized with 10 mM CHAPS and subsequently centrifuged at 100,000 x g. The supernatant was applied to a lectin wheat germ (WGA) agarose column (0.8x8.0 cm). The unbound proteins were removed by washing the column with 20 ml of Tris HCl buffer, pH 7.0 containing 2 mM CHAPS. The receptor was eluted with 20 ml of 0.1 M N-acetylglucosamine. The binding of ^{3}H-spiroperidol (^{3}H-Spi) to the partially purified solubilized DA receptor is displaced by nanomolar concentrations of (+) butaclamol and haloperidol, but not by (-) butaclamol. In some experiments, the solubilized DA receptor was pre-labelled with ^{3}H-Spi and subsequently adsorbed on WGA-agarose column. The ^{3}H-Spi prelabelled receptor was eluted from the column with N-acetylglucosamine. The results of this study indicate that the striatal DA receptor is a glycoprotein which probably contains N-acetylglucosamine. The adsorption of the ^{3}H-Spi labelled receptor on WGA-agarose column suggests that neuroleptics bind to a different site of the receptor than the lectin. Studies are now in progress to further characterize the partially purified DA receptor. Supported by NINDS 06801 and NIMH 02717.

186.2 SULPIRIDE INHIBITS DA-STIMULATED ADENYLATE CYCLASE ACTIVITY IN STRIATUM FROM SEXUALLY IMMATURE AND CASTRATED MALE RATS. M. Gnegy, G. Treisman* and A. Bernabei*, Dept. Pharmacology, Univ. Mich. Med. Sch., Ann Arbor, MI 48109.

Sulpiride (SPD), a substituted benzamide antipsychotic drug, is considered a selective antagonist at dopamine (DA) D-2 receptors because it does not inhibit DA-stimulated adenylate cyclase (DA-AC) activity. We found that SPD can block DA-AC activity in rat striatum from sexually immature (S-IMM) or adult male castrated (CAS-M) rats. Chronic treatment with SPD (20 mg/kg i.p. 2 x's daily, 15 d) resulted in supersensitivity of DA-AC activity in Ka (K_a^{app}) for DA was decreased 4-fold in the SPD-treated rats while the apparent Vmax (V_{max}^{app}) remained unchanged. There was no change in DA-AC after chronic SPD in adult or SHAM groups. Kinetic constants for DA-AC in SHAM, S-IMM and CAS-M groups are given below (Ka in μM; Vmax in pmol/min/mg protein):

	VEHICLE[a]		SPD	
	K_a^{app}	V_{max}^{app}	K_a^{app}	V_{max}^{app}
SHAM	1.4 ± 0.4	111 ± 12	1.6 ± 0.3	86 ± 11
S-IMM	4.7 ± 1	152 ± 20	1.1 ± 0.2*	110 ± 9
CAS-M	3.6 ± 0.8	137 ± 30	1.0 ± 0.3*	104 ± 21

[a] N = 5 for all groups; value is ± S.E.M. *P<0.02 as compared to VEHICLE control.

Basal and GTP-stimulated AC was not changed in any group after chronic SPD.

In in vitro studies we found that SPD at nM levels could inhibit the ability of low concentrations of DA to stimulate AC activity in striatal particulate fractions from S-IMM, CAS-M or adult ovariectomized female (CAS-F) rats. SPD did not affect basal, GTP or stimulation in S-IMM and CAS-M striatum, as did haloperidol and fluphenazine. The Ki's for SPD were very close to the reported inhibiting DA-AC from S-IMM, CAS-M and CAS-F rat striatum are 15 nM, 21 nM and 8 nM, respectively. The inhibition by SPD may be general for D-2 drugs because metoclopramide also inhibited DA-AC in striatum from CAS-M and CAS-F rats but not SHAM controls. These results suggest that sex hormones play a role in determining the pharmacological profile of DA receptors in rat striatum. The effects seem to be activational since they can be blocked by castrating adult rats. Supported by MH 36044-01.

186.3 SOLUBILIZATION OF A GUANINE NUCLEOTIDE SENSITIVE FORM OF THE D-2 DOPAMINE RECEPTOR FROM BRAIN REQUIRES AGONIST OCCUPANCY. Tan Creese and S.E. Leff. Dept. of Neurosciences, Univ. of California, San Diego, Sch. of Medicine, La Jolla, CA 92093.

The binding of the dopaminergic antagonist ^{3}H-spiperone and the agonist ^{3}H-dopamine has been partially characterized in both intact canine caudate membranes and digitonin-solubilized extracts. Soluble ^{3}H-spiperone binding sites (K_d~1nM) demonstrate a drug specificity comparable to the D-2 dopamine receptor previously characterized in rat and calf striatal membranes. Agonist competition for ^{3}H-spiprone binding in membranes shows that dopamine is potent (IC_{50}~3μM) and the curve is shallow (n_H 0.5). Furthermore, dopaminergic agonists' affinities are decreased in the presence of 0.1mM GTP. However, agonist competition for ^{3}H-spiperone binding in solubilized preparations is not GTP sensitive and reveals only low affinity binding characteristics (IC_{50} 10μM), n_H 1.0 for dopamine). Detergent treatment of caudate membranes after prior incubation with dopamine releases binding sites whose agonist affinity, determined by ^{3}H-spiperone competition, is guanine nucleotide sensitive. Additionally, specific high affinity ^{3}H-dopamine binding in the solubilized preparation is demonstrated only when membranes are prelabeled with ^{3}H-dopamine. GTP increases the dissociation rate of ^{3}H-dopamine from such prelabeled binding sites. These results indicate that the preservation of a guanine nucleotide sensitive form of the D-2 receptor after digitonin solubilization is dependent upon the presence of an agonist-receptor (A R) complex at the time of solubilization. Supported by PHS MH32990.

186.4 EFFECTS OF DURATION AND RATE OF STIMULATION ON THE NEGATIVE FEEDBACK REGULATION OF DOPAMINE RELEASE. L.X. Cubeddu* and I.S. Hoffmann*. (SPON: W.E. Stumpf). Div. Clin. Pharmacol., Univ. of North Carolina, Chapel Hill, N.C. 27514. Dept. Pharmacol., UCV, Apdo N. Granada, 40109, Caracas, Venezuela.

The present study was designed to study the operational characteristics of the feedback loop for regulation of dopamine (DA) secretion, in striatal dopaminergic neurons. Rabbit neostriatal tissue slices were incubated with ^{3}H-DA (0.3μM, 30 min) and then superfused at 1ml/min with physiological solution (pH 7.4, 37°C). Slices were stimulated twice (S_1 and S_2) with electrical pulses (12V, 1ms) at 60 and 125 min of perfusion. Drugs were added 15 min prior to S_2 and continued throughout the experiment. The increase in ^{3}H-overflow evoked by stimulation was expressed as % of tissue ^{3}H. Transmitter overflow was totally inhibited by reducing by 1/10 the Ca^{++} concentration of the perfusion fluid. Although transmitter overflow showed an increase with greater number of pulses (30-360 pulses), flat frequency-release curves (0.1-10Hz) were obtained for the striatal dopaminergic neurons. Haloperidol (0.03-0.3μM) and sulpiride (1μM) enhanced ^{3}H-overflow without affecting its metabolism or time course. Maximal enhancement of release by both neuroleptics was seen with short trains (30-60 pulses) and high frequencies of stimulation (3-10Hz). These drugs had negligible effects at lower rates (0.1-1Hz) or longer trains of stimulation (360 pulses). Therefore, the slope of the frequency-release curve was markedly increased by DA antagonists ($P<0.001$). Apomorphine inhibited transmitter overflow in a concentration-dependent manner (0.01-1μM). However, the inhibitory effect of apomorphine was markedly reduced at high rates of stimulation (10Hz). Haloperidol and sulpiride antagonized the inhibitory effects of apomorphine on transmitter release. These results indicate that activation of presynaptic DA-receptors, and thus facilitation of release by DA-antagonists is highly dependent on the rate and duration of stimulation of striatal dopaminergic terminals. In these neurons the feedback loop seems to act physiologically to depress the slope of the frequency-release curve.

186.5 PRESYNAPTIC REGULATION OF ENDOGENOUS DOPAMINE RELEASE FROM RAT STRIATAL SYNAPTOSOMES. Jiang, D.-H., Wagner, H.R., Yablonskaya-Alter*, E., Reches, A., Fahn, S., Department of Neurology, College of Physicians & Surgeons, Columbia University, New York, NY 10032.

Brain synaptosomes release neurotransmitters under depolarizing conditions. We have used high pressure liquid chromatography (HPLC) and electrochemical detectors (EC) to measure the release of endogenous dopamine (DA) from rat striatal synaptosomes. A crude synaptosomal pellet (P2) was prepared by established methods. The final pellet was resuspended in oxygenated Krebs buffer containing 10^{-4}M pargyline and preincubated at 37°C/10 min. Additional buffers were added to a final volume of 200 ul (protein conc.=1 mg/ml) and the incubation was continued an additional 10 min unless otherwise specified. The incubation was stopped by centrifugation and the supernatant was assayed for DA using HPLC with EC detection. Calcium (Ca^{++})-dependent DA release was concentration-dependent in the presence of increasing concentrations of K^+. Release was constant above 55 mM K^+ with a maximum release level of 181.0 pmols DA/mg protein. Half-maximal DA release occurred at 25 mM K^+. Release in the presence of 25 mM K^+ was biphasic with an early rapid phase (<30 sec) and a slower and larger second phase. Equilibrium conditions occurred within 10 min and remained stable for at least 10 additional minutes. Release in the presence of 25 mM K^+ was enhanced by the dopamine antagonist, haloperidol (10^{-5}M). Apomorphine, a dopamine agonist, partially (35%) inhibited release at high concentrations (10^{-5}M). Pergolide, an ergot derivative with DA agonist properties, did not affect release. This system appears to provide an in vitro means of studying the presynaptic regulation of striatal DA release.

186.6 EFFECTS OF KETANSERIN (R 41 468) AND PIRENPERONE (R 47 465), TWO NOVEL ANTAGONISTS OF THE $5HT_2$ SEROTONERGIC RECEPTOR, ON PROLACTIN SECRETION IN MALE RATS. M. Simonovic, G. A. Gudelsky and H.Y. Meltzer. Dept. of Psychiatry, University of Chicago Pritzker School of Medicine, Chicago, IL. 60637.

In vitro binding studies have demonstrated that ketanserin (KET) and pirenperone (PIR) possess high affinity for the serotonin ($5HT)_2$ receptor (Ki = 2.1 nM for both compounds) and no appreciable affinity for the $5HT_1$ receptor. The affinity of PIR for the dopamine (DA) receptor is relatively high (Ki = 15.8 nM) compared to that of KET (Ki = 220 nM). Biochemical and behavioral studies suggest that these two compounds are selective $5HT_2$ antagonists.

Rat prolactin (PRL) secretion is under tonic dopaminergic inhibition mediated by pituitary DA receptors. Hence, drugs known to interfere with dopaminergic transmission cause increased release of this hormone. Rat PRL secretion can also be stimulated by 5HT or 5HT agonists acting on central, probably hypothalamic, 5HT receptors. The pharmacology of these receptors is still obscure.

KET (1 - 10 mg/kg, i.p.) had no effect on resting serum PRL levels in male rats. In addition, KET (0.5 - 5 mg/kg, ip) did not block the stimulation of PRL secretion by the 5HT precursor, 5-hydroxytryptophan (100 mg/kg, ip) or by the 5HT agonist, 5-methoxy-N,N-dimethyltryptamine (5 mg/kg, ip). In contrast, PIR (0.001 - 10 mg/kg, ip) produced a rapid and sustained rise in serum PRL levels. The effect of PIR on PRL secretion was dose-related between 0.001 and 0.1 mg/kg (half-maximal effect was produced by 0.01 mg/kg); doses greater than 0.1 mg/kg had no further effect on serum PRL levels. The PRL-releasing effect of PIR (0.1 mg/kg, ip) was completely antagonized by two DA agonists, apomorphine (0.25 mg/kg, sc) and d-LSD (0.05 mg/kg, ip), while the pretreatment with 5HT antagonists, cinanserin (10 mg/kg, ip), cyptoheptadine (5 mg/kg, ip) KET (5 mg/kg, ip) or pizotifen (5 mg/kg, ip) had no effect. In addition, PIR (10^{-6} M) completely blocked the inhibitory effect of DA (10^{-6} M) on PRL release by pituitary glands in vitro.

The inability of KET to block serotonergic stimulation of PRL release does not rule out a $5HT_2$-mediated mechanism, as this compound is excluded by the blood-brain barrier. Its inability either to stimulate or to inhibit PRL secretion in vivo suggests that the interaction of KET with pituitary DA receptors is negligible. On the other hand, the stimulation of PRL secretion by PIR is probably due to its ability to block pituitary DA receptors. This conclusion is consistent with the high affinity of PIR for DA receptors and is further supported by our finding that it blocks the effect of DA on PRL secretion in vitro. However, a possible interaction of PIR with alpha adrenergic and histaminergic receptors should also be considered. (Supported, in part, by USPHS MH 30039).

186.7 **EFFECTS OF NA-ASCORBATE ON ^{3}H-ADTN BINDING.**
P. Hartig*, P. Sheth*, S. Finch* and D. Black*
(Spon: M. Larrabee), Department of Biology, The Johns Hopkins University, Baltimore, MD 21218.

Conflicting reports have appeared on the effect of ascorbate on the binding of DA agonists. We have confirmed that low (μM) levels of ascorbate cause large increases in the total binding of ^{3}H-ADTN to bovine caudate or rat striatal membranes prepared and assayed by the method of Kaayulp and Neff (Life Sciences 26, 1837 (80)). In contrast, ^{3}H-ADTN binding is not increased at low ascorbate concentrations when a P2 membrane preparation from bovine or rat brain is used. TLC analysis shows that high levels (mM) of ascorbate protect ADTN from oxidation during the binding assay but low levels (μM) do not. In the presence of low levels of ascorbate, the membrane preparations provide varying degrees of partial protection against oxidation. Using the Kaayulp and Neff membrane sample, ^{3}H-ADTN binding at high ascorbate levels shows the properties expected for dopamine receptor sites while at low ascorbate levels, dopamine agonists show reduced affinities for ^{3}H-ADTN binding sites and dopamine antagonists are very weak competitors.

These results show that different membrane preparation and assay methods play an important role in the effect of ascorbate on ^{3}H-ADTN binding. The enhanced ^{3}H-ADTN binding seen at low ascorbate levels in certain preparations is correlated with an increased oxidation of ADTN under these conditions. Dopamine agonists and antagonists display reduced affinities for this enhanced ^{3}H-ADTN binding.

(Supported by USPHS grant MH 36877 and NSF grant BNS 8108080)

186.8 ESTROGEN SENSITIVE DOPAMINE RECEPTORS IN RAT BRAIN: LOCALIZATION AND DISTRIBUTION. Robert E. Hruska and Karen T. Pitman*. Dept. Biochemical Pharmacology, School of Pharmacy, SUNY, Buffalo, NY and Neurotoxicology Section, NINCDS, NIH, Bethesda, MD.

Estrogen may have two separate and distinct effects. The first is a rapid effect and is measured as a decrease in dopamine (DA) function. This could be mediated through other neurotransmitter systems, but does not appear to involve the DA receptors labelled by ^{3}H-spiperone. The second effect develops slowly, may require pharmacological doses of estrogen, may require prolactin, and is measured as an increase in striatal DA receptor density. Our experiments only address the second effect of estrogen.

We have shown previously that estrogen treatment increases the density of striatal DA receptors. We have now localized this response and isolated it to one population of striatal neurons. Adult, male rats were injected with 17β-estradiol valerate in sesame oil(125 μg/rat, s.c., 6 days prior). The DA receptors labelled by ^{3}H-spiperone were measured in striatum, N. accumbens, cortex, hippocampus, and pituitary. Only the DA receptors in the striatum were increased in density after estrogen treatment. Those in the N. accumbens were not altered. In the cortex two sites were labelled and neither the DA site or the second site were changed by estrogen treatment. The DA receptors in the hippocampus were decreased in density. The number of DA receptors in the whole pituitary was not altered, but the pituitary was increased in weight and protein content. Expression of the results on a wet weight or protein basis made it appear that there was a decrease in density. Since the pituitary is still hypertrophied 6 days after estrogen treatment, we propose that the increase in striatal DA receptor density is the result of continuous exposure to estrogen. This argues against a withdrawal phenomena.

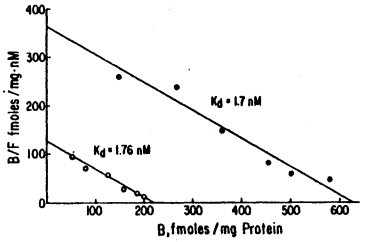
The striatal DA receptors, increased in density by estrogen treatment, belong to one population. Striatal injection of kainic acid destroys the neuronal cells originating in the striatum, but does not affect those originating outside the striatum. The unilateral injection of kainic acid decreased the density of the striatal DA receptors by about 30%. While estrogen treatment increased the density of the striatal DA receptors in the intact striatum by about 20%, it did not alter the density in the kainic acid lesioned striatum (i.e. the density remained decreased by 30%). The estrogen sensitive DA receptors are located on neurons originating in the striatum. This localization of DA receptors is similar to that found after haloperidol treatment and further supports our hypothesis that at least part of the effects of estrogen and haloperidol may be mediated similarly through an increase in prolactin levels. These results further demonstrate the specific response of striatal DA receptors to estrogen treatment. (Supported in part by RDF from Res. Fdn. of SUNY).

186.9 PREINCUBATION WITH DOPAMINE REVERSES THE DECREASE IN D-3 BINDING INDUCED BY 6-HYDROXYDOPAMINE OR RESERPINE BUT NOT BY KAINIC ACID. B.I. Schweitzer * and N. G. Bacopoulos. Departments of Pharmacology and Psychiatry, Dartmouth Medical School, Hanover, NH 03755.

The number of stereospecific binding sites (Bmax) of 3H-dopamine (3H-DA) and 3H-apomorphine (3H-APO) was reduced by 50-60% 4 or 20 hr after reserpine (4.0 mg/kg im) or six days after the intrastriatal injection of 30 ug 6-hydroxydopamine (6-OHDA). Both treatments lowered endogenous DA by 95% or more. In addition to lowering the Bmax, the depleting agents also lowered the equilibrium dissociation constant (Kd) to 47% (3H-DA) or 65% (3H-APO) of control. Preincubation of homogenates of depleted or lesioned striata with added DA at 37 degrees C for 30 min, restored the binding parameters of 3H-DA to control values and reversed the change in the Bmax of 3H-APO. The ED50 of this effect of DA was 50 nM, and it was mimicked by catecholamines but not by serotonin.

The intrastriatal injection of kainic acid (2.5 ug) also lowered the Bmax of 3H-agonists by 60-70% without changing the Kd or DA content. Preincubation of homogenates of kainic acid-lesioned striata (endogenous DA = 355 nM) did not reverse the decrease in Bmax. We conclude that the changes in D-3 receptors induced by 6-OHDA are due to a reversible change in receptor conformation rather than a permanent loss. In contrast the destruction of intrinsic striatal neurons by kainic acid produced an irreversible loss of receptors. These results explain the discrepancy between previous reports (Nature 274:278, 1978; European J. Pharmacol. 56: 277, 1979) and suggest that dopaminergic 3H-agonist receptors are located on neurons postsynaptic to the nigrostriatal projection. The concept that DA stimulates stereospecific 3H-agonist binding to subsequently washed membranes of rat brain, which we proposed (Life Sciences, 29:2407, 1981) is supported by evidence recently reported by another laboratory (Life Sciences, 30:1587, 1982). Supported by research grant MH33958.

FIGURE 1



Rats were sacrificed 6 days after kainic acid lesion and 3H-DA binding was measured as described previously (Life Sciences, 29: 2407, 1981). Empty circles lesioned striatum; filled circles: contralateral control side. Kd is the slope of the Scatchard plot.

186.10 PROPERTIES OF D-2 RECEPTORS LABELLED BY (^{3}H)BUTYROPHENONES IN HOMOGENATES OF RAT BRAIN. P.M. Beart*, D.J. de Vries*, H.W. Rzeczniczak* and A.L. Gundlach* (SPON: I. Darian-Smith). University of Melbourne, Clinical Pharmacology and Therapeutics Unit, Austin Hospital, Heidelberg, Victoria 3084, Australia.

Although (^{3}H)spiperone is a ligand for neuroleptic receptors, a major problem in accepting (^{3}H)spiperone binding as an association to dopamine receptors has been the low potency of dopaminergic agonists in displacing the binding. Recent evidence suggests that (^{3}H)spiperone binds to multiple sites (Beart, Trends Pharmacol. Sci. 3, 100-102, 1982), and this study investigated the properties of these binding sites in dopaminergic regions of rat brain.

Sprague-Dawley rats (150-300 g) were used and the corpus striatum, nucleus accumbens septi (NAS) and tissue enriched in the ventral tegmental area (VTA) were dissected from freshly removed brains. Membranes were prepared by homogenisation, centrifugation and washing, and used for binding studies. Specific (^{3}H)spiperone binding was stereospecific, rapid, saturable, reversible and showed no cooperativity in all regions studied. Saturation data (non-specific binding defined with 1 µM spiperone or 10 µM cis-flupenthixol) were more consistent with a two site model with the binding consisting of high and low affinity components, although in VTA resolution was difficult due to the low density of binding sites. In striatum and NAS the apparent K_D values for the high affinity sites were 93 ± 32 pM and 74 ± 30 pM respectively, while those for the low affinity sites were 4.0 ± 0.5 nM and 4.1 ± 0.8 nM respectively. Sites of high affinity represented 25, 15 and 5% of binding in the striatum, NAS and VTA respectively. The results of dissociation experiments in all three regions were also better described by a two component model.

The high affinity sites had properties consistent with a D-2 receptor. Drug displacement studies employing 25-50 pM (^{3}H)spiperone yielded K_i values for dopaminergic antagonists of 0.1-80 nM, while agonists had K_i values in the range 5-200 nM. Ergots and sulpiride were potent displacers of binding, while SKF 38393 (D-1 agonist) had a K_i of 13 µM. (^{3}H)Domperidone gave similar results, but bound less tightly to the high affinity site (K_D 0.2 nM).

Guanine nucleotides (100 µM) modulated (^{3}H)spiperone binding and produced 2-fold decreases in the affinity of apomorphine, ADTN, pergolide and lergotrile for the high affinity (D-2, defined with 5 µM (±)sulpiride) site. Hill coefficients were unchanged, as were the K_D and B_{max} values. GTP and guanylylimidodiphosphate failed to alter the interaction of haloperidol, sulpiride and bromocryptine. Manganese (1 mM) also did not modify the actions of the latter three drugs, whereas the affinity of the agonists was increased. Supported by National Health & Medical Research Council , Australia.

186.11 IN VITRO DOPAMINE RECEPTOR MODIFICATION BY AMANTADINE. R.M. Allen. Psychiatric Clinical Research Laboratory, Veterans Administration Medical Center, Dallas, Texas 75216.

Amantadine has been shown to prevent neuroleptic induced DA receptor hypersensitivity (Allen et al, Eur. J. Pharmacology, 65:313-315, 1980) and to have direct effects on both agonist and antagonist ligand binding (Allen, Soc. for Neurosci. Abstr., 1981). Bacapoulus (Life Science, 29:2407-2414) has demonstrated in vitro DA binding site plasticity with ^{3}HDA but not ^{3}H spiperone binding. In this study fresh dog striata were homongenized in 100 vol. Tris salt with .01% ascorbate and 1mM EDTA buffer, pH 7.4, preincubated for 10 min at 37° C, washed X 2 at 20,000g and resuspended in 50 volumes buffer. Inhibitions curve using 200pM spiperone as the ligand and apomorphine in concentrations ranging from 5nM to 10 µM were performed. The assays were performed with the above buffer, incubated at 22° C for 20 minutes, and rapidly filtered and washed 3 times with Tris Hcl pH 7.0, and counted on a Searle Mark II liquid scintillation counter. Apo above produced 3 definite inhibition points at 125nM, 235nM and 2500nM. The addition of 5nM amantadine abolished the very high and low affinity points and yielded an IC_{50} value [defined by 10^{-5} (+) Butaclamol] of 260nM. The finding of an intermediate but relatively high affinity site would suggest the presence of a D_4-like site with similar affinities for both agonist and antagonist ligands. Amantadine appears to modify DA receptor sites to a D_4-like configuration. Implications of this finding in the clinical activity of amantadine as well as alternative interpretations of the data will be discussed.

186.12 FOREBRAIN DOPAMINE RECEPTORS ARE LATERALIZED AND MODULATED BY ELECTRICAL SELF-STIMULATION OF VENTRAL TEGMENTUM IN RAT. Linda H. Schneider, Edgar E. Coons* and Randall B. Murphy, Departments of Psychology and Chemistry, New York University, New York 10003.

In rats, each implanted with an electrode in the left-side A10 cell region, we used [^{3}H]-spiroperidol (0.6nM) binding to examine and compare the effects of electrical stimulation on dopamine receptor levels in the ipsilateral and contralateral A10 terminal zones (specifically, olfactory tubercle assayed together with nucleus accumbens = OT/NA). As a within-subject control, we also examined dopamine receptor binding in the ipsilateral and contralateral striatum. Three different groups of rats were employed: unimplanted controls (N = 12), implanted but unstimulated controls (N = 19), and stimulated animals (N = 22). Binding was examined using standard filter binding techniques applied to individual sides of the individual rats' dopamine terminal zones.

We observed the unexpected result that in unimplanted animals levels of binding were significantly ($p < .01$) greater in left than in right striatum. An opposite (right > left) hemispheric difference in binding was observed in OT/NA but failed to reach significance. In the implanted but unstimulated rats a significant ($p < .002$) difference in the same direction as in the unimplanted rats' OT/NA data was evident; however, the striatal (left > right) hemispheric differences observed in the unimplanted controls were now reduced below significance. In the stimulated rats (which were sacrificed 90 minutes after the second of two electrical self-stimulation sessions) a reversal from control patterns in OT/NA dopamine receptor binding was observed and was found to be highly significant ($p < .002$) with respect to the implanted but unstimulated rats. Neither implantation nor stimulation resulted in significant side-to-side differences in striatal binding in contrast to differences seen in the unimplanted control group. We conclude that the binding effects observed after electrical stimulation arise as a direct result of this treatment because the left-right pattern of OT/NA dopamine binding was reversed in a separate study in which the electrical stimulation was delivered to the right A10 region instead of the left.

These data suggest that in studies of the ascending dopamine systems it is insufficient to utilize as a control the dopamine terminal zones contralateral to a treatment. The data also support the concept that mechanisms of interhemispheric receptor regulation exist in the rat.

186.13 AFFINITY CHROMATOGRAPHY OF THE NEUROLEPTIC DOPAMINE RECEPTOR. L. Antonian*, D.I. Schuster and R.B. Murphy. Dept. of Chemistry, New York University, New York, N.Y. 10003.

An affinity chromatography matrix has been devolped for extensive purification of the canine dopamine receptor. A haloperidol derivative, haloperidol hemisuccinate, has been specially synthesized as the ligand for attachment to the affinity support via a hydrophilic spacer arm. Experiments were performed on the affinity gel as well as on control gels. Batch experiments with a control gel showed 35-69% adsorption of the neuroleptic receptor, whereas batch experiments with the haloperidol affinity gel demonstrated adsorption of 85-100% of the solubilized dopamine receptor. The receptors are assayed by specific binding of [^{3}H]spiroperidol.

Chromatography of the solubilized dopamine receptor on the control gel resulted in the elution of two distinct protein fractions. Only one of the protein fractions showed specific binding of [^{3}H] spiroperidol which also represented a 2-4 fold purification of the neuroleptic receptor. Purification of the neuroleptic/dopamine receptor on the haloperidol affinity gel also yielded a protein profile similar to that of the control gel, yet the neuroleptic receptor remained adsorbed on the column. Conditions for specific elution of the neuroleptic receptor from the affinity support are under investigation.

186.14 DOPAMINE RECEPTORS ON HUMAN PARATHYROID GLANDS AND PARATHORMONE SECRETION AFTER DOPAMINERGIC DRUGS. I.N. Ferrier*, C.A. Bloxham* and A.J. Cross. Division of Psychiatry, Clinical Research Centre, Harrow, Middlesex, U.K., HA1 3UJ.

Dopamine (DA) receptors have been described on bovine parathyroid glands and, in view of their mediation of DA stimulated adenylate cyclase, are held to be D1 receptors. It has been shown that DA stimulates parathormone(PTH) secretion in cattle both in vitro and in vivo. The present study was undertaken in an attempt to determine if D1 receptors are present in human parathyroids and if PTH secretion responded to DAergic drugs.

Parathyroid glands were obtained at autopsy and were stored at -40 °C. Ligand binding assays contained crude membrane fractions and were incubated at 37 °C with 0.25 nM ^{3}H-piflutixol (^{3}H-PF). Specific binding was defined as that displaced by 10 µM (+) butaclamol. Saturation analysis revealed that the specific binding of ^{3}H-PF was saturable and was consistent with a single class of binding site (K_D = 0.32 nM, Bmax = 240 fmol/mg protein). By contrast no displaceable ^{3}H-spiperone binding was evident. The order of drug potency in inhibiting ^{3}H-PF binding to human parathyroids (IC_{50} domperidone >> DA > bromocriptine >> apomorphine (APO) >> haloperidol >> cis-flupenthixol (FLUP)) is similar to that in human brain.

PTH and prolactin (PRL) were measured by RIA (PTH antiserum C-terminal directed (residues 34-84)) in serum samples from 15 normal controls before and at 15 minute intervals after the administration of APO (0.75 mg s.c.), FLUP (3 mg p.o) or metaclopramide (MCP: 10 mg i.v.) and from 7 acute schizophrenic patients before and at weekly intervals after FLUP (3-8 mg/day p.o.). Rapid and sustained elevations of PRL after FLUP and MCP and suppression after APO, but no significant changes in PTH after any drug regimen, were observed.

These results suggest that while D1 binding sites are present on human parathyroids, the measurement of PTH after the administration of DAergic drugs is unlikely to provide a test of D1 receptor function in man.

187.1 AGONIST-SPECIFIC CHANGES IN THE PROPERTIES OF β-ADRENERGIC RECEPTORS ON INTACT S49 LYMPHOMA CELLS. E. E. Reynolds*, D. R. Hoyer*, and P. B. Molinoff. Dept. of Pharmacology, Univ. of Pennsylvania, Philadelphia, PA 19104.

The binding of (^{125}I)-iodopindolol (IPIN) to β-adrenergic receptors was characterized in intact S49 lymphoma cells maintained in suspension culture. Binding was stereospecific, saturable, reversible, and stable for up to 90 minutes at 37° C. The binding of IPIN reached equilibrium rapidly, allowing quantitation of receptor properties after short periods of incubation. Experiments were carried out in which cells were incubated with IPIN and various concentrations of competing drugs. The affinity of the receptor for isoproterenol changed from a K_D of less than 1 μM after a 1 minute incubation to a K_D of 20-50 μM measured at equilibrium after a 30 minute incubation. This time-dependent shift in affinity was agonist-specific in that similar effects were not observed in studies of the interactions of antagonists with receptors on intact S49 cells. In kinetic experiments in which inhibition of the binding of IPIN was studied, 5 μM isoproterenol inhibited almost all of the binding of IPIN at early time points (1-2 min.), but had very little effect at equilibrium (30 min.). In addition, IPIN binding reached equilibrium more rapidly in the presence of isoproterenol, suggesting that an agonist-induced increase in the affinity of the receptors for antagonists occurs. Studies of agonist inhibition curves of IPIN binding, as carried out in intact cells, were analyzed by non-linear regression analysis. A highly significant improvement of the fit was observed when the data was modeled for two affinity states of agonist-receptor complex rather than one state. The results are consistent with the hypothesis that the properties of some but not all of the receptors were affected by the presence of isoproterenol. These observations with regard to the properties of β-adrenergic receptors on intact S49 cells are generally similar to those previously observed in studies of adrenergic receptors on intact L6 muscle cells (J. Cyc. Nuc. Res., 6: 421, 1980). However, time-dependent shifts in agonist affinity were only seen when L6 cells were attached to the surface of the incubation dish and not after they had been detached from the dish. In contrast, S49 cells exhibit this effect both in suspension and when attached to poly-L-lysine coated dishes. Furthermore, agonists cause all of the receptors on L6 cells to shift to a form with a low affinity for agonists. In studies with S49 cells two forms of the receptor were seen when assays were carried out in the presence of an agonist. Studies of the properties of β-adrenergic receptors on intact cells suggest that there are important regulatory mechanisms that are seen only in intact cells and are lost upon homogenization of the cells. IPIN appears to be a useful ligand to study these phenomena because it allows precise quantitation of changes in receptor properties at short incubation times. S49 cells provide a potentially useful system with which to study these effects because it is possible to perform similar studies in S49 variants which either lack the guanine nucleotide binding regulatory protein (G/F) or in which the receptor and G/F are uncoupled. (Supported by the USPHS NS 18479).

187.2 ALPHA$_2$ ADRENERGIC ACTIVITY IN THE INTACT HUMAN PLATELET: RELATIONSHIP BETWEEN RECEPTOR BINDING AND INHIBITION OF ADENYLATE CYCLASE. R.H. Lenox, J. Ellis*, D. VanRiper*, Y.H. Ehrlich. Dept. Psychiatry Univ. Vermont College of Medicine, Burlington, VT 05405.

The alpha (α) adrenergic receptor of the human platelet possesses pharmacological characteristics consistent with an α_2 subtype, mediating inhibition of prostaglandin-stimulated adenylate cyclase (AC). Our laboratory has established assay conditions for the characterization of concentration dependent norepinephrine (NE) inhibition of prostacyclin (PGI_2) stimulated AC in intact human platelets prelabeled with ^{3}H adenine (Lenox et. al Neurosci. Abst. 6: 252, 1980). We have shown that NE acts as a full agonist inhibiting 85% of the PGI_2-stimulated AC activity at saturating concentrations, whereas clonidine (CL) acts as a partial agonist, maximally inhibiting only 35% of the same activity. Yohimbine (YOH) will completely reverse both NE and CL inhibition of AC activity, while CL only partially reverses NE inhibition (back to the 35% level).

We have investigated the relationship between binding characteristics of the α_2 radioligands and the inhibition of AC activity produced by these ligands in the intact cell. Since the properties of agonist binding have been shown to be extremely sensitive to ions and nucleotides, and characteristics of receptor binding in membranes vs intact cells can differ considerably, our binding assays have been conducted under the same conditions employed in the cyclase assays. Saturation of ^{3}H YOH (80-90 Ci/mmol) binding in intact platelets under these conditions followed single site kinetics (K_D 4.24 ± .25nM and Bmax 134 ± 15 sites/platelet). The occupancy of NE, E and CL was inferred from the concentration dependent inhibition of ^{3}H YOH binding carried out in parallel with concentration dependent inhibition of PGI_2 stimulated AC.

	Binding K_I (μM) ± SEM	Cyclase EC_{50} (μM) ± SEM	Ratio K_I/EC_{50}
NE	19.0 ± 5.3	0.65 ± .05	29.2
E	5.2 ± 1.0	0.24 ± .08	21.7
CL	0.24 ± .04	0.20 ± .04	1.2

The comparable affinities of CL in both assay systems stands in contrast to the relative affinities for NE and E, and is consistent with its pharmacological role as a partial agonist. We have initiated a series of investigations to address the relatively lower affinity observed for NE and E in the receptor binding assays. Preliminary experiments have indicated that NE inhibition of AC activity can remain effectively intact following a preincubation with the irreversible antagonist phenoxybenzamine which significantly reduces the specific binding of ^{3}H YOH. These data will be discussed in light of current concepts related to proposed multiple affinity states of the α_2 receptor and the possibility of spare receptors in the intact human platelet. Supported in part by PHS 5429-18-3 and Upjohn Company.

187.3 EFFECTS OF COMBINED ADMINISTRATION OF IMIPRAMINE AND CHLORPROMAZINE ON BETA-ADRENORECEPTORS IN RAT CEREBRAL CORTEX. M. Mikuni and H.Y. Meltzer. Dept. of Psychiat., Univ. of Chicago Pritzker School of Medicine, Chicago, IL. 60637

It has been well established that a variety of antidepressant drugs cause down regulation of β-adrenergic receptors in the rat brain, leading to the hypothesis that the therapeutic effects of these drugs may be related, in part, to their ability to decrease central β-adrenergic receptor sensitivity. There is also extensive clinical evidence that combined administration of antidepressant and neuroleptic drugs is necessary and sufficient pharmacotherapy for patients with delusional depression who fail to respond to either drug alone. In this study, we investigated the effects of combined administration of imipramine and chlorpromazine on β-adrenergic receptors in rat cerebral cortex.

Adult male Sprague-Dawley rats (200 g) were treated with either imipramine (Imip) (10 mg/kg, ip) or chlorpromazine (CPZ) (5 mg/kg, ip) or both, twice daily for 14 days. Control animals received the same volume of saline. All animals were sacrificed by decapitation 22 hrs after the last injection. The brains were immediately removed, dissected and frozen. Membranes of cerebral cortex were prepared as described previously in 50 mM Tris buffer (Bylund and Snyder, 1976). Incubation of membrane preparation (5 mg original wet weight) with ^{3}H-DHA (0.1-4.0 nM) was carried out in a final volume of 1.0 ml for 30 min at 25°C; specific binding was defined by 100 μM (-)-isoproterenol. Imip alone and Imip plus CPZ reduced the number of β-adrenergic receptor binding sites in the cerebral cortex (35%) as compared to saline controls, but there was no significant change in Bmax or K_D after treatment with CPZ alone.

These results indicate that there is no interaction between CPZ and Imip with regard to down regulation of β-adrenergic receptors. It is possible that the greater efficacy of the continuation of these two agents clinically represents the combination of their independent effects upon beta-adrenergic and dopamine receptors. Investigation of the effect of the combined treatment on α_2 and 5-HT_2 receptors are in progress since imipramine alone has been reported to decrease the number of these receptors in brain.

187.4 ^{3}H-RAUWOLSCINE AND ^{3}H-PARA-AMINOCLONIDINE: AUTORADIOGRAPHIC ANALYSIS OF THE DISTRIBUTION OF ALPHA-2 BINDING SITES LABELED WITH ANTAGONISTS OR AGONISTS. J.R. Unnerstall, T.A. Kopajtic* and M.J. Kuhar. Dept. Neurosci., Johns Hopkins Univ. Balto., MD 21205

^{3}H-Clonidine and ^{3}H-para-aminoclonidine (^{3}H-PAC) have been used as agonist ligands to study alpha-2 adrenergic receptors. ^{3}H-Rauwolscine (^{3}H-RW) is presently the most specific alpha-2 antagonist ligand available, and its binding in brain homogenates has recently been characterized (Perry and U'Prichard, Eur. J. Pharmacol. 76:461, 1981). We have characterized the binding of ^{3}H-RW in intact sections of rat brain processed for light microscopic autoradiography (LMA) and have compared the distribution of binding sites labeled with ^{3}H-RW or ^{3}H-PAC.

In 50 mM K^+-PO_4 buffer containing 50 mM NaCl (pH.7.4) at room temperature, the binding of ^{3}H-RW was comparable to that described by Perry and U'Prichard (see above). However, dissociation at 4°C was biphasic and Scatchard analysis of saturation experiments revealed curvilinear plots with approximate K_D's of 1 and 6 nM for the high and low affinity components respectively. Scatchard plots of ^{3}H-PAC binding in Tris-HCl buffer (pH7.6) with the addition of 10 mM $MgCl_2$ at room temperature were also biphasic with K_D's of 0.25 and 2.5 nM. For LMA, serial coronal sections were incubated in the presence of either 3 nM ^{3}H-RW or 1 nM ^{3}H-PAC. Nonspecific binding was defined in the presence of 10 uM phentolamine. Under these conditions, 70-80% of the high-affinity sites and 25-35% of the low affinity sites will be occupied for each ligand.

In general, autoradiograms generated by these two ligands revealed similar binding site distributions in the rat brain (see Young and Kuhar, PNAS 77:1696, 1980). However, in some regions, such as the superficial lamina of CA1 of the hippocampus, the molecular and polymorphic layers of the dentate gyrus, the dorsal parabrachial nucleus and the ventro-lateral reticular formation, ^{3}H-RW binding appeared higher than that of ^{3}H-PAC. Especially striking were the high levels of ^{3}H-RW binding seen in the striatum and the substantia nigra pars compacta and lateralis which are not seen with ^{3}H-PAC.

Since saturation experiments reveal two binding sites for both ^{3}H-RW and ^{3}H-PAC and since ligand concentrations were chosen to produce comparable receptor occupancies for the multiple ^{3}H-RW and ^{3}H-PAC sites, the differences seen by LMA in the distribution of ^{3}H-RW and ^{3}H-PAC binding sites may reflect a differential selectivity of these two ligands for the two states of the alpha-2 receptor. However, these data cannot rule out the possibility that ^{3}H-RW also labels a receptor other than the alpha-2 receptor at the ligand concentrations used in these experiments. Additional work is in progress to explore these questions.

187.5 THE BINDING OF ^{3}H-WB4101 AND ^{3}H-PRAZOSIN DIFFERS IN THE HIPPOCAMPUS OF THE RAT. J.J. Valdes, J.R. Unnerstall and M.J. Kuhar. Tox. Branch-Chem. Systems Lab, Aberdeen Proving Grounds, MD and Dept. of Neurosci., Johns Hopkins Sch. Med., Balto., MD 21205

^{3}H-WB4101 (^{3}H-WB) and ^{3}H-prazosin (^{3}H-PRZ) have been used to label alpha-1 binding sites. However, several published studies have shown that PRZ is much more selective than WB as an alpha-1 ligand and antagonist. We have seen differences in the distribution of binding sites labeled with either ^{3}H-WB or ^{3}H-PRZ in the rat brain using light microscopic autoradiography (LMA). For example, ^{3}H-WB binding is high and uniform in the hippocampus and dentate gyrus. ^{3}H-PRZ binding is low in these regions. In order to study this difference, we have compared the characteristics of ^{3}H-WB and ^{3}H-PRZ binding in rat hippocampal membranes.

In preliminary experiments in rat neocortical membranes, we discovered that in 50 mM Na^+-K^+-PO_4 buffer (pH7.4) the K_D's for both ^{3}H-WB and ^{3}H-PRZ were 2-3 times lower than those seen when binding was done in 50 mM Tris-HCl buffer (pH7.4). This effect was not due to the presence of Na^+ ions, and no change in the B_{max}'s was observed. In subsequent experiments, binding was done in the PO_4 buffer at 25°C for 60 min. Tissue concentration was 1 mg wet wt per ml incubation (final volume 5 ml). Nonspecific binding was defined in the presence of 10 uM phentolamine.

In the hippocampus, ^{3}H-PRZ binding was biphasic with K_D's of 0.07 and 1.6 nM and a total B_{max} of 15 fmole/mg tis. Binding to the high-affinity site represented 30% of the total binding. ^{3}H-WB also labeled two sites: a high-affinity site with a K_D of 0.2 nM and a B_{max} of 13 fmole/mg tis. and a second site of much lower affinity and high capacity. PRZ displacement of 0.2 nM ^{3}H-WB was biphasic with a broad plateua between 1 and 100 nM PRZ. Approximately 50% of the ^{3}H-WB binding was competitively displaced by 100 nM PRZ. The binding to the low-affinity site was not affected by this concentration of PRZ.

To summarize, ^{3}H-WB appears to label two populations of binding sites in the hippocampus. The high affinity ^{3}H-WB site is displaced by PRZ with high affinity and is probably the same site labeled with high-affinity by ^{3}H-PRZ. The ^{3}H-WB site of much lower affinity is displaced by PRZ only at uM concentrations. This latter site, although pharmacologically uncharacterized, is concentrated in the hippocampus and has characteristics similar to the ^{3}H-WB site seen in the periphery. These observations can account for the difference in the density of ^{3}H-WB and ^{3}H-PRZ binding seen by LMA in this region. Further, these results support previous studies which showed that ^{3}H-WB was not a selective alpha-1 ligand and indicated that ^{3}H-WB may not be the ligand of choice in studying the alpha-1 even in the central nervous system.

187.6 IMPAIRED RECOVERY OF BRAIN β-ADRENERGIC RECEPTORS IN AGED RATS FOLLOWING DESMETHYLIMIPRAMINE-INDUCED SUBSENSITIVITY, L. H. Greenberg, D. Brunswick and B. Weiss, Dept. of Pharmacology, Med. Coll. of Pa., Phila. 19129 & Neuropsychopharmacology Unit, Vet. Admin. Hosp., Phila., PA 19104

Repeated but not acute administration of the tricyclic antidepressant desmethylimipramine (DMI) produced subsensitivity of β-adrenergic receptors in the cerebral cortices and pineal glands from young (3-mo) and aged (24-mo) rats. However, brain tissues from aged rats showed an impaired ability to increase β-receptor density in response to reduced noradrenergic input (Greenberg & Weiss, J. Pharmacol. Exp. Ther. 211:301, 1979). In the present study we compared the ability of young and old rats to restore their density of β-receptors following DMI-induced receptor subsensitivity. DMI was administered twice daily for seven days to 2 groups of young rats (2-3mo) at a dose of either 5 or 10mg/kg, i.p., and to 1 group of aged rats (20-26mo) at a dose of 5mg/kg. Control rats of each age received saline for the same time period. Rats from each group were decapitated 4 hr and 1,2,4 and 8 days after the last DMI or saline injection. [^{3}H]dihydroalprenolol (DHA) binding was determined in homogenates of pineal gland and cerebral cortex, and DMI concentrations in serum and cortex were determined by radioimmunoassay. DMI produced a significant decrease in DHA binding in both brain areas of young & aged rats 4 hr after the last dose of DMI. In young rats, DHA binding in the pineals and cortices returned to control levels by 2 days after the last dose of DMI. In contrast, in aged rats it took 4 days for DHA binding to return to control values in the cortex and more than 8 days to return to normal in the pineals. The serum concentration and half-life ($t_{\frac{1}{2}}$) of DMI in the aged rats was significantly greater than that in the young rats at both drug doses (e.g., $t_{\frac{1}{2}}$ at the 5mg/kg dose was approximately 0.5 days in the young and 1.7 days in the aged rats). Similar differences between the groups were found for the $t_{\frac{1}{2}}$'s of DMI in cortex. Although the pharmacokinetic properties of DMI were altered in the aged rats, these differences were not sufficient to account for the delayed recovery of β-receptors in aged rats. These results suggest that one must beware of the age-related alterations in the pharamcokinetic properties of CNS-acting drugs when conducting studies of these agents in the aged. The results also suggest that brain tissue from aged rats cannot recover from β-receptor subsensitivity as readily as that from young rats. If this recovery process requires the synthesis of new receptors, then this synthetic mechanism may be impaired with age. Supported by Grants NS12642 and MH30096 and funds from the Veterans Administration.

187.7 ROLE OF AMINERGIC NEURONAL INPUT IN THE DOWN-REGULATION BY DESIPRAMINE (DMI) OF THE NOREPINEPHRINE (NE) RECEPTOR COUPLED ADENYLATE CYCLASE SYSTEM IN RAT CORTEX. F. Okada*, D.H. Manier*, A.J. Janowsky*, L.R. Steranka and F. Sulser. Vanderbilt University School of Medicine, Nashville, TN 37232 and Indiana University, Gary, Indiana 46408.

Previous studies have shown that the ability of antidepressants to elicit subsensitivity of the NE sensitive adenylate cyclase system linked to a reduction in the density of β-adrenoceptors depends on an intact noradrenergic neuronal input. In the present investigations, we studied the consequences of selective lesioning of serotonergic neurons with 5,7-dihydroxytryptamine (5,7-DHT) on the down-regulation by DMI of the NE receptor coupled adenylate cyclase system in cortex from normal animals and from animals with an increased density of β-adrenoceptors (d,l-propranolol, 10 mg/kg b.i.d. for 7 to 14 days). In agreement with results obtained by Brunello et al. (In: New Vistas of Depression, S.Z. Langer, B. Briley, eds., Pergamon Press, New York, in press, 1982), DMI failed to decrease the density of β-adrenoceptors (^{3}H-dihydroalprenolol binding) in the absence of serotonergic input (B_{max} 131 ± 4 and 133 ± 25 fmol/mg protein ± SEM in control and DMI treated animals respectively). However, DMI reduced the response of the cyclic AMP generating system to the β-agonist isoproterenol (10 μM) in lesioned and control animals to the same degree (from 67 ± 11 to 39 ± 6 and from 63 ± 9 to 30 ± 5 pmol cyclic AMP/mg protein ± SEM in control and 5,7-DHT lesioned animals respectively). In animals whose β-adrenoceptor population was up-regulated by propranolol, DMI failed to reduce both the sensitivity of the system to agonists and the B_{max} value of β-adrenoceptors. In fact, both the cyclic AMP responses and the B_{max} value of ^{3}H-DHA binding were further increased by DMI. Selective lesioning with 5,7-DHT had no influence on the up-regulation of the receptor system by propranolol. Moreover, the differentiation in the effects of DMI on recognition and action function of the receptor system did not occur in lesioned animals treated with propranolol. The results provide direct evidence for a complex functional linkage between serotonergic and noradrenergic neuronal systems at the molecular level indicating that serotonergic neuronal input is co-required for the regulation of the β-adrenoceptor moiety of the receptor coupled adenylate cyclase system but not for the induction by DMI of subsensitivity to isoproterenol. Studies are now in progress to elucidate the differences in the mechanism of the regulation by DMI of β-adrenoceptors and their coupling to adenylate cyclase following lesions with 5,7-DHT in normal and propranolol treated animals. (Supported by USPHS Grant MH-29228, the Tennessee Dept. of Mental Health and Mental Retardation and the Lake County Medical Center Developmental Agency, Lake County, Indiana).

187.8 MODULATION BY SODIUM, LITHIUM AND CALCIUM OF SPECIFIC 3H-PRAZOSIN BINDING IN NEOCORTEX. T.A. Reader and R. Brière*. Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada, H3C 3T8.

The use of binding assay techniques for the study of neurotransmitter-receptor interactions has now been well established and the recent introduction of ^{3}H-labelled Prazosin (PRZ; an α_1-antagonist) has enabled the determination of some of the properties of cortical postsynaptic receptors (1-3). In the majority of these in vitro studies the buffers used were made of Tris-HCl and in some cases Mg^{++} was added (4). This saline composition is quite unlike the normal ionic environment found in the CNS. As a first approach to obtain more physiological conditions for binding experiments, we investigated the effects of Na^+ (5), Li^+ and Ca^{++}, and established the best incubation conditions for ^{3}H-PRZ binding in ionic media which reflect more accurately the brain's ionic environment. Specific ^{3}H-PRZ (0.5 nM) binding to neocortical membrane preparations increased linearly (r= 0.990) with increasing protein concentration (from 142 to 1.721 μg/ml) (3,4). This binding reached equilibrium (25°C) at 25-30 min, and was maintained up to 60 min. Half saturation (0.5 nM) was obtained in 7.5 min. After equilibrium was reached, specific binding could be displaced by PRZ or phentolamine. Saturation experiments (0.1 to 5 nM) revealed one high affinity site and from the Scatchard-Rosenthal analysis a Bmax of 120 fmol/mg protein with a KD 25°C of 0.686 nM were derived (Hill number of 0.88). Increasing the concentration of Na^+ (0-200 mM) specific binding increased (but only in the presence of 10 mM $MgCl_2$). The optimal Na^+ concentration was established at 150 mM. Similarly, the effect of Ca^{++} (in the absence of Na^+) was to increase specific binding, but only if Mg^{++} was present. The optimal concentration for the Ca^{++} effect was determined at 1.4 mM. When both Na^+ (150 mM) and Ca^{++} (1.4 mM) were added to the incubation buffer, the affinity increased (KD 25°C of 0.123 nM) without any change in Bmax (Hill N= 0.997). In the presence of Na^+ alone the KD 25°C was of 0.414 nM (Hill N= 0.920). When Na^+ was replaced by Li^+ (in Ca^{++} 0 mM) there was a ten-fold decrease in the affinity (KD 25°C= 1.1nM) without changes in Bmax. These preliminary experiments show that ^{3}H-PRZ binding assays can be performed in buffers that approach the physiological salt-composition of brain tissue and indicate the participation of ions in the complex interactions between ligands and receptor sites. 187.9 CIRCADIAN RHYTHMS IN ALPHA- AND BETA-ADRENERGIC RECEPTOR NUMBER AND CYCLIC AMP PRODUCTION IN RAT CEREBRAL CORTICAL SLICES. M.A. Benedito* and M.S. Kafka. Neuroscience Branch, NIMH, Bethesda, MD 20205.

Circadian rhythms in neurotransmitter receptors (α- and β-adrenergic, cholinergic, dopamine, opiate, and benzodiazepine) have been demonstrated in rat brain. Noradrenergic agonist binding to α- and β-adrenergic receptors in the brain stimulates the activity of an adenylate cyclase (Daly et al., J. Neurosci., 1:49-59, 1981). The stimulated synthesis of cyclic AMP (cAMP) then, can be used as a physiological measure of receptors in the membrane. Male rats were entrained for 3 wk to a controlled light-dark cycle (L:D, 12:12) and enucleated 56 hr before sacrifice to eliminate time cues from the light:dark cycle. Groups of 18 rats were sacrificed every 4 hr over a 24-hr period, brains removed, cortices dissected and sliced. Cyclic AMP was measured by the conversion of ^{3}H-ATP to ^{3}H-cAMP. Alpha- and β-receptors were measured in membranes from frozen slices by the specific binding of ^{3}H-WB4101 with and without phentolamine, and ^{3}H-dihydroalprenolol (^{3}H-DHA) with and without dl-propranolol, respectively. Alpha-adrenergic receptor binding varied during the course of the day, increasing from a trough at 6H to peak at 14H. Alpha-receptor stimulated ^{3}H-cAMP accumulation, i.e., l-norepinephrine (NE)-stimulated ^{3}H-cAMP accumulation in ^{3}H-adenine-labelled cortical slices in the presence of sufficient dl-propranolol to block the β-receptors, increased from a trough at 6H to a peak at 10H. Beta-adrenergic receptor binding peaked at 14H and 2H with a trough at 18H. Beta-receptor-stimulated ^{3}H-cAMP accumulation, i.e., NE-stimulated ^{3}H-cAMP in presence of sufficient phentolamine to block the α-receptors, peaked at 14H with a trough at 18H. Combined α- and β-receptor-stimulated cAMP accumulation, i.e., ^{3}H-cAMP accumulation induced by NE measured in the absence of antagonists, peaked at 14H and 2H with a trough at 22H. Scatchard analysis of α- and β-adrenergic receptor saturation isotherms indicated no changes in the affinity of either receptor at times of maximal and minimal binding in slices. A change in specific binding is then, a change in the number of receptors. In slices from rat cerebral cortex α- and β-adrenergic receptor number and ^{3}H-cAMP formation due to the activation of α- and β-adrenergic receptors have similar circadian rhythms. The data suggest that the circadian changes in cAMP production are a cellular response to the circadian changes in α- and β-receptor number. The circadian rhythms in α- and β-receptor number could alter neuronal activity in the brain over the course of the day.

187.10 BIOCHEMICAL AND PHYSIOLOGICAL CHARACTERIZATION OF ADRENERGIC RECEPTORS ON EMBRYONIC SENSORY NEURONS. K. Dunlap and D.R. Canfield*. Dept. of Physiology, Tufts Univ. Sch. of Med., Boston, MA 02111.

Nor-epinephrine (NE) decreases the voltage-dependent Ca current in the soma membrane of embryonic chick sensory neurons (Dunlap and Fischbach, 1981). This effect is mediated by an α-adrenergic receptor: phentolamine, but not propranolol, blocks the response to NE. The NE-induced decrease in Ca current is also blocked by yohimbine (ED_{50} = 3.2 nm) suggesting that the receptor may be classified as α_2. To begin to characterize this receptor biochemically standard filtration binding techniques were employed using ^{3}H-yohimbine (New England Nuclear). Crude membranes were prepared from embryonic chick sensory neurons grown in the absence of other cell types in dissociated cell culture. Cells were homogenized in 50 mM Tris-10 mM $MgCl_2$ buffer, centrifuged 10 min at 15,000 x g, washed once in the same buffer, repelleted and suspended in buffer at a concentration of 1-2 mg protein/ml. Membranes were incubated 10 min at 37°C with the radioactive ligand ± excess cold yohimbine and then washed in a filtering manifold with 40 ml buffer. Specific binding (that displaceable by cold yohimbine) saturated at ca. 10 nM with an apparent K_D of 2.4 nM. At the K_D specific binding was approximately 50% of total binding. Maximum specific binding ranged between 40 and 80 fmole/mg protein in membranes prepared from different platings. ^{3}H-yohimbine binding was inhibited by NE with an ID_{50} ranging between 0.5 and 1.6 μM which agrees well with the ED_{50} for the NE-induced decrease in Ca current (0.6 μM). Attempts are now being made to observe ^{3}H-yohimbine binding in whole cells to allow the use of autoradiographic techniques to determine the distribution as well as density of these α-adrenergic receptors on the cell surface.

Preliminary evidence suggests that the NE-induced decrease in Ca current may involve a second messenger. When bath applied at 1 mM, monobutyryl cAMP mimicked the effect of NE in decreasing the sensory neuron action potential duration. In addition, this compound also potentiated the magnitude of the NE response when the two were applied together. IBMX (at 1 mM) alone decreased action potential duration when bath applied. Dibutyryl cAMP, dibutyryl cGMP and monobutyryl cGMP all were ineffective (at 1 mM or 10 mM).

187.11 CATECHOLAMINE RECEPTOR AGONIST EFFECTS ON CYCLIC AMP PRODUCTION IN STRIATAL SLICES. G.G. Leblanc*, R.E. Boehme* and R.D. Ciaranello. Dept. of Psychiatry, Stanford Univ. Sch. of Med., Stanford, CA. 94305.

Cyclic AMP is thought to act as a second messanger for catecholamines in the striatum. Dopamine (DA) and norepinephrine (NE) have previously been found to stimulate cAMP production in homogenates and intact slices of rat striatum. The identity of the receptor types which mediate the stimulation remains uncertain, and is to some extent dependent on the tissue preparation used. The present studies attempt to clarify the pharmacology of catecholamine regulation of cAMP levels in striatal slices, and to examine potential interactions between different receptor types.

Male rats were sacrificed, and the striata were dissected on ice and cut into 450μ slices on a McIlwain tissue chopper. Slices were incubated in Hepes-buffered Krebs salts, pH 7.35-7.4, under 95% O_2-5% CO_2 in an agitating water bath at 35°C. After one hour of preincubation, drugs were added and the slices were incubated for an additional 10 minutes. Following extraction in boiling .01N HCl, the cAMP content of the slices were assayed by a modification of the Gilman protein binding assay.

In striatal slices, maximally effective concentrations of isoproterenol (ISO) (10 μM) and NE (300 μM) stimulated cAMP to 300 and 1200% of control levels, respectively. The response to 300 μM NE was inhibited 90% by propranolol (10μM), while phentolamine (10 μM) and cis-flupenthixol (10 μM) each inhibited the response by 50%. DA and the alpha agonist 6-fluoronorepinephrine (6FNE) had no effect on cAMP levels at concentrations up to 300 μM. However, 300 μM DA or 50 μM 6FNE potentiated the ISO response approximately two-fold. These results contrast with those obtained in comparative studies of adenylate cyclase in striatal homogenates. Both DA (30 μM) and 6FNE (100 μM) stimulated adenylate cyclase activity by 100%, while isoproterenol (30 μM) was virtually inactive.

It is difficult to determine pharmacologically whether the actions of DA and 6FNE are mediated by an alpha-adrenergic receptor, a D-1 type dopamine receptor, or both. DA and 6FNE are alike in that both agonists appear to stimulate adenylate cyclase directly in striatal homogenates. Futhermore, our results suggest that stimulation of cAMP levels in striatal slices by both DA and 6FNE require concomitant beta-receptor stimulation. Hence, alpha- and DA-receptor agonists may differ from beta agonists in the mechanism by which they increase cAMP levels in striatal slices.

187.12 MOUSE STRAIN DIFFERENCES IN CEREBRAL CORTICAL BETA-ADRENERGIC RECEPTOR SUPERSENSITIVITY. J.A. Severson, C.E. Finch, R.N. Pittman and P.B. Molinoff. Univ. So. Calif., Sch. of Med., Depts. Psych. and Physiol., Los Angeles, CA 90033, Univ. Penn., Sch. of Med., Dept. Pharmacol., Philadelphia, PA 19174.

CBA/J mice, compared to BALB/cJ mice demonstrate many differences in the nigro-striatal pathway, such as fewer nigral and striatal neurons, lower nigral and striatal tyrosine hydroxylase activity and fewer striatal dopamine (DA) receptors. Additionally, CBA/J mice do not develop striatal DA receptor supersensitivity to chronic haloperidol treatment. This study was conducted to determine if the absence of receptor supersensitivity in CBA/J mice is limited to the striatal DA receptor or if the impaired response is generalized to monoamine receptors in other brain regions.

Male CBA/J, C57BL/6J and BALB/cJ mice received systemic infusions of 10 ug propranolol/hr for 1 wk via Alzet minipumps. Mice were sacrificed the day following removal of the pump and the cerebral cortex dissected for the determination of beta-adrenergic receptor subtypes by ^{125}I-HYP binding and competition with zinterol.

Cerebral cortical ^{125}I-HYP Bmax in BALB/cJ mice was 25-30% of that in CBA/J and C57BL/6J. BALB/cJ also had the lowest proportion of the beta-1 subtype (86%) vs 90% for C57BL/6J and 94% for CBA/J. Beta-2 receptors were similar in all strains.

Propranolol increased Bmax in all strains, but CBA/J's had the smallest increase (24%). BALB/cJ mice showed a marked increase in the number of beta receptors (192%) and C57BL/6J were intermediate (42%). In all strains the increase in beta receptors was limited to the beta-1 subtype.

These data indicate that the impaired supersensitivity response in CBA/J mice is not restricted to the striatal DA receptor and suggests a genetic influence on supersensitization that may be extended to other monoamine receptors. The enhanced supersensitivity of BALB/cJ mice to propranolol suggests that the extent of responsiveness to beta blockers is under genetic influence.

187.13 AGE RELATED DIFFERENTIAL REGULATION OF RAT CORTEX ADRENERGIC RECEPTORS DUE TO INNERVATION STATUS. C. H. Wang and D. C. U'Prichard. Neuroscience Graduate Program and Dept. Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Rat fetus exposed to a potent antimitotic agent methylazoxymethanol acetate (MAM) at gestation day 15 results in frontal microencephaly and adrenergic hyperinnervation (Johnston and Coyle 1979). We examed the effects of this congenital hyperinnervation on cerebral cortical β-, α_1-, and α_2-adrenergic receptors labeled with ^{3}H-dihydroalprenolol (DHA, β), ^{3}H-prazosin (PRAZ, α_1), ^{3}H-P-aminoclonidine (PAC, α_2H), ^{3}H-yohimbine (YOH, α_2L), and ^{3}H-rauwolscine (RAUW, α_2L). Previously, we reported that decrease in Bmax of all adrenergic receptor subtypes were observed at 10-16 weeks of age compared with the age-matched normal controls. In the present study, we observed differential alterations of these receptor subtypes at 20 weeks of age. β- and α_1-R Bmax values remained decreased (-26% for DHA and -10% for PRAZ) but α_2-R showed significant rebound increase compared with age-matched controls (+30% for PAC, +52% for YOH and +23% for RAUW). This increase in α_2-R were also observed at 30 weeks of age with similar magnitudes of Bmax alteration for the three α_2-ligands. All receptor assays revealed no significant change in Kd values. Further characterization of the altered receptors using competition of ^{3}H-antagonists by unlabeled agonists showed no difference between the MAM and control groups measured at 10 or 20 weeks of age indicating no selective change in affinity of certain receptor populations.

Intraventricular 6-hydroxydopamine (6-OHDA) administration to 30 week old MAM-treated and normal control rats resulted in early decrease (-20% to -30% observed 1 week after lesion) and subsequent increase (+20% to +40% observed 4 weeks after lesion) in ^{3}H-PAC and ^{3}H-YOH Bmax values in both 6-OHDA groups. The MAM-treated cortex has apparently different α_2-receptor plasticity compared to normal cortex in that it exhibits a more modest and retarded increase in responding to the presynaptic 6-OHDA lesion. These results suggest that rat cortex adrenergic receptors undergo chronic regulation by the presynaptic NE input and may vary in their homeostatic capacity in the congenital hyperinnervated state through different ages. The decrease in α_2-R observed soon after the 6-OHDA lesion may indicate labeling of presynaptic α_2-R in rat cortex. (Supported by USPHS grant NS 15595).

187.14 ION AND NUCLEOTIDE REGULATION OF α_1 RECEPTOR BINDING IN RAT KIDNEY P. Ernsberger and D.C. U'Prichard. Neuroscience Program and Dept. of Pharmacology, Northwestern University, Chicago, IL 60610

Previous studies have shown that monovalent cations and guanine nucleotides decrease and divalent cations increase the affinity of agonists in a number of receptor systems linked to adenylate cyclase. The α_1 receptor, selectively labeled with ^{3}H-prazosin (PRAZ), is generally assumed not to be coupled to adenylate cyclase in most tissues, and thus to be insensitive to mono- and divalent cations and guanine nucleotides. In the present study, PRAZ binding was examined in the rat kidney. Renal cortex or medulla was homogenized in 50mM Tris-HCl buffer, pH 7.7, containing 5mM EDTA. The supernatent from a 300g centrifugation was pelleted twice at 50,000g in Tris-EDTA, and then washed with Tris without EDTA. The final suspension in Tris was added to tubes containing 300pM PRAZ, with and without 10μM phentolamine (phent) as a blank, or varying concentrations of competing drugs, and incubated for 30 min. at 25C° prior to rapid filtration. Results for cortex and medulla were generally similar. Norepinephrine (NE) displaced PRAZ with a K_i of 410nM and a Hill slope (n_H) of 0.55, indicating a heterogeneous interaction. 100mM NaCl increased the K_i of NE about 2-fold (226±27% of control), as well as the n_H of NE (0.83 vs. 0.55). Na also decreased the K_D of PRAZ (186 vs. 261pM), while the B_{max} was unchanged (126 vs. 136 fmol/mg protein). Li had similar effects on PRAZ binding and NE competition, while K and Cs were inactive. Na caused no effect or a slight decrease in the K_i for the antagonists phent and WB4101. The effect of Na on NE competition reaches a maximum around 10mM NaCl, while the enhancement of PRAZ binding continues to rise up to 100mM. 5mM $MgCl_2$ decreased the K_i of NE (72±13% of control), without affecting n_H. Mg also increased the K_D of PRAZ (370 vs. 261pM), with B_{max} unchanged. Na reversed the Mg effect on both PRAZ binding itself and NE competition for PRAZ sites. 100μM GTP or Gpp(NH)p, but not ATP or GMP, increased the K_i of NE (200-400% of control). However, 100μM GTP had no effect on PRAZ saturation (K_D: 237 vs. 261pM). GTP had no effect on the K_i of phent and WB4101. GTP and Na effects were not additive. In summary, mono- and divalent cations and guanine nucleotides had effects on agonist competition at rat kidney α_1 sites labeled with PRAZ similar to those previously observed at cyclase-coupled α_2 sites. Ion and nucleotide regulation of α-adrenergic receptors will be examined in the kidneys of Dahl salt-sensitive rats, which display abnormalities in receptor number as well as the response to ions in vivo. (Supported by an American Heart Assoc. grant-in-aid, and an NSF Predoctoral Fellowship to P.E.)

188.1 IMMUNOCYTOCHEMICAL LOCALIZATION OF CHOLINERGIC NEURONS WITH A MONOCLONAL ANTIBODY TO CHOLINE ACETYLTRANSFERASE. C.R. Houser, G. Crawford*, L. Anderson*, R. Barber*, P.M. Salvaterra and J.E. Vaughn. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Choline acetyltransferase (ChAT), a specific marker for cholinergic neurons, has been localized immunocytochemically with a monoclonal antibody in light and electron microscopic preparations of rat CNS. The antibody is an IgG_1 subclass immunoglobulin that selectively removes ChAT activity from solution (Crawford, G. and Salvaterra, P.M., Trans. Am. Soc. Neurochem., 13:104, 1982).

Putative cholinergic systems were studied to test the specificity of the antibody and the method. In spinal cord and brain stem motor nuclei, the somata, dendrites and axons of motoneurons were stained for ChAT. ChAT-positive puncta also were present, and EM studies indicated that some of these structures were synaptic terminals. In the septo-hippocampal system, many stained somata were observed in nuclei of the medial septum and diagonal band. ChAT-positive fibers were present in the fimbria, and presumptive axon terminals were stained throughout the hippocampal formation. They were most numerous immediately superficial and deep to strata granulosum and pyramidale. In the habenulo-interpeduncular system, ChAT-positive somata were present in the medial habenular nucleus, and numerous terminal-like structures were stained in the interpeduncular nucleus. In all of these regions, ChAT-positive structures corresponded well with previously proposed cholinergic elements. Control specimens showed no specific staining.

Studies of regions where cholinergic systems are less completely characterized revealed ChAT-positive somata in the caudate, parts of the globus pallidus and substantia innominata, and the cerebral cortex. Regions containing ChAT-positive, presumptive synaptic terminals included the caudate, thalamus, cerebral cortex and amygdala.

The results of the present study suggest that ChAT is present within the dendrites and axons as well as the somata and axon terminals of many cholinergic neurons. Moreover, ChAT-positive fibers and terminals appear to be organized differently in different regions of the CNS. In the spinal cord and hippocampus, they form patterned relationships either with distinct cell types or laminae. In other regions, such as the cerebral cortex and thalamus, they exhibit a more diffuse distribution, forming a loose network of fine, varicose fibers throughout the neuropil. Supported by USPHS Grant NS12116.

188.2 Immunocytochemical localization of choline acetyltransferase in the rat brain. D. M. Armstrong, C. B. Saper, A. I. Levey, B. H. Wainer, R. D. Terry*; (DMA & RDT) Dept. Pathology, Albert Einstein College of Medicine, Bronx, NY 10461. (AIL & BHW) Dept. Pathology, Univ. of Chicago, Chicago, Il. (CBS) Dept. Neurology, Washington Univ. Sch. Med., St. Louis, Mo.

The immunocytochemical localization of choline acetyltransferase (ChAT), used in the biosynthesis of acetylcholine, was employed to map the neuroanatomical locations of cholinergic neurons in rat brain. Antiserum was localized by the peroxidase-antiperoxidase method in 50um Vibratome sections of rat brain fixed by vascular perfusion with a mixture of cold 4% paraformaldehyde and 0.1% glutaraldehyde.

Four major cholinergic cell groups were found: (1) ChAT-labelled neurons were observed scattered throughout the neostriatum (caudate, putamen) and associated areas (nucleus accumbens, olfactory tubercle). (2) Larger ChAT-labelled neurons were seen in an extensive cell system corresponding to the magnocellular basal nucleus. This more or less continuous set of neuronal clusters included neurons of the medial septal nucleus, nucleus of the diagonal band (both horizontal and vertical limbs), magnocellular preoptic nucleus and basal nucleus of Meynert. We and others have found that these cell groups provide extensive topographically arranged projections to cerebral cortex. (3) A group of large neurons showing ChAT-immunoreactivity was seen in the caudal midbrain, extending dorsally and medially from the caudolateral edge of the substantia nigra and enveloping the superior cerebellar peduncle. This cell group was coextensive with the descending projections of the substantia nigra, and included the pedunculopontine tegmental nucleus (PPT) up to its imperceptible merging with parabrachial nucleus, as well as a population of neurons in the lateral part of the central gray matter. We have recently observed projections to many forebrain extrapyramidal structures from PPT, and direct cortical projections from PPT and the lateral central gray matter. (4) Both visceral and somatic cranial nerve neurons contained ChAT-immunoreactivity.

The results of the present study were largely consistent with earlier observations of cholinergic systems, thus confirming the specificity of the antibody. In addition, failure to detect ChAT immunoreactivity within intrinsic cortical neurons suggests that virtually all of the cortical cholinergic projections arise in the magnocellular basal nucleus and the more caudal cholinergic cell groups (PPT, lateral central gray, parabrachial nucleus) from which there are known projections to the cerebral cortex.

188.3 ULTRASTRUCTURAL OBSERVATIONS OF THE LARGE,ACETYLCHOLINESTERASE-RICH NEURON IN THE RAT STRIATUM AFTER DIISOPROPYLFLUOROPHOSPHATE TREATMENT. K. Satoh*, S. Atmadja*, W.A. Staines* and H.C. Fibiger. Div. Neurological Sciences, Univ. of British Columbia, Vancouver, B.C., V6T 1W5.

It has been proposed that the large, aspiny neurons in the striatum are cholinergic (Fibiger, Brain Res. Rev., in press). In the present study, the fine structure, including synaptic relations, of these neurons in the rat striatum was investigated. Cholinergic neurons were identified by a combination of pharmaco-histochemistry for acetylcholinesterase (AChE) and electron microscopy. Animals were injected intramuscularly with diisopropylfluorophosphate (2.0 mg/kg) 2-8 hours before perfusion with aldehydes. Vibratome sections (50-60 μm) were processed for AChE cytochemistry (Karnovsky, J. Cell Biol., 23, 1964). With light microscopic assessments, small pieces of Epon sections containing intensely stained perikarya were serially cut on an ultratome. Electron microscopic examination of the cell soma and the proximal part of its dendrites was performed by employing more than 100 serial ultrathin sections with accompanying semithin sections (0.5-1.0 μm).

Fusiform or polygonal, large cell bodies (20-30 μm) containing numerous electron dense reactive particles within the cytoplasm showed ultrastructural features that have been noted previously as being characteristic of 'giant cells' (Kemp & Powell, Phil. Trans. R. Soc. Lond. 262, 1971). They were characterized by the indented nucleus with eccentric position and also by rich cytoplasmic organelles. Reactive particles were concentrated densely in stacks of rough endoplasmic reticulum which formed a typical Nissl body in the periphery of the perikaryon. The proximal dendrite (1-2 μm in diameter) with fine reactive deposits also contained abundant cytoplasmic structures; i.e. parallelly arranged microtubules, elongated mitochondria, numerous ribosomes and rough endoplasmic reticulum. Only rarely were small protuberances observed in such dendrites.

Proximal dendrites of AChE-rich cells received many synaptic contacts with symmetric membrane thickenings. The presynaptic terminals contained small vesicles, about 45 nm in diameter. The number of vesicles varied remarkably in the different terminals. Relatively large sized terminals (1-2 μm in diameter) were filled with numerous vesicles, while smaller types (<1 μm) contained a small number of vesicles, which were mostly found near the contact membrane, as well as other cytoplasmic organelles, thus giving the terminal a paler appearance. In as few instances, large vesicles were found in the cytoplasm of presynaptic terminals.

188.4 BIOTINYLATED PROTEIN A: A SENSITIVE AND VERSATILE REAGENT FOR IMMUNOCYTOCHEMISTRY. G. Nilaver, N. Latov*, S. Ginsburg*, and E. A. Zimmerman, Depts. of Neurology and Rehabilitation Medicine, College of Physicians & Surgeons, Columbia University, New York, NY 10032.

The indirect immunoperoxidase bridge technique of Sternberger (Immunocytochemistry, 1975) is commonly used for the localization of intracellular and cell surface antigens, as well as receptors. A major limitation of this technique is that the peroxidase-antiperoxidase (PAP) complexes have to be derived from the same species as the primary antibody (i.e. rabbit PAP for rabbit antibodies). Protein A (PA) derived from Staphylococcus aureus reacts with immunoglobulin of several mammalian species, and has consequently been used in a modified PAP technique for the detection of immune complexes with primary antibodies derived from a wide variety of species (Notani et al., J. Histochem. Cytochem., 1979). Based on high affinity avidin-biotin interactions, biotin labeled second antibodies and enzymes have recently been used to form avidin-biotin complexes (ABC), resulting in highly sensitive enzyme immunohistochemical staining procedures that yield superior results when compared to the unlabeled antibody (PAP) method (Hsu et al., J. Histochem. Cytochem., 1981). In this study biotin-labeled protein A (B-PA) was substituted for the second antibody in the ABC technique, and the procedure evaluated for the immunocytochemical localization of a variety of tissue antigens, employing primary antibodies generated in different mammalian species. Lyophilized PA was biotinylated employing biotinyl-N-hydroxysuccinimide, prepared as previously described (Bayer et al., Methods Enzymol., 1979). Primary antisera generated in rabbit (to AVP), guinea pig (to insulin) and sheep (to tyrosine hydroxylase) were tested on paraffin embedded sections of rat brain, pancreas and adrenals respectively, employing the B-PA in the ABC technique. Results of staining were compared to those obtained with the conventional PAP technique as well as with peroxidase conjugated protein A. With rabbit and guinea pig primary antisera, the use of B-PA in the ABC technique resulted in high staining intensity and negligible background, with dilutions (primary antiserum) 10 to 20 fold excess of that used in the PAP technique. Antiserum raised in sheep was less reactive with PA, requiring a secondary incubation with rabbit anti-sheep IgG prior to the application of B-PA.

188.5 **^{3}H-GLYCINE-UPTAKE NEURONS IN LAMPREY SPINAL CORD.** P.H. Sheridan*, L.J. Youngs*, N.R. Krieger and M.E. Selzer (SPON: *R.P. Lisak*). *Department of Neurology, University of Pennsylvania* School of Medicine, Philadelphia, PA 19104.

As part of a study of the synaptic transmitters used by identified neurons in the lamprey central nervous system, we have mapped the neuronal uptake of ^{3}H-glycine in the spinal cords of large larval sea lampreys Petromyzon marinus. Spinal cords were removed from the animals under Tricaine anesthesia and incubated in 10^{-6}M ^{3}H-glycine for 15 minutes. They were rinsed 6 times for 5 minutes each in lamprey solution, fixed in phosphate-buffered 2% glutaraldehyde for 2 hours, and washed in phosphate buffer. They were then sectioned with a cryostat at 16μ or dehydrated, embedded in Epon, and sectioned at 1-4μ. Sections were coated with a photographic emulsion and incubated at 4° C for 1-7 days.

By sectioning horizontally, it was possible to obtain complete serial sections of up to 1.5 mm lengths of cord in 100-150 sections. The outlines of labelled cells were traced with a Nikon drawing attachment. For one Epon embedded spinal cord sectioned at 3μ, tracings were superimposed to form complete maps for 0.6-1.5 mm lengths in three representative regions of cord: rostral (gill region), caudal (dorsal fin region), and midsection. Labelled neurons were distributed throughout the central gray columns. The cells were small (5-10μ) and numbered about 24 per hemisegment. No significant differences were observed among the three regions. A similar distribution of glycine-uptake neurons was seen in recently transformed adult sea lampreys.

None of the previously identified cell types were labelled, including lateral interneurons, edge cells, giant interneurons, dorsal cells, and Müller and Mauthner axons.

NIH grants NS14837, NS14257, RR05415.

188.6 GLUTAMINASE-LIKE IMMUNOREACTIVITY IN THE HIPPOCAMPUS OF THE RAT AND GUINEA PIG, R.A. Altschuler, R.J. Wenthold, W.G. Haser*, *D.T. Monaghan, C.W. Cotman, and J. Fex*. *Lab. Neuro-otolaryngology*, N.I.H., Bethesda, MD 20205, Dept. Biochem., Univ. Pittsburg, Pittsburg, PA and Dept. Pyschobiology, Univ. of California, Irvine, CA 92717.

Studies on the auditory nerve have led us to believe that glutaminase might serve as a marker for neurons and terminals where aspartate/glutamate is used as a neurotransmitter. In this study immunocytochemical techniques with antisera raised in rabbits against phosphate dependent glutaminase from rat kidney, were used to determine the localization of glutaminase in the hippocampus of the guinea pig and rat.

The indirect immunofluorescence technique of Coons was used on cryostat sections for LM visualization and the PAP technique of Sternberger was used on free-floating vibratome sections for LM and EM visualizations. A series of rats with kainic acid or colchicine injected unilaterally into the hippocampus, or with entorhinal lesions, were also examined with immunofluorescence techniques.

In both the rat and guinea pig glutaminase-like immunoreactivity could be seen in stratum lucidum of the regio inferior. At the EM level these could be identified as mossy fiber endings. In rats receiving colchicine injections 14 days prior to perfusion the number of granule cells in the dentate gyrus was severely reduced and no immunofluorescence was seen in the stratum lucidum. Neither kainic acid injections nor entorhinal lesions significantly affected the immunoreactivity in stratum lucidum.

It has previously been suggested that the hippocampal mossy fiber pathway might use an excitatory amino acid as a transmitter. The present study lends support to aspartate or glutamate as the transmitter of this pathway.

188.7 GABATRANSAMINASE-CONTAINING NEURONS IN RAT BRAIN. T. Nagai*, P. L. McGeer and E. G. McGeer. Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

Most previous histochemical methods for GABA-transaminase (GABA-T) have failed to yield detailed information on neuronal distribution of the enzyme because of high general levels and glial localization. Previous data from our laboratory demonstrated that the technique of staining for GABA-T following suppression with an irreversible GABA-T inhibitor, such as ethanolamine-O-sulfate, will provide significant information with respect to GABA-T containing cell bodies and fibers.[1] The technique is analogous to that used for AChE localization following DFP administration which primarily reveals regenerated enzyme. Gabaculine is another irreversible GABA-T inhibitor which has the advantage over ethanolamine-O-sulfate that it crosses the blood/brain barrier. Gabaculine was administered intravenously to rats which were then sacrificed by perfusion with fixative 12 to 48 hr later. Fixed tissues were stained for GABA-T by the previously described method.[1] At a suitable post injection survival time, intense GABA-T reactivity was found in numerous cell groups. For example, positive somata and apical dendrites of cerebellar Purkinje cells were identified. In the striatum, intensely positive cells were found throughout the nucleus. Larger size intensely positive cells were observed in the globus pallidus and the substantia innominata. In the substantia nigra, many intensely positive cells were found in both the zona reticulata and pars lateralis. Positive cells were found also in the nucleus septalis lateralis, nucleus mamillaries lateralis and nucleus posterior hypothalami. Numerous small size, intensely positive cells were found in the cerebral cortex just above the corpus callosum, i.e. in the deepest layer.

188.8 QUANTITATIVE HISTOCHEMICAL MEASUREMENT OF GABA-TRANSAMINASE: METHOD FOR EVALUATION OF INTRACEREBRAL LESIONS PRODUCED BY EXCITOTOXIC AGENTS. Cornelia Sarvey*, John Stork*, Judith A. Childs*, Barbara L. Yalisove*, Ruth E. Dayhoff* and Karen Gale, Dept. of Pharmacology, and Medical Computing and Biophysics Div, Georgetown Univ. Sch. of Med. & Dent. and VAMC, Washington, DC.

GABA-transaminase (GABA-T) activity of serial fresh frozen coronal sections through rat caudate-putamen (CP) was evaluated 4-6 weeks after intrastriatal application of kainic or ibotenic acid. Thin sections (16u) were processed for GABA-T histochemistry using the method of van Gelder (J.Neurochem.12:231,'65) with minor modifications. Alternate thick sections (200u) were assayed for GABA-T activity in vitro (deBoer and Bruinvels,J.Neurochem.28:471,'77). Sections stained for GABA-T were evaluated quantitatively by computerized densitometry using image analysis.

Gross examination of CP sections stained for GABA-T revealed an obvious lack of staining in the vicinity of lesions produced by either kainate (0.5-1.0ug) or ibotenate (10-20 ug); the extent of each lesion was clearly delineated by the stain. Quantitative analysis of the stained sections revealed that the lesioned tissue contained 80-90% less GABA-T activity than control CP tissue. This loss of GABA-T was in agreement with values obtained in adjacent sections assayed in vitro for GABA-T activity. In contrast to sections stained for GABA-T, gross examination of Nissl-stained sections did not reveal obvious differences between lesioned and non-lesioned tissue. Microscopic examination of Nissl-stained sections verified the loss of neuronal perikarya in the lesioned tissue; glial cells accounted for most of the staining in these sections.

Similar studies performed in substantia nigra demonstrated that the extent of damage induced by ibotenic or kainic acid in this nucleus and the relative destruction of tissue in the overlying reticular formation could be clearly and quantitatively evaluated using the densitometric analysis of the histochemical reaction for GABA-T. Moreover, two compartments of GABA-T were readily discriminated in substantia nigra: one associated with neural perikarya, which was sensitive to kainic and ibotenic acids (70-80% of total GABA-T), and a second associated with afferent terminals arising from forebrain projections (20-30%).

Our results suggest that following destruction of neurons with kainic or ibotenic acid, GABA-T activity is largely eliminated. Under these conditions, it appears that glial cells contribute relatively little to the GABA-T activity measured either histochemically or by direct chemical assay in homogenates. Computerized densitometry of brain sections stained for GABA-T activity is therefore a useful technique for defining kainic or ibotenic acid lesions both qualitatively and quantitatively.

188.9 THE DISTRIBUTION OF SEROTONIN IMMUNOREACTIVITY IN CELL BODIES AND TERMINALS IN THE BRAINSTEM OF THE STINGRAY, DASYATIS SABINA. C.A. Livingston, T.C. Ritchie and R.B. Leonard. Marine Biomedical Institute and the Dept. of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

The distribution of serotonin-like immunoreactivity within the brainstem of the stingray, an elasmobranch fish, was determined using the unlabeled antibody-PAP technique. With this method, we observed a wide distribution of serotonergic cell bodies, fibers and terminals throughout the rhombencephalon and mesencephalon. Many of the stained cell bodies were clustered ventromedially within the raphe, but there was considerable spread along the ventral and lateral aspects of the brainstem. Many of these cells were closely opposed to the pial surface. At the spinomedullary junction the distribution of these cells resembled that seen in the stingray spinal cord, where cells were found ventral to the central canal along the midline and in the adjacent white matter. Additional cells were scattered in the ventrolateral reticular formation and within the rostral continuation of the lateral funiculus in the caudal medulla. More rostrally, but still in the caudal medulla, the ventral medial group increased to form a distinct cluster, and cells were observed in greater density laterally, forming wings extending along the lateral margins of the medulla. At levels that should correspond to the rostral medulla, the most dorsally placed cells of the lateral group appeared to form a distinct nucleus. A large area of the medial reticular formation contained labeled fibers, and a dense network of stained fibers was seen within the visceral sensory nuclei. At levels where the caudal rootlets of the vestibular and lateral line nerves enter the brainstem (pontomedullary junction) the number of cells in the ventromedial group decreased. Further rostrally, the ventromedial cells again increased in number and spread laterally along the ventral border of the brainstem. Approaching the isthmus, large numbers of labeled cells extended a considerable distance dorsally along the lateral borders of the brainstem. At these levels scattered serotonergic cells were also observed in the dorsomedial reticular formation. The raphe cells and the cells in the medial portions of the lateral extensions were embedded within a densely stained neuropil. Another dense accumulation of fiber staining and a few cells were seen at the base of the cerebellar peduncle. In the midbrain, immunoreactive cells were densely distributed in a band across the ventral tegmentum. Caudally the band extended along the lateral aspects of the brainstem. The rostral mesencephalon, unlike more caudal brainstem regions, contained large areas devoid of immunoreactive structures. It is noteworthy that few cells were seen in the periaqueductal gray of stingrays.

Supported by grants: NS16093, NS11255 and NS07185.

188.10 CELLS OF ORIGIN OF THE DESCENDING AND INTRINSIC SEROTONERGIC NEURONAL ELEMENTS IN THE SPINAL CORD OF THE STINGRAY, DASYATIS SABINA. T.C. Ritchie, B.J. Williams and R.B. Leonard. Marine Biomedical Institute and Dept. of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas.

The origin and distribution of serotonergic fibers and terminals in the spinal cord of the stingray were studied with the unlabeled antibody, PAP technique and a double labeling method which allows simultaneous visualization of retrogradely transported HRP and 5HT immunocytochemical staining (PAP) within single cells. Serotonergic fibers and terminals were distributed throughout the spinal gray matter in fine varicose fibers and granules probably representing terminals. Stained neuronal elements were most dense in the superficial aspect of the substantia gelatinosa, particularly in its lateral aspect, with the density decreasing ventrally. The remaining regions of the spinal gray matter contained a uniform reticulum of varicose fibers and terminals. Serotonergic fibers were present throughout the lateral and ventral funiculi with the exception of the medial ventral funiculus. The staining was most dense in the lateral funiculus. In addition, small serotonergic cell bodies were seen on the majority of sections, despite the lack of pretreatment. These cells were restricted to the region ventral to the central canal, near the midline and more laterally within the anterior funiculus. Occasionally cells were seen at the ventromedial aspect of the ventral horn. Four to six weeks following transection at midspinal levels staining appeared normal rostrally, while below the lesion the majority of serotonergic neuronal elements disappeared. Only rarely were fibers seen in the dorsal horn, while more fibers were present in the ventral horn. Occasionally, relatively large varicose structures are observed cupping the ventral aspect of the ventral horn. The origin of this residual staining is most likely the numerous intrinsic serotonergic spinal cells. To determine the origin of the large descending serotonergic projection, HRP injections were made at midlevels in the spinal cord, which has no distinct enlargements, and the tissue sections were processed with the double labeling technique for HRP and 5HT. In the medulla, large numbers of neurons exhibiting positive staining for both 5HT and HRP were observed in areas known to contain 5HT cells in the stingray. Doubly labeled cells were clustered ventromedially in the medullary raphe complex, and spread laterally along the margin of the brainstem. Only rarely were doubly labeled neurons observed in the pons and at the ventrolateral aspect of the caudal midbrain. The distribution of spinally projecting serotonergic neurons in the stingray resembles the pattern observed in rat.

188.11 IMMUNOHISTOCHEMICAL LOCALIZATION OF NEUROPEPTIDES IN THE RABBIT INFERIOR MESENTERIC GANGLION. H. K. Kulmala, M. A. Simmons, N. J. Dun and S. A. Lorens. Depts. of Neurol. & Pharmacol., Loyola Univ. Med. Ctr., Maywood, IL 60153.

We have used a modified indirect immunofluorescence technique to visualize the presence of several neuropeptides in the inferior mesenteric ganglion (IMG) of the rabbit. The modification involves treatment of ganglion sections with the elution technique of Tramu et al. (J.Histochem.Cytochem.,1978) to reduce the high degree of background staining observed in the rabbit IMG. In the rabbit brain, however, we were able to successfully demonstrate serotonin immunoreactive neurons without this modification. Since we use commercially available antibodies raised in rabbits, an anti-rabbit second antibody is required, in this case goat anti-rabbit γ-globulin conjugated to fluorescein isothiocyanate (GAR). The GAR apparently binds to rabbit γ-globulins present in the periphery, but not in the CNS, resulting in non-specific staining.

Male rabbits were perfused transcardially with 0.5 L Ca^{++}-free Tyrode's solution followed by 1.0 L 4% paraformaldehyde (PF) in phosphate buffer (pH 6.5) and, finally, 3.0 L 4% PF in borate buffer (pH 11.0). The ganglion was removed, post-fixed for 90 min, placed in 5% sucrose in Sorenson's buffer and refrigerated for at least 12 h. The ganglion was frozen by liquid nitrogen vapors and sectioned at 16 μm in a -20°C cryostat. Sections were thaw-mounted, warmed to room temperature, then rehydrated with phosphate buffered saline (PBS). Sections were dipped in a solution containing 1 V 2.5% $KMnO_4$ + 1 V 5% H_2SO_4 in 50-100 V H_2O, then incubated overnight at 4°C with primary antiserum diluted 1:50 or 1:100 in PBS containing 0.3% Triton X-100. Sections were washed with PBS, incubated at 37°C for 30 min with GAR, rewashed in PBS, coverslipped with PBS:glycerin (1:3 v/v) and examined under a fluorescence microscope. Appropriate controls were performed.

Microscopic examination revealed the presence of enkephalin, somatostatin, substance P and vasoactive intestinal polypeptide immunoreactive fibers within the rabbit IMG. None of these substances appeared to be localized selectively to any portion of the IMG. In each case beaded fibers were seen throughout the ganglion and frequently appeared surrounding the principal ganglionic neurons. No cholecystokinin, luteinizing hormone-releasing hormone or serotonin immunoreactivity was seen. Thus this modified technique allows for the use of rabbit antisera for immunohistochemistry in rabbit peripheral tissues.

We have shown elsewhere that repetitive preganglionic stimulation elicits a slow depolarization and a long lasting hyperpolarization in the rabbit IMG that are resistant to cholinergic antagonists. These membrane potential changes may be mediated by one of the above neuropeptides.

188.12 IMMUNOLOGICAL LOCATION OF THE PEPTIDE PROCTOLIN AND SEROTONIN IN IDENTIFIABLE NEURONS OF COCKROACH AND CRAYFISH. C.A. Bishop, M. O'Shea and J.J. Wine. Dept. of Pharm. Physiol. Sci., Univ. of Chicago, Chicago, IL 60637 and Dept. of Psych., Stanford Univ., CA 94305.

Uniquely identifiable neurons, which are found in the central nervous systems of some invertebrates, may provide tools for the cellular study of peptide and amine transmitter functions. Whole-mount immunocytochemical techniques have assisted our search for such cells by providing us with maps of cell bodies which may contain specific neural peptides or biogenic amines. For example, we have described a map of the cockroach CNS for the bioactive pentapeptide proctolin. Information from this map was combined with biochemical, anatomical and physiological analyses to identify individual proctolin-containing neurons (Bishop & O'Shea, 1982, J. Comp. Neurol., in press; O'Shea & Bishop, 1982, J. Neurosci., in press). We will show that one of these identified neurons is the slow depressor motoneuron which innervates the main leg depressor muscles and that this neuron and its targets may now be used to study the transmitter function of proctolin.

We have also generated maps of serotonin immunoreactivity in the cockroach and crayfish and a proctolin map for the crayfish. In cockroach, serotonin immunoreactive cell bodies were found in all ganglia of the CNS. Stained varicosities were detected in all ganglia and stained fibers in all connectives. No stained processes, however, were detected in any of the nerve roots of the thoracic or abdominal ganglia. A comparison of the proctolin and serotonin maps shows more proctolin immunoreactive cell bodies in the ventral nerve cord but more serotonin cell bodies in the brain. The proctolin and serotonin systems appear to overlap only in the sub-oesophageal ganglion and the tritocerebral lobes of the brain where they may co-occur in neurons.

In crayfish, we are investigating two large (~70 μm) ventral, bilaterally symmetric cells in the first abdominal ganglion which stain with the serotonin antibody; and two pairs of bilaterally symmetric cells in the anterior portion of each abdominal ganglion which stain with the proctolin antibody. These latter cells seem to correspond to cells that appear opaque and stain with neutral red when the crayfish is between molts (R. Roth, pers. commun.). (Supported by NIH grants NS-06684 and NS-16298.)

188.13 THE INTERPEDUNCULAR NUCLEUS OF THE RAT: CYTOARCHITECTURE AND CYTOCHEMISTRY. Lisa M. Hemmendinger and Robert Y. Moore . Dept. of Neurology, SUNY at Stony Brook, New York. 11794.

Several recent immunocytochemical studies have indicated the presence of substance P, enkephalin, somatostatin, LHRH and serotonin immunoreactive neuronal perikarya and/or fibers in the interpeduncular nucleus (IPN), but have not described their precise distribution in relation to subdivisions of the nucleus. The present study was undertaken to define the cytoarchitectonic subdivisions of the adult rat IPN and to describe the distribution of chemically defined cell and fiber populations within them.

Paraffin-embedded frontal sections through the IPN were reacted using the PAP immunocytochemical method with an antibody to cathepsin D (Whitaker et al., Br. Res. 216:109, 1981), which enhances cytoarchitectural differences. This material permits a more extensive subdivision of the IPN than previously published, particularly when compared with Nissl-stained material. Four paired and 4 unpaired subnuclei can be distinguished in the IPN on the basis of neuron size, shape, staining characteristics and packing density. The rostral half of the IPN contains the rostral dorsal (RD), rostral ventral (RV) and paired rostral lateral (RL) subnuclei. The caudal half of the IPN contains the caudal dorsal (CD), caudal ventral (CV) and 3 paired subnuclei, the dorsolateral (DL), caudal intermediate (CI) and caudal lateral (CL).

These subnuclei were examined light microscopically for the presence of specific fiber and cell populations by means of immunocytochemistry, catecholamine histofluorescence and acetylcholinesterase staining. The results of these studies are summarized in the table below.

	RD	RV	RL	DL	CD	CV	CI	CL
Substance P	+•	+	–	–	–	–	–	+
Leu-Enkephalin	+•	+	+	+	+	+	–	–
Somatostatin	+	+	+	+	+	+	+•	+
LHRH	+	+	+	+	–	+	+	+
Serotonin	+	+	+	+	+•	+	+	+
Catecholamine	+	+	–	+	+	+	+	–
Acetylcholinesterase	+	+	–	+	+	–	–	+

+ fiber staining, •cell body staining, – no specific staining

The extent of innervation of each subnucleus varies, but the localization of specific fiber and cell populations within the IPN is well-delineated and conforms to the nuclear subdivisions defined using the Nissl- and cathepsin-stained material. In addition, at least 4 sets of immunocytochemically distinct neurons are present in varying numbers in specific subnuclei in the IPN.

These studies point out the cytoarchitectonic and cytochemical complexity of the IPN. Further morphological studies are underway to extend our understanding of the organization of this nucleus.

189.1 POSTNATAL DEVELOPMENT OF RETINOGENICULATE BOUTONS IN MONKEYS. Gay Holstein*, Tauba Pasik and Pedro Pasik. Department of Neurology, Mount Sinai Sch. Med., CUNY, N.Y., N.Y. 10029.

Profiles of retinal endings in magnocellular lamina 1 (L1) and parvocellular lamina 6 (L6) of the dorsal lateral geniculate nucleus (LGNd) were measured in coded electron micrographs of newborn, 1, 2, 4, 8 and 16 week old monkeys (M. mulatta). Using a computer assisted Coupland stereological procedure, the distribution of bouton diameters was reconstructed from areal measurements of profiles identified in at least 1200 μm^2 of net neuropil from each age-lamina condition, representing 1600-3700 μm^2 of actual tissue. This distribution was used to calculate mean bouton diameter and bouton density. The latter value was adjusted to the growth of the entire nucleus (Gottlieb et al., Soc. Neurosc., 1981) resulting in the absolute number of retinal endings per laminar type. It was found that the size distribution was essentially symmetrical in all ages sampled for both laminae. Evidence of bimodality was observed in L1 of the younger specimens. The mean diameter at birth was 1.51 µm and 1.34 µm for L1 and L6, respectively, and reached 1.78 µm and 1.57 µm at 16 weeks. Although values for L1 were typically higher, and fluctuations were apparent during development, no significant differences were found between or across laminae. Retinal bouton density was calculated using the Abercrombie correction factor for section thickness. The values at birth were 19.2 x $10^6/mm^3$ and 29.2 x $10^6/mm^3$ for L1 and L6 respectively, decreasing to 12.5 x $10^6/mm^3$ and 13.3 x $10^6/mm^3$ at 16 weeks. The density in L6 was consistently higher than that in L1. The absolute number of boutons was given by the product of laminar volume and bouton density. In L1, the total number increased from 62.4 x 10^6 to 118.2 x 10^6 during the first postnatal week, decreased by 64% of the latter value in the second week, and showed a subsequent small peak at 8 weeks. Because a pooled volume estimate was obtained for the parvocellular layers, the bouton number was calculated for the entire parvocellular LGNd based on the L6 bouton density data. The value at birth was 1031.3 x 10^6, remained stable during the first week, decreased 46% in the second week, and exhibited a second small rise at 4 weeks.

The results suggest different patterns of postnatal development in magnocellular and parvocellular retinogeniculate terminals. The changes in bouton numbers indicate a substantial initial proliferation in the former but not in the latter. Although the subsequent decrease occurs by the 2nd week in both, stabilization is evident earlier in the parvocellular layers. These findings are consistent with previous conclusions based on cell size changes occurring in early postnatal development of monkey LGNd (Gottlieb et al., Soc. Neurosc., 1980).

Aided by NIH Grants #EY-01926 and EY-01867.

189.2 THE DEVELOPMENT OF RETINOTOPIC PROJECTIONS TO THE VENTRAL LATERAL GENICULATE NUCLEUS IN THE CHICK EMBRYO. W. J. Crossland. Dept. of Anatomy, Wayne State University School of Medicine, Detroit, Michigan 48201.

In neural systems that connect topographically, such as the retinotopic projection upon the lateral geniculate nucleus and optic tectum, it is not known when the topographic map is first formed. Do retinal axons grow directly to their correct topographic termination regions or do they grow widely throughout the target structure, forming tentative connections that are broken later to reform in more appropriate sites?

This problem was investigated in the ventral lateral geniculate nucleus (GLv) of the White Leghorn chick embryo during axon growth. Anterograde transport of ^3H-proline or wheat germ agglutinin conjugated to horseradish peroxidase (WGAHRP) along the developing visual pathway showed that retinal axons are adjacent to the ventral thalamic cell mass on day six of incubation. The Glv primordium separates from the ventral thalamic cell mass on day seven of incubation. Labeled retinal fibers were not found among the cells of the GLv primordium until the ninth day of incubation. Small (0.3 1) injections of a 1% aqueous solution of WGAHRP (Sigma, L-2384) were made into different portions of the retina on the ninth & tenth days of incubation. After a seven-hour post-injection survival period, the embryos were sacrificed, the brains sectioned on a freezing microtome, and the sections reacted with tetramethylbenzidine.

Observations of the reacted, counterstained sections revealed that small retinal injections produced labeling in restricted parts of the optic tectum and GLv. The regions labeled in each structure always corresponded retinotopically. Furthermore, retinal injections that labeled the growing front of axons in the caudal optic tectum did not label any region within the GLv primordium.

Thus the retinotopic map had already been established at the earliest time at which axons could be found within the GLv. Whether the map is established with the same precision found in the adult GLv remains to be investigated.

(Supported by PHS grant EY-01796).

189.3 EARLY TOPOGRAPHIC ORGANIZATION OF GENICULOCORTICAL PROJECTIONS IN HAMSTER NEONATES. J.R. Naegele* and G.E. Schneider, Dept. of Psychology and Brain Science, MIT, Cambridge, MA 02139.

The topography of the geniculo-cortical projections has been extensively studied in adult rodents. However, very little is known about the topographic order within the geniculo-cortical system during development. We examined the topographic pattern of developing geniculo-cortical projections in neonatal hamsters using the retrograde transport of horseradish peroxidase (HRP).

Injections of HRP (Sigma, VI) were made in the posterior neocortex of hamster pups on postnatal days 0 (the day of birth) through day 14. To limit the spread of HRP from the injection site, HRP (10-20%) was embedded in polyacrylamide gels (Griffin, Watkins & Mayer, 1979[1]), formed into 145 µm diam. pieces and cut into short lengths (200-300 µm). The HRP gels were dried, adhered to the tip of a glass micropipette, and introduced into the neocortex. In other experiments, HRP (5-10%) was injected by iontophoresis. Survival times ranged from 6 to 30 hours. Following perfusion, brains were sectioned at 30 or 40 µm and reacted with tetramethylbenzidine. All sections were examined with light microscopy and polarization optics. The thalamocortical projections were studied by comparing the locations of retrogradely labelled thalamic neurons following injections in different regions of the posterior cortex. Dorsal-view reconstructions of the injected hemisphere were made to show the extent and location of the injection site. Since cytoarchitecture and fiber architecture are not well developed at early ages, the region of the LGNd which contained labelled neurons was compared with the extent of the injection site in order to determine the areal boundaries of visual cortex.

On postnatal day 0 (the 16th day after conception in this species), cortical injections of HRP labelled a scattered subpopulation of cells in LGNd without apparent topographic order. By postnatal day 1, we found evidence of some topography, although the precision of the mature system was not yet evident. As early as postnatal day 5, discrete iontophoretic injections into visual cortex resulted in localized columns of labelled neurons in LGNd, the location of which varied systematically with the center of the cortical injection site. At this age, the topography of the geniculo-cortical projection corresponds qualitatively with the mature pattern seen in adult hamsters. These findings indicate that topographic order in the hamster geniculo-cortical system develops both very early and very rapidly.

189.4 IS LOCUS COERULEUS INVOLVED IN PLASTICITY OF LATERAL GENICULATE NEURONS DURING LEARNING? D.H. Cohen, C.M. Gibbs*, J. Siegelman*, P. Gamlin, and J. Broyles*. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

We previously reported that during visual conditioning cells of the avian homologue of the lateral geniculate (LGN) show modification of their light-evoked discharge. All LGN neurons respond to whole-field illumination, the conditioned stimulus (CS), and 88% respond to foot-shock, the unconditioned stimulus (US). Of the US-responsive neurons, 51% show increased discharge (Type I) and 37% decreased discharge (Type II) with median response latencies of 100 msec. Only the Type II neurons show training-induced modification. The CS-evoked discharge of neurons unresponsive to or excited by the US habituate over training. Thus, not only is CS-US convergence necessary, but a particular source of US input is required as well.

To identify this source of US input, HRP was injected into the LGN, and the distribution of retrogradely labelled neurons included the locus coeruleus, subcoeruleus, central gray, pontine reticular formation, and various non-specific thalamic nuclei. Since the mammalian literature suggests that locus coeruleus (LC) neurons respond to nociceptive stimuli, we focussed first on this source of non-visual input. Autoradiographic experiments confirmed that LC projects to the avian LGN. Moreover, neurophysiological analysis of 48 LC neurons indicated that 81% were responsive to the US, 58% showing increased and 23% decreased discharge. The median response latency was 75 msec.

For further evaluation of possible LC involvement in mediating the Type II response of LGN neurons, electrolytic lesions were made bilaterally and after 10-14 days the US responsiveness of LGN neurons was evaluated. With lesions that extensively destroyed the rostral pole of LC, 85% of LGN neurons remained responsive to the US. However, most now showed Type I responses, the Type II response being almost eliminated. This suggests the LC is the principal source of the LGN Type II response to the US. Since the proportion of unresponsive cells did not change and the proportion of Type I responses increased, the data further suggest that US responsive LGN neurons receive both Type I and Type II inputs.

After LC lesions, the Type I LGN cells had longer response latencies and decreased response magnitudes, suggesting that LC also contributes Type I input to the LGN. Supporting this are preliminary findings that electrical stimulation of LC excites some LGN cells and inhibits others. We are now investigating the possibility that these Type I and II inputs derive from different populations of LC neurons. (Supported by NSF grants BNS8016396 (DHC) and PDF8166055 (CMG) and a grant from the Sloan Foundation (DHC).)

189.5 NORMAL DEVELOPMENT IN THE C LAMINAE OF THE CAT LATERAL GENICULATE NUCLEUS. J.E. Parsons*, D.M. Murakami* and P.D. Wilson (SPON: M. Nachman). Dept. of Psychology, Univ. of Calif., Riverside, Riverside, CA 92521.

Developmental patterns of soma sizes have been examined in layers A, A1, the magnocellular and parvocellular parts of C, and in layers C1 and C2 of the cat dorsal lateral geniculate nucleus (dLGN). Four days after an intraocular horseradish peroxidase injection, cats were sacrificed and 40μm brain sections were reacted with TMB and counterstained with thionin. The anterograde transport of the HRP labeled alternate layers in the dLGN and permitted identification of the boundaries of adjacent layers.

Mean soma diameters were obtained from the middle third of the binocular portion of the dLGN in cats ranging from 2 to 16 weeks of age. Our present results are in agreement with a previous report (Hickey, J. Comp. Neurol., 189:467, 1980) that cell bodies in the A laminae continued to grow up to the 4th week. Mean soma diameters for 4 week old cats (A 15.2μm) were about 2-3μm larger than somas of 2 week postnatal cats (A 12.6μm). The magnocellular and parvocellular parts of layer C were measured separately since it has been suggested that these are two functionally different sublayers. As was the case for A and A1, both C-magno and C-parvo increased in size from the 2nd week (C-magno 12.9μm, C-parvo 11.2μm) to the 4th week (C-magno 15.7μm, C-parvo 14.9μm). The mean soma diameters in the C1 and C2 layers of 4 week old cats (C1 14.5μm, C2 14.0μm) were also substantially larger than cell sizes in the C1 and C2 layers of 2 week old cats (C1 11.6μm, C2 12.0μm). Soma size measurements in the C layers of 16 week old cats do not appear to be markedly different from those obtained in 4 week old cats. In general, we have found that for 2 to 16 week old cats the period of greatest growth for somas in all of the C laminae occurs between 2 and 4 weeks of age. (Supported in part by Biomedical Research Support Grant and Academic Senate Committee on Research, University of California, Riverside)

189.6 EFFECT OF EARLY AND LATE MONOCULAR DEPRIVATION ON CELL SIZE IN THE C LAMINAE OF THE CAT dLGN. D. M. Murakami*, P. D. Wilson, and C. A. Yarosh*. Psychology Department, University of California, Riverside, CA 92521.

We previously reported that monocular deprivation affects the cell size of neurons in layer C1 of the cat dLGN (Soc. Neurosci. 6: 789, 1980). The changes were not significant until monocularly deprived cats were at least 20 weeks old. In order to test whether the period of peak sensitivity to monocular deprivation is different for the A and C layers, cats were monocularly deprived at 12 weeks of age (LMD) and compared to cats deprived at 2-3 weeks of age (MD). The LMD cats were sacrificed for histological study at 34 weeks of age and the MD cats were examined at 16 to 22 weeks of age. In order to reveal the C laminae, 20 ul of a 30% HRP solution was injected into the vitreous chamber of one eye. After 4 days survival, the animal was sacrificed and 40 um brain sections were reacted using TMB and counterstained with thionin. Mean soma diameters were measured for at least 100 neurons from the monocular segment and from the middle third of the binocular portion of layers A, A1, and C1. Samples of at least 50 cells were taken from the magnocellular and parvocellular portions of layer C and from layer C2.

In the LMD cats, the nondeprived and deprived monocular segments had only 2.2% difference in cell size. While a larger difference was found between the nondeprived and deprived binocular portions of layers A, A1, C-magno, and C1 in the LMD cats, the differences were much smaller than in the MD cats (layer A- MD 15.2%, LMD 6.5%; layer A1- MD 16.2%, LMD 6.5%; layer C magno- MD 11.5%, LMD 6.1%; layer C1- MD 9.7%, LMD 5.8%). The effect of LMD in the binocular portion of layers C-parvo and C2 was not significantly different than the effect in the monocular segment.

The results indicate that binocular competition still affects cell size in the dLGN of cats monocularly **deprived from 12 weeks of age. However, the effect is much smaller for layers A, A1, and C-magno in LMD** cats than in cats deprived from 2 and 3 weeks of age. The effect of deprivation is also less for C1 in LMD cats than in MD cats, but the difference is less. 190.1 A MODEL OF VISUAL CORTICAL PLASTICITY EMPLOYING PROPRIOCEPTION FROM EXTRAOCULAR MUSCLES. M. Shadlen* and J. A. Anderson. Center for Neurosciences, Brown University, Providence, RI 02912.

We have developed a model of visual cortex which explains certain plastic properties of visual cortical (striate) neurons. We have simulated development of orientation specific striate neurons.

Development and maintenance of receptive field properties are believed to be dependent upon activity and experience of an animal. We utilize the notion that an organism's organization of information may be related to that organism's actions in and upon its environment. We suggest that the movements of the eye may be intimately related to modification of striate neuron receptive fields.

In the model we communicate, the strength of connection between the i-th presynaptic lateral geniculate nucleus (LGN) neuron and the j-th postsynaptic striate neuron is dependent on two parameters:

1) activity of the i-th presynaptic neuron,
2) a non-visual input to the j-th postsynaptic neuron corresponding to movement of the eye.

Thus the receptive field of any j-th striate neuron is determined by the type of visual inputs it receives (here spots of contrast via LGN afferents) and the particular motion with which it is associated (here by virtue of proximity to extraocular afferent terminals in the visual cortex).

Although complex patterns serve as stimuli, we simulate development of line orientation receptive fields. The model predicts the observed clock-like anatomical arrangement of such receptive fields in the visual cortex.

A number of recent reports suggest that proprioception from extraocular muscles is important in determining cortical ocular dominance (for a critical review see Movshon, J.A. and Van Sluyters, R.C., Ann. Rev. Psychol. 32:523-74, 1981). Our model indicates that if proprioceptive signals play a role in visual cortical plasticity, it is possible that they contribute to the development and maintenance of striate receptive fields. Furthermore, they might provide a mechanism whereby simple patterns such as lines may be distinguished from a complex visual environment.

190.2 INTRAOCULAR TETRODOTOXIN HINDERS GOLDFISH OPTIC NERVE REGENERATION. D.L. Edwards and B. Grafstein. Physiology Dept., Cornell University Medical College, New York, N.Y. 10021

The goldfish visual system provides a convenient model in which to study axonal regeneration since the retinal ganglion cell (RGC) responds vigorously to injury and the time course of regeneration has been well characterized. In the present study we have examined the effect of intraocular tetrodotoxin (TTX) on the time course of recovery from optic nerve crushes.

In each goldfish, one optic nerve was crushed and the corresponding eye was injected with 0.07 µg TTX in citrate buffer, a dose that blocks activity for 2.5-3 d. TTX injections were repeated every 3 or 4 d. Control fish were similarly injected with citrate buffer vehicle. The time course of optic nerve regeneration was evaluated by a) behavioral testing of recovery of visual function, b) measurements of the time of arrival of regenerating axons at the optic tectum, c) axon counts in regenerating optic nerves and d) measurements of RGC numbers, size, and level of protein synthesis.

The behavioral testing showed that recovery of the startle reaction to a bright light (mean normal recovery time = 12 d post-crush) and food pellet localization (mean recovery time = 35-40 d) were both delayed in the TTX-treated fish. Intraocular TTX had no effect on the time when axons first reach the tectum (as indicated by the amount of ^{3}H-proline labeled protein axonally transported to the tectum at 15-18 d after crushing), but at 24 d post-crush the amount of labeled transported protein arriving at the tectum in TTX-treated fish was significantly less than normal. By 36 d this difference had disappeared. Silver-stained sections of nerves, examined at both 10 and 22 d post-crush, showed 20% fewer axons at a point 1 or 1.5 mm distal to the initiation of outgrowth. However, there was no effect of intraocular TTX on the number of RGCs, on the mean RGC area at 22 and 36 d post-crush, or on the incorporation of ^{3}H-proline into protein in RGCs at 36 d. In a separate experiment only a single injection of TTX was given at the time of crushing. Recovery of the startle reaction was delayed compared to citrate controls, but there was no difference in the time of recovery of food localization.

These combined behavioral and morphological observations show that RGC axons can regenerate and form viable synapses in the presence of TTX, but suggest that the TTX treatment may diminish either 1) the diameter of the regenerating axons, 2) the extent of axonal branching in the nerve or at the tectum, or 3) the rate of outgrowth of some of the population of regenerating axons. These changes are not accompanied by gross alterations in the retinal ganglion cell body response to axotomy.

190.3 ACTIVITY SHARPENS THE MAP DURING THE REGENERATION OF THE RETINOTECTAL PROJECTION IN GOLDFISH. J.T. Schmidt and D.L. Edwards, Biology Dept., SUNY Albany, Albany, NY 12222 and Dept. Physiol., Cornell Univ. Medical College, New York, NY 10021.

In the regenerating retinotectal projection of goldfish, we have used intraocular injections of tetrodotoxin (TTX) to test whether 1) effective synaptic connections can be formed in the absence of activity, and 2) whether activity plays a role in organizing or refining the retinotopic map. At the time of optic nerve crush, 0.07 µgm of TTX in citrate buffer was injected into the eye, a dose which blocks retinal ganglion cell activity for approximately 2½ days. Successive injections afforded a continuous 27 day block without toxic effect as evidenced by the continued movements of the injected eyes. Control fish were injected on the same schedule with citrate buffer.

Analysis of the field potentials evoked by optic nerve shock showed that fibers regenerating without activity had a normal ability to form synaptic connections in the tectum. There was a tendency for the response latency at 28-32 days to be longer than controls but this difference disappeared at longer regeneration times.

The retinotectal maps of the TTX fish were normally organized but the multiunit receptive fields were grossly enlarged. In control regenerates, one to three units (arbors of retinal ganglion cells) were recorded per penetration and their combined receptive field averaged 11-12 degrees, nearly the same as for single units. In TTX fish, each penetration yielded at least 5 to 10 units whose receptive fields were clustered over a wider area averaging 27 degrees across. (A lack of effect on individual ganglion cell receptive fields was confirmed by intraretinal recordings). Many fish were recorded up to 4 months after the release from TTX block, but no further refinement of the maps occurred. Apparently activity is needed during the regeneration process. If the nerve was recrushed and allowed to regenerate a second time without TTX, normal maps were formed, ruling out any permanent changes in the retinal ganglion cells. Blocks during various portions of the regeneration process showed that activity is not critical during the process of axonal elongation (first 2 weeks) but is critical during the period of synapse formation and maturation (14-34 days). The results are discussed in terms of an activity-dependent stabilization of synapses. Neighboring retinal ganglion cells are known to fire in a statistically correlated fashion and this could help in their elimination of incorrect branches following an early period of diffuse connections. Supported by NIH Grants EY03736 (To J.T.S.), NS 09015 and EY 02696 to Bernice Grafstein.

190.4 TESTS FOR A ROLE OF ACTIVITY IN THE FORMATION OF OCULAR DOMINANCE PATCHES. V. Boss* and J.T. Schmidt (SPON: A. Messer) Dept. of Biological Sciences, SUNY at Albany, NY 12222.

Following removal of one tectum in goldfish, the optic nerve fibers from both eyes are forced to compete for synaptic space in the remaining tectum, and their terminals eventually segregate into ocular dominance patches seen anatomically. This study tested whether segregation is prevented or delayed by blocking impulse activity in both eyes using tetrodotoxin (TTX).

In 3-4" goldfish (housed at 30°C) the left tectum and forebrain were removed and the right nerve deflected toward the remaining tectum. The regenerating nerve fibers would compete with the intact projection from the normal eye for synaptic space. Beginning 18 days after surgery (before segregation has begun), both eyes were given TTX injections every second day to achieve a continuous block of retinal activity. Control fish were injected with citrate-Ringers on the same schedule.

Ocular dominance patches were measured in two ways. First, 75 days after surgery HRP and ^{3}H proline were injected into the left and right eyes, respectively, to trace their projections to the tectum. Alternate frozen sections were processed for the HRP-TMB reaction and radioautography. In control fish ocular dominance patches in the projections from both eyes could be seen as early as 53 days and always by 64 days after surgery. By 75 days patches were well defined in the normal eye's projection in most control fish. In contrast, in the TTX fish very few patches could be seen in the the projection from the normal eye at 75 days; thus the segregation of the projections from the two eyes may be delayed when activity is blocked.

Second, the tecta of some of the 75 day fish were examined electrophysiologically using the field potentials evoked by optic nerve shock. Analysis of sources and sinks of synaptic currents provided a measure of the postsynaptic response to each eye. In control fish there were local maxima and minima in the responses to each nerve. The responses to the regenerating nerve were generally larger in those areas where the normal eyes' responses were small, and vice versa. In TTX fish the responses to both nerves were more uniform across the tectum. Lesions were placed at each penetration for correlation with the anatomical patches. The physiological data, like the anatomical data, suggests that the ocular dominance patches either fail to form or their formation is delayed in the absence of neuronal activity.

Supported by NIH Grant EY 03736 to JTS.

190.5 THE ROLE OF TEMPORAL ACTIVITY DURING AUDITORY MATURATION. D. H. Sanes* and M. Constantine-Paton. Dept. of Biology, Princeton Univ., Princeton, New Jersey, 08544.

We have begun to examine the role played by the temporal patterning of neural activity during the development of auditory tuning curves. Our paradigm involved raising young mice in an environment which entrains a large proportion of auditory nerve fibers, repetitive clicks. Our expectations were based on the hypothesis that coactive neural inputs might be more likely to form lasting connections with a post-synaptic neuron. Precise convergence onto post-synaptic cells might then be effected by selecting inputs with temporally similar action potential patterns from an initially larger array of terminals. If this were correct, then in the absence of temporal identity, such as when fibers are driven synchronously, functionally inappropriate connections should result. The post-synaptic neuron would then be expected to have less specific response properties.

Frequency tuning curves were taken from single units in the central nucleus of the inferior colliculus of normal and click-reared (CR) mice, aged 18-24 days. Q values, indicative of the degree of tuning, were calculated for both groups. The CR animal tuning curves were found to be significantly broader (t-test; $p<.01$) for units with best frequencies in the range 10-14.8 KHz. The CR tuning curves in this region seemed to be generally broader from the tip region (Q5) to at least 40 dB above threshold (Q40). These results were true of animals raised at a click repetition rate of 8 pulses per second. The effect was even more pronounced for animals raised in a higher repetition rate (20/s). These showed less variability and somewhat broader tuning curves than mice raised at 8/s.

A Fast Fourier Transform of the click used in rearing revealed that the power spectrum decreased dramatically above 15 KHz. Below this point the power spectrum was virtually flat (+/-5 dB). It was also found that mouse pups produce extremely narrow-band squeaks below 10 KHz. In this region the clicks did not seem to have any effect.

We do not believe that these results can be attributed to damage or trauma in the cochlea because the mean threshold for normal and CR units were identical for all frequency ranges. Furthermore, a small percentage on units in the 10-14.8 KHz range were sharply tuned. Nevertheless, we intend to fully test this possibility through physiological analysis.

At present our data is fully consistent with the hypothesis that temporal patterns of activity are involved in ontogenetic tuning of the response properties of neurons in the central auditory pathway.

190.6 SILENCING OF NATIVE AFFERENTS PERMITS INNERVATION BY FOREIGN AFFERENTS IN A FIRST-ORDER SENSORY INTERNEURON OF CRAYFISH. F.B. Krasne, D.L. Glanzman, and J.S. Gunther. Dept. of Psychology and Brain Res. Inst., University of California, Los Angeles, L.A., CA 90024.

Effects on neuron activity on synapse formation and elimination have been shown to be important in the developing mammalian visual system and in vertebrate skeletal muscle. However, whether such effects are due to general properties of neurons or to special properties of muscle and developing visual system is presently uncertain. We report here results which encourage belief in their generality.

Interneuron A (hereafter A) of crayfish last abdominal ganglion normally receives direct input from mechanoreceptors borne on the animals ipsilateral tail fan appendages. The axons of the peripheral mechanoreceptor somata travel to the ganglion over ganglionic roots 1-5. If these roots are cut, the axons regenerate, growing back into the ganglion and reforming synapses with A, as indicated by return of A's responsiveness to water currents. Cut contralateral roots 1-5, if tied across the midline, can substitute for native ipsilateral roots; however, such crossed innervation can ordinarily only be produced if A has been denervated.

We have now found that such crossed innervation can be produced even with ipsilateral roots intact if the sensory axons of these roots are silenced by immobilizing tail fan tactile hairs with glue (Histoacryl Blue). We feel reasonably confident that the glue is not damaging the receptors and causing degeneration, because responsiveness of A to water disturbances of glued fields returns to normal when animals shed their exoskeletons (and glue) at molt and because electrical stimulation of roots whose peripheral fields are glued remains fully competent to drive A.

190.7 EFFECTS OF DIFFERENTIAL ENVIRONMENTS AND HIBERNATION ON GROUND SQUIRREL BRAIN MEASURES. M. R. Rosenzweig, E. L. Bennett, M. Alberti,* H. Morimoto* and M. Renner. Dept. of Psychology and Melvin Calvin Lab., Univ. of California, Berkeley, CA 94720.

As part of a study of brain plasticity, we investigated development of brains of Belding's ground squirrels (Spermophilus beldingi) in two phases and under two kinds of environmental conditions. Phase I involved exposure to enriched or impoverished environments. Pregnant females were trapped in the Sierra in June and brought to the laboratory where they bore their litters. Shortly after weaning, the pups were assigned to either of two conditions: (1) Enriched Condition (EC) placed in groups of 10-12 in relatively large cages that contained diverse stimulus objects. (2) Impoverished Condition (IC) -- individuals in small cages without stimulus objects. Similar experiments were conducted during three summers, 1978-80. The length of the experimental period ranged from 47 to 75 days. Each year shortly before the termination of the experiment, feral juvenile ground squirrels of about the same age were live trapped in the same location as the females of that year. At sacrifice, the brains were dissected rapidly into 6 standard samples, weighed, and stored for analysis of nucleic acids. The feral and EC squirrels were found to be similar in most brain measures, and both exceeded the ICs significantly in brain weights, total RNA and total DNA. The only way in which the feral squirrels differed consistently from the lab-raised squirrels was that they showed greater RNA/tissue weight. Phase II took place in October-May and involved placing some juveniles in individual cages in a cold room ($\sim 2.5^0$ C) while others remained in EC at normal room temperature ($\sim$22). A baseline group was sacrificed at the outset of this phase and other groups were sacrificed at various times during the winter and early spring. After a preliminary hibernation experiment in 1978-79, further experiments have been conducted in 1979-80, 1980-81, and 1981-82. In experiments through 1981, hibernators sacrificed in May showed significantly greater total RNA than either the prehibernation baseline group or the winter-awake squirrels; this difference amounted to $\sim$15% whereas the significant effects of enriched vs. impoverished environments were only $\sim$5%. This research received support from NSF Grant BNS 791374 and from the Division of General Life Sciences, Dept. of Energy Contract DE-AC03-76SF00098.

190.8 SPINAL CORD, ROOTS AND NERVES: A UNIT EXHIBITING INJURY-INDUCED ALTERATIONS? L. J. Fisher*, J. A. Beel*, L. S. Stodieck*, and M. W. Luttges (SPON: R. Gerren). Department of Aerospace Engineering Sciences, University of Colorado, Boulder, CO 80309

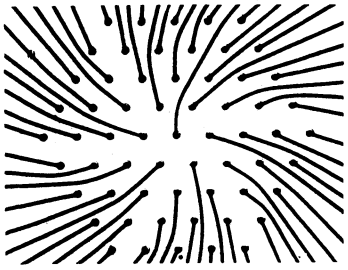
Previous studies (Luttges et al., 1976; Gerren and Luttges, 1979) demonstrated segmental alterations bilaterally as a consequence of unilateral sciatic nerve damage. These studies, combined with our current work, indicate such time-dependent segmental alterations may be functionally and structurally interrelated.

Sciatic nerves, ipsilateral and contralateral to nerve crush, were examined biomechanically. A bilateral, time-dependent increase in nerve strength and stiffness was observed. These alterations may have important consequences for attached nerve roots, terminals and spinal cord. Any absence of compensatory alterations may lead to an increased potential for mechanical injury elsewhere. These possibilities prompted an examination of injury-induced alterations in spinal cord protein constituents and metabolism using SDS polyacrylamide gel electrophoresis and radioactive amino acid precursors. Results from these studies indicate no overall change in protein composition or synthesis exhibited by the spinal cord in response to unilateral nerve crush. In contrast, alterations in synaptic terminal morphology have been reported and ongoing work reveals large differences in γ-amino butyric acid uptake and binding by synaptosome preparations obtained from the spinal cord following nerve damage. The overall structural stability of the spinal cord is the background against which specific segmental elements exhibit characteristic time-dependent alterations. This contrast also is evident in ortho- and antidromic electrophysiological studies focused on the spinal cord. Time-dependent, electrical alterations are observed bilaterally in both the spinal cord and nerves. Thus, a "segmental unit" can be defined as encompassing spinal cord, roots and nerves which share time-dependent alterations in response to experimental nerve damage. Injury-induced changes in the unit may subsequently affect other physiological functions supported by the unit. The comprehensive nature of the unitary segment must be considered when evaluating the consequences of incurred injury.

190.9 STUDIES OF CULTURED CELLS IN DISHES INCORPORATING INTEGRAL MICROCIRCUIT ELECTRODES. J. Pine and J. Gilbert*. California Institute of Technology, Pasadena, California 91125

The fact that cultured nerve and muscle cells grow as a monolayer, in close proximity to a flat substrate, makes it attractive to utilize electrodes embedded in the dish bottom to extracellularly stimulate nearby cells. It is also possible to use such electrodes to record signals arising from action potentials in nearby cells. Preliminary experiments have shown the feasibility of this technique in cultures of rat superior cervical ganglion neurons. (J.Pine, J. Neuroscience Meth., 2:19-31, 1980.)

We have fabricated culture dishes for studying small networks of nerve or muscle cells growing as microcultures in a region approximately 0.5 mm. in diameter at the center of the dish. This region lies over an array of 61 microelectrodes spaced 70 microns on centers, such that all locations in the region are within range of at least one microelectrode. The dish bottoms are glass cover slips on which a vacuum-deposited gold pattern defines electrodes about 15 microns in diameter and connecting leads radiating outward to the edge of the dish. The figure below shows the central region of a dish:



An insulating layer covers the gold pattern, with openings etched through it at the electrodes. The electrodes are platinized electrolytically to achieve a low impedance to the culture medium. The dish assembly, formed by cementing a lucite ring to the glass cover slip, is about 1 cm. square, and is mounted on a commercial integrated circuit chip carrier. External electronics can be used to record and stimulate from several electrodes simultaneously.

We are studying the effects of chronic stimulation on development of nerve and muscle cultures, and will report preliminary results.

190.10 SUPPRESSION OF ELECTRICAL ACTIVITY IS ASSOCIATED WITH NEURONAL DEFICITS: DEVELOPMENTAL ONSET AND NEUROCHEMICAL SPECIFICITY. Douglas E. Brenneman*, Elaine A. Neale, Linda M. Bowers*, and Phillip G. Nelson (SPON: Bruce K. Schrier). Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, Maryland 20205.

The role of electrical activity in neuronal survival was assessed in cultured neurons. Chronic blockade of spontaneous electrical activity with tetrodotoxin (TTX) produced neuronal deficits. The developmental vulnerability and neurochemical specificity of this effect was investigated in dissociated cultures of spinal cord and dorsal root ganglion cells. Cultures were prepared from 12-14 day old fetal mice.

The response of neurons to electrical blockade was estimated with cell counts and two neuronal surface markers: ^{125}I-tetanus toxin fixation and ^{125}I-scorpion toxin binding. Application of TTX during the 2nd or 3rd week in culture resulted in cell counts which were 68-75% of control. Both surface labels were decreased to 55-60% of control values after TTX treatment during this same developmental period. No changes from controls were observed after one week exposures of TTX during the 1st or 4th week in vitro as measured with tetanus toxin fixation.

Tetanus toxin fixation was saturable as a function of cell plating density. At high plating densities, neither an increase in initial plating density nor tetrodotoxin treatment affected the amount of tetanus toxin fixation.

Evidence of developmental sensitivity and neurochemical specificity for the neuronal deficits produced by electrical blockade was obtained with choline acetyltransferase (CAT) assays. Suppression of electrical activity during the first six days in culture had no effect on CAT activity and no effect on the appearance of the neurons. Application of TTX during the 7th day in culture decreased CAT activity to 68±4% of control. A 24 hour exposure to TTX on the 8th day in culture resulted in CAT activity only 58±4% of control. More chronic (3 weeks) treatment with TTX revealed that the decrease in CAT activity was related to the duration of electrical blockade.

Glutamic acid decarboxylase (GAD) activity was not changed after chronic application of TTX. Similarly, high affinity ^{3}H-GABA uptake was not altered by this cessation of electrical activity. ^{3}H-GABA autoradiography revealed no change in the number or appearance of GABA-positive cells after TTX treatment.

These data indicate that blockade of spontaneous activity produces a deficit in developing neurons in culture. This effect exhibits specificity both with regard to the developmental stage at which vulnerability occurs and with regard to the neurochemical system which is affected.

190.11 EFFECT OF FIBRILLATION ON AChE IN CULTURED RAT MYOTUBES S. Younkin, S. Brockman*, J. Newman*, and L. Younkin, Dept. Pharmacology, Case Western Reserve Univ., Cleveland, Ohio 44106

Fibrillating myotubes (derived from 20-day rat embryos) were compared with myotubes in which fibrillation was blocked on the fourth day of culture with 1 μM TTX. Cultures were sequentially extracted to separate globular, asymmetric, and non-extractable AChE. Individual globular and asymmetric forms were then analyzed by velocity sedimentation. At 5 days, control myotubes (which were just beginning to fibrillate) and TTX myotubes contained essentially the same level of AChE and the same distribution of the various forms of the enzyme - 71% globular (49% 4S, 22% 10S), 15% asymmetric, and 14% non-extractable AChE. From day 5 to day 8, overall levels of AChE increased 8.1-fold in fibrillating myotubes and 2.6-fold in TTX myotubes. Globular forms increased 6.4-fold (7.8-fold 4S, 3.5-fold 10S), asymmetric forms 14.9-fold, and non-extractable AChE 9.1-fold in fibrillating myotubes whereas in TTX myotubes globular forms increased 2.3-fold (2.6-fold 4S, 1.4-fold 10S), asymmetric forms 3.3-fold, and non-extractable AChE 3.3-fold. All of the major forms of AChE present in innervated adult skeletal muscle were present at 8 days in both fibrillating and TTX myotubes. Fibrillating myotubes contained 58% globular (48% 4S, 10% 10S), 27% asymmetric forms (4% 12.5S, 10% 16S, 13% other) and 15% non-extractable AChE. TTX myotubes contained 62% globular forms (51% 4S, 11% 10S), 23% asymmetric forms (4% 12.5S, 5% 16S, 14% other), and 15% non-extractable AChE. Careful light microscopic evaluation of fibrillating and TTX myotubes showed that the effect of TTX on AChE was not due to gross impairment of morphological development. Titration of AChE active sites in 8-day control and TTX myotubes with O-ethyl-S-diisopropylaminoethyl methyl-phosphonothionate showed that the reduction in AChE activity in TTX myotubes was primarily, if not exclusively, due to a reduction in the number of AChE molecules. To evaluate the effect of fibrillation on the synthesis of globular and asymmetric forms of AChE, we inactivated essentially all of the AChE in 7 day cultures of fibrillating and TTX myotubes with either methanesulfonyl fluoride or paraoxon and carefully evaluated the recovery of AChE. Our analysis indicates that fibrillation substantially increases the rate at which both globular and asymmetric forms are synthesized. We conclude 1) that muscle cells produce all forms of AChE in the absence of electromechanical activity and 2) that electromechanical activity substantially increases the level of both globular and asymmetric forms of AChE primarily, if not exclusively, by increasing synthesis. There are differences between our study and an earlier study (Rieger et al., Dev. Biol., 76: 358-365; 1980) that will be discussed.

190.12 LACTATE DEHYDROGENASE VARIATIONS AMONG SINGLE CULTURED MYOTUBES DUE TO CONTRACTION. P. M. Nemeth, L. Solanki* and J. C. Lawrence, Jr.* Depts. of Neurology and Pharmacology, Washington Univ. Med. Sch., St. Louis, MO 63110.

The effects of contraction on lactate dehydrogenase (LDH) activities of single cultured myotubes has been studied. Skeletal muscle cells were obtained from 19 day rat fetuses and allowed to fuse in vitro into spontaneously active myotubes. To obtain samples for enzymatic analysis, the cultures were rinsed with an isotonic solution of ammonium formate and freeze-dried. Individual myotubes were manually dissected from the lyophilized samples and LDH activities were measured by microanalytical biochemistry on 3-25 segments (each weighing 2-10 ng). Some variation of enzyme activity was found along the length of individual myotubes (average coefficients of variation 0.13±0.06). The LDH activity among individual cells after 1 week of culture (n=34) was 20 to 120 moles/kg/hr with an average of 70±22 (coefficient of variation 0.32). The heterogeneity among fibers was of the same magnitude as found in mature rat hindlimb muscles. Heterogeneity in vitro may be partly explained by the observed uneven contractile patterns within the culture. To test this idea, contractions were completely inhibitied by incubating the cultures with 10^{-5} M tetrodotoxin (TTX). Paralysis of 12 day old cultures increased LDH activity from 84 (12 day old controls, n=16) to 100 moles/kg/hr (n=24). Moreover, the paralysis enhanced the uniformity of enzyme levels among the cells. The coefficient of variation for LDH was 0.25 in normal compared to 0.15 in TTX-treated cultures. Enzyme variation along the length of paralysed myotubes was similar to normal cells; the average coefficient of variation was 0.12±0.05. The results show that primary cultures of rat myotubes are heterogenous with respect to LDH activities. Inhibition of spontaneous contraction reduces the differences among cultured myotubes. (Supported by MDA and by NIH AM28312 and NS18387 grants.)

190.13 EFFECTS OF ALTERED MOTOR UNIT ACTIVITY ON NORMAL AND REINNERVATING MUSCLE. K. E. Misulis* and W-D. Dettbarn (SPON: A. Burt). Neuromuscular Dis. Res. Ctr., Vanderbilt Univ., Nashville, TN 37212.

Nerve-muscle interactions such as muscle activity and neurotrophic factors are important for the development and maintenance of normal neuromuscular characteristics. One of these interactions, the patterns of electrical activity imparted to the muscle fibers by innervating nerves, was studied here.

Two models of altered motor unit activity were used to investigate the role of activity on normal and reinnervating fast and slow muscle. In the hypokinetic model, rats were suspended with the hindlimbs fully unloaded and the head tilting downward. Under pentobarbital anesthesia surgical gauze was wrapped around the base of the tail with silk tape and silastic; the attached gauze was secured to a small swivel snap clip (commercially available) which was clipped onto one bar of the top of an animal cage. This arrangement allowed locomotion around the cage by the forelimbs with rotation provided by the swivel clip and longitudinal movement by sliding of the clip on the bar. This technique permits patterned movement of the hindlimbs but no weight bearing.

The second model was the spinal rat. Under deep pentobarbital anesthesia adult rats were spinalized at T10 via a dorsal laminectomy. After a brief period of spinal shock the hindlimbs maintained a spastic posture. This model represents an increase in resting muscle tone, but the relative absence of movement-patterned phasic activity.

In both of these groups the left sciatic nerve was crushed for the study of reinnervation. The contralateral non-crushed side served as control. Parameters such as acetylcholinesterase (AChE) activity, muscle mechanics, and muscle and nerve electrical activity were studied.

Spinalization alone produced an increase in the relative activity of AChE in the soleus, but a decrease in the EDL. In contrast, hypokinesia resulted in an increase in AChE in both the soleus and EDL. Studies of reinnervation under these conditions revealed an apparent delay in recovery of mechanical activity (maximal twitch tension and rate of rise) and altered patterns of AChE recovery in spinal animals.

The results of experiments performed with these models will hopefully give insight into the role of electrical activity in neurotrophic phenomena, and in addition, indicate what factors are important in guiding and supporting reinnervation of muscles.

Supported by NIEHS #02028-02, NINCDS #12438-05 and MDAA.

190.14 CONTRACTILE PROPERTIES OF REINNERVATED RAT GASTROCNEMIUS MUSCLE : EFFECTS OF LOW FREQUENCY STIMULATION. B. G. Cole*, P. F. Gardiner and C. W. Y. Chan. School of Physical and Occupational Therapy, McGill Univ., 3654 Drummond, Montréal, Qué., H3G 1Y5 and Dep't d'Education Physique, Univ. de Montréal, Montréal, Qué. H3C 3J7

Direct low frequency stimulation of denervated muscle has been shown to reduce the atrophy which follows peripheral nerve injury. However, its influence on the contractile characteristics of fast muscle following reinnervation has yet to be established. The object of this study is to determine the effects on the in situ contractile properties of reinnervated rat gastrocnemius muscle of direct low frequency stimulation begun the day following denervation. Twenty-five adult rats were randomly divided into 3 groups - I = crush/stimulation; II = crush/no stimulation; III = control. In groups I and II, the left sciatic nerve was crushed at the level of the sciatic notch. The left gastrocnemius muscles of animals in group I were stimulated percutaneously at a frequency of 20 Hz for 5 min, 3 times daily. Maximal isometric contractions were elicited. Treatment began the day after surgery and continued until evaluation (8 wks following surgery) when muscle contractile and fatigue characteristics were assessed. Reinnervated muscles (groups I and II), whether stimulated or not, showed similar significant decreases in twitch tension (P_t), maximum rate of twitch and tetanic tension development (Max.dP/dt) as well as increases in twitch time to peak tension (tpt) and $\frac{1}{2}$ relaxation time ($\frac{1}{2}$ rt) when compared with control (III) muscles. The twitch-tetanus ratio, specific muscle tension and fatigue characteristics of the reinnervated muscles did not differ from controls. Stimulated muscles were significantly larger and had a significantly higher mean maximum tetanic tension (P_o) than their unstimulated counterparts.

Group	I	II	III
Muscle wt (g)	2.30 ± .25[a]	1.89 ± .15[ab]	2.99 ± .34
Pt (N)	3.52 ± .26[a]	2.99 ± .01[a]	4.49 ± .99
Po (N)	25.7 ± 1.8	21.1 ± 1.5[ab]	28.1 ± 3.5
tpt (ms)	20.1 ± 1.0[a]	19.6 ± 0.5[a]	17.5 ± 1.5
1/2 rt (ms)	13.1 ± 0.5[a]	13.7 ± 1.4[a]	11.4 ± 0.8
dP/dt (N/ms) Pt	0.27 ± .04[a]	0.22 ± .04[a]	0.41 ± .08
dP/dt (N/ms) Po	0.49 ± .03[a]	0.42 ± .05[ab]	0.71 ± .07

Means ± s.d. [b] denotes sig. diff. ($p < 0.05$) I vs II; [a] denotes sig. diff. ($p < 0.05$) from III.

Thus, direct low frequency electrical stimulation performed from the day following denervation until after reinnervation has a beneficial effect on muscle weight and maximal tetanic tension. These changes occur with no evident alteration in the intrinsic speed or fatigue characteristics of the stimulated muscle.

190.15 DEMYELINATION OF MUSCLE AFFERENT AXONS FOLLOWING VENTRAL RHIZOTOMY IN THE CAT. J.N. Weakly and T.W. Bouldin*. Depts. of Physiology and Pathology, Univ. of North Carolina at Chapel Hill, Chapel Hill, N.C. 27514

Intact myelinated sensory axons arising from the medial gastrocnemius (MG) muscle were examined in teased-fiber preparations following unilateral interruption of ventral spinal roots (L6-S1) supplying the motor innervation to the muscle. Sensory axons appeared normal for up to 1½ mo., after which abnormalities of the myelin sheath became evident. In 12 of 14 cats observed 3-6 mo. after ventral rhizotomy, 18.0% (mean; range, 3.3-89.9%) of sensory axons in the distal 1 cm of the ipsilateral MG nerve (just proximal to the muscle entry zone) showed paranodal and/or segmental demyelination. Less than 1% of control axons in the contralateral MG or ipsilateral sural (cutaneous sensory) nerves showed such abnormalities. The demyelination showed a proximo-distal gradient: 10.9% (mean, range, 2.3-33.0% in 5 cats) of MG sensory axons 3-7 cm proximal to the muscle entry zone were demyelinated.

No myelin-sheath abnormalities were seen in ipsilateral MG or sural axons 3-6 mo. after section of L6-S1 dorsal roots, indicating that demyelination did not result from damage to the central processes of sensory axons.

No abnormalities were observed in intact MG motor axons following removal of L6-S1 dorsal root ganglia and consequent degeneration of sensory axons. Moreover, demyelination was rare (10/270 axons in 3 animals) in the few sural axons which remained after dorsal root ganglionectomy. These results and the delayed onset of the demyelination suggest that the abnormalities in sensory axons following interruption of MG motor axons are not related to the degeneration process per se.

The demyelination of MG sensory axons was observed in animals in which there was no physiological or morphological evidence of regenerating motor axons. When regenerating axons were present, the incidence of demyelinated axons was not increased over values in nerves without regenerating axons. Thus, it appears unlikely that the myelin abnormalities observed in intact axons were induced by signals from nearby regenerating axons.

In summary, severance and degeneration of motor axons in a mixed nerve and consequent muscle inactivation are associated with demyelination of intact sensory axons arising from the muscle. The results raise the possibility that normal axon-Schwann cell relationships depend on the frequency or pattern of sensory discharge or on impulse-independent signals arising from the paralyzed muscle.

190.16 FUNCTIONAL AXON SPROUTING AFTER PARTIAL DENERVATION OF RAT HINDLIMB MUSCLES: EFFECT OF PREVIOUS EXERCISE TRAINING. P. F. Gardiner, J. L. Iadeluca*, and R. Michel*. Department of Physical Education, Université de Montréal, Montréal, Québec, H3C 3J7.

In several mammalian models, partial denervation of skeletal muscles is followed rapidly by sprouting of remaining intact axons which subsequently innervate muscle fibers denervated by the lesion (Pestronk et al., 1980; Brown et al., 1980). Since it has been previously suggested (Gerchman et al., 1975; Roy et al., 1978) that several characteristics of motoneurone metabolism and function may change as a result of chronic exercise training, a study was initiated to describe the effects of previous exercise training on functional axon sprouting in rat hindlimb muscles following partial denervation. Female Sprague-Dawley rats were assigned to control (C), partially denervated (D), or trained followed by partially denervated (T) groups. Animals in (T) were trained daily for 10 weeks on a rodent treadmill (26.8 m/min, 1 hour, 15% incline). In groups (T) and (D), partial denervation of triceps surae was accomplished by removing a 1 mm segment of L4 radicular nerve. In (T) this was performed the day following the final training session. Ten days following the lesion, soleus (SOL) and plantaris (PL) contractile responses to L5 radicular nerve stimulation were recorded in situ at 37°C. In (C) animals, L5 contributed means of 44% (SOL) and 25% (PL) of total muscle twitch tension. Both partially denervated muscles showed evidence of functional sprouting, in that L5-evoked tensions in gps D and T were displaced to the right of C. In PL of gp T, L5-evoked tensions were higher, with only this group possessing cases (17%) where tension exceeded 300 g/g. No comparable trend was evident in SOL. The data suggest that exercise training

191.1 AFFERENT AND EFFERENT CONNECTIONS OF THE INFRAGRANULAR LAYERS OF RAT VISUAL CORTEX. Russell G. Carey and Teresa L. Neal*. Div. of Neurobiol., Barrow Neurol. Inst., Phoenix, AZ 85013.

We have begun an investigation of the laminar organization of the subcortical projections to cortex in the rat and recently reported differential projections to the supragranular and infragranular layers of parietal cortex (Rieck & Carey, 1982). The present report will present our initial results of a similar study in the rat visual cortices and focus on the afferent and efferent projections of the infragranular layers. Discrete electrophoretic injections of conjugated WGA/HRP were made into area 17 and into the medial and lateral parts of area 18 (18M and 18L). Control injections were made in the granular and supragranular layers in each cortical area.

After injections into each area distinct patterns of labeled cells and/or terminal grains were observed in many subcortical regions including the superior colliculus, lateral posterior nucleus (LP), posterior nucleus (Po), the dorsal lateral geniculate (LGN), lateral dorsal nucleus (LD), intralaminar nuclei, and the claustrum. In the superior colliculus only the projection from area 17 terminates in the superficial layers, while area 18L terminates in the intermediate layers and area 18M terminates in a multi-layered pattern in the intermediate and deep layers. Both area 17 and 18L receive a projection from the LGN; however, area 18M does not. Each of the cortical areas maintain reciprocal connections with at least two regions of LP and at least one region of Po and LD. Each of these regions form a column of cells/terminals that course through the thalamus in a rostral-caudal dimension. The projection of area 18M is particularly distinct and terminates heavily in two separate zones within LP that extend nearly throughout the entire rostral-caudal extent of this nucleus. Further, of the three cortical areas only area 18M has dense reciprocal connections with the claustrum. Area 18L appears to receive a moderate projection from the claustrum but does not appear to project to the claustrum.

There is, however, a remarkable similarity in the pattern of labeled cells found within the intralaminar nuclei of the rostral thalamus regardless of which cortical area is injected. These labeled cells form a continous slender band of cells that extend from the central nucleus to the lateral dorsal nucleus and lie in the medullary lamina that courses between the anterior ventral nucleus and the ventral anterior nucleus and surround the anterior medial nucleus. A second set of labeled intralaminar cells can be traced through the medullary lamina, lateral to the medial dorsal nucleus, to the superior central lateral nucleus lateral to the habenula.

191.2 FUNCTIONAL CHARACTERISTICS OF THE VISUAL CORTICAL INPUT TO PARAFLOCCULAR PROJECTION ZONES OF THE BASILAR PONS OF THE RAT. C.E. Adams and D.J. Woodward. Departments of Cell Biology and Physiology, University of Texas Health Science Center, Dallas, TX 75235.

Previous investigations in this laboratory have described a visual cortical input to the paraflocculus via rostral lateral, ventrolateral, and dorsolateral basilar pontine regions. The aim of the present work was to examine functional characteristics of transmission in the visual cortico-basilar pontine component of this overall system. These studies are intended as preliminary to a developmental study of emergence of function in a system which has been shown to exhibit anatomical plasticity during ontogeny (Adams et.al., Neurosci. Abstr. 1981 #61.8).

Single units were recorded in the basilar pons of halothane anesthetized rats. The ipsilateral visual cortex (layer V) and contralateral paraflocculus were stimulated with concentric bipolar electrodes (David Kopf). Paraflocular stimulation provided for antidromic identification of pontine projection cells. Stimulation intensities ranged from 0.060-1.0 mA. Within the visual cortex, the lowest threshold response of pontine units was elicited by stimulation of the 17-18a border zone.

Response latencies of pontine projection cells fell into two groups. One (fast) group responded at latencies of 4-8 msec., while a second group (slow) was characterized by latencies of 8-12 msec. These two subgroups of pontine projection cells also differed in their ability to follow visual cortical stimulation at various frequencies. Cells within the "fast" group were found to follow stimulation frequencies of up to 20 Hz. Cells within the "slow" group exhibited a marked decrease in following capability at 15 Hz or above. Those pontine units which were responsive to visual cortical stimulation but unresponsive to antidromic stimulation exhibited similar dual latency groups and a slow-fast dichotomy was found as well for latencies of widespread pontine units activated by internal capsule stimulation.

These findings suggest that a dual projection system may exist within discrete cortico-pontine pathways of the rat, in this case, the visual cortico-ponto-paraflocular pathway. Similar data has been reported previously for the cat (Allen et.al., 1975b). A study of development of transmission in the visual cortico-ponto-paraflocular pathway is in progress.

191.3 IDENTIFICATION OF VISUAL CORTICAL AREAS THAT PROJECT TO THE SUPERFICIAL OR DEEP LAYERS OF THE SUPERIOR COLLICULUS IN CATS. Richard L. Segal*, Stephen B. Edwards and Robert M. Beckstead, Dept. of Anatomy, Schl. of Med., Univ. of Virginia, Charlottesville VA 22908.

There are at least fourteen visual field representations in the parieto-occipital neocortex of the cat's brain. Many of these areas are known to send axonal projections to the superior colliculus (SC) and to influence the visuomotor function of SC. Mainly because the SC has been considered as an entity, studies to date have provided little data on even the crude segregation of these cortical afferents in the tectal laminae. We have successfully identified which of these cortical areas project to the superficial (visual) or the deep (sensorimotor) portions of SC by placing small deposits of either horseradish peroxidase (HRP, Sigma IX) or wheat germ agglutinin conjugated HRP (WGA-HRP) that are restricted to layers either above or below the stratum opticum. The ipsilateral retrograde labeling of cells (which are always pyramidal cells of layer V) in the various visual cortical areas is not uniform. Whereas areas 17, 18 and 19 contain the most HRP-positive cells after a superficial SC injection, the most numerous cell-labeling after a deep enzyme deposit occurs in the posterior lateral suprasylvian areas (medial, PMLS and lateral, PLLS). Another region that contains a substantial number of HRP-positive cells after a deep tectal enzyme deposit is the newly identified anterior ectosylvian visual area (AEV). Tectal projections from the other visual areas appear to be less preferential in their laminar distributions such that these areas (anterolateral, antermedial, dorsal and ventral lateral suprasylvian areas and area 21a) contain small numbers of labeled cells after any tectal HRP deposit regardless of location or apparent volume. Area 20 appears to totally lack a corticocollicular projection since the enzyme deposits consistently fail to label neurons in this area. The contralateral, cortical cell-labeling is sparser and less extensive than the ipsilateral and located most prominently in PMLS, PLLS, and AEV. That the input from the primary visual cortex (areas 17 and 18) is directed mainly if not exclusively to the superficial layers is consistent with earlier reports. Not previously appreciated, however, is the present observation that whereas several visual areas contribute a sparse input to the deeper collicular layers, this sensorimotor region of the tectum is probably most strongly influenced by the posterior lateral suprasylvian and, perhaps to a lesser degree, by the anterior ectosylvian visual area.

191.4 SOME NOTES ON THE ULTRASTRUCTURE OF THE NUCLEUS OF THE OPTIC TRACT OF THE CAT WITH SPECIAL REFERENCE TO THE CORTICOPRETECTAL PROJECTION. B. Hutchins and J.T. Weber. Tulane University Medical School, New Orleans, La. 70112.

Both the normal morphology of the pretectal nucleus of the optic tract (NTO) and the visual cortical projections to the NTO have been examined at the ultrastructural level in the cat. Cortical terminals were identified with the aid of the anterograde transport of the enzyme tracer horseradish peroxidase (HRP). Large multiple injections of either wheat germ agglutinin-HRP (WGA-HRP) or Sigma Type VI HRP were placed within visual cortical areas 17 and 18 concurrently. Following a 48 hour survival period, the cats were perfused transcardially with 3% glutaraldehyde and 0.5% paraformaldehyde. 100 µm sections were cut on a vibratome with alternate sections being reacted with tetramethylbenzidine (TMB) for the identification of cortical terminals at the light microscopic level. The remaining sections were reacted with diaminobenzidine (DAB) intensified with cobalt chloride. The areas containing cortical terminals in the DAB reacted tissue were identified by direct comparison with the TMB sections. These DAB reacted regions were subsequently dissected and processed for routine electron microscopy. Since there is considerable confusion regarding the ultrastructural appearance of transported HRP, other areas, such as the lateral geniculate nucleus which is known to contain HRP labelled terminals following an injection of the visual cortex, were used for comparison.

Preliminary observations of the normal ultrastructure of the NTO reveal that numerous axonal presynaptic elements are in contact with several cell somas. Occasionally there are axo-axonal synapses, however, the greatest number of synapses are typically axo-dendritic. Of the axo-dendritic synapses, the postsynaptic elements are usually dendritic shafts. No synaptic specialization such as synaptic triads or glomeruli are observed.

Our experimental results provide confirmation at the ultrastructural level, of the controversial projection from the visual cortex to the NTO of the cat. The anterograde transported HRP for both WGA-HRP and the non-conjugated HRP appears consistently as small pleomorphic structures with multiple densities. The HRP labelled presynaptic elements within the NTO contain clear round or pleomorphic vesicles often associated with symmetric synaptic thickenings and pale mitochondria. Our initial observations indicate that the axon terminals range in size from small to large and are only in contact with dendritic processes. These latter dendritic processes also range in size from small to large.

191.5 VISUAL CORTICAL INPUTS TO RETINAL VS NONRETINAL RECIPIENT ZONES OF THE PRETECTAL COMPLEX OF THE CAT. J.T. Weber and B. Hutchins. Department of Anatomy, Tulane University Medical School, New Orleans, La. 70112.

The visual cortical projections to the pretectal complex of the cat were investigated using retrograde tracing methods. Iontophoretic injections of wheat germ agglutinin-horseradish peroxidase (WGA-HRP) were placed within the pretectum and the tissue processed according to the protocol for tetramethylbenzidine incubation (Mesulam, J. Histochem. Cytochem., '78). In all experiments, the retinae were removed and processed for WGA-HRP reaction product. Retinal recipient zones of the pretectal complex were determined on the basis of the presence of WGA-HRP labelled ganglion cells. The cortical maps of Tusa and colleagues (Br. Res., '78; '79; '80) were used to identify specific visual cortical areas.

Injections of WGA-HRP placed within the retinal recipient zones of the pretectum result in the labelling of neurons primarily within visual cortical areas 17, 19, 20A, 20B, PLLS, ALLS and PMLS. The labelled neurons are predominantly pyramidal and are located within layer V. Occasionally small ovoid labelled neurons, located in layer VI, are found within cortical areas 17, 19, 20B and PMLS.

When the injections of WGA-HRP are placed within the non-retinal recipient zones of the pretectum, labelled cells are found primarily within visual cortical areas 17, 18, 19, 20B, 21A, 21B, VLS, DLS, and ALLS. These latter labelled neurons are always located within layer V and are of the pyramidal cell type.

In both types of experiments (i.e., cases in which injections were placed within the retinal and nonretinal recipient zones of the pretectal complex), numerous labelled neurons are also seen within a region on the medial bank of the hemisphere which is ventral to area 17. Graybiel and Berson (M.I.T. Press, '81) have defined this latter region as the ventral splenial cortex.

Our results suggest that at least a part of the nonretinal input zones of the pretectal complex can now be considered visual by virtue of their cortical input. Further, depending upon the injection site, the difference in the areal and laminar distribution of cortical projecting neurons to the pretectum suggests that there are different functional areas within the complex.

191.6 CORTICAL COOLING DEPRESSES VISUAL NEURONAL RESPONSES IN THE TECTORECIPIENT ZONE OF THE CAT'S LATERAL POSTERIOR NUCLEUS. Michael J. Hughes and Leo M. Chalupa. Department of Psychology, University of California, Davis CA 95616.

The medial zone of the cat's lateral posterior nucleus (LPm) receives a strong input from the superior colliculus. Recently, we (Chalupa et al., 1981) documented the visual receptive field properties of LPm neurons in cats maintained on a mixture of nitrous oxide and oxygen, supplemented with small doses of chloralose. In the present study the same type of preparation was employed to determine the degree to which the cortex contributes to the receptive field characteristics of LPm neurons. The LPm region was identified with acetylcholinesterase histochemistry (Graybiel and Berson, 1980), and the visual response of 59 cells within the tectorecipient zone were studied before, during and after cooling of the cortex. The portion of the cortex which was cooled included areas 17, 18, 19 and the LS visual areas. Our main finding is that during cortical cooling the visual responses of 88% of the units in LPm were markedly attenuated or totally abolished. In the cells which responded to stimulus movement as well as to flashed stimuli, the response to both stimulus conditions was equally depressed. The few cells which were unaffected by cortical cooling did not differ in terms of their receptive field properties or loci within LPm from the cells whose responses were depressed. In contrast, cortical cooling had a less pronounced and a more selective influence upon the visual responses of cells isolated in the main laminae of the lateral geniculate nucleus. These observations indicate that in the anesthetized cat the cortical inputs to the tectorecipient zone of the lateral posterior nucleus play a major role in the functional organization of this region. However, at present it is not known if this is due to the direct and/or indirect cortical projections to LPm.

191.7 CORTICAL VISUAL INPUT TO THE MACAQUE PONS: THE TOTAL PROJECTION M. Glickstein, P. Inkpen* J.G. May III* and B. Mercier* (SPON: Charles Elbaum) MRC Unit on Neural Mechanisms of Behaviour 3 Malet Place, London WC1E 7JG U.K.

In previous experiments (Glickstein et.al. J. Comp. Neurol. 190: 209, 1980) we determined the cells of origin of monkey visual cortico-pontine projections by placing small injections of horseradish peroxidase (HRP) in the pontine nuclei and using di-amino benzidine for reacting cortical sections. In the present study we made much larger injections of HRP throughout the entire pontine nuclei and reacted cortical sections with the more sensitive tetra-methyl benzidine technique. We did these experiments to confirm and extend earlier findings about the origins of visual cortico-pontine projections.

The pontine nuclei were first located electro-physiologically after which a micro syringe was directed to the pons through the cerebellum of three monkeys in a horizontal stereotaxic plane. Large volumes (total of 2 to 4 μ litres) of HRP were placed in the pons by a series of multiple small injections. In two cases the injections were unilateral, in a third case, bilateral. HRP thus filled all of the pontine nuclei on one or both sides, and is likely to have been taken up by cortico-bulbar and pyramidal tract as well as cortico-pontine fibers. Confirming earlier work, there was a continuous group of labelled layer V pyramidal cells from the superior temporal to the intraparietal fissures on the dorsolateral aspect of the brain. Medially, this group was continuous at the level of the parieto-occipital notch with another large group of filled cells on the medial face of the hemispheres. This medial group extended from the splenium of the corpus callosum to the rostral bank of the parieto-occipital sulcus. Nearly all of the neurons which were found in these cortical areas, all of which are known to contain visual cells, were located in Brodmann's areas 19 or 7. Few cells were labelled in other cortical visual areas of the occipital or temporal lobe. There is a small projection from the rostral bank of the lunate sulcus. Confirming W. Fries' autoradiographic study (Neurosci. Abst. 7: 762 1981) there is also a small cortico-pontine projection from the striate cortex itself. Filled cells were found on the upper bank of the calcarine fissure with the greatest number in a region representing the extreme periphery of the lower visual fields.

Results suggest that cortico-pontine projections arise principally from those extra striate areas concerned with visual guidance of movement. Other prestriate areas and temporal lobe areas which are involved in visual form learning send far fewer fibers to the pons.

191.8 MORPHOLOGICAL FEATURES OF CORTICO-GENICULATE AXONS IN THE CAT. J. A. Robson. Dept. of Anat., SUNY Upstate Med. Center, Syracuse, NY 13210.

This study examines the morphological features of cortico-geniculate axons in normal adult cats. Horseradish peroxidase was injected into the optic radiations near the dorsal lateral geniculate nucleus in order to densely label both thalamo-cortical relay neurons (retrogradely) and cortico-geniculate axons (anterogradely). Light and electron microscopic techniques were then used to study the distribution, branching patterns and synaptic organization of the labeled axons within the nucleus.

Two types of axons can be seen in this material. Both types enter the nucleus dorsally and are oriented roughly along the "lines of projection." Both also cross laminar borders and can contribute terminal swellings to more than one lamina as well as to interlaminar zones. However the terminal arbors of these two types differ in their branching patterns, the distribution of their terminal swellings, and the synaptic organization of their swellings. The most frequently encountered type of axon is extremely fine and has sporadically distributed synaptic swellings. Some swellings arise as thickenings along otherwise smooth axons. Most, however, are at the ends of short collateral branches. The swellings are uniformly small with smooth surfaces and when examined electron microscopically they resemble the RSD terminals described by Guillery (Z. Zellforsch, 1969): that is, they are small (0.5-1.0 um); have round synaptic vesicles; and contain mitochondria with densely packed cristae. These terminals make asymmetric contacts usually onto small dendrites. In cases where labeled axons contact labeled relay neurons the synapes are onto peripheral dendrites. The second type of axon is far less common. These axons are characterized by their distinctive beaded appearance which is due to many closely spaced synaptic swellings. Swellings on short collateral branches are found occasionally but in general these axons have few branches. The synaptic swellings vary in size and shape. Some are small and resemble the RSD terminals described above. Others are larger (1.0-2.0 um). They have round synaptic vesicles and mitochondria with densely packed cristae and they form asymmetric contacts. However, they are frequently involved in synaptic arrangements involving more than one post-synaptic profile and, in addition to contacting peripheral dendrites, these terminals often contact proximal dendrites and somata. (Supported by NIH grant EY-03490 and the Alfred P. Sloan Foundation)

191.9 QUANTITATIVE ASPECTS OF THE CORTICO-GENICULATE PROJECTION IN THE CAT: A COMPARISON OF AREA 17 AND 18. H.C. Hughes. Department of Psychology, Dartmouth College, Hanover, N.H. 03755.

Cortico-geniculate projections are known to originate exclusively from layer VI of the visual cortex. In order to provide a more detailed description of these projections from areas 17 and 18, a quantitative analysis was performed. The data base for this analysis came from one cat which received a unilateral injection of horse-radish peroxidase (HRP) in the laminar LGN. The injection, which was delivered under hydrolic pressure via a recording micropipette, was clearly confined to the dorsal LGN and involved all the geniculate laminae. The topographic representation of the injection site extended from approximately 1° to 10° eccentricity near the horizontal meridian.

Sections (50μ) through area 17 and 18 were treated with O-dianisidine and counter-stained with thionine. Only sections containing the greatest density of retrograde labelling were selected for quantitative study. These densely labelled areas were reconstructed using camera lucida. The analysis included counts of labelled and unlabelled cells, and measurements of the soma diameters of labelled and unlabelled cells.

The results of this analysis lead to the following conclusions. 1) Cortico-geniculate cells tend to be concentrated in a deeper sub-lamina of layer VI (in layer VIb, cf. O'Leary, JCN 75, 1941). 2) In agreement with other reports, virtually all cortico-geniculate cells could easily be classified as pyramidal cells. 3) Area 17 contributes more than twice the number of cortico-geniculate cells than area 18 (average of 58 cells/200μ wide column versus 20 cells/200μ in area 18.) 4) Despite these numerical differences, areas 17 and 18 contain equivalent percentages of cortico-geniculate cells in layer VI. This is due to the fact that layer VI is wider and more densely populated in area 17. 5) The distribution of soma diameters of geniculo-cortical cells was equivalent in both areas (mean dia = 13.57μ for area 17 and 13.43μ for area 18). 6) Cortico-geniculate cells tend to be larger than other cells in layer VI (ave. dia. of unlabelled cells = 9.3μ).

These results lead to the expectation that area 17 exerts a more powerful influence over the LGN than area 18, but that it does so as a simple consequence of the greater number of cells in layer VI of the striate cortex, rather than by differences in the apportionment of layer VI cells within these areas.

191.10 EFFECTS OF CRYOBLOCKADE OF VISUAL CORTEX ON RETINAL GANGLION CELL OUTPUT. S. Molotchnikoff, F. Tremblay* and F. Lepore. Dept of Biological Sciences, Université de Montréal, Montréal, Québec, Canada.

Does the visual cortex affect the neuronal firing of retinal ganglion cells? The question has been raised, but as yet it has not been answered. To test this hypothesis the visual cortex was inactivated by a reversible cold block in urethane anesthetized and paralyzed rats (N = 30). Action potentials in response to a short flash (1 H_z) were recorded from ganglion cell axons at the level of the optic tract prior to, during and following cortical blockade. Antidromic spikes evoked by applying an electrical pulse to the lateral geniculate nucleus confirmed the axonal origin of the recordings. In initial experiments (N = 10) we recorded field potentials to examine how the waveform was modified. Flash presentation elicited two positive peaks with implicit times of 50 and 80 msec respectively. The magnitude of the second wave was generally 50% that of the first. As the visual cortex was cooled, a significant increase in latencies and amplitude of the second peak was observed. The cortical blockade therefore appears to influence exclusively the late response.

In a second series of experiments single unit recordings were carried out. Results indicated that the visual cortex was strongly involved in modulating the discharge pattern of retinal ganglion cells. In 30% of the cells, there was an increase in bursting pattern and a concurrent occurrence of additional short and long latency discharges. Data were also analyzed in terms of inter-spike interval histograms (IH). This analysis showed that the distribution of retinal efferent impulses was under the control of a cortico-retinal feed-back. Since the B-waves of the ERG were not modified (double pulse technique) it was assumed that the retinopetal fibers act at the level of the inner plexiform layer.

The data support the notion that in mammals the visual cortex and the retina have reciprocal relationships.

191.11 HETEROTOPIC CALLOSAL PROJECTIONS AND THE DEVELOPMENT OF CALLOSAL AFFERENTS IN RAT VISUAL CORTEX, Michael Miller and Brent A. Vogt. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

Complete section of the corpus callosum in hooded rats causes axons to degenerate in contralateral visual cortex. Only the lateral one third of area 17 receives callosal afferents, whereas degeneration in secondary visual areas is limited to patches or strips of cortex. After a large injection of horseradish peroxidase involving much of area 17, retrogradely filled neurons are identified throughout contralateral area 17 and areas 18a, 18b, and 29d. Thus, primary visual cortex is connected to the contralateral hemisphere by homotopic (lateral area 17 to lateral area 17) and heterotopic (e.g. medial area 17 to lateral area 17) projections.

Homotopic callosal projections from lateral area 17 arise from neurons distributed evenly in layers II/III, IV, and V (24-34% in layer V) and terminate in a bilaminar pattern; layers I-III and layer V. In contrast, callosal connections which are heterotopic by cortical region are also heterotopic by layer. Heterotopic connections arise primarily from cells located in layer V (60-80%). and terminate in a bilaminar or unilaminar pattern. An example of the unilaminar termination pattern is the projection of layer V neurons in area 18b to supragranular layers in lateral area 17. Secondary visual cortex forms a network of heterotopic callosal connections, however, unlike area 17 only areas which receive callosal afferents seem to contain callosal projection neurons.

During development, before cortical areas can be distinguished on cytoarchitectonic criteria (first postnatal week), all of the posterior neocortex receives projections via the corpus callosum. These fibers cross the callosum and wait in the intermediate zone before entering the newly segregated cortical laminae on postnatal day 3. The paring down of callosal axons into the mature organization seems to occur first in area 17 (by day 9) and then in secondary visual cortex (day 12).

Heterotopic connections may be involved in forming binocular visual receptive fields in the rat, and possibly in driving units with large, non-oriented receptive fields described in layer V of rodent primary visual cortex. These callosal connections appear to be established before the eyes of rat pups open at the end of the second postnatal week. Supported by grants EY 07054, NS 07016, and NS 18745.

191.12 EFFECT OF HEAD TILT ON THE VISUAL EVOKED RESPONSE TO A MOVING LINE, S. Reinis, R.H. Lahue*, D.S. Weiss*, J.P. Landolt and K.E. Money*. Dept. of Psychol., Univ. of Waterloo, Waterloo, Ont. and DCIEM, Downsview, Ont. Canada.

In previous work, we reported that the basic characteristics of most visual cortical complex cells changed when the head of the experimental animal was tilted to the right and to the left (Soc. Neurosci. Abstr. 6: 578, 1980; 7: 174-175, 1981). In this paper, we present data showing that the cortical visual evoked responses to a moving line change as well. Cats with surface recording electrodes implanted over the left and right visual cortices were immobilized with Pavulon® and a line was projected onto a screen placed 81 cm in front of their eyes. The line was moved at 30°/s, at angles of 0°, 45°, 90°, 135°, 180°, 225°, 270°, 315° and 360°, relative to the horizontal. The response to individual angles differed in the number and amplitude of the evoked waves at the onset of the stimulus, in the degree of synchronization during the movement of the stimulus across the screen, and in the number and amplitude of the waves following termination of the stimulus. Tilting the head by 45° to the right or to the left altered the character of the response in relation to the subjective horizontal. Also, an intravenous injection of deuterium oxide (4 ml/kg) altered the response to the moving line. These data further indicate that stimuli from the vestibular system and/or from the neck proprioceptors contribute to the analysis of the visual stimulus by the visual cortex. Supported by DCIEM Research Contract 97711-0-5951/8SE80-00185.

191.13 VISUAL CORTICAL CELL CHANGES FOLLOWING THE ADMINISTRATION OF NITROUS OXIDE, R.H. Lahue*, S. Reinis, D.S. Weiss*, J.P. Landolt and K.E. Money*. Dept. of Psych., Univ. of Waterloo, Waterloo, Ont. and DCIEM, Downsview, Ont. Canada.

Single cell activity in the central nervous system of cats has often been recorded in animals anaesthetized with nitrous oxide (N_2O). In these studies, it was tacitly assumed that the anaesthetic did not change the normal function of the cells that were studied. In order to assess the suitability of this anaesthetic for this type of research, we compared the characteristics of individual complex cells in the visual cortex before and during the administration of 25% N_2O - 75% oxygen mixture. (Animals were previously prepared under anaesthesia for microelectrode recording stereotaxically according to procedures reported earlier in Ann. N.Y. Acad. Sci. 374: 262-273, 1981.) We found that, in more than 80% of the cells, after the system was saturated with nitrous oxide, the optimal length of the moving line stimulus eliciting the response in the complex cell changes together with the area of its receptive field. The spontaneous intertrial activity of the cells changed as well. The directional preference and localization of the receptive fields did not change. In about 10% of the cells, the receptive field disappeared completely and re-appeared within 30 minutes after the N_2O was discontinued. These data indicate that N_2O modifies the characteristics of visual cortical cells in several ways, and, therefore, as an anaesthetic, it is not suitable for electrophysiological studies of this type. Supported by DCIEM Research Contract 97711-0-5951/8SE80-00185.

191.14 MONOCULAR LOSS, BINOCULAR MAINTENANCE OF PERCEPTION IN GANZFELD. S. J. Bolanowski, Jr. and Robert W. Doty. Center for Brain Research, University of Rochester Medical Center, Rochester, New York 14642.

We have found that when human observers (n=20) monocularly view a uniformly lit, contourless visual field, a Ganzfeld, a dramatic loss of perception or "blankout" begins after about 12 sec. During a 1-min period of steady viewing the "blankout" may subside briefly, sometimes in association with blinking or eye movements, but is present for a substantial proportion of the viewing time. Most surprisingly, when the Ganzfeld is viewed binocularly, this loss of visual perception does not occur, even when viewed for over 3 min.! The "blankout" process was reported by every observer to resemble a perceptual curtain, originating nasally and being drawn naso-temporally across the visual field. All subjects also described the persistence of perception in an area of the far temporal visual field into which "blankout" did not seem to project. This area corresponds to the "temporal crescent", the region within the visual field which is seen with only one eye. In addition, preliminary experiments suggest that the consensual pupillary reflex follows the "blankout" process, slight dilatation occurring during the periods of perceptual loss.

We have presented our dark adapted subjects colored and achromatic Ganzfelden (matched for equal luminance, 0 N.D. = 16.2± 1.2 cd/m^2 and variable in 1.0 log unit intensity steps) pseudorandomly to the right, left and both eyes. Each observer was asked to signal the onset of "blankout" and its duration by pressing a response key. On average, only negligible differences in response latency occurred between eyes and only small differences (<3 sec) were found among stimulus hues. The intensity of a monocularly presented Ganzfeld did not significantly affect latency for "blankout", suggesting that the mechanism mediating "blankout" onset operates across photopic, mesopic and scotopic levels, although the percentage of time in "blankout" does decrease with increasing intensity. Additional experiments in which binocular Ganzfelden were presented, constant intensity to one eye and variable intensity to the other, show that "blankout" does not occur if disparities in light intensity to the two eyes are within 2 log units.

These results indicate that central as opposed to retinal processes play a major role in mediating "blankout" and that the mechanism responsible for this phenomenon operates with a processing time of about 12 sec regardless of intensity or hue. Persistence of perception in the "temporal crescent" and under binocular viewing conditions are consistent with our hypothesis that the "blankout" arises from processes similar to those underlying binocular rivalry. Single unit activity has been observed in striate cortex of unanesthetized macaques which is concordant with these psychophysical effects (Kayama et al. J. Neurophysiol. 42: 1495, 1979).

192.1 MORPHOLOGY OF STELLATE CELLS IN LAYER IV OF CAT AREA 17. M.D.Kay*, J.F.Dashe*, W.H.Mullikin*, and T.L.Davis, Dept. Anat., School of Medicine, Univ. of Penn., Phila., Pa. 19104.

Reconstruction of synaptic patterns on somas and proximal dendrites of neurons in layer IVab suggested a diversity of cell types (Davis and Sterling, J.Comp.Neur.: 188,1979) . These results were supported by the finding of four classes of Gaba-accumulating neuron in layer IVab (Hamos et al, Soc. Neurosci. Abstr.:7,1981). It is not known, however, whether there is a corresponding diversity in the three-dimensional morphology of these neurons. We have begun to identify distinct morphological types of neurons in layer IV of the adult cat by obtaining Golgi-like filling of cells via intracellular or extracellular depositions of horseradish peroxidase. Filled cells were drawn using a camera-lucida and a 100X objective and the following morphological features noted: soma shape and size, number of primary dendritic branches, pattern and extent of dendritic arborization, and dendritic spine density.

So far, we have recognized eight morphological types of stellate cell in layer IV. Two types were aspinous, one having a large soma (21um) and smooth dendrites, the other having a medium soma (12 um) and varicose dendrites. Six types were spinous. Two of these had a small soma (9 um) one being sparsely branched and the other bushy. Three types had a medium, oval soma (11-12 um) but differed in the richness of their dendritic arborizations and spine densities. The eighth type had a fusiform soma (22 X 7 um) oriented tangentially to the pia and spiny dendrites extending longitudinally from the soma.

Since there is evidence that a given cell type in layer IV may represent but a small fraction of the total population (Solnick et al, Soc. Neurosci. Abstr.:7,1981) we anticipate finding additional morphological types. An important step will be to determine whether a cell type characterized by a distinctive morphology also has a distinctive pattern of synaptic input.

192.2 THE NUMBER OF NEURONS IN THE DIFFERENT LAMINAE OF THE BINOCULAR AND MONOCULAR REGIONS OF AREA 17 IN THE CAT. C. Beaulieu*, M. Colonnier and J. Thibodeau*. Department of Anatomy, Laval University, Quebec, Qué. G1K 7P4.

The number of neurons in individual laminae of area 17 was determined for both binocular and monocular regions in the left hemisphere of six cats. For each region, portions unaffected by curvature were chosen, i.e., portions where the pial surface was relatively straight and in which the columns of cells and radial bundles of axons were strictly parallel to each other. The numerical density was determined for each lamina by using the method of size-frequency distribution, applied to neuronal nuclei (Weibel '69, Int. Rev. Cytol: 26, 266). Measurements of the area and of the maximum diameter of the nuclei were made with a graphic tablet on photographs (X1200) of 1 um epon sections stained with methylene blue. The number of neurons under 1 mm^2 of cortical surface and standard deviation are given in the following table, for both regions. The figures have been corrected for tissue shrinkage.

	BINO	MONO	p<
I	1242 ± 602	1299 ± 227	-
II	7634 ± 1192	6762 ± 971	.05
IIIA	8780 ± 1595	6833 ± 1758	.05
IIIB	10111 ± 1895	8780 ± 2602	-
IVA	12685 ± 2505	10104 ± 1650	.05
IVB	13796 ± 2487	12477 ± 1576	-
V	5915 ± 219	4312 ± 731	.001
VIA	15175 ± 1169	10513 ± 974	.001
VIB	2178 ± 678	1508 ± 586	.05
TOTAL	77516 ± 6160	62588 ± 5038	.005

p was calculated with a Mann-Whitney U test.

Note that the number of neurons under 1 mm^2 of cortical surface is significantly less in the monocular region for the total cortical thickness and that this is due to significant differences in layers II, IIIA, IVA and especially to changes in layers V and VIA. This suggests that in the binocular region there are possibly additional interneurons specifically related to binocular interaction, or that there is a greater number of neurons projecting to other cortical and to subcortical areas. There is little data in the literature to support one or the other alternative.

Supported by grant MT3735 of the MRC of Canada.

192.3 STIMULUS SPECIFICITY OF BINOCULAR NEURONS IN THE CAT'S STRIATE CORTEX: A QUANTITATIVE COMPARISON OF RIGHT AND LEFT EYES B.C. Skottun* and R.D. Freeman, School of Optometry, University of California, Berkeley, CA 94720

A large majority (about 80%) of neurons in the cat's visual cortex can be driven by either eye. However, the relative strength of the input from the two eyes (ocular dominance) varies from cell to cell. We have asked whether the stimulus specificity for each eye is matched over this range of ocular dominance or varies in some systematic manner with relative interocular response strength.

Cats were prepared using standard procedures for extracellular recordings in the visual cortex (Area 17). After initial receptive field mapping with manually controlled stimuli, single cells were studied quantitatively using sinusoidal gratings presented on a specially designed TV monitor. Cells were classified as simple or complex according to the modulation of the response. The degree of modulation for each of the two eyes was generally highly correlated. On the other hand, for 9 out of 92 cells, modulation was different enough to suggest a "simple" category for one eye and "complex" for the other. Orientation preference was relatively similar in the two eyes, except for a small offset that we attribute to the bilateral interocular intortion of paralysed cats. Orientation selectivity (1/2 width at 1/2 height) was also highly similar (correlation r=0.73), although there was a slight tendency for tuning in the dominant eye to be broader. For spatial frequency, the two eyes were also well matched: optimal spatial frequencies and tuning bandwidth correlated with coefficients of r=0.92 and r=0.76 respectively. Finally, contrast-response functions varied from those that appeared linear (response vs log contrast) to those that exhibited saturation at low contrast levels. In most cases the shapes of the contrast-response functions were similar for the two eyes and the main difference was the slopes of the curves.

We conclude that the stimulus specificity for binocular striate cells is generally well matched for the left and right eyes and that this accordance is typically not dependent on ocular dominance. The results show these cells to be well suited for functions such as stereopsis.

192.4 THE COMPLETE PATTERN OF OCULAR DOMINANCE STRIPES IN MACAQUE STRIATE CORTEX. M. Connolly*, S. Le Vay, and D.C. Van Essen. Biology Div., Caltech, Pasadena, CA and Neurobiology Dept., Harvard Medical School, Boston, MA.

Previous studies of the configuration of ocular dominance columns in macaque striate cortex have demonstrated an array of alternating left-eye/right-eye stripes over the operculum and in the roof of the calcarine fissure. We have examined the complete pattern of stripes in a single hemisphere, using autoradiography after transneuronal transport of ^{3}H-proline from the left eye. Recordings were made from several regions of cortex prior to perfusion in order to establish the approximate layout of the visual field representation in the cortex. Two-dimensional maps of the left striate cortex were prepared independently by two techniques: 1) the manual reconstruction technique of Van Essen and Maunsell (JCN 191: 255, 1980), and 2) a computerized method, involving the generation of a complete three-dimensional model of the pattern of columns, photography of this model at a variety of angles (to provide face-on views of all parts of striate cortex), and the assembly of a two-dimensional montage from these photographs.

The two reconstructed versions were similar in overall size and shape of striate cortex and in the layout of ocular dominance stripes, although there were numerous differences in detail. As expected from previous studies, the stripes intersected the striate boundary approximately at right angles. In the region of peripheral representation they tended to run orthogonal to the horizontal meridian representation, but they were not strictly parallel to iso-eccentricity contours. There were two unexpected findings: 1) The periodicity of the stripes was not constant. The width of a left- plus right-eye pair ranged from less than 0.5 mm to more than 2.0 mm, a more than four-fold range. The broadest spacings occured along the vertical meridian and the narrowest in the far periphery. 2) Beyond about 20 degrees eccentricity the columns for the contralateral eye were often two to three times wider than those for the ipsilateral eye, resembling the pattern found with monocular deprivation. This contralateral bias in the periphery was confirmed in the opposite hemsphere and in the brains of two other monkeys. Lastly, the representation of the optic disc was about twice as long as it was wide, consistent with the possibility of a significant anisotropy in the visual representation within layer IVc of striate cortex.

192.5 CHOLECYSTOKININ-LIKE IMMUNOREACTIVE NEURONS IN RAT NEOCORTEX, Alan Peters and Michael Miller. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA., 02118

The distribution and form of cholecystokinin (CCK) immunoreactive neurons within the posterior pole of the rat cerebral hemisphere were studied using the immunoperoxidase technique. The antiserum obtained from Immuno Nuclear Corp. was directed against the carboxy terminal octapeptide of CCK.

There are CCK-positive neurons throughout the cortex, but they are most common in the supragranular layers. Comparing the shapes of these CCK-positive neurons with the forms of neurons revealed by Golgi impregnation, it is concluded that CCK-positive neurons are of three types. There are layer II/III bipolar cells which have very narrow and vertically elongated dendritic trees, layer I neurons which are both horizontal and multipolar, and other non-pyramidal cells. These other non-pyramidal cells can have either multipolar or bitufted dendritic trees, and although they are most common in layer II/III some are present in infragranular layers. The interpretation that all of the CCK-positive neurons are non-pyramidal is supported by electron microscopic study of some of these neurons, for all of those examined have both symmetric and asymmetric synapses on their perikarya, a characteristic feature of non-pyramidal neurons. It is also apparent in thin sections that the horseradish peroxidase reaction product forms a granular deposit throughout the cytoplasm and nucleoplasm, and shows no predilection for any particular type of organelle. By light microscopy three types of CCK-positive axons are apparent. These are vertically oriented axons believed to arise from the bipolar neurons, a plexus in layer II/III considered to arise from the multipolar and bitufted cells, and a plexus of coarse axons in layers V and VI derived from an unknown course.

Previous Golgi-electron microscopic studies have shown that axons of bipolar cells form asymmetric synapses, suggesting that they are excitatory neurons. In contrast, bitufted and multipolar neurons similar to the ones visualized by the CCK antibody have been shown to have axons forming symmetric synapses and to contain glutamic acid decarboxylase. Thus, although iontophoretically applied CCK excites cortical neurons, it appears to be present in some neurons which are excitatory and others which are inhibitory in function. (Supported by NIH grants NS 07016 and EY 07054).

192.6 TEMPORAL SUMMATION IN THE CAT VISUAL CORTEX. J. Duysens, G.A. Orban, J. Cremieux* and H. Maes*. Lab. Neuro- en Psychofysiologie, Katholieke Universiteit te Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

154 cells from the LGN and from areas 17 and 18 of paralyzed and N_2O anesthetized cats were examined in a search for the population of visual cortical cells responsible for the temporal low-pass filtering taking place at the cortex (Brenner et al., Soc. Neurosci. Abstr., 7:175, 1981). A stationary light bar was flashed over the most sensitive region of the receptive field for variable periods of time in a randomized order. The units were classified according to their qualitatively and quantitatively measured responses to moving or stationary presented stimuli (velocity-response curve and response plane).

It was found that the firing rate of the ON-responses of LGN cells (n=14) did not depend on the stimulus duration. In contrast, 30% of all cortical cells were seen either to increase their ON firing rate by more than 100% when progressing from the shortest (12.5 msec) to the longest (3200 msec) ON stimulation duration, or more frequently, to have a threshold ON duration, i.e. requiring a minimum ON duration which is longer than the shortest ON duration used. These cells, which apparently perform a temporal integration of LGN input, were more numerous in area 17 than in area 18, had mostly non-overlapping subregions (S or HS cells) and generally preferred low velocities. A combined velocity profile of all these cells showed a maximum response at the lowest velocity tested (0.5 deg.sec^{-1}) and a decrease to 50% of this maximum at 13 deg.sec^{-1}.

Cells that showed no sign of modulation of the ON response in function of changes in ON duration could be classified into two groups. In one group the ON response was either very weak or completely absent at all ON durations (34%). Some of these units, especially the S or HS cells, were found to have a threshold OFF duration when tested with variable OFF durations. The other group (36%) exhibited clear ON responses, independent of ON stimulus duration (as did units in the LGN). Units in this group belonged mostly to the C family (complex-like) and their average velocity profile showed very little velocity selectivity. It is concluded that for areas 17 and 18, the slow cells of the S family (simple-like cell) can be identified as the cell population specialized at temporally integrating visual signals coming from the LGN (Orban et al., this volume).

192.7 THE CORTICO-CLAUSTRAL LOOP CONTRIBUTES TO END-INHIBITION OF NEURONS IN AREA 17 OF THE CAT. Helen Sherk* and Simon LeVay (Spon: T. Sejnowski). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

We have recently described the response properties of neurons in the cat's visual claustrum, which is reciprocally connected with area 17 and other visual cortical areas (Sherk and LeVay, J. Neurosci. 1:993). They are orientation-selective, binocular and non-directional. A striking feature is their preference for very long bars or edges.

To determine the role of the return projection from the claustrum to visual cortex, we have recorded from neurons in area 17 after unilateral ablation of the visual claustrum with kainic acid. 462 cells were studied in area 17 in the deafferented hemispheres of six cats, and 636 cells in the intact hemispheres of these cats and in two other controls. All response properties were assessed qualitatively.

Properties studied included receptive field position and size, cell type (simple, standard complex, special complex, etc.), preferred orientation, sharpness of orientation tuning, direction selectivity, length summation, end-inhibition, preferred bar thickness, edge responses, ocular dominance, responsiveness and spontaneous activity. Tracks and marking lesions were reconstructed and each cell was assigned to a layer (1-3,4,5 or 6).

Only end-inhibition was affected by the claustral lesions. This was reduced on the side of the lesion in every cat. Of 442 cells in layers 1-3 and 4 of the control hemispheres, 42.5% showed moderate, strong or total end-inhibition, whereas only 19.3% of cells in the experimental hemispheres did so. Total end-inhibition was particularly rare on the side of the lesion: it was seen in only 13 cells (4.4%), compared with 78 cells (17.6%) on the control side.

The results suggest that the claustral loop makes a major contribution to the end-inhibition seen in visual cortex. Hubel and Wiesel (1965) originally suggested that cortical end-inhibition might be generated by inhibitory neurons that responded selectively to very long stimuli, and claustral cells fit this description. Since end-inhibition was not completely lost after claustral lesions, it is probable that intracortical mechanisms also play a role. (Supported by NIH EY-R01-1960).

192.8 STRIATE CORTEX: CONTRAST ADAPTATION INDUCTION AND RECOVERY. D.G. Albrecht, D.B. Hamilton*, and S.B. Farrar*. Dept. of Psychology, University of Texas, Austin, Texas 78712.

Prolonged viewing of a high contrast grating pattern produces a variety of perceptual effects; among others, the grating seems to gradually fade although not totally dissappear and the detection threshold increases. Converging psychophysical and physiological evidence suggests that striate cells play a fundamental role in these effects, presumably reflecting the underlying contrast gain control in the cortex.

We have been investigating the contrast adaptation properties of striate cells using stimuli similar to the psychophysical experiments to facilitate a comparative analysis. After first measuring the contrast response function (along with the receptive field plot, and spatial and temporal frequency tuning), we performed the following adaptation experiment. Each cell was stimulated by drifting its optimal spatial-temporal frequency grating pattern across the receptive field. The temporal sequence of events consisted of four intervals. (1) During the first (Pre-Adapt) 30 sec interval, the contrast was set to produce 5-10% of the cell's maximum response, to index pre-adapt sensitivity. (2) The next 120 sec consisted of a no-pattern rest interval. (3) After the rest, the contrast was set to produce the maximum response and was left on (Adapt) for 30 sec. (4) The adaptation was immediately followed (Post-Adapt) by a low contrast grating, presented for 30 sec at the pre-adapt contrast to index post-adapt sensitivity. This entire sequence of events was repeated from 4 to 8 times (with a 5 min wait between each repetition) to increase the reliability of the estimate.

Examination of the pattern of results (across cells) during the high contrast adaptation interval reveals several qualitatively different types of effects. Some cells produce their maximum response as soon as the high contrast grating is turned on whereas others actually take some period of time (1 to 20 sec) to reach their maximum. Once the maximum response of the cell is achieved, the response rate gradually declines, although there is a great deal of variation from cell to cell in the rate of induction: some cells reduce their response by 90% (to an asymptotic plateau) during the first 10 sec of adapt while others reduce their response by only 10% over the full 30 sec of adapt. (It may prove useful to characterize cells along a sustained transient dimension.) After the prolonged adaptation, contrast sensitivity was lower during the post-adapt interval, although once again comparing the rate of recovery across cells reveals a great deal of variation: some cells reach a recovery plateau in five sec while others still show strong adaptation after 30 sec.

192.9 TWO CONTRAST MECHANISMS REVEALED BY PATTERN VISUAL EVOKED RESPONSE IN THE ALERT MONKEY. M.Mackeben and K.Nakayama
Smith-Kettlewell Inst.of Visual Sciences, San Francisco, CA 94115

Steady state visual evoked potential (SSVEP) recordings were made from two macaque monkeys while they fixated and attended to a fixation light. Electrodes were implanted in the bone over pre- and post-lunate visual cortical areas (V4 and V1). The contrast of a sinusoidally counter-phase modulated gratings was varied between 1 and 82%. The responses were tested at a wide range of spatial and temporal frequencies. A contrast function run consisted of 78 trials (3 sec duration, 6 repetitions for each of 13 contrast values).

More than half of the 143 runs recorded in both monkeys yielded log contrast (C) vs. amplitude functions with two distinct linear limbs. While there was some overlap in the slope ranges (.3 to 1.5 μV/dB versus .6 to 4.0 μV/dB), for any one function the slope of the high C limb was always steeper than that of the low C limb. The appearance of the high C response was always accompanied by a change of slope in the phase characteristic, which indicates two different underlying mechanisms. The two limbs of the C function could be direct or indirect reflections of input from the parvo- and magnocellular layers of the LGN, which have been shown to have different contrast sensitivities (Kaplan and Shapley, J.Physiol., in press).

Extrapolating the low C limb to zero response amplitude gave us the theoretical thresholds, which were typically below 5% and above 10% for the low and high C limbs, respectively. Like in the human (Campbell and Maffei, 1970), calculating the contrast sensitivity from these values resulted in a good match with the psychophysically measured contrast sensitivity function of macaque monkeys (DeValois et al., 1974). Extrapolating the high C limb, however, did not produce such a match. In addition, we found that the extrapolated thresholds could vary with the temporal frequency of stimulus modulation. The narrow spatial frequency tuning reported earlier (Nakayama and Mackeben, Brain Res. 193, 1980) was found to be present only at high stimulus contrasts (Nakayama and Mackeben, Vis.Res., in press).

(Supported by NIH grant numbers 1R01 EY 03598, 2 EY 01186, and BRSG 08-S7RR05566B, and by the Smith-Kettlewell Eye Research Foundation).

192.10 RADIAL OR PINWHEEL MOTION EVOKES A STRIPED PATTERN OF ACTIVITY ON THE VISUAL CORTEX SURFACE. M. Cynader and C. Shaw. Dept.'s Psychol. & Physiol., Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.

Staring at the center of a rotating logarithmic spiral produces a powerful sensation of motion toward or away from the observer. The geometric basis of this motion in depth has been considered by Gibson, Koenderink, Regan & Beverley, and others. Here we use the C^{14}-deoxyglucose (2DG) method to explore the pattern of activity evoked in the visual cortex by stimulation with radial motion (both inward and outward) and compare it with that evoked by having animals fixate the center of a pinwheel (rotating clockwise and counterclockwise). This latter stimulus has no depth component associated with its motion.

Paralyzed 3-4 month old kittens viewed the spiral or pinwheel patterns binocularly for 30-40 minutes after I.V. administration of 100 μ Ci/kg of 2DG. After perfusion, visual cortex on one side was removed and carefully flattened between glass slides in order to provide a large surface over which 2DG uptake could be measured. The cortex was sectioned parallel to the surface (tangential sections). The sections were used to expose X-ray film. The other hemisphere was cut sagittally.

Both tangential and sagittal sections revealed that viewing a moving spiral pattern evoked a regular pattern of alternating stripes on the visual cortex surface. The stripes have a period of about 1200 μ and width of 600 μ. The stripes run medial to lateral, approximately perpendicular to the border between areas 17 and 18. The pattern of cortical 2DG uptake evoked by viewing a rotating pinwheel is similar to that evoked by radial motion. Again one observes a regular pattern of stripes running medio-lateral across large expanses of the cortex.

We compared the organization of these patterns of evoked glucose consumption with those resulting from stimulation of (1) one eye alone with stimuli of varied orientations, directions, and velocities, and (2) both eyes with a stimulus pattern of one orientation only, moving in both directions with varied velocity. Both monocular viewing and viewing of contours of one orientation evoked substantial inhomogeneities in the pattern of 2DG uptake on the cortical surface. In the case of monocular exposure, patches formed on the cortical surface without substantial tendency for elongated bands. With stimulation at one orientation, the pattern of activity was more regular, with zones of locally parallel bands, but the overall clarity and consistency of the pattern evoked by radial or pinwheel motion was absent.

The remarkably clear and simple patterns of cortical activity evoked by the spiral or pinwheel patterns suggest that the information they convey is an important feature of cortical processing mechanisms.

192.11 PROCESSING CAPABILITY OF THE PRIMARY VISUAL CORTEX AND POSSIBLE PHYSIOLOGICAL BASIS FOR AN APPARENT MOTION ILLUSION. Gordon L. Shaw, Physics Dept. U. of Calif., Irvine, CA 92717, Patricia C. Rinaldi, Div. of Neurosurgery, U. of Calif., Irvine and John C. Pearson*, Physics Dept., U. of Calif., Irvine.

The primary visual cortex is known to process stimuli in a given part of the visual field such that divisions of the cortical column into orientation and ocular dominance minicolumns are present. Applying a model incorporating both the Hebb learning hypothesis and a Mountcastle-like organizational structure to the visual cortex, we predicted that the processing capabilities of the column involve dynamic interactions among minicolumns and are much greater than presently documented. In particular, processing of rotational stimuli in area 17 was suggested by the model. Motivated by this, a psychophysics experiment was performed which demonstrated a spatial-temporal filling in process in apparent motion. We have now presented this "human illusion" to cats. Stimuli were presented to cats maintained under N_2O and flaxidel. Extracellular microelectrodes were placed in area 17 with the aid of stereotaxic coordinates and isolated single units were observed. The center of the visual field and optimum bar orientation were determined for the monitored neuron, and then repeated time sequences corresponding to "clockwise" and to "counterclockwise rotations" of the stimuli were presented, both with and without the optimum stimulus orientation. Some representative, preliminary data are presented. Although the "filling in" process has not as yet been clearly observed, a number of striking features have been found. For example: a) We observed dramatic sharpening as well as greatly increased peak firing response when the optimum stimulus is left out of the sequence (for one cell, the width of the post-stimulus histogram at the time of the second bar presentation decreased from 30 ms to less than 4 ms). b) Some cells show two activity peaks or even four peaks of large size when only one bar orientation is shown. However, when a time sequence of other orientations is shown, then some of these peaks are suppressed. c) We noted a striking change in firing activity dependent soley on the change of the sense of presentation from "clockwise" to "counterclockwise". We have found no simple explanation (such as "lateral inhibition") which will explain these phenomena.

192.12 RESPONSE OF CAT'S GENICULATE AND VISUAL CORTICAL CELLS TO STROBOSCOPICALLY ILLUMINATED MOVING LIGHT BARS. G.A. Orban, J. Cremieux*, J. Duysens and H. Maes*. Lab.Neuro- en Psychofysiologie, Katholieke Universiteit te Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

Single unit recordings were made in area 17 and LGN of anesthetized and paralyzed cats. Both for LGN and cortical cells velocity-response curves in opposite directions of motion, response planes and duration-response curves were measured using computer driven stimuli and a randomized multihistogram technique (Orban et al., J. Neurophysiol., 45:1043, 1981; Duysens et al., Brain Res., 231:279, 293, 1982). The most sensitive region of the RF was taken as the middle of the movement path of a stroboscopically illuminated moving light bar. Stimulation was arranged in such way that a flash always fell in the middle of the movement path. A test with 10 velocities and 6 frequencies (50, 29, 15, 8, 4, 2 Hz) shows the changes in velocity characteristics and directionality with strobe frequency. For some cells, we measured the critical fusion frequency (CFF) with a test with 12 frequencies and 2 velocities (the best low velocity and a high velocity). Inspection of the PSTHs in response to stroboscopically illuminated moving light bars allowed us to classify the cells in two groups : a) cells responding to single flashes, b) cells responding only when there are several flashes falling in the field.

The first type was found both in the cortex and LGN and had periodically modulated responses at frequencies up to 15 Hz. These cells had an optimum response for an intermediate frequency (between 4 to 15 Hz), often showing a decrease in response when fusion occurred. At low frequencies the apparent size of the RF was enlarged. All LGN cells belonged to this type which in the cortex was chiefly related to cell types other than S family.

The second type which was exclusively found in the cortex, had no periodically modulated response and showed a decrease of response with decreasing frequency and increasing velocity. This type belonged mostly to the S family, showed strong preference for low velocities and had a duration threshold (Duysens et al., this volume).

192.13 TWO DISTINCT COMPONENTS OF THE HUMAN VISUAL EVOKED RESPONSE. Erich E. Sutter. Smith-Kettlewell Institute of Visual Sciences, San Francisco, CA 94115.

The human pattern evoked response was analyzed by means of a new technique of nonlinear systems analysis (Sutter, 1982). The contrast reversal of gratings was modulated with specially designed binary sequences and the second order response characteristic was extracted by means of cross-correlation. This approach has the advantage over a more conventional analysis of the pattern response that it permits the identification of cascading subsystems if the nonlinearyty is of zero memory type. On the basis of this assumption two functionally independent components have been isolated which can be compared in their characteristics to the well known response properties of visual cortical neurons in animals.

The subjects were stimulated with reversing gratings (3c/deg) covering areas of the visual field extending from 2^{o} to 10^{o}. The second order nonlinear analysis suggests a cascade of three subsystems: A linear filter at the input stage, a nonlinearity with negligible memory followed by another linear filter at the output stage. On the basis of this model two components can be differentiated by means of the properties of these subsystems and their dependence on the stimulated retinal area:

- Component 1 shows more transient behaviour at the input stage than component 2.
- Both components show similar response structure of the output stage. The response latency of Component 1, however is 20ms shorter than that of component 2.
- Component 1 dominates the large field response whereas both components are well represented when the stimulus is restricted to the foveal and peri-foveal area.

193.1 LACK OF DORSAL LATERAL GENICULATE INPUT TO EXTRASTRIATE CORTICAL AREAS MT AND DORSAL VISUAL 2 IN THE MACAQUE MONKEY. Gregg P. Standage and Louis A. Benevento. P.O. Box 6998, University of Illinois College of Medicine, Chicago, Ill. 60680.

Our recent anterograde autoradiographic tracing studies (e.g, J. Comp. Neurol. 203: 455, 1981) on the projections of the dorsal lateral geniculate nucleus (DLG) to extrastriate (or prestriate) visual associaton cortex have indicated that there are certain functional cortical areas which do not receive DLG input. In order to further clarify the organization of these geniculo-prestriate pathways we performed a series of retrograde tracing experiments with the use of the particularly sensitive wheat germ conjugated horseradish peroxidase (W-HRP). 0.015 µl injections were made in a number of extrastriate areas. Identification of the particular area injected was made by single unit recordings and postmortem histology comprised of both axon and nissl stains and by the presence of retrograde labelled cells in certain layers of striate cortex. The limits of the DLG projection to extrastriate cortex as described in the anterograde experiments seemed to be confirmed. W-HRP filled cells were found in both the DLG and pulvinar when the injections were confined to area 19 and anterior area 18 located on the visible surfaces of the preoccipital gyrus. When the injection was confined to MT (or the movement area of the superior temporal sulcus), no labelled cells were found in the DLG despite a dense number in the pulvinar. In particular it was a crescent shaped region of the dorsal portion of the inferior pulvinar (PI) which contained a dense number of W-HRP filled cells. This region of PI forms a special subdivision which extends into the adjacent,overlying lateral pulvinar. The connections between this region of the pulvinar and MT are reciprocal. Thus, MT would receive its main subcortical input from this specialized zone in the pulvinar and none from the DLG. The present experiments further show that the dorsal portion of visual area 2, in the posteror bank of the lunate sulcus, does not receive a DLG input. This is in contrast to more ventral portions of visual area 2 indicating that visual 2 may be organized differently throughout its extent. When the present results are taken together with those from the anterograde experiments and compared to the findings in the cat, it seems that there are differences in the DLG and extrageniculate thalamocortical organization in the two species. This includes the types of information which are carried by the geniculo-extrastriate pathways, which in the monkey seem to arise, in large part, from the superior colliculus and cortex. (Supported by N.I.H. Grant EY 2940).

193.2 TOPOGRAPHICAL ORGANIZATION OF THALAMIC PROJECTIONS TO PRESTRIATE VISUAL CORTICAL AREAS IN THE MARMOSET (C. JACCHUS). N.L. Hayes and O.-D. Creutzfeldt*. Dept. of Anatomy, Univ. of Mississippi Medical Center, Jackson, MS 39216 and Dept. of Neurobiology, Max Planck Institute for Biophysical Chemistry, Gottingen, FRG.

The visually responsive cortical area anterior to VII in new world primates (VIII) has been subdivided into at least three regions which differ to a large extent in their interconnections with the thalamus in general and with the subnuclei of the pulvinar in particular (Lin and Kaas, 1980). The extent to which thalamic neurons with projections to different regions of VIII are topographically segregated was investigated in Callithrix with a double retrograde tracer study using HRP and ^{3}H-apo-HRP as simultaneously distinguishable tracers. In the same preparations it was possible 1) to explore the possible existence of thalamic neurons with collateral projections to more than one subdivision of VIII, 2) to examine the topographical relationship between populations of thalamic neurons projecting to different areas of VIII, and 3) to explore the pattern by which the three dimensional thalamic nuclei are mapped onto the two dimensional cortical layer IV within and across cytoarchitectonic boundaries.

In each animal, pairs of injections (one HRP, one ^{3}H-apo-HRP) were made in each hemisphere, according to two experimental designs: 1) to combine injections in different subdivisions of VIII and 2) to generate a series of injections along variously oriented lines along the cortex (e.g., parallel to the superior temporal sulcus, parallel to the 17/18 border).

Cortical injections involving layer IV labeled populations of thalamic neurons which in the pulvinar were arranged in dorsomedial to ventrolaterally oriented "slabs" which extended uninterrupted across the borders between the medial, lateral and inferior subdivisions of the pulvinar. In general, a progression from medio-dorsal to ventro-lateral of injection sites on the cortex was paralleled by a progression from rostral to caudal of labeled neurons in the pulvinar-LP complex; a similar progression from anterior to posterior on the cortex was paralleled by a progression from medial to lateral in the thalamus. Three-dimensional reconstruction revealed that the shape of the slabs is quite irregular and that slabs labeled from different cortical areas are closely apposed and interdigitate; however, in no case were double-labeled neurons observed in the pulvinar-LP complex. In the intralaminar nuclei, cells labeled from different cortical injection sites were intermingled with no apparent topographical segregation; among this population several double-labeled cells were observed.

193.3 NORADRENERGIC INNERVATION OF VISUAL SYSTEM STRUCTURES IN MONKEY. J.H. Morrison, S.L. Foote, and F.E. Bloom. The Salk Institute, La Jolla, CA 92037.

A remarkably large proportion of the primate cortex may be considered visual in function. The various visual cortices have been sub-divided and characterized by their cytoarchitectonic properties, patterns of connectivity with thalamic nuclei and other cortical regions, and the visual maps and response properties of their resident neurons. Two major visual thalamo-cortical systems exist: 1) a geniculo-striate projection which terminates heavily in layer IV of primary visual cortex (area 17), and 2) a pulvinar-extrastriate projection which terminates more widely in areas 18 and 19 in the occipital lobe and several visual regions in the inferior temporal gyrus. Given the proposed involvement of the noradrenergic system in cortical sensory processes and attentional mechanisms, it was of interest to determine whether the NA innervation of the pulvinar-extrastriate system differed fundamentally from that of the geniculo-striate system. Using antisera directed against human dopamine ß-hydroxylase, we have characterized the noradrenergic innervation of several of these cortical and sub-cortical visual areas in the squirrel monkey. We recently reported that the noradrenergic innervation of primary visual cortex (area 17) is sparse and exhibits a unique laminar pattern of innervation: layer IV contains very few noradrenrgic fibers, and yet is densely innervated by serotonergic fibers (Morrison et al, PNAS, 1982). Precisely at the 17-18 border, this laminar pattern shifts such that layer IV contains more NA fibers and fewer serotonergic fibers in area 18 than in 17 and the overall density of NA fibers is higher in area 18 than in 17. The pattern of noradrenergic innervation within the visual thalamic nuclei is consistent with that in the visual cortex: the pulvinar is densely innervated by NA fibers, whereas the lateral geniculate nucleus is virtually devoid of NA innervation.

Thus, it appears that in squirrel monkey the pulvinar-extrastriate system is more densely innervated than the geniculo-striate system. The lack of NA innervation of lateral geniculate in the primate is of particular importance given that this thalamic nucleus receives a moderately dense NA innervation in the rat. These and other observations (Morrison et al, Brain Research Bulletin, 1982) suggest that coincident with the extensive phylogenetic development and differentiation of neocortex in the primate there is a parallel elaboration and differentiation of the ascending noradrenergic projection. 193.4 CORTICAL PROJECTIONS OF AREA MT IN THE MACAQUE. Leslie G. Ungerleider, Robert Desimone and Mortimer Mishkin. Lab. of Neuropsychology, NIMH, Bethesda, MD 20205.

Area MT is a visuotopically organized area within the caudal superior temporal sulcus characterized by heavy myelination and a high proportion of directionally selective cells. Although it is known that MT receives direct input from both striate cortex and V2, the cortical projections of MT are unknown. To examine these projections and their topographic organization, tritiated amino acids were injected into selected MT sites in five cynomolgus monkeys, and the brains were processed for autoradiography. Visual field representations of the injection sites, which were identified electrophysiologically, included the center of gaze and positions ranging from 8° to 25° in the upper and lower visual fields.

MT was found to project to at least two zones within the superior temporal sulcus (STS) and two in the intraparietal sulcus (IPS), each zone having a distinctive myeloarchitecture. Within STS, one zone is located in the posterior bank of the sulcus, bordering the lower visual field representation of MT. Only MT sites representing the lower visual field and center of gaze project to this zone. As in MT, the central visual field is represented ventrally, and the peripheral field, dorsally.

A second projection zone in STS is a crescent-shaped area in the floor and anterior bank of the sulcus, which surrounds MT anteriorly and medially and lies partly within cytoarchitectonic area PG. Projections to this zone are highly convergent, with only a suggestion of topography. Although the zone is myeloarchitecturally uniform, a separate, discrete patch of label consistently seen at the posteromedial tip of the crescent suggests that this segment may be a separate projection area.

Within IPS, a posterior projection zone begins in the annectent gyrus caudally and extends along the fundus of the posterior third of IPS. We previously found a direct striate projection to this zone, which may correspond to Zeki's area V3A. The other zone in IPS lies in the anterior two-thirds of the sulcus, extending from the fundus onto the posterior bank; this zone is located in area PG. Both projection zones, anterior and posterior, receive convergent input from all parts of MT, including upper and lower visual field representations.

In addition to the forward projections of MT, which span all cortical layers and often appear as columns, there are backward projections to striate cortex and V2. Projections to both areas are laminar, terminating in layers I and VI and also in IVa in striate cortex.

The results suggest that MT provides a major link through which visual information is relayed forward from striate and prestriate areas into the parietal lobe.

193.5 ANTAGONISTIC DIRECTION SPECIFIC MECHANISMS IN AREA MT IN THE OWL MONKEY. Francis Miezin*, EveLynn McGuinness* and John Allman. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

It is well known that most Area MT neurons are strongly selective for the direction of stimulus motion. We wished to know how MT neurons behaved when stimuli were presented against moving textured backgrounds such as occur commonly in natural stimulus conditions. We have explored the receptive field structure and directionally selective mechanisms in MT using a newly developed microprocessor-based video display that can present simultaneously bars and random dot patterns moving in different directions. In nearly all MT neurons tested, when a bar moving in the cell's preferred direction is presented against a background of random dots moving in the same direction, the response is greatly reduced relative to the response to the bar moving on a background of stationary random dots. When the background is moved in the opposite direction, the response to bar stimulation in the preferred direction is either less inhibited or in some cases strongly facilitated. The effects of background stimulation generally could be obtained by stimuli restricted to the neuron's conventionally defined receptive field but were stronger when background stimulation extended into the surrounding visual field.

In a related set of experiments we sought to map the extent and nature of the antagonistic mechanism in the surround. By continuously driving MT neurons by stimulating the conventionally defined receptive field and by simultaneously moving fields of random dots in the surrounding visual field, we have found that MT neurons are affected by stimuli presented at considerable distances from the conventional receptive field. These surround effects are often directionally selective with the preferred direction of the center being the direction of maxiumum inhibition in the surround. This antagonistic direction-selective mechanism provides an ongoing comparison between movement occurring locally in the visual field and more global retinal image movements such as would occur during eye and head movement or bodily transport. Thus they may be related to the mechanisms that accomplish the perceptual stability of the visual world during eye, head and body movements as well as to perceptual mechanisms in figure-ground discrimination. 193.6 INDICATIONS OF FUNCTIONAL RELATIONSHIP BETWEEN PREFRONTAL AND INFEROTEMPORAL CORTEX. J.M. Fuster, J.P. Jervey* and R.H. Bauer. Dept. of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024.

In the monkey, local cooling of either prefrontal or inferotemporal cortex--but not parietal cortex--induces a deficit in performance of a visual memory task (delayed matching to sample). During performance of that task, prefrontal and inferotemporal cells have been seen to undergo characteristic changes of activity correlated with the presence and short-term retention of the memorandum (a color). Anatomical studies demonstrate reciprocal connections between prefrontal and inferotemporal areas. The present study explores the possible functional significance of that reciprocal connectivity in visual memory performance.

Rhesus monkeys were trained in delayed matching to sample with two colors, red and green. One of the colors, the sample, was presented at the start of each trial; after a delay (16-20 sec), both colors were presented side by side and the animal had to choose the one matching the sample. The sample color and its location at the time of choice were changed randomly between trials. In some of the animals, bilateral cooling probes were implanted on dorsolateral prefrontal cortex, covering the sulcus principalis and the area directly above and below; micropositioner pedestals were implanted over inferotemporal cortex. The other animals were prepared in the reverse manner: with cooling probes over a large portion of the inferotemporal convexity and micropositioner pedestals over prefrontal cortex.

Single-unit discharge was recorded with microelectrodes during task performance. Prefrontal cooling was tested on 60 inferotemporal units (most in middle temporal gyrus and lower bank of superior temporal sulcus) and inferotemporal cooling was tested on 49 prefrontal units (most in inferior convexity and lower bank of sulcus principalis). The bilateral cooling of either cortical region induced the following changes in the other: 1. Changes in the spontaneous firing of many units; increases of firing predominated over decreases. 2. Both augmentations and diminutions of unit reaction to the sample color. 3. Attenuation of the differences in the reaction of some units to the two sample colors. 4. Attenuation of some sample-related differences in unit activity during the retention period. In no case were color-dependent differences increased by cooling.

The results indicate that the two cortical regions investigated are normally subject to mutual influences, probably by way of the reciprocal connections that link them. The effects of cooling on performance and on unit activity suggest that those mutual influences subserve visual discrimination and short-term memory.

193.7 A NEW VISUAL AREA IN THE PARIETO-OCCIPITAL SULCUS OF THE MACAQUE. E. Covey, Div. Otolaryngology, Duke Univ. Med. Ctr., Durham, N.C. 27710, R. Gattass*, Dept. Neurobiologia, Instituto de Biofisicia, UFRJ, Rio de Janeiro RJ, Brazil and C.G. Gross, Dept. Psychology, Princeton Univ., Princeton, NJ 08540.

We report a previously undescribed cortical visual area in the macaque which we provisionally call Area PO. It lies on the anterior bank of the parieto-occipital sulcus and adjacent portions of the precuneate gyrus and the anterior bank of the intraparietal sulcus. Posteriorly and medially, Area PO borders Area V2 along the floor of the parieto-occipital sulcus. Dorsally and anteriorly, it borders Area 7. The ventrolateral border of Area PO lies in the floor of the intraparietal sulcus, perhaps adjacent to Area 3A of Zeki. Area PO is distinguishable from each of the surrounding areas in fiber stained sections and in neuronal response properties such as receptive field size. On the basis of anatomical studies of Ungerleider et al., it does not appear to receive projections from either V1 or V2.

The representation of the visual field in Area PO was mapped with multi-unit electrodes in five M. fascicularis. The animals were immobilized and anesthetized and in each animal 20-40 electrode penetrations were typically made over several recording sessions. Area PO contains a representation of the entire contralateral visual field. Its visuotopic organization appears more complex than that of visual areas V1, V2 or MT. The representation of the upper field is located medially and that of the lower field is located laterally. The representation of the horizontal meridian lies along the ventromedial border of Area PO (within the parieto-occipital sulcus) and splits to extend up the anterior bank of the parieto-occipital sulcus. One portion of the representation of the vertical meridian lies along the ventrolateral border (within the intraparietal sulcus). Another portion lies along the dorsal and anterior border (within the parieto-occipital sulcus and on the medial surface). The representation of the periphery of the visual field is relatively large as compared to that in V1, V2 or MT. This finding and the medial location of Area PO suggests that it may be homologous to Area M in the owl monkey described by Allman and Kaas.

193.8 A PHYSIOLOGICAL COMPARISON OF THE LATERAL PULVINAR AND AREA 7 IN THE BEHAVING MACAQUE. Steven E. Petersen*, David Lee Robinson, and William Keys*. Lab. Sensorimotor Research, National Eye Inst., Bethesda, MD 20205.

Anatomical data show that a thalamocortical pathway exists between a subdivision of the lateral pulvinar and area 7 of the cerebral cortex. We recorded single cells from awake, trained rhesus monkeys, and compared the functional properties of cells in area 7 and the region of the lateral pulvinar reported to project to area 7. The neurons of these two areas share several passive visual properties:

(1) crude, if any, retinotopic organization.
(2) relatively long mean latencies (pulvinar = 88 ms; area 7 = 96 ms).
(3) very broad latency ranges (pulvinar = 36-224 ms; area 7 = 40-236 ms).
(4) large receptive fields.
(5) a lack of orientation selectivity.
(6) a preference for large stimuli, although frequently the receptive fields in the pulvinar have antagonistic surrounds or internal inhibition, a property rare for area 7 neurons.
(7) a large number of pan-directional cells, although there is a higher incidence of directional selectivity in our sample of lateral pulvinar cells than in area 7 cells.

About one-third of the visually-responsive cells in the lateral pulvinar, and one-half of the area 7 cells have an enhanced response when the discharge to a stimulus which is the target for a saccadic eye movement is compared to the activity when fixation is maintained. We have not determined if these cells ot the lateral pulvinar also give an enhanced response when the animal attends to a peripheral stimulus but does not saccade to the light, a characteristic of many cells in area 7.

Some cells in the lateral pulvinar discharge in relation to saccadic eye movements. These cells respond during and/or after eye movements with excitatory, inhibitory or combined inhibitory-excitatory responses. Such activity is frequently present with saccadic eye movements made spontaneously in total darkness. We have not identified cells in area 7 that are active with spontaneous saccades nor are there published reports of such activity.

Our data suggest that the ascending pathway from this region of the lateral pulvinar may be an important source of visual input to area 7. However, these experiments imply that the non-visual activity present in the lateral pulvinar probably influences other areas of the brain.

193.9 PULVINAR INFLUENCES ON GENICULO-CORTICAL ACTIVITY IN THE CAT. A. L. Sica and W. S. Battersby*. Lab. of Neurophysiology, Queens College, CUNY, NY,NY 10467. The effects of pulvinar stimulation on the response in area 17 to a shock in the lateral geniculate nucleus were investigated with both gross and microelectrodes. Data were obtained from 27 male cats prepared for acute study, and maintained on a mixture of N_2O and O_2 during experimentation. The gross recordings show that activation of either the ipsilateral or contralateral pulvinar increases the amplitude of the cortical response; the magnitude and time course of this response enhancement were similar following stimulation of either pulvinar. These effects were abolished by a "functional block" (topical application of KCl) of the medial to posterior-medial suprasylvian gyrus. Extracellular recordings in area 17 show that stimulation of the ipsilateral pulvinar influences the suppression period and afterdischarge of the unit response to a geniculate shock. These effects varied as a function of interstimulus interval; i.e., suppression was shortened and the afterdischarge increased at brief delays, in contrast, suppression was prolonged and the afterdischarge decreased at longer delays. The close similarity of these effects with those found with stimulation of the midbrain reticular formation (Alter & Battersby, 1973) suggests that the pulvinar and suprasylvian gyrus may form a thalamo-cortical pathway for relaying activity ascending bilaterally from midbrain structures to striate cortex. Recordings of pulvinar units revealed both functional afferents from the contralateral superior colliculus, and the presence of inhibitory influences descending from the suprasylvian gyrus. In conclusion, our results support a relay function for the pulvinar, and suggest that it may participate in the extensive changes in cortical activity, e.g., arousal, observed with midbrain stimulation.

Alter, I., and Battersby, W. S. Temporal dispersion of unit discharges in visual cortex due to MRF-LGB interaction. The Physiologist, 1973, 16 (3),

193.10 CHANGES IN THE VISUAL EVOKED RESPONSE FOLLOWING Ep ABLATION. R.J. Sinclair* and S. Horenstein. Dept. of Neurology, Saint Louis University, Saint Louis, Missouri 63104.

Changes in the early portions of the visual evoked response (VER) and some later components occurred after unilateral ablation of the cortex of the posterior ectosylvian region in cats trained in a visual discrimination task.

Five adult cats had been trained in a Y-maze equipped with mechanical dippers to deliver food reinforcement and photostimulators to deliver an intense short duration flash. The Y-maze consisted of three long alleys connected by a central atrium. The mechanical dippers were placed at the end of the alley opposite the atrium. The animals were trained to leave the alley where they had just obtained food and move to either of the remaining two for the next reinforcement. Silver ball electrodes were implanted subdurally over both suprasylvian visual areas (Vss), with a frontal sinus reference electrode. EEG signals were delivered by telemetry to an FM receiver and then fed into an electroencephalograph connected to a PDP11 computer for averaging. During the preoperative testing period, evoked responses (ER) for 512 milliseconds were obtained following left and right unilateral and bilateral and homologous double simultaneous stimulation (DSS). Three experimental animals then received unilateral lesions of area Ep. One of the controls received an unilateral AI lesion and the other one of AII. Postoperative testing repeated the preoperative procedure.

Pre- and post-operative data were analyzed statistically for latency and amplitude changes in the major components of the ER for two groups: two Ep subjects with neglect, and two AI/AII subjects without neglect. The third Ep subject had ipsilateral Vss degeneration under the electrode site and no neglect, and was excluded from analysis. The data disclosed different patterns of change for the neglect compared to the non-neglect subjects, suggesting that those associated with neglect resulted specifically from the lesion of area Ep. In the neglect group the amplitude of the earliest ER component was affected. This possibly represents the first stimulus registration within the cortex. Since this followed a cortical lesion, a corticofugal mechanism which modulates incoming sensory information at lower levels of the sensory pathways is inferred. Significant changes were found in the latency of early components Po/No, conventionally associated with a comparator process for identifying novel or motivationally significant stimuli. Changes in latency of some later components may indicate a possible "chain reaction" following from disturbances in early stages of sensory processing.

193.11 EXTRAPOLATION OF MOTION PATH IN HUMAN VISUAL PERCEPTION V.S. Ramachandran* and S.M. Anstis* (SPON: J. Brockes) School of Social Sciences, University of California, Irvine, CA 92717

Moving objects have two properties. First, they persevere in their state of uniform motion along a straight line (Newton's first law). Second, all points on the surface of a moving object tend to move in the same direction with identical velocities.

Since the visual system has evolved to process information from the physical world, one might expect similar principles for the perception of moving objects. Using dynamic, ambiguous apparent motion displays we have found that a point which moves in one direction will tend to be perceived as continuing in its motion in that direction.

We used a matrix of four dots forming the four corners of a diamond subtending 1°. Pairs at opposite corners flashed in alternation (SOA=100 msec) gave rise to ambiguous motion that fluctuated between two oblique directions, either NW-SE or NE-SW. If the four dots were embedded in two long parallel oblique rows of dots flashed in apparent motion sequence, a "visual momentum" effect strongly favoured the perception of motion along this oblique direction--i.e., collinear to the flashing sequence. This might be regarded as a perceptual equivalent of Newton's law.

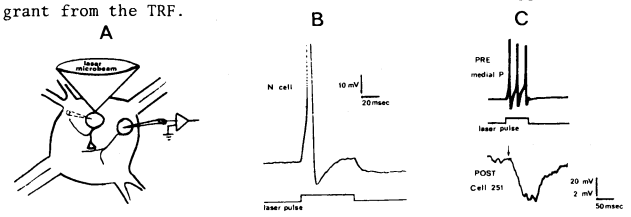
In our second experiment we alternated two uncorrelated random-dot patterns (subtending 5°) in a continuous cycle (SOA=75 msec). Surprisingly, we did not see random incoherent motion. For any given small area the dots tended to move in identical directions giving rise to 'cohesive motion'; but the actual direction fluctuated from moment to moment. To one margin of the display we then added a vertical strip of dots 1° wide which was correlated in alternate frames and moved left-right unambiguously. The entire display now "adhered" to the strip and moved synchronously with it. We conclude that when viewing ambiguous dynamic noise there is a tendency to see spatially uniform motion.

The results of these two experiments are complementary and they suggest that there are at least two properties of moving physical objects that translate into specific rules which are incorporated into the visual system. One of these is the fact that moving objects usually don't change direction abruptly. The second rule is that when a surface moves all points on it generally move in perfect synchrony. These redundancies of moving objects in nature are captured by the brain's motion detecting networks and manifest as a spontaneous tendency for seeing uniform unidirectional motion when confronted with ambiguous dynamic dot displays.

It would be interesting to look for physiological correlates of these contextual effects both in striate and extrastriate areas where direction specific cells are found.

194.1 A NOVEL TOOL FOR EVALUATION OF NEURONAL NETWORKS: LOCALIZATION OF PRESYNAPTIC NEURONS BY LASER PHOTOSTIMULATION OF INVERTEBRATE CNS NEURONS. I.C. Farber* and A. Grinvald. (SPON: V.I. Teichberg).Dept. of Neurobiology, Weizmann Inst. of Science, Rehovot, Israel.

A microelectrode search for the neurons which are presynaptically connected to a given cell may be difficult even in a simple central nervous system if many pairs of cells have to be impaled, or if the neurons are small, or for other technical reasons. An attractive solution is to be able to stimulate all presynaptic neurons with laser light; thus a rapid scanning of a laser microbeam over each of the individual neurons may be used to find the neurons which will synaptically affect a given electrically-monitored neuron. We discovered a photostimulation probe designated RGA-30. After the dye molecules bind to neuronal membrane, illumination of a stained neuron with a laser microbeam induces a rapid depolarization and subsequent firing which activates its synaptic endings. Our experiments were carried out on the segmental ganglia of the leech Hirudo medicinalis and on the supraesophageal ganglion of the giant barnacle. The ganglion was stained with a normal saline containing 20 uM of the probe (a thiobarbituric acid pyrazolone oxonol dye) for 20 min. A 50 mW He/Ne laser was used with appropriate optics to form a 1 u spot of light. This microbeam could be positioned precisely on the desired membrane spot by adjusting the microscope focus under visual control. Fig. 1A illustrates the experimental arrangement. Figure 1B shows the instantaneous depolarization of the N sensory cell with a pulse of light. This cell could be restimulated 7 times. Figure 1C shows that the medial sensory P cell which was photostimulated (top two traces) is indeed presynaptically connected to cell 251 by an inhibitory synapse. Using this dye it was possible to photostimulate all the 14 sensory cells, the Retzius cells and 10 different pairs of motoneurons. In each case the membrane potential quickly recovered within 1-5 mV, but the membrane resistance dropped to a value of 70-50% of the original. Preliminary TTX and ionic substitution experiments suggest that a significant part of the depolarization is due to light activation of the sodium channels. Supported by a grant from the TRF.



194.2 TWO PHASES OF SPIKE FREQUENCY ADAPTATION IN APLYSIA NEURONS HAVE DIFFERENT SENSITIVITY TO CALCIUM INFLUX. D. V. Lewis* and W. A. Wilson. (SPON: W. Anderson) Neurophysiology Lab, Dept. of Pediatrics, Duke Univ. Med. Sch., Durham, N.C. 27710.

When the silent cell, R2, of Aplysia californica is depolarized by a 60 sec constant current stimulus, two phases of spike frequency adaptation are observed. There is an initial rapid phase lasting from 5 to 10 sec during which the firing frequency falls to between 10 and 40% of the initial rate, followed by a slow adaptation phase characterized by a very gradual steady decline in firing rate (Zbicz, K. and Wilson, W. A. J. Pharmacol. Exp. Ther. 217:222-227, 1981). When intracellular free calcium is monitored by Arsenaso III spectrophotometry, calcium rises abruptly during the first 10 sec of the 60 sec spike train and then shows little change during the remaining 50 sec. Thus the most rapid rise in calcium occurs simultaneously with the rapid adaptation phase. Removal of extracellular calcium, intracellular EGTA, or blockade of calcium influx with calcium blockers each reduces or eliminates the fast phase of adaptation. Although intracellular calcium changes are not detectable the firing rate shows a slow steady decline during the entire 60 sec stimulus.

We conclude that the rapid adaptation phase is strongly dependant upon calcium influx and probably mediated by a calcium activated potassium conductance (Lewis, D. V. and Wilson, W. A. J. Neurophysiol. In press). The slow phase of adaptation is far less dependant upon calcium influx although the possibility remains that it may depend upon a intracellular calcium pool not detected by Arsenazo III.

194.3 ENHANCEMENT OF SLOW OUTWARD CURRENT BY PENTOBARBITAL IS INDEPENDENT OF Ca^{++} ENTRY. G.J. Evans*, J.R. Huguenard, W.A. Wilson, and D.V. Lewis* (SPON: A. Roses). V.A. Epilepsy Center and Departments of Pharmacology and Pediatrics, Duke University, Durham, NC 27710.

It has been demonstrated that pentobarbital (PB) enhances slow spike frequency adaptation (SFA) and the slow outward K^+ current (SOC) associated with slow SFA in the Aplysia neurons R2 and LP1. Since Ca is known to enter these cells during a spike train or during a 60 second depolarization in voltage clamp (VC), it was suspected that SOC might represent the Ca activated K^+ conductance (gK_{Ca}) described by Meech et al. (Comp. Biochem. Physiol., 1972, 42: 493). We therefore have examined the relative importance of depolarization vs. Ca entry for SOC and slow SFA. Compartmental analysis of the tail currents that follow a VC depolarization or a spike train consistently reveals two components. Since this analysis is a sensitive index of changes in SOC (Evans, et al. Soc. Neurosci. Abst. 1981: 810), it was used in this study.

100μM PB had no effect on the amplitude or kinetics of tail currents that followed Ca entry accompanied by little or no depolarization (i.e. intracellular Ca injection or a 2 second spike train). This was true even if [Ca]i was elevated for as long as 60 seconds by eliciting 1 controlled spike per second from VC. In addition, the Ca mediated hyperpolarization induced by white light in these cells was unaffected by PB.

When Ca entry was prevented by replacement of [Ca]o with a Ca channel blocker (1mM La) or addition of 3mM EGTA to Ca-free sea water, the tail currents following a short spike train or prolonged slow spiking were abolished, indicating their dependence on Ca entry. PB was unable to restore them. With Ca entry restricted, the SOC and the tail current were reduced, but PB remained effective in enhancing SOC.

These data indicate that PB does not act on the K_{Ca} channel. Also, SOC and its enhancement by PB do not depend on Ca entry. Yet [Ca]i was shown to play a key role in SOC. Intracellular injection of EGTA, in conjunction with 0 Ca - 3mM EGTA sea water, reduced the SOC tail current and abolished the post spike tail current.

It would appear that while SOC is sensitive to the level of [Ca]i, barbiturates are able to enhance SOC without increasing Ca entry or affecting the interaction of the K_{Ca} channel with Ca. We hypothesize that SOC may depend on the activation of K_{Ca} channels by Ca from an alternate source, i.e. the voltage sensitive release of Ca from intracellular stores. Furthermore, we propose that barbiturates enhance SFA and SOC by increasing depolarization induced intracellular Ca release.

Supported by NIH Grant 15212 and the VA Hospital, Durham, NC.

194.4 DIPHENYLBARBITURIC ACID: A SPECIFICALLY ANTICONVULSANT BARBITURATE? J.R. Huguenard and W.A. Wilson, V.A. Epilepsy Center and Departments of Pharmacology and Medicine, Duke University Medical Center, Durham, NC 27705.

Phenobarbital (PB) is widely used as an anticonvulsant agent. Unfortunately, the neurodepressant effects of PB are not totally selective in supressing the excess neuronal activity associated with seizures, and often cause some drowsiness.

Diphenylbarbituric acid (DPB) is a compound structurally similar to two commonly used anticonvulsants, phenobarbital and diphenylhydantoin. DPB has been demonstrated to be effective in preventing seizures induced by pentelenetetrazol and electroshock (Raines, et. al., JPET 186: 315-22, 1973). Although DPB was effective in these anticonvulsant drug screens, it showed relatively little neurotoxicity.

A proposed anticonvulsant mechanism of the barbiturates is the enhancement of a voltage sensitive slow outward current (SOC) which serves to supress repetitive firing during a prolonged stimulation. The supression of repetitive firing with time is termed spike frequency adaptation (SFA). SFA occurs in two phases, an initial rapid decrement in firing rate complete within 10 seconds followed by a much slower phase which occurs over a period of minutes. Barbiturates enhance SOC and the slow phase of SFA (Zbicz and Wilson, JPET 217: 222-27, 1981).

We were interested in determining whether barbiturate enhancement of SOC and adaptation correlated with anticonvulsant effects rather than sedative effects. We therefore wanted to determine whether DPB, a specifically anticonvulsant, non-sedative barbiturate would demonstrate an enhancement of the SOC and adaptation.

Giant neurons from Aplysia californica were used in this study. Prolonged voltage clamp pulses to near spike threshold were used to elicit SOC. The amount of SOC was quantitated by analyzing the tail currents (obtained upon return to holding potential) which could be represented by the sum of two exponential decay processes (components).

DPB enhanced the slow phase of adaptation, the SOC and the amplitude of the slow component of tail. Increasing effects on these parameters were seen in the concentration range of 1 to 20μM. This range is at least an order of magnitude lower than the effective range for phenobarbital.

It appears, therefore, that enhancement of SOC and adaptation by barbiturates is not involved in the mechanism of producing neurotoxicity (drowsiness), but rather that this enhancement may correlate with the anticonvulsant action of these drugs.

194.5 SEROTONIN ENHANCES INWARD CURRENT IN APLYSIA, Terry C. Pellmar. Laboratory of Preclinical Studies, NIAAA, Rockville, MD 20852.

Iontophoretic application of serotonin (5HT) to RB cells of Aplysia abdominal ganglion produces a voltage-dependent inward current at potentials more depolarized than -40mV. In a previous study (Pellmar & Carpenter, J. Neurophysiol. 44 1980, 423), ion substitution experiments and application of channel blocking agents suggested calcium as the current-carrying ion. To further test this proposed mechanism, the following series of experiments were performed. In the presence of 30mM tetraethylammonium (TEA), 4mM 4-aminopyridine (4-AP) and 10mM barium (substituted for calcium), RB cells showed a negative slope region (NSR) in their current-voltage (I-V) relationship when measured at the end of 2 second commands from a holding potential of -60mV. Iontophoretic application of serotonin in this solution failed to produce a voltage-dependent response when membrane potential was held at -10mV. Yet, when 5HT ($5x10^{-4}$M) was added to the solution, the NSR was enhanced. When holding potential was depolarized to -10mV, the NSR as well as the effects of serotonin were greatly reduced. Addition of 20mM cobalt to the bathing solution blocked both the NSR and the inward current produced by serotonin. Changes in potassium concentration (1mM, 10mM and 40mM) produced no consistant shift in voltage-sensitivity nor change in amplitude of the current elicited by addition of serotonin. Intracellular injection of cesium broadened action potentials and often greatly reduced the iontophoretically elicited voltage-dependent response in normal sea water. However subsequent addition of TEA, 4-AP and Ba revealed an NSR which could be enhanced by 5HT. These experiments support the conclusion that in RB cells, serotonin produces a voltage-dependent current carried by calcium.

194.6 SLOW SYNAPTIC ACTIONS PRODUCED BY CELL R15 IN APLYSIA. R.O. Brown*# and E. Mayeri#+. #Dept. Physiology, Univ. of Calif., San Francisco, CA 94143 and +Dept. Basic Sciences, California College of Podiatric Medicine, San Francisco, CA 94115.

Cell R15 is a large, neurosecretory, bursting pacemaker neuron in the abdominal ganglion of Aplysia californica. It is thought to be a peptidergic neuron because it synthesizes large amounts of low molecular weight proteins and polypeptides (Loh and Gainer, Brain Res. 92:193, 1975). Moreover, a pronase-sensitive factor from isolated R15 somata causes rapid weight increase when injected into the hemocele of Aplysia, suggesting that R15 is involved in the regulation of water balance (Kupferman and Weiss, J. Gen. Phys. 67:113, 1976). We report here that R15 has effects on neurons of the left lower quadrant (LLQ) of the abdominal ganglion, producing slow synaptic potentials in phase with R15's bursting pacemaker activity.

R15 was typically firing in 6 second bursts of 25 spikes, with 10 second silent periods between bursts. The most commonly seen effect was an excitation which began a few seconds after the onset of the R15 burst, rose slowly and smoothly to a peak depolarization of as much as 8 mV, and returned slowly to baseline when the R15 burst was over. The magnitude of the depolarization could be reduced in a graded fashion by prematurely terminating the R15 burst with hyperpolarizing current, and it could be increased by depolarizing R15 during its burst. That the response could be manipulated in this way suggests that the interaction is a direct one. The depolarizing response was also reduced when the postsynaptic cell was hyperpolarized.

While R15's effect was most often excitation, in some instances it was inhibition or biphasic excitation-inhibition. In all cases the effects disappeared when R15 was prevented from firing by injection of hyperpolarizing current. When R15 was thus turned off, some active neurons excited by R15 became silent, and some silent neurons inhibited by R15 began spiking.

The R15 actions were not seen in all animals. Often there were no effects on LLQ neurons, even though R15 was firing normally, and appeared to be healthy. When the action was present, however, it affected many or most of the LLQ neurons on the dorsal surface, and persisted for the duration of the experiment (up to 10 hours). This raises interesting questions as to what factors govern this interaction, and where the site of control is located.

Because R15 produces peptides, and considering the slow time course of its synaptic actions, it seems likely that the transmitter mediating R15's effects on LLQ neurons is a peptide.

194.7 AN ANALYSIS OF THE BURSTING BEHAVIOR OF THE APLYSIA R_{15} NEURON DURING EXPOSURE TO NORMOXIC AND HYPOXIC BATH CONDITIONS. P.E. Coyer. Dept. of Neurol. and the Neurosciences Program, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

For the R_{15} neuron of the Aplysia abdominal ganglion, measurements of membrane potential (E_M, at a point corresponding to the trough of the after-hyperpolarization), the amplitude of the burst pacemaker potential (BPP), the interburst interval, and spike frequency within a burst were carried out during periods of normoxia (control), hypoxia (experimental), and reoxygenation. An analysis of the bursting behavior of R_{15} was performed by plotting the spike frequency per burst versus the amplitude of the BPP and BPP as a function of E_M. Preliminary data for 5 R_{15} neurons is presented below. To test for possible changes in resting gK during hypoxia, R_{15} neurons were exposed to a low (0.1 mM versus the normal 10 mM K^+) concentration during normoxia and hypoxia. Under these conditions, R_{15} hyperpolarized to a greater extent during exposure to hypoxia, and it became more apparent that an increase in the resting conductance to potassium accounted for the hyperpolarization observed during hypoxia. This observation substantiated the finding of an increase in the amplitude of the BPP and a corresponding increase in the spike frequency per burst. In fact, the spike frequency per burst was a linear function of the height of BPP, which increased during hypoxia probably due to hyperpolarization of the membrane potential. The length of the interburst interval was neither affected by the degree of membrane hyperpolarization nor the change in height of the BPP. These changes in E_M, BPP, and spike frequency per burst were reversible following reoxygenation, but this observation does not exclude the possibility of a synaptic mechanism which increased resting gK.

	# of cells	$\bar{X} \pm$ S.D. E_M (mV)	BPP (mV)	SPIKES (#)
Normoxia	5	-37.3 ± 2.8	3.1 ± 0.5	4.8 ± 0.6
Hypoxia	5	-48.9 ± 3.6	7.9 ± 0.3	10.5 ± 2.1
Reoxygenation	5	-39.8 ± 1.6	4.1 ± 0.1	6.2 ± 1.2

194.8 INTRACELLULAR FREE POTASSIUM CONCENTRATION IN SNAIL NEURONES MEASURED WITH ION-SELECTIVE MICROELECTRODES. F.J. Alvarez-Leefmans and S.M. Gamiño*. Department of Neuroscience, CINVESTAV del IPN, Apartado Postal 14-740, México 14, D.F.

Many studies on intracellular ionic activities in neurones have been made in the soma of cell 1F of Helix ganglia and yet very few measurements have been reported on the intracellular free potasium concentration $[K^+]_i$. Since K^+ is by far the most abundant cytosolic cation, precise knowledge of its free intracellular concentration is of great importance not only for understanding several membrane phenomena but also for correct and realistic calibration of ion-selective microelectrodes for measurement of other intracellular ions. $[K^+]_i$ was measured in cell 1F and 2F of the sub-oesophageal ganglia of Helix aspersa, using K^+-selective microelectrodes prepared with Corning liquid ion-exchanger 477317 by a method similar to that described by Tsien and Rink (J. Neurosci. Methods., 4: 73, 1981). The electrodes had a virtually ideal, Nernstian, response between 70 and 110 mM K^+ in mixed calibration solutions whose composition was such that the sum of $[Na^+]$ and $[K^+]$ was constant (110 mM) and buffered (pH=7.5) with 5 mM Na-Hepes. Adding 3 mM Mg^{2+} to the solutions had no measurable effect on electrode response.

The ganglia were superfused with a solution containing (mM): NaCl, 80 or 100; KCl, 4; $MgSO_4$ or $MgCl_2$, 5: $CaCl_2$, 4.5; Na-Hepes, 5; pH 7.5 equilibrated with 95% O_2 and 5% CO_2. All experiments were done at room temperature (20-24.5°C), during February and March 1982. Cells 1F and 2F of the right parietal ganglia were impaled first with a 3 M KCl microelectrode (5-20MΩ) and then the K^+-selective microelectrode. Four experiments were selected which satisfied the following criteria: (1) resting potential more negative than -47mV, and not,or only transiently perturbed by the second impalement, (2) K^+-electrode gave Nernstian responses between 70 and 110 mM before and after impalement. For these neurones the mean intracellular K^+ activity corresponded to the activity of 88.1 mM free K^+ concentration in the calibrating solutions (S.E. ± 2.2 mM, range 84-93.2 mM). Other impalements which did not meet the above criteria but allowed a measure of $[K^+]_i$ to be made, in cells with resting potentials more negarive than -38 mV gave a mean $[K^+]_i$ of 93.8 mM (S.E. ± 3.6 mM, range 85-102.4 mM, n=4).The $[K^+]_i$ in these cells was not significantly ($P > 0.3$) different to that found in the first group. The mean $[K^+]_i$ for both populations of cells was 91.0 mM (S.E. ± 2.2).

194.9 MOTORNEURON MEMBRANE CONSTANTS AND SIGNALING PROPERTIES IN THE NEMATODE ASCARIS. R.E. Davis* and A.O.W. Stretton. Neurosciences Program and Department of Zoology, University of Wisconsin, Madison, Wisconsin 53706.

In the motornervous system of Ascaris, the dorsal and ventral cords are connected by a repeating pattern of single identified motorneuron processes, called commissures (Stretton, A.O.W. et.al., PNAS, 75: 3493. 1978). Using two intracellular microelectrodes for stimulation and recording, we have determined the cable properties of these commissural motorneurons:

Property	Average	Range
R_{input}(MΩ)	6	4.8-10
λ(mm)	6.3	5-11
R_i (Ωcm)	82	49-128
R_m (Ωcm^2)	53,000	34,000-108,000
τ_m (ms)	35	25-48
C_m (μF/cm^2)	.83	.5-1.2

The membrane capacitance (C_m) is similar to that found in other biological membranes. Due to the large membrane resistance (R_m), however, the space constant (λ) is relatively high, accounting for the observed ability of these cells to conduct spontaneous passive signals over long commissural distances with only slight decrement. The only signals we have been able to evoke in these motorneurons are graded signals, i.e., signals which lack a clear threshold and whose amplitude is a graded function of stimulus strength. In these cells we have never observed spontaneous all-or-none action potentials nor have we been able to evoke them (at normal resting potential or after hyperpolarization). Thus, lacking the classical long-distance signaling mechanism, these motorneurons rely on their unusual membrane properties to convey information effectively over the long distances separating the ventral cord (input zone) and the dorsal cord (output zone to muscle). Nonetheless, active voltage-dependent membrane channels do appear to be present as indicated by our ability to elicit anode-break responses. These responses, however, are themselves graded (i.e., increase in amplitude with increasing strength of the hyperpolarizing pulse).

We have also examined neuromuscular synaptic transmission. For both exitatory and inhibitory motorneurons, synaptic transmission is graded. In addition, we have evidence that these cells tonically release neurotransmitter. Taken together, these cable and motorneuron signaling properties seem appropriate for a system in which passive signaling plays a major role. (Supported by USPHS Grant # AI 15429.)

194.10 POSTSYNAPTIC HABITUATION IN IDENTIFIED FLATWORM NEURONES? C. L. Keenan* and H. Koopowitz (SPON: R.K. Josephson). Developmental and Cell Biology, University of California, Irvine, CA 92717.

Multimodal sensory cell types (bBRA and SC) in the brain of the polyclad flatworm, Notoplana acticola, habituate to repeated light, vibration and touch stimuli. The rates of habituation depend on a number of parameters, including stimulus intensity, frequency and temporal pairing of different modalities. Although latency decreases with increasing stimulus intensity, it does not change significantly during habituation. Habituation is accompanied by decreases in epsp amplitude. This could either be due to decreases in presynaptic transmitter release or decreased postsynaptic efficacy. We have investigated changes in postsynaptic membrane properties following habituation and dishabituation. Membrane properties were evaluated by analyzing the charging characteristics of cells during the passage of square-wave hyperpolarizing current pulses. Using Rall analyses (Rall, 1969) we find decreases in membrane resistance following habituation to vibration stimuli. Dishabituation by light-off stimuli, following a train of vibration stimuli, is accompanied by an increase in membrane resistance. Both the time constant and electronic length also show concommitant changes that suggest altered membrane resistivity during habituation and dishabituation.

The response of the membrane to subthreshold depolarizing pulses before and after habituation are contrasted with the previous data. Changes in post synaptic cell membrane characteristics during habituation will be discussed.

194.11 ESTIMATION OF SPECIFIC MEMBRANE AND CABLE PROPERTIES OF LEECH RETZIUS CELL ELECTROTONIC COUPLING. K.M. Chapman and J. Yang* Neurosciences Section, Brown Univ., Providence, RI 02912

The paired Retzius (R) cells within the leech segmental ganglia are coupled by a non-rectifying electrontonic junction, which has been described as a simple resistance between the two somata. However, several investigations of the coupling permeability, using tracer molecules, suggest the electrical contacts occur between overlapping fine axonal arborizations deep within the neuropil. If so, the electrotonic coupling may in fact show cable-like properties. The present investigation tests this possibility, and also provides new quantitative estimates of the passive electrical properties of the R cells.

Subthreshold test currents with sinusoidal or pseudorandom modulation were injected into one soma - the "driver" cell - and the electrotonic potentials were measured from both. The impedance Z(f) at the driver cell, and the coupling ratio H(f) (electrotonic voltage ratio of "follower" cell to driver cell) were measured as transfer functions on the frequency range f= 0.2 Hz to 128 Hz, and were compared with corresponding properties of the resistive and cable-coupled theoretical models.

At high frequencies, electrotonus of the follower cell consistently lagged the driver cell by more than 90°, so that the phase ∠H(f) of H(f) crossed -90° with significantly negative slope. This finding is consistent with the cable model but not with the resistive model, and we conclude therefore that a finite cable segment between the R cell somata better describes the coupling. Quantitative estimates of the electrical parameters were derived from 4 specific transfer function values (as mean ± SEM): D.C. resistance Z(0)=11.3±1 MΩ; D.C. coupling ratio H(0)=0.26±.01; slope d(∠H(f))/d(log f) with which phase ∠H(f) crosses -90°, -117±12°/decade; frequency f for ∠H(f)= -45°, 6.2±.2 Hz. These yield 4 model parameter estimates: cable segment length LN = 1.25 x length constant; hemi-infinite cable conductance = 0.75 x soma conductance; soma resistance Rl = 20 MΩ; soma capacitance C= 1.3 nF. For an assumed typical soma radius of 35 μm and cytoplasmic resistivity 79 Ω cm, these model parameters correspond to an equivalent coupling cable of radius 2.6 μm and length 810 μm, with specific membrane resistance R_m= 3.1 kΩ cm^2 and capacitance C_m= 8.6 ΩF/cm^2. (Supported in part by USPHS Grant HL 19995 and NIH Grant NS 11482 and by the Grass Foundation)

194.12 DENDRITES OF A BARNACLE NEURON ARE EXCITABLE: DETERMINATION WITH VOLTAGE-SENSITIVE DYES. V. Krauthamer* and W.N. Ross. Dept. of Physiology, New York Medical College, Valhalla, NY 10595

Optical recording techniques using voltage-sensitive dyes were used to simultaneously monitor potential changes at 32 different locations on individual neurons in intact ganglia. These recordings were correlated with specific positions on the cell by injecting the fluorescent dye Lucifer Yellow into the soma. Using this technique, in combination with standard intracellular and extracellular electrical measurements, we determined the locations of action potential initiation and the spread of passive potentials when current was injected into the cell body.

Supraesophageal ganglia from the giant barnacle Balanus nubilus were stained with the voltage-sensitive dye NK2367 and mounted on the stage of a compound microscope. The preparation was imaged with a x40 water-immersion lens onto a 10 x 10 square array of photodiodes, each element corresponding to 40 x 40 μm^2 in the object plan (Grinvald, Ross and Farber, P.N.A.S., U.S.A. 78: p. 3245-3249 (1981). Cells were impaled with a microelectrode and action potentials and hyperpolarizing potentials were evoked repetitively. The resulting changes in absorption, detected on each element at 750 ± 25 nm, were recorded on a laboratory computer. Signal averaging and timing established that the optical changes resulted from potential changes on only the stimulated neuron. Clear signals were detected from most positions on the cell, including fine processes.

When current is injected into the soma action potentials appear first in the dendritic tree and later in the soma. The earlier time-to-peak shows that the spike must be initiated in this region and hence this region contains active membranes. Action potentials with the same early time-to-peak as in the processes were also recorded from a point on the axon within the ganglion. Controls established that the recordings from the dendrites could not be due to signals coming from the axon. Therefore, we conclude that the action potential was simultaneously and separately initiated in these two regions of the cell. The implications of excitable dendrites for synaptic integration in these cells remains to be explored.

Supported in part by UPHS grant NS16295, Fellowship NS06929 (to V.K.) and the Irma T. Hirschl Foundation.

194.13 THE CRAYFISH MEDIAL GIANT NEURON: AN ELECTROTONIC MODEL AND SYNAPTIC PHYSIOLOGY OF IDENTIFIED DENDRITES. R.M. Glantz and T. Viancour Dept. Biology, Rice University, Houston, Tx. 77001

A single spike in the crayfish Medial Giant neuron, (MG) is sufficient to release a complete escape reflex. Since this response is elicited exclusively by cephalic sensory input, its occurrence is substantially dependent upon the integrative properties of the MG cephalic neurites. In order to gain further insight into the integrative mechanisms we examined the MG's dendritic geometry and passive cable properties. With 3 micropipettes inserted along the axon the MG input resistance (R_N= 35,800 ± 1600 ohms (±S.D.)) length constant (λ= 4.40 ± 0.95 mm), time constant (τ= 2.72 ± 1.35 ms) and axon diameter (p = 208 ± 34μm) were directly measured in 5 animals. The specific membrane resistance(Rm = 2016 ± 234 ohms), the axoplasmic resistivity (R_i= 59.0 ± 30.0 ohms) and the specific membrane capacitance (Cm + 1.42 ±0.93 μ f) were derived from these measurements.

Dendritic geometry was examined in 15 MGs filled with Lucifer Yellow-CH and photographed in a fluorescence microscope in serial focal planes in whole mount. The length and several diameter measurements were obtained for every neurite in each neuron. These dimensions were used to calculate an average geometric MG with neurite lengths, diameters. tapers etc. reflecting mean values of the sample.

By combining the biophysical meausrements with the averaged geometric dimensions we created a synthetic MG neuron by assuming that the passive properties of axonal and dendritic membrane were identical. The MG geometry was compartmentalized and the R_N at the base of the dendritic tree (integrative segment) and at varying distances from the dendritic tree was calculated by an iterative procedure (Rall, 1959, Exptl Neurol. 1:491-527) which yielded values in good agreement with our measurements. As a further test of the model, EPSPs and electrontonic potentials were simultaneously measured at the integrating segment and at various points along the axon cylinder. The measured and calculated attenuations were in good accord.

The MG electrotonic structure has several notable features: a) The most remote dendritic branches are only 0.75λ from the integrating segment; b) The summed dendritic input conductance amounts to only 10% of the input conductance of the integrating segment while the axon contributes 57%.

When excited by monosynaptic inputs from the cephalic roots, the integrating segment exhibits an 11-14% increase in input conductance. Previous studies have shown that monosynaptic inputs are restricted to single lobes of the brain and must therefore converge on identified branches of the MG dendritic arbor. Our calculations indicate that for a ΔG of even 10% to appear at the integrating segment the affected neurite must exhibit an 11.4 fold increase in G_N and a 130 fold increase in specific membrane conductance. Thus dendritic R_M decreases from 2016 to 16 ohm. cm^2. As expected from these considerations postsynaptic spatial summation is markedly nonlinear. Supported by N.S.F. Grant No. BNS 79-10335.

194.14 HIGH AFFINITY BINDING OF [^{3}H]PHENCYCLIDINE TO A MEMBRANE PREPARATION FROM INSECT MUSCLE. A. T. Eldefrawi, M. T. Filbin* and M. E. Eldefrawi*. Dept. of Pharmacology and Exp. Ther., University of Maryland School of Medicine, Baltimore, MD 21201.

Binding of [^{3}H]phencyclidine ([^{3}H]PCP) to a membrane preparation from housefly thorax was measured in 5 mM Tris-citrate, pH 7.1, using a filter assay. Specific [^{3}H]PCP binding was defined as that displaced by an excess (x 1000) of unlabeled PCP. Displaceable binding was abolished by placing the tissue in a boiling water bath for 2 min prior to incubation with [^{3}H]PCP. Specific [^{3}H]PCP binding was saturable both with time and at [^{3}H]PCP concentrations higher than 20 nM and increased linearly with tissue concentration. Binding was of high affinity. Scatchard analysis of data obtained from equilibrium binding studies revealed a single binding component with a K_d of 11.09 nM and B_{max} of 3 pmol/mg protein (28 pmol/g original tissue). The K_d obtained from the on (k = 1.22 x 10^5 s^{-1}) and the off (k_{-1} = 1.027 x 10^{-3} s^{-1} M^{-1}) rate constants was 8.4 nM. Neither carbamylcholine nor L-glutamate alone, or in the presence of mM concentrations of ATP, GTP, cAMP and cGMP, had any effect on [^{3}H]PCP binding. Specific [^{3}H]PCP binding was inhibited by the six PCP derivatives tried (IC_{50}'s nM-μM). Specific binding was also inhibited by calcium and by the following calcium antagonists: verapamil, nicardipine, nifedipine, +D600, -D600 and lanthanum, with IC_{50}'s in the μM-mM range. When the membrane preparation was stored overnight at 4°C, specific binding decreased by 15-20%, even when stored in the presence of one of the following antiproteases: EDTA, pepstatin, trypsin inhibitor or phenylmethane sulphonyl fluoride (PMSF). It is suggested that [^{3}H]PCP binds with high affinity and specificity to a calcium-binding protein. (Supported in part by NIH grant ES02594 and Army Research Office grant DAAG 29-81-K-0161.)

194.15 EFFECT OF LANTHANUM IONS ON NEUROMUSCULAR TRANSMISSION IN THE INSECT. H. Washio and T. Miyamoto.* Lab. of Neurophysiology. Mitsubishi-Kasei Institute of Life Sciences, Machida, Tokyo, Japan 194.

The effect of extracellular lanthanum on neuromuscular transmission was studied in leg muscles of cockroach, Periplaneta americana, and segmental muscles of larval mealworm, Tenebrio molitor. Although lanthanum is more effective than magnesium is in suppressing evoked transmitter release, the frequency of miniature postsynaptic potentials (MEPSPs) was substantially increased in the presence of 0.1 mM La^{3+}. The potentiation of MEPSP frequency by La^{3+} was suppressed in a high Ca saline and enhanced in the absence of Ca^{2+}. An inhibitory action on the spontaneous release of transmitter which had been found in the presence of cobalt (Washio, H., J. Exp. Biol., in press) was not observed in a saline containing lanthanum. Lanthanum ions blocked insect neuromuscular transmission at a concentration as low as 0.05 mM. The quantum content estimated by the failure method was reduced by 80% in the presence of 0.1 mM La^{3+}. Thus, the reduction in the EPSP amplitude produced by La^{3+} is due to a decrease in the amount of transmitter release by a nerve impulse. The excitatory postsynaptic current (EPSC) was measured with a voltage clamp method during neuromuscular transmission and the falling phase was exponetial in a lanthanum-saline. The time constant of EPSC decay was increased appreciabley in the presence of 0.1 mM La^{3+}, despite a decrease in the quantum content. The response to L-glutamate applied iontophoretically was also reduced in the presence of lanthanum. External recording of MEPSPs has shown that adding lanthanum to the bathing medium increased the half-decay time of the potentials. These results suggest that lanthanum may affect the sensitivity of the glutamate receptor-ionophore complex in addition to its prejunctional action in insect muscle fibers.

195.1 A THERMORECEPTOR POTENTIAL IN PARAMECIUM TETRAURELIA. T.M. Hennessey*, Y. Saimi*, and C. Kung*. Lab. of Molec. Biol. and Dept. of Genetics, Univ. of Wisc., Madison, Wisc. 53706.

Wild-type Paramecium tetraurelia avoid temperatures from 37° to 42°C when tested in a buffered 1 mM calcium solution (Hennessey and Nelson, J. Gen. Microbiol. 112:337, 1979). A graded change in the membrane potential (ΔV_m) of up to 20 mV more depolarized than the resting level has been recorded intracellularly in the same solution by raising the temperature of a temperature-controlled bath. We refer to this ΔV_m in response to heat as the "thermoreceptor potential". The ΔV_m can be sustained for up to 1 min at constant high temperatures, but is readily reversible upon cooling. Spontaneous action potentials are also seen riding on the thermoreceptor potential at high temperatures.

The calcium-mediated action potential mechanism, localized in the cilia, is not involved in the generation of the thermoreceptor potential in P. tetraurelia. An identical $\Delta V_m/\Delta T$ of 1.3 mV/C° can be seen in wild type, deciliated wild type, and in a calcium channel mutant (pwB). A similar analysis in P. multinucleatum and P. caudatum has shown that the ciliary calcium channels are not involved in the depolarization in response to cooling (H. Toyotama, Ph.D. thesis, Osaka Univ., 1980). Thus, it appears that thermoreception, like mechanoreception (Ogura and Machemer, J. Comp. Physiol. 135:233, 1980), involves ion channels on the body membrane of Paramecium.

A behavioral mutant, teaB, shows a poor behavioral response to high temperatures as well as a significantly smaller $\Delta V_m/\Delta T$ of 0.6 mV/C°. Some of the behavioral and electrophysiological defects of teaB have been described previously (Satow and Kung, J. Membrane Biol. 59:179, 1981). An analysis of this mutant, as well as other possible thermosensory-minus mutants (E. Richard, unpublished) will aid in the analysis of the thermosensory transduction pathway in Paramecium.

195.2 ECCENTRIC CELL DYNAMICS IN THE INTACT LIMULUS COMPOUND EYE, G.H.RENNINGER. Biophysics Interdept. Group, Dept. of Physics, Univ. of Guelph, Guelph, Ontario N1G 2W1, Canada.

Under uniform illumination sustained oscillations can develop in the optic-nerve response of the horseshoe crab's compound eye when it is left in situ (Barlow, R.B., Fraioli, A., J. Gen. Physiol., 71:699,1978; Renninger, G.H., Barlow, R.B., Soc. for Neurosci. Abstracts, 5:804(#2715),1979). These result from a synchronization of nerve-impulse generation between eccentric cells which communicate by means of lateral inhibition. Lateral inhibition is delayed with respect to the impulse initiating it (Ratliff, F., et al., Vision Res., 14:1155,1974) and is strong in the intact eye.

Eccentric cell membrane events underlying impulse synchronization in intact eyes were observed by means of glass intracellular electrodes (resistance ≅ 20 MΩ; cell resistances ≅ 10 MΩ). Each eye was uniformly illuminated and hyperpolarizing current (up to 2 na) was injected to reduce or eliminate impulse generation. At low light intensities the membrane potential showed random fluctuations similar to those reported in cells illuminated alone. At light intensities which can produce oscillatory optic-nerve responses, however, the membrane potential became more regular and an oscillatory component appeared. Frequencies of oscillation were 6-7 s^{-1}.

Simultaneous observations of eccentric cell membrane potentials and of the aggregate optic-nerve response were also made, allowing a direct confirmation of the correlation between synchronized activity among optic-nerve fibers and oscillatory membrane components and permitting the conclusion that these components are an oscillating hyperpolarization due to lateral inhibition arising from the optic-nerve discharge. These observations also provided a measurement of the phase relationship between the oscillations. At the higher intensities the optic-nerve response consists of bursts of activity separated by intervals containing few impulses. In such cases it was possible to measure the delay between the onset of lateral inhibition due to a burst and the occurrence of the first impulses in the burst. After correction for the impulse conduction delay in optic-nerve fibers between the intracellular and optic-nerve electrodes, which corresponded to a conduction velocity of ca. 2 ms^{-1}, this delay turned out to be 45±10 ms. The delay in inhibition permits synchronization of impulses; it equals about 30% of the period of the resulting oscillations. Previous theoretical calculations (Coleman, B.D., Renninger, G.H., J. Math. Biol., 3:103,1976) suggested that the delay in lateral inhibition should be significantly smaller than the values (≅ 100 ms) reported for excised eyes. (NSERC Canada Grant #A6983)

195.3 STRUCTURE OF LIMULUS RHABDOM IN LIGHT AND DARKNESS: RHABDOM TURNOVER IN THE NATURAL STATE. S. C. Chamberlain* and R. B. Barlow, Jr. (SPON: R. Verrillo). Institute for Sensory Research Syracuse University, Syracuse, NY 13210

We have previously reported (Science 206:361-363) that the rhabdom of the Limulus lateral eye is transiently broken down and rebuilt at first light onset each day. This process requires that efferent input from the central circadian clock precede first light onset. Since the original experiments were performed in the laboratory with sudden light onset, we have now examined the structure of the rhabdom of animals freshly caught and fixed in the natural environment. We find no essential differences between the ultrastructure of the rhabdom turnover process observed in the laboratory and rhabdom turnover as it occurs in nature.

In late June, transient turnover of the lateral eye rhabdom occurs at some point in time between 0400 and 0600. Synchrony from animal to animal is poor, but the synchrony among ommatidia within a given retina is quite good. At this time of day, the efferent fibers are still active, and the overall retinal structure is still that of nighttime. Apparently relatively little light is required to trigger rhabdom turnover, and processes other than sudden light onset must be responsible for synchronizing the process across the retina.

Quantification of the amount of microvillar membrane in the rhabdom at each point in time revealed that rhabdom breakdown represents a 3.5 times transient reduction in the area of photosensitive membrane. The maximum amounts of microvillar membrane are found early in the morning just before rhabdom turnover, and late in the afternoon (1800). During progressive light exposure through the course of the day, the area of membrane in the rhabdom increased in agreement with our earlier studies in the laboratory. We conclude that the rhabdom is maximally organized and contains the largest area of microvillar membrane when it is in darkness at night or when it is in light during the day.

In a parallel study we investigated the amount of efferent input necessary to prepare the rhabdom for turnover at first light onset. Animals were placed in darkness in early evening, then exposed to dim red light for 5 min before being fixed at 2 hr intervals. The results suggest that 3 to 5 hrs of efferent activity must precede light onset for rhabdom turnover to occur.

While both light and efferent input are required for rhabdom turnover, the amounts of each are relatively small, allowing the process to occur in nature as early as 0400 when the light intensity is low, and the daily period of efferent activity is not yet concluded.

195.4 QUANTITATIVE ELECTRON PROBE MICROANALYSIS OF LEECH PHOTORECEPTORS. B. Walz* and A.P. Somlyo* (SPON: P.A. Liebman). Abt. f. Vergl. Neurobiologie, Univ. Ulm, D-7900, FRG and The Pennsylvania Muscle Institute, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104.

Leech photoreceptors exhibit a peculiar compartmentalization. Each cell contains a large "vacuole" into which the photoreceptive microvilli protrude. The "vacuole" is connected with the extracellular space over narrow (~20nm) clefts (septate junctions). The ionic composition of the cytoplasm and "vacuole" have been unknown. We used electron probe microanalysis of dry, ultrathin cryosections to determine quantitatively the elemental composition of the cytoplasm, "vacuole" and extracellular space (ECS). The data collected from five leeches are shown below:

		mmoles/kg dry wt. ± S.E.M.					
	n	K	Na	Cl	S	Mg	P	Ca
CYTO.	18	393±30.6	130±14.7	216±13.8	332±13.5	40±3.0	571±14.5	9±1.2
VAC.	17	50±9.8	552±80.4	216±57.3	304±15.3	1±3.5	77±7.6	28±2.1
ECS	15	74±6.2	997±77.3	826±68.0	275±18.2	14±3.4	28±5.0	33±2.9

The use of Thiery's silver cytochemical stain showed a positive reaction in the "vacuole," suggestive of carbohydrate rich material.

Our results show that: 1) the composition of the "vacuole" is similar to that of the extracellular space, as shown by the comparable Na/K (11 to 13) and K/Ca (1.8 to 2.2) ratios in these two compartments; 2) the "vacuoles" have a high S content and a relatively large deficit of Cl compared to $[Na^+]+[K^+]+2[Ca^{2+}]$; 3) the cytoplasmic K concentration is comparable to that in other nerve cells, and the Cl concentration is relatively high: significantly ($P<0.001$) higher than the cytoplasmic Na.

We conclude that the "vacuole" of the leech photoreceptor is in ionic communication with the extracellular space, as suggested by electrophysiological studies (Lazansky, A. & Fuortes, M.G.F. J. Cell Biol. 42: 241-252, 1969), and contains sulfonated glycosaminoglycan(s) that can partially exclude Cl; electroneutrality is maintained in part by organic anions, presumably sulfate. The high cytoplasmic Cl content is in excess of that predicted by passive distribution, and suggests the operation of a Cl pump.

195.5 RESPONSE PROPERTIES AND OUTPUT EFFECTS OF IDENTIFIED MECHANOSENSORY INTERNEURONS IN THE CRAYFISH, PROCAMBARUS CLARKII. M.R. Plummer, J. Tautz, and J.J. Wine, Neurosci. Prog. and Dept. of Psych., Stanford Univ., Stanford, CA 94305.

The terminal abdominal ganglion of the crayfish contains approximately 50 bilateral pairs of projecting sensory interneurons which get input chiefly from the animal's tailfan. Of these, 22 have been uniquely identified on the basis of their structure, modality and physiological properties (Sigvardt, K.A., Hagiwara, G. & Wine, J.J., J. Comp. Physiol., in press). Interneurons with similar properties have been grouped together into six classes. We are analyzing the response properties and outputs of these interneurons, concentrating on two of these classes. One class (water movement-sensitive cells) responds best to directional water displacements, does not adapt, and responds poorly to touch of the animal's carapace. The other class of cells (touch cells) also responds to water movements but adapts, and responds strongly to touch. We have constructed a device with which we can present waterborne stimuli of known frequency and amplitude to the tailfan while recording intracellularly from the sensory interneurons.

With regard to the response properties of these cells, we have found that different interneurons have different frequency response characteristics and that certain neurons are excited at some frequencies and inhibited at others. In general, the touch cells have much higher thresholds than the water movement-sensitive cells although the touch cells will respond to higher frequencies than the water movement-sensitive cells.

With regard to output, we have found that some interneurons, when depolarized intracellularly, influence the activity of motor neurons in the rostral abdominal ganglia as well as in the terminal ganglion. To date, all of the neurons with these effects have been touch cells. For example, depolarization of one particular touch cell activates the peripheral inhibitor of the tonic flexor muscles (fI). When a 100 Hz water oscillation is used as a stimulus both the interneuron and fI are excited. Since the touch cell excites fI, it could be responsible for the response seen in the inhibitor. Hyperpolarization of the touch cell so that it does not fire during stimulus presentation results in a reduction of the response in fI. Therefore, one function of the touch cells may be to mediate postural changes in response to sensory stimuli.

195.6 CENTRAL PROJECTIONS OF AFFERENT AXONS IN THE ANTENNAL NERVE OF LARVAL *MANDUCA SEXTA*. K. S. Kent* and J. G. Hildebrand, Dept. of Biological Sciences, Columbia University, New York, N. Y. 10027.

As background for studies of the postembryonic development of the antennal pathway in the central nervous system (CNS) of the moth *Manduca sexta*, we have traced the central projections of axons of the antennal nerve (AN) in fifth-instar larvae. We selectively stained one or more sensory neurons with cobalt sulfide followed by Timm's intensification of wholemounts. We observed that axons from neurons innervating tactile hairs on the larval antenna and on the head capsule near the antenna enter the brain via the AN and ramify as they run toward the circumesophageal connective (CEC). The axons then run through the CEC to the subesophageal ganglion, where they have additional characteristic arborizations. Cells innervating the other classes of antennal sensilla project to two other regions in the brain. One of these regions, medial to the point at which the AN enters the brain, is a nodular ball of neuropil that appears to be densely innervated by many fine fibers. Selective staining and ablation experiments suggest that this neuropil structure is the larval antennal center (LAC). A few "through fibers" extend beyond the LAC in the brain. These "through fibers" might be primary afferent axons or axons of higher-order cells in the antennal pathway that have been stained trans-synaptically. The other region of neuropil receiving fibers from non-tactile sensilla is ventral to the LAC, and its volume and density of innervation are much less than those of the LAC. We believe that these two regions of neuropil receive antennal chemosensory inputs.

When all classes of axons in the AN were stained in a preparation, additional central projections were apparent. Several fibers enter the brain and ramify diffusely close to the AN. Both these fibers and the "through fibers" described above are candidates to be the axons from the neurons in the antennal imaginal disk that are believed to provide contact guidance for the centripetal growth of adult antennal-sensory fibers during adult development (Sanes and Hildebrand, *Wilhelm Roux' Archiv 178*, 71, 1975).

These studies have been supported by NIH grant AI-17711 and NSF grant BNS 80-13511.

195.7 PHOTORECEPTOR SPECIFIC ANTIGENS: LOCALIZATION AND IDENTIFICATION BY MONOCLONAL ANTIBODIES. Norbert E. Kremer, Gail H. Stewart* and Fulton Wong*. Marine Biomedical Institute, UTMB, Galveston, TX 77550 and Dept. of Biochemistry, University of New Hampshire, Durham, NH 03824.

Monoclonal antibodies specific for photoreceptors of the squid have been isolated by screening hybridomas obtained from mice immunized with the whole squid retina. Potential antibody-producing clones were first screened by an ELISA assay and further selected by an indirect immunocytochemical method. These monoclonal antibodies stain the photoreceptors but not other cell types in the visual system of the squid. The photoreceptor-specific antigens localized by the monoclonal antibodies were identified as particular bands or dots on nitrocellulose transfers generated from one-dimensional or two-dimensional gel electrophoresis of squid retinal proteins. A set of twelve monoclonal antibodies studied and reported on here can be characterized broadly according to their immunocytochemical staining patterns: 1) those staining the outer segments of the photoreceptors; 2) those staining the whole cell, and 3) those staining preferentially the inner segments of the cells. Of the antibodies studied, in the same categories, there are some which give the same staining pattern but identify different polypeptides on the nitrocellulose transfers.

We sought to further identify the antigens localized by the various antibodies. Two antigens have been identified as different forms of rhodopsin. One form is localized by an antibody to the outer segment, while the other form is localized by other antibodies to the entire photoreceptor, including the axon and terminal region in the optic lobe. Analysis on SDS polyacrylamide gels shows that the first form runs as a diffuse band of approximately 47K molecular weight and has a Concanavalin A binding site. The second form migrates as a sharp band at 45K molecular weight and does not bind to Concanavalin A. Both forms become fluorescent upon reduction of extracts with $NaBH_4$, indicating presence of a retinyl chromophore. The localizations of these two forms of rhodopsin may have functional implications. The form which runs as a diffuse band (localized to the outer segment) must be involved in phototransduction. Further study of the protein which migrates as a sharp band (localized to the entire photoreceptor) may give clues to rhodopsin biosynthetic or degradation processes. (This research was supported by BNS 81-07067 and EY-03308 to F.W.)

195.8 THE NEUROBIOLOGY OF CALCIUM SENSITIVITY IN HERMIT CRABS. Karen A. Mesce, Dept. of Biology, Univ. of Oregon, Eugene, OR 97403.

Hermit crab shell selection involves a complex sequence of behaviors culminating in a decision about which shell to inhabit. The presence of calcium at the shell surface promotes the exploration of the shell leading to its selection (Mesce, Science 215:993, 1982). The detection of calcium at a shell surface by Pagarus hirsutiusculus hirsutiusculus requires physical contact. Such a requirement serves to increase the signal to noise ratio in a marine environment that already contains approximately 10 mM calcium.

To understand the neural basis of calcium reception in hermit crabs, both morphological and physiological aspects of possible chemosensory structures were examined. Using the staining technique of Slifer (Ent. News 71:179, 1960) to locate putative chemoreceptors, hairs on the legs, antennae, antennules and mouthparts were found to stain within seconds with an 0.5% solution of crystal violet. Subsequently these and other non-hairlike structures that stained quickly were examined at the electron microscopic level.

Cinematographic analysis shows that the antennules and thoracic appendages come into extensive contact with shell surfaces during shell exploration. Surgical ablation of antennules, antennae and mouthparts does not significantly alter shell selection behavior. However, if such ablations are paired with applications of distilled water to the leg hairs, shell selection is disrupted. Distilled water selectively damages chemoreceptive sensilla in lobsters (Derby and Atema, J. Exp. Biol., in press).

Multi-unit recordings from neurons that innervate appendage hairs and antennular aesthetascs verified that such structures are chemosensory. In the case of leg chemoreceptors, there was a high level of tonic background activity. When calcium solutions in the range of 10-40 mM were applied to leg sensilla, a variety of neural responses were obtained. In some preparations there was an increase in neural discharge in response to calcium solutions and in others there was a depression of activity to levels below pre-stimulus treatment. Similar results have also been obtained by Seelinger (J. Comp. Physiol. 113:95, 1977), who examined the responses of isopod chemoreceptors to calcium solutions.

Supported by NIH Training Grant 5T32 GM 07527 and NSF Grant BNS-79 04513.

196.1 AXONS HOMOLOGOUS TO THOSE OF THE DROSOPHILA GIANT FIBER PATHWAY OCCUR IN MUSCA AND SARCOPHAGA. David G. King. Departments of Anatomy and Zoology, Southern Illinois University, Carbondale, Illinois 62901.

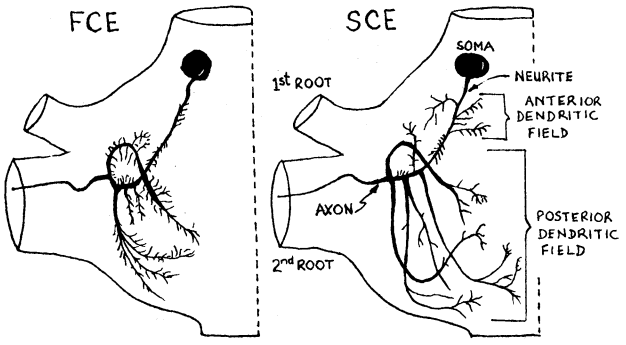
The dipteran giant fiber pathway, first described by Power (J. Comp. Neurol. 88:347), consists of three pairs of conspicuous axons. In Drosophila melanogaster a cervical giant fiber neuron (Koto et al., Br. Res. 221:213) or giant descending neuron (Strausfeld & Nassel, Handbook of Sens. Physiol. VII/6B) sends a large axon from the brain into the thoracic ganglion. Here the cervical giant fiber contacts two other axons. One of these, a thoracic interneuron, makes peripheral synapses onto the dorsal longitudinal muscle motor axons (King & Wyman, J. Neurocytol. 9: 753). The other, a motor axon, innervates the tergotrochanteral muscle.

The cervical giant fiber has homologues in several species of flies (Strausfeld & Nassel, op. cit.). Valentino (Neurosci. Abs. 3:190) has reported synapses similar to those of the peripherally synapsing interneuron in the posterior dorsal mesothoracic nerve of Musca domestica. In the present study microscopic examination of Musca and of Sarcophaga bullata has confirmed the presence of homologous synapses in both species. The axon which forms terminal axoaxonal synapses onto the dorsal longitudinal muscle motor axons follows a ganglionic course in Musca and in Sarcophaga which is indistinguishable from the course of the peripherally synapsing axon in Drosophila. Similarly, the ganglionic courses of the cervical giant fibers and the tergotrochanteral motor axons are similar in all three species. In Musca and Sarcophaga the cervical giant fiber may branch more extensively than in Drosophila (cf. Koto et al., op. cit., & Coggshall et al., Z. Naturforsch. 28:783). In Sarcophaga, the largest of the three flies studied, synapses homologous to those of the peripherally synapsing axon were located in the root of the posterior dorsal mesothoracic n., within the ganglion proper, rather than peripherally within the nerve. The central synaptic contacts among the three pairs of giant fiber pathway axons were not examined in this study.

The giant fiber pathway in Drosophila is a valuable system for genetic and developmental neurobiology, since several mutations are known to modify this pathway (Thomas, Neurosci. Abs. 6:742 & 7:543; Costello & Thomas, Neurosci. Abs. 7:543; Thomas, Costello & King, Neurosci. Abs. 8). Comparative study of homologous pathways in additional species will permit broader investigation into the ontogenetic and evolutionary determination of specific neuronal features. Flies which display significant modifications of the giant fiber pathway (such as Glossina; see King, Neurosci. Abs. 7:410) may be especially interesting.

196.2 FAST AND SLOW LOBSTER MOTONEURONS HAVE UNIQUE DENDRITIC MORPHOLOGIES. C. K. Govind and R. H. Hill.* Scarborough Coll. Univ. Toronto, West Hill, Ontario, M1C 1A4, Canada and Boston Univ. Marine Program, Marine Biol. Lab., Woods Hole, MA. 02543.

The closer muscle in the claws of lobsters, Homarus americanus, is innervated by a fast closer excitor (FCE), a slow closer excitor (SCE) and a closer inhibitor motoneuron. Since each of the FCE and SCE is identifiable in the 1st thoracic ganglion by the location of its soma (Govind, C. K. and Lang, F., 1981 J. Exp. Biol. 94:329-339) we compared their morphology by injecting their soma with cobalt or Lucifer Yellow (Figure). Both neurons are similar in general morphology being monopolar with a single neurite orginating from a soma located in the antero-ventral region of the ganglion. The neurite travels vertically to the dorsal surface and along this surface, where it gives off its primary dendrites, to the 2nd root which it enters as an axon. The FCE and SCE motoneurons however differ in their dendritic morphologies in several respects. First the SCE has an anterior dendritic field consisting of 3-4 primary dendrites which is completely lacking in the FCE. Second the posterior dendritic field usually has 5 primary dendrites in the SCE but only 3 in the FCE. Third these posterior primary dendrites of the SCE are longer and extend further across the ganglion than their conterparts in the FCE. Fourth while the axon of the SCE is a continuation of the neurite that of the FCE originates from one of the posterior primary dendrites. In summary the SCE has a more extensive and elaborate dendritic field than the FCE. This together with the peculiar origin of their axons may account for the lower firing threshold and prolonged motor patterns in the SCE than in the FCE of intact lobsters. Supported by NSERCC and MDA of Canada.



196.3 VARIABILITY IN THE OCULOMOTOR SYSTEM WITHIN AN ISOGENIC CLONE OF DAPHNIA MAGNA. T.R. Consi* and E.R. Macagno. Columbia University, New York, NY 10027.

Measurements of the number, position, structural features and synaptic connectivity of neurons within isogenic populations have revealed both great constancy and variability of these parameters. For example, our observations on a parthenogenetic clone of Daphnia magna showed constant numbers of neurons in the compound eye and optic lamina, but variable branching patterns and numbers of synaptic sites among identified neurons in the optic ganglion. We report here our recent observation that the number of fibers in particular muscles of the oculomotor system varies among random individuals of our Daphnia clone, as well as within individual parthenogenetic broods.

Three bilateral pairs of muscles move the compound eye of Daphnia. The three muscles on each side of the head share a common origin on the carapace and insert dorsally, laterally and ventrally on the eye. The muscle fibers of the lateral pair, although small (maximum diameter is 4-6 microns at the nucleus), can be readily visualized in whole mounts using Nomarski optics. Using this technique we measured the number of fibers per lateral eye muscle on both sides of 72 specimens from our clone. This number was found to range from two to four, with three being most common. Individual animals often had different numbers on the left and on the right. The data is presented below.

LATERAL EYE MUSCLE FIBER NUMBER		NUMBER OF ANIMALS	%
RIGHT	LEFT		
2	2	7	9.7
2	3	13	18.1
3	2	14	19.4
3	3	36	50.0
3	4	0	0.0
4	3	2	2.8
4	4	0	0.0
	Totals:	72	100

The distributions of fiber numbers among the progeny of individual Daphnia were found to be similar to that of the general population and independent of the numbers of fibers in the mother's lateral eye muscles.

Observations with the electron microscope of a serially-sectioned animal with three fibers per lateral eye muscle revealed that a single motor neuron innervates each muscle. The motor axon trifurcates as it approaches the muscle, the branches running along each muscle fiber and forming numerous synapses. The innervation of lateral eye muscles with 2 or 4 fibers is being examined.

196.4 Identification Of Target Tissues Of Aplysia Neuron R14 By Long-Duration Pressure Injection of Cobaltic Hexamine Chloride. A.R. Rittenhouse* and C.H. Price. Department of Biology, Boston University, Boston, MA 02215

The axonal tree of the identified Aplysia neuron R14 in the parietovisceral ganglion (PVG) was traced to peripheral locations by intracellular injection of the heavy metal complex, $[Co(NH_3)_6]Cl_3$. Standard electrophysiological techniques were used to monitor the cell while injecting 200 mM $[Co(NH_3)_6]Cl_3$ by pressure and/or current. We found that $[Co(NH_3)_6]Cl_3$ entered R14 more easily than other metals, did not clog the microelectrode as other dyes often do, and was transported at a rate comparable to that of Lucifer Yellow (~1.5 mm/hr). After constant injection and incubation periods up to 24 hr, the Co^{2+} was precipitated with 5% ammonium sulfide. The tissue was dehydrated and cleared, leaving a permanent, grey to black staining of the soma, ganglionic axons, and finer peripheral processes up to 15 mm distal.

The large diameter, single axon arising from the cell body immediately branches into 3 major axons. One axon projects rostrally into the vulvar nerve (VN), and occasionally into the parietovisceral connective, bifurcates within the VN, and both exit this nerve to innervate the dorsal artery. A second axon travels the length of the branchial nerve where it ramifies in the sheet of muscle (MS) surrounding the base of the heart. A third axon traverses the PVG to the left hemiganglion where it branches into 4 or 5 axons. The pathways of these latter axons vary and may enter the pericardial (PCN), genital (GN), or spermathecal (SPN) nerves. However, their target tissues are invariant and include the ganglionic artery, the digestive gland sheath (DGS), the pericardial wall (PCW), the base of the heart (via the auricular nerve), and the gastroesophageal aorta (GEA).

On many of these tissues numerous varcosities of various sizes can be seen and are presumed release sites. Positive correlations between intracellular soma spikes of R14 with extracellular recordings of its peripheral axons show that R14 sends processes onto the ganglionic artery, anterior aorta, dorsal artery, GEA, MS, into the right and left efferent vein nerves, AUN, and DGS. All these tissues are involved in the flow of hemolymph in Aplysia and appear to be target tissues for R14. Thus, in addition to the well-described motor innervation of Aplysia circulatory tissues, our data suggests that R14 plays a prominent role in the control of cardiac output, perhaps similar to this neuron's glycinergic anterior aorta contractions (Sawada et al., Brain Res., 207: 486-490, 1981). Furthermore, the presence of endings in vascular tissue reinforces the idea that R14 may also secrete a physiologically active peptide.

196.5 **MEMBRANE INFOLDING IN AXONS FROM THE BUCCAL GANGLION OF APLYSIA CALIFORNICA.** Katherine Graubard and Kelly Bennett*, Department of Zoology, University of Washington, Seattle WA 98195

Most molluscan axons are not smooth cylinders, but instead have a less regular shape with invaginations of surface membrane into the axoplasm. In order to estimate membrane channel density or to compute cable properties of such axons, the total amount of plasma membrane must be known. In the past, unit membrane capacity has been seriously overestimated when membrane folds were ignored.

Two Aplysia, weighing 210g and 70g, were dissected in low-calcium, high-magnesium saline. Nerves were pinned so that axon bundles appeared straight within the nerve sheath. The tissue was fixed in: 2.5% glutaraldehyde, 0.1M s-collidine pH 7.4, 0.43M NaCl, 0.02M $MgCl_2$ at 4° C. Secondary fixation was in 1% OsO_4 with the same salts and buffer. Tissue was dehydrated in graded alcohols and embedded in epon. Shrinkage of the axon bundles within the nerve sheath did not exceed 12% and was probably much less.

Measurements were made from electron micrographs of transverse sections cut from the middle portions of the radular nerve and buccal nerves 1, 2, and 3. The perimeter and cross-sectional area of each sampled axon was measured. The diameter, d, is that of the circle which encloses the same area as is contained in the measured axon cross-section. The infolding factor is the number by which πd must be multiplied in order to compute the measured perimeter of the axon (a cylinder without membrane folds has an infolding factor of one).

An infolding vs diameter plot shows a tendency toward more infolding for larger diameters. This agrees with a previous study of the right connective of the abdominal ganglion (Graubard, Brain Res. 88:325-332, 1975) in which a wider range of axon diameters, in larger animals, revealed a power function relationship between diameter and infolding. This study finds somewhat less infolding at each diameter, and still less for the 70g animal than for the 210g one. We are now examining individual axons to determine if the point scatter is due to variations in infolding along the length of an axon or to some property of individual axons.

The four nerves examined show differences between each other and when compared with the right connective of the abdominal ganglion. Buccal nerves 1 and 2 contain large numbers of very small axons which are packed together without individual glial coverings. The other axons in these nerves and in nerve 3 show varying amounts of glial wrap, some of which is much more extensive than any seen in either the radular nerve or the right connective. (Supported by NINCDS grant NS 15697-03).

196.6 ARE DIFFERENT PROTEINS SYNTHESIZED IN DISTINCT DOMAINS IN A NEURON? Bruce Tedeschi* and David L. Wilson. Dept. of Physiology and Biophysics, Univ. of Miami Sch. of Med., Miami, FL 33101.

The R2 neuron of the invertebrate Aplysia californica was used to test whether different messenger RNA species are translated in distinct, limited domains within the cell. After 15 min. of labeling of the R2 neuron with ^{35}S-methionine, the cell soma was frozen in an ethylene glycol-seawater solution, removed from the abdominal ganglion, and divided into two or three parts. In some cases the whole cell was used. Proteins from the cell parts were extracted and then separated by two-dimensional gel electrophoresis. The labeled (newly synthesized) polypeptides were detected with Kodak XAR x-ray film following PPO imbedding for fluorography. For quantitative analysis, selected gel regions, corresponding to spots on the film, were cut out and counted in scintillation fluid.

A map of spots consistently seen in the label pattern of proteins from whole cells was made. Twenty six of these spots were examined on each of the gels from parts of cells. The analyzed gels were obtained from five R2 neurons, two of which had been divided into two parts after labeling, and three of which had been divided into three parts. Models were used to predict the ratio of counts in the various cell parts. There was no evidence for limited domains of synthesis within the cell for any of the 26 examined polypeptides.

Reservations concerning the generalizability of our result include: a) we have examined only one type of neuron, b) only the more abundantly synthesized polypeptides were examined, c) an even shorter labeling time might be necessary to avoid possible transport of the newly synthesized proteins from sites of synthesis, d) a wrap of glial cells is present surrounding the R2 neuron, and e) only the cell soma was divided into parts (It would be of great interest to compare the synthesis of proteins in the soma and dendrites of a vertebrate neuron, should an adequate system be found).

We conclude that a number of the more abundantly synthesized proteins in the R2 neuron do not appear to be synthesized in small domains within the protein-synthesizing regions of the cell. This result demonstrates the sensitivity of present techniques of protein analysis and presents restrictions on theories of how cytoplasm is organized.

196.7 INTRACELLULAR RECORDING OF BURSTING PACEMAKER ACTIVITY FROM INTACT APLYSIA. Gayne M. Bablanian* and Steven N. Treistman (SPON: S. Fredman). Univ. of Rhode Island, Kingston, RI 02881 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Neuron R15, found in the abdominal ganglion of Aplysia californica, has been extensively studied as a model for the generation and modulation of bursting pacemaker activity. However, the functional significance of this cell's activity pattern has not been established. In order to determine the functional significance of R15's bursting pacemaker pattern, we have been making intracellular recordings from the cell in intact Aplysia.

In these studies, the abdominal ganglion is exposed by a small, dorsal incision in an animal pinned foot-down in a paraffin-lined dish. The sides of the incision are pulled up and away, so as to allow access to the ganglion while preventing loss of hemolymph or mixing of hemolymph with the seawater surrounding the animal. Cell R15 and/or other cells may then be impaled with an intracellular micropipette electrode.

Using this preparation, we have found that in approximately 70% of impaled R15's, easily recognizable bursting pacemaker activity is present. The most consistent source of irregularity in burst activity is due to excitatory inputs which reach the abdominal ganglion via the right connective nerve. Cutting this nerve results in a greater regularity of bursting activity.

Some of the existing data supports the view that R15 is an integral part of an osmoregulatory response in Aplysia. We have examined this possibility in the intact preparation. Substitution of 90% sea water for normal sea water produces a hyperpolarization of R15 which either silences it or significantly increases the interburst interval over that produced by control bath changes in 75% of trials. In a number of trials in which slowing of the cell did not occur, increased EPSP activity was evident during stimulus presentation. In many of these cases, slowdown of R15 after hypotonic substitution was evident after cutting the right and left connective nerves to the head ganglion. Hypotonic sea water had no effect on cell R2. Our results show that bursting pacemaker activity is not an artifact of ganglion isolation and that a role for R15 in osmoregulation is possible. Supported by grant BNS 81-09348.

196.8 APLYSIA ATRIAL GLAND PEPTIDE(S): I. ACTIVATION OF NEURONAL INPUT INTO BUCCAL MUSCLE I5. II. STIMULATION OF EGG LAYING IN STYLOCHEILUS. Vanita A. Padgaonkar* & Jeffrey L. Ram (SPON: H. Goldman). Dept. of Physiology, Wayne State Univ., Detroit, MI 48201.

The atrial gland (AG) of Aplysia is a glandular structure at the rostral end of the large hermaphroditic duct. Like the egg-laying hormone (ELH) of the bag cell neurons, AG peptides cause egg laying upon injection into mature Aplysia (Arch et al., J. Comp. Physiol. 128:67).

I. We examined whether AG factors have effects similar to ELH on excitatory input into buccal muscle I5. In buccal ganglia-I5 preparations ELH has been shown to increase excitatory input into muscle I5 (Ram, Brain Res. 236:505). I5 electrophysiological input was recorded with an extracellular electrode in buccal ganglia-I5 preparations. The preparation was constantly superfused with buffered sea water (Instant Ocean containing 10 mM glucose, 5 mM tris (pH 8.0), and 100 µg/ml streptomycin) except that the pump was stopped for 10 min when samples were applied. Stopping the pump and adding comparable volumes of buffered sea water had no effect on I5 activity.

As little as 1/10000 of the AG of a single animal increased excitatory input to muscle I5. With higher concentrations, activity began within 10 min of sample application and typically peaked shortly after the pump was turned back on. The increased input to I5 lasted from half an hour to several hours, gradually declining to previous levels, and this excitatory response could be obtained again on subsequent applications. The factor(s) causing the response is/are stable to boiling. Comparable extracts made from gonad, small hermaphroditic duct, winding gland, esophagus, crop, posterior gizzard, liver, or rectum did not have excitatory effects similar to the effects of AG extracts on I5 input. CCK1-8 and LHRF also had no effect on I5 input.

AG was fractionated on Sephadex G-50 in formic acid, and fractions were subsequently freeze-dried. AG fractions most active in exciting I5 input eluted with approximately the same V_e/V_0 as ELH.

II. AG homogenates and Sephadex G-50 fractions were bioassayed for stimulation of egg laying by injection into Stylocheilus, which has been shown to lay in response to ELH (Ram, ibid.). Stylocheilus laid in response to 1/500 and 1/1000 AG but not following 1/2000, 1/5000, or 1/10000 AG. Blind injections of the same Sephadex G-50 fractions tested above for neurostimulatory activity gave egg laying only for neuroactive fractions.

Supported by NIH grant NS15041 to JLR.

196.9 A SECOND NEUROACTIVE SUBSTANCE FROM R3-R14 NEURONS: CHARACTERIZATION AND EFFECTS ON ANTERIOR AORTA OF APLYSIA. D. Gibson*, C.Y. Lin*, and D.J. McAdoo (spon.: R. Bowker). Marine Biomedical Institute, Univ. Tx. Med. Br., Galveston, Texas 77550-2772.

We believe that cells R3-R14 in the abdominal ganglion of Aplysia release at least two different messengers: glycine (Sawada et al. 1981, Brain Res. 207; Price et al. 1979, J. Neurobiol. 10) and peptides (Gainer and Wollberg, 1974, J. Neurobiol. 5). We are investigating the possibility that the peptides made in these cells have hormonal effects. We have extracted an acidic fraction of about 500 Dalton molecular weight from these cells. This fraction is active on aorta muscle, the apparent target of glycine, where it blocks excitatory junction potentials (EJPs) but does not affect inhibitory potentials (IJPs). Simultaneous recording from nerve and muscle and from multiple sites on the muscle indicate that the effect is post-synaptic, and it can be used to determine the focus of innervation of electrically-coupled muscle fibers.

Possible release sites of this material are processes of R14, which terminate on the aorta, and axons of R3-R14 which terminate at the gill efferent vein, on a direct path to the aorta via the heart. Our material is equally effective when applied to the outside of the aorta or to its luminal surface, whether extracted from cell bodies or from axons.

Separation techniques to date include sizing on a Sephadex G10 column, cation exchange on a Dowex column, and further separation with a reverse phase HPLC column, after which the recovered material remains active in doses down to 1/10 of the material from one animal.

Most recording was done with surface electrodes which could not be dislodged by muscle contraction. Intracellular microelectrodes were used to corroborate these records and to assay the effect of this material on resting potential.

In summary, it appears extremely likely that R3-R14 releases more than one chemical substance to act on circulatory musculature.

196.10 PRODUCTION OF MONOCLONAL ANTIBODIES AGAINST BIOLOGICALLY ACTIVE PEPTIDES FROM THE ATRIAL GLAND OF APLYSIA CALIFORNICA. S.D. Painter, G.T. Nagle, K.L. Kelner and J.E. Blankenship. Marine Biomedical Inst., Univ. Tx. Med. Br., Galveston, TX 77550.

The atrial gland of Aplysia californica contains at least three peptides (A, B and ERH) which induce bag cell discharge in vitro and egg-laying behavior in vivo. It has not yet been shown, however, that endogenous A, B or ERH normally mediate these responses in the animal. Moreover, since the atrial gland appears to be an exocrine gland, releasing its contents into the lumen of the reproductive tract, we were interested in further studying the possibility of atrial gland secretion into the hemocoel and in locating alternative endogenous sources of these peptides.

A crude preparation of small molecular weight molecules was isolated from atrial gland homogenates by Sephadex G-50 column chromatography. Biologically active material (approximately 3000-15000 daltons molecular weight) was dialyzed against distilled water and then injected intraperitoneally into mice (0.5 mg in Freund's adjuvant/mouse/injection). Serum was collected and shown to contain antibodies against the natural biological material and against synthetic A, B and ERH (synthesized by Dr. D.H. Schlesinger of New York University), as detected by enzyme-linked immunosorbent assay (ELISA). The serum antibodies have also been used (1:1000 dilution) to specifically label the atrial gland immunocytochemically, using the unlabelled antibody peroxidase-anti-peroxidase (PAP) method.

To generate monoclonal antibodies, spleen cells were collected from immunized mice and fused with P3 myeloma cells by a modified method of Köhler and Milstein. Hybridoma cells were selected by growth in HAT medium. Supernatants from the resulting clones were screened for the presence of antibodies directed against the purified biological material and against synthetic A, B and ERH. The most interesting clones were selected and subcloned by limiting dilution. We now have several cultures which produce antibodies selective for B and ERH. These monoclonal antibodies will be used to investigate the source, release and function of these biologically active peptides by immunocytochemistry and radioimmunoassay. (Supported by NSF PCM 79-12175, NIH NS 11255, NS 07010, NS 07025, and NS 07185)

196.11 BIOSYNTHESIS OF LOW MOLECULAR WEIGHT PEPTIDES IN THE ATRIAL GLAND OF APLYSIA CALIFORNICA. K.L. Kelner and J.E. Blankenship. Marine Biomedical Inst., Univ. Tx. Med. Br., Galveston, TX 77550.

To date, three low molecular weight (MW) peptides, designated A, B and ERH, have been isolated from the atrial gland of Aplysia californica. Each peptide has been sequenced, is 34 amino acids in length, and all have isoelectric points between 8 and 9. All three peptides cause egg laying in the intact animal and, when applied to the isolated nervous system, induce a discharge of the neurosecretory bag cells. We have studied the in vitro biosynthesis of small peptides in the atrial gland by 3H-amino acid incorporation. Freshly dissected glands were incubated for 2 h at 15C in artificial sea water containing 55 mM glucose and 50 mCi of an 3H-amino acid mixture. Glands were homogenized in an acid medium containing peptidase inhibitors and centrifuged. Approximately 1 mg of the lyophilized supernate was applied to an SDS polyacrylamide gradient gel (8-15%). Scintillation counting of 2 mm gel slices revealed a predominant peak with a MW less than 5000 and multiple unresolved peaks at higher MW. The small MW peak contained about 35% of the label which had been incorporated into macromolecules. Alternatively, when 150 mg of the lyophilized supernate was applied to a Sephadex G-50 column, these small labelled peptides were resolved into two equal peaks of radioactivity with apparent MW of approximately 8000 and 5000. The 8000 MW peak was coincident with a small peak of absorbance at 280 nm (OD=0.5), while the 5000 MW peak co-eluted with a larger peak of absorbance (OD=1.3). When the material in these peaks was subjected to isoelectric focusing, the radioactivity from each peak was found as a single band with isoelectric points of about 9 for the 8000 MW peak and 4 for the 5000 MW peak. When quantitatively bioassayed for egg laying activity, the column effluent showed a single symmetrical peak of activity centered over the 8000 MW peak. Injection of the 8000 MW peak material into an animal from which the bag cells had been removed caused egg laying at approximately the same dose as in an intact animal. Since only ERH, but not peptides A or B is able to elicit egg laying in bag cell-less animals, this suggests that a large proportion of the 8000 MW material is ERH, not A and B. Further purification of the 8000 MW peak by DEAE ion exchange chromatography yielded a biologically active fraction which migrated as a single band on SDS gradient gels and which comigrated with synthetic ERH (synthesized by Dr. D. Schlesinger, New York University). In conclusion, we have demonstrated that the atrial gland of Aplysia californica is able to synthesize two classes of small MW peptides: 1) a basic peptide group which causes egg laying and which appears to be largely ERH, and 2) an acidic peptide group which has, as yet, no known biological activity. Supported by NSF PCM 79-12175, NIH NS 11255 and NS 07185.

196.12 FACTORS AFFECTING THE MORPHOLOGY OF IDENTIFIED MOLLUSCAN NEURONS GROWN IN CELL CULTURE. S.B. Kater, H.R. Miller* and C.S. Cohan*, Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242.

Identified neurons from the buccal ganglion of the snail, Helisoma, express a distinctive morphology, physiology and connectivity within the surroundings of their normal ganglionic environment. We now report that these identified neurons can be removed from their complex environment and transplanted into the defined conditions of cell culture. We have begun to address the following questions: 1) do isolated cells retain features which enable them to be distinguished from one another, and 2) what factors affect the expression of cell-specific characteristics in culture. In order to answer these questions we have cultured neurons in either defined medium, medium which contained Helisoma conditioning factor (CF), or dishes in which CF was preadsorbed to the polylysine surface (Wong, et al, J. Neurosci. 1:1008, 1981).

In cell culture, neurons 4, 5, and 19 retained the characteristic action potential waveforms which distinguish them from one another in the ganglion. These waveform properties remained relatively constant throughout 7 days of culture and were independent of the extent of growth exhibited by each cell.

The morphology of cultured neurons was, as expected, quite different from that in the CNS. When co-cultured with Helisoma brains, isolated neurons 4 and 5 characteristically were multipolar and displayed diffuse neuritic sprouting which was radially arranged about the soma. Neuron 19, under the same conditions, displayed a very different morphology. There was much less outgrowth, it was usually restricted to one or two quadrants of the cell body, and associated with extensive preliminary veiling. Growth of 19 often stopped by day 1 or 2, whereas the growth of 4 and 5 may peak on days 4 to 6. When these same neurons were grown on CF adsorbed plates very different results were observed. Under these conditions neuron 19 displayed the profuse neuritic sprouting that was characteristic of 4 and 5 under co-culture conditions. Thus, neuron 19 has different requirements from neurons 4 and 5 for its growth.

Taken together these initial observations suggest that 1) the characteristic action potential waveforms of a neuron are independent of conditions which affect cellular morphology, and 2) different identified neurons respond differently to particular environmental cues which may evoke, retard, or modify the expression of neuronal morphology.

197.1 SYNAPTIC MONOCLONAL ANTIBODIES. 1. AN ANTIGEN WHICH HAS A HORMONE RECEPTOR-LIKE DISTRIBUTION IN THE RAT BRAIN. R.S. Lasher, L.N. Minier, P.F. Erickson, E.E. Mena and C.W. Cotman. Dept. Anat., Univ. Colo. Med. Sch., Denver, CO 80262; Dept. Psychobiol., Univ. Calif., Irvine, CA 92717

In an experiment designed to raise monoclonal antibodies (MABs) to synaptic antigenic determinants, a (Balb/C x C57/B1) mouse was immunized first with concanavalin A-binding proteins purified from synaptic junctions (SJ-CONA), and then with synaptosomal plasma membranes (SPMs) just prior to the fusion. Using a solid phase assay employing I-125 goat anti-mouse IgG+IgM, over 30 culture media were found which contained antibodies reacting with native SPMs, denatured SPMs and denatured synaptic junctions. Antibody from one culture produced a faint, patchy fluorescence over neuronal processes when living cultures of rat cerebellum were incubated first with medium and then with FITC-goat anti-mouse IgG+IgM. MAB from clone 2,9D of this culture was found to be an IgM by Ouchterlony immunodiffusion. It continues to produce the same fluorescent pattern with living cells as seen before cloning.

After indirect immunoperoxidase methods, examination with the light microscope revealed intense nuclear staining in pyramidal and granule cells in the hippocampus, Purkinje cells and deep nuclear neurons in the cerebellum, and in neurons in the caudate-putamen. Somewhat less intense nuclear staining was seen in neurons in most layers of the cerebral cortex, in the amygdala, medial thalamus, lateral mammillary area, and cerebellum (mainly basket-stellate cells and some granule cells). Correspondingly intense cytoplasmic staining was seen in these same areas in neurons lacking nuclear staining. After electron microscopy of the cerebellum, cerebral cortex and hippocampus, reaction product was seen to be uniformly distributed over the plasma membranes of many neuronal processes and synapses; it was also associated with smooth ER and mitochrondria in the cytoplasm, and with euchromatin in the nucleus. A small amount of product was seen in the cytoplasm of neurons whose nucleus contained large amounts of product. A few glial processes were also lightly stained.

MAB 2,9D also reacts with SJ-CONA, as well as with crude homogenates of rat liver, kidney, thymus, testes and skeletal muscle. The antigenic determinant is distributed in a pattern very similar to that seen for the binding of various hormones (e.g., corticosterone) in the rat brain, raising the possibility that it may be associated with a hormone receptor or a functionally similar type of molecule. Supported by NIH grants #NS-13133, NS-09199 and NS-08957.

197.2 ASTROCYTE SUBCLASSES DETECTED BY MONOCLONAL ANTIBODIES. C. Lagenaur. Inst. of Neurobiology, Heidelberg Univ., 6900 Heidelberg, F.R.G.

Three monoclonal antibodies have been identified that appear to be useful in defining subpopulations of central nervous system astroglia. The best characterized antibody, anti-SSEA-1, has been previously characterized as to its reactivity with the cell surface of mouse embryonic cells of morula and later stages (Fox, N. et al., Develop. Biol. 83:391, 1980). Two additional monoclonal antibodies, designated anti-M3 and anti-M4, were derived from rats immunized with mouse cerebellar membranes that had been fractionated via sucrose-deoxycholate gradient centrifugation. Using anti-glial fibrillary acidic protein as a marker for mature astrocytes, the cellular distribution of the antigens could be determined by indirect immunofluorescence. M3 was found to be expressed by nearly all astrocytes in primary cultures of early postnatal mouse cerebella; SSEA-1 was expressed by only 20-40% of all astrocytes. M4 was expressed by less than 10% of all astrocytes, becoming increasingly detectable after 3-5 days in vitro. Both SSEA-1 and M4 were not detectable on fibronectin positive fibroblast-like cells, while M3 was expressed by at least some of these cells. The comparison of in vivo and in vitro expression of these three cell surface antigens may prove useful in distinguishing relationships between astroglial subclasses.

197.3 MONOCLONAL ANTIBODIES RECOGNIZE SPECIFIC CELL TYPES IN THE DEVELOPING RAT CEREBELLUM. Joel M. Levine*, Phyllis Kawanabe* and William B. Stallcup*. The Salk Institute, Molecular Neurobiology Lab, San Diego, CA. 92138. (SPON: J. Patrick).

We have produced two monoclonal antibodies that bind to cell surface components of cells in rat cerebellar cortex at 2 different stages of development. We immunized mice with B49 cells, a clonal line with properties of both neurons and glia, and fused the spleen cells with the P3x63Ag8.653 myeloma line. Hybridomas were screened by indirect radioimmune binding to living B49 cells and by immunofluorescent staining of cerebellar cultures. Positive cells were cloned by limiting dilution.

Antibody D1.1 immunofluorescently labels cells of the external granular layer (EGL) as well as neuroepithelial cells throughout the brain. The D1.1 antigen is expressed by dividing cells (as shown by ^{3}H-thymidine autoradiography) as early as embryonic day 19 when the EGL begins to form. It is present throughout the period of cellular proliferation but is no longer detected after postnatal day 20 when the EGL disappears. No cells in the adult cerebellum are labeled with D1.1. Postnatal cerebellar cells in culture also express the D1.1 antigen. However, with increasing maturation in vitro, both neurons and astrocytes lose the D1.1 antigen. Crude preparations of gangliosides from B49 cells inhibit antibody binding suggesting that the D1.1 antigen is carried on a ganglioside. Similar preparations from cell lines that do not bind the antibody have no inhibitory activity.

Antibody D120.43 is directed against the NG2 surface antigen, a marker previously shown to be on the surfaces of subpopulations of the neurons and astrocytes surviving in cultures of postnatal cerebellum (Dev. Biol., 83:154). D120.43 binds to process bearing cells within the molecular layer of adult rat cerebellum as well as cells throughout the brain. On the basis of cell morphology and position, some of the D120.43 positive cells are identified as basket and stellate interneurons. In contrast to D1.1, D120.43 does not label proliferating cells of the EGL but rather it appears on cells as they begin to differentiate within the developing molecular layer. D120.43 immunoprecipitates 2 polypeptides of molecular weights 300,000 and 500,000 from detergent extracts of ^{125}I-labeled B49 cells.

The antibodies described here identify cell surface antigens that mark 2 different stages in the development of cerebellar interneurons: 1) a proliferative stage during which multipotent stem cells carry the D1.1 antigen on their surfaces and 2) a differentiated stage during which stellate and basket cells express the NG2 antigen. These latter 2 cell types retain the NG2 marker in the adult.

197.4 ATP-DEPENDENT Ca^{2+} TRANSPORT ACTIVITIES IN SYNAPTOSOMES: PURIFICATION OF A CALMODULIN-SENSITIVE Ca^{2+} PUMP FROM SYNAPTIC PLASMA MEMBRANES. Diane M. Papazian*, Hannah Rahamimoff*, and Stanley M. Goldin. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

Membrane fractions derived from osmotically lysed synaptosomes contain two nonmitochondrial ATP-dependent Ca^{2+} transport activities differing in their regulation by calmodulin and in their stability. Synaptic plasma membranes contain a labile, calmodulin-activated, (Ca^{2+} + Mg^{2+}) ATPase catalyzing ATP-dependent Ca^{2+} transport after reconstitution into liposomes. Synaptosomal vesicles, a fraction including but not exclusively composed of synaptic vesicles, contain a more stable, calmodulin-insensitive ATPase catalyzing Ca^{2+} uptake into native and reconstituted vesicles (Papazian, D.M. et al., Soc. Neurosci. Abstr. 7:367,1981).

The calmodulin-activated (Ca^{2+} + Mg^{2+}) ATPase of synaptic plasma membranes has been purified at least 50-fold by calmodulin-Sepharose-4B affinity chromatography. The purification procedure removes most of the Mg^{2+} ATPase activity. The major protein in the purified preparation, M_r = 140,000, has been identified as a (Ca^{2+} + Mg^{2+}) ATPase; it is phosphorylated by [γ^{32}P] ATP in a Ca^{2+} dependent manner to form an acyl (hydroxylamine-sensitive) phosphoenzyme. After reconstitution into liposomes, the purified enzyme efficiently catalyzes ATP-dependent Ca^{2+} transport, with a ratio of 1 Ca^{2+} transported per ATP hydrolyzed.

The synaptic plasma membrane (Ca^{2+} + Mg^{2+}) ATPase has been compared with proteins of M_r = 94,000 (major component) and 140,000 purified from synaptosomal vesicles by "transport specific fractionation" on the basis of their involvement in ATP-dependent Ca^{2+} transport (Papazian, D. et al., Proc. Natl. Acad. Sci. USA 76:3708, 1979). The M_r = 94,000 protein is hypothesized to comprise a distinct Ca^{2+} transport component, corresponding to the stable, calmodulin-insensitive Ca^{2+} transport activity of synaptosomal vesicles.

Thus, the M_r = 94,000 and 140,000 proteins may represent two distinct synaptosomal ATP-dependent Ca^{2+} transport systems, differing in their regulation by calmodulin, their subcellular localization, and their physiological roles within nerve terminals Supported by NIH Grant 16475.

197.5 COMPARISON OF THE HIGH AFFINITY CA^{2+}- STIMULATED MG^{2+}- DEPENDENT ATPASES OF RAT BRAIN SYNAPTIC AND MICROSOMAL MEMBRANES. M.L. Michaelis, E.K. Michaelis, H.H. Chang*, and T.E. Kitos*. Center for Biomedical Research, Univ. of Kansas, Lawrence, KS. 66045

The regulation of intraneuronal free calcium concentrations in the range of 0.1 - 1.0μM has recently been the subject of intensive investigation. Two ATP-utilizing systems may play a role in controlling intrasynaptosomal free Ca^{2+}: 1) Ca^{2+} sequestration by endoplasmic reticulum-like structures, and 2) Ca^{2+} extrusion from the nerve terminals via a plasma membrane Ca^{2+} pump similar to that in erythrocytes. Although high affinity (Ca^{2+} - Mg^{2+}) ATPase activity has now been reported to exist in both microsomal and synaptic plasma membrane fractions from brain, it has not yet been determined whether the synaptic plasma membrane high affinity Ca^{2+} - stimulated Mg^{2+} ATPase differs from that of the brain microsomal fraction. This report describes the use of highly purified rat brain synaptic plasma membranes to obtain detailed information about the properties of the synaptic membrane (Ca^{2+} - Mg^{2+}) ATPase in order to determine whether this enzyme has any characteristics which distinguish it from the microsomal enzyme.

The high affinity synaptic membrane (Ca^{2+} - Mg^{2+}) ATPase activity was found to be strictly dependent on the presence of Mg^{2+}, to have a high affinity for Ca^{2+} ($K_{0.5}$ = 0.23μM), to have a relatively high affinity for both Mg^{2+} and ATP ($K_{0.5}$ = 6.6μM for Mg^{2+} and K_M = 18.9μM for ATP), and to exhibit positive cooperativity in the activation of the enzyme by ATP (Hill coefficient of 1.5). The membrane (Ca^{2+} - Mg^{2+}) ATPase activity was not inhibited by ouabain or oligomycin, nor was it significantly affected by changes in K^+ or Na^+ concentrations in the incubation. The plasma membrane enzyme was, however, quite sensitive to low concentrations of vanadate (5μM). Examination of microsomal (Ca^{2+} - Mg^{2+}) ATPase under conditions identical to those used with plasma membranes, i.e., the presence of 5μM Mg^{2+}, 1 mM ATP, and a divalent cation chelating CDTA buffer system, revealed (Ca^{2+} - Mg^{2+}) ATPase activity with high affinity for Ca^{2+} in microsomes also ($K_{0.5}$ = 0.48μM Ca^{2+}). The basal Mg^{2+} ATPase in microsomes was 3-fold higher than in synaptic membranes, and thus the Ca^{2+} - stimulated activity represented a much smaller fraction of the total divalent cation ATPase activity in microsomes than in synaptic membranes. Unlike the plasma membrane enzyme, the microsomal Ca^{2+} - stimulated Mg^{2+} ATPase was not affected by 5μ vanadate. Thus the two enzyme systems do indeed have similar characteristics, but they appear to differ in their sensitivity to low vanadate concentrations and to exhibit slightly different affinities for Ca^{2+} under the assay conditions used in these studies. 197.6 PURIFICATION OF A MEMBRANE PROTEIN DISTRIBUTED IN A GRADIENT IN CHICK RETINA. Joseph R. Moskal*, G. David Trisler*, and Marshall W. Nirenberg. Lab. Biochem. Genetics, NHLBI, NIH, Bethesda, MD. 20205.

A 35-fold dorsal-ventral gradient of cell surface molecules (TOP) in chick neural retina, that can be used as a marker of cell position, has been identified by the use of a monoclonal antibody obtained by the fusion of P3X63 Ag8 myeloma cells with spleen cells from mice immunized with 14-day chick embryo dorsal retina (Trisler et al., Proc. Natl. Acad. Sci., (1981) 78, 2145). Antigenicity was destroyed by trypsin; however, trypsinized retina cells that were cultured for 24 hr bound 50% as much antibody as intact retina. TOP was purified as follows: dorsal retina cells were homogenized in hypotonic buffer and membranes were pelleted and washed by repetitive centrifugation at 30,000 x g. Particulate protein was solubilized (1% Triton X-100, 0.2% SDS, 1 mM phenylmethylsulfonylfluoride, 5 mM EGTA, 150 mM NaCl and 25 mM HEPES; pH 7.5) and the 30,000 x g supernatant fraction was applied to antibody-Affigel 10 columns that were prepared with antibody to TOP or antibody synthesized by parental myeloma, P3X63 Ag8, that had been purified by Protein A-Sepharose column chromatography. The antibody-Affigel 10 columns were washed with the above buffer followed by the same buffer with 0.1% rather than 1% Triton X-100, and bound material was eluted with a solution containing 0.2 M acetic acid containing 0.1% Triton X-100 and 150 mM NaCl; pH 3.0-3.5. Samples were prepared for SDS-PAGE according to Neville (J. Biol. Chem., (1971) 246, 6328) diluted 10-fold with Laemmli's electrode buffer (Nature, 227, 680), subjected to electrophoresis, and stained with silver (Merril et al., Electrophoresis, (1982) 3, 17). Only 1 major band with an M_r of 46,000-49,000 was detected in the eluate from the anti-TOP IgG-Affigel column; whereas, this band was not detected in the eluate from the P3X63 Ag8 IgG-Affigel column. Isoelectric focusing (pH 2.5-5.0) of affinity-purified TOP resulted in a sharply focused band at pH 4.0-4.1. Affinity-purified TOP from embryonic chick cerebrum and thalamus had the same molecular weight (SDS-PAGE) and isoelectric point as TOP purified from chick retina. These results demonstrate that the antigens purified from brain and retina have similar properties. Further work is needed to determine whether the structures of these antigens are indeed identical.

197.7 5'-NUCLEOTIDASE IN SCHWANN CELL PLASMALEMMAE FROM DENERVATED CAT PERIPHERAL NERVE. S.M. Ross*, M.I. Sabri and P.S. Spencer, (SPON: M.I. Sabri). Inst. of Neurotoxicology, Albert Einstein Coll. of Med., Bronx, NY 10461.

Interest in the mechanisms involved in the control of cell-cell interactions has focused attention on surface membrane glycoproteins. A previous study reported isolation and partial characterization of plasma membrane fractions (PM) harvested from an enriched population of undifferentiated Schwann cells resident in denervated cat peripheral nerve (Ross et al., Trans. Am. Soc. Neurochem. 13:267, 1982). This report describes the further purification and characterization of PMs. SDS-PAGE of Schwann-cell PMs revealed the presence of Coomassie-blue-positive diffuse bands (M.W. 60-65K), two PAS-positive bands (M.W. 150-200K), and the absence of myelin-specific proteins. 5'Nucleotidase (5'N), a glycoprotein-dependent enzyme, was enriched in PM preparations. The plant lectin, concanavalin-A (Con-A), reduced 5'N activity in a dose-dependent manner (100-800ug/ml) and, at high concentrations (600ug/ml), activity was inhibited in both crude homogenate (CH) and PM preparations by approximately 80%. Con-A bound specifically to D-mannose and D-glucose moieties of glycoproteins associated with 5'N since activity returned to control levels with pretreatment of the specific hapten sugar, alpha-methyl-D-mannoside (50mM) and to near control values with glucose (50mM). Wheat germ agglutinin (200 ug/ml) also inhibited 5'N activity in CH and PM preparations (55 and 32% of controls, respectively). Preliminary experiments revealed that optimal 5'N activity was obtained at physiological pH (7-8) and at relatively high temperatures (55°C). 5'N activity was magnesium independent (up to 8 mM), although 1 mM EDTA reduced activity to 43 % of control values. Various nucleotides were screened for enzyme specificity and studies indicated that two diphosphorylated nucleotides, UDP and ADP (100uM), reduced 5'N activity to 36 and 23% of PM control values, respectively; these nucleotides thus may serve as substrates for hydrolysis by this enzyme. Results from this study suggest that 5'N is a stable PM enzyme which contains free D-mannose and/or D-glucose residues in glycoproteins resident on the exposed surface that are essential for its activity. The physiological role of 5'N may be of particular importance in neuron-glial interactions since 1) its hydrolysis product, adenosine, is membrane permeant and has been implicated as an intercellular mediator in the nervous system, and 2) exposed glycoproteins essential to 5'N activity may represent an important molecular species involved in cell-cell recognition.

197.8 MONOAMINES STIMULATE PHOSPHATIDYLETHANOLAMINE METHYLATION IN RAT BRAIN. C.E. Leprohon*, J.K. Blusztajn*, and R.J. Wurtman. (SPON: T. Maher). Dept. Nutr. & Fd. Sci. MIT, Cambridge, MA 02139.

We have previously shown that mammalian brain synaptosomes synthesize phosphatidylcholine (PC) from phosphatidylethanolamine (PE) by a stepwise methylation catalyzed by phosphatidylethanolamine-N-methyltransferase(s) (PEMT). This newly formed PC can be hydrolyzed to liberate free choline, which may then be available for acetylcholine synthesis.

Catecholamines have been shown to modify the activity of PEMT in a variety of peripheral tissues (Hirata & Axelrod, 1980). However, to date there has been little compelling evidence that the catecholamines are able to stimulate PEMT in central nervous tissue. We now provide evidence that three monoamines, norepinephrine (NE), serotonin (5-HT) and dopamine (DA), enhance the in vitro activity of PEMT in rat brain.

The synaptosomal-enriched P2 pellet from rat brain was resuspended in a buffer (pH=7.5) containing 2.5 μCi (CH_3-^{3}H)-s-adenosylmethionine (15 Ci/mmol) and 100 μM NE, 5-HT or DA. NE, 5-HT and DA increased the incorporation of CH_3-^{3}H groups into the PE methylated products, phosphatidylmonomethylethanolamine (PME) and phosphatidyldimethylethanolamine (PDE) but not into PC. DA was more potent than either NE or 5-HT, with the first methylation (PME) being most sensitive to DA.

pmoles $CH_3{}^3H$ per mg protein per 30 min (mean ± S.D., n=3)

	PME	PDE	PC
Control	0.21±0.02	0.48±0.06	0.16±0.01
NE	0.31±0.01	0.71±0.08	0.16±0.01
5-HT	0.30±0.02	0.67±0.01	0.19±0.01
DA	0.70±0.02	0.69±0.01	0.17±0.01

Osmotic shock and addition of 100 μM ATP and 5 mM $MgCl_2$ to the incubation buffer enhanced the response of PEMT to DA such that a 6-fold increase in CH_3-^{3}H incorporation into PME, and significant increases into both PDE and PC, were observed. The stimulation of PE methylation by DA was completely blocked by co-incubation with 100 μM haliperidol. Phenoxybenzamine and propranolol (100 μM) partially blocked the effect of NE on PEMT. Co-incubation with dibutyryl cyclic AMP or forskolin had no effect on basal or DA-stimulated PE methylation suggesting that adenylate cyclase activation does not modify PEMT activity.

These results suggest that the monoaminergic neurotransmitters may modify the phospholipid composition of synaptic membranes, perhaps mediating some of the slow, nonionic effects of neurotransmission; they may also affect choline availability. (Supported by MH-28783 and Canadian MRC).

197.9 REGIONAL DISTRIBUTION OF PHOSPHATIDYLETHANOLAMINE-N-METHYLTRANSFERASE(S) ACTIVITY IN RAT BRAIN. D. Reinstein*, C. Leprohon*, J.K. Blusztajn* and R. Wurtman. (SPON., E. Spindel) Dept. Nutri. & Food Sci., MIT, Cambridge, MA 02139.

We have previously shown that rat brian synaptosomes contain an enzyme, phosphatidylethanolamine-N-methyltransferase(PEMT), which catalyzes the synthesis of phosphatidylcholine(PC) from phosphatidylethanolamine. This newly formed PC can be hydrolyzed to liberate free choline, possibly for acetylcholine synthesis. We determined whether PEMT was preferentially distributed in cholinergic terminals by simultaneously measuring PEMT and cholineacetyltransferase(CAT) activities in various brain regions.

Incorporation of ^{3}H-methyl groups from S-adenosylmethionine(SAM) into phosphatidylmonomethylethanolamine(PME) was greatest in striatum. ^{3}H-methyl incorporation into PC only showed regional differences when exogenous phosphatidyldimethylethanolamine(PDE) was included in the incubation medium, with pons and cerebellum having the greatest activity. These regional differences in PEMT revealed no simple relationship to CAT activity (see Table).

Transection of the fimbria/fornix decreased hippocampal CAT activity by 80% but had no effect on hippocampal PEMT activity. Together, these data indicate that PeMT is not solely distributed in cholinergic terminals.

We have shown that monoamines, SAM and S-adenosylhomocysteine influence in vitro PEMT activity. Regional differences in levels of these compounds may contribute to the observed distribution of PeMT activity. Therefore, we greatly diluted the concentration of these compounds by osmotically shocking the synaptosomes before PEMT measurement. Osmotic shock had no effect on the regional distribution of PEMT activity, suggesting that regional differences in activity cannot be explained by the presence of endogenous activiators and/or inhibitors. Regional differences in ^{3}H-methyl incorporation into PDE were also observed with the addition of PME to the incubation medium. This pattern followed the same trend as that observed for ^{3}H-methyl incorporation into PC in the presence of PDE.

	^{3}H-methyl incorporation (X±SD) (pmol/mg protein x 30 min.)			(nmol/mg protein x 15')
	PME	PDE	PC	CAT
Striatum	0.54±0.09	1.13±0.17	0.81±0.07	18.8
Cortex	0.31±0.06	1.39±0.05	1.26±0.04	10.9
Hippocampus	0.36±0.04	0.94±0.03	0.89±0.03	14.3
Cerebellum	0.35±0.04	1.88±0.12	2.21±0.04	1.2
Hypothalamus	0.41±0.07	1.11±0.16	0.70±0.07	10.4
Pons	0.50±0.07	3.41±0.07	3.57±0.12	17.3

Thus, while regional differences in PEMT activity exist in rat brain, the significance of this distribution pattern remains unclear. (Supported by MH-28783 and the Canadian MRC).

197.10 FREEZE-FRACTURE ULTRASTRUCTURE OF DEVELOPING AND ADULT RAT RETINAL GANGLION CELL AXON MEMBRANE. J.A. Black*, R.E. Foster, and S.G. Waxman. Dept. of Neurology, Stanford Medical School, VA Medical Center, Stanford, CA and Neurotoxicology and Exp. Therap. Br., U.S. Army Research Institute, Aberdeen Proving Ground, MD.

The intra-retinal segment of the rat retinal ganglion cell axon membrane is non-myelinated in both the neonatal and adult animal. In contrast, the optic nerve segment of this axon is non-myelinated in neonatal rats but fully myelinated in the adult. We previously studied the development of the axolemma during myelination of the optic nerve (Black et al., 1982a). In this study, we examine the freeze-fracture structure of intra-retinal ganglion cell axolemma in developing and adult Long Evans rats in order to determine whether there are any ultrastructural changes in the non-myelinated axolemma during this developmental period.

Retinas from young animals were fixed in situ with 5% glutaraldehyde prior to rapid excision and immersion fixation for 1 hr. Adult retinas were perfused with 5% glutaraldehyde and then immersion fixed for 1 hr. All tissues were then processed according to conventional freeze-fracture methods, and replicas were examined with an electron microscope. Intramembranous particle (IMP) densities (mean±SEM) and sizes (mean±SEM, in nm) for axon membrane E- and P-fracture faces for various ages of retinas are given below:

	E-face		P-face	
Age	IMP/μm^2	size	IMP/μm^2	size
2 day	146±13.7	7.2±0.1	556±42.9	7.2±0.1
8 day	101±11.9	6.9±0.2	510±34.9	6.4±0.1
16 day	112±11.5	7.2±0.1	740±73.1	6.8±0.1
28 day	94±13.5	7.2±0.1	1281±176.9	6.4±0.1
Adult	222±29.5	8.5±0.1	1741±144.5	7.8±0.1

IMPs were generally randomly distributed on both E- and P-faces, except in the optic disc region where linear aggregations of IMPs are observed (Black et al., 1982b). E-face IMP density in the adult is greater than that in developing nerve fiber layer axons; the mean IMP size is also substantially greater in the adult than in the younger animals. On the P-face, there is a gradual increase in IMP density beginning at 8 days of age, with the greatest density in the adult. IMP size is also greatest in the adult. These data demonstrate that the non-myelinated axon membrane of the intra-retinal segment of the ganglion cell displays ultrastructural changes with age. These changes in membrane structure can be compared to the developmental alterations in the myelinated segment of this fiber (optic nerve) and to other developing non-myelinated CNS tracts (Segura-Garcia and Perrelet, 1981). [Supported by the VA, NIH, and Kroc Foundation]

197.11 GLYCOPROTEINS OF CULTURED CHICK CILIARY GANGLION NEURONS. M.Y. Giovanni*, A. Messing, D.E. Pleasure and M.C. Glick.* The Children's Hospital of Philadelphia, Departments of Pediatrics, Neurology, and Pathology and Laboratory Medicine, School of Medicine, University of Pennsylvania, Philadelphia, PA 19104.

A glycoprotein, M_r=200,000, was found to be associated with excitable membranes in mouse and human neuroblastoma cell lines (Littauer, U.Z., Giovanni, M.Y., and Glick, M.C., J. Biol. Chem. 255:5448, 1980). To determine the extent of this glycoprotein in neuronal systems, dissociated chick ciliary ganglion neurons were examined. These cells provide a primary monolayer culture of non-mammalian species and are an appropriate system to study in vitro neuritic processes which are electrically excitable.

Chick ciliary ganglion neurons from 8-day embryos were cultured relatively free of non-neuronal cells (Messing, A., Brain Research 232:479, 1982) for 6 days and then metabolically labeled for 2 days with L-[^{3}H]fucose or D-[^{3}H]glucosamine as glycoprotein precursors. At 8 days, other cultures were labeled with borotritide for examination of the external glycoproteins. The harvested neurites and cell bodies were examined by 7-14% polyacrylamide gel electrophoresis under denaturing conditions. The radioactive glycoproteins from either of the metabolically labeled cultures showed similar gel profiles. As with the differentiated neuroblastoma cells, a distinct peak was observed in the region of M_r=200,000. Other peaks were seen in the regions of M_r=140,000, 115,000, 90,000, 62,000, 43,000, 30,000 and 17,000. The profile of the externally labeled sialic acid residues showed that most of the fucosylated proteins were also sialylated. The major protein band detected by Coomassie brilliant blue staining was in the region of M_r=50,000, and coincided with a glycoprotein labeled with D-[^{3}H]glucosamine.

The detection of a glycoprotein, M_r=200,000, in cultured chick ciliary ganglion neurons may provide additional support to the correlation of this glycoprotein with the possession of electrically excitable membranes. Supported by NIH Grants HD 08356, HD 07107, NS 07064 and NS 05572.

197.12 GANGLIOSIDE PATTERN CORRELATION WITH METABOLIC RATE IN SALAMANDERS. Louis Irwin and Karen Loehr*. Dept. Biol., Simmons College, 300 The Fenway, Boston, MA 02115.

The functional or adaptive significance of phylogenetic variation in the ganglioside pattern of vertebrate brains remains to be explained, though a prominent theory relates ganglioside composition to thermal habitat (Rahmann H. 1977. Jap. J. Exp. Med. 48:85). We have tested this and the related possibility that ganglioside composition varies with metabolic rate, in the mole salamanders. Adult Ambystoma maculatum were acclimated for 4 weeks to 10°C, 20°C, or fluctuating temperatures that corresponded to those in the natural habitat during June and July in Massachusetts. Metabolic rates of individual salamanders were measured by closed system respirometry; then gangliosides were isolated from whole brain, separated by thin-layer chromatography, and quantified by scanning densitometry. Neither total ganglioside content nor the proportional concentration of the major gangliosides differed significantly among the three treatment groups. However, the relative content of a major ganglioside that comigrated with mammalian GD1a was negatively correlated ($r=-.56$) with individually determined metabolic rates. While the correlation was significant ($p < .01$) when computed without regard to treatment group, it was much stronger in salamanders exposed to fluctuating temperatures ($r=-.99$, $p < .01$) than to those acclimated to 10°C ($r=-.44$, ns) or to 20°C ($r=-.14$, ns). These results suggest that ganglioside patterns may be influenced indirectly by thermal habitat, but that the actual correlation may relate more directly to metabolic rate. (Supported by grants from NIH and the Simmons College Fund for Research.)

197.13 GROWTH OF NERVE FIBERS ON HYDROGEL SUBSTRATES CONTAINING FIBRONECTIN AND GLYCOSAMINOGLYCANS. S.T.Carbonetto and D.C.Turner* Depts of Pharmacology and Biochemstry, SUNY/Upstate Medical Ctr. Syracuse, NY 13210.

Hydrogel substrates prepared from poly-hydroxyethylmethacrylate (HEMA) permit the attachment of neurons cultured from chick embryo dorsal root ganglia but support little nerve fiber growth. Fibronectin added to HEMA before polymerization is trapped almost irreversibly within the hydrogel, rendering it an excellent substrate for nerve fiber growth (Carbonetto et al., Science in press). We report the use of defined HEMA-gel substrates to further characterize the interactions of growing nerve fibers with fibronectin and other components of the extracellular matrix.

Known constitutents of the extracellular matrix of the nervous system include fibronectin, collagen and several glycosaminoglycans. Unlike simple HEMA-gels or HEMA-gels containing fibronectin, HEMA-gels containing the glycosaminoglycans heparin, chondroitin sulfate or hyaluronate do not support nerve cell attachment, let alone fiber growth. Treatment of HEMA-gels containing fibronectin with heparin or incorporation of heparin along with fibronectin in the gel matrix greatly reduces the efficacy of fibronectin as a substrate for nerve fiber growth.

Fibronectin contains distinct functional regions including separate binding sites for glycosaminoglycans, fibronectin, and gelatin and a region which mediates attachment of muscle cells and fibroblasts. Fragments which bear one or more of these functional regions can be isolated following partial proteolysis of native fibronectin. (Ehrismann et al., J. Biol. Chem. 256, 4056,1981). Our preliminary studies with 4 different proteolytic fragments of fibronectin indicate that only those fragments which contain the cell attachment region support nerve fiber growth. Nerve fiber growth on HEMA gels containing 135 and 160 kd fragments of fibronectin was equivalent to growth on HEMA gels with native fibronectin (200kd). By contrast a 93 kd subfragment, lacking the cell attachment site of the 135 kd fragment from which it is derived, promoted little nerve fiber growth when incorporated into HEMA gels.

It appears that growing nerve fibers interact with a select region of fibronectin in the substrate and that this interaction can be modulated by glycosaminoglycans.

197.14 GANGLIOSIDE BIOSYNTHESIS IS INHIBITED BY TUNICAMYCIN IN THE NEUROBLASTOMA X GLIOMA HYBRID NG 108-15. R.L. Schnaar, S.P. Guarnaccia * and J. H. Shaper *. Dept. of Pharmacology, Johns Hopkins University School of Medicine, Baltimore Maryland 21205.

The antibiotic tunicamycin is thought to specifically block the transfer of GlcNAc-1-P from UDP-GlcNac to dolichol phosphate, thereby specifically blocking the synthesis of N-linked oligosaccharide chains on glycoproteins. We have studied the incorporation of [^{3}H]glucosamine into the glycoconjugates of the neuroblastoma x glioma hybrid cell line NG 108-15, and found approximately equal incorporation into glycosphingolipids and glycoproteins. Tunicamycin caused a 78% reduction in incorporation of radiolabelled glucosamine into gangliosides and neutral glycosphingolipids at a concentration which causes a 90% reduction of radiolabel incorporation into glycoproteins. Protein synthesis (measured as [^{3}H]leucine incorporation into TCA-precipitable material) was reduced only 6% under these conditions. The effect of tunicamycin on glycosphingolipid biosynthesis was apparent after 4 hours of incubation, and maximum inhibition was seen within 6 hours. In order to assess the basis for the inhibition, 3 x 10^8 cells were incubated for 3 h with either control medium or medium containing tunicamycin (5 µg/ml), followed by an additional 3 h in the presence of [^{3}H]glucosamine. The cells were collected and fractionated to separate glycoproteins, neutral glycosphingolipids and gangliosides. Nucleotide sugar precursor pools were purified for evalulation of relative specific activities. UDP-GlcNAc and UDP-GalNAc pool sizes increased >3-fold, and specific activities decreased 50% upon treatment with tunicamycin. When corrected for this value, the percent inhibition of glucosamine incorporation into various glycoconjugates by tunicamycin in these cells was: glycoproteins, 82%; neutral glycosphingolipids, 54%; and gangliosides, 50%. Gangliosides were affected differentially, with the most striking inhibition apparent in GM_3 synthesis which was reduced 77% in the presence of tunicamycin. This data demonstrates that tunicamycin has effects on glycoconjugate biosynthesis beyond the inhibition of N-linked glycoprotein glycosylation. While the basis for tunicamycin inhibition of ganglioside and neutral glycosphingolipid biosynthesis is not known, two possibilities are apparent. The antibiotic may directly inhibit the relevant glycolipid glycosyltransferases, or it may block glycosylation of the transferases (which may themselves be glycoproteins) reducing their activities. Whether direct or indirect, the effects of tunicamycin on glycosphingolipid as well as glyocprotein biosynthesis must be taken into account when interpreting effects of this agent on intact cells and organisms. Supported by NIH Grant HD14010, and March of Dimes Grant 5-302.

197.15 CONTROL OF AMILORIDE SENSITIVE NA FLUX IN NEUROBLASTOMA AND GLIOMA CELL LINES. V. Sapirstein and D. Benos (Spon: G. Hauser). E.K. Shriver Center, Waltham, MA. 02254 and Depts. of Biol. Chem. Physiol. and Biophys. and LHRRB Harvard Med. Sch., Boston,MA.02115

We have studied the amiloride sensitive sodium influx into C6 glioma and NB2A neuroblastoma cell lines. In late log phase cells grown continuously in the presence of fetal calf serum showed Na influxes of approximately 20 nmoles/mg protein for both C6 and NB2A cells; < 5% of this was found to be amiloride sensitive. Serum removal for 24 hours did not appear to cause any significant change in this flux, however upon addition of serum to the incubation media there was an increase of 20-40% in the total Na flux within 2 minutes. All of this increment in Na influx was inhibited by amiloride with a $K_{1/2}$ of 50uM. By adding serum back at various times after serum deprivation it was determined that 6 hours was required to observe a detectable increase in the amiloride sensitive Na flux. Addition of 5ug/ml of cycloheximide 4 hours after serum removal was found to block the increase in Na transport indicating induction of de novo protein synthesis mediated this increase in amiloride sensitive Na transport. Moreover, inhibition of de novo lipid synthesis by 0.1 mM fenfluramine blocked the induction of this transport activity suggesting that a coordinated synthesis of lipid and protein is required for the expression of this sodium transport site. The effect of serum removal on Na influx was augmented by the growth of cells in media containing 1.8mM EGTA. Under these conditions NB2A cells displayed a serum stimulated, amiloride sensitive Na influx that was 3 times that of control cells suggesting Ca may influence the expression of the amiloride sensitive Na influx site.

The observation that addition of serum to the media is required to observe the induced increase suggests that the de novo synthesis of membrane components is not sufficient for the functional assembly of this transport site. Since insulin stimulates Na fluxes in several tissues we determined if the rapid effect of serum addition was mediated by this hormone. Experiments indicated that insulin (5m Units) stimulated sodium influx by 72% in NB2A cells; these increments in Na transport however were only slightly inhibited by amiloride (8%). Addition of the calcium ionophore, A23187, or EGTA to the assay media likewise stimulated the Na flux in the serum deprived cells to the same extent as insulin and like this hormone increased only an amiloride insensitive component. The acute effects of insulin, A23187 and EGTA on Na influx may represent the activity of a totally distinct transport site or the same one that was induced by serum removal except lacking the amiloride sensitive component. Studies designed to answer this question are now in progress. Supported by HD05515, NS16186, AM25886 and the Andrew W. Mellon Foundation.

197.16 PHOSPHOLIPID METHYLATION IN MYOGENIC CELL LINES. T.K. Koch*, A.S. Gordon and I.F. Diamond. Univ. of Calif., San Francisco, CA 94143.

The biosynthesis of phosphatidylcholine from successive N-methylation of phosphatidylethanolamine has been implicated as a major mechanism for the transduction of receptor-mediated signals. We have recently developed a rapid and sensitive high resolution method to follow phosphatidyl methyltransferase activity. Lipids are extracted with hexane:isopropanol and the phospholipids separated by high performance liquid chromatography. Using this method, we found an active transmethylation pathway in two differentiated myogenic mouse cell lines, BC3H1 and L8. Addition of carbachol and isoproterenol had no effect on phospholipid methyltransferase activity. However, isoproterenol did cause stimulation of 3'-5' cyclic adenosine monophosphate (cAMP) production in both cell lines. Despite new methodology for a more sensitive analysis of phospholipid composition, no alteration in the transmethylation pathway could be demonstrated with ß-adrenergic stimulation of BC3H1 and L8 even when cAMP stimulation was documented.

197.17 ORTHOGONAL ARRAYS IN MINCED MUSCLE MEMBRANES: PREPARATION VIABILITY, ENERGY DEPENDENCE AND EFFECTS OF CATIONS. James D. Hatton and Mark H. Ellisman. Dept. of Neurosciences, University of California at San Diego, La Jolla, CA 92093.

Orthogonal arrays of particles are known to be plentiful in the sarcolemma of freeze-fractured fast-twitch skeletal muscle, especially so in the sarcospinalis from rabbit. To examine the plasticity of these arrays in muscle membranes, pieces of this muscle were excised from anaesthetized rabbits, minced in 4° C 10 mM tris-buffered .25 M sucrose (pH 7.4), and stored at 4° C for 4, 8 and 24 hr and 2, 3, 4, 5, 6, and 7 days. No change in array number, distribution or morphology was noted at any interval. The addition of 2-50 mM Ca^{++} (as $CaCl_2$) to a similar prep caused the disappearance of arrays by 3 days. When N-ethyl maleimide or phenyl methyl sulfonyl fluoride (PMSF) were added as proteolysis inhibitors, arrays remained intact despite Ca^{++} treatment up to 7 days. Here, however, the addition of 10-50 mM Ca^{++} produced a clustering of whole arrays into patches. Other divalent cations (Mg^{++} and Mn^{++}, as their chloride salts) also induce array disappearance (perhaps through proteolysis) and produce array-clustering, though to a lesser extent than does Ca^{++}. These effects are not noted with the addition of 10-50 mM NaCl, KCl or choline chloride, suggesting that array-clustering is neither dependent on univalent cations nor on Cl^- ion per se.

In similar experiments, minced muscle was incubated for 3 days at 4° C in the presence of PMSF. It was found that the addition of 10-100 mM adenosine triphosphate (ATP) increased the total number of arrays, but did not induce clustering. Meanwhile, the addition of 10-50 mM dinitrophenol reduced the number of arrays, to nearly zero in the case of the highest concentration. Ouabain ($5X10^{-4}$ M) alone produced no effect on array density, but did inhibit the ATP-induced array proliferation. This suggests that (at least) the appearance of orthogonal arrays in the membrane may be related to Na^+-K^+ ATPase activity. Finally, the addition of 10-50 mM dibutyryl c-AMP produced neither clustering nor an increase in array density, suggesting that this putative second messenger is not involved in either of these effects.

197.18 EFFECTS OF SAPONIN ON ACETYLCHOLINE RECEPTOR CLUSTERS OF CULTURED RAT MYOTUBES VISUALIZED BY FREEZE FRACTURE. D.W. Pumplin* and R.J. Bloch, Anat. and Physiol. Depts., Univ. of Maryland Sch. of Medicine, Baltimore, Md. 21201.

Clusters of acetylcholine receptors (AChRs) in substrate-apposed membrane of cultured rat myotubes are often organized linearly: regions of AChR enrichment ("AChR domains") interdigitate with sites of closest approach of the membrane to the substrate ("contact domains") [1]. To learn if lipids are heterogeneously distributed in these two membrane domains, we studied the effects of the cholesterol-specific detergent, saponin, on AChR clusters using freeze fracture electron microscopy.

Rat myotubes cultured on glass cover slips were exposed at 22° to 0.2% saponin in a modified buffered saline for 15 sec to 8 min then fixed in 2% glutaraldehyde. Circles cut from the cover slips were freeze-fractured using the complementary replica method [2]. Replicas from the specimen carrier side consisted almost entirely of P faces from substrate-apposed membranes of myotubes and fibroblasts.

The overall linear organization of AChR clusters was not disturbed by treatment with saponin. AChR domains, containing the large intramembrane particles (IMPs) corresponding to AChR [2], remain distinct from contact domains. Within the AChR domains the following changes were seen after 1 min of saponin exposure: formation of shallow, poorly defined depressions; aggregation of the large IMPs; and large scale (>100nm) deformations of the membrane. In contrast to these changes in the AChR domains, the contact domains were almost unaffected by saponin: they showed little membrane deformation and no IMP aggregation. Myotube membrane outside of the clusters was likewise unaffected.

In fibroblasts, the following changes were seen: (i) at 30-60 sec, individual, sharply defined pits (44nm diam) formed; (ii) ≥1 min, large pits aggregated; (iii) ≥3 min, IMPs tended to aggregate into membrane surrounding the pit aggregates. These changes, and those seen in myotubes, were blocked by prefixation.

Saponin not only affects myotubes and fibroblasts differently, it also distinguishes between the AChR and contact domains within AChR clusters. This can be interpreted in two ways. (i) Cholesterol may be enriched in AChR domains, or may become so upon exposure to saponin. (ii) Cholesterol is homogeneously distributed between AChR and contact domains, but only the AChR domain can deform enough to reveal the effects of saponin-cholesterol complex formation.

197.19 DEVELOPMENTAL REGULATION OF THE APPEARANCE OF SYNAPTIC BASAL LAMINA ANTIGENS IN ANEURAL MUSCLE CULTURES. L. Silberstein* and Z.W. Hall. Dept. of Physiology, U. Calif. Sch. of Med., San Francisco, CA 94143.

The basal lamina (BL) that runs between the presynaptic and postsynaptic membranes at the adult neuromuscular junction has distinctive functional properties (1,2,3) and may be distinguished immunologically from the extrasynaptic BL to which it is attached (4). In regenerating muscle, the synapse-specific accumulation of acetylcholine receptors occurs precisely at the old endplate, even in the absence of a neural partner, at the site marked by the synpatic BL formed prior to injury (2,3). This observation suggests a specific interaction between components of the extracellular matrix and acetylcholine receptors (AChR) clusters.

We have previously reported that myotubes of a mouse muscle cell line, C_2, have surface accumulations of BL antigens that are recognized by each of three synapse-specific antisera (5). We report here experiments in which we have studied quantitatively the developmental expression of two of the synaptic BL antigens (JS-I and JS-II), and the progressive association of one of them with AChR clusters.

A radioimmunoassay was used to measure the amount of the JS-I and JS-II antigens in C_2 cultures. Both were present at very low, or undetectable, levels in myoblasts and began to increase within 24 hours after myoblast fusion began. Over the next four days, both continued to increase approximately tenfold. The overall time course of expression of the BL antigens resembles that seen for the accumulation of acetylcholinesterase (AChE) or AChRs in myotubes after fusion.

One of the antigens (JS-I) is often found in close association with AChR clusters. The degree of this association increases with time in culture. Thus, in myotubes examined two days after fusion has begun, approximately 50% of AChR clusters are associated with JS-I patches, while two days later, over 95% of the clusters are so associated. Over the same time period, a comparable increase in the percentage of patches associated with AChR clusters occurred Furthermore, the density of JS-I antigens at AChR patches was noticeably higher in later cultures. This observation is consistent with the increase seen by radioimmunoassay. This system may provide a useful in vitro model for understanding the specific association in vivo between AChR clusters and synaptic BL.

197.20 AUTORADIOGRAPHIC STUDIES OF α-BUNGAROTOXIN BINDING IN HIPPOCAMPAL CULTURES. G.A. Banker and J.E. Mazurkiewicz*. Department of Anatomy, Albany Medical College, Albany, New York, 12208.

We have studied the development and localization of binding sites for α-bungarotoxin in hippocampal cell cultures prepared from the brains of fetal rats. Two types of cultures have been examined. Some were prepared at high cell densities (15,000 cells/cm^2), which permit the cells to become extensively innervated; others were prepared at low plating densities (1,500 cells/cm^2), so that some cells develop without contacting any other neurons or glia. After varying periods of development in vitro, the cultures were incubated with (^{125}I)-α-bungarotoxin (1 to 6 X 10^{-9} M) for 1 hour, then fixed and processed for light microscopic autoradiography. Non-specific binding was assessed in control cultures treated with excess unlabeled toxin or with tubocurare (10^{-4} M) before exposure to (^{125}I)-α-bungarotoxin.

Specific binding sites for α-bungarotoxin were not detectable on the first day in culture, but appeared within the first week. Thereafter their density increased rapidly, becoming maximal by two to three weeks. This roughly parallels the increase in binding seen during hippocampal development in vivo. After two to three weeks in culture about two-thirds of the neurons were labeled by this method. No specific labeling of non-neuronal cells was observed.

After two weeks in culture binding sites were present on cell somata and along the cells' dendritic processes. Within the resolution of this method, the binding sites appeared to be uniformly distributed over these regions rather than clustered in patches. Binding sites were not detected on the cells' axons, which are thinner in diameter than the dendrites. The pattern of labeling was the same on uninnervated, completely isolated cells as it was on cells in dense cultures which received heavy synaptic input. Thus the acquisition of binding sites for α-bungarotoxin during neuronal development can occur independent of innervation.

197.21 CO-LOCALIZATION OF ACh RECEPTOR CLUSTERS AND NUCLEI IN CULTURED MYOTUBES. Libbe L. Englander* and Lee L. Rubin. The Rockefeller University, New York, N.Y. 10021.

During nerve-muscle synapse formation, some acetylcholine receptors appear to redistribute from extrasynaptic to synaptic sites. There is evidence, however, to suggest that the synaptic cluster is subsequently maintained by local receptor insertion. We have begun to examine how the cell might be organized for this local insertion of membrane components by studying the formation of acetylcholine receptor clusters on cultured chick myotubes induced by factors derived from Torpedo electric organ extracellular matrix. We have now examined in detail the relative positions of clusters and myotube nuclei 36 hours after treating cultures with these factors.

The acetylcholine receptor clusters were visualized with rhodamine α-bungarotoxin; the nuclei were stained with the fluorescent dye 4',6-diamindino-2-phenylindol-2HCl. Photomicrographs of 10 cells (a total of 78 fields) were used to make measurements of the area and position of each cell, its nuclei and its clusters. On the average, 50% of the 548 clusters counted were within 5-6 microns of their nearest nucleus although the average distance between nuclei is 36.8 microns. To establish firmly an association between cluster and nuclear location, we calculated the mean distance of clusters from their nearest nucleus in each cell and the expected mean nearest distance and standard deviation under the null hypothesis that clusters were randomly placed relative to nuclei. The test yielded a χ^2 of 76.24 ($p<.001$), emphatically suggesting an association between the nuclei and clusters.

Such an association could develop if clusters formed preferentially over nuclei. It is also possible, however, that clusters first form randomly and then induce nuclei to localize beneath them; we are examining the latter possibility. In addition, we are determining the position of other intracellular organelles, such as the Golgi apparatus, to establish whether they are located preferentially near the cluster-related nuclei.

197.22 COMBINING RECEPTOR AUTORADIOGRAPHY AND IMMUNOCYTOCHEMISTRY: AN ANALYSIS OF β-ADRENERGIC RECEPTORS ON GFAP+ ASTROGLIA. Ken D. McCarthy* (SPON: Susan K. Burgess). Dept. of Pharmacology, Univ. of North Carolina, School of Medicine, Chapel Hill, NC 27514.

A number of studies indicate that cultured astroglia isolated from neonatal rat or mouse brain possess a variety of receptors which regulate cyclic AMP accumulation. However, the issue of whether or not such receptors are characteristic of mature astrocytes has not been resolved. This is due, in part, to the difficulty in isolating mature astrocytes in sufficient number to complete receptor analyses via standard radioligand binding techniques. The research described here concerns a novel method which can be used to monitor the density of β-adrenergic binding sites on single cells which have been identified via immunocytochemical methods.

Primary cultures containing predominatly immature astroglia and oligodendroglia and a few morphologically mature astrocytes were harvested from brain cell cultures, seeded onto polylysine coated glass slides and incubated for 2-7 days prior to analysis. The cells were then rinsed, aldehyde fixed, and permeabilized to permit the intracellular staining of the astroglial cell marker, glial fibrillary acidic protein (GFAP). The cells were then incubated in culture medium (BME) containing rabbit antiserum to GFAP, rinsed and incubated with BME containing rhodamine conjugated goat anti-rabbit antiserum and (-) (^{125}I)-iodopindolol (^{125}I-PIN). The cells were then rinsed in PBS containing propranolol, frozen, lyophilized, and opposed to emulsion coated coverslips. After 2-3 weeks the autoradiograms were developed and the grains over GFAP+ cells visualized via reflected polarized light microscopy. The number of silver grains per μm^2 over cells and background was quantified by an Apple II+ computer interfaced with a digitizer.

Extensive biochemical binding assays have been completed to examine the influence of the methods described above on receptor binding characteristics. These experiments indicate that the methods described above do not alter 1) the rate of association of ^{125}I-PIN to cells, 2) the rate of dissociation of ^{125}I-PIN from cells, 3) the number of ^{125}I-PIN binding sites per cell, 4) the K_D of ^{125}I-PIN, or 5) the stereospecific displacement of ^{125}I-PIN by (-) propranolol and (+) propranolol. However, one consistent effect resulting from fixation was an increase (10-100 fold) in the potency of both (-) and (+) isoproterenol to displace ^{125}I-PIN from binding sites. This effect appears to be due to the ability of an agonist, such as isoproterenol, to induce a rapid decrease in the affinity of β-adrenergic receptors for agonists on intact, nonfixed cells.

Preliminary results using the method described above suggest that there can be more than a 10-fold difference in the number of ^{125}I-PIN binding sites amoung GFAP+ cells. Experiments in progress are designed to correlate the degree of morphological differentiation of GFAP+ cells with the number of ^{125}I-PIN binding sites per cell. Supported by NS16992 and NS16229.

197.23 EVIDENCE FOR FUNCTIONAL A_1 AND A_2 ADENOSINE RECEPTORS ON HAMSTER AND HUMAN SPERMATOZOA. B.E. Morton, M. Thenawidjaja* and S. Dimsdale*. Department of Biochemistry and Biophysics, University of Hawaii School of Medicine, Honolulu, Hawaii, 96822.

The presence of adenosine receptors upon hamster caudal epididymal (HCE) spermatozoa was observed. Evidence for this discovery included data of the binding to HCE sperm of N^6-cyclohexyladenosine (CHA), Bmax 2.87 pmoles/10^{10} cells, Kd 12.9 nM; and the binding of 1,3-diethyl-8-phenylxanthine (DPX), Bmax 7.7 pmoles/10^{10} cells, Kd 19.8 nM. [^{3}H]-CHA was displaced from HCE sperm by a series of nucleosides and purine bases in order quite different than that observed for [^{3}H]-DPX and in a manner consistent with the presence of both A_1 and A_2 classes of adenosine receptors on these cells. The A_1 adenosine receptor had been found only in brain and testes. On a unit weight basis the Bmax of CHA for HCE sperm exceeds that of testes by 10 fold, suggesting that the testicular A_1 adenosine receptor may reside entirely upon spermatozoa.

Spermatozoa may be valuable for adenosine receptor studies not only because, unlike other tissue, each cell carries receptors, but also because the practical consequences of receptor occupancy manifest themselves in terms of sperm motility. Thus, CHA inhibited and L-PIA moderately stimulated HCE sperm motility at concentrations approaching one molecule/cell while at μM concentration the effects of these nucleosides agonists were reversed. The antagonist, caffeine, totally overrode these effects to cause its well-known powerful stimulation of motility. Another antagonist, DPX, had no effect upon sperm motility by itself but potently blocked all effects of CHA. Further consequence of receptor occupancy detected was the stimulation of [^{45}Ca] efflux from HCE spermatozoa by very low concentrations of CHA. Adenosine receptors were also demonstrated to be present on human spermatozoa.

The biological significance of adenosine receptors upon mammalian spermatozoa is potentially great. Although evidence suggesting the presence of excitatory neuroreceptors for catecholamines, acetylcholine and taurine exists, the discovery of inhibitory (A_1) adenosine receptors presents a means whereby the female may retard inward sperm migration and in certain cases coordinate it with ovulation. The agitated motility of capacitated spermatozoa, appearing several hours after their entry into the female, would now appear to represent their release from inhibitory restraint prior to concerted migration to the ovum.

It is therefore possible that endogenous A_1 and A_2 ligands exist not only in female reproductive tract but also in that of the male of those species whose motility is suppressed until ejaculation. These systems may have contraceptive potential.

198.1 SUSCEPTIBILITY OF THE SQUIRREL MONKEY TO SEVERAL DIFFERENT MOTION CONDITIONS. R.A. Fox*, N.G. Daunton and J. Coleman*. San Jose St. Univ. and NASA-Ames Research Center, Moffett Field, CA, 94035.

The exact stimulus eliciting vomiting in animal studies of motion sickness is difficult to specify because the vestibular stimulation produced by many motion conditions is confounded by voluntary movements by the animals. This is an important problem because experiments with animal models of motion sickness can provide useful information about antimotion sickness drugs or the role of neural mechanisms, only when animals are exposed to the same motion stimuli in each experimental session.

A series of tests were conducted to determine the susceptibility of 15 adult squirrel monkeys to motion sickness in freely moving and restrained test conditions. Canal stimulation was varied by exposing the monkeys in freely moving conditions to varying degrees of angular velocity (60,90,120,150 deg/sec), and in restrained conditions to one angular velocity (150 deg/sec) and to cross-coupling effects of whole-body roll movements during rotation. Otolith stimulation was investigated by using sinusoidal vertical linear acceleration during free movement conditions, and off-vertical rotation and earth-horizontal (BBQ) rotation while restrained.

The percentage of freely moving animals vomiting during vertical axis rotation was 27, 93, 86, and 92 for the angular velocities of 60, 90, 120, and 150 deg/sec respectively. None of the monkeys vomited during vertical axis rotation or cross-coupled rotation when restrained. Otolith stimulation appears to be a less provocative stimulus for the squirrel monkey as the percentage of animals vomiting were 13, 0, and 7 for the conditions of free movement during oscillation, restraint during off-vertical and BBQ rotation respectively.

Motion sickness to the point of vomiting occurred regularly only in conditions where self-motion was possible. Such effects could occur because voluntary movement during motion augments vestibular effects by producing self-inflicted cross-coupling, but the failure to elicit vomiting with experimenter-produced cross-coupling argues against this interpretation. Alternatively, these results might imply that feedback from movement control mechanisms may play an important role in sensory conflict as suggested by Oman's sensory-motor conflict theory.

198.2 EFFECT OF VESTIBULOSPINAL TRACT LESIONS ON CAT NECK AND FORELIMB TILT REFLEXES. A.D. Miller, P.S. Roossin*, R.H. Schor and V.J. Wilson. Rockefeller University, New York, NY 10021

Tilt about the longitudinal (roll) axis of decerebrate cats produces extension of the side-down forelimb and contraction of side-up neck extensors. The otolith organs form a major input to this reflex; a semicircular canal contribution at tilt frequencies above 0.1 Hz is required to maintain a compensatory response. In cats whose semicircular canals have been inactivated, only vestibular neurons excited by side-up static tilt exhibit muscle-like reflex dynamics (Schor, Miller and Wilson, Soc Neurosci Abst 7: 690, 1981), suggesting that these neurons might contribute to the reflex observed in the ipsilateral neck and contralateral limb.

The present experiments examined the role of the medial (MVST) and lateral (LVST) vestibulospinal tracts in the production of roll tilt reflexes, in decerebrate cats with intact labyrinths. Sectioning the medial longitudinal fasciculus, which contains the MVST, had no major effect on the phase of the reflex EMG recorded from the forelimb extensor triceps brachii and the neck extensors splenius and biventer cervicis, although some gain was usually lost at high stimulus frequencies. Spinal lesions at C_2-C_3, both cord hemisections and smaller unilateral lesions restricted to the area of the LVST, produced two major effects on the forelimb. Background EMG activity was usually abolished in the triceps ipsilateral to the lesion, with some loss of activity in the opposite limb. The tilt reflex response in the ipsilateral limb appeared normal, although it was usually necessary to raise the background excitability of the preparation by administering L-Dopa (50 mg/kg i.v.) in order to observe the reflex. In contrast, the response in the limb contralateral to the lesion showed a phase reversal of 180 degrees at low stimulus frequencies, implying that the reflex in intact cats receives a crossed otolith-spinal input. Responses in the neck extensors splenius and biventer, recorded from compartments caudal to the spinal lesion, were relatively unaffected.

These results demonstrate that neither the MVST nor LVST is essential for the production of roll tilt reflexes in the neck. The reflex pathway to forelimb extensors has a crossed otolith-spinal component, which probably involves the LVST. (Supported in part by NASA grant NSG-2380, PHS grants NS02619 and RR07065, NIH Postdoctoral Fellowship NS06128, and NIH Research Service Award 7524).

198.3 ANTIMUSCARINIC AND SOMATOSTATIN-INDUCED BARREL ROTATION ARE ELICITED BY MICROINJECTION OF VESTIBULAR NUCLEAR COMPLEX. R.E. Burke & S. Fahn, Department of Neurology, College of Physicians & Surgeons, Columbia University, New York, NY 10032.

Barrel rotation (BR) is a behavior observed in rats which consists of sustained extension of the limbs on one side of the body and torsion of the trunk about the long axis towards the opposite side, resulting in repetitive lateral rolling. This phenomenon was first described following intraventricular injection of somatostatin (SRIF) (Cohn & Cohn, Brain Res., 1975), and it has since been observed following injection of vasopressin, Substance P and other neuropeptides. Biologically inactive analogues of SRIF do not induce BR. We have reported that "experimental dystonia" in rats induced by intraventricular injection of chlorpromazine-methiodide (CPZMI) is identical in appearance to SRIF-induced BR, and that it is an antimuscarinic effect. The purpose of the present investigation was to determine the site of action of SRIF and antimuscarinics to elicit BR when injected intraventricularly. Our approach was to study dose-response for microinjections of these compounds to elicit BR with changes in placement of intraventricular and then intracerebral cannula positions.

We found that right lateral ventricle injections of increasing doses of CPZMI or SRIF in 3 µl failed to elicit BR. Dye studies of such injections showed distribution to R and L lateral and IIIrd ventricles. In contrast, caudal IVth ventricle injections of small doses of either compound in 3 µl promptly elicited BR. Dye studies of these injections distributed to IVth ventricle and Aqueduct. We concluded that IVth ventricle injection of these compounds is necessary and sufficient to elicit BR. Control injections of striatum, cerebral cortex, and cerebellar deep nuclei failed to elicit BR. Excluding cranial nerve nuclei, cholinergic receptors adjacent to the IVth ventricle are located largely in locus coeruleus (and other surrounding nuclei) and the medial vestibular nucleus (Wamsley et al., J. Neurosci., 1981). We found that CPZMI 10 nmole and SRIF 1 nmole in 0.5 µl failed to elicit BR when injected unilaterally into the locus coeruleus, but elicited BR promptly when injected unilaterally into the vestibular nuclei. In addition, whereas the direction of BR could be right or left following intraventricular CPZMI or SRIF injections, it was always to right following right vestibular nuclei injection.

Thus, dose-response studies of these microinjections suggest that antimuscarinics and SRIF act at the vestibular nuclei to elicit BR when injected intraventricularly. This conclusion is supported by the behavioral observation that, following labyrinthectomy, vertebrates develop limb extension and torsion about the long axis with lateral rolling, as seen in BR.

198.4 THE EFFECT OF ACOUSTIC TUMOR SIZE AND LOCATION ON OCULAR COUNTERROLLING. Shirley G. Diamond and Charles H. Markham. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Dynamic ocular counterrolling (OCR) testing was performed on patients with tumors in the internal auditory canal and/or cerebellopontine angle. Their responses to constant velocity roll about their naso-occipital axes were compared to responses obtained from normal subjects.

The test protocol consisted of patients being tilted to 90° right ear down at a constant velocity of 3°/sec, held there for 30 sec, rolled in the opposite direction to 90° left ear down, held there 30 sec, and brought back through the upright position. This was termed Trial I. Without stopping, the procedure was repeated for Trial II. Acceleration and deceleration during the first and last 20° of rotation was 0.21°/sec², considered to be below the threshold of the semicircular canals. Photographs were taken at each 10° of roll.

Measurements of OCR were made with a two-projector apparatus using a superimposition technique. This system is accurate to 0.25°. Each eye was measured independently.

Measurements were plotted on forms preprinted with the norms derived from the means and standard deviations of our group of normal control subjects.

Analysis of OCR profiles of patients with diagnosed tumors of various sizes revealed three distinct groups: 1) those with OCR profiles almost normal in appearance or with mildly abnormal responses to tilt to the side opposite the tumor; 2) moderately abnormal to both directions of tilt, more so to the side opposite the tumor; 3) severe derangement of the entire pattern of response with the eyes rolling instead of counterrolling to the appropriate direction of tilt.

These types of OCR abnormalities corresponded to the size and location of the tumors and the extent to which the tumor impinged on the utricular nerve and brainstem. The slightly disturbed profiles were seen in patients with small (< 1 cm) intracanalicular tumors. If the tumor completely filled the internal auditory canal and extended into the cerebellopontine angle, the OCR profile showed greater disorganization. If the tumor also caused major compression of the brainstem, OCR profiles showed profound disturbance which persisted in testing several months after surgery. This implies that a combination of utricular and brainstem involvement may lead to a permanent disruption of pathways subserving the OCR response.

198.5 MECHANISMS OF AMPHIBIOUS ACCOMMODATION IN TURTLES. D. P. M. Northmore and A. M. Granda. Institute for Neuroscience, Univ. of Delaware, Newark, DE 19711.

Adaptations to amphibious vision were studied in the freshwater pond turtle, Pseudemys, and in the wholly marine Chelonia. The focal length of the anterior half of one eye of each specimen was measured. The other eye was frozen, sectioned and photographed to determine its dimensions. Combining these measurements gave estimates of the bulk refractive indices of the lenses. Schematic eyes were then drawn depicting the unaccommodated eye of Pseudemys as emmetropic in air and 90D in water; that of Chelonia as 10D myopic in air and 30D hyperopic in water. These figures agreed with retinoscopic measurements of refractive error. Accommodation was studied by electrical stimulation of the anterior half of the eye while measuring the radii of lens curvature with Purkinje images. The latter showed that the power of the lens was increased almost entirely by deformation of its anterior surface, accomplished largely by a squeezing action of the annular pad by the ciliary muscle. An additional role was played by the constriction of the iris. In both species, the range of accommodation was more than sufficient to neutralize their hyperopia underwater. Surprisingly, the Chelonian eye at rest requires little correction in air, although as expected, it needs less correction underwater than does the eye of Pseudemys.

198.6 PROJECTIONS TO THE THALAMUS FROM BRAINSTEM RETICULAR AREAS AND VESTIBULAR NUCLEI IN THE RAT. G.A. Kevetter, W.R. Mehler, & W.D. Willis; Marine Biomed. Inst., Dept. of Anat., Physiol. Biophys. & Otolaryn.. Univ. Texas Med. Br., Galveston, TX 77550 and NASA - Ames Res. Ctr., Moffett Field, CA 94035

Cells in the brainstem that project to the thalamus were studied in the rat. In order to label as many cells as possible, large, multiple, unilateral injections of horseradish peroxidase and fluorescent dyes (DAPI and nuclear yellow) were made into the caudal half of the thalamus. Our intention was to include both intralaminar and principal thalamic nuclei. With the exception of the dorsal raphe nucleus labeled cells were located bilaterally. Cells found in a given area, however, were concentrated either ipsilateral or contralateral to the side of injection. The largest number of labeled cells were found consistently in the contralateral dorsal column nuclei and the spinal and principal trigeminal nuclei. In the medulla other labeled cells also were found chiefly contralateral to the side of the injections. A strikingly dense group of labeled cells were found along the lateral border of the contralateral descending vestibular nucleus in 4 out of 5 of the initial experiments. Sporadic cell labeling appeared in the other vestibular complex nuclei, especially in a Z-like group dorsal to the medial nucleus and throughout nucleus prepositus hypoglossi and paramedian reticular formation regions. At pontine and mesencephalic levels ipsilateral cell labeling predominated. The ipsilateral nucleus pontis oralis, locus coeruleus, dorsolateralis tegmenti and the lateral wing of the dorsal raphe nuclei exhibited moderate numbers of labeled cells. Some cells frequently appeared in the ipsilateral ventrolateral mesencephalic tegmentum and in a dorsolateral tegmental cell group. (Supported by NIH grants 09743 and 11255, training grant NS 05743 and a grant from the Moody Foundation).

198.7 THE CYTOARCHITECTURE AND SACCULAR INNERVATION OF NEURONS WITHIN NUCLEUS Y OF THE MOUSE. D.R. Trune and C.J. Frederickson. Dept. Otolaryngology, Ohio State University, Columbus, OH 43210 and Dept. Psychology, University of Texas at Dallas, Richardson, TX 75080.

Our laboratories have been independently studying nucleus y in the normal mouse to determine its boundaries, neuronal forms, and saccular afferents as the normative basis for its subsequent examination after sensory deprivation in otoconia-deficient mutant mice (Smith et al, Soc. Neurosci. Abstr., 7:481, 1981; Trune and Lim, Assoc. Res. Otolaryngol. Abstr., p. 61, 1982). Our observations of Nissl- and Golgi-stained material have revealed two predominant (though not exclusive) neuronal types within this central vestibular cell group.

The most common cytological type within nucleus y is the fusiform cell. In Golgi-Cox impregnated material, the soma of this neuron is fusiform or cylindrical in shape and gives rise to one or two dendrites at each of its poles. These dendrites often branch secondarily but the entire dendritic field usually remains within the boundaries of nucleus y. These neurons in Nissl-stained tissue also appear somewhat fusiform or oblong in shape, with the length (12-20 μm) about 1 1/2 times the width (8-15 μm). The Nissl substance is more prominent at the poles of the soma and thin or absent on either side of the nucleus. These neurons occur throughout the nucleus although they are less frequent in its caudal region.

The second dominant cell type is the stellate cell. Golgi-Cox impregnation of these reveals 4-6 dendrites emanating from the spherical cell body. These dendritic fields are mostly confined to nucleus y as well. In Nissl stains, their somas are spherical, range in diameter from 12-25 μm, and have a distinct, complete ring of Nissl substance surrounding the nucleus. These neurons also occur throughout nucleus y, but the largest of these cells are most common in the caudalmost region.

Microinjections of horseradish peroxidase into the saccule, labeling 4-12 axons, reveal that the saccular afferents terminate in the immediate vicinity of both the fusiform and stellate cells. Although counterstaining shows most terminals do not contact the perikarya, some terminals are found closely apposed to somas or dendritic stumps. This latter pattern of apparent synaptic contact occurs on both the stellate and fusiform cell types.

198.8 **CENTRAL PROJECTIONS OF THE HORIZONTAL AMPULLARY NERVE OF THE GUITARFISH, RHINOBATOS PRODUCTUS (CHRONDRICHTHYES: BATOIDEA). D.M. Koester, R.F. Dunn. Div. Vest. Disorders, Dept. Otol., Univ. of Pittsburgh, Sch. Med., Eye & Ear Hosp., Pittsburgh, PA 15213.**

The central projections of first order horizontal ampullary nerve (HAN) afferents of the guitarfish were elucidated by the anterograde transport of HRP. Anesthesia used for the surgical procedures and perfusion consisted of a controlled mixture of halothane, oxygen, and nitrous oxide bubbled through seawater. The HAN was exposed dorsally on one side and transected distal to the octavus ganglion at the level where the HAN enters the crista. HRP crystals were applied to the proximal stump of the HAN for 25-30 minutes. Prior to closure of the exposed area, the nerve was rinsed with distilled water to prevent diffusion of HRP within the otic capsule. Two weeks postoperatively, the guitarfish were perfused and transverse sections of the brain stems and horizontal sections of the octavus nerve were reacted with TMB.

Anterograde transport of HRP reveals labeled first order HAN afferents that enter the medulla and bifurcate to give rise to ascending and descending pathways within discrete regions of the ipsilateral octavus nuclear column. The ascending fibers are confined primarily to the ventrolateral portion of nucleus octavus anterior (NOA). Rostral to the level of entrance of the Vth cranial nerve, several ascending fibers course dorsally from NOA and project to the lateral and medial granular layers and lower lip of the vestibulolateral lobe of the cerebellum. Fibers of the descending pathway are confined predominantly to the ventral portion of nucleus octavus descendens (NOD) and nucleus octavus posterior. Throughout the rostrocaudal extent of the NOD, several descending fibers and/or collaterals exit its ventromedial border and form a broad fiber tract that projects to a small nuclear region ventral to the reticular formation. Some of these fibers project and presumably terminate within the reticular formation. In addition, a few descending fibers emanate from the dorsal border of NOD and course through nucleus intermedius. The termination site of these fibers is uncertain although it appears they project to the Purkinje-like cell layer of the posterior lateral line lobe.

Primary afferent projections to nucleus magnocellularis are uncertain as the axons of the efferent components of the HAN course through this nucleus to exit the brain via the octavus nerve root.

Retrograde transport of HRP reveals several labeled fusiform cells, both ipsilaterally and contralaterally, within a longitudinal column that is located immediately beneath the fourth ventricle, dorsal to Steida's fascicle and extends from the level of entrance of the octavus nerve to the rostral border of the visceral motor column. These cells are presumed to be the cells of origin of the efferent components of the HAN.

198.9 IDENTIFICATION AND LOCALIZATION OF GUITARFISH OCTAVUS NUCLEI BY NERVE DEGENERATION. R.F. Dunn and D.M. Koester. Div. Vestibular Disorders, Dept. Otolaryngology, Univ. Pittsburgh Sch. Med., Eye & Ear Hospital, Pittsburgh, PA 15213.

Previous studies have shown that different regions of the horizontal semicircular canal crista initiate distinctive impulse response functions which are transmitted to the CNS through anatomically separated nerves. Functional distinctions between the horizontal canal and the two vertical canal ampullary nerves have also been demonstrated. Therefore, identification and mapping of the central octavus nuclei are of interest so that the central distribution of the first order afferent neurons may be determined. The octavus nuclei were identified from transverse-sectioned brains of Rhinobatos productus and R. lentigenosus stained with cresylviolet, or Fink-Heimer I following unilateral transection of the octavus nerve proximal to its ganglion.

Results from the transection studies indicated octavus nerve degeneration primarily confined to four nuclei located along the ventral column within the octavolateralis region. Rostrocaudally the nuclei were: nucleus octavus anterior (NOA); nucleus magnocellularis (NM); nucleus octavus descendens (NOD); and nucleus octavus posterior (NOP). The columnar distribution of the nuclei became readily apparent when mapped onto either a midsagittal plane or onto a ventral plane. Whereas the projections were prepared section by section from serial sections, the resulting map was analogous to outlining a shadow of the nucleus projected onto either plane. The transition between the NOP and NOD appeared rather abrupt, separated by only a narrow region which could easily be missed without mapping. The area between the NOD and NOA was readily defined by the entrance of the lateral line-octavus-VII complex where these nerve fibers sweep into the CNS. The large cells of NM were easily identified in the cresylviolet stained sections at the level where the octavus nerve enters the CNS. Degenerating nerves, also observed at this level, coursed ventrally towards a small nucleus near the reticular formation. Whether or not these fibers were descending fiber projections, or possibly collaterals, remains uncertain. The cellular components within the octavus nuclei in both species appeared similar to each other and to that described in other skates.

Confinement of degenerating first order octavus afferents to the ipsilateral octavus nuclei was similar to octavus projections reported for other elasmobranchs. The distribution of primary afferent neurons within the octavus nuclei, together with the cytoarchitectural identification and spatial localization, are prerequisite for determining to what extent the anatomical separation established in the peripheral end organs is maintained centrally.

198.10 MOTION-INDUCED ALTERATIONS IN 2-DEOXYGLUCOSE UPTAKE IN BRAIN STEM NUCLEI OF SQUIRREL MONKEYS AS DEMONSTRATED BY SEQUENTIAL DOUBLE-LABEL METHOD. K. R. Brizzee and W. Dunlap*. Dept. Neurobiology, Delta Regional Primate Res. Ctr., Covington, LA 70433 and Dept. Psychology, Tulane Univ., New Orleans, LA 70118.

Six young adult squirrel monkeys were injected intravenously with 167μCi/100 gram body weight of (1-^{3}H)-2-deoxy-D-glucose (New England Nuclear, 7.2 Ci/mmole) in 0.5 ml sterile saline. Two hours after this initial injection these animals were injected with 16.7μCi/100 gram body weight of (1-^{14}C)-2-deoxy-D-glucose (53 mCi/mmole) in 0.5 ml sterile saline. Three of the animals were maintained in a quiescent state in a lighted room for a period of one hour. The other three were subjected to horizontal rotary motion at 25 r.p.m. together with a vertical movement of 6 inches at 0.5 Herz for one hour. At the end of this period each animal was anesthetized with ketamine, and the brain was quickly dissected out and frozen in isopentane cooled to -60°C with dry ice. Transverse cryostat sections of the brain stem were cut alternately at 200μm and 20μm from the nucleus gracilis caudally through the superior vestibular nucleus rostrally. Micropunch samples (Eik-Nes and Brizzee, Biochem. et. Biophys. Acta 97, 320, 1965) of the individual vestibular nuclei, the nucleus gracilis, nucleus cuneatus, nucleus of the trigeminospinal tract, nucleus of the tractus solitarius, and the hypoglossal nucleus, at various rostro-caudal levels were obtained from the 200μm sections with a small stainless steel punch measuring 850μm in diameter. The frozen punch samples were prepared for liquid scintillation counting. Differential (^{3}H) and (^{14}C) counts (c.p.m.'s) were made employing external standards. The 20μm sections were prepared for (^{14}C) radioautography by standard methods employing Kodak SB-5 X-ray film.

Data from the scintillation counts revealed that the ^{14}C/^{3}H ratio (c.p.m.'s) was significantly higher ($p = <.03$) in the vestibular nuclei than in the other brain stem nuclei sampled in animals subjected to the motion regimen and higher in the vestibular nuclei in motion-stimulated animals than in those which were not subjected to the motion regimen. The (^{14}C) radioautographs from the motion-stimulated animals revealed a selectively high uptake of 2-DG in the medial and inferior vestibular nuclei as compared with the other brain stem nuclei sampled by the micropunch method. However, heavy grain densities in the motion stimulated monkeys were also observed over the inferior olivary nucleus, lateral reticular nucleus, and the nodulus, uvula and nucleus fastigius of the cerebellum which were not punch-sampled. (Supported by NASA-Ames NAC-2-101 and NIH RR00164)

198.11 CENTRAL NERVOUS SYSTEM GLUCOSE UTILIZATION RATE IN THE NYSTAGMIC RAT. J.W. Patrickson*, F.A. Kutyna, H.J. Bryant, M. Kadekaro, and J.B. Clark* (SPON: G.P. Mueller). Depts. of Physiology and Neurology, Uniformed Services University of the Health Sciences, Bethesda, MD. and Lab Cerebral Metabolism, NIMH, Bethesda, MD.

Methods previously used to identify and analyze central nervous system (CNS) structures involved in the integration of the vestibulo-ocular reflex (VOR) have been limited to a segmented analysis of the system. We used Sokoloff's 2 deoxy-D-[^{14}C] glucose method (J. Neurochem. 28, 897-916, 1977) to comprehensively map the CNS functional activity during activation of the VOR. Male Sprague-Dawley rats (275-300g) were anesthetized with halothane, and the crista ampullaris of the left horizontal canal was surgically destroyed. The lesion resulted in an asymmetric input to the vestibular nuclei which elicted the VOR. After recovery from anesthesia, the freely moving animals developed horizontal nystagmus with the fast component toward the unlesioned (contralateral) side. Glucose utilization rates of corresponding right and left brain structures were compared in sham-operated control animals (N=7) and in lesioned experimental animals (N=7).

Control animals showed no significant differences between corresponding left and right CNS structures. Comparing both sides, glucose utilization rate (mean ± standard error expressed as μm/100g tissue/min) in lesioned animals increased in the following CNS structures: the contralateral medial (122±5††) vs.(90±5) and superior (117±5††) vs. (93±5) vestibular nuclei, the contralateral abducens nucleus (116±6††) vs. (85±4), the ipsilateral interstitial nucleus of Cajal (91±7††) vs. (75±8), and the ipsilateral cerebellar nodulus (128±7††) vs. (86±5). In lesioned versus control animal glucose utilization rate increased in the following structures: the contralateral medial (122±5††) vs. (116±6) and superior (117±5††) vs. (111±7) vestibular nuclei, the ipsilateral interstitial nucleus of Cajal (91±7††) vs. (77±5), and the ipsilateral cerebellar nodulus (128††±7) vs. (98±8). In experimental versus control animals glucose utilization rate decreased in the following CNS structures: the ipsilateral medial (90±5††) vs. (116±7) and superior (93±5†) vs. (111±5) vestibular nuclei, the ipsilateral abducens nucleus (85±4††) vs. (113±7), the contralateral medial rectus motor division of the oculomotor nucleus (85±3†) vs. (95±7), and the bilateral nuclei ambiguii (51±4††) vs. (74±7).

These results provide a quantitative survey of CNS functional activity during nystagmus produced by unilateral horizontal canal ablation.

201 SYMPOSIUM. SUBSTANCE P AS A NEUROTRANSMITTER. I.B. Black, Cornell Univ. Med. Coll. (Chairman); S. Leeman, Univ. Mass. Med. School (Co-Chairman); M. Otsuka*, Tokyo Med. and Dent. Univ.; S. Rosell*, Karolinska Institutet; M.R. Hanley, Imperial College, London; T. Jessell, Harvard Med. School.

Substance P (SP) has been the focus of increasing interest, since accumulating evidence suggests that this undecapeptide may function as a neurotransmitter at a number of loci in the nervous system. M. Otsuka will review relevant studies, and describe electrophysiologic actions of the peptide on peripheral and central neurons. Some of the factors regulating SP expression and metabolism in sympathetic and sensory neurons will be reviewed by I. Black. The pharmacology of the peptide, with particular reference to the evolution of new antagonists, will be discussed by S. Rosell. M. Hanley will describe recent work dealing with the characterization of SP receptors. Finally, T. Jessell will examine the role of SP in pain perception.

202 WORKSHOP. APPLICATION OF VIDEO ENHANCEMENT AND INTENSIFICATION TECHNIQUES TO NEUROBIOLOGY. C. Edwards (Chairman, SUNY Albany), R.D. Allen* (Dartmouth), R.J. Lasek (Case Western Reserve), S.B. Kater (Iowa), R.S. Smith (Alberta), C.A. Mason (N.Y. University).

Allen will explain how AVEC-videomicroscopy produces such a large increase in image contrast that the motion in living cells of "submicroscopic" structures 10-100 nm in diameter may be detected. In squid and lobster nerve the velocities of the bidirectional movements of synaptic vesicles, etc., along microtubules are almost uniform, while larger organelles saltate. Similar events during reticulopodial movement in foraminifers and in cells in culture suggest that "cytoplasmic transport" of vesicles along MTs may be a general process.

Lasek, Brady and Allen have used this technique to visualize particle movements in the squid giant axon. The smallest particles move preferentially in the orthograde direction at rates equivalent to fast axonal transport and appear to correspond to vesicles about the size of synaptic vesicles. Larger particles move in both directions. Remarkably the particle movement continues in axoplasm after removal from the axon by extrusion.

Smith and Kendal have used this technique to investigate the rapid transport of membrane-bound organelles across the Node of Ranvier in frog nerve. Organelle trajectories funnelled towards the node corresponding to the distribution of axonal microtubules. Some organelles hesitated at the entrance to the node and then displayed an axially-oriented oscillation of frequency about 0.1 Hz. Within the node bi-directional organelle transport appeared to be associated with axially arranged structures.

Kater has combined intracellular dye injection with a Silicon Intensified Target (SIT) Camera modified to provide a linear intensity range to view neurons in their normal neuronal and glial surroundings. This alleviates the problems of 1) fluophore fading and 2) photooxidation from high light levels. He has examined the movement of tracers along specific neurite processes as well as the complex morphologies of neurons in invertebrate ganglia, in mammalian brain slices and of growing, regenerating neurites.

Hatten and Mason have studied the migration of developing neurons in culture. It has been proposed that glia are the structural guides for migration of neurons in the developing brain. Video/intensification techniques have been used to study: a) glia process outgrowth; b) association of neurons with glia; c) migration of neurons along glia.

Edwards and Dowd have studied beef chromaffin cells in culture. Normally, the enzyme dopamine-β-hydroxylase (DβH) is present in vesicle membrane and not in plasma membrane. In the presence of Ba^{2+}, which stimulates secretion of chromaffin material, DβH has been found by immunofluorescence techniques and a SIT tube to lie in patches on the cell membrane.

203.1 A MUTATION AFFECTING THE DEVELOPMENT OF AN IDENTIFIED NEURON IN A DROSOPHILA MOTOR SYSTEM. J. B. Thomas, W. J. Costello and D. King (SPON: M. P. Charlton). Biol. Dept., Yale Univ., New Haven, CT 06511, Ohio Univ. Coll. Osteo. Med., Athens, OH 45701 and Southern IL. Univ. Sch. Med., Carbondale, IL 62901.

An X-linked mutation, nj156, has been isolated which affects an identified component of the giant fiber motor pathway in Drosophila melanogaster.

In Drosophila, the giant fiber pathway mediates a visually-induced escape response. In wild-type flies, the giant fiber originates in the brain and descends unbranched via the cervical connective to the thoracic ganglion. Here it forms electrical synapses with the peripherally synapsing interneuron (PSI) and with the motorneuron of the jump muscle, the tergotrochanteral muscle (TTM) (King & Wyman, 1980, J. Neurocytol. 9:753-770; Tanouye & Wyman, 1980, J. Neurophysiol. 44:405-421). The PSI courses dorsally and exits the ganglion in the posterior dorsal mesothoracic nerve (PDMN). Within the nerve the PSI makes chemical synapses onto the five motor axons which drive the wing depressor, the dorsal longitudinal muscle (DLM).

In nj156 adults the giant fiber cannot drive the DLM. The motor axons of this muscle are unaffected; they can be stimulated to produce excitatory junctional potentials in the DLM. This suggests that the normal functioning of the PSI is being affected. EM serial sections through the PDMN reveal that the PSI in nj156 is present, but the axoplasm appears more electron-dense than in normal flies. Pre-synaptic densities are present in the PSI where it contacts the DLM motor axons. However, few or no vesicles are present.

The development of this component was compared in normal and in mutant flies. In normal flies, the PSI axon can be seen in the PDMN by 40 hrs. of pupal development and shows mature synaptic profiles with DLM axons by 70 hrs. In contrast, nj156 flies show no distinct PSI axon within the PDMN at 70 hrs. The PSI axon is either absent at this time or is morphologically abnormal.

203.2 MONOCLONAL ANTIBODIES TO DEVELOPING DROSOPHILA RETINA. R. M. Lebovitz* and D. F. Ready* (SPON: D. L. Gorlick). Dept. of Bio., Princeton University, Princeton, NJ 08544.

The compound eye of Drosophila melanogaster is composed of over 750 identical ommatidia in a precise hexagonal array. This is established during the third instar larva by a wave of differentiation which sweeps across the eye disc from posterior to anterior. Along a furrow which marks the front of this wave, unpatterned cells are recruited into clusters which are precursors of adult ommatidia. Cells within a cluster appear to be determined to become either photoreceptors or accessory cells at the time of recruitment. To investigate cell surface changes correlated with neural determination, we are selecting monoclonal antibodies to antigens which appear on cells as they acquire their identities at the furrow.

Mice were immunized with membranes isolated from adult fly heads or imaginal discs. The resulting hybridoma lines were screened on eye disc whole mounts using an indirect immunofluorescent assay. Of 255 antibodies screened, three (Drospr 301, 302, and 401) showed a topographic distribution on the disc correlated with pattern formation. We have examined the cellular localization of antigens recognized by the three antibodies. Drospr 302 and 401 binding sites appear on cells immediately behind the furrow, coincident with the first organization of cells into photreceptor clusters. In the light microscope Drospr 302 appears bound uniformly over the surface of photreceptor cells including their axons. Binding sites for 401 are concentrated between the cells in a cluster and may be associated with specialized junctions which hold clusters together. A third antibody, Drospr 301, binds to the apical tips of photoreceptor cells. Unlike Dropsr 302 and 401, Drospr 301 binding sites are first observed on clusters well behind the furrow. A solid-phase radioimmunassay technique show that the sites recognized by these three MAbs are antigenically distinct.

We have examined three eye mutants in which the neural pattern of the eye is disrupted. The first two, rough and lozenge^{50e}, which show a disorganized ommatidial array in the adult exhibit normal binding for all three antibodies. The third, glass^{3} lacks the Drospr 301 antigen although the eye disk appears morphologically normal and binds Drospr 302 and 401 in a wild-type pattern. Adult eyes of glass^{3} mutants do not have rhabdomeres.

Supported by a Sloan Fellowship BR2040 to DFR.

203.3 FIRST DETECTED EYE-OPENING IN A SEGREGATING INBRED STRAIN OF RATS (WLE-c/+): COMPARISON OF GENETICALLY NEARLY-IDENTICAL PIGMENTED VS. ALBINO LITTERMATES. I. S. Westenberg and J. M. Bolam*. Institute for Study of Developmental Disabilit., Chicago, IL 60608.

Previously reported differences between albino rat stocks and pigmented rat stocks in time of eye-opening are possible correlates of albino-pigmented differences in retinal projections. However, the albino stocks differed genetically from the pigmented stocks not only at the albino (c) locus but also at many other loci. Thus, it could not be determined if eye-opening differences were associated specifically with the genetic difference at the c locus. Comparison of albino vs. pigmented mice that differed at the c locus but were otherwise genetically identical showed little or no differences in first eye-opening. This suggested that the previously observed differences in rats were correlates of factors other than just the albino mutation. However, findings in mice may not be generalizable to rats in this case. To test this possibility we used rats in an experiment similar in design to the previous experiments with mice. Our goal was to determine if there is a difference in eye-opening specifically associated with a genetic difference at the c locus in rats.

Litters consisting of at least 1 albino and 1 pigmented rat of the segregating inbred strain WLE-c/+ (Westenberg-Long-Evans) were examined daily for eye-opening. Albino rats had 2 mutant c genes at the c locus (c/c); their black-hooded littermates had 1 mutant c gene and 1 normal gene at the c locus (c/+). In each litter there were 3 possible outcomes: The first eye-opening(s) could be in c/c (a), in c/c and c/+ (tie), or in c/+ (p).

Results in 24 litters were 10 a, 7 tie, and 7 p. The p frequency was larger than expected by chance, but not significantly more so than the a frequency. Thus, in this strain of this species of rodent a difference in first detected eye-opening does not appear to be specifically associated with albinism.

The difference between these results and previous results from rats may be related to the experimental design (within-strain vs. between-strains comparison) or the genotype of the pigmented rats (c/+ vs. +/+). The within-strain design was chosen as more efficient for isolating the effects of a single mutant gene. It is unlikely that c/+ pigmented rats' results would have differed from +/+ pigmented rats', but this remains to be tested. It is possible that c/c-c/+ comparisons in rats of other genetic backgrounds will produce different results.

While differences in first eye-opening of the sort seen in between-strains comparisons were not seen in this within-strain comparison, there is evidence that some aspects of the albino-pigmented retinal projection differences seen in between-strains comparisons are also seen in within-strain comparisons.

Supported by NIH grant EY03013.

203.4 CHARACTERIZATION OF TREMBLER MOUSE SCHWANN CELLS IN VIVO AND IN VITRO. Karl J. Fryxell* and Jeremy P. Brockes (SPON: L.C. Fritz). Division of Biology, California Institute of Technology, Pasadena CA, 91125.

The trembler (Tr/+) mouse mutant has a pronounced reduction in peripheral myelin, while both central myelin and peripheral unmyelinated nerves appear normal. Experiments (by Aguayo, Bunge and collaborators) in which axons of one genotype are confronted by Schwann cells of another genotype (in vivo or in vitro) produce a clear answer---the trembler deficit is expressed in the Schwann cell and not in the axon. The myelin proteins P_0 and P_1 are apparently reduced to the same extent in trembler nerve. We would like to understand the nature of this Schwann cell-specific function, which is required for the accumulation of myelin proteins, but is not required for Schwann cell survival or normal wrapping of unmyelinated axons.

In the original description of the trembler mutation by Falconer in 1951, no difference was found between Tr/+ and Tr/Tr mice in behavior, fertility or lifespan. We have found, however , that homozygotes (of at least one of the Tr alleles) have much less myelin and myelin proteins than heterozygotes do. These homozygotes die at 12-21 days of age, but the juvenile homozygotes may be identified as such by several criteria, including linked genetic markers, behavior, body weight and nerve appearance.

Homozygous trembler Schwann cells show remarkable heterogeneity in their response to competent axons in vivo. Most of these Schwann cells do not make compact myelin, yet they are faintly labeled by a rabbit antiserum to the myelin protein P_0, as detected by indirect immunofluorescence on frozen sections. (Wild-type Schwann cells in unmyelinated nerves are not labeled.) A small fraction of the homozygous trembler Schwann cells, however, are very brightly labeled by the antiserum. Some, perhaps all, of such cells also make compact myelin. Preliminary results suggest that the brightly labeled cells are not distributed along particular "super axons," and also that the occasional production of compact myelin is not correlated with differences in axonal diameter.

We have found that mouse Schwann cells may be immunologically purified by methods similiar to those used for rat Schwann cells (Brockes et al., Brain Res. 165: 105-118, 1979), enabling us to grow "genetically pure" cultures of Tr/Tr Schwann cells. Preliminary experiments indicate that cultured Tr/Tr Schwann cells respond normally to glial growth factor. Additional experiments will be presented to further characterize Tr/Tr Schwann cells in culture.

203.5 SPONTANEOUS OCCURRENCE OF A MUTATION CAUSING SEVERE DEFECTS OF CEREBELLUM AND MOTOR COORDINATION IN MICE. D. Wahlsten, J. Lyons* and W. Zagaja*. Dept. of Psychology, Univ. of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

In October of 1980 two mice with severe defects of behavioral and cerebellar development were discovered two weeks after birth in a litter of inbred BALB/cCF mice. Breeding of their close relatives revealed that the disorder has a completely recessive mode of inheritance and can be transmitted equally well by males and females. Crosses between known carriers of the defect and crosses between a carrier and the sibling of an affected mouse yielded proportions of affected offspring which were close to the expected Mendelian ratios, indicating single-locus autosomal recessive inheritance.

The syndrome produced by this mutation has several features.

a. At birth about half of the affected mice show a blood bleb under the skull at the anterior margin of the interparietal plate near midline.

b. Within two days of birth, all affected mice have either a short tail or a distinctly blunted tail. Extreme cases have almost no tail at all.

c. All affected mice show delayed development of the righting reflex, and some are never able to right themselves properly. Those which can eventually right themselves and walk exhibit obvious abnormalities of gross motor coordination such as head-tossing, tumbling, chaotic circling and incessant ambulation.

d. The cerebellum is reduced in size and has highly unusual patterns of foliation. In the most severe cases there is only a small amount of cerebellar tissue present at the peduncles. The major cell types in cerebellum appear to be present and in approximately correct positions relative to each other, as seen in Nissl-stained sections.

e. Mortality is very high, and reproduction is impossible. Severely affected animals sometimes die soon after birth or are eaten by the mother. Many others die around the time of weaning, mainly because they are exceedingly active but have difficulty eating solid food.

The syndrome bears a striking resemblance to that produced by the now-extinct "shaker-short" gene (st) in mice reported by Dunn (Proc. Nat. Acad. Sci., 20: 230, 1934). The cerebellar malformation is similar to that found in humans with the Dandy-Walker syndrome, an instance of a Type IV Chiari malformation as discussed by Caviness (Devel. Med. Child Neurol., 18: 103, 1976).

203.6 APPLICATION OF CELLULAR LEVEL HYBRIDIZATION HISTOCHEMISTRY TO THE STUDY OF NEUROENDOCRINE GENE EXPRESSION. C. Gee*, J.L. Roberts* and S.J. Watson (SPON: E. Shapiro). Dept. of Biochem., College of Physicians and Surgeons, Columbia Univ., New York 10032, and Mental Health Resh. Inst., Univ. of Michigan, Ann Arbor, MI 48109.

Progress has been made in the study of gene expression following the advancement of recombinant DNA technology. Routinely, messenger RNA (mRNAs) are extracted from the total tissue and quantitated by specific hybridization to complementary DNA (cDNA) probes. However, due to the low abundance of cells producing specific neuropeptides in neurotissues, and that the same gene can be expressed in various cell types which may be regulated differentially in the same tissue, the study of whole tissue hybridization histochemistry, a technique developed for cellular localization of specific mRNAs can be applied advantageously. It involves the fixation of mRNAs in tissues and hybridization of radiolabeled specific cDNA probes to the section. The cDNA:mRNA hybrids are then autoradiographed and visualized at the light microscope level.

In situ hybridization histochemistry has been refined to the level of single cell resolution in the pituitary. Qualitative information on gene expression at the level of mRNA content can be obtained easily. We have used this technique to study the regulation of propiomelanocortin (POMC) gene expression in the two lobes of the rat pituitary. The absence of glucocorticoids (adrenalectomy) causes an increase in the size and number of POMC expressing cells as well as an increase in autoradiographic grain density, implying an increased POMC mRNA concentration. Treatment of the animal with glucocorticoids gives an opposite effect. Thus, we can distinguish between the regulation of gene expression in normally expressing cells and hormonally induced differentiation of non-expressing cells.

This technique has been used along with classical immunohistochemistry on serial sections to positively identify peptide hormone synthesizing cells. We are working on optimizing the hybridization conditions for the brain. This includes the quantitative fixation of mRNAs, deproteinization to make the mRNA more accessible to probes, and varying the hybridization time, temperature and buffer. ^{32}P-labeled cDNA probes can be used for rapid tissue screening. ^{3}H or ^{35}S can be used for high resolution, but they require longer exposure time. Biotin-derivitized cDNA is being used for both resolution and shorter exposure time. (This work is supported by NIH grant AM 27484 to J.L. Roberts).

203.7 EXPRESSION OF THE PROOPIOMELANOCORTIN GENE IN EARLY STAGES OF FETAL RAT PITUITARY DEVELOPMENT. J. Pintar*, J.L. Roberts*, and C. Gee* (SPON: S. Edelstein). Departments of Anatomy and Medicine, Mt. Sinai School of Medicine, New York, NY 10029. and Dept. of Biochemistry and Center for Reproductive Sciences, Columbia University, New York, NY 10032.

Peptide hormones derived from proopiomelanocortin (POMC) have critical functions during embryogenesis as well as postnatally. Although adult-like anterior and intermediate lobe pituitary POMC processing patterns are established before birth (Pintar, Allen, and Kendall, Endo. Soc. Abst., 1981), little is known about the regulation of POMC synthesis and accumulation in either pituitary or brain during pre-natal development. In order to determine when during development POMC gene expression begins, we have used POMC specific DNA probes (Roberts et al, PNAS 76:2153) to identify POMC mRNA in nucleic acid extracts of different tissues at various stages of fetal development. Pregnant Sprague-Dawley rats were decapitated and fetuses from day 15 and day 19 gestation were dissected. Total nucleic acid was extracted from the pituitary, brain, and liver (whole pituitary from day 15 and separated lobes from day 19) using the proteinase K-SDS method to ensure reproducible mRNA recovery from the small amounts of tissue available. Aliquots of isolated nucleic acid from these tissues were spotted onto nitrocellulose and hybridized with ^{32}P-labelled POMC cDNA. POMC mRNA was detected in pituitary and brain, but not liver, at both stages of development. As in the adult, the pituitary was much richer in POMC mRNA than the brain at these ages. The level of sensitivity was such that the amount of POMC mRNA present in 1/5 total nucleic acid from one embryonic day 15 pituitary was easily detectable. Preliminary results have suggested that POMC mRNA can be detected even at the Rathke's pouch stage, well before POMC has been detected by radioimmunoassay or immunocytochemistry. These results demonstrate that recombinant DNA techniques can detect POMC message levels present in embryonic brain and pituitary glands and suggest that localization of cells synthesizing POMC mRNA by in situ hybridization of POMC cDNA probes should be feasible.

203.8 IDENTIFICATION OF AN ADRENOCORTICOTROPIC HORMONE-LIKE SUBSTANCE IN DROSOPHILA MELANOGASTER BY DNA HYBRIDIZATION AND IMMUNOCYTOCHEMISTRY. C.S. Royden*, P.H. O'Farrell*, E. Herbert*, M. Uhler*, Y.N. Jan and L.Y. Jan. Departments of Physiology and Biochemistry, University of California, San Francisco, CA 94143.

Striking tissue distributions of hormone-like peptides in the nervous system have stimulated intensive efforts to define their function. The power of genetic, cytogenetic and molecular analyses in Drosophila melanogaster could make important contributions to defining the functional significance and genetic complexity of these peptides. Assuming conservation of primary sequence and of function across an enormous evolutionary distance, we have used probes from mammalian systems to detect related peptides immunologically and related coding sequences by DNA hybridization.

We used immunocytochemical techniques to determine whether the Drosophila nervous system contains any peptides homologous to those in the mammalian nervous system. We screened antibodies to 12 mammalian peptides. Three of these, antibodies against ACTH, enkephalin and substance P, specifically stained the Drosophila nervous system and reproductive system. Antibodies to enkephalin and ACTH stained similar structures in the nervous system, including fibers in the optic ganglia, thoracic ganglia and cervical connective. They also produced similar staining patterns in the anterior ejaculation duct of the male reproductive system.

The localization of these immunoreactive materials to neuroactive tissues in organisms as diverse as mouse and Drosophila is a striking result which suggests that these peptides, like acetylcholine, are part of a mechanism so basic to neurologic function that it is conserved across this evolutionary distance. An alternative, and we feel less likely, possibility is that although the sequence is conserved, the function might be unrelated and the localization to nervous tissue is coincidental.

In order to study the structure and function of the ACTH-like substance further, we chose to isolate the gene using DNA hybridization techniques. Using T4 polymerase, we made a ^{32}P-labelled DNA probe from the ACTH portion of pro-opiomelanocortin from mouse cDNA. A bank of Drosophila restriction fragments in the phage λ vector Charon 4 was screened by hybridization with this probe. The DNA was hybridized at three levels of stringency, 15°, 28° and 40° below the melting temperature (Tm) of double stranded DNA. No hybridization to plaques was observed at the highest stringency, while we found several positive plaques at moderate stringency, and many at the lowest stringency. We isolated 10 plaques showing hybridization at moderate stringency; six rehybridized upon rescreening. The DNA from these plaques was isolated, and the amount of homology between these and the original probe is currently under study.

203.9 STUDIES ON THE STRUCTURE OF PRECURSORS TO OXYTOCIN, VASOPRESSIN AND NEUROPHYSINS IN THE RAT USING PROTEIN CHEMICAL AND RECOMBINANT DNA TECHNIQUES. T.G. Sherman*, J.L. Roberts*, J.C. Fiddes* and J.F. McKelvy. (SPQN: Y. Grimm-Jorgensen.) Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794 and Center for Reproductive Science, Columbia Univ., NY, NY 10032 and Cold Spring Harbor Laboratories, Cold Spring Harbor, NY 11724.

Multiple high molecular weight forms of neurophysin (Np) have been translated in vitro using wheat germ extract or rabbit reticulocyte lysate with an RNA fraction enriched in poly(A)- containing RNA species isolated from liquid N_2 frozen rat hypothalamic tissue from normal and 16 day salt-loaded Sprague-Dawley rats, and a homozygous strain of Brattleboro rats. Normal and salt-loaded hypothalamic poly(A) RNA coded for 3 protein species immunoprecipitable with protein A-purified anti-rat Np IgG: 2 proteins of 17,000 daltons with isoelectric points (pI) of 5.28 and 5.60, and a larger, more neutral precursor at 18,500 daltons and of pI 6.15. Homozygous Brattleboro rat poly(A) RNA failed to direct the translation of the 18,500 dalton protein, yet retained the two smaller, more acidic proteins. Using one dimensional reverse phase high performance liquid chromatography, all 3 proteins were shown to contain the 4 cysteine-containing tryptic peptides of mature rat neurophysins. In addition, each protein yielded an additional, unique cysteine-containing peptide.

Given the observed differences in the translatable poly(A) RNAs between Brattleboro and normal rat hypothalamus, and the difficulties in examining subtle differences between the multiple Np precursors by protein chemical methods, we decided to use recombinant DNA methods. Poly(A) RNAs coding for the Np precursors were greatly enriched, with respect to total poly(A) RNA, by fractionation on an isokinetic sucrose-SDS gradient. Aliquots of poly(A) RNA, recovered from each of 25 fractions, were translated in vitro and the distribution of total translation products and immunoprecipitable Np precursors were determined along the gradient. Fractions of RNA displaying the greatest Np precursor enrichment (approx. 20-fold) served as templates for oligo(dT)-primed cDNA synthesis. These single stranded ^{32}P-labeled cDNAs were used as probes to screen a rat hypothalamic cDNA library containing approximately 6000 recombinants. Nearly 60 positive clones were identified, several of which generated restriction fragments of predicted size, based on restriction sites reflecting known amino acid sequences of rat neurophysins. Further screening and sequencing of recombinants so identified are in progress and should provide definitive information on the relationship between the multiple forms of Np precursors.

203.10 CLONING OF COMPLEMENTARY DNA TO PHENYLETHANOLAMINE-N-METHYLTRANSFERASE. E.E. Baetge, H.M. Moon*, B.B. Kaplan, D.H. Park, D.J. Reis and T.H. Joh. Lab of Neurobiology and Dept. of Anatomy, Cornell Univ. Med. Coll., New York, NY 10021 and Lab of Molecular Neurobiology, N.Y.S. Inst. for Basic Research, Staten Island, NY 10314.

In order to study the expression, organization and structural relationship of the genes involved in catecholamine biosynthesis, we sought to synthesize and clone complementary DNA (cDNA) to poly(A)mRNA coding for the catecholamine synthesizing enzymes. We report here the cloning of cDNA to phenylethanolamine N-methyltransferase (PNMT) which catalyzes the conversion of norephinephrine to epinephrine.

Specific PNMT poly(A)mRNA was isolated from bovine adrenal medulla by affinity chromtography of PNMT antibody-polysome complexes on a Protein A Sepharose column. Polyribosomal mRNA bound to the column was eluted with 20 mM EDTA in 25mM Tris-Cl, pH 7.6, and poly(A)mRNA was purified by oligo-dt cellulose chromatography. With this procedure, PNMT mRNA was enriched 50-fold as judged by translation and quantitative immunoprecipitation of a 31,000 MW protein with PNMT antibody. PNMT mRNA thus enriched was used as a template for the synthesis of cDNA. The 3' OH terminus of double stranded cDNA was extended with 10-15 deoxycytosine residues and inserted into the Pst 1 site of poly dG tailed plasmid PBR322 (15-25 residues per 3' OH terminus). The resultant recombinant plasmids were used to transform competent E. coli strain 294. Tetracycline-resistant, ampicillin sensitive clones were screened by positive hybridization selection, and preliminary analysis identified 2 clones containing PNMT cDNA inserts, pPNMT-22 and pPNMT-24. pPNMT-22 cDNA insert was isolated from the plasmid DNA by digestion with Pst 1 and found to be approximately 350 base-pairs in length. The pPNMT-22 cDNA insert was labeled by nick translation with ^{32}P-dCTP to 1 x 10^8 cpm/ug and used in Northern blot analysis. The pPNMT-22 probe strongly hybridized to an RNA species of approximately 1000 nucleotides, a size appropriate for a mRNA coding for a 31,000 MW protein

(Supported by NIH Grant MH24285 and HL18974).

203.11 CONSTRUCTION OF A RECOMBINANT DNA LIBRARY CONTAINING SEQUENCES COMPLEMENTARY TO HUMAN ADULT CORTEX POLYADENYLATED RNAs. A. J. Michael*, R. B. Gammon*, S. Pardue*, D. E. Croall*, D. Sparkman*, W.S.T. Griffin, and M. R. Morrison. Departments of Neurology and Cell Biology, University of Texas Health Science Center at Dallas, 5323 Harry Hines Blvd., Dallas, Texas 75235.

Construction of a recombinant cDNA library containing sequences encoded by adult human brain is a prerequisite for the study of transcriptional and post-transcriptional changes during normal and abnormal human brain development. Undegraded polyadenylated RNAs, representative of those present in vivo, were isolated from adult human cortex (Morrison, M. and Griffin, S., Anal. Biochem., 113: 318, 1981). This RNA was used as a template for the synthesis of a recombinant DNA library first strand cDNAs were reverse transcribed from the polyadenylated RNAs with 20-40% efficiency, and denaturing gel electrophoresis demonstrated that full length cDNAs had been synthesized. The single-stranded cDNAs were tailed at their 3' ends with approximately 30 dC residues. Double-stranded cDNAs were then synthesized, using oligo (dG) as a primer for the reverse transcriptase. The double stranded cDNAs were cloned into the Pst I site of plasmid pBR322, using the standard (dG), (dC) tailing procedures (Villa-Komaroff, L. et al., PNAS, USA, 1975: 3727, 1978). Transformation efficiencies of E coliK12 RR1 were 100-250 tetracycline-resistant, ampicillin-sensitive clones/ng double-stranded cDNA. Thus, one microgram of tailed, double-stranded cDNA yielded a library of at least 100,000 clones. The library was stored on Millipore filters as 1) a semi-ordered collection, 2) isolated DNA, and 3) glycerol stocks of transformed cells. Insert sizes were mostly between 600 and 1100 base pairs.

Clones will now be isolated which correspond to the different mRNAs encoding the α_1, α_2, β_1, and β_2 tubulin subunits so that the structure of these mRNAs can be compared. Clones corresponding to developmentally-regulated mRNAs will also be identified and used to study the regulation of their expression. Supported in part by NIH 14886 and grants from the Leland Fikes and the Chilton Foundations.

203.12 REGULATION OF TYROSINE HYDROXYLASE mRNA ACTIVITY IN A RAT PHEOCHROMOCYTOMA AND ISOLATION OF A cDNA CLONE FOR TYROSINE HYDROXYLASE. E.J. Lewis*†, A.W. Tank*§, N. Weiner§ & D.M. Chikaraishi*† (SPON: J. Masserano). †Dept. of Molec. & Cell. Biology, National Jewish Hospital/National Asthma Center; and §Dept. of Pharmacology, U. of Colorado Health Sciences Center, Denver, CO 80206.

A number of variant cell lines which respond differentially to glucocorticoid and cyclic AMP derivatives with respect to induction of tyrosine hydroxylase (TH) were isolated from the rat pheochromocytoma PC12 cell line. Cell cultures, maintained in RPMI supplemented with 10% horse and 5% fetal calf sera, were incubated for 3 days with either dexamethasone (dex) (1 μM) or 8BrcAMP (1mM). RNA was extracted from cells and mRNA activity for TH (mRNA-TH) was determined following translation of total RNA in an in vitro protein synthesizing system derived from rabbit reticulocytes, using ^{3}H-leucine as tracer. Total translation products were then immunoprecipitated with antisera raised to purified tyrosine hydroxylase and the amount of radioactivity in TH was compared to that of total translation products. In a representative experiment, the mRNA-TH activity in one of these cell lines was elevated from a basal level of 0.067% of total translational activity to 0.2% in cultures incubated with 8BrcAMP and to 0.5% in cultures incubated with dex. The mRNA-TH activity in cultures containing both inducers was 0.85% of total translational activity.

A cDNA clone to mRNA-TH was isolated from a cDNA library constructed from polyA+-mRNA highly enriched in mRNA-TH. Double-stranded cDNA was made using AMV reverse transcriptase and E. coli DNA polymerase. This cDNA was inserted into the Pst I site of plasmid pBR322 using the G-C tailing technique, and the recombinant plasmids used to transform the E. coli strain HB101. Clones containing inserted sequences were screened by hybridization of plasmid DNA to ^{32}P-cDNA made from RNA isolated from induced and non-induced cell cultures. Those clones demonstrating differential hybridization between these two probes were further screened using hybrid selected translation and immunoprecipitation. From this screening, a clone was identified which contains approximately 350 base pairs which are complementary to mRNA-TH.

204.1 SEROTONIN AND NOREPINEPHRINE INNERVATION PATTERNS IN VISUAL CORTEX OF THE RAT: REGIONAL SPECIALIZATION. M.E. Molliver, M.S. Lewis*, R. Grzanna, and H.G.W. Lidov. Dept. Cell Biology/ Anatomy, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

The patterns of serotonin (5-HT) and norepinephrine (NE) innervation of cerebral neocortex in the albino rat have been studied with particular attention to the laminar distribution of axons in visual cortex, employing antibodies directed at 5-HT and DBH.

Overall, the 5-HT innervation density is relatively low in dorsal neocortex and is greater in more ventro-lateral areas. There is a corresponding change in axon morphology and distribution. The 5-HT axons have small varicosities with smooth, elongated intervaricose segments of varying length. DBH-positive axons have far more numerous varicosities. In area 17, the density of 5-HT axons is highest in layer I and slightly less in V and VI. There is a somewhat lower density in layers II-III and a markedly low density in layer IV. Many 5-HT axons in layers I, V, and VI are tangentially oriented in both sagittal and coronal planes, whereas in layers II-III, a radial orientation is common, best seen in parasagittal sections.

The 5-HT axon density in area 17 is far less than in SI, the most outstanding difference being the decreased density in layer IV of visual cortex. In contrast to the 5-HT distribution, NE axons in visual cortex have a higher density of fine arborizations in layer IV, and the axons are more evenly distributed across the layers.

The 5-HT axons exhibit a high degree of regional specialization most evident in visual cortex where the pattern of innervation differs from 5-HT in other areas (e.g., SI), and from that of NE axons. The main new finding is that the 5-HT innervation in rat visual cortex is strikingly different from that in primate area 17 where the 5-HT axons are especially numerous in layers IVA and IVC but very low in V and VI (cf. Morrison et al., PNAS 79:2401-2405, 1982).

The 5-HT axons are likely to contact different classes of cortical neurons in different species as well as in different cortical areas. The 5-HT raphe-cortical innervation pattern is not diffuse but exhibits regional specificity and order. Consequently, the functional role of 5-HT axons is different in separate cortical areas and differs from that of the NE projections. Moreover, the functions of the monoamine projections in primate visual cortex are likely to differ from those in the rat. Studies are in progress to determine whether a particular subset of MA neurons projects to visual cortex. [Support: NIH Grants #NS-15199 and NS-08153]

204.2 PHYSIOLOGICAL AND MORPHOLOGICAL ANALYSIS OF AFFERENT AXONS IN THALAMO-RECIPIENT LAMINAE OF MACAQUE STRIATE CORTEX. G.G. Blasdel and J.S. Lund. Depts. of Anatomy and Ophthalmology, Medical University of South Carolina, Charleston, S.C. 29425.

Morphological analysis of afferent axons entering macaque striate cortex, following intracellular recording and HRP filling, reveals consistent patterns of arborization. Six axons judged physiologically to derive from magnocellular LGN laminae (because they lacked color selectivity, and responded transiently with high contrast sensitivity to flashed stimuli) were observed to terminate primarily in layer 4c-alpha with sparse projections into 6. All spread in a stripe-like or patchy fashion and cover large areas when viewed normal to the pia. Reconstruction of axons against ocular dominance bands, following eye injection with H-3 Proline, reveals that the patchy or stripe-like terminations fall largely within one eye's set of ocular dominance 'columns'.

Three axons with sustained, color-opponent receptive fields (characteristic of parvocellular LGN laminae) were found to terminate either in layer 4c-beta alone or in layers 1 and 6 (1 axon). The two axons arborizing in 4c-beta conform to a highly stereotyped pattern also observed in many other 4c-beta axons, recovered following white matter injections of HRP. Their preterminal trunks follow long tortuous trajectories through the grey matter before terminating in highly circumscribed clumps that fill the thickness of 4c-beta but extend no farther than 200 micra in any lateral direction. The tangential area covered by a single 4c-beta axon is approximately 1/6 that observed for a single 4c-alpha axon but the density of boutons per unit volume is about the same. A different pattern is seen for the axon projecting into layers 1 and 6; this axon, which had a blue-ON center, arborizes in 4 separate patches and spreads over a distance greater than 2 mm. Axons with small terminal fields in layer 4a, recovered following white matter injections of HRP, have a honeycomb appearance when reconstructed in 3 dimensions and viewed normal to the pia. These axons can also contribute sparse projections to laminae 2-3.

Physiological recordings with metal electrodes confirm earlier observations (Hubel, Wiesel and LeVay, 1974) of a precise retinotopic map in both 4c-alpha and 4c-beta. In addition, they reveal a difference in contrast sensitivity which is greater for non-oriented units in 4c-alpha than it is for non-oriented units in 4c-beta. Given the enormous spread of afferent axons in 4c-alpha (up to 1.2 mm in some cases), it is unlikely that the observed retinotopic map, which can be seen within the width of a single ocular dominance column, derives directly from the geometry of afferent inputs.

204.3 HISTOCHEMICAL SUBDIVISIONS OF THE MACAQUE'S LATERAL GENICULATE BODY AND STRIATE CORTEX: DEMONSTRATION BY PSEUDOCHOLINESTERASE AND ACETYLCHOLINESTERASE STAINING AND EFFECTS OF EYE ENUCLEATION. A.M. Graybiel and C.W. Ragsdale, Jr.* (SPON: R. Held). Dept. of Psychology and Brain Sci.,Mass. Inst. of Tech.,Cambridge,MA 02139

We have compared the distributions of butyrylcholinesterase (BuChE), acetylcholinesterase (AChE) and cytochrome oxidase in sets of serial frozen 30-50μm sections through the lateral geniculate body (LGN) and visual cortex of 9 adult Rhesus macaque monkeys. Five of the monkeys were normal, 4 had undergone unilateral (left) eye enucleation 5-30 days before perfusion.

In the LGN, the most striking finding was that BuChE staining was intense in the parvocellular layers but very weak in the magnocellular layers. Eye enucleation resulted in a sharp and progressive decline in BuChE staining in the denervated parvocellular layers. By contrast, all LGN cell-layers were stained with AChE and eye enucleation did not change the AChE staining patterns noticably. Cytochrome oxidase was also present in all cell-layers but declined after denervation.

In area 17, BuChE and AChE were both distributed in highly differentiated layering patterns which distinguished striate from peristriate cortex. BuChE was densest in layers 4Cα and upper 4Cβ and at the borders of layer 5. The base of layer 4 was pale. In the infragranular layers there were hints of periodicity and BuChE-positive cells. AChE staining was densest in layers 1, 4A, 4C and 6. In addition, both enzymes were distributed in a gridwork of 100-300μm-wide patches visible in tangential sections through the supragranular layers. These patches were much more prominent in BuChE than in AChE and sometimes precisely coincided, but sometimes were clearly out of phase, with cytochrome oxidase patches visible in adjoining sections.

Monocular eye enucleation produced, at all survival times, regularly alternating 300-500μm-wide stripes of high and low cytochrome oxidase activity in tangential sections through layer 4 as described previously for 10 day enucleates by Horton and Hubel (1981). A striking stripe pattern also appeared in AChE sections through layer 4 where, most clearly in the 10 day animal, 300-500 μm-wide AChE-rich and AChE-poor bands alternated. In BuChE sections stripes of high enzyme activity were also present, but they were thin and difficult to visualize except in tangential sections through the layer 4/5 border. The stripes of high AChE and BuChE activity were in register with one another but, remarkably, corresponded to the stripes of low cytochrome oxidase activity.

We conclude that both pseudocholinesterase and acetylcholinesterase stains mark functional subdivisions of the macaque primary visual pathway and may prove valuable and at least partly independent markers in studying the responses of this system to altered visual input. Supported by NIH 5R01 EY02866 and 5P30 EY02621.

204.4 ORIENTATION SHIFT BETWEEN UPPER AND LOWER LAYERS IN MONKEY VISUAL CORTEX. B.M. Dow, R. Bauer*, A.Z. Snyder*, R. Vautin*. Neurobiology Division, School of Medicine, SUNY, Buffalo, NY 14226.

A major feature of Hubel and Wiesel's orientation column model (J. Comp. Neurol. 158:267-294, 1974) is constant orientation preference of all cells in a line running perpendicular to the surface from layer 2 to layer 6. Our systematic experiments using vertical or nearly vertical penetrations (Exp. Brain Res. 41:54-60, 1980) have led us to question the validity of this feature. In particular, we have found a major shift in preferred orientation of recorded cells as our electrode crosses over from the supragranular to infragranular layers. This finding has now been documented histologically with measurements of penetration angles and recording sites.

In a series of 57 penetrations in foveal striate cortex of awake monkeys trained to fixate according to the paradigm of Wurtz, we have recorded single cells or cell clusters at regular intervals of 200-400μ from pial surface to white matter, and have used a computer-assisted method to measure orientation of the preferred stimulus at each recording site. The data include 379 recording sites, an average of 6 sites per penetration. In the great majority of penetrations orientation as a function of depth in the supragranular layers could be reasonably well approximated by a straight line. The mean slope of this line for 57 penetrations was 20.7°/mm. In 12 marked penetrations the mean penetration angle with respect to the surface normal was 17.7°.

As the electrode entered the lower layers there was typically a shift in orientation preference. Subsequent lower layer cells tended to have nearly the same orientation as the first (shifted) cell. On the basis of 7 penetrations with well localized electrolytic lesions the shift site was determined to be at the border between layers 4C and 5. The size of the orientation shift between upper and lower layers was determined quantitatively by extrapolating separately obtained least squares fitted lines for upper and lower layer orientation (as a function of depth) to the midpoint between the cell pair exhibiting the orientation shift. Among 57 penetrations 40 (70%) fell into a large-shift group with shift sizes ranging from 45-90° (mean 70.2°), and 17 (30%) fell into a small-shift group with shift sizes ranging from 0-44° (mean 18.7°).

The data thus indicate a major shift in orientation between the supragranular and infragranular layers, and are suggestive of intracolumnar inhibition, presumably mediated by inhibitory neurons projecting either down from upper layers or up from lower layers.

Supported by NIH grants EY02349 and T32 EY07019.

204.5 LATTICE-LIKE INTRINSIC NEURAL CONNECTIONS IN PRIMATE STRIATE VISUAL CORTEX. K.S. Rockland and J.S. Lund. Dept. of Ophthalmology, Medical Univ. of S.C., Charleston, S.C. 29425.

Horseradish peroxidase (HRP) injections were made in striate cortex of squirrel and macaque monkeys. These injections (0.5-1.2 mm in diameter) resulted in periodic patches of HRP label, transported in both the orthograde and retrograde direction, around the injection site. In squirrel monkeys, the HRP-labeled intrinsic connections occur at two cortical levels (layers 2-3 and 4B) and form a lattice-like pattern near the injection site. The walls of the lattice preferentially include labeled cell bodies and axon terminals, with no labeled neurons in the regularly spaced lacunae within the lattice walls. Axon segments course in the walls and also cross through the central lacuna region. Further from the injection, the pattern in layers 2-3 consists of more punctuate HRP labeled loci with interconnecting axon trunks. This shift in pattern presumably reflects lower levels of HRP accumulation. A similar pattern is seen in the macaque in layers 2-3, although the exact periodicity is not identical in the two species: the punctuate HRP loci are spaced about 500-600 μ apart in macaque and about 350-450 μ apart in squirrel monkeys. In both species, the supragranular layers are known also to contain an ordered array of cytochrome oxidase rich loci. Alternate sections were stained for cytochrome oxidase and HRP activity (40 μ tangential sections matched by blood vessels). In both primates the cytochrome rich loci do not regularly coincide with the punctuate HRP pattern. In squirrel monkey the cytochrome dots (450-500 μ apart) lie within the walls of the more densely labeled HRP lattice, and both the HRP and cytochrome systems surround the same regularly arranged series of lacunae. This suggests that the HRP labeled system constitutes a fixed-position network. In squirrel monkey, similarly structured but more extensive connectional lattice is labeled by HRP in layer 4B (where no cytochrome rich loci occur). The 4B lattice includes both pyramidal and spiny stellate neurons (only pyramidal neurons are stained in the supragranular lattice), and has been mapped over 2-3mm from the injection site (vs. 1.5mm for layers 2-3). The two patterns appear in register, but do not show marked interconnections, with a characteristic unlabeled gap between them in lower 3, 4A. A connectional lattice in 4B is also indicated in macaque. The supragranular HRP lattice resembles the pattern and scale of deoxyglucose (DG) uptake in visual cortex after stimulation with lines of single orientation (Horton and Hubel, '81). The various patterns of DG uptake (eg; lines vs. lattice) after different stimuli may be correlated with specific but different subsets of the anatomical lattice which are emphasized under different conditions of visual stimulation. (Supported by EY03321).

204.6 CLUSTERED INTRACORTICAL CONNECTIONS IN CAT VISUAL CORTEX. C.D. Gilbert and T.N. Wiesel. Dept. of Neurobiology, Harvard Medical School, 25 Shattuck St., Boston, Mass. 02115.

Lesion studies have shown that intrinsic cortical connections (those which are restricted to a given area) can extend for several millimeters parallel to the cortical surface (Fisken et al, 1975; Creutzfedlt et al, 1977). From both intracellular (Gilbert and Wiesel, 1979) and extracellular (Gilbert and Wiesel, 1981; Rockland and Lund, 1982) tracing studies, it has been demonstrated that axons participating in these connections do not give off collaterals all along their length, but instead tend to give them off in clusters which are separated by gaps with relatively little innervation.

In the present work we attempted to examine these connections in greater detail. Two days following a focal extracellular injection of horseradish peroxidase (HRP) into a particular cortical area, the label was distributed in clusters of cells surrounded by diffuse granular labeling. These clusters were found at considerable distances from the injection site. More clusters, covering a larger proportion of the area, were observed after injections in area 18 than after injections in area 17. It was not possible to determine the degree to which this labeling pattern reflected diffusion and differential uptake versus axonal transport from the injection site.

From the intracellular HRP injections in area 17 we observed a number of pyramidal cells in superficial and deep layers showing clustering of their axon collaterals. When reconstructed using a 3-dimensional computer graphics system and rotated to obtain a view tangential to the cortical surface, these axons exhibited numerous clusters and were seen to extend over considerable distances (3 to 6 mm). Cells in layer 2+3 projected both to distant points within their own layer as well as within layer 5. The axon of such one cell had clusters covering the same area in both layers, and the clusters in layer 5 were located directly under those in layer 2+3. Surprisingly, some pyramidal cells did not project into the white matter, and formed intrinsic connections exclusively. Finally, the axonal fields of all our injected cells have been asymmetric, extending for greater distances along one cortical axis than along the orthogonal axis. This may have implications concerning the functional role of these connections.

204.7 LIGHT AND EM ANALYSIS OF CYTOCHROME OXIDASE-RICH ZONES IN THE STRIATE CORTEX OF SQUIRREL MONKEYS. E. Carroll* and M. Wong-Riley (SPON: F.D. Anderson). Dept. of Anat., Med. Coll. of Wis., Milwaukee, WI 53226.

Oxidative metabolism in the central nervous system has been demonstrated by cytochrome oxidase (C.O.) histochemistry (Wong-Riley, '79). In the primate striate cortex, distinct patterns of high C.O. activity were found in laminae II, III, IVA, IVC and VI (Horton & Hubel, '80; Humphrey & Hendrickson, '80). We sought to extend these studies at both the light and EM levels to determine the cellular and subcellular distribution of reactivity within the striate cortex of squirrel monkeys. Cells with high C.O. staining were observed throughout the grey matter and included mostly stellate (lam 2-6) and some pyramidal (lam 2-3 and 5-6) neurons. Intermittent puffs of C.O. activity were observed in lam 2-3 as described before; their average diameter was 210μm and were spaced about 500μm apart (center-to-center). Puffed areas alternated with areas of less intense C.O. activity whose dimensions were roughly 250μm. Approximately 2/3 of the cells located within the puffed areas were intensely stained whereas in adjacent inter-puffed areas only 1/4 of the cells were considered reactive. Electron microscopic examination of puffed areas revealed that reactive neurons of the stellate variety usually contained 2-3 times as many mitochondria as did non-reactive cells; their nuclei were often greatly invaginated and their cytoplasm stained more intensely. An occasional reactive pyramidal cell was also observed. Non-reactive cells were smaller with scanty cytoplasm and had few if any symmetrical axo-somatic synapses. Asymmetrical axosomatic synapses were observed thus far only on moderately and highly reactive cells. In non-reactive interpuffed areas, fewer cells were intensely reactive. Dendritic profiles contained 30-40% of the total population of mitochondria within the puffs. Of these, 1/2 were very reactive and 1/3 moderately reactive. Approximately 30% of the total population of mitochondria resided in axon terminals. Of these, 50% were moderately reactive and were found equally in terminals forming symmetrical synapses with flattened vesicles or asymmetrical synapses with round vesicles. 20-30% of axonal mitochondria were intensely reactive and were more prevalent in terminals of the symmetrical type. 30-50% of the mitochondria in myelinated axons were reactive.

These results indicate that cytochrome oxidase activity in reactive puffed areas of the striate cortex is localized within certain neuronal types and primarily within dendritic profiles. Reactive puffed areas also contained at least twice as many metabolically highly active neurons as did adjacent non-puffed regions.

204.8 CYTOCHROME OXIDASE BLOBS IN MONKEY AREA 17: RESPONSE PROPERTIES AND AFFERENT CONNECTIONS. David H. Hubel and Margaret S. Livingstone, Department of Animal Neurobiology, Harvard Medical School, Boston, Massachusetts 02115

Despite forces to the contrary we have managed to extend our studies of cytochrome oxidase blobs in striate cortex of macaque and squirrel monkeys. As reported last year, cells in cytochrome oxidase rich regions of layers II and III (blobs) show poor orientation tuning or none at all. In the macaque the blobs lie in rows centered in the ocular dominance columns.

Not surprisingly, in the macaque, cells in the blobs were strongly monocular, much more so than cells outside the blobs. Cells in any one blob always favored the same eye. In the squirrel monkey, which has poorly defined ocular dominance columns, the blob cells were more binocular.

Some of the blob cells strongly resembled cells in the ventral layers of the lateral geniculate (Wiesel and Hubel, 1966); in particular many had broad band spectral sensitivities, with centers and surrounds differing in their sensitivities to red, and highly sustained responses evoked from the very large receptive field surrounds. Firing tended to occur in rhythmic bursts. Other blob cells were more like dorsal layer cells in showing clear opponent-color responses. We have seen both Type-II cells (no receptive field surround, color-opponent centers) and double-opponent cells (e.g. center: on to long wave lengths, off to short; surround: off to long, on to short). We saw one extraordinary binocular cell, clearly a single unit, with double-opponent properties in each eye but of opposite sign.

After proline injection into the lateral geniculate body, puffs of label were seen in layers II and III, and these puffs coincided with the blobs. This suggests that the blobs have different inputs from non-blob regions but leaves open the question of whether the input is direct from the geniculate or transneuronal via layer IV. After injection into the lateral geniculate of horseradish peroxidase (not wheat-germ conjugated) the blobs were likewise labeled. We understand that ordinary horseradish peroxidase, unless intracellularly injected, is only rarely transported transneuronally (Mesulam, 1982), and therefore suspect that the blobs receive direct geniculate input. Since layers IVA and IVC also stain intensely for cytochrome oxidase it seems that darker cytochrome oxidase staining may correspond to regions with geniculate afferents. Consistent with this is the fact that lesions in the lateral geniculate produce in the cortex patches of pale staining in layers IVA and C and in the blobs.

204.9 THE ORGANIZATION OF CORTICAL MODULES IN PRIMATE STRIATE CORTEX, Roger B. H. Tootell* Martin S. Silverman* Eugene Switkes* and Russell L. De Valois* Dept. Psychology, Univ. Calif. Berkeley, Berkeley, Calif. 94720. (spon: G. H. Jacobs).

The arrangement of orientation and ocular dominance columnar systems into discrete cortical modules has been suggested previously (Hubel and Wiesel, 1977), but evidence for such modules has been sparse. We here present positive 2DG evidence for cortical modules and describe aspects of their internal structure.

We have examined (in the same flat-mounted sections) the location of cytochrome oxidase (CO) spots and the pattern of 14C-2-Deoxyglucose (2DG) uptake produced by various visual parameters. In each visual condition, the topographic relationship between the CO and 2DG patterns in layer III was quantitatively analyzed by computer. The systematic relationship of 2DG patterns (produced by various types of stimuli) to the CO spots allowed us to develop a model of the cortical module. We find that CO spots lie in the center of ocular dominance strips, and at the borders of orientation columns. All our 2DG evidence is consistent with a lack of orientation specificity in the CO spots, relative to interspot regions. We also see clear evidence for a columnar organization related to spatial frequency. In animals which were binocularly shown a high spatial frequency grating at all orientations, 2DG uptake was maximal around the CO spots and minimal on the spots. The converse 2DG pattern was seen in animals which were binocularly shown a low spatial frequency pattern at all orientations. Since these 2DG patterns extended through all cortical layers except layer IVc, this constitutes preliminary evidence for spatial frequency columns in the monkey. Further, orientation columns produced by high spatial frequency stimuli may differ from those produced by multi-frequency stimuli. One animal was shown a horizontally-oriented high spatial frequency grating: this produced a pattern of 2DG strips (except in layer IVc) which run exactly perpendicular to the ocular dominance strips in the same tissue. Another animal shown a multi-spatial frequency pattern at the same orientation showed no such unusual 2DG pattern.

We see, then, a clear mapping of function relative to the CO spots. Suprisingly, we also see an obvious structural correlate of the CO spots. We have found conspicuous spot-like increases in myelination in striate layer III, with the same periodicity as the CO spots. Less apparent myelin-heavy spots can also be seen in layers V and VI. We also see myelin-heavy strips running through the middle layers of V2: these are almost certainly related to the CO strips which we have reported to run through V2 (Tootell and Silverman, Neurosci. Abstr. '81).

204.10 SPATIAL INVARIANCE OF RECEPTIVE FIELD LOCATION IN THE PRESENCE OF EYE MOVEMENTS OF FIXATION FOR NEURONS IN MONKEY STRIATE CORTEX. B. C. Motter* and G. F. Poggio. Dept of Physiology, The Johns Hopkins University, School of Medicine, Baltimore, MD 21205

It is usually assumed that in visual cortex the location in space of a neuron's receptive field has a fixed topographic correspondence to a specific location on the retina. Thus, an accurate definition of the location and spatial organization of cortical receptive fields should take into account the precise position of the eye in relation to the position of the stimulus in the visual field. We have examined the effect of changes in eye position during fixation on the response of neurons in the striate cortex to a moving bar stimulus. The onset time of the response was taken as an indicator of the position of the response field of the neuron. All neurons examined were located within the central 3 degrees of visual field representation. The positions of left and right eyes were measured by an infrared corneal reflex oculometer with a resolution of 2 min-arc. All aspects of stimulus and behavioral control and data collection were under computer control. In our experimental conditions, rhesus monkeys trained to fixate without eye position feedback align their visual axes on the target with a monocular spatial variability of about 8 min-arc (1 SD) in both horizontal and vertical directions. Accordingly, the position of the response field of a cell during fixation should have a minimum variability of about 8 min-arc. Stimuli sweeping through a receptive field at a rate of 2 degrees/sec should therefore evoke responses with an onset variability of about 70 msec (1 SD). Our measurements on a set of cells driven by such stimuli and with a well defined response onset yielded an average variability of 30 msec. Moreover, by directly correlating eye position with response onset we observed that during fixation the cortical neural response to a sweeping stimulus is independent of the actual position of the eye along the axis of stimulus motion. The timing of the neural discharge accurately signals the position of the stimulus relative to the fixation target and does not reflect small changes in eye position. Indeed, changes in the position of the fixation target, or of the stimulus, by as little as 6 min-arc are consistently reflected in changes in the time of occurrence of the neural discharge indicating that neuronal sensitivity for the position of visual objects depends also on a mechanism for the spatial invariance of receptive field position during fixation. These observations suggest that the location of the receptive field of striate neurons remains dynamically stable, representing a region of space which is not displaced to and fro by the small eye movements of fixation.

204.11 ORGANIZATION OF MOVEMENT AND DIRECTION SENSITIVITY IN AREAS 17 AND 18 OF CAT CEREBRAL CORTEX. B. R. Payne and N. Berman. Depts. of Anatomy and Physiology/Biochemistry. The Medical College of Pennsylvania, Philadelphia, PA 19129.

Direction of movement is an important parameter for neurons in areas 17 and 18 of cat cerebral cortex but, unlike cells sensitive to a particular axis of movement (orientation selectivity), the functional architecture of direction sensitive neurons is not clear. An understanding of the organization of direction sensitive neurons in areas 17 and 18 is important because these two regions are responsible for the direction sensitivity of neurons in other cortical and subcortical visual centers. In areas 17 and 18, the magnitude of the difference in preferred direction between two nearby neurons may be either small (close to 0°) or large (close to 180°). Small differences reflect changes in axis-specificity while large differences reflect reversals in preferred direction. In a previous study, we have shown that these two types of changes are organized systematically in the laminar dimension and result in a grouping of neurons preferring similar directions. To investigate the possibility of a radial organization to this grouping we made a series of electrode tracks perpendicular to the cortical surface. Along each track a series of closely spaced isolated neurons was recorded. Electronically controlled stimuli were presented and quantitative methods of data collection were used to determine the range of movement directions of a bar stimulus over which each neuron responded; its preferred axis of movement and its response to movement in the two possible directions along this axis. We found, in agreement with others, that axis of movement is highly organized in the radial dimension. However, the direction sensitivity of neurons along this dimension shows a different but still highly organized pattern. Neurons more sensitive to one of the two possible directions of movement along a movement axis tend to be segregated together in the upper cortical layers. The neurons more sensitive to movement in the opposite direction tend to be located deeper in the same cortical column. This grouping of neurons was occasionally interrupted by cells showing axis specificity with little or no direction sensitivity. These non-directional cells were usually recorded in the middle cortical layers. Therefore, the common direction preferences of cells extends across some but not all cortical laminae, i.e. neurons in the supragranular layers are more sensitive to one direction of movement while neurons in the infragranular layers are more sensitive to the opposite direction. This organization may be related to the rich reciprocal connections between the supragranular and infragranular layers within one cortical column.

204.12 MULTI-MICROELECTRODE RECORDING FROM THE STRIATE CORTEX OF THE CAT, AIMED AT ESTABLISHING SYNCHRONY BETWEEN NEURONS. C. R. Legendy* (SPON: H. G. Vaughan, Jr.). Dept of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Extracellular single-unit recordings were made from the striate cortex of the unanesthetized cat, scanning natural objects in the room. Temporal linkage between spikes of the recorded units was sought by means of a digital computer. Instead of gathering the spikes into a cross correlogram as is done more often in correlation studies, the computer was programmed to detect temporally confined events termed spot correlations. These are epochs characterized by nearly periodic firing by two or more units, lasting usually 2-4 such periods, with all participating units having nearly the same period. Spot correlations are interpreted as manifestations of synchronized ignitions extending over larger neuron pools. Statistical significance is computed from the variance of the nearly-equal interspike intervals and interchannel latencies, and from the rate of pattern recurrences. The latter are defined as temporally close occurrences of patterns having nearly the same period and interchannel latency; e.g., several repetitions in a few minutes.

205.1 REDUCTION OF NEURONAL DEATH BY EMBRYONIC NEUROMUSCULAR BLOCKADE PERSISTS AFTER HATCHING. R. W. Oppenheim. Neuroembryology Lab, Dorothea Dix Hospital, Raleigh NC 27611

Chronic treatment of chick embryos with neuromuscular blocking agents during the period of naturally-occurring death of spinal motoneurons [embryonic (E) day 5 to E10] has previously been shown to result in a virtually total reduction of neuronal death. Embryos retain these "extra" motoneurons as long as the neuromuscular blockade is maintained; once normal embryonic neuromuscular function resumes, however, a delayed cell death occurs. It was of considerable interest to know whether there is a critical period after which neuromuscular blockade is no longer necessary for maintaining the "extra" motoneurons. Because chronic neuromuscular blockade results in impaired pulmonary respiration, treated embryos typically die after hatching (E21).

Recently, however, 4 curare-treated embryos survived hatching and were kept alive for 3-4 days posthatching. Despite being unable to stand and locomote normally (owing to severe ankylosis and muscle atrophy), these chicks were active and moved about by lying on their sides and making vigorous wing flaps and alternating leg movements. This indicates that any residual curare that was present at hatching was rather quickly excreted or metabolized. On the 3rd or 4th day, posthatching, animals were deeply anesthetized and sacrificed by cardiac perfusion with Carnoys fixative. Brachial and lumbar spinal cords with adjacent sensory and sympathetic ganglia were removed, processed for paraffin histology, sectioned (15 μm) and stained with thionin. Select limb muscles were processed for acetylcholinesterase (AChE) histochemistry. Motor, sensory and sympathetic neurons were counted; additional morphometric measurements were also carried out. At present only the lumbar spinal cord has been evaluated. The curare-treated animals had 20,250 ± 1,803 motoneurons in the lateral motor column (LMC) versus 9,660 ± 1,057 for the controls ($p<0.001$). By contrast, there were no differences between curare and control animals in the following measures: number of sensory or sympathetic ganglion neurons; size of LMC, sensory or sympathetic neurons; number of nucleoli in LMC, sensory or sympathetic neurons; length or volume of the lumbar spinal cord. Muscles (AChE) and brachial spinal cords are presently being examined.

It will be necessary to examine animals that survive for considerably longer following chronic neuromuscular blockade in ovo, before one can conclude that the reduction of cell death is permanent. Nonetheless, the present results indicate that 3-4 days of posthatching neuromuscular activity does not result in the loss of the "extra" motoneurons. This differs from the situation in ovo and therefore suggests that these neurons may have passed a critical period after which neuromuscular blockade is no longer necessary for their maintenance.

205.2 ACTIVITY PATTERNS OF CHICK HINDLIMB MUSCLES WITH INAPPROPRIATE INNERVATION. M.J. O'Donovan* and Lynn T. Landmesser. Dept. of Biology, Yale University, New Haven, CT 06511.

We have previously reported that hindlimb flexor and extensor muscles in stage 34-36 chick embryos are activated in an alternating manner during spontaneous or evoked movement sequences in an isolated spinal cord-hindlimb preparation (O'Donovan et al., Neurosci. Abstr. 7:688, 1981). Using this preparation we have now examined the activation patterns of 35 inappropriately innervated hindlimb muscles in 23 embryos, in which one limb had either been shifted anteriorly (3-4 segments) or rotated about the A-P or D-V axis. Surgery was performed at stage 16-18 which is prior to motoneuron outgrowth into the limb bud. In 12 embryos the motoneurons innervating one of the experimental muscles were retrogradely labeled with horseradish peroxidase (HRP), which enabled their identity to be determined from the position of their cell bodies within the spinal cord (Landmesser, L. T., J. Physiol. 284:371, 1978).

Muscle activity was recorded electromyographically during spontaneous or evoked movement sequences in stage 34-38 embryos. In seven cases the recorded activity pattern was opposite (flexor vs extensor) to that normally found for that muscle. In the majority of cases (28) however the abnormally innervated muscles were activated in a functionally appropriate manner.

For 12 muscles (in 12 embryos) the identity of their motoneurons was established using retrograde HRP labeling. In each case the motoneurons were activated according to their original identity rather than the normal function of the muscle they synapsed with.

We conclude that the central connections responsible for generating these movements are not influenced by the motoneuron's peripheral target. The fact that the majority of abnormally innervated muscles behave appropriately appears to reflect a preferential innervation by functionally appropriate motoneurons. This may occur because the rules governing the peripheral projection patterns within the limb may restrict a motoneuron's choice of peripheral target (Lance-Jones, C. and Landmesser, L.T., Proc. R. Soc. Lond. B. 214:19, 1981).

205.3 LOCALIZATION OF CHOLINESTERASE PATCHES IN PARALYZED AND UNINNERVATED SKELETAL MUSCLE DURING IN VIVO DEVELOPMENT. G. S. Sohal, Dept. of Anatomy, Medical College of Georgia, Augusta, GA 30912.

Acetylcholinesterase (AchE) is primarily associated with the basal lamina at the vertebrate neuromuscular junction. The mechanism by which AchE becomes localized in the synaptic cleft during the course of embryonic development is little understood. In vitro studies on rat or chick myotubes suggest that the appearance of AchE patches is dependent on the presence of neurally-evoked muscle contractile activity. However, studies on Xenopus myotubes suggest that accumulation of AchE on muscle membrane may not require neural influences. Because of the conflicting views on the regulation of AchE in birds and mammals on one hand and amphibians on the other hand this problem was reexamined during in vivo development. Duck embryos were paralyzed either presynaptically with botulinum toxin or postsynaptically with curare. Fifteen μ/g botulinum toxin or 2 mg curare in 0.1 cc saline solution was dropped onto the vascularized chorioallantoic membrane twice daily from day 9 onward. Daily motility observations indicated that the embryos were completely paralyzed. In some embryos the superior oblique muscle was made aneural (uninnervated) by permanently destroying the trochlear motor neurons in the midbrain with an electrocautery on embryonic day 7; three days prior to the arrival of motor nerve fibers in the muscle. Embryos were sacrificed on day 17 and the superior oblique muscles were fixed in 4% phosphate-buffered formaldehyde and processed for cholinesterase staining according to the method of Karnovsky. In both paralyzed and aneural muscles patches of AchE were observed on the muscle membrane. In the paralyzed muscle the reaction product was often associated with a region of nerve-muscle contact showing postsynaptic infoldings and densities. In the aneural muscle reaction product was sometimes associated with muscle membrane without any infoldings and at other instances surface invaginations were present. Sometimes AchE patches appeared to coexist with basal-lamina like material. AchE staining was absent when muscles were preincubated with neostigmine or when eserine sulfate was added to the incubation media. These observations suggest that accumulation of AchE in the developing duck muscle is independent of neural influences.
(Supported by grants from NIH and MDA).

205.4 PHYSIOLOGICAL AND NEUROANATOMICAL CHANGES FOLLOWING CHRONIC NEURAL BLOCKADE IN XENOPUS EMBRYOS. Lanny J. Haverkamp. Neurobiology Progr., Univ. N. Carolina, Chapel Hill, NC 27514 and Neuroembryology Lab., Dorthea Dix Hosp., Raleigh, NC 27611.

In an extended and quantified replication of the classic studies of Harrison, Carmichael, et al., we have earlier demonstrated the behavioral effects of drug-induced (chloretone, lidocaine, or α-BTX) immobility on the development of swimming behavior in Xenopus embryos (Haverkamp and Oppenheim.1981. Soc. Neurosci.Abstr.7:181.). After approx. 30 hrs. of drug exposure (during that developmental period when motility normally appears and is refined), experimental animals exhibited quantitative, though not qualitative, abnormalities in swimming behavior when compared to stage-matched control embryos. After this period, which extends from 2-48 hours after removal from the drug (depending upon the drug used), experimental and control animals were behaviorally indistinquishable.

The physiological activity of primary motoneurons was studied in normal and in experimental embryos subjected to the same drug treatment paradigm used in the behavioral studies. Recordings were made from suction electrodes placed bilaterally between the myotomes. Mean values and variability of phase coupling of activity on the two sides as well as burst duration as a percent of period were similar amoung groups at each stage studied. Period length was significantly greater in recovering experimental animals during those stages at which they demonstrate quantitative behavioral deficiencies.

The neuroanatomical effects of neural blockade were studied through comparisons of the lengths and arborizations of primary motoneuron dendrites, retrogradely filled with HRP. Quantifications of dendritic length, thickness, branching, and Scholl analyses indicate that early embryonic exposure to either chloretone or lidocaine results in a distinct decrease in dendritic numbers, length and branching. It appears at this time that the neuroanatomical differences between normal and experimental animals gradually subside after their removal from the drug environment, though definitive statements cannot yet be made due to the wide variability of the increasingly complex dendritic arborizations of single neurons.

Drug-induced blockade of functional activity during a period encompassing the onset of embryonic motility results, therefore, in only transient alterations of motor system development. Although the bases for these disturbances are not yet clear, these studies indicate that early alteration of function does not result in any permanent effects on motor system structure or function.

205.5 NEURONAL PLASTICITY: ITS RELATION TO ELECTROPHORETIC MIGRATION IN RESPONSE TO POSTSYNAPTIC POTENTIAL GRADIENTS. Barry Horwitz. Physics Department, Texas Woman's University, Denton, Texas 76204.

A postsynaptic mechanism for transforming electrical activity at a synapse into structural modifications near the synapse is proposed. The firing of a synapse produces a postsynaptic potential (PSP) which is attenuated as it spreads electrotonically into other parts of the neuron. The potential difference so generated gives rise to an intraneuronal electric field, and permits the electrophoretic migration of charged metabolites, both along the inner surface of the fluid membrane and in the cytoplasm. It was demonstrated by Poo (Ann. Rev. Biophys. Bioeng. 10: 245-276, 1981) that, when placed in an external electric field, both concanavalin A and acetylcholine receptors within approximately 15 minutes accumulate toward the cathodal site of cultured myotubes, 30 μm in diameter. The field strengths used were 1-10 V/cm. We will show that the internal electric fields generated by PSPs can be of comparable magnitude. Therefore, we suggest that these fields can play a significant role in locally organizing the distribution of charged species, thus allowing differential biochemical activity at different synaptic locations. Three diverse sets of experimental observations are used to illustrate the electrophoretic effect. They are (1) the relationship between the number of preganglionic axons innervating ciliary ganglion neurons, and the number of major dendrites possessed by the ganglion neurons (Purves and Hume, J. Neurosci. 1: 441-452, 1981); calcium action potentials in growth cones (Grinvald and Farber, Science 212: 1164-1167, 1981); and, membrane heterogeneity in myelinated axons (e.g., Waxman, Trends in Neurosci. 4: 7-9, 1981).

(Supported, in part, by TWU Institutional Grant 29069)

205.6 APPORTIONMENT OF AXON TERMINALS TO TARGET NEURONS IN A MAMMALIAN AUTONOMIC GANGLION. Richard I. Hume and Dale Purves. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

The apparently competitive process by which patterns of innervation are established during development is not well understood. A major obstacle has been the difficulty of assessing the way in which individual axons branch within a target structure and apportion their terminals on the surfaces of particular neurons. We report here a study of these aspects of innervation in a simple neuronal system, the ciliary ganglion of adult rabbits.

Electrical recording and intracellular staining of individual preganglionic axons with horseradish peroxidase (HRP) showed that each axon innervates only about 10-20 of the approximately 400 ganglion cells. In whole mounts, neurons whose cell bodies were enveloped by HRP-labeled boutons from a single axon were surrounded by other somata which appeared to receive no contacts from the labeled axon. Electron microscopical examination of labeled presynaptic terminals on individual ganglion cells confirmed that the boutons of single axons were sharply confined to particular target neurons. Labeled terminals on individual postsynaptic profiles (either cell bodies or dendrites) were not usually mixed with unlabeled endings. Thus the terminals of a labeled axon appeared to be relatively segregated from the terminals of other axons on the surface of individual postsynaptic cells.

Component steps in the synaptic responses of multiply innervated ganglion cells were usually smaller than synaptic potentials in singly innervated neurons; thus an axon probably makes fewer boutons on each of the neurons it shares than on neurons that it captures completely. Moreover, neurons innervated by several different axons tended to have fewer synapses on their somata than neurons innervated by only one or two preganglionic axons.

Taken together, these findings suggest that the correlation between the dendritic geometry of ganglion cells and the number of different axons that innervate them (Purves & Hume, 1981) arises from a reduction in the competition between axons innervating the same cell, perhaps as a result of terminal segregation on dendritic arbors.

205.7 NEURONAL GEOMETRY, REFLEX FUNCTION, AND ACTIVITY PATTERNS OF RABBIT CILIARY GANGLION CELLS. David A. Johnson and Dale Purves. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

Evaluation of the suggestion that dendritic geometry modulates competition between axons innervating the same target cell (see Hume and Purves, 1981 and preceding abstract) requires considerable additional information about the neurons involved. In the work reported here we asked how the geometry of individual ciliary ganglion cells is related to their reflex function and to neuronal activity.

Of three hundred ganglion cells impaled with microelectrodes in anesthetized rabbits, nearly all (293) showed tonic synaptic input from preganglionic axons, even in darkness. Two hundred and eighty-one of the neurons studied showed a change in this synaptic drive upon retinal illumination. The majority of ganglion cells (86%) increased their rate of discharge in response to illumination of the ipsilateral retina; many cells, however, were inhibited by retinal illumination (41%), usually of the contralateral retina. Some of the cells that were inhibited by illumination of one eye were also excited by illumination of the other eye.

Fifty neurons whose reflex behavior to light had been characterized were subsequently stained with horseradish peroxidase. There was no obvious correlation between the reflex response of cells to retinal illumination and their dendritic geometry. Thus neurons with similar reflex properties included cells lacking dendrites altogether as well as cells with complex dendritic arborizations; conversely, neurons with similar geometries often had different reflex characteristics.

With respect to temporal patterns of synaptic activity, the frequency of tonic (and reflex) activity tended to increase in proportion to the the degree of multiple innervation. However, different inputs to a multiply innervated cell fired without apparent relationship to one another.

These findings show that the range of dendritic geometry and number of inputs previously observed in this ganglion (Purves and Hume, 1981) is not incidental to the presence of neurons with different reflex behaviors in the ganglion. Neither can the persistent multiple innervation of some ganglion cells be explained by synchronous activity of their several inputs. On the other hand, these observations are consistent with the idea that dendrites regulate convergence by modulating competition between axons innervating the same neuron.

205.8 OPTIC NERVE SECTION DELAYS SYNAPTIC RE-ARRANGEMENT IN NEONATAL RABBIT CILIARY GANGLIA, Patrick C. Jackson.† Dept. Physiol. & Biophys., Washington Univ., St. Louis, Mo 63110.

During the first weeks of normal post-natal development there is a marked reduction, without cell death, in the number of preganglionic axons innervating individual rabbit ciliary ganglion cells (Johnson & Purves, 1981). Thus, at birth virtually all cells are innervated by more than one axon (on average ≈5/cell) whereas by four weeks of age 25-35% of the cells are innervated by only one axon.

Light entering the eye after about 10 days of age (just prior to eye opening) normally causes a reflexive contraction of the ipsilateral iris sphincter which receives motor innervation from ciliary ganglion cells. To test whether neuronal activity plays a role in the elimination of preganglionic inputs, ganglionic activity was altered by severing one or both optic nerves intracranially in newborn rabbits; since the rabbit shows little consensual light response, unilateral optic nerve section should reduce substantially light-induced neuronal activity in the ipsilateral ganglion.

The number of preganglionic axons innervating individual ciliary neurons was determined in vitro by counting the increments in the recorded response of ganglion cells impaled with microelectrodes 2-32 wks after optic nerve section. Cutting one optic nerve at birth delayed, but did not prevent, the usual reduction of polyneuronal innervation in the ipsilateral ciliary ganglion; no such delay was evident in the contralateral ganglion. Animals subjected to bilateral nerve section showed a delay in the elimination of preganglionic inputs similar to that produced by unilateral nerve section.

Age	Number of Inputs (Mean ± SEM) n > 100 cells/group		
	Normal	Optic Nerve Cut	
		Contralateral	Ipsilateral
birth	4.6 ± 0.1		
2 weeks	3.3 ± 0.1	3.3 ± 0.1	3.8 ± 0.1
4 weeks	2.3 ± 0.1	2.3 ± 0.1	3.4 ± 0.1
8 weeks	2.4 ± 0.1	2.5 ± 0.1	2.5 ± 0.1

Evidently the time course, but not the final outcome, of input elimination is influenced by the level of activity through this developing reflex circuit.

Johnson, D.A. & Purves, D. (1981). J. Physiol. 318: 143-160.

205.9 MEMBRANE POTENTIAL AND THE REGULATION OF ACETYLCHOLINE RECEPTOR SYNTHESIS IN EMBRYONIC CHICK MUSCLE CELLS. B. H. Shieh*, L. Pezzementi and J. Schmidt. Dept. of Biochemistry, State Univ. at N.Y. at Stony Brook, Stony Brook, N. Y. 11794.

The effect of elevated extracellular potassium on acetylcholine receptor synthesis was studied in chick embryonic muscle cultures. Receptor synthesis was measured by assaying appearance of -bungarotoxin binding activity over a 24-hr period. At physiological ionic strength, potassium chloride, in the 3.3 mM to 50mM range, gave rise to a complex dose-response curve whose prominent features are a considerable reduction of receptor appearance rate at 20 mM and a more than 2 fold increase at higher concentrations. The effect of potassium chloride on receptor synthesis appeared to be fairly specific: neither was there a duplication of its effect by other electrolytes or solutes, nor did it alter total protein synthesis or receptor stability by more than 30% at any concentration tested; cellular acetylcholinesterase levels actually declined with increasing KCl concentrations. In order to explore the mechanism of the potassium effect, tetrodotoxin (10^{-6}M), veratridine (3 X 10^{-6}M), D-600 (1.6 X 10^{-5}M), and ryanodine (3 X 10^{-7}M) were tested in the presence of various concentrations of potassium. Sodium channel toxins as well as calcium effectors modified the potassium response. Based on these findings we propose that the effects of potassium are due to (a) cessation of spontaneous muscle activity upon raising KCl from 3 to 10 mM; (b) depolarization of the muscle membrane and persistent activation of a calcium channel as concentration is raised from 10 mM to 20 mM; (c) finally, inactivation or desensitization of the calcium channel, or some other signaling element proximal to the sarcoplasmic reticulum, upon further depolarization.

205.10 DISTRIBUTION OF ACETYLCHOLINE RECEPTORS AND SYNAPTIC BASAL LAMINA PROTEOGLYCAN IN NORMAL AND DENERVATED XENOPUS SARTORIUS MUSCLE. Diana Card Linden and M. J. Anderson*. UCLA School of Medicine, Department of Physiology, Los Angeles, CA 90024 and Carnegie Institution of Washington, Baltimore, MD 21210.

Xenopus sartorius muscles were reacted with fluorescein labeled monoclonal antibodies specific for synaptic basal lamina proteoglycan (SBL-antibody) and tetramethylrhodamine labeled α-bungarotoxin (R-αBGT). In all normal and contralateral control muscles dense localized accumulations of basal lamina proteoglycan were coincident with clusters of junctional acetylcholine (ACh) receptors, revealed by the R-αBGT staining. These proteoglycan accumulations commonly extended laterally beyond the subneural aggregates of junctional ACh receptors and sometimes were observed extending beyond the distal extent of organized ACh receptor staining in tips of terminal branches. In occasional examples, an entire terminal branch stained with SBL-antibody, but was devoid of ACh receptor clusters. Extrajunctional SBL-antibody staining was diffuse and of lower intensity than that at the neuromuscular junction, and frequently appeared to be organized into fine radially distributed fibrils.

After 3-4 weeks of denervation many endplates showed normal patterns of both SBL-antibody and R-αBGT staining. However, in some cases, diffuse perijunctional ACh receptor clusters were observed and these were commonly associated with similar regions of increased SBL-antibody staining. After 5 weeks denervation, dense ACh receptor accumulations were present in endplate-free regions of muscle fibers, and these also were usually associated with plaques of increased SBL-antibody staining. By this time most junctional ACh receptor clusters were notably disorganized, with extensive diffuse perijunctional ACh receptor staining, associated in most cases with corresponding accumulations of SBL-antibody. However, within individual junctions some well-defined bands of normal SBL-antibody and ACh receptor stain still remained.

On the basis of these observations we conclude that the organization of ACh receptor and basal lamina proteoglycan are under coordinate regulation by the motor neuron in adult muscle fibers. This research was funded by an NRSA Award #NS-07101 to DCL.

205.11 NORMAL SENSITIVITY TO ACh OF INACTIVE BUT INNERVATED MUSCLES. E. J. Muñoz-Martínez, L. Colín-Barenque* and J. Cueva*. Depto. Fisiología y Biofísica, CINVESTAV, Apartado Postal 14-740, 07000 México, D.F. MEXICO.

The present experiments were designed in an attempt to clarify whether or not the ACh-supersensitivity of denervated muscle fibres results from the lack of muscle activity.

Sensitivity to ACh was studied in the denervated as well as in the innervated but inactive rat soleus muscle. Motor inactivation was produced by spinal cord section; unilateral section of the sciatic nerve was also performed in the spinalized rats. The inactivity of the innervated muscle was assesed by chronic electromyography.

Three to five days after the surgical procedures both the denervated and the innervated soleus muscles of spinalized rats showed comparable atrophy. The denervated soleus showed dose-dependant ACh contractures, extrajunctional depolarizations to iontophoretically applied ACh and an increase in the binding of ^{3}H-α-bungarotoxin. The contralateral, inactive but innervated soleus showed no ACh contractures and the ACh sensitivity was restricted to the end-plate. A small increase in toxin binding per mg of dry tissue was detected in these muscles but there was no increase when the binding was corrected for muscle atrophy.

To exclude the possibility that small levels of undetected muscle activity could have prevented the development of ACh-supersensitivity in the innervated soleus of spinal rats, some denervated muscles were chronically stimulated at 0.05/sec for 4 days. The increase in toxin binding induced by denervation was not changed by the stimulation even though the muscle atrophy was less pronounced than in the contralateral, innervated soleus, suggesting that the denervated and stimulated soleus was more active than the inactive, innervated ones.

It is concluded that the lack of muscle activity does not play a significant role in the induction of denervation supersensitivity.

205.12 ABRUPT SUPPRESSION OF ACETYLCHOLINESTERASE PRODUCTION IN DENERVATED RAT DIAPHRAGM. S. Brimijoin, J. A. Edwards. Department of Pharmacology, Mayo Clinic, Rochester, Minn. 55905.

Previous work in this laboratory has shown that the 4S (monomeric) form of acetylcholinesterase (AChE) has a much faster apparent turnover than do the other forms of this enzyme in rat diaphragm (Brimijoin and Carter, J. Neurochem. 38: 588, 1982). 4S AChE is also the first form to decrease in activity when diaphragm is denervated (Carter and Brimijoin, J. Neurochem. 36:1018, 1981). We now report evidence that the production of AChE monomer by rat diaphragm is drastically curtailed within 1 hr of denervation.

The left hemidiaphragms of 8 Sprague-Dawley rats (200-250g) were denervated by intrathoracic transection of the phrenic nerve (stump length, 5 mm). After 8 hr the animals were exsanguinated by perfusion with 0.9% NaCl and the muscles of these and of 5 unoperated control rats were removed and homogenized (in 50 mM Tris HCl, pH 7.4, 1M NaCl, 1% Triton X-100, 0.2 mM EDTA). Samples were spun at 10,000 g for 10 min. The supernatants were then fractionated on 5 ml linear sucrose density gradients (5-20%) by ultracentrifugation (120,000 g for 16 hr).

As determined by a radiometric assay for enzyme activity, roughly equivalent amounts of the 3 major forms of AChE were resolved (ie, 4S, 10S, and 16S enzyme). Of the forms, 10S AChE showed the same activity in denervated and control diaphragms (2.2 ± 0.1 and 2.2 ± 0.3 units, respectively); 16S AChE activity rose nonsignificantly after denervation (to 2.0 ± 0.1 from 1.5 ± 0.2 units); and 4S AChE activity fell by 40% (to 1.2 ± 0.1 from 2.0 ± 0.1 units, $p < 0.001$). Exactly the same amount of 4S AChE activity was lost in 5 left hemidiaphragms incubated in vitro in oxygenated physiological salt solution for the same duration (final value, 1.2 ± 0.1 units).

To test whether the loss of monomeric AChE after denervation reflected reduced production or increased degradation of enzyme, animals were treated with the protein synthesis inhibitor, cycloheximide (20 mg/kg, s.c., every 4 hr). In innervated diaphragms the activity of 4S AChE fell to 0.8 units after 8 hr of treatment with cycloheximide. In diaphragms denervated at the onset of treatment the activity fell to 1.2 ± 0.1 units. This result implies that the halflife of monomer was even longer in the denervated muscle (10.8 hr) than in the innervated muscle (6 hr). Therefore, loss of monomer after denervation stems from reduction in synthesis only. With an 11 hr halflife it would take a full 8 hr for denervated muscles to lose 0.8 units of monomer, even with zero synthesis. Therefore the effect of denervation on the production of 4S AChE must begin almost at once.

206.1 IMPACT OF FOOD DEPRIVATION ON HYPOTHALAMIC α-ADRENERGIC RECEPTOR ACTIVITY AND NOREPINEPHRINE (NE) TURNOVER IN RAT BRAIN. M. Jhanwar-Uniyal*, F. Fleischer*, B.E. Levin and S.F. Leibowitz (SPON: N.E. Miller). Rockefeller Univ., New York, NY 10021 and Dept. Neurosci., N.J. Medical School, Newark, NJ 07103.

Catecholamine (CA) agonists alter feeding behavior when injected directly into specific hypothalamic areas. The medial paraventricular nucleus (PVN) has been identified as the most responsive brain area to NE, which stimulates food intake through α-adrenergic receptors. In contrast, the lateral perifornical area (PFH) is particularly responsive to dopamine and epinephrine, which suppress food intake through dopaminergic and β-adrenergic receptors. The present study examined the impact of food deprivation and subsequent feeding on α-adrenergic receptor binding in 15 discrete hypothalamic and extra-hypothalamic areas. The impact of deprivation on NE turnover was also examined.

Male albino rats, on a 12:12 light-dark cycle, were exposed to 5 different time intervals of food deprivation and sacrificed (at 5:00 A.M.) one hr prior to onset of light. The rats were deprived of food (water was provided ad lib) for either 0 hrs (N=5), 6 hrs (N=3), 12 hrs (N=3), 24 hrs (N=3), or 48 hrs (N=5), with an additional group (N=4) deprived for 42 hrs and then permitted to eat for the next 6 hrs. The rats were sacrificed by decapitation, and discrete brain areas were microdissected. Standard radioligand binding procedures were employed, with the antagonist ^{3}[H]WB-4101 (1.0 nM) used to label α-adrenergic receptors. The microenzymatic assay (Levin et al., 1980) was used to measure NE turnover in 4 brain areas of 7 satiated and 7 48-hr food-deprived rats injected with α-methyl-p-tyrosine.

The results demonstrate that: 1) of 15 brain areas examined, only two areas, namely the PVN and PFH, exhibit any change in α-adrenergic receptor binding in response to food deprivation. 2) The PVN showed a large decrease in specific ^{3}[H]WB-4101 binding after 12, 24 and 48 hrs deprivation. (For example, after 48 hrs binding in satiated rats, 314.3 fmoles/mg protein, decreased by 84% to 49.6 fmoles/mg protein ($p<.001$) in deprived rats.) 3) The PFH showed a large increase in specific ^{3}[H]WB-4101 binding after 12, 24 and 48 hrs deprivation. (After deprivation, binding increased from 123.1 fmoles/mg protein in satiated rats to 363.8 fmoles/mg protein ($p<.01$) in deprived rats.) 4) After 48 hrs deprivation, a significant increase ($p<.025$) in NE turnover was observed in the PVN, with no change occurring in the PFH, ventromedial and dorsomedial nuclei. 5) In rats permitted to eat for 6 hrs after 42 hrs of deprivation, the down-regulation of PVN α-adrenergic receptors was significantly attenuated. These results indicate that food deprivation produces dramatic and site-specific effects on α-adrenergic receptors and NE turnover in the hypothalamus. (This study was supported by MH 22879.)

206.2 EFFECT OF CENTRALLY ADMINISTERED NEUROTENSIN ON MULTIPLE FEEDING PARADIGMS. A.S. Levine, J. Kneip*, M. Grace* and J.E. Morley. Neuroendocrine Research Laboratory, VA Medical Center, Minneapolis, Minnesota, 55417 and the Departments of Food Science and Nutrition and Medicine, University of Minnesota, St. Paul-Minneapolis, Minnesota.

The tridecapeptide, neurotensin, produces a variety of effects when administered into the central nervous system, including a decrease in body temperature, locomotor activity and pain thresholds. Recently, it has been reported that intraperitoneal administration of neurotensin suppressed food intake in 3 hr food deprived rats. We have previously postulated that dopamine and the endogenous opiates act as a tonic signal for the induction of feeding, being held in check by monoamines and neuropeptides (Life Sci. 27:355, 1980). The present study was undertaken to examine the effect of neurotensin on multiple paradigms known to stimulate feeding. Following a 30 hour starvation period, neurotensin suppressed feeding at the 20 µg (1.5±0.2 g/30 min, $p<0.01$), 10 µg (1.6±0.6 g/30 min, $p<0.25$) but not at the 1 µg (1.8±0.6 g/30 min) dose when compared with saline controls (2.6±0.3 g/30 min). Norepinephrine (20 µg ICV) induced feeding (1.7±0.2 g/30 min) was suppressed at the 20 µg neurotensin dose (0.9±0.2 g/30 min, $p<0.01$) but not at the 10 µg (1.2±0.3 g/30 min), or 1 µg (1.3±0.2 g/30 min) dose. In contrast, neurotensin did not suppress muscimol (the gamma amino butyric acid agonist) (500 ng ICV) induced feeding (2.9±0.5 g/30 min) at the 20 µg (2.0±0.5 g/30 min), 10 µg (2.0±0.4 g/30 min) or the 1 µg (3.2±0.7 g/30 min) dose. Insulin induced feeding (10 units) (3.6±0.3 g/3 hrs) also was not suppressed by neurotensin at the 20 µg (4.3±0.5 g/3 hrs), 10 µg (2.6 ±0.5 g/3 hrs), or 1 µg dose (3.6±0.4 g/3 hrs). Dynorphin, the putative endogenous opiate kappa agonist, induced feeding (1.8± 0.3 g/hr) when administered ICV (10 µg). Neurotensin suppressed dynorphin induced feeding at the 20 µg (0.9±0.2 g/hr, $p<0.05$) and 10 µg (0.9±0.2 g/hr, $p<0.05$), but not at the 1 µg dose (1.3±0.4 g/hr). Recently it has been shown that several anorectic peptides, including CCK and somatostatin, suppress feeding via the vagus. In the present study, subdiaphragmatic vagotomized rats were given ICV neurotensin (20 µg) or vehicle at 2000 hrs and food intake was measured for the ensuing 2 hours. Neurotensin suppressed spontaneous feeding ($p<0.01$) in vagotomized rats (2.5±0.3 g/2 hrs) when compared with saline controls (4.2±0.5 g/2 hrs) suggesting that an intact vagus is not necessary for neurotensin's anorectic effect. Thus, neurotensin suppressed feeding initiated by food deprivation, norepinephrine and dynorphin but not that initiated by muscimol or insulin. We conclude that neurotensin may play a role in short-term appetite regulation by a complex interaction with monoamines and neuropeptides, particularly norepinephrine and the kappa opiate agonist, dynorphin.

206.3 CONTINUOUS AND PHASIC INFUSION OF NOREPINEPHRINE (NE) INTO THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN) INCREASES DAILY FOOD INTAKE AND BODY WEIGHT IN RAT. Sarah F. Leibowitz, Constantin Marinescu* and Saul S. Lichtenstein*, Rockefeller Univ., NY 10021.

Previous studies have demonstrated that a single manual injection of NE directly into the PVN will elicit a feeding response in satiated rats. Multiple manual injections of NE throughout the day (4 injections over 7 daytime hours) are effective in potentiating eating at each time of injection and consequently increasing total daily food intake (Roossin, Rosenn and Leibowitz, 1980). The present study examined the impact on ad lib feeding of chronic remote infusions (continuous and phasic) of NE into the PVN.

Male albino rats (350-400g) were chronically implanted with a Khavari cannula-swivel assembly aimed at the PVN. They were tested in an open-top chamber, which permitted their cannula-swivel to be connected to the injector needle and polyethylene tubing arrangement attached to a Hamilton gas-tight microsyringe (see Myers, 1977). After a few days of adaptation to the testing procedure, the experiment, which lasted 20 days, was initiated. The protocol consisted of two 10-day sequences, during which time the rats were infused, in counterbalanced order, with either 0.04% ascorbic acid in saline or NE dissolved in ascorbic acid (12 nmoles/1.0 µl/hr). For some rats (N=6), this infusion, of NE or vehicle, was given continuously throughout the 10-day sequences, whereas for other rats (N=6), the infusion was phasic, with a 0.5 µl injection occurring at 30-min intervals. The rats were maintained on an ad lib feeding schedule, and food intake (lab chow powder + milk) and body weight measurements were taken daily.

The results indicate that chronic noradrenergic stimulation of the PVN is effective in modulating total daily food intake and body weight. With the ascorbic acid infusion, the rats' daily food intake was 29.1±3.6g with continuous infusion and 32.8±2.4g with phasic infusion. With infusion of NE, daily food intake was increased by 11.3% ($p<.05$) with continuous infusion and by 14.9% ($p<.01$) with phasic infusion. This potentiation of eating was observed consistently throughout the entire 10-day sequence. Body weight was similarly increased by NE. Under ascorbic acid conditions, the rats' baseline rate of weight gain ranged from 1.2 to 1.6g/day. This increased, by approximately 100% ($p<.05$), to 2.9g/day with continuous NE infusion and to 3.2g/day with phasic NE infusion. Over the course of the 10-day NE sequence, the rats gained approximately 10% of their original body weight, compared with 3-5% under ascorbic acid conditions.

These results, along with preliminary data obtained with chronic PVN infusion of a catecholamine synthesis inhibitor, indicate that the α-noradrenergic system of the PVN is effective in altering long-term feeding patterns and body weight gain. (This research was supported by grant MH 22879.)

206.4 EVIDENCE THAT THE KAPPA OPIATE RECEPTOR IS INVOLVED IN THE INITIATION OF FEEDING. J.E. Morley, A.S. Levine, M. Grace* and J. Kneip*. Neuroendocrine Research Laboratory, Minneapolis VA Medical Center, Minneapolis, Minnesota, 55417 and the Departments of Medicine and Food Science and Nutrition, University of Minnesota, Minneapolis-St. Paul, Minnesota.

A large body of evidence has suggested a role for the endogenous opiates and their receptors in the regulation of appetite. Recently we have shown that dynorphin, the putative kappa agonist, produces feeding in rats (Life Sci. 18:1901, 1981). In this study we have examined the relative effects of ketocyclazocine (KC), cyclazocine, and ethylketocyclazocine, all kappa agonists, butorphanol, a kappa-sigma agonist, and morphine and morphiceptin, mu receptor agonists, on food consumption. All kappa agonists induced feeding when administered at 0800 h as did morphine (F 5.72; $p < 0.005$). Kappa agonists induced feeding within 2 hours whereas morphine took 3-4 hours to induce feeding. KC failed to induce feeding during the nocturnal feeding period (2000 and 0200 hours) and morphine suppressed feeding at these times. KC enhanced feeding at 1400 h, whereas morphine suppressed it. KC and morphine suppressed 24 h starvation induced feeding when food was made available immediately after injection and had no effect when food was presented 2 and 4 hours after injection. High doses of naloxone (5 mg/kg) suppressed KC (10 mg/kg) induced feeding while actually enhancing high dose morphine (25 mg/kg) induced feeding. Repeated daily injections of KC or morphine for 5 days resulted in an enhancement of the feeding response with initiation of feeding occurring earlier. The kappa-sigma agonist, butorphanol, markedly enhances feeding in rats at doses ten times lower than those required by morphine to initiate feeding. This butorphanol effect on feeding is highly resistant to naloxone's suppressive effect (doses up to 10 mg/kg). β-casomorphin, 10 µg to 75 µg ICV, failed to induce feeding whereas dynorphin, 10 µg ICV, was a potent inducer of feeding. The most parsimonous interpretation of these studies is that kappa agonists are endogenous initiators of feeding. The kappa receptors are maximally saturated at times of food deprivation and during spontaneous nocturnal feeding. The mu opiate receptors inhibit feeding due to their sedative effect and antagonism of this effect leads to enhancement of the feeding response. It is postulated that kappa opiate receptors represent an important component of the natural feeding drive.

206.5 NALOXONE AND NALTREXONE CHANGE FOOD SELECTION IN HUNGRY RATS UNDER CONDITIONS OF FAMILIARITY. S. Turkish* and S.J. Cooper* (SPON. B.J. Sahakian). Dept. of Psychol., Univ. of Birmingham, Birmingham B15 2TT, U.K.

Considerable evidence affirms that opiate antagonists, naloxone (NAL) and naltrexone (NALT), attenuate food intake in many species (Sanger, D.J., Appetite, 2: 193, 1981). Much less attention has been paid to their effects on food selection. In our model, both NAL and NALT markedly affected the choice between two foods in hungry rats, provided they were tested under conditions of familiarity. Both drugs acted selectively to reduce the palatability of the more preferred food, so that the food selection was diverted towards the less preferred food. Adult, male, hooded rats were given 15 min access to two foods: chocolate-coated cookies (Cadbury's), and Diet 41B food pellets. The pellets were familiar as the home cage diet. Food intake and the duration of feeding were recorded for each food, as well as a variety of non-feeding behaviors. Each subject was tested under one of 4 conditions:- 24h food-deprived + test familiarity, including the cookies as familiar food (DEP-FAM); food-deprived + test novelty, including the cookies as novel food (DEP-NOV); non-deprived + familiarity (NDEP-FAM); non-deprived + novelty (NDEP-NOV). Under the DEP-NOV condition, control rats showed a definite selection in favor of the food pellets. NAL (0.5 and 2 mg/kg, s.c.) did not alter this choice. However, under the DEP-FAM condition, control rats showed an exclusive choice of the highly palatable cookies, and ignored the food pellets altogether. Both NAL and NALT (0.5 and 2 mg/kg in each case) significantly reversed this food selection which was related to palatability (significant drug x food choice interactions, $p < 0.001$, in each case). Whilst both drugs reduced the intake and feeding duration for the palatable cookies, they increased the intake and feeding duration of the food pellets. In effect, the strong preference for the more palatable food evident in control rats tested under conditions of familiarity was sharply attenuated by NAL or NALT treatment. The opiate antagonists did not impair preference behavior or food discrimination per se, since the food selection in the DEP-NOV condition was not altered. No significant effect of NAL on feeding behavior was observed under either NDEP condition. However, NOV induced excessive grooming under both DEP and NDEP conditions. This grooming was significantly attenuated by NAL treatment. The reduction in novelty-induced grooming appeared to be independent of NAL's effect on feeding selection which was manifest under conditions of familiarity. Opiate antagonists may therefore exert separable effects on food selection and on behavioral responses elicited by novelty.

206.6 GLUCOPRIVATION-INDUCED RELEASE OF BRAIN NEUROTRANSMITTERS. J. O'Fallon and S. Ritter. Dept. of Animal Science and College of Veterinary Medicine, Washington State University, Pullman, Wa 99164.

Both in vivo and in vitro studies have demonstrated that norepinephrine (NE) release is increased in various brain regions during glucoprivation. Since increased feeding also occurs during glucoprivation, it has been suggested that a causal relationship may exist between the increased release of NE and the appearance of feeding behavior. However, we recently showed that the rate of NE release from hypothalamic neurons in vivo indeed reflects their supply of utilizable energy substrate (i.e., β-hydroxybutyrate or glucose), but that NE release and feeding behavior were dissociable under a number of circumstances. This suggests that increased NE release during glucoprivation might be an epiphenomenon, not causally related to the feeding response. If so, one might expect glucoprivation to alter release of other neurotransmitters which have thus far not been implicated in glucoprivic feeding. In order to test this hypothesis, we measured the effects of in vitro glucoprivation on release of tritiated putative neurotransmitters from brain tissue prisms. Mouse brains were dissected and prisms from cortex, cerebellum, hypothalamus, midbrain and pons-medulla were preincubated for 20 min in a buffer containing an appropriate inhibitor of transmitter degradation. Tissues were then incubated for 20 min with a tritium-labelled transmitter (NE, dopamine, serotonin, gaba-aminobutyric acid, β-alanine, D-aspartate or choline), and subsequently washed prior to transfer to superfusion chambers. In the chambers, the prisms were superfused with buffer solution containing glucose concentrations between 0 and 5 mM. Aliquots of the superfusate were collected over a 45 min period and counted. We found that in the absence of depolarizing agents, spontaneous release of most neurotransmitters was enhanced in the presence of low glucose concentrations. Aspartate was a notable exception. The magnitude of the effect varied across transmitters and the magnitude for a given transmitter was dependent upon brain region. Thus, our preliminary findings suggest that NE neurons may not be unique in their response to glucoprivation. In addition, our results indicate that glucose availability may significantly influence brain neurotransmission.

206.7 BRAIN DA-DEPLETION BLOCKADE OF HYPOTHALAMIC OBESITY DOES NOT OCCUR WITH SIMULTANEOUS BRAIN NE DEPLETION. D.V. Coscina, J.N. Nobrega, and J.J. Warsh. Sections of Biopsychology and Biochemical Psychiatry, Clarke Institute of Psychiatry, University of Toronto, Toronto, Ontario, Canada, M5T 1R8.

Past research has shown that damaging brain dopamine (DA) neurons by central injection 6-hydroxydopamine (6OHDA) disrupts many behaviors including feeding. However, conflicting reports exist over the ability of such 6OHDA treatment to block the over-eating and obesity which follow medial hypothalamic lesions (MHL). To address this issue, we injected groups of 6 adult female rats intracisternally once weekly for 3 consecutive weeks as follows: (1) 200 µg 6OHDA in 1% ascorbic acid vehicle 1 hr after 30 mg/kg desipramine (DMI) i.p.; (2) 240 µg 6OHDA in vehicle 1 hr after 50 mg/kg pargyline (PAR) i.p. (pretreatment on week 1 only); (3) vehicle after DMI as in (1); (4) vehicle after PAR as in (2). An additional 6 rats received no treatment (normal controls). Following 4 weeks of body weight and food intake measurements, all 4 injected groups received bilateral radiofrequency MHL. Body weights and food intakes were measured for an additional 5 weeks before sacrificing all rats for striatal and neocortical assays of endogenous DA, norepinephrine (NE) and serotonin (5HT) content. Compared to normal controls, MHL produced equivalent obesity (360-385% greater weight gain) in all groups except DMI-6OHDA rats (67% less gain than normals). Regardless of pretreatment, 6OHDA produced equivalent depletions of striatal (84-91%) and cortical (70-78%) DA without affecting 5HT. However, the DMI-6OHDA rats, who displayed no obesity after MHL, possessed normal levels of cortical NE. This contrasted with the PAR-6OHDA rats, who were obese after MHL, and possessed 72% depletion of cortical NE. MHL after either pretreatment plus vehicle was without long-term effect on striatal or cortical DA, NE and 5HT. Our findings show that selective depletion of brain DA is indeed capable of blocking the development of overeating and obesity after MHL. However, simultaneous depletion of brain DA and NE to comparable degrees produces no such blockade. These results resolve conflicting reports about the ability of central 6OHDA to block MHL obesity by showing that such blockade occurs only when brain DA depletion substantially exceeds that of brain NE. Such findings support previous suggestions of an important balance between brain DA and NE systems in the control of several behaviors. (Supported in part by MRC grant MA-6579 to D.V.C.).

206.8 THE EFFECTS OF BIOGENIC AMINES, VASOPRESSIN AND HYPERTONIC SALINE ON BLOOD PRESSURE AND DRINKING AT THE SUBFORNICAL ORGAN (SFO). J.B. Simpson and A. Josefiak*, Dept Psych., Univ. Washington 98195

The SFO is a circumventricular organ of the third ventricle which functions in fluid balance. Injections in rats of angiotensin II (AII) or cholinergic agonists there provoke correlated increases in water intake and blood pressure (Mangiapane and Simpson, AJP, 1980, 1982). We investigated neurochemicals which are endogenous to the SFO for effects on drinking and blood pressure.

Male, Long-Evans rats each received a single intracranial cannula for injection of one compound in a 0.5 ul volume into the central zone of the SFO. A chronic aortic catheter was used to monitor blood pressure in the conscious, unrestrained rodents.

Injection of the catecholamines, norepinephrine and dopamine, into SFO did not increase drinking and did not alter blood pressure. Prior injection of these amines did not affect the dipsogenic or pressor effects of AII at the SFO. In contrast, injection of serotonin (5-HT) provoked dose-dependent increases in aortic pressure and drinking. Onset of the pressor response always preceded the onset of drinking, both occurring within 1 min.

The peptide vasopressin (AVP),also endogenous to the SFO, was injected into another group of rats and, like 5-HT, produced dose-dependent increases in blood pressure and drinking. The pressor and dipsogenic effects of 5-HT and AVP, in terms of latencies and elicited behavior, were indistinguishable from the effects of acetylcholine and AII applied to the SFO.

We also studied water intake following SFO application of hypertonic NaCl. Lesions of the SFO impair both the AVP secretion and the drinking following systemic hypertonic NaCl (Mangiapane, et al, Fed Proc, 1982), and Thrasher et al (AJP, 1980) suggest that osmoreceptors for thirst and AVP secretion are within one of the forebrain circumventricular organs. We found, however, that SFO application of graded doses of 1.0 ul of NaCl (.153 M, .156 M, .162 M, and .174 M) did not provoke drinking. In addition an 11 min infusion of .156 M or .162 M NaCl at 0.18 ul/min also did not cause water intake.

Catecholamines, which are endogenous to the SFO, apparently do not function in control of drinking or blood pressure, whereas the indoleamine 5-HT does. Likewise, AVP application to the SFO provokes dipsogenic and pressor effects in analogous fashion to AII injections. Hypertonic saline does not affect water intake at the SFO, suggesting that this circumventricular organ does not harbor osmoreceptors for drinking.

206.9 Fourth ventricular alloxan injection causes feeding but not hyperglycemia in rats. Sue Ritter and Mary Strang, Dept. of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164 and University of Iowa Hospital, Iowa City, IA 52242.

Intracerebroventricular administration of the antiglycolytic agents 5-thioglucose (5TG) and 2-deoxy-D-glucose stimulates feeding and sympathoadrenal discharge. Recently, the diabetogenic agent, alloxan, has been reported to inhibit glucose metabolism in cultured fibroblasts and pancreatic islets. Assuming that alloxan might also exert an antiglycolytic effect on brain glucoreceptor cells controlling feeding and sympathoadrenal activity, we measured food intake and blood glucose in eight rats immediately following IV ventricular alloxan injections (0,5,10, 15 and 20 μg in 5 μl saline, pH 3.0). Compared to control, 4-hr food intakes were significantly elevated after 10, 15 and 20 μg of alloxan ($p<.01$). At these doses, rats ate 2.5 ± 0.5, 2.5 ± 0.5 and 2.0 ± 0.8 g of food above control levels, respectively. Intake after saline injection was 0.6 ± 0.3 g of food. In contrast to feeding, blood glucose was not altered by any dose of alloxan, even though a typical hyperglycemic response was obtained when 5TG (90 μg in 5 μl) was injected subsequently through the same cannula.

The ability of alloxan to stimulate feeding without evoking hyperglycemia is consistent with our previous observation that a higher alloxan dose (40 μg) permanently impairs the glucoprivic feeding response without altering the blood glucose response. These data support the hypothesis that the feeding and sympathoadrenal responses to glucoprivation are mediated by separate cell populations differentially susceptible to alloxan's effects. The possibility that intraventricular alloxan stimulates feeding by inhibition of glucose metabolism in brain glucoreceptor cells is a reasonable hypothesis but requires further experimental support.

206.10 ENHANCED INTAKE OF PREFERRED FOODS FOLLOWING INJECTION OF CAPSAICIN INTO THE CAUDAL BRAINSTEM. Elizabeth H. South and Robert C. Ritter. WOI Regional Program in Veterinary Medicine, University of Idaho, Moscow, ID 83843, and Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Thermal lesions of the area postrema (AP) and the adjacent nucleus of the solitary tract (NST) cause increased intake of preferred foods and solutions (Edwards & Ritter, Brain Res. 216:265, 1981) and exaggerated drinking in response to angiotensin (AII) and extracellular thirst challenges (Edwards & Ritter, Neurosci. Abst., 1980). In addition AP-NST lesions usually produce a chronic body weight reduction (Hyde & Miselis, Neurosci. Abst., 1980). Therefore, it appears this small brainstem region participates in several ingestive and body weight controls.

To determine the role of neurochemically discrete cell populations in the behavioral and physiological alterations produced by thermal AP-NST lesions, we have injected the neurotoxins, capsaicin, 6-hydroxydopamine (6OHDA), and 5,7 dihydroxytryptamine (5,7DHT), into the region of the AP and NST. None of the neurotoxin treatments altered drinking in response to AII, feeding in response to 2-deoxy-D-glucose, or caused permanent reduction of body weight.

The capsaicin-injected rats did, however, eat an average of 58% (6.5±0.5 gr, n=12) more than the control rats (4.1±0.3 gr, n=20) when given a preferred food (cookies) for a 30-min test period. The intake of preferred foods was not increased in 6OHDA- or 5,7DHT-treated rats. Also capsaicin-treated rats fed ad libitum rat chow and cookies for 24-hr periods significantly suppressed rat chow intake. They consumed an average of 93±1% of their total calories in cookies as compared to 74±3% for the controls. There was no significant difference in total calorie intake or in water intake between capsaicin-treated and control rats. Thus pretreatment with capsaicin, a neurotoxin that damages substance P-containing sensory neurons, enhances preferred food consumption and alters diet choice in rats. These findings parallel those found following thermal AP-NST lesions. However, the capsaicin-induced enhancement of preferred food intake occurs in the absence of the alteration in drinking behavior and the chronic weight reduction observed after thermal lesions. Capsaicin, therefore, allows us to selectively examine the cell populations involved in one facet of the AP-NST lesions syndrome.

206.11 PRESENCE OF PREFERRED FOOD OR GLUCOSE CAUSES EXAGGERATED ALTERATION OF DIET CHOICE IN AREA POSTREMA-LESIONED RATS. G.L. Edwards and R.C. Ritter. WOI Regional Program in Veterinary Medicine, University of Idaho, Moscow, ID 83843 and Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Rats with lesions of the area postrema (AP) and adjacent nucleus of the solitary tract (NST) overconsume preferred foods and solutions during short tests. The fact that lesioned and control rats eat similar amounts of laboratory chow ad lib. or after food deprivation suggests the AP-NST lesions have a specific effect on intake driven by palatability.

In order to determine whether the chronic presence of a preferred substance altered caloric intake or diet choice, we offered AP-lesioned and control rats a choice between a preferred substance and rat chow as their daily ration. The animals were offered chow alone, or together with saccharin (0.13%), 5%, 15%, 35% glucose, or cookies for periods of 5 days each. Total caloric consumption by the two groups was not different under any condition. However, when cookies, 15%, or 35% glucose were available, lesioned rats took significantly greater portions of their total intake from these substances than did control rats. For example, in the presence of 35% glucose, lesioned rats took 93±1% of their calories as glucose whereas controls took only 76±4% of their calories as glucose. Lesioned rats also exhibited a greater reduction in lab chow intake when calorically dense glucose solutions or cookies were available. For example, in the presence of 35% glucose, control intake of lab chow averaged 7.5±1.0 g/day while lesioned rats ate only 2.1±0.3 g/day. Rat chow consumption of lesioned and control rats did not differ in the presence of 5% glucose or saccharin.

These data suggest that enhanced responsiveness to preferred foods in AP-NST lesioned rats does not alter caloric intake but does influence the choice of calorie source.

207.1 EVIDENCE FOR GANGLION CELL SPECIFICITY OF SEVERAL MONOCLONAL ANTIBODIES THAT BIND TO CHICK RETINA. V. Lemmon and S.C. McLoon. Dept. of Anatomy, Medical University of South Carolina, Charleston, S.C. 29425.

We are interested in studying the development of retinofugal projections both in vivo and in vitro. For many of our studies it would be most useful to identify specific classes of cells and even subclasses in the developing retina and central visual nuclei. Over the past few years it has been recognized that the monoclonal antibody technique can be used to produce cell specific markers. Several antibodies have been made which appear to be specific for elements of the inner plexiform layer, ganglion cell layer and/or optic fiber layer in the developing chick retina. In order to further define the cell selectivity of these antibodies we have lesioned the tectum of early embryos which causes a subsequent loss of most of the retinal ganglion cells. These retinas were examined for changes in the binding of our different antibodies.

Chick embryos at 3 days of incubation were transferred to embryo culture chambers to facilitate access. The right tectum was ablated completely with an electrocautery. On E17 the embryos were fixed and the left retina of each was sectioned on a cryostat. The sections were processed for immunohistochemistry using each of the antibodies. Retinas from embryos without lesions were processed in the same manner to serve as controls.

Nissl stained sections of the retinas from embryos with tectal lesions showed an extensive loss of cells from the ganglion cell layer compared to normal retinas. Only 6% of the ganglion cells remained, and they represent a unique class which projects to the thalamus and pretectum. The remainder of the neurons in the ganglion cell layer are displaced amacrine cells. Antibody Ret 2, which binds to the optic fiber layer (OFL) in normal retinas, was undetectable in retinas of the lesioned embryos. Antibody Ret 3 binds to the inner plexiform layer (IPL), ganglion cell layer, and OFL in normal retinas and staining with it was also completely abolished in the experimental retinas. Antibody Ret 5 shows staining in the OFL, IPL and the outer plexiform layer (OPL) in normal retinas but only bound to the OPL in the retina of lesioned embryos. Several antibodies that bound to the entire retina showed the same staining pattern in the experimental retinas.

It appears that antibody Ret 2 and 3 may bind specifically to chick retinal ganglion cells. Furthermore, they may represent binding to a specific class or classes of ganglion cells since they did not appear to stain the 6% of the ganglion cells which survive tectal ablations. Nor did they appear to stain the displaced ganglion cells. Although antibody Ret 5 shows some ganglion cell staining characteristics, it clearly cross-reacts with other retinal elements.

(Supported by grants from the National Society to Prevent Blindness and NIH EY03713.)

207.2 ^{3}H-GABA UPTAKE SELECTIVELY LABELS IDENTIFIABLE NEURONS IN THE LEECH CNS. H.T. CLINE* (SPON: G.S. Stent). Graduate Group in Neurobiology, Univ. of California, Berkeley, Ca. 94720.

Isolated adult ganglia and embryonic nerve cord from the leech can convert glutamate to gamma-aminobutyric acid (GABA), indicating the presence of glutamic acid decarboxylase, an enzyme concentrated in neurons which synthesize GABA for neurotransmission. In order to locate the putative GABA-ergic neurons in the leech nerve cord, midbody ganglia from adult specimens of Haementeria ghiliani and Hirudo medicinalis were incubated with uM concentrations of ^{3}H-GABA, embedded in plastic, sectioned and processed for autoradiography. Reconstructions of the ganglia from serial sections reveals cell bodies which selectively accumulate exogenous ^{3}H-GABA. In Haementeria ghiliani a specific subset of 28-33 cell bodies per ganglion label with ^{3}H-GABA. There are variations in the labeling pattern between ganglia taken from different segments, comparable to the ganglionic variations in the monoamine-containing neurons, but ganglia from any given segment have the same pattern of labeled cell bodies from preparation to preparation. The labeled cell bodies are distributed in all 6 glial packets; most of the cell bodies are bilaterally paired, although there are some apparently unpaired ^{3}H-labeled neurons in the medial packets.

The neuropil and interganglionic connective also accumulate ^{3}H-GABA in reproducible patterns. Neurites from 2 pairs of labeled cell bodies in the dorsal surface of the ganglion can easily be traced across the neuropil in the anterior commissure by their accumulation of grains. Lines of grains can be followed along the longitudinal fiber tracts in the neuropil and into the lateral axon bundles of the connective. Transverse sections through the connective reveal bilaterally symmetric spots of grains in the lateral axon bundles which may be processes of some of the bilaterally paired ^{3}H-GABA-labeled neurons in the ganglion. In addition, there is a spot of label in Faivre's nerve, the unpaired medial connective. Incubation at 4^{o}C abolishes labeling in the cell bodies, neuropil and connective. Glia accumulate ^{3}H-GABA under the incubation conditions, but this does not interfere with the interpretation of the autoradiograms because there are only 6 large glial cells per ganglion, and they are easily distinguished from the neuronal cell bodies in sectioned material.

Neurons which accumulate ^{3}H-GABA have been tentatively identified in the living ganglion, injected with Lucifer Yellow or HRP prior to GABA incubation and autoradiography, and then sectioned material was examined for the presence of both markers.

207.3 MONOCLONAL ANTIBODIES AS PROBES OF THE LEECH NERVOUS SYSTEM. R. McKay, S. Hockfield, J. Johansen, L. Kleina, I. Thompson Cold Spring Harbor Lab, P.O. Box 100, Cold Spring Harbor, NY 11724

With a surprisingly high frequency monoclonal antibodies raised against the leech nerve cord bind to antigens present in small subsets of the four hundred neurons in the typical midbody ganglion of the leech (Zipser and McKay, 1981, Nature 289, 549). The large number of antigens which have a restricted neuronal distribution suggests that each neuron in the midbody ganglion could be molecularly unique.

An advantage of the leech for this immuno-histochemical study was that a single cell type could be identified morphologically. Using this anatomical feature we have dissected single cell types and with Western blots analyzed the cellular distribution of specific antigens. EM studies using these antibodies show that (1) axons occupy stereotyped locations in fiber tracts and (2) many different subcellular organelles carry these specific antigens. These general studies suggest that many rather than a single specific feature of the connectivity and physiology of a particular class of neuron may be a consequence of the presence of specific molecules in that class of cell.

One antibody (Lan3-2) binds to both medial and lateral nociceptive (N) cell bodies in midbody ganglia (7-19) of H. marmorata. However in ganglia 5, 6, 20 and 21 only a single cell body binds Lan3-8. Electrophysiology on H. medicinalis confirms that ganglia 5 and 6 have only a single N cell. Double-labeling with lucifer yellow and a second antibody which recognizes only the lateral N cell in Hirudo suggests that the single N cell in ganglia 5 and 6 is the medial N cell and the cell in 20 and 21 the lateral N cell. Immunoelectron microscopy shows that the Lan3-2 antigen binding sites are found on the surface of nociceptive cells and central axons. The axons carrying this surface antigen travel in a stereotyped, antigenically homogenous group in the leech fiber tracts. These peripheral cells that express this antigen do so from the earliest stages of neurite growth. Additionally this antibody binds to three bands on Western blots of leech neural proteins. Three different species of leech each with specific technical advantages were used to obtain this information. From these results we propose that the surface proteins recognized by this antibody may play a role in the mechanisms which guide the precise outgrowth of these axons during the development of the leech nervous system.

207.4 MONOCLONAL ANTIBODIES RECOGNIZE SUBSETS OF NEURONS IN CAT SPINAL CORD AND BRAIN, S. Hockfield and R. McKay, Cold Spring Harbor Lab, Cold Spring Harbor, N.Y. 11724.

Molecular differences among neurons may play a role in the specificity of neuronal connections and account for the physiological and anatomical differences among neurons. Monoclonal antibodies have been generated that recognize molecularly homogenous subsets of neurons.

Monoclonal antibodies were raised by immunizing mice with homogenized, formaldehyde fixed grey matter of the adult cat cervical spinal cord. Hybridoma lines were screened immunohistochemically on 50 m thick vibratome sections of fixed cat spinal cord and other areas of the CNS using HRP histochemistry. Of 800 cell lines screened, 47 secreted antibodies that bound to spinal cord sections. On the basis of the neural elements recognized, the antibodies can be grouped into four classes: 1. axons only; 2. axons and cell bodies; 3. cell bodies only; and 4. glial cells. Of the five neuronal antibodies cloned and studied in more detail, each recognizes a subpopulation of neural elements throughout the CNS; none stains the CNS uniformly.

Two antibodies which recognize projection neurons provide an example of the specific staining we observe. The morphology of neurons stained by antibodies Cat-201 and Cat-301 match that of projection neurons in the spinal cord, but the distribution of Cat-301 positive cells is more extensive than that of Cat-201. Similarly, Cat-201 recognizes neurons in only a few brainstem nuclei while Cat-301 recognizes neurons in many more locations. As an example of the specificity of antigen distribution, in the pons Cat-201 only binds to neurons in the trigeminal motor nucleus while Cat-301 binds to many neurons in the trigeminal motor and main sensory nuclei, the facial motor nucleus, the vestibular nuclei, and the reticular formation, but to few neurons in the periventricular grey matter. EM localization shows that Cat-301 antibody binding sites are found around synaptic profiles, that is, HRP-bound antibody is found along the surface of the cell body and proximal dendrites but is excluded from the immediate region of synaptic junctions, often forming a cup of stain around the presynaptic profile.

These monoclonal antibodies recognize molecular differences which distinguish neurons from one another. None of our antibodies binds uniformly to all the neurons in the CNS, indicating that the number of different molecular features among neurons is likely to be large.

207.5 SYMMETRICAL GIANT NEURONS IN ASYMMETRICAL MOLLUSCAN GANGLIA. Douglas Munoz, Peter A. Pawson and Ronald Chase. Dept. Biology, McGill University, Montreal, Quebec, H3A 1B1.

The central nervous system of gastropod molluscs is composed of a collection of ganglia that have been subject to extensive change during evolution. One way to reconstruct the evolutionary history is to examine cellular homologies. For example, in Aplysia, the abdominal neuron R2 and the pleural neuron LP1 presently reside in non-paired asymmetrical ganglia, but they share properties which suggest an evolutionary origin in bilaterally symmetrical ganglia (Hughes and Tauc, 1963). We have studied a similar situation in the terrestrial snail Achatina fulica where the neurons RPr1, in the right parietal ganglion, and V1, in the visceral ganglion, constitute an homologous pair. The evidence for this is as follows:

1) Both cells have unusually large soma diameters (RPr1, 194-345μ; V1, 219-375μ). In a given animal, the sizes are closely matched (mean difference, 24 ± 6μ).
2) HRP injections reveal extensive axonal projections, with each cell appearing as a mirror image of the other.
3) The electrical properties are very similar, e.g. resting potential, input resistance, time constant, anomalous rectification, and the presence of a large (15-20mV) hyperpolarization after the action potential.
4) There is a high degree of synchrony in spontaneous PSPs.
5) Tactile stimulation of the skin over an extensive area, or electrical stimulation of peripheral nerves or connectives, evokes synchronous compound EPSPs. Responses are consistently larger in the ipsilateral cell.
6) Stimulation of the pre-synaptic neuron V2 evokes facilitating monosynaptic EPSPs in both cells.
7) Direct stimulation of either cell leads to muscle contractions in the foot and mantle. The responses persist during suppression of chemical synaptic transmission in the CNS.
8) The motor responses of each cell show both short-term facilitation and long-term habituation.
9) Application of serotonin, octopamine or GABA produces depolarization in both cells; ACh is hyperpolarizing; glycine and glutamic acid are ineffective in both cells.

The foregoing results suggest that V1 and RPr1 are an homologous pair. If so, they probably arose in bilaterally symmetrical ganglia of an early gastropod. Their contemporary locations in Achatina suggest an origin in the once symmetrical intestinal ganglia. This interpretation is consistent with the previously stated hypothesis (Haeckel, 1913) that the supra-intestinal ganglion has fused with the right parietal ganglion and the sub-intestinal ganglion has fused with the visceral ganglion.

207.6 SEROTONIN ANTIBODY STAINING AND LUCIFER YELLOW INJECTION REVEAL DIFFERENT FEATURES OF THE NORMAL AND REGENERATE MORPHOLOGY OF AN IDENTIFIED NEURON. A. D. Murphy, D. L. Barker and S. B. Kater. Dept. of Zoology, Univ. of Iowa, Iowa City, IA 52242.

Tonic activity in the serotonergic cerebral cells (SCCs) of Helisoma can initiate or modulate feeding motor output from the buccal ganglia. In addition, bath applications of 5-HT mimic the effects of SCC activity on feeding motor output (Granzow and Kater, Neurosci. 2:1049-1063, 1977). In the current study we axotomized the SCCs by crushing the cerebro-buccal connectives (CBCs) and allowed them to regenerate in vitro in modified L-15 culture medium. After approximately one week of culture, normal effects of SCC activity on the feeding motor output of the buccal ganglia were restored. Despite extensive surveys, however, direct synaptic connections from the SCCs to buccal neurons have never been observed in either normal or regenerate preparations. These observations suggest a humoral mechanism for the effects of SCC activity on "feeding."

Lucifer Yellow stains of the SCCs displayed relatively unadorned stick-like axons coursing through the buccal ganglia without elaborations in the neuropile and exiting buccal nerves. The 5-HT-antibody technique, on the other hand, revealed very fine processes arising from these axons and elaborating varicosities (possible humoral release sites) in or near the ganglionic and nerve sheathes. This staining technique also allowed us to see fine processes on distant targets (e.g., the gut and salivary glands) which have not been seen using Lucifer Yellow staining. 5-HT antibody staining has also provided complementary information to that provided by Lucifer Yellow staining of SCCs during regeneration. The growth patterns of regenerating SCCs following CBC crush is very distinctive and reproducible. The 5-HT antibody technique allowed us to examine the relationship between sprouts from the proximal axon stumps and the surviving distal axon segment. It also disclosed that the severed distal segment has at least a limited capacity to extend sprouts of its own. Lucifer Yellow staining provides a very useful but only partial sketch of a rich neuronal landscape. Antibodies made to neural transmitters such as 5-HT can provide additional brush strokes to the canvas. (Supported by NIH grants NS 15350 and AM 19858.)

207.7 INTRANEURONAL INJECTION OF HORSERADISH PEROXIDASE LABELS GLIAL CELLS ASSOCIATED WITH AN IDENTIFIED APLYSIA NEURON Ronald S. Goldstein*, Klaude R. Weiss, and James H. Schwartz. Center for Neurobiology and Behavior, Columbia Univ. College of P&S, New York, 10032

After injecting the cell body of the giant serotonergic neuron (GCN) in the cerebral ganglion of Aplysia with horseradish peroxidase (HRP), we found that some glial cells were labeled along the cerebrobuccal connective and posterior lip nerve, the two nerves that contain the major axon branches of the injected neuron. Starting at a distance of about 3 mm from the site of the injection, only glial cells in the nerve that are close to an axon branch of GCN contained HRP. Labeling appears to be selective because, at most, only one out of three glial cells were labeled within an area of 20 μm of the axon. Moreover, no HRP was detected in any of the many glial cells within the cerebral ganglion which come into intimate contact with the GCN's initial segment and cell body. Reaction product diffusely labeled the cytoplasm of glial cell bodies and processes after intraneuronal injection of HRP. This distribution was markedly different from that observed in glial cells after uptake of HRP from the extracellular space; HRP, presumed to be taken up by endocytosis, was found to be localized to vesicles, tubules, and multivesicular bodies. Labeling of adaxonal glia is not restricted to GCN, but also occurs when HRP is injected into R2, the giant neuron of the abdominal ganglion and B2, a motor neuron of the buccal ganglion.

We presume that the transfer of HRP reflects a functional connection between the axon of the neuron and special glia cells that permit passage of the 40,000 molecular weight protein. We have not observed any junctions between axons and glial cells in Aplysia, but morphological connections with glia have been described in other invertebrate axons. While the mechanisms of transfer have not yet been characterized, the ability to identify glial cells specialized for individual neurons could provide the opportunity of determining how a neuron relates specifically to a group of glial cells.

207.8 BINDING SITES FOR Fc IgG IN RABBIT CILIARY PROCESSES, N. S. Peress V. A. Roxburgh* and M. C. Gelfand*. Lab. of Neuropathology, V. A. M. C. Northport, NY 11768.

Binding sites for IgG and C have been defined in renal glomeruli and choroid plexus. These structures are analogous in form and function to the processes of the ciliary body and like the ciliary processes exhibit immune complex entrapment in Systemic Lupus Erythematosus (SLE), murine SLE and experimental serum sickness. The present study demonstrates the presence of binding activity for the Fc fragment of IgG selectively on the processes of the ciliary body of adult rabbit eyes. Other regions of the eye including the cornea, iris, choroid and retinae were negative. Binding activity was demonstrated by an in vitro assay employing IgG-coated sheep red blood cells (IgGEA) and frozen sections of longitudinally split rabbit eye. The eyes of 8 normal adult rabbits, a single pregnant rabbit and 2 of her fetuses were studied. All slides were code numbered and examined by an independent observer who counted the number of RBCs on each of 3 randomly chosen HPFs of ciliary processes, retinae, choroid, iris and cornea. For each animal, two slides were counted for each area and reagent. The intensity of reagent binding to a particular ocular tissue was graded from 0 to +6 (a score of trace correlated with 1-10 RBC/HPF, 1+ with 11-20 RBC/HPF, 2+ with 21-40 RBC/HPF, 3+ with 41-60 RBC/HPF, 4+ with 61-80 RBC/HPF, 5+ with 81-100 RBC/HPF and 6+ with $>$ 100 RBC/HPF) based upon cell counts. All adult rabbit eyes exhibited adherence of the IgGEA reagent to the epithelial layers of the ciliary processes which was 6+ in 5, 5+ in 1, 4+ in 1 and 2+ in 2. In contrast both fetal eyes exhibited only trace to 1+ adherence of the IgGEA reagent to the epithelium of the ciliary processes. Adult and fetal ciliary IgGEA binding was totally blocked by 4.0 mg/ml IgG, aggregated and non-aggregated, but not by similar concentration of Albumin or the $F(ab')_2$ fragment of IgG. In the adult eye, approximately 50% blocking was achieved at the 0.4 mg/ml concentration of aggregated IgG. Therefore the calculated affinity of the binding sites for IgG (K_D) is approximately $2x10^{-9}$M. Specificity was further suggested by the absence of adherence of both non-sensitized RBCs and of IgM sensitized RBCs. These studies therefore demonstrate maturation dependent binding sites for Fc IgG on rabbit ciliary processes. These IgG binding sites may be important determinants of this tissue's selective entrapment of circulating immune components. They may also function in clearing the aqueous humor.

207.9 LAMINA SPECIFIC MONOCLONAL ANTIBODIES STAIN RETINAL NEURONS MAINTAINED IN VITRO. M.B. Eschmann*, D. Witte*, C. Gottlieb* and D. Gottlieb. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

We have recently described monoclonal antibodies which bind to restricted layers of the chick retina (Lemmon and Gottlieb, J. Neurosci., in press). One of these, RET4, recognizes an antigen found in the optic fiber layer, ganglion cell layer, inner plexiform layer and the inner half of the nuclear layer. All other parts of the retina are unstained by RET4.

Cultures of dispersed retinal cells were made from seven-day embryonic retinas and maintained in vitro on polylysine-coated coverslips for one to four days. When such cultures were stained by indirect immunofluorescence with RET4 antibody strong fluorescence was seen on some cells; many others were clearly negative. The stain was clearly associated with the plasma membrane. This result was obtained whether or not the cells were fixed prior to staining. Since the antigen can be detected on living cells, it must be present on the cell surface. RET4 positive cells assume a variety of forms. Some are multipolar, with processes at least 100 μ long. Others are bipolar. The RET4 negative cells also have a variety of forms. Another monoclonal antibody 224-1A6-A1 has been described (Lemmon et al., Dev. Brain Res. 3:349) which stains all layers of the retina. This antibody stains nearly all of the cells in dispersed cell cultures of the retina; the stain is associated with the plasma membrane. It stains living cells indicating the antigen is on the cell surface. A number of small round cells are not stained.

Two other monoclonal antibodies RET1 and RET5 were studied in this manner. RET1 is specific for the optic fiber layer; RET5 binds selectively to the inner and outer plexiform layers. Both antigens are present in the seven-day retina. We could not detect these antigens in dispersed cell cultures. Two explanations for this result are: 1) the antibodies fail to stain because the antigens are inaccessible in cultured cells or 2) the antigens fail to be expressed in dispersed cell cultures. We are currently trying to decide among these explanations.

Our results show that monoclonal antibodies can help identify retinal cells in vitro according to their layer of origin in vivo. Since several of these antibodies are against cell surface antigens, they may also be useful for selecting populations of cells for culture.

Supported by PHS Grants NS12867 and GM28002.

207.10 ULTRASTRUCTURAL ANALYSIS OF DORSAL AREA OF TURTLE DORSAL VENTRICULAR RIDGE, INCLUDING COMMENTS ON CELL CLUSTERS. J.C. Weiss Dept. of Anatomy, Univ. of Chicago, Chicago, Il 60637

Dorsal ventricular ridge (DVR) is a subcortical structure receiving sensory information from the thalamus in reptiles. It includes four cytoarchitectonic areas in the turtle Pseudemys scripta, each characterized by distinct thalamic projections. The areas contain four concentric zones distinguished by the distribution of spiny and aspiny neurons. A marked feature is the presence of neuron clusters with touching somata. This is an electron microscoic study of dorsal area, which receives its thalamic input from the tectorecipient nucleus rotundus.

In the ependymal cell layer, tanycyte tails extend into zones 2 and 4 (Z2 and Z4) and cytologically resemble protoplasmic astrocytes. 23 synapses, with mainly asymmetric active zones and containing round synaptic vesicles, were observed on astrocytic processes in Z2 and Z4. Zone 1 (Z1) neurons have fusiform somata whose long axes parallel the ventricular surface. Their nuclei contain coarse, but finely clumped chromatin; the cytoplasm contains rough endoplasmic reticulum (RER) located primarily in Nissl bodies, lipofuchin granules, multivesicular bodies, extensive arrays of Golgi apparatus, and many mitochondria. Synapses occur mainly on dendritic spines of Z1 neurons, less frequently on dendritic shafts, and infrequently on somata. The majority (60/67) had round synaptic vesicles and asymmetric active zones. In contrast to Z1, neurons in Z2 and Z4 have large amounts of free RER giving their cytoplasm an electron dense quality. Synapses occur mainly on spines and shafts of Z2 and Z4 neurons. As in Z1, the majority (1270/1428) contain round synaptic vesicles and involve asymmetric active zones. Z2 and Z4 contain clusters of neurons distributed among isolated neurons; clusters are larger and more frequent in Z2. Protoplasmic and fibrous astrocytic processes, axon boutons, dendrites, and axon fasicles surround the clusters. Though less numerous, the same structures occur inside the clusters. Most synapses inside clusters had round synaptic vesicles, asymmetric active zones and occured mainly on spines; asymmetric and symmetric synapses were also seen on dendrites and somata. Some neurons in clusters have somata whose plasma membrane are in direct apposition. In contrast to snake DVR, no nexūs were seen. These observations lead to the speculation that entire clusters or single cells within clusters may be sequestered from the surrounding environment by interposition or retraction of astrocytic processes (Hatten and Tweedle, 1982, Brain Res. Bull. 87,197), possibly through the action of synapses on astrocytic processes. (Supported by PHS Grant NS12518)

207.11 CHRONIC GROWTH OF NG108-15 CELLS WITH DIAZEPAM ALTERS DNA PATTERNS IN THE NUCLEUS M. D. Dibner, R. Z. Lockart*, R. A. Lampe* and K. M. Pezzella*. Central Research and Development Department, E.I. Du Pont Glenolden Laboratory, Glenolden, PA 19036.

Neuroblastoma x glioma hybrid cells (NG108-15) possess large numbers of the peripheral-type benzodiazepine receptor. We examined cells grown for one week in medium containing 5% fetal calf serum and 10 μM diazepam. Growth of cells with diazepam led to minimal alterations in cell growth and gross morphology. In contrast, there were significant alterations in nuclear DNA patterns. Cells were fixed, stained according to the Feulgen procedure, then scanned and analyzed using a computer-assisted video monitoring system. This system objectively and quantitatively compared the images of the nuclei in treated and control untreated cells. Benzodiazepine-treated cells were discriminated from control cells with 97% accuracy by use of three features. One was a difference in DNA staining intensity and two were measures of DNA texture. Growth of cells with diazepam for 1, 4 or 7 days yielded a time-dependent change in these staining characteristics. Also, growth for 7 days with 1 nM, 100 nM or 10 μM diazepam showed a dose-dependent change in nuclear staining characteristics. In one experiment, differentiation of NG108-15 cells by growth for one week with 1 mM dibutyryl cyclic AMP led to gross morphologic alterations in whole cells as well as changes in DNA patterns similar to those seen with diazepam. In a second experiment, these changes were less pronounced. We are currently assessing the involvement of the benzodiazepine receptors in these phenomena and hope to further characterize the morphologic changes in these cells following treatment with benzodiazepines.

208.1 **QUANTITATIVE ANALYSIS OF DOPAMINE RECEPTOR SUBTYPES NOT LINKED TO ADENYLATE CYCLASE ACTIVATION IN RAT STRIATUM**

Rita M. Huff & Perry B. Molinoff. Dept. Pharmacology, Univ. of Penn., Philadelphia, PA 19104

A means of quantitatively assaying two classes of dopamine receptors in the striatum that are not linked to activation of dopamine sensitive adenylate cyclase has been developed. The binding of ^{3}H-domperidone and ^{3}H-spiroperidol, reported to be selective ligands for D-2 receptors, was examined in membranes prepared from rat striatum. Scatchard analysis of the binding of ^{3}H-domperidone resulted in markedly curvilinear plots consistent with the presence of multiple classes of binding sites. Nonlinear regression analysis of untransformed data showed that the curvature was best explained by the presence of two populations of binding sites; 21% of the sites had a K_d value of 130 pM and 79% of the sites had a K_d value of 1300 pM. In contrast, the binding of ^{3}H-spiroperidol appeared to be to a single class of receptors as indicated by linear Scatchard plots and Hill coefficients equal to one. Studies of the inhibition of the binding of ^{3}H-spiroperidol by a number of competing ligands, including domperidone, sulpiride, and dopamine in the presence of GTP, was consistent with the interaction of these agents with two classes of binding sites. GTP was included in studies with agonists to avoid problems due to formation of a high affinity complex with a guanine nucleotide regulatory binding component. Hofstee plots of these data, analyzed by a computer assisted iterative method, gave relative proportions of two classes of binding sites along with the affinities of these sites for the drug in question.

Analysis of the inhibition of the binding of ^{3}H-spiroperidol by 6 competing ligands gave the same relative proportion for two classes of sites as previously determined by analysis of the binding of ^{3}H-domperidone. In addition, the two classes of receptors labelled with ^{3}H-spiroperidol had affinities for domperidone (93 pM and 1800 pM) which were nearly the same as the K_d values determined directly from analysis of ^{3}H-domperidone binding isotherms. Furthermore, the capacity of the binding sites for ^{3}H-spiroperidol was equal to the total capacity of binding sites for ^{3}H-domperidone. These findings suggest that the two radioligands bind to the same two classes of binding sites. A comparison of the properties of binding sites for ^{3}H-spiroperidol in the frontal cortex to those of the two classes of binding sites present in the caudate suggest that neither of the two classes of sites are receptors for serotonin. The approach described will make it possible to assess the effect of physiological or pharmacological manipulations on the densities or properties of subtypes of dopamine receptors. (This work was supported by USPSH NS 18591).

208.2 APPARENT IRREVERSIBLE MODIFICATION OF DOPAMINE RECEPTORS BY EEDQ: BEHAVIORAL AND RADIOLIGAND BINDING STUDIES.

M.W. Hamblin and Ian Creese. Department of Neurosciences, University of California, San Diego, School of Medicine, La Jolla, CA 92093.

N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ), an irreversible alpha-adrenergic antagonist, also acts as a potent and longlasting in vivo antagonist of D-2 dopamine receptors after peripheral administration to rats. Animals given EEDQ 3-10 mg/kg i.p. exhibit catalepsy and greatly reduced apomorphine induced stereotypy, behavioral effects associated with D-2 dopamine receptor blockade. These effects are apparent up to 4 days after drug administration, with scores returning to control levels by day 7. In vitro receptor binding assays of striatal membrane preparations from these animals using the radioligand ^{3}H-spiperone directly demonstrate that EEDQ is a potent D-2 dopamine receptor antagonist. This antagonism proceeds via a reduction in D-2 receptor Bmax, with no change in the observed K_D for ^{3}H-spiperone, and is resistant to extensive washing of the membrane preparation after in vivo EEDQ exposure. These observations and the known chemical reactivity of EEDQ suggest that EEDQ inhibition of D-2 receptors is irreversible. Administration of behaviorally active doses of EEDQ effect a reduction of 50-85% in D-2 receptor number. Recovery of these losses, to levels 75% of that of control ^{3}H-spiperone binding values at 7 days after administration of 10 mg/kg, parallels the recovery from catalepsy and blocked apomorphine induced stereotypy. These doses of EEDQ also reduce binding of ^{3}H-flupentixol to D-1 and ^{3}H-dopamine to D-3 type dopaminergic binding sites, putative dopamine receptors with no known behavioral correlates. Recovery of radioligand binding to D-1 and D-3 sites also occurs rapidly. Because of the apparent covalent nature of its interaction with dopamine receptors and because of its activity after peripheral administration, EEDQ may prove useful in the study of the function and turnover of multiple dopamine receptor subtypes.

208.3 ACUTE RESERPINE MIMICS THE EFFECTS OF NIGROSTRIATAL 6-HYDROXYDOPAMINE LESIONS ON "D-3" SPECIFIC ^{3}H-DOPAMINE BINDING IN RAT STRIATUM.

S.E. Leff, M.W. Hamblin and Ian Creese. Dept. of Neurosciences, Univ. of California, San Diego, Sch. of Med., La Jolla, CA 92093.

In the attempt to understand the neuroanatomical localization of multiple dopamine receptor subtypes in rat brain, selective 6-hydroxydopamine lesions of the nigrostriatal tract have been used to remove this afferent to the striatum. Most reports agree that this lesion induces a progressive increase in D-2 dopamine receptors. Some reports have indicated that another class of dopaminergic binding sites ("D-3") identified as having high (K_D~nM) agonist affinity but low butyrophenone antagonist (K_i~μM) affinity is markedly decreased by this lesion. These results were interpreted to indicate that at least a portion of D-3 binding identifies an autoreceptor on nigrostriatal terminals (Sokoloff et al., Nature 288:283, 1980; Nagy et al., Nature 274:278, 1978). However, in all of these studies no controls for the depletion of dopamine produced by this lesion were conducted. We have extended these studies and have observed the following: 1) Chronic 6-hydroxydopamine lesions produce increases in D-2 specific binding in striatum; 2) 6-Hydroxydopamine lesions or acute reserpine treatment (after Bacopolous, Life Sciences 29:2407, 1981) produces a marked (~50%) decrease in D-3 specific binding in striatum; and 3) decreases in D-3 binding produced by acute reserpine can be partially reversed by pre-incubating membranes in the presence of added dopamine or the first supernatants of control striatal homogenates. These findings question the proposal that D-3 binding identifies terminal autoreceptors and, along with other data to be presented, suggests that these binding sites are postsynaptic. Current studies are being conducted to determine how much, if any, of this binding represents labeling of a high affinity agonist binding state of the D-1 dopamine receptor. Supported by PHS MH32990.

208.4 IMMUNOCYTOCHEMICAL LOCALIZATION OF D-2 BINDING SITES IN THE RODENT FOREBRAIN.

A.C. Church, J.E. Kleinman* and R.J. Wyatt. Adult Psychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Our understanding of the neurochemical circuitry of dopaminergic brain regions has been inhibited by an inability to precisely determine which cellular elements are postsynaptic to the the dopamine terminals. These postsynaptic sites should contain at least one of the different types of dopaminergic receptors described recently by Kebabian and Calne (1979). One of the dopamine receptors, the D-2 receptor, is potently inhibited by the drugs used to treat schizophrenia. A description of D-2 circuitry could lead to a better understanding of the schizophrenic syndrome. Although autoradiographic techniques provide histochemical quantification, they lack sufficient resolution. Therefore an attempt has been made to see the D-2 receptor site using immunocytochemical techniques.

Lisuride, a high affinity agonist for the D-2 receptor (K_D=5 x 10^{-10}M), was chemically linked to bovine serum albumin to form a conjugate. The lisuride-BSA conjugate was injected subcutaneously into rabbits and serums were screened for antibodies to both the conjugate and to lisuride. In order to see the lisuride binding sites, the anti-lisuride serum was then used in combination with the peroxidase anti-peroxidase unlabeled antibody technique.

Results indicate that of a high number of D-2 like binding sites are present in the mouse caudate nucleus and olfactory tubercle. Pericellular and apparent terminal staining was found in both brain areas and this staining was abolished by conincubation of tissues slices with both lisuride and excess fluphenazine. Further results on the localization of this apparent D-2 binding sites will be presented.

208.5 CHARACTERISTICS OF MATURING DA RECEPTORS AFTER IN UTERO EXPOSURE TO NEUROLEPTICS. Helen Rosengarten* and Arnold J. Friedhoff. Millhauser Lab., N.Y.U. Medical Center, New York, N.Y. 10016.

In a previous study we demonstrated an apparent down regulation of caudate DA receptors in pups following exposure to haloperidol during the entire gestational period (Science 203, 1133, 1979). We have now determined that haloperidol (1.25 mg/kg or 2.5 mg/kg) and cis-flupenthixol (2mg/kg) can alter the receptor number if administered to pregnant dams only during days 14-17, a period marked by dopaminergic neuronal differentiation and synaptogenesis. Scatchard analysis (^{3}H-spiroperidol binding) revealed a decrement of approximately 25% (Control B_{max} = 97 ± 0.06 fmoles /10 mg wet weight) in 15 day old pups, while Kd values remained unchanged (0.165 ± 0.5nM and 0.18 ± 0.02 nM for control and experimental pups, respectively).

There were no changes in Bmax or Kd in the mesolimbic region. cis-Flupenthixol (2 mg/kg) induced a similar change in caudate and failed to alter binding in the mesolimbic area.

Tissue level of haloperidol in 15 day old pups, treated in the prenatal period, measured by radioimmunoassay (Wurzburger et al. JPET 217,757, 1981) were found to be below the sensitivity of the procedure (20 pg/8 mg of caudate tissue). The addition of 20 pg of haloperidol to naive caudate membrane homogenates had no effect on ^{3}H-spiroperidol binding.

Implications of these findings for the role of dopamine in regulation of behavior and for human offspring exposed to neuroleptics in utero will be discussed.

208.6 POSSIBLE MODULATION OF STRIATAL D_2 DOPAMINE RECEPTORS BY SEROTONERGIC NEURONS. Daiga M. Helmeste and Siu Wa Tang. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Canada M5T 1R8.

Increased densities of D_2 dopamine receptors have been widely reported to exist in post-mortem schizophrenic brains (1). We were interested in investigating whether manipulation of the CNS serotonergic system could result in secondary changes in striatal D_2 dopamine receptor densities, as measured with ^{3}H-spiperone.

In the first experiment, rats were treated chronically with D-fenfluramine (serotonin releaser and uptake inhibitor), 2.5 mg/kg i.p., twice daily for 28 days. ^{3}H-Spiperone scatchard analysis (0.05 to 2.0 nM), using 10 µM sulpiride to define specific binding to D_2 receptors, showed a 20% decrease in receptor density in fenfluramine-treated rats (mean ± SE: 213 ± 8 fmoles/mg protein in controls, n = 5; 174 ± 7 in fenfluramine-treated, n = 5; P < 0.01) with no change in Kd (mean ± SE: 0.07 ± 0.01 nM for controls; 0.06 ± 0.01 for fenfluramine-treated).

In the second experiment, rats received electrolytic lesions of the raphe nuclei. Six weeks post-operatively, striatal homogenates were prepared and assayed for D_2 receptor binding using 0.2 nM ^{3}H-spiperone and 10 µM sulpiride to define specific binding. Raphe-lesioned rats which had approximately 80% or greater depletion of serotonin content showed a trend towards an increase in D_2 binding (mean ± SE: 147 ± 8 fmoles/mg protein, n = 6) of 15%, which was not statistically significant compared to controls (129 ± 8, n = 13). Raphe lesioned rats which had serotonin depletions of less than 80%, showed no such trend (121 ± 8, n = 6).

These results suggest that manipulation of the CNS serotonin system may have secondary effects on the dopamine system, as measured by D_2 receptor binding in the striatum. They also raise the possibility that the changes in D_2 receptor densities seen in post-mortem schizophrenic brains could result from changes in other neurotransmitter systems, such as the serotonergic system.

208.7 ^{3}H-S-SULPIRIDE, BUT NOT ^{3}H-SPIPERONE, LABELS A SINGLE DOPAMINERGIC BINDING SITE IN STRIATUM AND RETINA. Nancy R. Zahniser and Margarita L. Dubocovich. Dept. Pharmacol., Univ. Co. Sch.Med., Denver, CO 80262.

Functional studies have shown that both sulpiride and spiperone are antagonists at dopamine receptors of the D-2 subtype. We have compared the number and characteristics of the sites labeled by ^{3}H-S-sulpiride (New England Nuclear) with those labeled by ^{3}H-spiperone in order to determine the selectivity of each radioligand in binding to this dopamine receptor subtype.

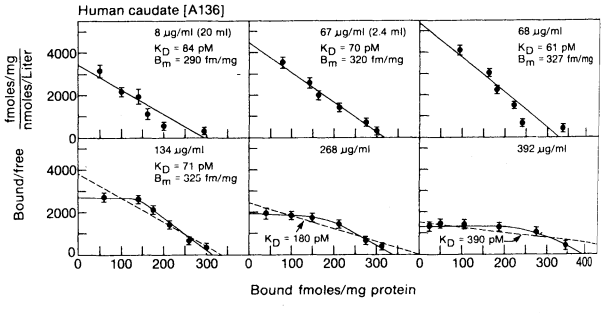
Binding to plasma membranes prepared from albino rabbit striatum and retina and rat striatum was carried out in Krebs' buffer (no ascorbate) at 37°. Samples were incubated for 20 min, and the reaction was terminated by dilution with ice-cold buffer and rapid filtration. Protein concentrations for ^{3}H-S-sulpiride assays were 0.20 mg for rabbit striatum, 0.30 mg for rabbit retina and 0.15 mg for rat striatum; these concentrations were 3-fold higher then those used for ^{3}H-spiperone assays. The relative potencies of drugs in inhibiting the binding of both radioligands in striatum were similar (spiperone = (+)butaclamol = domperidone = α-flupenthixol > S-sulpiride > N,N-di-n-propyldopamine > dopamine = β-flupenthixol > (-)butaclamol = R-sulpiride). Hill coefficients (n_H) for the inhibition of ^{3}H-S-sulpiride binding by both agonists and antagonists were not different from 1. In contrast, inhibition of ^{3}H-spiperone binding by agonists and most antagonists had n_H < 1. The notable exception was S-sulpiride for which n_H = 1. Scatchard analysis of ^{3}H-S-sulpiride binding was carried out only in striatal tissue. In striatum the number of sites labeled by ^{3}H-S-sulpiride as defined by spiperone and those labeled by ^{3}H-spiperone as defined by the isomers of sulpiride were not significantly different (rabbit: 412 + 87 fmol/mg protein vs. 537 + 36 and rat: 376 + 48 vs. 336 + 22; N = 3-6). Similar results were obtained when isomers of butaclamol were used to define specific binding. Using the isomers of flupenthixol to define the specific binding of ^{3}H-spiperone in rabbit striatum and retina, significantly more sites were labeled (135% in striatum and 160% in retina) than when specific binding was defined with the isomers of sulpiride. In contrast, the number of striatal ^{3}H-S-sulpiride binding sites were identical whether spiperone or the isomers of flupenthixol were used to define specific binding. The results indicate that ^{3}H-S-sulpiride labels a single site with an affinity of approximately 10 nM regardless of how specific binding is defined. ^{3}H-Spiperone appears to label the same site if specific binding is defined with the isomers of sulpiride but labels additional sites when specific binding is defined with the isomers of flupenthixol. It is most likely that the single site labeled by ^{3}H-S-sulpiride is the D-2 receptor subtype. (Supported by USPHS NS 09199 and BRSG 05357)

208.8 DOPAMINE RECEPTOR PARAMETERS (DETECTED BY ^{3}H-SPIPERONE) DEPEND ON TISSUE CONCENTRATION. P. Seeman, C. Ulpian* and J. Wells*. Pharmacology Dept., Faculties of Medicine and Pharmacy, University of Toronto, Toronto, Canada M5S 1A8.

Since a very wide range of K_D values (13 pM to 1600 pM) had been reported in the literature for ^{3}H-spiperone binding to dopamine receptors, we investigated whether the apparent K_D could vary with the final concentration of membrane protein in the incubate.

As shown in the Fig., we found that below a concentration of 100 µg protein per ml of final incubate, the Scatchard relation was linear for the binding of ^{3}H-spiperone to (previously frozen) human striatum, yielding K_D values of about 50 pM. At concentrations of protein higher than 100 µg per ml incubate, both the K_D and B_{max} (density of binding sites) increased significantly, if one assumed that the Scatchard relation was still linear. As shown in the Fig., however, such high concentrations of protein did not yield a linear Scatchard relation. The nonlinearity stems from the depletion of the fat-soluble ^{3}H-spiperone to the membrane.

We conclude that the K_D and B_{max} values for ^{3}H-spiperone are only reliably measured at concentrations of protein less than 100 µg per ml incubate. We also found that repeated washing of the tissue removed 10 to 58% (average 20%) of the receptors, but 30% of the protein; we thus recommend that the tissue not be washed when measuring the total density of dopamine receptors per gram of wet tissue, but that the tissue be simply homogenized and finally diluted to between 50 and 100 µg protein per ml incubate.

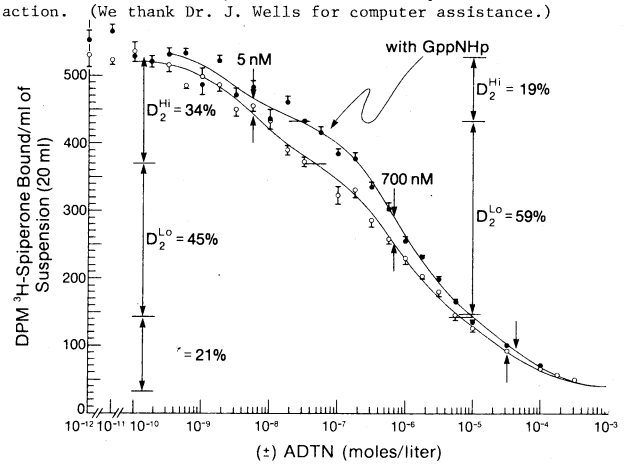


208.9 MODULATION OF THE D_2 DOPAMINE RECEPTOR IN CALF CAUDATE BY GUANINE NUCLEOTIDE. K.A. WREGGETT*, S.R. GEORGE* and P. SEEMAN. (SPON: J. Khanna). Department of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

^{3}H-Neuroleptics can label dopaminergic sites with differing affinities for agonists. Agonist/^{3}H-spiperone (^{3}H-SPIP) curves have low Hill slopes and are sensitive to guanine nucleotides. We quantitatively tested whether the nucleotide could totally convert ^{3}H-SPIP sites with high affinity for the agonist (D_2^{Hi}) into sites with low affinity for the agonist (D_2^{Lo}). Total conversion was not found.

To minimize depletion of the radioligand a final volume of 20 ml with 40 µg protein/ml was used. The competition of ADTN versus 50 pM ^{3}H-SPIP was analysed by computer. The shallow curve (n_H = 0.45) was resolved into three sites discriminated by ADTN. With 100 µM Gpp(NH)p the curve steepened slightly (n_H = 0.49); the high-affinity (5 nM) component (D_2^{Hi}) decreased from 34% to 19% with an increase in the low-affinity (700 nM) component (D_2^{Lo}) from 45% to 59%. The very-low-affinity (50 µM) site was not affected (21% of total sites).

The results indicate that guanine nucleotides can convert about half of the D_2^{Hi} sites into D_2^{Lo} sites. Such incomplete conversion suggests that the remaining D_2^{Hi} sites are either distinctly different sites or else may arise from the receptor-nucleotide interaction. (We thank Dr. J. Wells for computer assistance.)



208.10 IRREVERSIBLE ^{3}H-LIGANDS FOR DOPAMINE RECEPTOR PURIFICATION. L. Lilly*, J. Magnan*, A. Davis and P. Seeman. (SPON: S.W. Tang). Departments of Pharmacology, University of Toronto, and Psychopharmacology, Clarke Institute of Psychiatry, Toronto, Canada.

Established protein purification techniques can be readily applied to receptor isolation if a specific, irreversible, ^{3}H-ligand is available. We report the use of two ligands, ^{3}H-phenoxybenzamine (POB) and ^{3}H-(-)-chloroethylapomorphine (NCA; gift of New England Nuclear, Boston) in purifying dopamine sites from mammalian brain.

^{3}H-POB, at a concentration of 10 nM, completely associated with digitonin-solubilized canine striatum after 90 minutes. Less than 20% of the binding, however, was found to be dopamine (D_2) related as defined using 10 µM (+)-butaclamol; the remainder was to alpha- and beta-adrenoceptors, among others. Thus, the lack of specificity proved to be a disadvantage for ^{3}H-POB.

It has been suggested by Baldessarini et. al. (Eur. J. Pharm. 67: 105-110, 1980) that NCA might prove to be a useful ligand in dopamine receptor isolation and characterization. To investigate if ^{3}H-NCA could label an agonist conformation of the dopamine receptor, we compared it with the D_2 receptor as labelled by ^{3}H-spiperone. On striatal membranes, NCA was not a potent displacer of ^{3}H-spiperone binding. In the solubilized preparation, incubation of 10 nM ^{3}H-NCA for 90 minutes was found to label a site of the same isoelectric point (pI 7.5) and molecular size as did ^{3}H-dopamine (4 nM, 16 hour incubation). However, ^{3}H-spiperone-labelled D_2 receptors have an isoelectric value of pH 5.06. (See Fig.) ^{3}H-NCA does not, therefore, appear to label the ^{3}H-spiperone-binding protein. We are currently studying the cross-reactivity of D_2 receptor antibodies with the ^{3}H-NCA-labeled site

Fig. Isoelectric focusing of solubilized canine striatum.
