Monday, November 7–Wednesday, November 9	1-758

\*4764 volunteer abstracts, 20 symposium and workshop abstracts.

## **1983 PROGRAM COMMITTEE**

John G. Hildebrand, Chair Columbia University Neal H. Barmack Neurological Sciences Institute Allan I. Basbaum University of California Michael V. L. Bennett Albert Einstein College of Medicine Ira B. Black **Cornell University** Marc Colonnier Hospital of L'Enfant-Jesus Martha Constantine-Paton Princeton University Joseph T. Coyle Johns Hopkins University School of Medicine Irving Kupfermann Columbia University Dennis M. D. Landis Massachusetts General Hospital Eduardo R. Macagno Columbia University

Peter R. MacLeish Harvard Medical School Mortimer Mishkin Laboratory of Neuropsychology, NIMH Paul H. O'Lague University of California Edward M. Schmidt Laboratory of Neural Control, NIH-NINCDS Lawrence P. Schramm Johns Hopkins University School of Medicine James H. Schwartz Columbia University College of Physicians and Surgeons Michael J. Brownstein, Consultant Laboratory of Clinical Science, NIH David H. Cohen, ex officio State University of New York Jennifer H. LaVail, ex officio University of California School of Medicine Dominick P. Purpura, ex officio Stanford University School of Medicine

### CHRONOLOGICAL LIST OF SESSIONS

(see page viii for Thematic List of Sessions.)

1

Session Number and Title

um	er and Title F	age
	SUNDAY	
	Public Lecture—4:00 рм	
1.	Recent advances in the retinex theory of color vision	
	and some implications for cortical computation. E.	
	H. LAND No abstr	ract

#### Symposium-8:30 AM

2. Sexually dimorphic behaviors: differentiation in mammals. Chaired: T. O. Fox .....

#### Workshop-8:30 AM

3.	Reciprocal inhibition and coactivation of antagonist	
	muscles: two fundamental modes of motor control.	
	Chaired: D. R. HUMPHREY	I
	Slide Sessions—8:30 AM	
4.	Pain modulation: bulbospinal mechanisms	1
5.	Cell and tissue culture: neurons, glia, and neuronal	
	models	4
6.	Development and plasticity: trophic interactions I	8
7.	Muscle I	11
8.	Basal ganglia: anatomy and physiology I	14
9.	Peptides: physiological effects I	17
10.	Action potential and ion channels I	20
11.	Development of the visual system: retinothalamic	
	projections	23
12.	Learning and memory: anatomy I	26
13.	Catecholamines: dopamine receptors I	30
	Poster Sessions—8:30 AM	
14.	Visual cortex: cortico-subcortical relationships	35
15.	Cortex and cortico-subcortical relationships 1	38
16.	Cochlea	41
17.	Development and plasticity: peripheral regeneration	45
18.	Effects of activity and inactivity on development	53
19.	Development and plasticity: retinotectal system I	56
20.	Development of motor systems	60
21.	Control of posture	62
22.	Oculomotor system: mechanics and psychophysics	67
23.	Excitable membranes and synaptic transmission:	
	invertebrate studies	71
24.	Transmitters in invertebrates	74
25.	Transmitter immunocytochemistry	79
26	Cualia nualactidas	81

Sessie Num	on ber and Title	Page
27.	Structure and function of the neuroendocrine cell	90
28.	Aging and behavior I	92
29.	Aging and behavior II	96
30.	Neural plasticity in adult animals I	101
31.	Cardiovascular regulation: functional aspects I	104
32.	Peripheral autonomic nervous system I	108
33.	Regulation of autonomic function I	111
34.	Endocrine and autonomic regulation: neural control of immune system	115
35.	Endocrine and autonomic regulation: brain ventricular	
	system	118
36.	Behavioral pharmacology: dopamine	119
37.	Behavioral pharmacology: serotonin	125
38.	Behavioral pharmacology I	127
39.	Behavioral pharmacology II	134
40.	Peptides: biochemical characterization	137
41.	Peptides: physiological effects II	140
42.	Axoplasmic transport I	145
43.	Axoplasmic transport II	146
44. 45.	Symposia—1:00 РМ Cell recognition in development of the nervous sys- tem. <i>Chaired</i> : U. RUTISHAUSER Monoaminergic innervation of cortex: new evidence of anatomical and physiological specificity. <i>Chaired</i> : S. L. FOOTE	151
	Slide Session—1:00 PM	101
46.	Visual cortex: extrastriate visual areas I	152
47.	Drugs of abuse: nonopiates I	155
48.	Characterization of cholinergic receptors	158
49.	Blood-brain barrier I	161
50.	Sensory transduction I	164
51.	Invertebrate learning and behavior I	167
52.	Peptides: receptors I	170
53.	Regional localization of receptors and transmitters I	173
54.	Control of posture and movement I	177
55.	Cardiovascular regulation: functional aspects II	180
	Poster Session—1:00 PM	100
56.	Feeding and drinking: central mechanisms I	183
57.	Feeding and drinking: central mechanisms II	186
58.	Feeding and drinking: central mechanisms III	191

59. Feeding and drinking: central mechanisms IV ..... 192 60. Feeding and drinking: cues for need state I ..... 195

61. Angiotensin and drinking..... 197

62. Feeding and drinking: cues for need state II..... 200 63. Neuropeptides and behavior: vasopressin and oxytocin 202

mechanisms I ..... 205

64. Process outgrowth, growth cones, and guidance

Session Number and Title

65.	Subcortical auditory pathways I	211
66.	Sensory systems in invertebrates I	215
67.	Limbic system: hippocampus and amygdala	218
68.	Cerebellum: microelectrode recordings	224
69.	Pharmacology of synaptic transmission	227
70.	Membrane biophysics: voltage clamp and model	
	analysis	232
71.	Lipids, myelin, and glial proteins	235
72.	Cell and tissue culture: behavior of neural, glial,	
	muscle, and model cells	238
73.	Subcortical somatosensory pathways	244
74.	Somatosensory cortex and thalamo-cortical	
	relationships	248
75.	Spinal cord: cytochemistry and pharmacology	252
76.	Spinal cord: afferent input and local circuits	257
77.	Excitatory amino acids I	260
78.	Neurotoxicity I	265
79.	Diseases of the CNS	268
80.	Opiates I	273
81.	Neuropeptides and behavior: opiates	276
82.	Opiates II	279
83.	Spinal cord and brain stem I	283
84.	Opiates, endorphins, and enkephalins: physiological	
	effects I	287
85.	Peptides: anatomical localization I	290
86.	Metabolism of transmitters and modulators	295
87.	Staining and tracing techniques	298
88.	Identified cells	301

Presidential Symposium—8:00 РМ

89. Neuroscience for society. *Chaired*: D. P. PURPURA...... No abstract

## TUESDAY

#### Symposium—8:30 AM

90.	Lesions of the visual system during infancy or adult-	
	hood: effects on morphology, physiology, and be-	
	havior. Chaired: R. E. KALIL	304

#### Workshop—8:30 AM

91. New approaches to the study of the mechanism of fast axonal transport. *Chaired*: D. S. FORMAN ..... 304

#### Slide Sessions-8:30 AM

92.	Development: endocrine control and transmitter	
	plasticity	304
93.	Cortex I	308
94.	Peptide transmitters in invertebrates	311
95.	Vestibular reflexes: functional organization	314
96.	Endocrine control: central pathways I	317
97.	Synapse elimination, competition, and neuron death I	320
<b>98</b> .	Sensory systems in invertebrates II	323
99.	Opiates, endorphins, and enkephalins: receptors I	327
100.	Learning and memory: anatomy and physiology	330
101.	Biogenic amines I	333

Session		
Number	and	Title

	Poster Sessions—8:30 AM	
102.	Morphology of neurons and glia	336
103.	Cell surface, cytoskeleton, and related	
	macromolecules	342
104.	Cellular localization of receptors	347
105.	Membrane structure and function	350
106.	Cortex and cortico-subcortical relationships II	352
107.	Locomotion I	356
108.	Spinal cord and brain stem II	361
109.	Evoked potentials	364
110.	Evoked potentials: visual	368
111.	Specificity of synaptic connections	371
112.	Development and plasticity: sensory systems	375
113.	Neural plasticity in adult animals II	380
114.	Invertebrate motor function	381
115.	Neuropeptides and behavior	384
116.	Adrenal medulla	387
117.	Regulation of pituitary function I	389
118.	Epilepsy: physiology I	394
119.	Epilepsy: mutants and toxins	399
120.	GABA and benzodiazepines: binding sites I	403
121.	GABA and benzodiazepines: CNS distribution of	
	binding sites	408
122.	GABA and benzodiazepines: electrophysiology and	
	behavior	410
123.	Endocrine control: central pathways II	415
124.	Effects of chronic drug administration:	
	neurotoxicology	420
125.	Effects of chronic drug treatment: psychotropics	424
126.	Psychotherapeutic drugs: antidepressants	427
127.	Psychotherapeutic drugs: neuroleptics	431
128.	Psychotherapeutic drugs: anxiolytics	434
129.	Opiates, endorphins, and enkephalins: anatomical	
	localization	438
130.	Peptides: physiological effects III	442
131.	Functions of glia	447

#### Symposium—1:00 PM

132.	Developmental strategies for selective synapse forma-	
	tion. Chaired: E. FRANK	452

#### Workshop—1:00 PM

133.	Heterogeneity of neurotransmitter receptors. Chaired:	
	H. I. YAMAMURA and I. CREESE	452

#### Slide Sessions-1:00 PM

	Poster Sessions—1:00 PM	
143.	Basal ganglia: behavior and pharmacology I	481
142.	Learning and memory: pharmacology I	478
141.	Visual cortex: intrinsic organization I	474
140.	Spinal cord: somatosensory physiology and behavior	471
139.	Reflex function I	468
138.	Feeding and drinking: neuropharmacology	465
137.	Chemical senses: olfaction and taste I	462
136.	Regulation of pituitary function II	459
135.	Postsynaptic mechanisms I	456
134.	Peptides: anatomical localization II	453

## 

Session	
Number and Title	

Page
------

146.	Subcortical auditory pathways II	495
147.	Action potential and ion channels II	499
148.	Action potential and ion channels III	508
149.	Membrane biophysics I	511
150.	Limbic system and hypothalamus	514
151.	Nutritional and prenatal factors in development I	519
152.	Vestibular compensation and brainstem pathways	522
153.	Reflex function II	526
154.	Neuroethology: nonavian auditory system and	
	vocalization	530
155.	Neuroethology: teleosts	532
156.	Neuroethology: nonteleosts	534
157.	Neuroethology: avian auditory system and	
	vocalization	537
158.	Circuitry and pattern generation I	539
159.	Cardiovascular regulation: hypertension and stress	542
160.	Cardiovascular regulation: central transmitters I	547
161.	Stress, hormones, and the autonomic nervous	
	system I	552
162.	Monoamines and behavior I	555
163.	Monoamines and behavior II	561
164.	Transmitter uptake, storage, and secretion I	564
165.	Transmitter uptake, storage, and secretion II	568
166.	Characterization of noncholinergic receptors	571
167.	Coexistence of transmitters and neuromodulators	575
168.	Characterization of nicotinic receptors	577
169.	Characterization of muscarinic receptors	581
170.	Opiates, endorphins, and enkaphalins: biochemical	
	characterization	584
171.	Peptides: receptors II	589
172.	Cellular aspects of disease	592
173.	Metabolic studies	595

#### Grass Foundation Lecture—8:00 PM

174. Neurobiological bases of innate motor acts in vertebrates. S. GRILLNER...... No abstract

#### Symposia—8:30 AM

- 175. The dynorphin peptides. Chaired: A. GOLDSTEIN..... 600
- 177. Functional reconstruction of neuronal systems. Chaired: D. H. PERKEL and P. A. GETTING ...... 600

#### Slide Sessions-8:30 AM

	Shue Dessions	0.00 / 1.01			
178.	Electrophysiolo	gy of CNS	neurons I	••••••	601

- 180. Cerebellum: olivo-cerebellar function606181. Regulation of autonomic function II610

Session		
Number	and Title	

184.	Molecular biology of gene expression	620
185	Biological rhythms I	623
186.	Epilepsy: pharmacology	627
100.		•=.
	Poster Sessions—8:30 AM	
187.	Control of limb movements	630
188.	Locomotion II	634
189.	Learning and memory: anatomy II	636
190.	Learning and memory: physiology	641
191.	Learning and memory: hippocampal physiology	645
192.	Interhemispheric relations	649
193.	Human neuropsychology I	653
194.	Human behavioral neurobiology	655
195.	Basal ganglia: anatomy and physiology II	658
196.	Spinal cord and brain stem III	663
197.	Nutritional and prenatal factors in development II	666
198.	Neurotoxicity II	668
199.	Action potential and ion channels IV	672
200.	Electrophysiology of CNS neurons II	677
201.	Sensory transduction II	682
202.	Retina I	685
203.	Synaptogenesis I	687
204.	Regeneration: central I	693
205.	Regeneration: central II	697
206.	Development of the visual system: retina and	
	geniculate	700
207.	Regulation of pituitary function III	703
208.	Regulation of pituitary function IV	707
209.	Interaction between neurotransmitters	713
210.	Transmitters and receptors in disease I	718
211.	Regional localization of receptors and transmitters II	723
212.	Pineal gland	728
213.	Postsynaptic mechanisms II	732
214.	Vestibular sensory organs	737
215.	Opiates, endorphins, and enkephalins: physiological	
	effects II.	740

Page

#### Symposia—1:00 РМ

216.	Excitatory amino acid neurotransmitters. Chaired: C.	
	W. Cotman	744
217.	Applications of neuroscience to human prostheses.	
	Chaired: F. T. HAMBRECHT	744
218.	The neurogenetics of identified cells. Chaired: R. J.	
	WYMAN	745

#### Slide Sessions—1:00 PM

219.	Peptides: biosynthesis and metabolism I	745
220.	Oculomotor system: cortico-collicular organization	749
221	Circuitary and nottom generation II	752

- 221. Circuitry and pattern generation II752222. Cell surface and related components756
  - CONTINUED IN SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 9 PART 2

## THEMATIC LIST OF SESSIONS

(Includes slide and poster sessions, symposia, and workshops only.)

#### Theme A: Development and Plasticity

Session Number	Session Title	Туре	Day	Time
271		Poster	Thu	8 30 AM
271.	Aging I	Poster	Thu	8.30 AM
309	Aging II	Slide	Thu	1.00 pm
246	Cell lineage and differentiation I	Poster	Wed	1.00 PM
263	Cell lineage and differentiation I	Slide	Thu	8·30 AM
44	Cell recognition in development of the nervous system	Symp.	Mon	1:00 PM
274	Development and plasticity: autonomic nervous system	Poster	Thu	8:30 AM
276	Development and plasticity: biochemical and pharmaco-			
270.	logical correlates I	Poster	Thu	8:30 am
320.	Development and plasticity: biochemical and pharmaco-			
	logical correlates II	Poster	Thu	1:00 pm
273.	Development and plasticity: denervation	Poster	Thu	8:30 am
319.	Development and plasticity: endocrine control	Poster	Thu	1:00 рм
277.	Development and plasticity: limbic system	Poster	Thu	8:30 am
17.	Development and plasticity: peripheral regeneration	Poster	Mon	8:30 am
19.	Development and plasticity: retinotectal system I	Poster	Mon	8:30 am
223.	Development and plasticity: retinotectal system II	Slide	Wed	1:00 pm
112.	Development and plasticity: sensory systems	Poster	Tue	8:30 am
182.	Development and plasticity: trophic agents I	Slide	Wed	8:30 am
243.	Development and plasticity: trophic agents II	Poster	Wed	1:00 pm
6.	Development and plasticity: trophic interactions I	Slide	Mon	8:30 am
244.	Development and plasticity: trophic interactions II	Poster	Wed	1:00 pm
179.	Development of invertebrates I	Slide	Wed	8:30 am
242.	Development of invertebrates II	Poster	Wed	1:00 pm
20.	Development of motor systems	Poster	Mon	8:30 am
352.	Development of the visual system: cortex	Poster	Fri	8:30 am
206.	Development of the visual system: retina and geniculate	Poster	Wed	8:30 am
11.	Development of the visual system: retinothalamic projections	Slide	Mon	8:30 am
92.	Development: endocrine control and transmitter plasticity	Slide	Tue	8:30 am
275.	Developmental disorders	Poster	Thu	8:30 am
308.	Developmental specificity	Slide	Thu	1:00 pm
132.	Developmental strategies for selective synapse formation	Symp.	Tue	1:00 рм
18.	Effects of activity and inactivity on development	Poster	Mon	8:30 am
245.	Morphogenesis and pattern formation	Poster	Wed	1:00 pm
30.	Neural plasticity in adult animals I	Poster	Mon	8:30 am
113.	Neural plasticity in adult animals II	Poster	Tue	8:30 am
248.	Neural plasticity in adult animals III	Poster	Wed	1:00 pm
354.	Neural plasticity in adult animals IV	Poster	Fri	8:30 am
241.	Neurogenetics	Poster	Wed	1:00 рм
78.	Neurotoxicity I	Poster	Mon	1:00 рм
198.	Neurotoxicity II	Poster	Wed	8:30 am
360.	Neurotoxicity III	Poster	Fri	8:30 am
151.	Nutritional and prenatal factors in development I	Poster	Tue	1:00 pm
197.	Nutritional and prenatal factors in development II	Poster	Wed	8:30 am
64.	Process outgrowth, growth cones, and guidance mech-			٠
	anisms I	Poster	Mon	1:00 pm

302.	Process outgrowth, growth cones, and guidance mech-			
	anisms II	Slide	Thu	1:00 pm
204.	Regeneration: central I	Poster	Wed	8:30 am
205.	Regeneration: central II	Poster	Wed	8:30 am
226.	Regeneration: central III	Slide	Wed	1:00 pm
111.	Specificity of synaptic connections	Poster	Tue	8:30 am
287.	Sprouting I	Poster	Thu	8:30 am
288.	Sprouting II	Poster	Thu	8:30 am
97.	Synapse climination, competition, and neuron death I	Slide	Tue	8:30 am
247.	Synapse elimination, competition, and neuron death II	Poster	Wed	1:00 pm
203.	Synaptogenesis I	Poster	Wed	8:30 am
342.	Synaptogenesis II	Slide	Fri	8:30 am
218.	The neurogenetics of identified cells	Symp.	Wed	1:00 pm
267.	Visual cortical development	Slide	Thu	8:30 am

#### Theme B: Cell Biology

Session Number	Session Title	Туре	Day	Time
42.	Axoplasmic transport I	Poster	Mon	8:30 am
43.	Axoplasmic transport II	Poster	Mon	8:30 am
346.	Axoplasmic transport III	Slide	Fri	8:30 am
49.	Blood-brain barrier I	Slide	Mon	1:00 pm
255.	Blood-brain barrier II	Poster	Wed	1:00 pm
222.	Cell surface and related components	Slide	Wed	1:00 pm
103.	Cell surface, cytoskeleton, and related macromolecules	Poster	Tue	8:30 am
72.	Cell and tissue culture: behavior of neural, glia, muscle, and			
	model cells	Poster	Mon	1:00 pm
5.	Cell and tissue culture: neurons, glia, and neuronal models	Slide	Mon	8:30 am
172.	Cellular aspects of disease	Poster	Tue	1:00 pm
104.	Cellular localization of receptors	Poster	Tue	8:30 am
131.	Functions of glia	Poster	Tue	8:30 am
88.	Identified cells	Poster	Mon	1:00 pm
343.	Immunohistochemistry of specific cellular components	Slide	Fri	8:30 am
71.	Lipids, myelin, and glial proteins	Poster	Mon	1:00 pm
105.	Membrane structure and function	Poster	Tue	8:30 am
173.	Metabolic studies	Poster	Tue	1:00 pm
184.	Molecular biology of gene expression	Slide	Wed	8:30 am
102.	Morphology of neurons and glia	Poster	Tue	8:30 am
91.	New approaches to the study of the mechanism of fast axonal			
	transport	Wksh.	Tue	8:30 am
87.	Staining and tracing techniques	Poster	Mon	1:00 pm
27.	Structure and function of the neuroendocrine cell	Poster	Mon	8:30 am
176.	The acidic interior of secretory vesicles: mechanisms and im- plications for neurobiology	Symp.	Wed	8:30 am

#### Theme C: Excitable Membranes and Synaptic Transmission

Session Number	Session Title	Туре	Day	Time
10.	Action potential and ion channels I	Slide	Mon	8:30 am
147.	Action potential and ion channels II	Poster	Tue	1:00 pm
148.	Action potential and ion channels III	Poster	Tue	1:00 pm
199.	Action potential and ion channels IV	Poster	Wed	8:30 am

300.	Biochemistry of synaptic regulation	Symp.	Thu	1:00 pm
321.	Diseases of synapses and axons	Poster	Thu	1:00 pm
330.	Effects of drugs on receptors	Poster	Thu	1:00 pm
178.	Electrophysiology of CNS neurons I	Slide	Wed	8:30 am
200.	Electrophysiology of CNS neurons II	Poster	Wed	8:30 am
322.	Epilepsy: miscellany	Poster	Thu	1:00 pm
118.	Epilepsy: physiology I	Poster	Tue	8:30 am
266.	Epilepsy: physiology II	Slide	Thu	8:30 am
23.	Excitable membranes and synaptic transmission: invertebrate			
	studies	Poster	Mon	8:30 am
149.	Membrane biophysics I	Poster	Tue	1:00 pm
345.	Membrane biophysics II	Slide	Fri	8:30 am
70.	Membrane biophysics: voltage clamp and model analysis	Poster	Mon	1:00 pm
69.	Pharmacology of synaptic transmission	Poster	Mon	1:00 pm
135.	Postsynaptic mechanisms I	Slide	Tue	1:00 pm
213.	Postsynaptic mechanisms II	Poster	Wed	8:30 am
254.	Presynaptic mechanisms I	Poster	Wed	1:00 pm
304.	Presynaptic mechanisms II	Slide	Thu	1:00 pm
50.	Sensory transduction I	Slide	Mon	1:00 pm
296.	Synaptic structure and function I	Poster	Thu	8:30 am
341.	Synaptic structure and function II	Slide	Fri	8:30 am

#### Theme D: Neurotransmitters, Modulators, and Receptors

Session Number	Session Title	Type	Dav	Time
		<b>J</b>		
283.	Acetylcholine: biosynthesis and electrophysiology	Poster	Thu	8:30 am
281.	Acetylcholine: biosynthesis and regulation	Poster	Thu	8:30 am
282.	Acetylcholine: cellular structures and projection pathways	Poster	Thu	8:30 am
38.	Behavioral pharmacology I	Poster	Mon	8:30 am
39.	Behavioral pharmacology II	Poster	Mon	8:30 am
36.	Behavioral pharmacology: dopamine	Poster	Mon	8:30 am
37.	Behavioral pharmacology: serotonin	Poster	Mon	8:30 am
101.	Biogenic amines I	Slide	Tue	8:30 am
333.	Biogenic amines II	Poster	Thu	1:00 pm
291.	Catecholamines: adrenergic physiology	Poster	Thu	8:30 am
325.	Catecholamines: adrenergic receptors	Poster	Thu	1:00 pm
332.	Catecholamines: anatomical localization	Poster	Thu	1:00 pm
289.	Catecholamines: biochemical characterization I	Poster	Thu	8:30 am
290.	Catecholamines: biochemical characterization II	Poster	Thu	8:30 am
13.	Catecholamines: dopamine receptors I	Slide	Mon	8:30 am

SYMPOSIUM. SEXUALLY DIMORPHIC BEHAVIORS: DIFFERENTIATION IN MAMMALS. <u>T. O. Fox</u>, Children's Hosp., Harvard Med. Sch. (Chairman); <u>J. F. DeBold</u>, Tufts Univ.; <u>M. J. Baum</u>, M.I.T.; <u>K. L. Olsen</u>, SUNY, Stony Brook; <u>F. S. yom Saal</u>, Univ. Missouri, Columbia. The study of sexually dimorphic behaviors, including those with the study of sexually dimorphic behaviors, including those the study of sexually dimorphic behaviors. 2

The study of sexually dimorphic behaviors, including those involved in reproduction, aggression, play and other activities, has led to the elucidation of many aspects of neural sexual differentiation. Concepts associated with the development and maintenance of these behaviors provide much of the rationale for studies on sexual differentiation of the brain. This symposium addresses several advances in our understanding of sexual behaviors and their determinants, with special attention to generalizations which may be appropriate only within species and consequently to emerging concepts which diverge from previously accepted dogma. The results of experiments to assess the effects of gonadal steroids on behavior require control of the environmental, social, and hormonal status of the animals and ability of investigators to observe subtleties of behavior. Effects of different doses of androgens and of non-hormonal influences on aggressive behaviors by both female and male rodents will be described (DeBold). The relative influence of androgens and estrogens varies among species and feminine sexual behavior and neuroendocrine cyclicity in adulthood. This process of defeminization occurs in male rodents in response to the action of estradiol, formed in the developing brain from circulating androgens. Evidence indicates that coital defeminization as observed in rodents does not occur in males of several higher mammalian species. This includes a carnivore, the ferret, despite the presence in males of high levels of neural estrogen biosynthesis and receptors during the perinatal period of sexual differentiation (Baum). Possible involvement of androgen receptors can be examined, and attempts can be made to distinguish these from the effects mediated by estrogen formation, by analyzing the responses of

Possible involvement of androgen receptors can be examined, and attempts can be made to distinguish these from the effects mediated by estrogen formation, by analyzing the responses of genetic mutants with androgen resistance. These display defects in androgen receptors along with deficiencies of male traits. Comparisons between mice and rats with androgen resistance are being made for both male and female aspects of reproductive behaviors (Olsen). Male-typical and female-typical behaviors are expressed to variable extents in the other sex. The extent and nature of this phenomenon is species dependent. Intra-uterine position correlates with the extent of heterotypical behavior displayed. Parameters of these effects on both females and on males will be discussed. This system provides a means for examining individuality in behavior and for asking how this influences populations and evolution of behaviors (vom Saal).

WORKSHOP. RECIPROCAL INHIBITION AND COACTIVATION OF ANTAGONIST 3 WORKSHOP. RECEPROCE INHIBITION AND CONCTIVATION OF ANTAGONIST MUSCLES: TWO FUNDAMENTAL MODES OF MOTOR CONTROL. D.R. Humphrey, Bnory Sch. Med.; A.M. Smith, Univ. Montreal; Y. Lamarre, Univ. Montreal; T.R. Nichols, Univ. Washington; Y. Shinoda, Tokyo Med. Dent. Univ.; E. Bizzi, MIT. Following the pioneering studies by Sherrington in the decere-tering the pioneering studies by Sherrington in the decere-tering the pioneering studies by Sherrington in the decere-tering the pioneering studies of the studies of

inhibition as the major pattern of activation of the antagonist muscles which act about a particular joint. Recent studies have emphasized, however, that many motor activities involve a coacti-vation of antagonist muscles, either as a means of stabilizing the course of movement of a joint during motor learning or in the presence of unpredictable external perturbations, or of fixing the position of a joint in one plane as a postural support for orthogonal movements about the same joint, or movements of adja-cent joints. This workshop focuses on the conditions under which these fundamental patterns of muscle activation occur, and their central correlates. Lamarre will present evidence from studies with normal and deafferented monkeys and humans, which indicates that reciprocal inhibition, coactivation and triphasic patterns of antagonist activation are centrally generated, with peripheral marize evidence from studies in the cat which indicates that these two forms of muscle activation can be evoked by stimulation of dif-ferent brain stem sites. He will discuss also the motor control ferent brain stem sites. He will discuss also the motor control advantages that are offered by these two different patterns of muscle activation. Smith will summarize data from studies of cerebellar neuron activity in the monkey which indicates that a suppression of Purkinje cell discharge may be necessary for swit-ching between reciprocal inhibitory and coactivation modes of con-Shinoda will summarize evidence from studies of branching trol patterns of single axons in cerebello-thalamo-motor cortex and corticospinal pathways, which indicates that axonal divergence is sufficient to suggest that functional groupings of muscles will ultimately be affected by activity in even single central neurons. Humphrey will present evidence from studies in the monkey which indicates that the efferent outflow of the motor cortex is organized not for the control of single muscles, but for entire sets of muscles that are responsible for certain fundamental move-ments, and their postural support; in the latter function, antagonist muscles are often coactivated. Bizzi will conclude the for-mal presentations by summarizing evidence from EMG studies in man concerning the patterns of muscle activation that are seen across the arm, during voluntary, guided movements, in which case both movement and postural support patterns must be generated. The session will close with a round table discussion, in which new avenues of research are suggested and discussed.

#### PAIN MODULATION: BULBOSPINAL MECHANISMS

LIGHT AND ULTRASTRUCTURAL IMMUNOCYTOCHEMICAL LOCALIZATION OF 41 SEROTONIN SYNAPSES ON PRIMATE SPINOTHALAMIC TRACT NEURONS M.A. Ruda and J. Coffield\*. NAB, NIDR, NIH, Bethesda, MD 20205. Serotonin (5-HT) neurons in the brain stem are a major source of descending inhibition in the spinal cord. Spinothalamic tract (STT) cells comprise a major pathway for the transmission of nociceptive information from the dorsal horn to higher centers of the neuraxis. Using the combined techniques of retrograde transport of horseradish peroxidase (HRP) and immunocytochemistry, synaptic interactions between these systems can be identified. To label STT cells, HRP was injected into the thalamus of 2 rhesus monkeys. After 72-84 hrs, the animals were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde in phosphate buffer. The cervical and lumbar spinal cords were sectioned on a Vibratome at 50  $_{\rm Um}$  and processed with CoCl\_-intensified DAB to yield a black reaction processed with cool-intensified up to be done to processed specific afferent input, the tissue was subsequently processed for PAP immunocytochemistry to produce a red-brown label. Tissue used for light microscopic (LM) analysis was processed with 0.75% Triton X-100 to facilitate penetration of the immunocytochemical stain throughout the section. Tissue for ultrastructural  $(\mathbb{E}\mathbb{N})$  analysis was initially screened at the LM level, after clearing in glycerin, with a lOOX oil immersion objective to identify STT cells contacted by S-HT immunoreactive axonal endings. LM and EM analyses focused on the somata and proximal dendrites of STT cells in laminae I and V. Most 5-HT contacts were located on proximal dendrites of these STT cells rather than on the cell somata. In lamina I, both small and large bipolar and multipolar Sometal in finantial to be sampled appeared to receive a variable number of 5-HT contacts. In lamina V, larger multipolar neurons  $(25-35 \ \mu\text{m})$  often received more than five 5-HT contacts while small bipolar neurons received less. More than half of the laminae I and V STT cells sampled appeared to receive 5-HT con-STT cells were marked by clectron dendrites. At the EM level, immunoreactive endings contained PAP reaction product. In laminae I and V, 5-HT axonal endings contacting STT cells varied from 0.8-2.5 km in length, and contained oval agranular vesicles and a few dense core vesicles. They formed symmetrical or slightly asymmetrical synaptic contacts. STT cells receiving 5-HT synapses typically received synapses from numerous other unlabeled endings. These observations demonstrate that a subset of STT cells in laminae I and V can be postsynaptically modulated directly by descending 5-HT afferent input. Since STT neurons receiving 5-HT input are contacted by numerous other axonal endings, a major site of modulation of the transmittal of noxious information appears to occur directly on the proximal portion of STT cells.

IONTOPHORETIC STUDY OF BIOGENIC AMINE AND PEPTIDE EFFECTS ON PRI-4.2 NATE SPINOTHALAMIC TRACT CELLS. <u>Wm.S.Willcockson\*, J.M.Chung</u>, Y.Hori\*, K.H.Lee\*, and W.D.Willis (SPON: J.P.Gallagher). Marine Biomed. Inst. & Depts. of Physiol. & Biophysics and Anatomy, Univ. TX Med. Branch, Galveston, TX 77550. A full understanding of the role of the spinothalamic tract (STT) in the transmission of pair vocine divertionic in the

(STT) in the transmission of pain requires investigation of the neurochemicals mediating synaptic events in this pathway. Proposed mediators include the biogenic amines serotomin (SHT) and norepi-nephrine (NE), the amino acids glutamate (Glu),  $\gamma$ -aminobutyrate (GABA) and glycine (Glv) and the endogenous peptides enkephalin (EXK) and substance P (SP). SHT, NE, GABA and Gly have had predom-inantly inhibitory effects when jontophoresed onto dorsal horn

interneurons. Glu and SP usually excite dorsal horn cells. The compounds studied include Glu, GABA, Gly, 5HT, NE, dopamine (DA), acetylcholine (ACh), methionine-enkephalin (M-ENK), leucineenkephalin (L-ENK), substance P (SP) and cholecystokinin (CCK). The drugs were applied iontophoretically from 7-barreled glass microdrugs were applied iontophoretically from 7-barreled glass micro-electrodes. Experiments were performed on anesthetized monkeys (<u>Macaca fascicularis</u>). STT cells in the lumbosacral spinal cord were identified antidromically by stimulation in the contralateral thalamus. Drugs were tested for effects on background activity, Glu-induced firing, and activity evoked by pinching the skin. While Glu excited STT cells and was thus used for tests of the other compounds, the amino acids GABA and Gly inhibited Glu- and pinch induced division for the skin.

other compounds, the amino acids GABA and Giy inhibited Glu- and pinch-induced activity in all STT cells tested. STT cells were also inhibited by 5HT, NE and DA. No cases of excitation were observed. Ach inhibited the Glu response of most STT cells, al-though 3 of 21 cells exhibited a slight enhancement of activity. M-EEK and L-ENK produced strong inhibition of background, Glu-

M-EAK and J.EAK produced strong infibition of background, Gu-induced, and pinch-evoked activities. Intravenous naloxone reduced these inhibitory effects. SP had complex effects on STT cells. In addition to excitation or inhibition, biphasic effects such as in-hibition followed by excitation and excitation followed by inhibi-tion were observed. Commonly, single cells had multiple responses to SP, including any combination of single or biphasic effects

to SP, including any combination of single or biphasic effects depending upon changes in dose or electrode position relative to the cell. CCK was strongly inhibitory on all STT cells tested and when applied simultaneously with L-ENK, inhibition was additive. Although most of the effects of amines, amino acids and pep-tides were anticipated from previous work on unidentified inter-neurons, we did not predict the complex actions of substance P, which suggested more than one type of substance P receptor. Fur-thermore, we thought CCK would have an action opposite to that of ENK. (Supported by NIH grants NS 09743 and NS 11255 and a grant from The Woody Foundation.) from The Moody Foundation.)

POSTSYNAPTIC EFFECTS IN SPINAL LAMINA I AND II NEURONS PRODUCED 4.3 Physiology, UNC-Chapel Hill, Chapel Hill, NC 27514

Stimulation of midline, medullary-pontine regions has been shown by others to inhibit nociceptive reactivity in animals and to inhibit the responses of neurons to noxious stimuli. The present study used intracellular recordings to examine postsynaptic potentials and conductance changes in marginal zone (lamina I) and substantia gelatinosa (lamina II) neurons following small, single stimuli delivered to the midline medulla and pons. Tungsten monopolar microelectrodes (10 meg-ohm) were used to deliver test volleys (1-10  $\mu$  amp, 0.2 msec) to the medulla, and horseradish peroxidase (HRP)-containing micropipettes were used to record neurons intracellularly and to label some neurons for correlative morphological studies. Small hyperpolarizing pulses were delivered through the micropipette to measure the conductance changes. Nociceptive neurons were either inhibited by stimulation of midline medulla or showed no effect. Of those inhibited, all but one demonstrated an IPSP following single stimuli to the medulla. The average latency of the IPSP was 31 msec (range 9.6 - 114 msec; conduction distance  $\sim$  300 mm) indicating that elements with conduction velocities of  $\sim$  10 m/sec Indicating that elements with produced monosynaptically. The ave duration of the IPSP was 206 msec (range of 40 - 450 msec), indicating either very long-lasting synaptic effects or heterogenous conduction velocities of activated descending The average fibers. These IPSPs all occurred with a small conductance increase, which indicates postsynaptic inhibition, but the small size indicates either additional inhibitory mechanisms or remote placing of inhibitory synapses from the recording site. Half the multireceptive (receiving both innocuous and noxious inputs) and innocuous mechanoreceptive neurons were also inhibited by stimulation of midline medulla. For both classes the IPSP had an average latency of 30 msec and a long duration (average around 250 msec). The IPSPs again occurred with a conductance increase. The other half of the neurons in these 2 classes were excited by The other half of the hearons in these 2 classes were <u>excited</u> by stimulation of midline medulla. This excitation was evident as an EPSP which led to an action potential, which in some neurons was followed by a long-lasting IPSP. The EPSP's latency was around 30 msec (300 mm conduction distance) although the duration was much shorter than for the IPSPs (around 12 msec). These distances events the account of the source of the source were the source of the sour findings suggest heterogenous pathways from midline medulla and pons which can selectively postsynaptically inhibit nociceptive neurons and some multireceptive and innocuous mechanoreceptive neurons in laminae I and II, and selectively <u>excite</u> some multireceptive and innocuous mechanoreceptive neurons in these same laminae. Supported by NINCDS grants NS-16433 and NS-00534.

SIGNAL DETECTION ANALYSIS OF THE RESPONSE PROPERTIES OF DORSAL 4.4

AND A DETECTION ANALYSIS OF THE RESPONSE PROPERTIES OF DUSAL HORN NEURONS TO NOXIOUS THERMAL STIMULI. K.C. Kajander\*, D.C. Tam, T.J. Ebner and J.R. Bloedel. (Spon: G.W. King). Depts. of Neurosurgery and Physiology, Univ. of Minn., Mpls., MN 55455. Experiments were designed to evaluate the use of signal detec-tion theory for analyzing the capability of lumbar dorsal home tion theory for analyzing the capability of lumbar dorsal horn neurons to distinguish between thermal stimuli of different in-tensities with and without brainstem stimulation. In decere-brate cats, the unitary responses of 113 neurons to noxious ther-mal stimuli were evaluated with and without electrical stimula-tion of either the periaqueductal gray (PAG) or the nucleus rap-he magnus (NRM). The thermal stimuli consisted of 10° and 12°C temperature pulses with a 2 second rise time beginning from ei-ther a  $42^\circ$  or  $45^\circ$ C baseline. The neurons selected for study in-creased their spontaneous activity in response to the baseline temperature pulse with an increased discharge rate. Each neuron perature pulse with an increased discharge rate. Each neuron was studied under four conditions: conditions 1 and 2 were the 10°C temperature step (S1) with and without brainstem stimula-tion, conditions 3 and 4 were the 12°C temperature step (S2) with and without brainstem stimulation. The time of response onset and without brainstem stimulation. The time of response onset (latency), the duration of the response, and the mean and stan-dard deviation of the discharge rate were determined for each stimulus presentation. Discriminability (d') based on the mean firing frequencies of the responses evoked by S1 and S2 was cal-culated for appropriate neurons. Electrical stimulation prod-uced increases (13 of 25 cases) or decreases (11 of 25 cases) in d' for different neurons. In only one case was d' unaffected by the brainstem stimuli. These changes in d' did not always paral-lel changes in mean firing rate, since the latter decreased in all but one case. Two different estimates of criterion, L(x) were calculated. Using estimates based on mean firing frequency lel changes in mean firing rate, since the latter decreased in all but one case. Two different estimates of criterion, L(x)were calculated. Using estimates based on mean firing frequency of the response in the four different conditions, L(x) was found to always shift to higher values during electrical stimulation. However, when using estimates of L(x) based on the first stan-dard deviation of the firing frequency in the four different con-ditions, L(x) was calculated to be larger for the S2 conditions than for the S1 conditions when the d' value was greater than 2.2. This relationship was reversed when d' was less than 2.2. These data indicate that changes in neuronal responses reflected in changes of d' and L(x) can occur in the spinal cord as a result of activating descending projections from the brainstem known to of activating descending projections from the brainstem known to be important in altering pain perception. This research was sup-ported by NIH Grants ROI-NS 18338 and ROI-NS 09447.

INHIBITORY TASK-RELATED RESPONSES OF MONKEY MEDULLARY DORSAL HORN INHIBITORY TASK-RELATED RESPONSES OF MONKEY MEDULLARY DORSAL HORN NEURONS. G.H. Duncan\*, M.C. Bushnell, R. Bates\* and R. Dubner. Neurobiology & Anesthesiology Br., NIDR, NIH, Bethesda, MD 20205. In previous studies we described mechano- and thermosensitive medullary dorsal horn neurons which, in the behaving monkey, had additional responses associated with significant events within the task. Excitatory task-related responses were studied in detail and were shown to be independent of stimulus intensity or modality. The present study investigated in detail the occur-

rence of inhibitory task-related responses. Data were collected from 4 Rhesus monkeys trained to perform detection tasks involving thermal and visual stimuli. Monkeys initiated a trial by detecting the onset of a light cue and de-pressing a button. They were trained to continue depressing the pressing a button. They were trained to continue depressing the button for a variable period of 3-8 sec. The monkeys terminated the trial by releasing the button after detecting one of the following events: (1) termination of a warming stimulus  $(37^{\circ} 43^{\circ}C)$ ; (2) onset of a noxious thermal stimulus  $(45^{\circ}-49^{\circ}C)$ ; or (3) onset of a second light cue. Single unit activity was recorded in the medullary dorsal horn during performance of the behavioral tech. tasks. Projection neurons were identified by antidromic responses to stimulation of the thalamic ventroposterior medial nucleus. A medullary dorsal horn neuron was defined as having a task-related response if the averaged activity associated with a behavioral event was significantly different from the averaged

neuronal activity occurring between trials (p < .05). Thirty-three medullary dorsal horn neurons were encountered which exhibited task-related responses. Twenty of these 33 neurons contained inhibitory task-related responses. Both the excitatory and inhibitory responses shared many general characteristics: (1) occurrence in neurons whose response properties were otherwise classified as trigeminal mechanoreceptive, trigeminal thermoreceptive or nonspecific reticular; (2) occurrence in trigeminothalamic neurons; (3) association with behavioral events related to trial initiation, trial continuation or trial termination; and (4) independence of modality or intensity of the relevant stimulus. The most common patterns of task-related response involved either exclusive excitation (13/33) or combinations of inhibition and excitation (16/33). Only 4 neurons demonstrated exclusively inhibitory task-related responses.

We have postulated previously that task-related responses may provide signals for altering the gain-control of somatosensory information or for facilitating appropriate goal-directed motor behaviors (button press, button release, or drinking). The presence of inhibitory task-related responses may serve as an enhancing mechanism for these signals.

RAPHE MAGNUS INHIBITION OF UPPER THORACIC SPINOTHALAMIC CELL RESPONSES TO INTRACARDIAC INJECTIONS OF BRADYKININ. N. <u>W. Steve</u> University of

The indication of the first indication on the first i documented to be a spinothalamic tract neuron. The somatic receptive field of each spinothalamic neuron was mapped and its of cardiopuimuma. d. Each of the 19 response to electrical stimulation of sympathetic afferent fibers was determined. Sympathetic afferent libers was determined. Each of the 19 neurons studied received viscerosomatic convergent inputs. RM stimulation (100 Hz, 200  $\mu$ sec duration, 50-500 $\mu$  Å) inhibited the background activity as well as responses to somatic stimuli of all neurons tested. However, particular attention was devoted to RM effects on spinothalamic cell responses to a noxious cardiac stimulus, intracardiac injection of the algesic chemical bradwing (2)  $\mu$  (r). cardiac stimulus, intracardiac injection of the algesic chemical bradykinin (2  $\mu$  g/kg). Bradykinin injection resulted in an increase in cell activity of 13 of 19 neurons from 12  $\pm$  2 to 25  $\pm$  3 impulses per second (p<sup><.001</sup>). Stimulation of RM (average current 300 $\mu$  A) near the peak of the response to bradykinin reduced the cell discharge rate to an average of 3 $\pm$ 1 impulses per second (p<sup><.001</sup>). All 13 bradykinin responsive cells were inhibited by RM stimulation. Six of the 13 responsive neurons exhibited a bursting pattern of activity synchronous with the arterial pressure wave. RM stimulation either eliminated the patterned activity or resulted in more random activity in each case. RM inhibition of spinothalamic responses to a noxious cardia stimulus suggests that the descending systems linked to analgesia may be effective against cardiac pain as well as somatic pain. Supported by National Heart, Lung, and Blood Institute Grants HL22732, HL07430, and HL00557.

ACTIVITY OF RAPHE-SPINAL(DLF) NEURONS IN RELATION TO NOCIFENSIVE 4.7 Horacio Vanegas, Nicholas M. Barbaro\* and Howard L. BEHAVIOR <u>Fields</u>. Departments of Neurology, Neurosurgery and Physiology, University of California, San Francisco, CA 94143.

The nucleus raphe magnus and adjoining regions of the rostral ventromedial medulla (RVM) project via the spinal dorsolateral Ventromedial medulia (kVM) project via the spinal doisoidetai funiculus (DLF) to inhibit nociceptive transmission and nocifensive reflexes. We have shown (Fields et al., Soc. Neurosci. Abstr. §:806; 1982) that, just before heat-elicited tail-flick (TF), the activity of some RVM neurons suddenly increases (on-cells) or abruptly decreases (off-cells). We have now studied whether such neurons project to the spinal cord via the DLF.

Rats were initially anesthetized with pentobarbital (60 mg/kg IP) and later maintained in a lightly anesthetized state by a constant infusion of methohexital (15-30 mg/kg.hr IV). The cervical spinal cord was exposed and bathed in mineral oil. TF was elicited by controlled heating of the ventral surface of the tail to 54°C for a maximum of 10 sec. A stainless steel Pt-Au tip-plated microelectrode was stereotaxically driven into an RVM region where TF could be inhibited by stimulating with continuous trains of 50 Hz cathodal pulses (400  $\mu$  sec,  $\leq$  10  $\mu$  A). The same microelectrode was then connected for single unit recording. The cord surface over the DLF was stimulated through bipolar, 0.5 mm diameter silver ball electrodes.

Of 48 cells that were antidromically driven from DLF, as proven by collision tests, 9 (19%) increased their firing rate just prior to TF collision tests, 9 (19%) increased their firing rate just prior to TF (on-cells), 9 (19%) abruptly ceased firing just before TF (off-cells), and 30 (62%) showed no change in activity related to TF (neutral cells). Other on-cells (N=6) and off-cells (N=10) could not be driven antidromically from DLF. Calculated conduction velocities (m/sec) were 17.6 (10.9-27.8) for on-cells, 10.3 (5.2-18.8) for off-cells and 12.9 (6.6-28.8) for neutral cells. Histological verification showed that all units were located within RVM at the level of the rostral portion of the VII nucleus. Cells that were antidromically driven from DLF were consistently more caudal than cells that were not driven.

These results show that RMM cells having activity changes that directly precede nocifensive reflexes project to the spinal cord via On-cells have a higher mean conduction velocity than offthe DLF. cells (p<0.02, two-tailed trest), and both values are within the range for myelinated fibers. On- and off-cells which project to the These results suggest that either the on- or the off-cells, or both, are the output cells for RVM modulation of nociceptive transmission and nocifensive reflexes at the level of the spinal cord. #### CHOLINERGIC INTERACTIONS BETWEEN IDE COLL CUNEIFORMIS AND NUCLEUS RAPHE MAGNUS IN THE RAT. Mich M Pobbahani Deborah Haggard\*. Dept. of Physiology, Univ. CHOLINERGIC NUCLEUS Michael M. Bebbehani, Deborah Haggard\*. Dept. of Physiology, Univ. of Cincinnati Coll. of Medicine, Cincinnati, OH 45267. It is now well established that activation of the cells in the nucleus raphe magnus (NRM) and its adjacent area, the nucleus magno cellularis

(NMC) produces analgesia by inhibiting dorsal horn neurons that respond to noxious stimulation. Anatomical studies have shown that a major to noxious stimulation. Anatomical studies have shown that a major source of afferents to the NRM is from the periagueductal gray and the nucleus cuneiformis (NC). In this study we examined the response of the NRM neurons to NC stimulation and tested the possibility that acetyleholine (ACh) may be involved in the interaction between NC and NRM and that it may produce its effect through inhibition of GABA release

Male Sprague-Dawley rats were anesthetized with 1.2g/kg of urethane and prepared for single unit recording. Two stimulating electrodes separated by 1mm, were placed into the NC area. (AP -5.8, D 5.5, L 1.5.) A five barrel electrode consisting of ACh (0.5M), scopolamine (0.5M), either glutamic acid (200mM), or picrotoxin (5mM) NaCl (2M) and a recording electrode was placed in NRM at coordinate of 12-12.5mm caudal to bregma, 0.0 to 0.1mm lateral and 8.9mm below the surface with the electrode inserted at 20 degrees with respect to the vertical plane. The activity of 50 cells in the NRM was examined. Thirty percent of

the cells responded to NC stimulation by excitation. The response latency ranged between 7 to 35 msec., with a mean of 12 msec. Sixteen percent of the cells were inhibited by NC stimulation and the others did not respond. When the response of the NRM cells to ACh was examined, 50% of the cells that responded to NC stimulation were excited by iontophoretically applied ACh, and their response to NC stimulation and to ACh could be totally or partially blocked by scopolamine. In 20% of the cells ACh and stimulation of NC produced excitation that could not be blocked by scopolamine. In 6% of the cells the response to ACh was blocked, but the response to NC stimulation was not affected and in 14%, the response to NC was blocked by scopolamine. In the majority of the cells, scopolamine caused a reduction in the baseline firing of the cells without any effect on the height of the action potentials. Scopolamine, at a dose the cells responded to NC stimulation by excitation. The response latency any effect on the height of the action potentials. Scopolamine, at a dose that blocked the response to ACh, also reduced the response to glutamic acid. Iontophoretically applied picrotoxin caused an increase in the baseline firing of the cells and blocked the response of the NRM neurons to ACh. The results of this study indicate that the major projection from NC to NRM is excitatory and that ACh plays an important role in the interaction between these sites. Since the effect of ACh could be blocked by scopolamine it is concluded that its action is mediated through muscarinic receptors. The action of picrotoxin indicates that the ACh effect may be due to inhibition of GABA release by a presynaptic mechanism.

THAT MORPHINE PRODUCES EVIDENCE ANALGESTA ΒY 48 DISINHIBITING BRAINSTEM NEURONS

Greg Zorman\*, Horacio Vanegas, Ian Hentall and Howard Fields (SPON: D. Greenberg). Departments of Neurology, Physiology and Neurosurgery, University of California, San Francisco 94143. The rostroventral medulla (RVM) contains a class of descending

The rostroventral medulla (KVM) contains a class of descending neurons which show an abrupt pause in firing prior to tail flick (TT) elicited by a noxious thermal stimulus (Fields et al, Neurosci. Abstr. 8:806, 1982). To study the contribution of these "off-cells" to the modulation of pain we have recorded their TF related activity after administration of morphine and naloxone. Male Sprague-Dawley rats (325-375 gm) were initially anesthetized with 70 mg/kg pentobarbital (i.p.) and maintained by constant infusion of methohexital (15-30 mg/kg/hr i.v.) which assured a stable baseline TF latency. A stainless steel Pt-Au

assured a stable baseline TF latency. A stainless steel Pt-Au tip-plated microelectrode was stereotaxically placed in the RVM at sites where TF could be inhibited by continuous trains of  $\leq 10 \text{ }\mu\text{A}$ , 50 Hz, 400 µsec monopolar, cathodal pulses. The same electrode was then used for recording the activity of "off-cells" during tail heating. Peristimulus histograms were plotted as a function of either TF or tail temperature: a) before morphine; b) after administration of morphine (2.5 mg/kg i.v.); and c) after administration of naloxone (0.25 mg/kg i.v.). One off-cell was studied per rat.

All off-cells were spontaneously active. Most cells increased their background activity following morphine administration, while one clearly decreased. After morphine the TF was blocked and the pause in off-cell discharge was abolished in all cells. In rats where longterm stable recordings were possible, naloxone restored the TF and, concurrently, the pause in firing. All cells recorded were shown histologically to be in the RVM.

These results suggest that systemically administered opiates produce analgesia by disinhibiting brainstem neurons that control nociceptive transmission at the level of the spinal cord.

PREFRONTAL INFLUENCES UPON PERIAQUEDUCTAL GRAY AND ADJACENT 4.10 REGIONS. S.G.P. Hardy and H.J. Haigler. Dept. of Anatomy, Univ. of Mississippi Medical Center, Jackson, MS 39216.

In anatomical studies, it has been demonstrated that the prefrontal cortex (PFC) sends numerous projections to the periaque-ductal gray (PAG) and adjacent regions. Furthermore, it has been speculated that the PFC may modulate analgesic functions ascribed to these regions. Neurons in these regions, which alter their firing rates in response to PFC stimulation, are identified in tiring rates in response to PFC stimulation, are identified in this study. These neurons are also characterized as to whether they alter their firing rates in response to noxious stimulation and the microiontophoresis of various neurotransmitter substances. In urethane anesthetized rats, bipolar stimulating electrodes were placed in the medial PFC. The electrical stimulus admini-stered to this site was a 12 sec train of 500 µsec square waves, delivered at the rate of 10/sec, and having a peak-to-peak inten-city of 200.800 µk. Evtracellular recordings wave med from sity of 300-800  $\mu$ A. Extracellular recordings were made from spontaneously firing neurons in the region of the PAG, using a 5-barrel micropipette. The recording and balance barrels were filled with 2M and 4M NaCl, respectively, and the remaining barrels were filled with methionine-enkephalin (ME;0.01M), norepinephrine (NE;0.2M) and acetylcholine (ACh;0.02M). Noxiou stimulus (foot pinch) was administered to the left hind paw, Noxious using an analgesy meter (Stoelting).

using an analgesy meter (Stoelting). Most of the 73 neurons recorded responded to PFC stimulation with a response latency of 15-20 msec. Forty-nine neurons alter-ed their firing rates (71% decreased; 29% increased) following the PFC stimulus. Furthermore, 77% of these neurons also respond-ed to the presence of a noxious stimulus. Of these, 64% in-creased their firing rates in response to noxious stimulation. The influence of concomitantly-administered PFC and noxious stimuli was studied in 4 neurons, in which PFC stimulation was inhibitory and noxious stimulation was facilitory. In each case the neuronal response to noxious stimulation was completely blocked by the presence of PFC stimulation.

When the previously mentioned neurotransmitter substances were ejected into the recording sites, it was observed that each would occasionally cause the neuron to alter its firing rate in a manner which mimicked the response to PFC stimulation. This mimicry was elicited in 100%, 52% and 29% of the neurons studied with ME, NE and ACh respectively.

The results of this study demonstrate that one of the functions of the PFC is to inhibit nociresponsive neurons of the PAG region. Furthermore, the results of this study suggest two putative neuro-transmitters which may mediate this PFC effect, i.e. ME and NE. This project was supported in part by NIDA Grant 1-R01-DA-01344-06 to HJH and NIH Grant 5-S07-RR05386.

THE PERIAQUEDUCTAL GRAY PROJECTIONS TO THE RODENT SPINAL TRI-CEMINAL, RAPHE MAGNUS, GIGANTOCELLULAR PARS ALPHA AND PARA-GIGANTOCELLULAR NUCLEI ARISE FROM SEPARATE NEURONS. A.J. Beitz, 4.11 W.A. Mullett\* and L.L. Weiner\*. Dept. of Vet. Biology, Univ. of Minnesota, St. Paul, MN 55108. Possible collateral branches of midbrain periaqueductal gray (PAG) axons which distribute to the nucleus raphe magnus,

nucleus reticularis gigantocellularis pars alpha, nucleus reticularis paragigantocellularis and the spinal trigeminal nucleus were analyzed with the double fluorescent retrograde tracer technique, developed by Kuypers and co-workers (1980). T five adult Sprague-Dawley Rats received injections of the Twentytracers fast blue (FB) and nuclear yellow (NY) into various combinations of the above four nuclear groups. Fast blue combinations of the above four nuclear groups. Fast blue (3-5%) was typically injected 48-84 h prior to killing the animal while NY (1-2%) was injected 24-36 h prior to perfusion. The animals were subsequently perfused with 125 ml of hypertonic saline (1.5%) followed by 1000 ml oʻlo% formalin in citrate buffer (pH 7.18). Thirty-five micron frozen sections were subsequently cut, air dried and viewed with an Olympus BH-2 fluorescent microscope. The location of NY-labeled, FB-labeled, Jabeled labeled labeled reaction the DAC more then labeled and double labeled neurons within the PAG were then plotted for each case. Double labeled neurons were identified by the presence of a light blue fluorescence in the cytoplasm of the cell body and dendrites and an intensely yellow or white fluorescent nucleus. With the exception of a small number of double labeled neurons observed in the PAG following injections of fluorescent dyes into the nuclei reticularis paragiganto-cellularis and gigantocellularis pars alpha, no double labeled cells were found in this midbrain region following injections of tracers into various combinations of the above four nuclear Injection of the retrograde tracers into these nuclei groups. groups. Injection of the referograde tracers into these nuclei resulted in labeling predominantly within the ventrolateral, lateral and dorsal portions of the PAG. No double labeled neurons were observed in the majority of our cases despite the fact that the location of FB- and NY-labeled cells within the PAG overlapped extensively. The results of this investigation indicate that the nucleus raphe magnus, the nuclei reticularis gigantocellularis pars  $\alpha$  and paragigantocellularis and the spinal trigeminal nucleus are innervated by separate neuronal populations within the PAG.

- PYRAMIDAL TRACT MEDIATION OF CORTICOSPINAL INHIBITION 4.12
  - E. Carstens, M.J. Guinan<sup>\*</sup>, S. Pretel & S.N. Suberg. Dept. Animal Physiol., Univ. of Calif., Davis, CA 95616. Electrical stimulation in the medial posterior sigmoid gyrus (hindlimb region of somatosensory cortex) inhibited the responses of contralateral spinal dorsal horn neurons to noxious skin heat-ing in the cat (Pretel et al., <u>Soc. Neurosci. Abs.</u> 8:767, 1982). We have investigated the role of the pyramidal tract in mediating this corticospinal inhibition by determining if (1) medullary pyramidal stimulation inhibits dorsal horn neurons in a similar manner, and (2) corticospinal inhibition is blocked by lesion of the medullary pyramid.

The responses of single lumbar dorsal horn units to noxious heating of glabrous footpad skin, or to other stimuli, were recorded in cats anesthetized with sodium pentobarbital and ventilated with 70% N\_20. Electrical stimuli (single 0.1 msec pulses, or 100 msec pulse trains at 100 Hz, 3/s, up to 300  $\mu$ A) were delivered through bipolar electrodes positioned in the posterior sig-moid gyrus, medullary pyramid, and in some experiments in the cerebral peduncle or internal capsule (IC). Single-pulse stimulation in the medullary pyramid (contralater-

al to the spinal unit and rostral to the pyramidal decussation) orthodromically excited 18 of 19 tested units in laminae IV-VI. Pyramidal stimulation using pulse trains inhibited the responses of each of 24 units evoked by noxious skin heating. Thresholds for inhibition were lower than those for excitation. The respon The responses of dorsal horn units to a series of graded heat stimuli in-creased linearly from threshold  $(40-44^{\circ}C)$  to  $52^{\circ}C$ . When the series was repeated during pyramidal train stimulation (15-70  $\mu$ A) the slope of the linear temperature-response line was reduced with little change in threshold in 8 units, as was the case with cortical stimulation. Stimulation in the IC or cerebral peduncle bi-laterally also had a similar effect in 9 units. Inhibition pro-duced by pyramidal or IC stimulation was unaffected following systemic administration of the serotonin antagonist methysergide (1 mg/kg) in 4 units, similar to the lack of effect of methysergide on corticospinal inhibition.

Inhibition of dorsal horn unit heat-evoked responses produced by cortical stimulation was reduced or abolished following electrolytic lesion of the medullary pyramid contralateral to the spinal unit in 3 cases. Corticospinal inhibition was not affected by a similar lesion below the level of the pyramidal decussation in a fourth unit.

The results indicate that corticospinal inhibition may be mediated by axons descending in the medullary pyramid.

#### CELL AND TISSUE CULTURE: NEURONS, GLIA, AND NEURONAL MODELS

5.1 DISSOCIATED CHICK SUPERIOR CERVICAL GANGLION NEURONS IN CULTURE. A.D. Zurn\* and F.L. Mudry\* (SPON: B. Fulpius). Dept. of Biochemistry, University of Geneva, Switzerland.

Superior cervical ganglia from 8-day chick embryos are dissociated with trypsin and cultured on polyornithine-coated culture dishes conditioned with medium from chick heart cells. The cells survive for 3-4 weeks when grown in Eagle's minimum essential medium (MEM) supplemented with heat-inactivated horse serum (1.5%) fetal calf serum (1.5%), glucose (0.3%), glutamine (2mM), KCl (35mM), choline chloride (150 $\mu$ M), MEM amino acid mix and vitamin mix, penicillin-streptomycin and lµg/ml nerve growth factor (NGF). The cultures contain 5-10% non-neuronal cells as determined either by morphological criteria or by fluorescence microscopy using tetanus toxin and anti-tetanus toxin antibodies. 95-100% of the neurons survive up to 10-12 days in culture. Their number then gradually decreases to 50-60% of the initial amount after three weeks. The size and shape of the neurons (phase-bright, neuritebearing, tetanus-toxin-positive cells) is heterogeneous. They all take up norepinephring (NE) as detected by autoradiography after incubation with  $6\times10^{-7}$  M (<sup>3</sup>H)-NE. Incubation of three-week-old cultures with the radiolabeled precursors (<sup>3</sup>H)-choline and (<sup>3</sup>H)tyrosine reveals that the sympathetic neurons synthesize up to 30 times more catecholamines (CA) than acetylcholine (Ach). Both Ach and CA synthesis increases with time in culture, CA synthesis increasing at a two-fold higher rate than Ach. In the absence of NGF, only little CA is synthesized but the amount of Ach is approximately the same as in the presence of NGF. Thus there to be two subpopulations of sympathetic neurons in the chick superior cervical ganglion, a cholinergic one surviving in the presence or absence of NGF and an adrenergic one surviving only in its presence. (Supported by the Swiss National Science Foundation grant 3.685.0.80).

5.2 THE INFLUENCE OF SERUM ON THE DEVELOPMENT OF SYMPATHETIC NEURONS IN CULTURE E. Wolinsky\*, P.H. Patterson, S.C. Landis, and A. Wil-lard, Dept. Neurobiology, Harvard Medical School, Boston MA 02115 Culturing neurons under serum-free conditions offers greater control of the extracellular environment than the usual serum supplemented conditions. Iacovitti et. al. (<u>Neurosci. 7</u>:2225, 1982) have reported that neuronal survival and tyrosine hydroxy

lase activity are comparable between serum-containing and hormone supplemented cultures of sympathetic neurons, but that unlike supplemented cultures of sympathetic neurons, but that unlike conventional cultures, serum-free cultures do not produce acetyl-choline or store significant amounts of norepinephrine, and con-tain few varicosities and vesicles. We have modified the N2 serum-free recipe of Bottenstein and Sato (PNAS USA 76:514, 1979) by replacing the basal medium mixture of F12 and DME with L15. Under these conditons, varicosities and vesicles are abundant and of normal appearance, and metabolic labelling studies indicate that norepinephrine synthesis and storage in these serum-free cultures is similar to that in serum-containing cultures. Survival and tyrosine hydroxylase levels are also normal, and serum-free cultures resemble conventional cultures in their binding of a panel of monoclonal antibodies, response to heart cell conditioned med-ium by induction of acetylcholine synthesis (Patterson and Chun, Devel. Biol. 56:263, 1977), and response to chronic depolariza-tion by increased tyrosine hydrosylase activity (Walicke, Campenot, and Patterson, <u>PNAS USA 74:5767</u>, 1977). The neurons grown in the L15-based N2 medium do not produce

detectable acetylcholine. We attribute this to the absence of a cholinergic inducing factor normally presented to the cultured cells at low levels in adult rat serum. Serum dose-response experiments support this view. Interstingly, serum from neonatal rats does not induce acetylcholine synthesis. This could reflect a schedule of cholinergic factor production consistent with the appearance of cholinergic properties in the sympathetic innerva-tion of the rat sweat gland (Landis and Keefe, <u>Devel. Biol.</u>, in press, 1983).

Neurons grown in the modified N2 medium display a high frequency of electrical coupling, as was observed by Higgins and Burton (<u>Neurosci</u>, 7:2241, 1982) using the original N2 formulation. We are exploring the effects of serum, heart cell conditioned medium, and the individual N2 hormone supplements on coupling. The utility of serum-free conditions is exploited in this systematic testing of individual hormones and nutrients at known concentrations.

5.3 EFFECT OF EXTRACELLULAR MATRIX (ECM) ON DOPAMINE RELEASE FROM PHEOCHROMOCYTOMA (PC 12) CELLS. <u>S.L. Kozak\* and C.L. Bethea</u>. Division of Reproductive Biology and Behavior, Oregon Regional Primate Center, Beaverton, OR 97006.

Substrates of various origins can affect morphology, growth and functional properties of many cell types. PC 12 cells (a clonal line of rat pheochromocytoma) synthesize, store and secrete dopamine as well as other transmitters. These cells are rounded and loosely attached when cultured on plastic, but become flattened and exhibit significant neurite extension when cultured on ECM secreted by bovine corneal endothelial cells (Fugi et al., J. Neurosci. 2:1157, 1982). To determine if functional properties could be altered along with the morphological changes induced by this substrate, we examined dopamine release from PC 12 cells cultured on ECM vs. plastic. Cells were seeded on ECM and plastic (25 and 50 x 10° cells/17mm well). After overnight attachment, the medium was replaced and aliquots were harvested and acidified at 1,2,3,6 and 18 h. Medium dopamine was (1) detectable by radioenzymatic assay after 3 h; (2) reflected cell number; (3) increased with time; and (4) was higher from cells on ECM than plastic at both cell concentrations.

detectable by radioenzymatic assay after 3 h; (2) reflected cell number; (3) increased with time; and (4) was higher from cells on ECM than plastic at both cell concentrations. Dopamine release from 25 and 50 x 10<sup>°</sup> cells was then examined at 12,24 and 72 h and was higher from cells on ECM than plastic. The cells were harvested into 0.1N PCA at 72 h for dopamine and DNA content determinations. There was no difference in the dopamine content or DNA content of cells on ECM or plastic therefore dopamine content/ug DNA was not different, whereas medium dopamine/µg DNA was 1.7 fold higher from cells on ECM than plastic (ECM = 98 ng/µg DNA vs. plastic = 55 ng/µg DNA). Dopamine content of cells on ECM and plastic averaged 5.6% of medium dopamine

of cells on ECM and plastic averaged 5.6% of medium dopamine. In several experiments dopamine release, dopamine content and DNA content were examined in cells on ECM and plastic at 3, 6, 12, 24, 48 and 72 h. Medium dopamine levels from ECM cultures showed an increase over plastic cultures of 49% (3 h, n=5); 62% (6 h, n=4); 45% (12 h, n=4); 88% (24 h, n=4); 53% (48 h, n=3); and 52%(72 h, n=3) with a mean increase of 58% for all time points. Both medium and cellular dopamine and DNA content increased with time indicating growth contributed to the rising levels of medium dopamine. However no difference was observed in dopamine or DNA content between cells on ECM vs. plastic. Higher medium dopamine/µg DNA in ECM cultures confirmed the stimulatory effect of ECM on dopamine release. In summary, the maintenance of PC 12 cells on ECM promotes neurite extension and enhances the release of dopamine. Although the mechanism by which ECM enhances dopamine release is unresolved, these data provide further evidence of substrate influence on cellular function.

5.4 SPONTANEOUSLY RELEASED PROTEINS FROM CULTURES OF SENSORY GANGLIA INCLUDE PLASMINOGEN ACTIVATOR AND A CALCIUM DEPENDENT PROTEASE. <u>Randall N. Pittman.</u> Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

Two dimensional gel electrophoresis and fluorography were performed on proteins spontaneously released into culture medium from dorsal root, nodose and trigeminal ganglion neurons. Each population of sensory neurons released a limited number of proteins in the pH (4.6-7.5) and MW ranges (10-280K) studied. DRG neurons released about 6-7 major proteins into the medium, two of which were not released by sympathetic neurons and one that did not appear to be released by neurons from nodose or trigeminal ganglia. Neurons from nodose ganglia released 6-8 proteins of which at least one was not released by sympathetic, DRG, or trigeminal ganglion neurons. Proteins released by neurons were distinctly different from those released by neurons were distinctly different from those released by neurons neurons were dis-

A number of possible functions may be associated with proteins released by neurons including process outgrowth, recognition and synapse formation. It has been suggested that migrating granule cells release plasminogen activator, a highly specific serine pro-teinase (PNAS 78:7810; Nature 298:753), and it has been shown that growth cones of neuroblastoma cells release plasminogen activator (Sci. 213:1532). The proteins released by sensory neurons were analyzed for plasminogen activator activity as well as for other specific proteinases. Because serum contains protease inhibitors, techniques were developed for growing DRG and trigeminal neurons chronically in serum-free medium. Under these conditions cultures can be obtained which contain only neurons or neurons plus satel-lite cells. In cultures of DRG neurons grown for 4 weeks in serum free medium, a typical urokinase-like plasminogen-dependent protease activity was released into the culture medium which had a MW of 51K. A protein with similar properties was also found associated with membrane fractions from these cultures. Larger quan-tities of plasminogen activator were released from co-cultures of DRG or trigeminal neurons and satellite cells, suggesting that satellite cells either induce neurons to release more activator or are also releasing plasminogen activator. In addition to the are also releasing plasmingen activator, in addition to the plasmingen activator, a calcium-dependent protease activity was also released into the medium by cultures containing neurons and satellite cells but not from neuron-alone cultures. This neutral satisfies certain but not from neuron-atome curtures. This neuron protease had a MW of 60K, and required mM concentrations of  $Ca^{2+}$  for activity. Assay conditions which should have revealed release of lysosomal proteases were negative; therefore, the proteases characterized here are probably not resulting from cell lysis but rather appear to be spontaneously released. Total cell homogenetic nates, however, did contain a protease with characteristics simi-lar to cathepsin D (the major lysosomal protease in brain).

5.5 MORPHOLOGICAL AND BIOCHEMICAL EFFECTS OF NGF OR APPLIED ELECTRIC FIELDS IN THE PRESENCE OR ABSENCE OF NON-NEURONAL CELLS OF CHICK DORSAL ROOT GANGLIA. B. F. Sisken, S. Estes\*, E. Barr\*, and R. Kryscio\*. Wenner-Gren Res. Lab, Dept. of Anatomy, and Dept. of Statistics. Univ. of Kentucky. Lexington, KY 40506.

boosal ROOI GARGIA. B. F. Sisken, S. Estes", E. Daff", and K. <u>Kryscio</u>\*, Wenner-Cren Res. Lab. Dept. of Anatomy, and Dept. of Statistics, Univ. of Kentucky, Lexington, KY 40506. Eight day chick embryo dorsal root ganglia (DRG) were cultured in complete medium containing 10% dialyzed fetal bovine serum and 600 mg% glucose, or in complete medium with 8 ug/ml cytosine arabinoside (ara C). This drug specifically inhibits DNA synthesis and is commonly used to reduce the mitotically-active non-neuronal cells without affecting the neuronal cell population. It was used, therefore, to allow a reasonable assessment of neuronal regeneration at both the morphological and biochemical levels. Neurite outgrowth, protein content and "H-proline incorporation

Neurite outgrowth, protein content and "H-proline incorporation into TCA-precipitable proteins were determined in four treatment groups: control, 2.5s NGF (10 nM), single pulse electromagnetic fields (PEMF) and 10nA direct current (DC). All parameters were assayed for each group at 3 and 6 days <u>in vitro</u> (DIV). Confirmatory evidence was obtained by grain localization on radioautograms after incorporation of the labeled amino acid precursor. In normal media, both electrical treatments stimulated neurite outgrowth at 3 DIV. The values were intermediate to that produced by NGF. All group values decreased by 6 DIV. Conversely, protein content increased with time due to the growth of the nonneuronal cells. In the ara C cultures at 3 DIV, neurite outgrowth increased in control cultures approximating the values of both PEMF and DC cultures; NGF cultues were unaffected at this time and remained significantly higher than any of the other groups. In ara C cultures at 6 DIV, dramatic differences were noted. Neurite outgrowth in control, PEMF and DC groups increased while the NGF group decreased significantly. The protein content in the NGF did not chapte with time.

the NGF cultures did not change with time. Protein synthesis was comparable in all four groups at 3 DV and 6 DIV, but decreased at 6 DIV in ara C medium. Radioautograms of such cultures revealed heavy label in neurons and neurite especially in the ara C series. At 6 DIV, these labeled neurites extend out radially in all groups but those treated with NGF; in these ganglia, the labeled neurites form dense circular rings around the centrally-placed neurons. Our conclusions are that ara C addition promotes neurite production by decreasing non-neuronal overgrowth demonstrating the independent ability of neurons to grow neurite processes.

5.6 DIFFERENTIATED SCHWANN CELLS CULTURED FROM ADULT SCIATIC NERVES CONTAIN ASTROCYTE TYPE INTERMEDIATE FILAMENTS, <u>K.L. Fields\*</u>. (SPON. R. Katzman). Depts. of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

In work done on tissue sections, we found that antisera raised to the 49,000 MW protein of CNS 10nm astrocyte filaments stain long,thin elements in rat sciatic nerve. This same pattern is seen with all anti-GPAP antisera, and the staining is absorbed by purified GPA protein. The pattern is different from that found with anti-vimentin or anti-neurofilament antisera (Yen and Fields, J. Cell Biol. 88:115, 1981). In teased nerves, the staining is associated with non-myelinated nerve fibers, or the cells associated with them, not

In teased nerves, the staining is associated with non-myelinated nerve fibers, or the cells associated with them, not with myelinated nerve fibers or collagen. The staining network looks just like the classical osmium-fixed, teased nerve fibers described by Tuckett in ox splenic nerve (<u>J. Physiol.19</u>:267,1896) (Gould and Fields, <u>Trans. Am.Soc.Neurochem. 13</u>:59,1982). In dissociated cell cultures from adult rat sciatic nerve,

In dissociated cell cultures from adult rat sciatic nerve, cells staining with anti-49K serum are present. They are round or elongated bipolar cells, and are stained by antivimentin or anti-49K sera only after alcohol fixation, demonstrating that the antigen is cytoplasmic, rather than extracellular. Flat fibroblastic cells do not stain with anti-49K sera, nor do Schwann cells from neonatal rats. All the 49K-antigen positive cells have the Schwann cell surface antigen, Thy-1.

Cytoskeletal preparations from adult nerve cultures, but not from neonatal nerve cell cultures, contain a protein band at 50,000 MW, which binds anti-49K antibody in immunoblotting experiments.

These results indicate that all Schwann cells in nerves do not have the same type intermediate filaments, but that some of them, apparently those associated with C-type fibers, have the same protein subunit as astrocytes.

MYELIN-DEFICIENT MOUSE MUTATION: COMPARISON WITH ALLELIC SHIVERER MYELIN-DEFICIENT MOUSE MUTATION: COMPARISON WITH ALLELIC SHIVKEK MUTATION IN SITU AND IN VITRO. X.-Y. Shen\*, A. L. Hall\*, M. K. Wolf and S. Billings-Cagliardi. Department of Anatomy. University of Massachusetts Medical School, Worcester, MA 01605. <u>Myelin-deficient (shi<sup>mld</sup></u>), a mouse mutation producing CNS hypomyelination, is allelic with <u>shiverer (shi</u>) and closely resembles <u>shi</u> except that the deficiency of myelin basic protein (MBP) is not as complete. We are outcrossing <u>shi<sup>mld</sup></u> to a B6C3H which is the first shift of the hypomyelin basic protein (MBP) is not as complete. 5.7 (Mbr) is not as complete. We are obterossing  $\underline{s_{11}}$  to a bosin hybrid stock for accurate comparison with  $\underline{shi}$  and all other hypo-myelinated mutants. Affected  $\underline{shi}$ mld/ $\underline{shi}$ mld mice were examined at N4 and subsequent outcrosses (more than 90% comparability). Blocks of cerebellum and optic nerve were taken from P-18 to P-24 blocks of cerebellum and optic nerve were taken from P-18 to P-24 mice, and primary explants from P-0 affected cerebellum were maintained in vitro for 18-24 days, for examination by light and transmission electron microscopy. Both in situ and in vitro, shimld resembles shi in almost all ultrastructural features. Both mutants are deficient in CNS myelin; however, our B6C3H affected animals appear to make more myel . than others studying these mutations have reported. In both mutants, oligodendrocytes produce bundles of redundant microprocesses and myelinate produce bothers of region and microprocesses and myerinate inappropriate targets, many myelin sheaths are incorrectly wrapped, and most sheaths are incompletely compacted. The major feature distinguishing shimld from shi is the presence of a true major dense line (MDL) in some shimld myelin sheaths. The region of MDL usually forms one or two complete lamellae, or a patch containing small parts of several adjacent lamellae. The second of the state of the second piece that finds of a patch containing small parts of several adjacent lamellae. Rarely, an entire myelin profile shows the MDL throughout all its lamellae (as many as 7). Injected normal optic nerve oligodendrocytes produce normal myelin around the  $\frac{shimld}{shiml}$  axons in the immediate vicinity of the optic nerve fragment, just as they do in jp, jp<sup>msd</sup>, gk, and shi. We conclude: 1. Both shi and shimld appear to make more myelin on the B6C3H background than on other backgrounds. The remainder of the genome influences the quantity of myelin formed. 2. The amount of MDL in B6C3H mutants appears to be in keeping with the amount of MBP. Affected  $\frac{shi}{CNS}$  has no MBP and no MDL, while affected  $\frac{shind}{shimd}$  CNS has no MBP and no MDL. 3. Other cytological abnormalities seen in these two mutants do not seem to be influenced by the small amount of MBP in  $\frac{shind}{shi}$ . We speculate that the  $\frac{shi}{shimd}$  locus does not concern the message for MBP, but rather a regulatory factor. Abnormality of this factor causes both the deficiency of MBP and MDL and the other cytological abnormalities. Supported by NIH Grant  $\frac{gNS}{N} = 11425$  to MKW and SB-G. IDENTIFICATION AND CHARACTERIZATION OF CELL TYPES IN CULTURES OF RAT RETINA USING MONOCLONAL ANTIBODIES. <u>K. Akagawa<sup>\*</sup> and C. J.</u> Barnstable. (SPON: D. L. Edwards). Department of Neurobiology Harvard Medical School, Boston MA and The Rockefeller University, 1230 York Avenue, New York.

To identify and characterise the cell types of rat retina <u>in</u> <u>vitro</u>, we have studied the expression of cell-type specific an-tigens using monoclonal antibodies both in monolayer and aggrega tion cultures.

Photoreceptors which are labelled by antibody RET-P1 are small and round cells which have no or one small process. Though they do not develop outer segments in monolayer cultures, they form characteristic rosette structures in aggregation cultures, in

Which outer segment markers appear to develop. Amacrine cells can be labelled by HPC-1, raised against rat hippocampus, using either immunofluorescence or PAP staining. Most of the labelled cells are bipolar and have long processes

Bipolar cells and photoreceptors are labelled by an antibody, RET-B2. In monolayer cultures of 2 day old retina the antibody, RET-B2. In monolayer cultures of 2 day old retina the antigen only appears after 7 days in vitro. The bipolar cells extend long processes and have many different morphologies, some of which are very similar to those of the amacrine cells. Thus without antibody markers it would have been impossible to distinguish amacrine and bipolar cells in these cultures.

Ganglion cells are the only cells that are labelled by anti Thy-1 antibody in vivo. In monolayer cultures from 2 day old rats Thy-1 +ve cells were found in cell clumps but not in the dispersed cell monolayer. This suggests that the triggering of Thy-1 expression is dependent upon some cell interactions. Such interactions are not necessary for the maintainence of expression of the antigen since in cultures of retinas from older animals that are already expressing Thy-1, solitary ganglion cells can be

that are already expressing iny-1, solitary gaugiton certs can be found that are Thy-1 +ve. We have also studied the uptake of various transmitter candi-date amino acids using autoradiography. Cells which take up GABA in monolayer culture have long processes whereas those taking up glycine have small short processes. Many of the GABA cells appear to be amacrine cells. Aspartate is taken up into many types of cells including small round cells that have the morphology of the RET-P1 + ve photoreceptor precursors. In aggregation cultures, cells labelled by GABA and glycine uptake were located on the surface of the aggregates.

SHIVERER OLIGODENDROCYTES FORM SHIVERER MYELIN AROUND NORMAL AXONS. M. K. Wolf, C. Schwing-Stanhope\*, A. L. Hall\*, and S. Billings-Gagliardi. Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605.

Normal oligodendrocytes in severed fragments of immature optic nerve, explanted onto cultures of cerebellum deficient in myelin, colonize the cerebellar tissue and myelinate its axons. They are equally successful whether the culture is from a mutant mouse with CNS hypomyelination or from a normal mouse stripped of its own mature oligodendrocytes and myelin by treatment with cytosine arabinoside (Ara-C). We now find that oligodendrocytes from B6C3H hybrid shiverer (shi) mutant optic nerve, colonizing normal begin hybrid sinvered (and) what optic here, consisting ideals correbellum demyelinated by Ara-C, form myelin with defects identical to those of shi myelin in situ or in cultures of shi cerebellum. Four cultures were produced from each P-0 B6C3H cerebellum. Four cultures were produced from each P-0 B6C3H hybrid normal cerebellum. Two were left untreated to test <u>in</u> <u>vitro</u> myelination of that cerebellum; two were grown in medium without embryo extract and with added Ara-C, 4.5 µg/ml, for 7 days <u>in vitro</u>, then washed free of Ara-C and fed medium with embryo extract. One such Ara-C treated culture tested the completeness of mvelin suppression in that cerebellum; the other received an explant of optic nerve from a known homozygous P-8 to P-10  $\frac{\sinh(\sinh)}{\sin}$  mouse. All cultures were processed for transmission electron microscopy at 17 to 20 days  $\frac{\ln}{\ln}$   $\frac{vitro}{vitro}$ . Ara-C treated cultures lacked mature oligodendrocytes and myelin, but contained abundant astrocytes. Ara-C treated cultures with <u>shi</u> optic nerve contained numerous myelinated axons near the optic nerve fragment. All this myelin had the ultrastructural features herve fragment. All this myerin has been according to the straight of shi myerin: sheaths often incorrectly wrapped and usually not compacted; absence of a true major dense line; bundles of redundant oligodendrocyte microprocesses; inappropriate mvelination of these bundles and of oligodendrocyte cell bodies. Ultra-structurally normal mvelin was not seen. We conclude: 1. The structurally normal myelin was not seen. We conclude: 1. The added optic nerve fragments are the source of myelinating glia in these cultures: if immature normal glia survive the Ara-C treatment, they do not produce myelin. Therefore, these cultures can be used to study the response of mutant oligodendrocytes to normal axons. 2. Oligodendrocytes of <u>shi</u> express every major feature of the <u>shi</u> disease in the presence of normal axons and astrocytes. This is further evidence that all these defects are intrinsic to oligodendrocytes. 3. Since the discours is  $e^{-1}$ intrinsic to oligodendrocytes. 3. Since the disease is ex-pressed in the presence of genetically normal astrocytes, it seems unlikely that <u>shi</u> astrocytes have any direct role in the disease.

A MONOCLONAL ANTIBODY TO THY-1 ENHANCES PROCESS REGENERATION BY DIFFERENTIATED RAT RETINAL GANGLION CELLS IN CULTURE. Dana DIFFERENTIATED RAI REINAL GANGLION CLELES IN CULTURE. Data (SPON: T.N. Wiesel). Depts. of Neurobiology(1) and Neurology(2), Harvard Medical School, Boston, MA 02115; Dept. of Neurobiolo-gy(3), The Rockefeller University, New York, NY 10021. Solitary retinal ganglion cells can be identified in culture with fluorescent markers. Ganglion cells are labelled by the re-transmoted the sensitive of formation of the sensitive of the provide the restrict of the sensitive of the sensitive of the provide the provide the sensitive of the sensitive of the provide of the provide the provide the sensitive of the provide of the provid

trograde transport of fluorescent dyes injected into the projec-tion sites of the optic nerve two days prior to retinal dissocia-

tion sites of the optic nerve two days prior to retinal dissocia-tion. In culture, the identity of ganglion cells is verified by a second label, 2012, a monoclonal antibody against Thy-1, that in retina is specific for ganglion cells. As previously reported (Suppl Invest Ophthal 24, 138, 1983), a significantly greater proportion of ganglion cells regenerate processes when plated on anti-Thy-1-coated glass coverslips than on plain glass, or on glass coated with collagen. In this study we tested the specificity of this effect and its relationship to adhesion. The action of anti-Thy-1 was not a

relationship to adhesion. The action of anti-Thy-1 was not a non-specific property of immunoglobulin bound to the glass coverslip since: (i) IV2G10, an antibody against a cytoplasmic antigen, did not enhance process outgrowth of ganglion cells, and (ii) anti-Thy-1 had no effect on process outgrowth of amacrine cells, identified autoradiographically by uptake of tritiated glycine and GABA.

There appeared to be a requirement for the Thy-1 antibody to be bound to the coverslip since adding antibody at varying concentrations 3-4 hours after plating on plain glass caused no

centrations 3-4 hours after plating on plain glass caused no enhancement of process growth. We tested whether the effect of anti-Thy-1 was related to adhesion of cells to the substrate. Antibody RET-N2 reacts with an antigen on the surface of all retinal cells, including gan-glion cells. Although approximately the same number of ganglion cells adhered to both substrates, RET-N2 did not enhance process regeneration like anti-Thy-1. Fibronectin was also ineffective immending content of the state in promoting regeneration. On the other hand, poly-L-lysine From these results, it is not yet clear whether the effect of anti-Thy-1 is a consequence of the strength of adhesion or of a more specific surface modulation involving Thy-1, or both.

The ability to identify and grow retinal ganglion cells in

culture has also enabled us to study their membrane properties using intracellular and patch-clamp pipettes. Supported by NIH grants EY03735, EY00606 and NS17309, and the Hartford Foundation.

- 5.11 ANALYSIS AND PURIFICATION OF NEURONS BY IMMUNOFLUORESCENCE AND FLUORESCENCE-ACTIVATED CELL SORTING. P.A. St.John and J.L. Barker, Lab. of Neurophysiology, NINCDS, NIH, Bethesda, MD. 20205 Experiments with cell cultures of neurons and myotubes have pro-vided important insights into mechanisms of synaptogenesis at this peripheral synapse. Cell cultures may provide similar insights into synaptogenesis in the central nervous system. The spinal cord, where the cellular neurobiology in vivo has been particular-ly well studied, is a good subject for studies in vitro. However, previous work on spinal cord cultures has shown that they contain a variable mixture of cell types. In an effort to gain control over the types of neurons present in cultures, we have begun to use a fluorescence-activated cell sorter to separate different subpopulations of cells from the embryonic mouse spinal cord and dorsal root ganglia.

All experiments were performed on dissociated spinal cord and And experiments were performed on dissolated spinal cold and dorsal root ganglion cells from 13-day embryonic mice, cells of the age used for cell cultures. In the irst series of experi-ments, individual cells, not reacted with fluorescent probes, were examined in the cell sorter for amount of forward-angle light scatter, a measurement influenced by cell size and makeup. For-ward-angle light scatter was sufficient to distinguish live cells from dead cells and debris in the absence of staining, and sorting based on this criterion produced a population of live cells with over 95% purity (based on trypan blue exclusion). The purified, sorted cells could be grown in culture, and neurons survived in these cultures for at least 3 weeks.

In initial studies to determine the feasibility of sorting subpopulations of cells using fluorescent probes, we have labeled fixed, permeable cells with antibodies to intracellular antigens in suspension were fixed and reacted with antibodies against several neuropeptides and transmitter-related enzymes. Although immunoreactivity for the antibodies tested could not be detected Immunoreactivity for the antibodies tested could not be detected unambiguously in a fluorescence light microscope, the greater sen-sitivity of the cell sorter showed that the cells did contain specific immunoreactivity for antibodies to the following: glu-tamic acid decarboxylase (up to 50% of cells), glutaminase (30%), vasoactive intestinal peptide (10-20%), substance P (up to 10%), somatostatin (up to 30%), and neuron-specific enolase (15-25%). In future experiments, fixed and labeled cells will be purified with the cell sorter for use in producing cell type-specific, sur-face-directed antibodies

with the cell sorter for use in producing cell type-specific, sur-face-directed antibodies. In other experiments, live, unfixed cells were analyzed or sorted following labeling of motor neurons by retrograde transport from muscle injections (Schaffner, St. John, and Barker, this volume), or labeling by a neuronal surface-directed monoclonal antibody (the A285 clone) or lectins. Experiments are in progress to grow these specifically labeled and sorted cells in culture.

5.13 THE DEVELOPMENT OF GLUTAMIC ACID DECARBOXYLASE IMMUNOREACTIVITY IN MOUSE SPINAL CORD CULTURES. M.T. Caserta and J.L. Barker, Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD. 20205 Spinal cord (SC) neurons grown in tissue culture have been shown to be an excellent system for studying the electrophysiological responses of neurons to gamma aminobutyric acid (GABA), a major inhibitory trapsmitter in the vertebrate contral pervous system inhibitory transmitter in the vertebrate central nervous system. It has been shown that most mature cultured SC neurons respond to GABA and that these neurons are invested with terminals that react with antibodies to glutamic acid decarboxylase (GAD), the bio-synthetic enzyme for GABA. We have examined developing SC neurons in culture by immunohistochemical localizaton of GAD at the light and electron microscopic (EM) levels with a well-characterized sheep antibody to rat brain GAD (Oertel, et al. Neuroscience 6: 2689).

SC cultures were prepared from dissociated SC and dorsal root ganglion (DRG) cells of 12–13 day mouse embryos and were grown for up to 4 weeks. In mature cultures (2 weeks or older), GAD immunoup to 4 weeks. In mature cultures (2 weeks or older), GAD immuno-reactivity was confined to terminals which could be seen envelop-ing neurons of varying size and morphology. However when cultures were pretreated with colchicine, GAD containing cell bodies were visualized. These GAD-positive neurons were small to intermediate in size (<20µ diameter) and were usually found within clusters. Large neurons resembling motoneurons or DRG cells were not la-belled. EM immunocytochemistry demonstrated numerous GAD-positive terminals synapsing on dendritic and axonal processes as well as cell bodies. The vesicles in these terminals were either round or cell bodies. The vesicles in these terminals were either round or No terminals with solely flattened vesicles were pleomorphic. ever observed. GAD-positive cell bodies could be demonstrated as early as 4 days in culture without colchicine pretreatment. Most of the immunoreactivity was localized to the Golgi region of the soma with a few labelled terminals visible. EM analysis showed that many synapses had already been formed in these young cultures and that a few axodendritic profiles were immunoreactive at this stage.

The development of another neuronal enzyme, neuron specific enolase (NSE), was compared to GAD and found to develop much later in cultured SC neurons (2 to 3 weeks). This late development of NSE cultured SC neurons (2 to 3 weeks). This late development of NSE is consistent with previous in <u>vivo</u> developmental studies. These results suggest that the early maturation of GAD-containing neu-rons is not a generalized phenomenon of cells in tissue culture but specific to this subpopulation. Work is now in progress to compare the development of SC GABAgeric neurons <u>in vivo</u> to their development <u>in vitro</u>. What role this inhibitory transmitter, GABA is playing <u>in the developing</u> SC is an important question that can best be addressed in tissue culture which allows ready access for biochemical, morphological and electronbysiological analysis. biochemical, morphological and electrophysiological analysis.

PURIFICATION OF EMBRYONIC MOUSE MOTONEURONS BY FLOW CYTOMETRY, 5.12

PURIFICATION OF EMBRYONIC MOUSE MOTONEURONS BY FLOW CYTOMETRY. A.E. Schaffner, P.A. St.John and J.L. Barker, Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MO. 20205 One approach to a better understanding of how the nervous sys-tem works might involve the purification of nomogeneous popula-tions of nerve cells. This would simplify the morphological and electropharmacological characterization of the cells as well as their interactions with presynaptic and postsynaptic neurons and targets. Two laboratories have reported successful purification of embryonic chick motoneurons by employing the techniques of retrograde transport of a fluorescently labeled lectin with sub-sequent sorting of specifically labeled cells in a fluorescence-activated cell sorter (FACS) (Okun and McPheeters, <u>Soc. Neurosci</u>. 6: 733; O'Brien et al., Soc. Neurosci. 8: 129). We have isolated 6: 733; O'Brien et al., Soc. Neurosci. 8: 129). We have isolated motoneurons from mammalian embryos using similar techniques. Limbs of 13 day mouse embryos were injected with 10mg/ml of fluo-resceinated horseradish peroxidase or wheat germ agglutinin. After 4-8 hours of retrograde transport at 370C, spinal cords and dorsal root ganglia were mechanically dissociated and the cells analyzed and/or sorted on a FACS. An initial analysis indicated that 22% of the cells were specifically labeled. When cells were sorted into specifically labeled and unlabeled populations and assayed for choline acetyltransferase (ChAT) activity there was a 3.8-fold enrichment in ChAT activity (cpm/cell) in the specifically labeled population compared with unlabeled cells. To test whether labeled dorsal root ganglion (DRG) neurons might be contributing to the high yield of labeled cells, DRGs were removed from the cords and DRGs and cords analyzed separately. In this experiment, approximately 9% of spinal cord cells were specifical-ly labeled while 36% of cells from the DRG were specifically labeled (presumably from sensory connections). Thereafter all DRGs and meninges were routinely stripped from the cords. We have used two approaches to determine the location of labeled cells in situ. Several embryos were injected and processed for cryostat sectioning. Fluorescent cells in the spinal cord were confined to the anterior horn. In one embryo fluorescence was also seen in a the anterior horn. In one embryo fluorescence was also seen in a DRG. In another experiment, cords were dissected into "dorsal" and "ventral" halves and analyzed separately using flow cytometry. There was no specific fluorescence (<0.1%) in cells from the dorsal cord. However, >5% of cells from the ventral cord were specifically labeled. We are presently working on conditions that will allow the survival of sorted motoneurons in culture. In other experiments, purified motoneurons will be used as antigens to generate antibodies against surface determinants on motoneurons or cholinergic neurons in general. Such antibodies should provide a powerful tool for identifying these cell types both <u>in vivo</u> and in vitro and elucidating their involvement in neuropathologies.

EFFECTS OF ACTIVITY DEPENDENT NEURAL FACTORS ON MUSCLE GROWTH AND 6.1 MAINTENANCE IN THE YOUNG CHICK EMBRYO. J.W.Bloom\*, E. Cosmos and Butler\*. (Spon: R. Butler). Neurosciences Dept. McMaster University Health Sciences Centre, Hamilton, Ontario L&S 325. Although brachial muscles of the chick embryo do form in the complete absence of innervation, both their growth rate and, eventually, their survival are dramatically reduced (Butler, J. et al., J.Exp.Zool.224:65,1982). These observations stress an important role for activity-dependent and/or neurotrophic factors on early muscle growth and maintenance. To differentiate between these possibilities, activity-dependent neural influences were manipulated independent of neurotrophic influences by pharmacological neuromuscular blockade(reduced activity)and by electrical stimulation(increased activity)of intact chick embryos. Electrical stimulation was repeated in embryos in which the brachial musculature had been rendered aneurogenic by neural tube removal. Anterior(ALD)and posterior(PLD)latissimus dorsi muscles were

analyzed histochemically and quantitatively. In intact embryos treated with d-tubocurarine, chronic reduction of activity by 40-60% was noted from 4-11 days in ovo; however, only a modest decrease in the growth of the ALD and PLD muscles was observed. Further, chronic augmentation of activity from day 6-10 via spinal indirect stimulation did not increase and in some cases reduced, the growth of normally innervated ALD and PLD muscles. These experiments indicate that in the intact embryo rather large perturbations, both upward and downward, of the amount of activity reaching the musculature have little effect on muscle growth or maintenance during the first half of embryonic development. We are attempting to achieve 100% actireduction by a-bungarotoxin treatment since very great reductions in activity markedly reduced growth of leg muscles in intact embryos (Laing, N., J.E.E.M. 72:269, 1982). To test the role of activity in the absence of trophic factors,

aneurogenic muscles were chronically electrically stimulated for 2-4 days beginning on day 6 or 7. When activity alone was added back to the aneurogenic ALD muscle, its growth was increased by 100% compared to unstimulated aneurogenic controls. In addition, the aneurogenic PLD muscle, which usually degenerates by day 7.5, use received by divect climulation and carfinded to area, through was rescued by direct stimulation and continued to grow throughout the experimental period.

Thus, activity plays an important role in early muscle devel-opment as demonstrated by the marked enhancement of the growth (ALD,PLD) and survival(PLD)of aneurogenic muscles when activity alone is experimentally imposed upon them.

#### 6.3 TROPHIC INTERACTION IN HIPPOCAMPAL CELL CULTURE MEDIATED BY NTF. W.Seifert, S.Beckh\* and H.W.Müller\*. Max-Planck-Inst., Dep. Neurobiology, 34 Göttingen, BRD.

A dissociated cell culture system of the developing hippocampus in serum-free medium has been established in our laboratory in recent years. By using a cover-slip technique we demonstrated that primary glialcells produce a soluble trophic factor which promotes sur-vival and outgrowth of hippocampal neurons (W.Seifert et al. 1981, 1983).

This neurotrophic factor has been further characterized by a rapid and quantitative bioassay based on this coverslip technique (H.W.Müller and W.Seifert, 1982, W.Seifert and H.W.Müller, 1983).

Studies in our laboratory have demonstrated that NTF is a relatively hat-stable and protease-resistant molecule of low molecular weight. It seems to be specific for central neurons and did not exhibit trophic activity for peripheral neurons in cell culture (H.W. Müller, S.Beckh and W.Seifert, 1983).

NTF is produced by primary cultures of astrocytes and secreted into serum-free medium in a time-depen-dent manner. Experiments will be discussed concerning (i) the survival activity and the neurite-promoting activity of NTF, and (ii) the problem of short-term versus long-term sur-

vival of neurons in this serum-free culture.

Screening of tissue extracts with our bioassay has revealed rather high NTF-activity in adult rat brain and even higher activity in embryonic brain. This fact might suggest a biological significance for NTF in de-velopment and maintenance of CNS neurons. Experiments on the developmental appearance of NTF will be dis-cussed.

NEUROTROPHIC SUPPORT OF SPINAL CORD NEURONS 6.2 ΤN CUL-

NEUROTROPHIC SUPPORT OF SPINAL CORD NEURONS IN CUL-TURE. H. Popiela, R. Beach. and B. Festoff. VA Medical Center, Kansas City, MO 64128. Guided by the hypothesis that peripherally-produced neurotrophic factor (NTF), retrogradely transported to central neurons, is extractable from nerve fibers while in transit, we extracted adult chicken peripher-al nerves (NE) using a similar procedure as for extraction of muscle-directed NE (Popiela, 1978, Exp. Neurol. 62: 405-416; Popiela et al., 1982, J. Neurosci. Res. 8:547-567). NE was added to serum-, hormone-, and factor-supplemented medium and assayed on dissociated spinal cord neurons from 8 day old chick embryos. In the presence of NE, neurons are well maintained and respond by prolific outgrowth of neurites (fig., NE). If the medium is not supplemented with extract but

such as skeletal muscle or brain, contains a fraction such as skeletal muscle of brain, contains a fraction of the neurotrophic activity found in nerves when added at similar protein concentrations. NE is not replaceable with a muscle-directed factor previously purified from NE (NTP) nor with transferrin including several chicken transferrins. These studies show that adult chicken transferring. These studies show that adult chicken peripheral nerves contain a factor sup-porting spinal cord neuron maintenance and neurite outgrowth that is not replaceable by transferring. Supported by NIH (ROINS17197), ALSSOA, Medical Research Service of the VA, and the University of Kan-sas Regional ALS Research Center.

Substance P and Somatostatin Regulate Sympathetic Noradrenergic Function. J.A. Kessler, J.E. Adler, I.B. Black. Division of Developmental Neurology, Cornell University Medical College, New York, New York 10021

Peptidergic-noradrenergic interactions were examined in the rat sympathetic superior cervical ganglion (SCG) in explant and dis-sociated cell culture. The putative peptide transmitters, substance P and somatostatin each increased activity of the catecholamine-synthesizing enzyme, tyrosine hydroxylase (TOH), after one week exposure in culture. Maximal increases occurred at  $10^{-7}$ M for each peptide, and either increasing or decreasing the concen-tration reduced effects. By contrast, the peptide had no effect on TOH activity in ganglion homogenates, excluding a direct effect on the TOH enzyme or the radiochemical catalytic assay. Conse-quently, substance P and somatostatin increased TOH activity quently, substance P and somatostatin increased TOH activity through processes that transpired in culture and not through direct interaction with the apo- or holo-enzyme. Similar increases in TOH were produced by the metabolically stable substance P agonist,  $[pGlu^5, MePhe^8, Sar^9]$ -substance P(5-1)). Moreover, the substance P antagonist, D-pro<sup>2</sup>, D-phe<sup>7</sup>, D-trp<sup>9</sup>-substance P, prevented the effects of the agonist, suggesting that the elevation of TOH activity was mediated by peptide interaction with specific substance P receptors. Our observations suggest that peptides may modulate sympathetic catecholaminergic function. 6.5 EFFECTS OF CONDITIONED MEDIA ON NEURITE OUTGROWTH AND SURVIVAL OF PURIFIED MOTONEURONS. A.L. Calof and L.F. Reichardt. Div. Neurosci., Dept. Physio., Univ. Calif., San Francisco, CA 94143 We are interested in the role of target tissue in guiding the growth and synaptic differentiation of spinal motoneurons, and have used a modification of the retrograde transport/fluorescence-activated cell sorting technique of McPheeters and Okun (Soc. Neurosci. Abstr. <u>6</u>: 733) to purify motoneurons. Lucifer Yellow VS is coupled to wheat germ agglutinin, the conjugate is purified by gel filtration, and it is injected into all limbs of stage 28-29 chick embryos. After 24 hrs. in organ culture, examination of fixed sections of these embryos reveals label in the spinal cord confined to the ventral horn. Single-cell suspensions show 5-7% of cells labeled with small, brightlyfluorescent cytoplasmic granules.

For sorting, spinal cords are dissociated to single cells and then sedimented through BSA to remove debris. Cells are sorted using a Becton-Dickenson FACS IV equipped with logarithmic amplification (LA). Emitted fluorescence passes through a 475nm long pass filter prior to analysis and sorting. LA reveals a peak of fluorescent events with intensities well above background (autofluorescence), and comprising 4-7% of scatter events. This peak is sorted, vielding purties of about 80%.

a 475mm long pass filter prior to analysis and sorting. LA reveals a peak of fluorescent events with intensities well above background (autofluorescence), and comprising 4-7% of scatter events. This peak is sorted, yielding purities of about 80%. Purified motoneurons display rapid neurite outgrowth when plated onto polylysine (PLYS)-coated dishes preincubated with serum-free medium conditioned by cultures of chick myotubes (MCMgp). They respond similarly to substrata treated with bovine corneal endothelial cell conditoned medium (BCE-CMgp). We have sought to establish the identity of the MCMgr factor with the BCE-CMgr factor, which has been partially purified in our laboratory (Lander et al., J. Cell Biol. 94: 574-585). Rat sympathetic neurons respond to MCMgr as well as BCE-CMgr. Thus, media conditioned from both cell types can promote neurite outgrowth from cells with axons in the periphery. The MCMgr factor is sensitive to trypsin, but not to collagenase, neuraminidase, or chondroitnase ABC; and it has a buoyant density in CsCl similar to that of the BCE-CMgr factor. Like BCE-CMgr, the neurite-outgrowth promoting effects of MCMgr can be mimicked by conditioned media from other cell types (chick fibroblasts, chick embryonic spinal cord).

types (cnick Tibroblasts, chick embryonic spinal cord). When plated at adequate density, motoneurons extend neurites and survive on MCMSp-treated substrata for ~ld in serum-free medium. This response is not seen on PLYS alone, or on laminintreated PLYS. MCMSp added to the culture medium enables motoneurons to survive for >7d in culture, but this survival effect so far does not appear to be specific to medium conditioned by myotubes. Supported by grants from NSF and MDA to LFR. 6.6 SPECIFICITY OF NEURONOTROPHIC INFLUENCE ON TARGET-DEPRIVED NEUR-ONS IN THE DEVELOPING RAT VISUAL SYSTEM. F. Haun and T. J. <u>Cunningham</u>. Dept. of Anatomy, The Med. Coll. of Pennsylvania, Phila., FA 19129.

Neurons in the developing CNS are particularly vulnerable to separation from their target tissue. This sensitivity may be due to removal of target-derived neuronotrophic influences operative during normal development. We have been investigating this possibility in the developing visual system of the rat. Large unilater-al lesions of the visual cortex are made in newborn Long-Evans rats; these lesions destroy all cortical targets of the dorsal lateral geniculate nucleus (dLCN). Immediately following the lesion, we transplant cell suspensions of El4-15 fetal posterior cortical neurons into the lesion cavity to determine if these transplanted cells affect the otherwise rapid degeneration of the ipsilateral dLCN. In a previous report (Anat. Rec. 205:77A) we showed a temporary saving of at least twice the volume of the affected dLCN, compared to control animals with lesions but without transplants. In the present study we compared the effective-ness of transplants of El4-15 posterior cortex with transplants The solution of the second se labeled host rats to determine whether the effect is specific to particular neuronal populations of the host nucleus. Five days after the lesion, the dLGN of animals without transplants shows a severe depletion of both El4 and El6 labeled neurons (with 4% and 20% respectively of those on the unoperated side remaining). Rats with cerebellar transplants gave similar results. In animals with posterior cortical transplants we find not only a significant saving of dLGN volume but specificity of the neuronal populations which contribute to this volume. The percentage of remaining El4 labeled neurons is comparable to animals without transplants. The survival of later-generated El6 neurons however is increased by more than two-fold. We conclude that: a) fetal cortex transplants exert at least a temporary survival-promoting influence on targetdeprived or axotomized neurons of the developing dLGN, an effect that is relatively specific to the appropriate target; and b) the particular dLGN neurons protected by the transplant are less mature. Notably, these two kinds of specificity have been shown using an in vivo assay, which suggests the possibility of studying trophic relationships among visual system neurons developing in

- 6.7 RETINOIC ACID EFFECTS ON THE NERVE GROWTH FACTOR RECEPTOR. B. E. Haskell\*, R. W. Stach, K. Werrbach-Perez\* and J. R. Perez-Polo. Department of Human Biological Chemistry and Genetics, The University of Texas Medical Branch, Galveston, Texas 77550. Retinoic acid (RA) mimics some of the effects of nerve growth factor (NGF) on explanted chick embryo dorsal root ganglia (DRG) and on human neuroblastoma cell lines. Specifically, NGF stimulates profuse neurite outgrowth from these targets, an event often used to assay for NGF activity. DRG exhibit neurite development in <u>vitro</u> in response to retinoic acid both in serum-supplemented medium and in the chemically-defined, hormone supplemented N-2 medium of Bottenstein and Sato. Maximal response to RA occurs in N-2 medium after 3 days in the presence of  $5 \times 10^{-7}$  <u>M</u> retinoic acid. In LAN-1 neuroblastoma cells, increased neurite outgrowth is associated with a dramatic increase in NGF binding to neurites and cell bodies as determined by immunofluorescence using affinity purified rabbit antibodies directed to mouse  $\beta$ -NGF. At concentra-tions of RA and treatment times deemed optimal for these responses there is an inhibition in cellular proliferation of LAN-1 cells. Also, RA has been reported to increase the apparent number of receptors for insulin and epidermal growth factor and to modify cell surface glycoproteins in vitro. Since the nerve growth factor protein (NGF) is a well characterized neuronotrophic factor acting on vertebrate embryonic sensory and sympathetic neurons and human neuroblastoma lines, it was of interest to determine if receptors to NGF were affected by RA and to correlate these changes with morphological aspects of differentiation directed by NGF in vitro. NGF acts on responsive cells by binding to two different cell surface membrane receptors. These two receptors have equilibrium dissociation constants of approximately  $10^{-11}$ Have equilibrium dissociation constants of approximately  $10^{-11}$  M for the high affinity receptor (type I) and approximately  $10^{-9}$  M for the low affinity receptor (type II). Kinetic analysis of NGF receptors can be carried out on whole cell preparations or solubilized receptors with no detectable change in light the lized receptors with no detectable change in ligand binding kine-tic properties or structural properties of the receptor molecules. Also, quantitative determination of the presence of solubilized NGF receptor by Rosenthal and kinetic analysis demonstrated a five-fold increase in the number of receptors present after 3 days in RA but no detectable change in receptor number after one day. These results are in agreement with the hypothesis that retinoic acid may increase the number of demonstrable NGF surface receptors on LAN-1 cells.

6.8 CELLULAR INTERACTIONS IN DEVELOPMENT OF THE PRIMARY OLFACTORY PATHWAY. <u>A. I. Farbman and M. I. Chuah</u>\*, Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201

It has been shown in an earlier study from this laboratory that the olfactory bulb, the target organ of olfactory receptors, exerts an effect on development of the receptors. The effect is expressed as an approximate doubling of the amount of a specific expressed as an approximate doubling of the amount of a specific olfactory marker protein (OMP) in organ cultures, i.e., when olfactory mucosa taken from fetal rats (day E15) is explanted in combination with presumptive olfactory bulb (POB) and grown for 7 days, about twice as much OMP is found than in cultures of olfactory mucosa alone. OMP was estimated in cultures by two methods: 1) a solid phase radioimmunoassay using <sup>3</sup>H-labeled OMP, 2) a quantitative immunohistochemical procedure in which posi-2) a qualitizative immunoristochemical procedure in which posi-tively stained receptor cells were counted and compared in cultures of mucosa with and without POB. The cell counts indicated that the increased amount of OMP in explants with the POB was due to an approximate doubling of OMP-positive receptor neurons. In order to determine whether the increased OMP in cultures including operations. POB came about as a specific influence of the bulb, mucosa was cultured in combination with other tissues including cerebrum, cerebellum, cervical spinal cord and heart, all taken from EI5 embryos. Radioimmunoassays of these cultures showed they con-tained the same amounts of OMP as in explants of mucosa alone, i.e., no enhancement was produced by these tissues. Therefore, i.e., no enhancement was produced by these tissues. Therefore, the facilitating or enhancing effect of the bulb seems to be specific. It was of interest to determine whether a diffusible factor from the bulb could be identified. We made "sandwich" cultures in which olfactory mucosa and POB were co-cultured on opposite sides of a thin ( $25 \ \mu m$ ) Millipore filter, 0.45  $\mu m$  pore size; in addition thin ( $12.5 \ \mu m$ ) Nucleopore filters, pore sizes, 3 and 8  $\mu m$ , were used in these sandwich cultures. Diffusible factors, if they existed could pass through these pores. The radioimmunoassay results indicated there was no enhancement of Of radioimmunoassay results indicated there was no enhancement of OMP in these cultures even when the amount of POB tissue was increased  $3X.\ Light$  and electron microscopic examination of these sandwich cultures showed that the growing olfactory axons did not pass through the filter pores to contact the bulb. The results indicate that the presumptive olfactory bulb specifically increases OMP level by a mechanism that requires direct contact between receptors and hulb.

We are grateful to Dr. Frank Margolis, Roche Institute of Molecular Biology, Nutley, N.J. for his generous gift of OMP, 3H-OMP and antibody to OMP. This research was supported by USPHS grants #Ns-of181 and NS-18490.

6.9 ENHANCEMENT OF DOPAMINE NEURON SURVIVAL AND AXONAL PROLIFERATION BY MEMBRANES FROM STRIATAL TARGET CELLS. A. Heller, P.C. Hoffmann and B. Wainer. Depts. of Pharmacological and Physiological Sciences and Pediatrics, Univ. of Chicago, Chicago, II. 60637

Embryonic mouse dopamine (DA) neurons of the rostral mesencephalic tegmentum (RMT) when dissociated into single cells can be cultured either alone or in combination with dissociated cells from target areas such as the corpus striatum (CS). In rotatory cultures the cells reassociate to form aggregates. Only in the presence of target cells do the neurons develop and maintain axonal patterns similar to those seen <u>in vivo</u> (Hemmendinger et al., PNAS 78:1264,1981). In RMT-CS coaggregates there is a 4-fold enhancement of DA neuron survival compared to cocultures with cells from non-target areas (Hoffmann et al., Brain Res. In press). Since the aggregates are formed from single cells, the information necessary for these interactions appears to be intrinsic to the neurons, themselves. In order to identify factors responsible for these phenomena, membrane preparations from areas containing target and non-target cells were added to single cell suspensions of the RMT along with single cells from a non-target areas, the tectum (T), the latter being added to maintain equal numbers of dissociated cells in the various combinations. Membranes were obtained by high speed centrifugation (106,000 x g) following tissue homogenization in distilled water. The following combinations were examined: 1) RMT-CS, 2) RMT-T-CS, 3) RMT-T with T-membranes and 4) RMT-T with CS-membranes. The resulting aggregates were cultured for 8 days, exposed to 10<sup>-0</sup>M DA for 10 min and processed for histofluorescence. The aggregates were sectioned at 10 um and examined under the fluorescence microscope. For each combination sections were randomly selected and the number of DA neurons counted, yielding the following values: RMT-CS, 21/26; RMT-T-CS, 23/25; RMT-T with CS-membranes, 5/2, respressed as numbers positive/total number of sections observer were: RMT-CS, 21/26; RMT-T-CS, 23/25; RMT-T with T-membranes, 2/27; RMT-T with CS-membranes of embryonic CS cells are responsible for the ability of such target cells of their axons by observing randomized colo

6.11 PRIMARY CULTURE OF DISSOCIATED FETAL MESENCEPHALIC RAPHE: DIFFRRENTIAL STIMULATION OF SERCTONERGIC GROWTH BY TARGET TISSUE. Efrain Azmitia, Patricia M. Whitaker, Jean Lauder, and Alain Privat. Dept. of Anatomy, Mount Sinai Sch. Med., N.Y., N.Y. Fetal mesencephalic dopaminergic neurons show enhanced maturation when co-cultured with striatal target cells (Prochiantz et al, 1979). Mesencephalic 5-HT neurons have multiple forebrain but not hindbrain targets (Azmitia and Segal, 1978). A tissue culture system was developed using micro-titration plates to study the effects of fetal cells from hippocampus (HIP), spinal cord (SC), olfactory bulb (OB), striatum (ST), and cortex (CTX). Tissue from rat fetuses (E 14-16) were dissected and dissociated in Versene 1:5000 (GIECO). The cells were centrifuged (500 X g, 10 mi), resuspended in complete medium (Eagle's minimum essential medium, Hank's buffer, non-essential aminoacids, 1% glucose, and 10% fetal calf serum-GIECO), and 200 ul final volume plated in Linbro tissue cultures (5-6 wells per condition) were incubated at 37°C in a water-saturated 95% 0,/5% CO<sub>2</sub> atmosphere. Initial plating density (IPD) was determined with a Levy Hemacytometer Chamber. Serotonergic cells were immucoytochemically stained in the wells using<sub>2</sub> an antibody raised against 5-HT conjugated to hemocyanin. -H-5-HT uptake was measured in gach well (NEN, 24 Ci/mmole, 5 X 10° M,20 min incubation at 37°C in Hanks buffer with 1% glucose, non-specific uptake determined in presence of 10° M flucoxetine). Protein determigation were made in each well using a modified Lowry. Uptake of 'H-5-HT was linear within an IPD of 0.5-2 10° cells/cm<sup>-</sup>. The number of 5-HT immunoreactive cells was also linear within this range (0.5% of total cells). Each 5-HT cell concentrated approximately 1 femtonole of serotonin within 20 min. 'H-5-HT uptake (IPD=10° raphe cells/cm<sup>-</sup>) was stimulated by IPD of 10° cells/cm<sup>-</sup> from HIP (11 fold), SC (9.7 fold), OB (10.7 fold), CTX (6.4 fold), and ST (5.3 fold) after 5 days in c 6.10 AGE-DEPENDENT REQUIREMENTS FOR HETEROLOGOUS NEURITE EXTENSION FACTOR AND NERVE GROWTH FACTOR IN CULTURED SYMPATHETIC NEURONS. M. D. Coughlin. Dept. of Neurosciences, McMaster University, Hamilton, Ontario, Canada L&N 325. The superior cervical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the 14 gestational day (TAN) and the superior servical ganglion (SCG) of the superior servical ganglion (SCG) (S

The superior cervical ganglion (SCG) of the 14 gestational day (E14) mouse embryo extends neurites and differentiates biochemically when cultured in the absence of added nerve growth factor (NGF). In contrast, ganglia from newborn (NB) mice require added NGF for survival in culture. Moreover, neurite outgrowth in culture requires a neurite extension factor derived from conditioned medium (CMF) or an antigenically similar factor produced by neurons themselves (Coughlin and Kessler, J. Neurosc. Res. 8: 289, 1982). Whereas maximum survival and neurite extension of dissociated

Whereas maximum survival and neurite extension of dissociated sympathetic neurons in culture is obtained in the presence of both added NGF and added CMF, the relative requirements for these factors change during development. Maximum survival of E14 neurons requires added CMF and is not significantly altered by the presence of antiserum to NGF (anti-NGF). Although NGF promotes survival of E14 neurons over control levels, survival is approximately half of that obtained with CMF alone. In contrast, survival and neurite outgrowth of NB SCG neurons absolutely requires NGF. Although CMF alone enhances survival of NB neurons, this effect is reversed by addition of anti-NGF, suggesting that such survival depends on endogenous NGF carried into culture. In the presence of NGF but fail to extend neurites. These results suggest

These results suggest that at early embryonic stages, sympathetic neurons do not require added NGF for survival but do require exogenous sources of a neurite extension or axonal guidance factor. At later stages, SCG neurons develop both a requirement for NGF and the capacity to respond to NGF with production of an autologous neurite extension factor antigenically similar to CMF.

6.12 STIMULATION OF NEURITE OUTGROWTH BY ADULT AMPHIBIAN HEART-CONDI-TIONED MEDIUM. <u>H.T. Whelan, P.C. Letourneau\*</u>, <u>M.H. Tuszynski\*</u>, <u>and K.F. Swaiman\*</u>. Div. of Pediatric Neurology, and Dept. of Anatomy, University of Minnesota Medical School, Minneapolis, MN 55455.

Conditioned culture medium has been used for characterizing many neurotrophic substances. Much of the work thus far has concentrated on medium conditioned by <u>embryonic</u> heart cells in culture.

Central nervous system regeneration, even through adulthood, occurs in urodele amphibians, such as Ambystoma tigrinum (the tiger salamander). Large scale organ-by-organ screening for possible neurotrophic factors was thus undertaken using <u>adult</u> tiger salamanders with spinal cord lesions in hopes of finding neurotrophic mediators effective in <u>adults</u>. The ability to stimulate neurite outgrowth was assayed in dis-

The ability to stimulate neurite outgrowth was assayed in dissociated neuron cultures from ll-day-old chick embryo dorsal root ganglion. The ability to increase choline acetyl transferase (CAT) activity was assayed in dissociated neuron cultures from l6-day-old fetal mouse cortex. Two to four weeks after spinal cord transection, organ homogenates from brain, spinal cord, heart, kidney, liver, skeletal muscle, gonads, spleen, pancreas, blood, and regenerating tail-bud at the site of cord transection were individually prepared and aliquots added to the culture medium.

The results were compared with those achieved by adding  $\beta$ -nerve growth factor ( $\beta$ -MGF), chick embryo heart cell-conditioned medium (HCM), or both to similar neuron cultures. Control cultures contained medium with no additives.

Although several tissue types (i.e. heart, brain, cord, spleen) appeared promising initially, only heart homogenate repeatedly produced extensive neurite outgrowth and produced an increase in CAT activity (10%). These changes paralleled the effects of  $\beta$ -NCF and HCM.

Further characterization of the neurotrophic effects of the salamander heart homogenate was achieved by fractionation of cell components by ultracentrifugation. Effects on neurons in culture were enhanced in the nuclear and microsomal fractions, especially after disrupting the organelles and centrifuging away the debris.

This activity is eliminated by heating or excessive freezethawing, suggesting a protein neurotrophic factor. Further characterization is under way.

- A LATE AND LONG-LASTING POST-ACTIVITY POTENTIATION IN THE 7.1 SKLETAL MUSCLE OF THE RAT. J. García Ramos. Department of Physiology and Biophysics, Centro de Investigación y de Estu-dios Avanzados del Instituto Politécnico Nacional, México, D.F. and CEUNICYT, Universidad de Colima, Colima, Col., México. After a brief period of relatively high frequency activity
  - not producing fatigue of the gastrocomenius-soleus muscle of the anesthetized rat, a late or delayed potentiation lasting for more than 60 min was observed. The improved responses to test shocks appear well separated from the postetanic potentiation

This delayed potentiation was induced with indirect stimula-tion through the sciatic nerve as well as with direct stimula-tion applied to the previously denervated (5 days) or to the curarized muscle. The late potentiation was transiently blocked by the protein-synthesis blocking agents (cycloheximide and blocked by the structure of the late to the structure of the late by the protein-synthesis blocking agents (cycloheximide and chloramphenicol) and not present at low temperatures (below 35 degrees, centigrade). During this potentiation neither the electromyograms nor the impedance changes of the whole muscle showed any correlated variation. Several brief periods of rela-tively high frequency stimulation applied at intervals from 1 to 60 min showed additive effects. In opposition, the lack of that stimulation may result in reduction of the responses to toot chools. test shocks.

These observations suggest that relatively rapid activity Inese observations suggest that relatively rapid activity of a muscle causes certain biochemical changes of transient duration which may constitute the basis for the muscle hyper-trophy and for its better performance during training. The reversion of these biochemical reactions at rest could be responsible of the fall in muscle efficiency and the atrophy of discussion. of disuse.

ADAPTATION IN FUNCTION OF THE PHARYNGEAL CONSTRICTOR MUSCLES OF ADAPTATION IN FORCITOR OF THE PHARMAGEAL CONSTRUCTOR MUSCLES OF THE RHESUS MONKEY. A.J. Miller, L. Rower, G. Chiericit\*, and D. Clendenning\*. Craniofacial Center, Department of Growth and Development and Department of Otolaryngology, University of California, San Francisco, CA 94143 The palatopharyngeus muscle and pharyngeal constrictor muscles

paratopharyngeus muscle and pharyngeal constrictor muscles were studied to determine their function with changes in head posture, upper airway obstruction, swallowing and inducement of laryngospasm. Pairs of fine wires were placed in an array along a rostro-caudal axis of the pharyngeal wall, 2-4 mm lateral of the midline to record the electromyography activity (EMG). A flexible fiberoptic scope was used to monitor pharyngeal movements. EMG activity was synchronized with the view of the pharyngolaryngeal movements on a split-screen and re-

pharyngolaryngeal movements on a split-screen and re-corded on videotape. Tonically discharging motor units were recruited in certain regions of the pharynx including the caudal superior pharyngeal constrictor (SPC) and the rostral middle pharyngeal constrictor (MPC). This tonic activity could remain even during phasic contractions of these muscles during swallowing. Not all fibers of the pharyngeal constrictors were recruited during the peristaltic-like contractions of the pharynx during swallowing. Rhythmic respiratory discharge could be induced within the pharyngeal constrictor muscles with nasal obstruction, flexion of the head, or a change from the supine to erect position. Fibers of the SPC discharged during inspiration while the inferior pharyngeal constrictors are important to postural maintenance of the pharynx, hyoid bone, and thyroid cartilage. maintenance of the pharynx, hyoid bone, and thyroid cartilage. Supported by U.C.S.F. Academic Senate Research Grant.

- MUSCLE AFTERDISCHARGE MASKS NEUROMUSCULAR BLOCKADE IN MODERATE 7.2
  - HUBGLE AFTERDISTINGE ANSWS REDROTOSCULAR BLOCKADE IN FOREATE HYPOCALCENIA, B.M. Allen\*, G.G. Sonjen, & D.B. Sanders. Dept. Physiology & Div. Neurol., Duke Univ., Durham, NC 27710. We recorded [Ca<sup>2+</sup>] with a calcium-selective electrode (Ione-tics, Inc.) in a flow cell in an extracorporeal loop connected to a carotid artery in cats. EMG and contractions evoked by stimu-lation the propried agray were recorded from EDI muchlo ble of lating the peroneal nerve were recorded from EDL muscle. We already reported (Allen et al., Fed. Proc. 41:1734, 1982) neuro-muscular blockade and slowed relaxation of the contraction, caused by lowering arterial  $(Ca^{2+})$  by i.v. citrate. We now find that contractile force initially increased as arterial  $[Ca^{2+}]$  was lowered, even as the amplitude of the transmitted EMG action potentials was depressed. Enhanced contractions and slowed relaxation were accompanied by EMG afterdischarges in the wake of stimulus-evoked action potentials. Multiple firing of the muscle membrane explains the apparently enhanced strength of contraction. The EMG afterdischarges and the spontaneous discharges appearing in profound hypocalcemia, had the character of single muscle fiber potentials, not of motor unit discharges. (We have recently seen similar EMG signs in a patient with severe hypocalcemia.) In profound hypocalcemia, and during recovery from it, contractions evoked by trains of stimuli (but not by single shocks) were more depressed than the corresponding EMG action potentials. This suggests failure of excitation-transmission cou-pling, possibly due to loss of calcium from sarcoplasmic reticu-1.um.

Amplitudes of contractions and EMG action potentials Fig. 1: evoked by motor nerve stimulation as functions of arterial  $[Ca^{2+}]$ during hypocalcemia and recovery. Note hysteresis. A: stimula-tion by trains of shocks; B: single shocks. (In part supported by NIH Grants NS 18670 and NS 18949).

RANDOM REINNERVATION OF LG AND SOL MUSCLES BY THEIR COMMON NERVE? M.J. Gillespie, T. Gordon and P.K. Murphy. Depts. of Physiology & Pharmacology, University of Alberta, Edmonton, Alberta, T6C 2H7. In order to determine whether nerve fibers show a preference for their former muscles we have examined the contractile and

histochemical characteristics of two muscles in the rat hindlimb, fast lateral gastrocnemius (LC) and slow soleus (SOL) after rein-nervation by their common nerve. The LGS nerve was cut before its entry into the LG and sutured to the surface of the muscle thus presenting that muscle with fast and slow nerve fibers. The nerve fibers must course through LG as they normally do to reinnervate SOL muscles. After 3-14 months reinnervated LG and SOL weighed 68% and 59% of control muscles respectively, while twitch and tetanic forces were similarly reduced. For reinnervated SOL muscles con-traction time (CT) was considerably faster than control values (42.5 vs 72 msec), while half relaxation time (1/2RT) was similar. Though CT in reinnervated LG muscles was almost normal (35 vs 32 msec) 1/2RT was longer than control (37 vs 30 msec).

This data might be explained if the LG became reinnervated by more slow nerve fibers than normal leading to a longer relaxation phase with the fast muscle fibers determining the normal CT. Similarly, reinnervation of soleus by more fast nerves than normal could account for the decreased CT and normal 1/2RT. This prediction was born out when the proportion of fast and slow motor units in the reinnervated muscles were determined physiologically (Table 1). Results show a considerable increase in the proportion of units with a concomitant decrease in FR units in reinnervated LG. SOL muscles were composed of 70% fast contracting units and 30% S units. The CT and 1/2RT of FF, FI, FR and S motor units in the reinnervated muscles were normal so that the data supported the above interpretation of the whole muscle contractions.

Thus the nerve-muscle specificity that dictates connectivity in the embryo does not appear to operate in adult reinnervation. Rather the very similar proportions of slow and fast motor units in both reinnervated muscles resembled the proportions of fast and slow fibers in the common LGS nerve. This is consistent with the idea that slow and fast muscles show no preference for their former nerves and indeed suggests that reinnervation may occur in a random fashion.

INCREASED GROWTH FACTOR-LIKE ACTIVITY FROM HYPERTROPHIED SKELETAL 7.5 MUSCLE. M.G. Bissell and S. Kaufman\* Lab. of Neurochemistry, NIMH Bethesda, MD 20205

Passive mechanical stretching of skeletal muscle leads to hy-pertrophy of the tissue in response. Using a technique developed in this laboratory for stretching monolayers of chick embryo myo-tubes in vitro, it has been shown previously that skeletal myotubes respond to passive stretch by increased amino acid uptake (as measured by uptake of aminoisobutyric acid, AIB), increased incorporation of amino acids into, and accumulation of total cellular protein. These increases have been shown to be inhibited by ouabain, after a 30 minute lag period, and by tetrodotoxin. Stretch has also been shown to be associated with an early in-crease in the Vmax of the membrane Na/K-dependent ATPase, as measured by rubidium-86 uptake. These stretch effects take place serum free medium and have been shown to be mimicked by the addi-tion of serum to unstretched cultures.

More recently, we have carried out additional studies on whole animal model of skeletal muscle hypertrophy. This in  $\underline{v}$ This in vivo tenotomy model involves the surgical section of the Achilles tendon of the gastrocnemius muscle of one limb while a "sham" operation is of the gastrocnemius muscle of one limb while a "sham" operation is carried out on the other limb. Following the operation, the weight-bearing load is redistributed from the gastrocnemius to the two smaller synergist muscles, the soleus and plantaris, which rapidly hypertrophy. Using this system, we have seen significant increases in wet weight of the soleus and plantaris, as early as four to six hours post-tenotomy. We have made aqueous extracts of hypertroph-ied soleus and plantaris muscles from rats 48 hours after cutting the ten definition of the soleus and plantaris where here derived in the tendon. These extracts, like serum, cause dose-dependent in-creases in AIB uptake and amino acid incorporation when added to unstretched chick myotube cultures. Similar extracts from the corresponding nonhypertrophied muscles on the unoperated contralateral hindlimbs of the same animals show a significantly smaller effect when added to the cultures. The substance (or substances) responsible for this effect, like the similarly active serum com-ponent, is heat labile and retained by a dialysis bag. The active factor (s) from rat hindlimbs is degraded by treatment with  $\alpha$ -chymotrypsin. Its effect on AIB uptake is not additive with 10% stretch. Like the effect of serum, its effect on AIB uptake is sensitive to actinomycin D and ouabain, but unlike stretch it is effective within 5 minutes of application. Further characterization of the substance or substances responsible for these effects are currently underway.

7.7 ELECTRICAL STIMULATION EXERCISE CONDITIONING PROTOCOL FOR PARA-LUZED MUSCLE. J.A. Gruner, R.M. Glaser\*, S.R. Collins\*, S.D. Feinberg\*. Dept. of Physiology, Wright State Univ. School of Medicine, Dayton, OH 45435.

Electrical stimulation has been shown capable of restoring function to paralyzed muscle in individuals where there is no lower-motoneuron involvement. Few studies, though, have carefully examined the relationships between various exercise parameters, such as work load, repetition rate, and duration on the rate of increase and final levels of strength and endurance obtained in electrically stimulated muscle. Moreover, such studies have rarely been concerned with developing exercise protocols which may safely be prescribed for paraplegic individuals whose physical condition, including cardiopulmonary fitness and skeletal integ-rity, may vary greatly and are difficult to accurately assess.

An electrical stimulation exercise system was designed which could be safely applied to most paraplegic individuals. The exer cise system consists of a platform, backboard, and ramp which the individual is wheeled up onto. A system of weights and pulleys is built into the platform so that when the knee is extended, a cable attached to the subject's ankle will raise a weight behind the subject. Knee extension is produced by stimulating the quadriceps muscle using 0.2 ms pulses at 30 hz delivered via surface elec-trodes (3M). An Apple II+ computer controls the stimulus ampli-tude via feedback so that the weight can be lifted a preset distance (for a constant work load). A typical exercise session consists of 2 bouts of 20 leg lifts with each leg extending alternately once every 30 seconds. Bouts are 10 minutes apart. The work load for a given exercise session is adjusted according to the individual's past achievement using the following algorithm If the first 20 lifts are not successfully completed, the weight for that leg is decreased by 1.25 lbs. If both bouts are completed successfully in two successive sessions, the weight is increased by 1.25 lbs on the next session.

Six subjects have been exercised 3 sessions per wk, starting at 2.5 lbs. Three subjects increased in load at the maximum rate until reaching about 15 lbs after 23 sessions (1 subject) and 23 at 2.5 lbs. lbs at the end of 36 sessions (2 subjects). Two other subjects initially dropped to 1.25 lbs where they were held for 10 to 14 sessions, after which they began to steadily increase in load. these subjects, the rate of increase of the muscle's work capacity should be reflected by the rate of increase in weight lifted. Some Should be relected by the late of increase in weight integration some spasticity was often present in antagonist muscles so that the amount of work measured externally may have underestimated the actual work performed. Also, it was noted that some individuals who could not voluntarily extend their knees or produce measurable quadriceps EMG activity could "voluntarily" extend the duration of the stimulation-induced contraction. NEUROMUSCULAR FUNCTION IN A HEALTHY AGED POPULATION. Α.Α. Vandervoort<sup>\*</sup>and A.J. McComas. Departments of Neurosciences and Medicine, McMaster University Medical Centre, Hamilton, Medicine, McMaster Unive Ontario, Canada, L8N 325.

In view of the importance of maintaining normal mobility in the ageing population we have studied function in two opposing groups of leg muscles, the ankle dorsiflexors (DF) and plantarflexors (PF), in a large group of elderly subjects. Attempts have been made to answer three major questions. First, to what extent does muscle strength decline with age? Second, can descending motor pathways be effectively utilized in activating motoneurones? Third, other than in maximal force generation, are there changes in the contractile properties of aged muscles? The findings in 70 healthy men and women, aged 60-100 years, were compared with those in 28 young adults aged 20-32 years; all subjects were volunteers and the study was approved by the local ethics committee. The results of the study disclosed: (i) relatively small (15-20%) decreases in maximum voluntary DF and PF torques in 60-69 year old men and women compared with controls, (ii) normal activation of DF and PF motoneurones during maximal effort, even in the oldest subjects, (iii) slowing of the isometric twitch between the third and seventh decades, and (iv) reduction in the maximum voluntary: twitch torque ratio for aged PF muscles. Ultrasonic imaging of calf musculature indicated that the reductions in PF voluntary and twitch torques were greater than the loss of muscle cross-sectional area. We conclude that the PF and DF muscles of elderly subjects remain effective for daily activities despite the loss of functional muscle mass.

7.8 MUSCLE GAIN CHANGES INDUCED BY INTERMITTENT SUBMAXIMAL ISOMETRIC EXERCISE. T.M. Banas\* and P.E. Crago, Department of Biomedical Engineering, Case Western Reserve University, Cleveland, OH 44106. Muscle fatigue, when viewed as an internal disturbance to

neuromuscular regulation, can potentially be used in the study of stretch reflex function if the exercise does not compromise the interpretation of the electromyogram (EMG) as a measure of motor neuron pool output. We found that intermittent submaximal exercise can substantially reduce muscle force generation without reducing muscle action potential conduction velocity. This is in contrast to sustained maximal voluntary contractions where conduction velocity has been shown to decrease, thus limiting the reliability of the EMG in reflex assessment.

Torque was measured at the interphalangeal joint of the thumb of adult normal subjects during isometric contractions of the Flexor pollicus longus (FPL). The joint was held at 10 degrees of flexion. EMG was measured from surface electrodes over the FPL or from intramuscular wire electrodes. Muscle gain was calculated as the slope of the linear regression of torque on EMG . Steady state values of torque and smoothed, rectified EMG were measured as the average values during the last half of two second contractions at torque values chosen randomly between three and fifteen N-Cm. The subjects rested for five seconds between contractions. The power spectral density of the raw EMG was calculated from ten similar contractions at an intermediate torque level.

The torque-EMC relationship and the power spectral density were measured before, a few minutes after, and at intervals of 30-45 minutes after a period of exercise. The exercise consisted of 30-60 isometric contractions at 15 N-Cm torque for 11 seconds, with 10-20 seconds rest between each contraction. The slope of the torque-EMG relationship was only slightly reduced a few minutes after the exercise, but was reduced by 1/3 to 1/2 after 30-45 minutes. The slow decrease in gain that took place after the exercise may have been due to a gradual decrease of an exercise induced potentiation, but this hypothesis was not tested directly. Typically the slope remained low for the next 30-45 minutes and then began to increase.

The power spectral density was measured at the same EMG level both before and after the exercise. The torque was typically 10 N-Cm before the exercise and was recalculated on the basis of the Now before the exercise and was recalculated on the basis of the new torque-EMG relationships after the exercise. The shape of the spectrum was changed very little by the exercise, except for a possible slight shift to higher frequencies. Thus it appears unlikely that there were any changes in muscle fiber conduction velocity accompanying the reduction in muscle gain. Funded by NSF (PCM 79-15319) and by NIH (NS-19135).

7.9 ELECTROPHYSIOLOGIC DIFFERENCES BETWEEN MAMMALIAN FAST AND SLOW MYOFIBERS. J.A. Florendo,\* J.F. Reger,\* and P.K. Law (SPON: R. Caldwell). Depts. of Anatomy, Neurology, and Physiology Biophysics, Univ. of Tennessee Ctr. Hlth. Sci., Memphis, TN. 38163.

Miniature end-plate potentials (mepps) and indirectly elicited action potentials were recorded in vivo at 37°C from surface fibers of the fast-twitch extensor digitorum longus (EDL) and the slow-twitch soleus (SOL) muscles of 3 to 4-monthold Bar Harbor 129 mice.

Mepps of the EDL exhibited a significantly higher frequency, smaller amplitude, and shorter duration than the mepps of the SOL. Histograms demonstrated that EDL and SOL fibers had overlapping but skewed distributions in all three parameters.

	EDL	SOL	
Frequency (hz)	8.79 + 4.50	2.40 + 1.36	
Amplitude (mv)	0.75 + 0.15	1.02 + 0.21	
Duration (msec)	1.29 + 0.31	2.92 + 0.89	

Mean  $\pm$  SD from 52 EDL and 56 SOL fibers. All differences significant at P < 0.005 by Student's t-test.

Action potentials of EDL fibers exhibited a significantly greater amplitude and shorter duration than SOL fibers. A single stimulus elicited several action potentials from an EDL fiber but only one action potential from a SOL fiber. Histograms demonstrated that EDL and SOL fibers had overlapping but skewed distributions of amplitude and duration.

	EDL	SOL
Amplitude (mv)	96.30 + 3.55	79.75 + 8.17
Duration (msec)	0.99 + 0.06	1.28 + 0.10

Mean + SD from 86 EDL and 77 SOL fibers. All differences significant at P < 0.005 by Student's t-test.

Fast- and slow-twitch muscle fibers can thus be identified and distinguished on the basis of these electrophysiologic parameters.

7.11 OCULOMOTOR NUCLEUS INNERVATION OF THE LATERAL RECTUS MUSCLE IN THE CAT. J.R. McClung\*, S.J. Goldberg, J.S. Nelson\* and C.H. Fowlkes\*. Dept. of Anat., Med. Coll. of Va.-VCU, Richmond, VA 23298.

Most motoneuron pools are organized such that all of the cells are localized in a specific nucleus and innervate a single muscle. There are examples, however, in both the skeletal and extraocular systems where unusual innervation patterns exist. The motoneuron pool innervating the cat retractor bulbi muscle, for example, is divided and contained in both the principal and accessory abducens nuclei and the oculomotor nucleus. Some of the VIth Nerve retractor bulbi axons also branch and innervate the lateral rectus muscle. Anomalous innervation of the lateral rectus muscle by the oculomotor nerve has been observed in human congenital abnormalities of the abducens nucleus (Duane's Syndrome), and some IIIrd Nerve innervation of the lateral rectus muscle has recently been suggested to occur normally in the cat. The present studies document that, in the cat, the motoneurons

The present studies document that, in the cat, the motoneurons which innervate the lateral rectus muscle are found in the ipsilateral principal abducens nucleus in expected numbers and are present in small numbers in the accessory abducens and occulomotor nuclei.

are present in small numbers in the accessory abducens and oculomotor nuclei. The lateral rectus muscle nerve was dissected from the muscle and the cut proximal end was sealed in plastic tubing and exposed to a 50% solution of HRP. This carefully isolated preparation allowed the use of TMB histochemistry for localization of the retrogradely labeled motoneurons without evidence of HRP leakage or spreading to other orbital structures. In addition, stimulation of the abducens nucleus elicited expected twitch contractions of 12 to 15 grams and simultaneous stimulation of the oculomotor nucleus added 300 to 500 milligrams in twitch tension. Oculomotor nucleus muscle both before and after total bilateral extirpation of the abducens nuclei. These procedures eliminated any participation by either principal or accessory abducens motoneurons in the response.

These findings show the lateral rectus, a primary ocular rotatory muscle in the cat, to have a diverse innervation derived from three brainstem nuclei and this emphasizes problems both in defining a motoneuron pool and in understanding the manner in which motoneurons are recruited at widely separated sites.

7.10 GPI-1B AND GPI-1C AS GENOTYPE MARKERS IN NORMAL/DYSTROPHIC MYO-BLAST TRANSPLANT STUDY OF IMMUNOCOMPATIBLE MICE. P.K. Law. Departments of Neurology and Physiology/Biophysics, Univ. of Tennessee Ctr. Hlth. Sci., Memphis, Tennessee 38163. We have shown that surgically transplanted mesenchymal cells

We have shown that surgically transplanted mesenchymal cells from the limb-buds of normal mouse embryos improved the structure and function of dystrophic mouse muscles (Muscle & Nerve 5:619-627, 1982). In order to study the mechanisms responsible for such improvement, we seek immunocompatible host and donor mice that exibit distinct genotype markers and the trait of dystrophy. These conditions are satisfied with mice of C57BL/6  $\frac{+}{+}$  gpi-1<sup>C/C</sup> strain (courtesy of Dr. A. C. Peterson, Montreal) and C57BL/6  $\frac{dy^{2J}}{dy^{2J}}$  gpi-1<sup>b/b</sup> strain (Bar Harbor). The survival and development of donor myoblasts in host muscles will be analyzed with electrophoresis of muscle isozymes of GPI. We report here a reliable and convenient GPI electrophoresis method using 1% agarose gel films (Corning 470100).

The mouse soleus, weighing about 7 mg, was thoroughly homogenized in 0.12 ml of ice-chilled double-distilled water. The sample was centrifuged at 600g for 10 min. and then at 1300g for 10 min. at room temperature. 0.5  $\mu$ l of the supernatant was applied to each well of the agarose film. Electrophoresis was conducted at pH 8.6 in a LKB 2117 Multiphor, anode to cathode, for 3.5 hours at 5 mA per channel or 2.5 V/cm field strength. The gel bed was cooled by running water at 4°C. The staining solution used was specific for GPI. It was modified from Eicher and Washburn (Proc. Natl. Acad. Sci. USA <u>75</u>:946-950, 1978), and consisted of 8 ml of 0.2 M Tris-HC1, pH 8.0; 20  $\mu$ l of G6PD (0.3 IU/ul); 0.4 ml of Mg acetate (53.6 mg/ml); 0.6 ml of fructose-6-phosphate (100 mg/ml); 0.4 ml of phenazine methosulfate (2.5 mg/ml). Staining time was 4 min. at 37°C. Densitometric tracings of the gel bands were analyzed and the gels photographed. Donor muscles exhibit GPI-IC and host muscles exhibit GPI-IB.

Donor muscles exhibit GPI-1C and host muscles exhibit GPI-1B. The test muscle receiving myoblast transplant may exhibit a variety of electrophoretic patterns which can be interpreted as follows: (1) GPI-1B, GPI-1C. A mosaic muscle with donor and host cells. Mosaic fibers are not present. (2) GPI-1B, GPI-1C, GPI-1BC. A mosaic muscle with host fibers, donor fibers and mosaic fibers. (3) GPI-1C, GPI-1BC. A mosaic muscle with donor fibers and mosaic fibers. Host fibers have degenerated. (4) GPI-1B, GPI-1BC. A mosaic muscle with host fibers and mosaic fibers. (5) GPI-1BC. A mosaic muscle with only mosaic fibers. (6) GPI-1C. Mosaic muscle with only mosaic fibers. (7) GPI-1BC. A mosaic muscle. (7) GPI-1B. Donor cells do not survive in the host muscle. (Supported by MDA)

TWO CLASSES OF GABAERGIC NEURONS REPRESENT THE MAJORITY OF NEO-8.1 STRIATAL NEURONS IN THE RAT. W.H.Oertel and E.Mugnaini. Neurological Clinic, Technical University, Munich, FRG and Department of Biobehavioral Sciences, U.Conn., Storrs, CT 06268, USA.

The rat neostriatum contains evenly distributed medium size neu-rons with scattered large neurons inbetween in a ratio of approximately 50:1.Retrograde transport studies have demonstrated that the majority of the medium size neurons project to the globus pal-lidus, the entopeduncular nucleus and substantia nigra pars reticulata.Physiological,biochemical and cytochemical reports indicate that the neostriatal neurons include GABAergic,cholinergic and peptidergic cell populations. In the present study on the rat neostriatum we have reinvestigated the immunocytochemical localization of glutamic acid decarboxylase(GAD), the enzyme which synthesizes GABA, with a sheep antiserum to rat brain GAD. Untreated rats and rats that had received a stereotaxic injec-

tion of colchicine(10-20 $\mu g)$  into the neostriatum 12-50 hr prior to sacrifice were used. The animals were perfused with a zinc-formalde-hyde fixative.Floating brain sections were processed for GAD-like immunocytochemistry with the PAP method of Sternberger.

The neostriatum of untreated rats contained scattered distinctly GAD-immunoreactive pleomorphic medium size to large neurons. The majority of medium size neurons were not immunoreactive.After colchicine injection, however, the majority of medium size neurons throughout the neostriatum exhibited distinct GAD-immunoreactivity. Thus, the rodent neostriatum contains two classes of GABAergic neurons: a minor cell class which can be demonstrated immunocytochemically with the employed GAD-antiserum in untreated animals, and a major cell class that is stained only following topic injection of colchicine.Cells belonging to the first category vary considerably in shape and size,whereas cells of the second category are more homogenous and appear to correspond to the principal neostriatal nerve cell, commonly referred to as medium size neurons.

Previous investigations have indicated that neostriato-pallidal and neostriato-nigral terminals are numerous and, at least to a large extent, use GABA as their transmitter. Such GABAergic neostriatal projections may originate from the major population of GADpositive neurons. Apparently, only by blocking axoplasmic transport with colchicine, the concentration of GAD in these nerve cell bodies reaches levels detectable by our technique. The minor population of GAD-positive neurons stainable without colchicine treatment may have particular functional and anatomical features. The data indicate that two categories of GABAergic neurons re-

present the majority of rat neostriatal neurons. Localization of neurons synthesizing acetylcholine or neuropeptides and their relation to GABAergic neurons is presently under investigation. Supported by DFG Oe 95/2-1(WHO) and US-PHS 09904 (EM).

The presence of somatostatin in the striatum is of particular interest since alterations in concentrations of this peptide have been found in degenerative neurologic illnesses. It has been recently demonstrated that sytemic cysteamine results in

8.3 DEPLETION OF STRIATAL SOMATOSTATIN BY LOCAL CYSTEAMINE INJECTION.

M. F. Beal and J.B. Martin, Department of Neurology, Harvard Medical School, Boston, MA 02114.

reduction of somatostatin-like immunoreactivity (SLI) in rat brain including the striatum. In the present study we examined the effects of local cysteamine injections in the rat striatum. Injections were made in a volume of 1.0 or 2.0 µl at the coordinates 8.4 mm anterior, 2.7 mm lateral and 4.5 mm vertral to the dural surface. Animals were subsequently decapitated and the brains sectioned at 2 mm intervals with dissection of the striatum, cortex and hippocampus. SLI was measured by radioimmunoassay. In an initial experiment 7.5 µg, 15.0 µg, 30.0 µg 50.0 µg and 100.0 µg of cysteamine were injected into 6 animals in each group and 30 µg of ethanolamine was injected into controls. Animals were sacrificed at 2 hours. A dose response was demonstrated with a maximal depletion of approximately 50% of the total striatal SLI seen at the 30  $\mu\,g$  and higher doses. The cortex and hippocampus were unaffected. A time course experiment was done using a dose of 30 µg of cysteamine in 1 µl and 30 µg of ethanolamine in controls. A significant depletion of striatal SLI to approximately 50% of controls  $(1.09 \pm .06$  to  $.57 \pm .03$ mg/mg protein at 1 hour) was found at the time intervals 1,3,6,24 and 72 hours. In addition at the 3rd hour and at subsequent time intervals there was an approximately 20% depletion of SLI in the contralateral striatum. Initial results showed a decrease in striatal dopamine turnover. Histologic examination of the two highest doses of cysteamine (50 and 100  $\mu$ g) using Nissl stained serial sections showed that gial scarring was localized to the needle tract and directly adjacent neurons appeared normal. These studies show that local injections of cysteamine result in depletion of SLI and may be useful in studying the interactions of somatostatin with other known striatal neurotransmitters.

8.2 IMMUNOHISTOCHEMICAL LOCALIZATION OF LEU-ENKEPHALIN AND GLUTA-MIC-ACID-DECARBOXYLASE IN THE NUCLEUS CAUDATUS OF THE RAT. M. Morelli, M. Del Fiacco\*, J.-Y. Wu and G. Di Chiara. Institutes of Exp.Pharmacology and Toxicology, and Anatomy, University of Cagliari, Italy. Baylor College of Medicine, Houston U.S.A.

GABA-ergic and Enkephalinergic neurons have been described as projecting from the nucleus caudatus to the substantia nigra of the rat. These neurons are considered to play a very important role in modulating striatal motor responses such as catalepsy, turning behaviour and stereotypy. In order to study the precise localization of these neurons we applied the immunocytochemical technique to consecutive (6,um) sections of the nucleus caudatus of the rat. Male rats were injected with 30 ,ug of Colchicine in the caudal part of the caudate head in order to block the axonal flow. The dilution of the specific Leu--Enkephalin (L-Enk) and GAD (glutamic-acid-decarboxylase) antibodies was 1:600 and incubation was carried out at 4°C overnight. The sections were processed using the PAP immunoreaction technique. Several sections incubated with non immunized rabbit serum showed no reaction products. In the normal caudate nucleus, a dense network of GAD and L-Enk immunoreactive fibers could be observed throughout the entire area. In these animals immunoreactivity in neuronal perikarya was not observed. In the caudate nucleus injected with Colchicine, L-Enk and GAD containing perikarya could be demonstrated throughout the entire extent of the nucleus. L-Enk immunoreactive cells were clustered in the ventral and lateral part of the posterior half of the head of the nucleus caudatus, while only few positive cells were found in the medial and dorsal part of it. In the body of the nucleus caudatus L-Enk containing perikarya were concentrated in its ventralmost part. GAD immunoreactive cells in the nucleus caudatus were more evenly distributed. The major concentration of CAD positive somata was found in the external part of the caudatus, both dorsally and ventrally; only relatively few somata were stained in the medial part of the nucleus. Thus the topography of Leu-Enkephalineraic somata in the nucleus caudatus is in part superimposable to that of GAD positive somata. Both GAD and L-Enk positive somata were of medium size. The possibility that GABA and L-Enk coexist in striatal neurons will be discussed.

84 THE RELATION OF STRIOSOMES IN THE CAUDATE NUCLEUS OF THE CAT TO THE ORGANIZATION OF EARLY-DEVELOPING DOPAMINERGIC FIBERS, GAD-MC-F. Chesselet, J.-Y. Wu, F. Eckenstein, and T.E. Joh, Dept. of Psychol. and Brain Sci., Mass.Inst.Tech., Cambridge, MA 02139

In the caudate nucleus of the cat, histochemically distinct tissue compartments called striosomes have been identified in cross sections as 0.3-0.5mm-wide regions in which the neuropil is low in acetylcholinesterase (AChE) activity and high in met-enkephalin-like immunoreactivity. These zones, in turn, have been correlated in serial-section analyses with patches or gaps in corritical and thalamic afferent-fiber distributions, with zones of weak efferent-cell labeling and with clusters of  $^{3}H$ -thymidine ( $^{3}H$ -thy) labeled cells in cats exposed to the  $^{3}H$ -thy as E23-E30 fetuses. We report here immunohistochemical experiments designed to determine the relation of this macroscopic ordering to the distribu-tions of three key neurotransmitter systems in the striatum: the cholinergic, as marked by antibodies to choline acetyltransferase (CAT); the GABAergic, as marked by antibodies to glutamic acid de-carboxylase (GAD); and the early forming "islandic" dopaminergic, as marked by antibodies to tyrosine hydroxylase (TOH). For the TOH experiments, we studied late fetal and neonatal

kittens, in which early forming dopaminergic fibers form discrete

kittens, in which early forming dopaminergic fibers form discrete patches visible in TOH preparations. We pre-exposed the animals at E25-E27 to  ${}^{3}$ H-thy and used autoradiography to identify the strio-somes as clusters of  ${}^{3}$ H-thy-labeled neurons. Serial-section com-parisons showed that these  ${}^{3}$ H-thy clusters (the striosomes) were in register with the TOH patches (the dopamine "islands"). For the GAD experiments, serial sections through the caudate nucleus of adult cats were processed alternately for AChE and for GAD-like immunoreactivity by Sternberger's PAP method. GAD-positive cell bodies were rarely seen but the striatal neuropil was GAD-positive and there were patches of very intense GAD-like immunore-activity. These GAD-positive patches were strictly aligned with (and often somewhat smaller than) the AChE-poor striosomes. (and often somewhat smaller than) the AChE-poor striosomes.

For the CAT experiments, we visualized both the AChE-poor strio-somes and AChE-positive cell bodies by using adult cats pretreated with DFP. With a serial immunofluorescence (FITC)-AChE method, we found virtually every CAT-positive neuron in the caudate nucleus to be AChE-positive. We plotted 1892 of these neurons (mean surface areas:  $300-320 \mu m^2$  and  $420-440 \mu m^2$ ) and found that 1486 (78.5%) lay outside the striosomes, 282 (14.9%) alongside them and 124 (6.5%) inside them. The striosomes comprised 14.3% of the area charted.

These findings demonstrate that the striosomes correspond to the islandic dopamine system and contain GAD-positive neuropil. A correspondence with cholinergic cell-body distributions seems unlikely unless the striosomal borders are rich in these cells. 5.5 THE DISTRIBUTION OF MUSCARINIC BINDING SITES IN THE FELINE STRIA-TUM AND ITS RELATIONSHIP TO OTHER HISTOCHEMICAL STAINING PATTERNS. <u>M.A. Nastuk and A.M. Graybiel</u>. Dept. of Psychology and Brain Sci., Mass. Institute of Technology, Cambridge, MA 02139

The distribution of muscarinic binding sites in the feline striatum was examined by applying the autoradiographic method of Rotter et al. '79 to tissue from 9 fetuses (estimated E45-E59), 14 kittens (5 h-5 wk) and 1 adult cat. The ligand used was  $[^3H]$ propylbenzilylcholine mustard (PrBCM), a specific irreversible muscarinic antagonist. Adjacent sections were stained for acetylcholinesterase (AChE) or Nissl substance, or processed by de la Torre's glyoxylic acid method for catecholamine (CA) fluorescence. Atropine controls for each case were negative.

The PrBCM autoradiograms show patchy non-uniform patterns of binding in fetuses and kittens. Typical late fetal binding distributions include ca. 200-300µm wide zones of high binding density (heavy labeling) as well as zones of low binding density (sparse labeling) at all levels of the cau.te nucleus (CN) and putamen. There are also inhomogeneities in the nucleus accumbens. In the CN there is a mediolateral density gradient in the background matrix with more binding laterally than medially. The patches are also much more prominent laterally. Postnatal animals show a different characteristic binding pattern, though ventrally in the CN the prenatal pattern can persist for at least 5 weeks. Dorsolaterally the binding becomes nearly uniform except for small patches that are partly or totally surrounded by unlabeled capsules. The grain density within these patches is not much greater than that of the background matrix. In the adult, PREM binding is dense throughout the striatum and shows no mediolateral gradient. The binding is not fully homogeneous, however, because there occasionally are patches of labeling in the CN that are denser than the background.

In the fetuses and kittens there are striking correspondences between the PrBCM patch-patterns and those visible in serially adjoining AChE, CA fluorescence, and Nissl sections. AChE-rich, CArich patches (the "dopamine islands") are aligned with patches of dense PrBCM binding, and zones of low AChE and low CA fluorescence are aligned with zones of weak PrBCM binding. By contrast, the PrBCM and Nissl patterns are complementary, with PrBCM-dense patches matching cell-sparse zones, and PrBCM-weak zones matching cell-rich zones. In the adult cat, each of the rare PrBCM-dense patches was found to be in register with an AChE-poor striosome.

We conclude (a) that regions of high muscarinic receptor density develop in relation to zones containing early forming dopamine fibers, and (b) that this physical correspondence likely has a functional corollary. (Supported by the Wills Foundation, NIH 2T32 CM07484-06 and

8.7 MULTIPLE PATTERNS OF CORTICOSTRIATAL PROJECTIONS AND THEIR RE-LATIONSHIP TO OPIATE RECEPTOR PATCHES IN RATS J.P. Donoghue and M. Herkenham Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205

Although the general arrangement of corticostriatal projections is known in the rat, the precise projection pattern from major cortical fields and their relationship to other features of striatal organization have not been clearly established. We have examined corticostriatal projections from: (i) primary motor cortex (MI), (ii) primary somatic sensory cortex (SI), (iii) visual cortex, and (iv) the prelimbic cortex plus adjacent cortical fields (medial frontal cortex) using axonally transported [<sup>3</sup>H]amino acids or lectin-peroxidase conjugates. In some cases mu opiate receptors were marked in adjacent sections with (<sup>3</sup>H]naloxone or [ $^{125}$ I]DAGO-enkephalin to compare the location of corticostriatal projections with opiate receptor-rich patches.

Striatal projections from these four cortical regions differ from each other with respect to both terminal location and pattern. (i) MI corticostriatal fibers are distributed bilaterally and nearly uniformly in the lateral one-third of the striatum. These projections overlap both opiate receptor dense and sparse regions. (ii) SI projections are mainly ipsilateral and form patches that generally lie posterior to the MI projection zone, but may overlap in some regions. The patches of SI projections may abut, but do not overlap opiate receptor patches. (iii) Visual cortical projections are distributed ipsilaterally in a continuous band between the dorsal edge of the striatum and an inner, discontinuous strip of opiate patches. (iv) Medial frontal projections are distributed bilaterally over a large portion of the rostral striatum and form distinct patches that coincide with the opiate receptor patches. In the nucleus accumbens the patches also overlie cell clusters visible in Nissl-stained sections.

Thus, visual and somatic sensory areas of cortex project to striatal regions that are low in opiate receptors. In contrast, medial frontal cortex projects into receptor-dense regions, and motor cortex has a broad projection that overlaps both regions. These data suggest that certain cortical inputs to the striatum are rigidly segregated from each other and are functionally related to other aspects of striatal compartmentalization, such that shown by the opiate receptor patches. The data also suggest that dopamine may act indirectly on the opiate receptor-rich regions of the striatum through the prelimbic cortex because this area is the main cortical target of brainstem dopaminergic fibers. 8.6 BUTYRYLCHOLINESTERASE IN THE DORSAL AND VENTRAL STRIATUM: OBSER-VATIONS ON HISTOCHEMICAL DISTRIBUTIONS IN ADULT, FETAL AND NEONATAL CATS. C.W. Ragsdale, Jr. and A.M. Graybiel, Dept. of Psychol. & Brain Science, Mass. Inst. Tech., Cambridge, MA 02139

The striatum of the adult cat contains both acetylcholinesterase (ACRE) and butyrylcholinesterase (BuChE) activity demonstrable by thiocholinesterase histochemistry. ACRE activity in the caudate nucleus (CN) is characterized by 0.3-0.6mm wide enzyme-poor strio-somes. Prolonged incubation of striatal tissue in BuChE solutions (with ACHE inhibition) also results in patterned staining of striatal neuropil and staining of fiber bundles. In 5 of 6 cats studied, BuChE-positive areas in the CN largely fell outside of the AChE-poor striosomes, as though avoiding them, and there were sometimes BuChE rims around the striosomes. In a sixth cat, there were BuChE-rich patches which were found to coincide with the striosomes. In all animals there was a progressive decrease in BuChE staining from dorsal to ventral in the CN, but much of the ventral striatum had high levels of BuChE. In particular, a broad curved band of high BuChE activity extended ventrally from the medial n. accumbens and stretched over the olfactory tubercle to the ventral putamen. This band contained complexly arranged enzyme-poor and enzyme-rich zones which often coincided with, but were more prominent than, inhomogeneities seen in AChE staining. Striking 100-200µm wide BuChE-pale patches were distributed in an arc running through this BuChE-rich region. In the olfactory tubercle there were wedges of very dense Buche activity (ca. 200µm across) which reached the surface of the brain and formed anteriorposterior strips in flattend tangentially sectioned material. These enzyme-rich zones lay in the hollows of, and at least partly overlapped, the cell-dense islands of Calleja. Traced serially, they seemed to merge with the ventral pallidum. In the fetal material (E34-E61) there was a striking arrange

In the fetal material (E34-E61) there was a striking arrangement of BuChE activity in the ganglionic eminence (GE). Save for a dorsal BuChE-negative part, the GE had layers of staining parallel to the ventricular surface, large regions of heavy staining, and stained radial strands running from the ventricular face to the CN. This staining underwent reorganization and reduction during gestation. In the CN, BuChE-positive patches were visible at least by E43, replacing a previously more homogeneous distribution and remaining prominent in the perinatal period. These BuChE patches were aligned with the AChE-positive patches visible in the same brains, and also with circumscribed patches of cytochrome oxidase observed in a newborn kitten. In this neonate, the cytochrome oxidase patches were risper and less interconnected than either the BuChE or the AChE patches. Finally, there were correspondences between all three sets of enzyme patches and patterns in adjoing Nissi sections.

in adjoining Nissl sections. Supported by the Wills Foundation and NIH EY02866-05.

8.8 PEPTIDE IMMUNOHISTOCHEMISTRY AND ACETYLCHOLINESTERASE STAINING DEFINE NUCLEAR BOUNDARIES OF THE RAT AND HUMAN BASAL FOREBRAIN. <u>S.N. Haber</u> and <u>W.J.H. Nauta</u>. Mailman Research Center, McLean Hospital, Belmont, MA 02178, and Dept. of Psychology and Brain Science, Mass. Inst. of Technology, Cambridge, MA 02139. Recently, we have shown that enkephalin-like immunoreactivity

Recently, we have shown that enkephalin-like immunoreactivity (ELI), Substance P-like immunoreactivity (SPLI), and dynorphinlike immunoreactivity (DLI) appear in striatal efferent fibers projecting to the globus pallidus in a unique pattern called woolly fibers. These fibers have been shown in the rat and in human to extend the assumed boundaries of the pallidum to include: a massive ventral pallidum extending into the olfactory tubercle, regions of the amygdaloid complex, and parts of the bed nucleus of the stria terminalis (BNST). Accetylcholinesterase (ACHE) staining of both fibers and cell bodies, frequently used as a marker for the basal nucleus of Meynert, is also found in these regions. The purpose of this study was to describe the differential distribution of peptide immunoreactivity and ACHE staining on adjacent sections in both the rat and human basal forebrain area in an attempt to define the nuclear boundaries of this region.

both the rat and human basal forebrain area in an attempt to define the nuclear boundaries of this region. After fixation, tissue was sectioned serially at 50 micra and processed for Met-enkephalin, Substance P (antibodies donated by Drs. Robert Elde and Ray Ho, respectively), dynorphin (antibodies donated by Dr. S.J. Watson), and ACHE. Peptide immunohistochemistry employed the PAP technique, and ACHE staining the Jensen-Blackstad technique. Some animals were treated with DFP to accentuate the ACHE-cell visibility, and then processed for both peptide and ACHE staining. Additional sections served as absorbtion controls or were stained with cresylviolet.

ACHE fiber staining does not take the unique form of woolly fibers and therefore can easily be distinguished from peptidepositive intrapallidal fibers. The results sharply contrast the distribution of ACHE-positive and woolly fibers. Both occupy large regions of the basal forebrain, but they overlap very little, and appear to avoid each other. While dense concentrations of ACHE-positive cell bodies also appear outside the boundaries of woolly fibers, scattered ACHE cell bodies do invade peptide-rich areas, particularly in the ventral pallidal - olfactory tubercle region. These cell bodies appear to constitute a group separate from the more densely packed ACHE-positive cells in woolly fiberfree regions. It is possible that the scattered ACHE-positive cells located within the peptide-rich areas, and thus lying in the path of striatal efferents, have a circuitry different from the densely packed ACHE-positive cells in peptide-poor regions of the basal forebrain. Supported by the Scottish Rite Foundation and NIH grant NS19170-01. SUBDIVISIONS OF THE PALLIDUM AND THE SUBSTANTIA NIGRA DEMONSTRATED BY IMMUNOHISTOCHEMISTRY, M.-F. Chesselet and A.M. Graybiel, Dept. of Psychol. and Brain Sci., Mass. Inst. Tech., Cambridge,MA 02139 Using the Sternberger PAP method to characterize immunohisto-chemical patterns in the pallidum and the substantia nigra (SN),we have plotted the distribution of fibers containing somatostatin-like (SOM), substance P-like (SP), and enkephalin-like (ENK) immu-noreactivity (antisera from R. Elde); dynorphin-like immunoreactivity (DYN) (antiserum from S.Watson); and glutamic acid

decarboxylase immunoreactivity (GAD) (antiserum from J. Wu). In the SN, there are discrete SOM-positive zones in rat, cat and monkey. In rat, SOM fibers lie in the pars compacta (defined by numerous tyrosine-hydroxylase imaunoreactive cell bodies,TH-CB, detected with an antiserum from T. Joh), but in monkey, SOM fibers are mainly concentrated in a characteristic network in the pars lateralis. A similar distribution was found in the cat and so, other neurochemical markers in the pars latoralis were studied in this species. At rostral levels, the pars lateralis is separated from the pars compacta and reticulata by a fiber bundle and con-tains ENK, GAD, SP as well as SOM fibers but no TH-CB. It is heavily stained in butyrylcholinesterase (BuChE) sections and thus is distinct from the pars reticulata which contains no SOM, little ENK and BuChE, but dense DYN as well as GAD and SP fibers. Caudal-Law and Ducht, Four dense DIN as Well as GAD and Sr Tibers. Caudal-ly, SOM fibers remain confined to the pars lateralis which con-tains TH-CB and dense DYN, GAD and SP fibers. To determine the ori-gin of SOM fibers in the cat SN, we combined fluorescence immuno-histochemistry and fast blue(FB) retrograde tracing after FB injections in SN. No neurons containing both FB and SOM were found in the caudate-putamen, amygdala, raphe or caudal midbrain tegmentum. However, doubly labeled cells appeared ventrally in the subthalamic region. Though en passage uptake of FB must be considered, these cells could constitute a source of SOM afferents to the SN. Heterogenous peptide distribution have also been found in the

pallidum and studied in detail in the cat. Rostrally, the globus pallidus (GP) contains dense ENK and GAD and moderate DYN, but SP fibers are present only in its external rim. Caudally, the GP contains SP and SOM fibers (and cells heavily stained for acetylcho-loinesterase) in addition to ENK, GAD and DYN. In the entopeduncular nucleus (EN), GAD, DYN and SP fibers are dense throughout, whereas ENK is weaker and mainly confined to a curved lateral part including the rostral and caudal poles. No SOM fibers but a few SOM neurons were also present.

These results demonstrate neurochemical compartments within the EN, GP (rostral and caudal) and SN (the pars lateralis beeing one). This suggests that fiber projections arising from these intranucle-ar subdivisions are influenced by different neurotransmitters.

We thank Drs Elde,Watson,Wu and Joh for antisera. Funded by the Wills Foundation and a Forgarty Fellowship No.IF05TW03204-01 to MC

8.11 NON-TOPOGRAPHIC ORDER IN THE BASAL GANGLIA: EVIDENCE FOR A SECOND LEVEL OF ORGANIZATION SUPERIMPOSED UPON THE TOPOGRAPHICALLY ORDERED STRIATO-NIGRAL PROJECTION SYSTEM. <u>C.R. Gerfen</u>, The Salk Institute, La Jolla, CA 92037. It is commonly believed that the topographic relationships that characterize cortical afferents to the striatum are maintained in the efferent projections of the striatum to the pallidum and substantia nigra. However, Yetterian and Van Hoesen (Brain Res., <u>139</u>:43-63, 1978) have proposed that a second order organization may be seen in cortico-striatal proposed that a second order organization may be seen in cortico-stricted projections. Thus, in addition to projecting heavily to a restricted topographically related portion of the caudate nucleus, a given cortical area also projects secondarily to regions within the rostral part of the caudate that also receive inputs from cortical areas with which it is reciprocally linked via associational connections. Evidence is presented the present study to suggest that a similar kind of organization exists

In the present study to suggest that a similar kind of organization exists in the projection of the stricturm onto the substantian largra in the rat. Discrete, nonoverlapping injections of the fluorescent retrograde tracers diamidino yellow (DY) and fast blue (FB) were placed into the medial or lateral parts of the pars reticulate of the substantian largra (SNr) in the same animal. A largr number of DY labeled strictal neurons were found in the medial part of the stricture are in the neurons was found in the medial part of the striatum, as is to be expected from the known topography of the striato-nigral projection. However, within the same region there were distinct areas which were devoid of DY labeled neurons but contained instead many FB labeled neurons. Conversely, within the lateral portion of the striatum clusters of DY labeled neurons were interspersed in a dense matrix of FB labeled neurons. Clusters of striatal neurons giving rise to non-topographic projections were distributed across the mediolateral and dorsoventral extent of the striatum such that there were no obvious discontinuities in the distribution of striatal neurons projecting to the SN as a whole. The

the distribution of striatal neurons projecting to the SN as a whole. The numbers of striatal neurons projecting to non-topographically related regions of the SN was substantial, though clearly less than those projecting topographically. Interestingly, less than 10% of the striatal neurons that projected non-topographically were labeled with both dyes. Iontophoretic injections of the anterogradely transported lectin PHA-L into various parts of the caudate-putamen (using the method detailed elsewhere - Soc. Neurosci. Abstr., 8:786, 1982) gave rise to labeled fibers with terminal-like swellings within the SNr that were concentrated in the topographically related zone of the SNr. For example medial striatal injections labeled terminals in the medial SNr. In addition, foci of labeled fibers and terminals were seen in non-In addition, foci of labeled fibers and terminals were seen in non-topographically related parts of the SNr, and in many cases, areas devoid of terminal labeling separated the primary and secondary terminal zones. These results, indicate that the projection of the striatum upon the SNr is only partly topographically organized, and that there is a second level of organization superimposed upon the topographic striato-nigral system.

DIFFERENTIAL PROJECTIONS FROM ACHE-POSITIVE AND ACHE-NEGATIVE 8 10 VENTRAL-PALLIDUM CELLS IN THE RAT. <u>E.A. Grove,\* S.N. Haber, V.B.</u> <u>Domesick and W.J.H. Nauta</u>. Dept. of Psychology and Brain Science, Mass. Inst. of Technology, Cambridge, MA 02139 and Mailman

Research Center, McLean Hospital, Belmont, MA 02178. The term ventral pallidum (VP) originally denoted a dorsal part of the subcommissural forebrain region called substantia innomiof the subcommissural torebrain region carled substantial information in the subcommission of the large neurons of the olfactory tubercle (Heimer, L. in: <u>Limbic Mechanisms</u>, 1978). The identification of this complex region as an extension of the globus pallidus (external segment) is based not only on cytomorphological likeness but also on histochemical similarities with the main body of the globus pallidus (dorsal pallidum, DP), e.g.: 1. high iron content, and 2. the dense plexus of enkephalin-positive striatal efferents pervading VP and DP alike. VP is, how-ever, distinguished from DP by a second, substance P-positive striatal-fiber plexus that densely fills VP but abruptly dwindles at the VP-DP junction (Haber and Nauta, <u>Soc. Neurosci. Abst. 7</u>). Anterograde evidence indicates that VP receives its striatal inner vation from a large antero-ventromedial striatal sector that includes the nucleus accumbens and is in turn innervated by several fiber systems originating from within limbic circuitry. Further autoradiographic findings suggest that VP, unlike DP, projects not only to the subthalamic nucleus but also to the nuclei basalis

only to the subthalamic nucleus but also to the nuclei basalis lateralis amygdalae (ABL), medialis dorsalis thalami (MD), and lat-eralis habenulae (HL) (Haber et al., <u>Soc. Neurosci. Abst.</u> 8). The interpretation of VP efferents is complicated by the fact that VP contains among its majority of AChe-negative neurons scattered AChe-positive cells that could be non-pallidal elements of the AChe-positive basal magnocellular complex. To determine from which of the two cell types the various VP projections origi-nate, experiments with the combined HRP-AChe procedure of Mesulam were undertaken. Preliminary experiments had shown cell labelling in VP by HRP placed in medial cerebral cortex (CC), ABL, MD, HL, ventral tegmental area (VTA) or dorsomedial midbrain tegmentum. Combination of the TMB procedure with the Jensen-Blackstad stain for AChe revealed that nearly all VP neurons labelled from either CC or ABL were AChe-positive, those labelled from MD, HL or VTA almost all AChe-negative. Findings concerning the apparent VP projection to (or through) the dorsomedial tegmentum thus far have been inconclusive.

These observations indicate that the two categories of VP cells have largely different projection targets. Further studies are in progress to determine whether both categories should be classified as sub-types of pallidal neurons, or as fundamentally different cell types.

8.12 MOTOR RESPONSES TO MICROSTIMULATION OF THE PUTAMEN IN THE AWAKE MONKEY. G.E. Alexander and M.R. DeLong, Johns Hopkins Univ. Sch. of Med., Dept. of Neurology, Baltimore, Maryland 21205. Microstimulation of the motor cortex has contributed impor-

tantly to our understanding of how this region influences the somatic musculature. This technique was therefore applied to the jection from motor cortex.

Three rhesus monkeys were trained to permit repeated examina-tion of somatic musculature, joints, and skin surfaces. Neuronal activity was sampled at 250-500 um intervals and studied in relation to both the animals' active movements and the responses to passive manipulation of body parts. Once the response properties of each neuron had been characterized, microstimulation was delivered to the recording site through the microelectrode, and the threshold for evoking movements was determined. Currents were restricted to a maximum of 40 uamps (300 usec pulses, 400 pps, 100 msec trains). For comparison, microstimulation was also carried out in the motor cortex and in the capsular portion of the corticospinal tract.

A total of 814 neurons and corresponding microstimulation sites in the putamen were examined in 63 tracks from 4 hemi-spheres. The functional characterization of the neurons confirmed the somatotopic organization of the putamen described recently. Effective microstimulation sites also were grouped somatotopically with respect to the anatomic distributions of the evoked movements. Discrete movements of the contralateral arm, leg and orofacial structures were observed. Close correspondence between neuronal response properties and microstimulation effects was evident. Thresholds of effective microstimulation in the putamen were as low as 10 uamps, but the majority were in the range 15-25 uamps, while most values obtained in motor cortex were within the range 5-15 uamps. Chronaxie measurements within the putamen and motor cortex were in the range 250-350 usec, compared to a range of 125-225 usec for the capsular corticospinal fibers.

These results indicate that microstimulation of the putamen in the awake monkey produces motor responses comparable to those elicited from the motor cortex. We cannot dismiss the possibility that the responses arise from activation of motor cortex by antidromic conduction along corticostriatal axons. This possibility is diminished, however, not only by the results of the chronaxie measurements, but also by the observation that micros-timulation of the corticostriatal fibers at the external border of the putamen did not elicit motor responses. Based on the of the putamen did not elicit motor responses. Based on the available evidence it would appear that activation of output neurons of the putamen may result in discrete movements.

9.1 HETEROGENEITY IN SECRETORY RESPONSE TO GDRH WITHIN THE RAT PITUITARY GONADOTROPE POPULATION: QUANTITATIVE ANALYSIS AT THE SINGLE CELL LEVEL. <u>P.F. Smith\*</u> and J.D. Neill\*. Department of Physiology & Biophysics, University of Alabama in Birmingham, Birmingham, AL 35294 (SPON:E. Geisert)

Heterogeneity in the amount of hormone secreted by pituitary cells of the same class in response to hypothalamic hormones has been reported, but its extent and functional significance remain unexplored. The recent development of a reverse hemolytic plaque assay (Neill and Frawley, <u>Endocrinology</u> 112:1135, 1983) has permitted us to analyze this heterogeneity at a single cell level. In the plaque assay, cells are cultured in the presence of protein A-coupled RBC, hormone antiserum, and complement, producing a zone of hemolysis (a plaque) surrounding individual hormone-secreting cells. In the present study, we have shown that the extent of hemolysis (size of the plaque in um<sup>2</sup>) is linearly related to the amount of hormone (expressed as pg) secred by a cell.

The amount of normone (expressed as pg) so fored by a Cella Pituitary glands from adult female Holtzmann rats killed on the morning of proestrus or diestrus I were mono-dispersed with trypsin. The cells were incubated in Petri dishes for measurement of LH secretion by radioimmunoassay (NIADDK-rLH-RPI) or in Cunningham slide chambers for measurement of the fraction of cells forming plaques and the size of plaques formed. A wide range of secretory responses (>50 fold) was obtained by incubating 10 different batches of cells from the same dispersion in the presence of GnRH (0-100 nM) for varying lengths of time. For each batch, we derived mean plaque size vs. mean amount of hormone secreted per plaque-forming cell, and constructed a standard curve relating  $\mu$ <sup>2</sup> of plaque area to pg of hormone secreted. Variations in secretory response among gonadotropes within a given treatment group was determined by measuring individual plaque areas and reading each from the standard curve as pg of hormone. Among pituitary gonadotropes derived from proestrus rats exposed to a maximally effective dose of GnRH (100 nM), the mean LH release/cell was 450 pg with a range of 10-2000 pg. Mean LH release by GnRH-treated (100 nM) cells from diestrus rats was 200 pg of LH per plaque-forming cell with a range of 2-2500 pg; however approximately half of the gonadotropes (as detected by PAP-ICC for LH) did not release detectable (<2 pg) amounts of hormone.

These results reveal surprisingly large differences ( $\sim 1000$  fold) in secretory activity among cells of one type from the same organ. Investigations of the morphologic and molecular basis of these differences will be required to understand regulation of the secretory process.

9.3 TRH AND EXPERIMENTAL SPINAL INJURY: EFFECTS OF TREATMENT DOSE AND TREATMENT TIME, <u>A. I. Faden and T. P. Jacobs</u>\*. Neurobiology Research Unit, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

We have previously demonstrated that early treatment posttrauma with thyrotropin-releasing hormone (TRH) significantly improves neurological recovery following experimental spinal injury in the cat (N. Eng. J. Med., 305: 1063, 1981). At high doses (2 mg/kg, i.v. bolus: 2 mg/kg/hr x 4 hr), TRH proved superior to treatment with either naloxone or high dose corticosteroids (Neurology, 1983). In the present studies we compared effects of early (beginning 1 hr post-trauma) high-dose TRH treatment against two lower doses of TRH (0.2 mg/kg and 0.02 mg/kg). Each dose was given as i.v. bolus followed by i.v. infusion over 4 hr (total doses: 10 mg/kg, 1 mg/kg and 0.1 mg/kg, respectively). Another group of cats received high dose TRH beginning 24 hr post-injury. Control animals were administered equal volume infusion of physiological saline. Neurological injury was produced by the Allen method in which a 30 gm weight was dropped 20 cm onto a 10 mm impact plate resting on the dura mater. Animals were followed for 6 weeks post-trauma before sacrifice for histopathological examination. Neurological scores were graded by a neurologist unaware of treatment group utilizing a 5-point ordinal scale for forelimb and hindlimb function; summation of forelimb and hindlimb scores yielded a total functional neurological score ranging from 0 to 10. TRH treatment proved statistically superior to that of saline treatment with regard to neurological recovery at all three TRH doses, with the beneficial effects being dose-related. Median neurological scores were; saline = 5.0; TRH (0.02) = 7.0; TRH (0.2) = 8.5; TRH (2.0) = 9.0. Moreover, late treatment with high dose TRH proved nearly as effective as early treatment (median score = 8.0). These findings confirm the beneficial effects of TRH in experimental traumatic spinal injury and show that it has therapeutic effectiveness at 12 the dose previously demonstrated to be efficacious. Moreover, TRH improves neurological recovery even when given 24 hr post-injury. These findings provide fur 9.2 GASTRIN RELEASING PEPTIDE STIMULATES INSULIN SECRETION AND REDUCES FOOD INTAKE IN THE BABOON. Leslie J. Stein<sup>\*</sup>, Dianne P. Figlewicz<sup>\*</sup>, Daniel Porte, Jr.<sup>\*</sup>, and Stephen C. Woods. Dept. of Psychology and the Northwest Regional Primate Center, University of Washington, Seattle, WA 98195. Intravenous (iv) administration of the frog skin-derived

Intravenous (iv) administration of the frog skin-derived peptide bombesin reduces meal size and stimulates insulin secretion in the baboon. Gastrin releasing peptide (GRP), a mammalian peptide, is structurally similar to bombesin and mimics many of bombesin's physiological effects in mammalian systems, including the ability to reduce meal size in rats. In the present series of experiments, we evaluated the ability of GRP to affect food intake and insulin secretion in the baboon.

Four overnight-fasted babons received a 5-minute iv infusion of either saline or GRP (1-8  $\mu$ g/kg) and were then allowed to eat for 30 minutes. Blood samples were obtained before the beginning of the infusion (basal, t= -6 min); at the end of the infusion, immmediately prior to the presentation of food (t= 0 min); and at the end of the 30-minute meal (t= +30 min). Mean food intake following saline infusion was 366 ± 116 (SEM) kcal. Infusion of GRP at 1, 2, and 4  $\mu$ g/kg suppressed 30minute meal size slightly; food intake following infusion of 8  $\mu$ g/kg GRP was reduced to 64 ± 27 kcal. Fasting immunoreactive insulin (IRI) concentrations were elevated by all doses of GRP. After the 30-minute meal, IRI was suppressed following 8  $\mu$ g/kg GRP, presumably as a result of the large reduction of meal size observed after administration of this dose. The data are summarized in the following table.

IRI CONCENTRATIONS (µU/ml) FOLLOWING IV SALINE OR GRP

-6 0	64+28 159+58
-6 0 30	3 61

Fasting glucose levels were not affected by GRP infusion. After the meal, plasma glucose was suppressed compared to the saline control condition following infusion of 8  $\mu g/kg$ . These data indicate that GRP, like bombesin, is a potent

These data indicate that GRP, like bombesin, is a potent stimulant of insulin secretion in the baboon. Additionally, GRP can reduce meal size in this species. It is not yet possible to compare the efficacy of GRP with that of bombesin because the doses of the peptides that have been tested thus far are not equivalent on a molar basis.

9.4 SUBSTANCE K: A NOVEL TACHYKININ IN MAMMALIAN CNS J. E. Maggio\*, J. C. Hunter\*, B. E. B. Sandberg\*, L. L. Iversen\* and M. R. Hanley (SPON: C.-M. Lee). MRC Neurochemical Pharmacology Unit, MRC Centre, Hills Road, Cambridge CB2 2QH, UK. The tachykinins are a family of naturally-occurring bioactive peptides sharing the carboxyl-terminal sequence -Phe-X-Gly-Leu-Met-NH2, where X is an aromatic or a branched aliphatic amino acid (Erspamer, V., <u>Trends Neurosci</u>, <u>4</u>:267, 1991). Until this year, Substance P was the only member of this group found in mammalian tissue; nevertheless, other (amphibian) tachykinins are more potent than Substance P in several peripheral bioassays and central behavioural effects in mammals (Erspamer, V., <u>op.</u> <u>cit</u>; Sandberg, B. E. B. and L. L. Iversen, <u>J. Med. Chem.</u>, <u>25</u>: 1009, 1982). This could imply the existence in mammals of another endogenous tachykinin peptide with such activities. Recently we reported the discovery of a novel endogenous mam-

Recently we reported the discovery of a novel endoarenous mammalian tachykinin (Maggio, J. E., B. E. B. Sandberg, C. V. Bradley, L. L. Iversen, S. Santikarn, D. H. Williams, J. C. Hunter and M. R. Hanley, <u>Irish J. Medical Sci. 152(Suppl. 1)</u>:45, 1983; Maggio, J. E. <u>et al in Substance P - Dublin 1983</u>, Boole Press, Dublin, 1983, in press). This new neuropertide, named "Substance K" to reflect its kinship with both Substance P and the amphibian tachykinin kassinin, was isolated using a radioImmunoassay which crossreacts negligibly with Substance P. The biological activities of Substance K are noticeably different from those of Substance P, and it seens possible that Substance K is an endogenous ligand for mammalian receptors of the "SP-E" type (Lee, C.-M., L. L. Iversen, M. R. Hanley and B. E. B. Sandberg, <u>Naunyr-Schmie</u> <u>deberg's Arch. Pharmacol.</u>, <u>318</u>: 281, 1982).

Some Substance P research should be re-evaluated in light of the fact that Substance P is not the only tachykinin neuropeptide in mammals. 9.5 SUBSTANCE P INTRATHECALLY AT SPINAL T LEVEL INCREASES ADRENAL MEDULLARY OUTPUT OF FREE ADRENALINE AND NORADRENALINE IN THE RAT. Kiran Yashpal\*, S.G. Gauthier and J.L. Henry, Depts. of Neurology and Neurosurgery, and of Psychiatry, McGill Univ., Montreal, Que. Injection of neuroanatomical tracers into the adrenal medulla

In period of incursationical tracers into the adrenal medulia of the rat has demonstrated labelled cells in the intermediolateral nucleus (ILN) of segments  $T_7-T_{1,2}$ , with  $T_6$  containing the largest number, and substance P-immunofeactive fibres can be observed surrounding both labelled and unlabelled neurones in the ILN. Substance P is found in cell bodies of brain stem structures projecting directly to sympathetic preganglionic neurones in the ILN of the thoracolumbar spinal cord and it may therefore be involved in supraspinal control of sympathetic output to the adrenals. In an attempt to identify the physiological role of substance P in spinal pathways controlling adrenal medullary output, the present experiments were done to determine the effects of the intrathecal administration of substance Y on the release of catecholamines from the adrenal medullae.

The second main second of the second second

Substance P produced an increase in plasma concentrations of both catecholamines. Adrenaline levels increased by an average of 145.5% above baseline (n=6), and noradrenaline levels increased by an average of 181.5% (n=6). The effects were greatest at 1 min after administration and were almost completely reversed at 30 min. When vehicle solution alone replaced the substance P solution the rapid increase in catecholamine levels was not seen. In five additional cases, the analogue (D-Pro<sup>2</sup>-D-Phe<sup>7</sup>-D-Trp<sup>9</sup>)-substance P (10  $\mu$ g in 10  $\mu$ 1) was given intrathecally 15 min before substance P and the increases in catecholamine levels were effectively blocked.

These results demonstrate that intrathecal administration of substance P increases adrenal output of adrenaline and noradrenaline and suggests that this peptide may be an excitatory chemical mediator of synaptic transmission in brain stem-spinal pathways controlling adrenal medullary output. (Supported by the Canadian Medical Research Council) 9.6 ELECTROPHYSIOLOGIC STUDIES OF NOCICEPTIVE CHOLECYSTOKININ-CONTAINING NEURONS IN THE MIDBRAIN CENTRAL GRAY. <u>R.B. Innis</u> and <u>G.K. Aghajanian</u>. Depts. Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

University School of Medicine, New Haven, CT 06508. Cholecystokinin (CCK) is a neuropeptide which has fulfilled almost all criteria for a neurotransmitter. The purpose of this study was to characterize the electrophysiologic properties of the anatomically well defined, densely packed neuronal cluster located in the midline periaqueductal gray of rat anterior midbrain (see Innis, et al., PNAS, 76:521, 1979). We recorded extracellularly in the chloral hydrate anesthetized rat.

A distinctive firing pattern was found in the region of this CCK neuronal cluster. The spike was typically biphasic with an initial positive deflection followed by a smaller negative deflection. The spontaneous firing rate was erratic. The cells sometimes fired in bursts and at other times fairly regularly (1-7 Hz) for up to an hour. Noxious stimuli such as toe pinch caused an increase in firing rate and a decrease in spike amplitude and duration. Continued painful stimuli led to a cessation of firing due to depolarization blockade.

a cessation of firing due to depolarization blockade. Several lines of evidence indicate that these cells are CCK containing neurons. First, dye spots deposited at the end of a recording session have always been histologically located in the narrow region of the CCK neuronal group. Second, co-localization experiments have shown the electrode tip (marked by a small area of tissue damage) surrounded by a dense cluster of immunohistochemically stained CCK containing neurons.

Recent reports show that CCK blocks the analgesic effect of opiates. Thus, the increased firing rate induced by toe pinch is consistent with this anti-analgesic action. Furthermore, we found that intravenously administered morphine (0.1 mg/kg) potently inhibits the spontaneous and pain stimulated firing of these cells. This morphine induced inhibitioin can itself be reversed with the specific opiate receptor antagonist, naloxone. Preliminary exeriments with microiontophoretically applied morphine and naloxone suggest that each has the same effect as the systemically administered drug. Since these locally applied opiate agents are active, we examined the area carefully for endogenous opiate peptides. Immunohistochemical staining with antiserum to met-enkephalin shows a moderately dense distribution of apparent terminal fibers in the neuropil of this CCK neuronal cluster.

In summary, we have successfully recorded from CCK-containing neurons in the midbrain central gray. These neurons may be involved in pain perception and opiate analgesia.

9.7 LONG TERM ENHANCEMENT OF EXCITATORY AMINO ACID TRANSMISSION BY ARGININE<sup>8</sup>-VASOPRESSIN (AVP): A FUNCTION OF AVP IN LATERAL SEPTUM OF RATS? I.J.A.Urban and M.Joels. Spons: European Neuroscience Association. Rudolf Magnus Institute for Pharmacology. Medical School, University of Utrecht, The Netherlands.

School, University of Utrecht, The Netherlands. The lateral septum complex (LSC) of rats is richom immunoreac-tive arginine<sup>8</sup>-vasopressin (AVP). A great deal of neurons in dorsal part of the LSC are the neurons which are strongly orthodro-mically excited (SOE) by stimuli administered to fimbria-fornix (fi-fx). According to evidence obtained with selective agonists and antagonists, presumably glutamate or other closely related amino acid is the neurotransmitter mediating the synaptic excita amino acid is the neurotransmitter mediating the synaptic excita-tions elicited in LSC neurons by fi-fx stimuli. AVP ejected micro-iontophoretically on SOE setal cells with currents at which it did not alter the spontaneous activity of these neurons, markedly in-creased the excitations elicited in SOE neurons with Glu, aspartate but also with quiscalate and N-methyl-D-aspartate, selective agonists for two kinds of excitatory amino acid receptors. In nearly 50% of these neurons, the AVP-elicited increase in responses to a-mino acids lasted for more than 10 min after termination of the mino acids lasted for more than 10 min after termination of the AVP application. The inhibitory responses induced in SOE cells with GABA were not affected during the iontophoretic administra-tion of AVP. In many SOE cells in which AVP enhanced the amino a-cid response, the number of times that they fired an action poten-tial to a fixed series of fi-fx stimuli markedly increased during and after iontophoretical administration of AVP. This AVP-elicited increase in responsiveness of SOE cells to the trans-synaptic sti-muli frequently persisted for more than 10 min after termination of the AVP administration. The synchronized excitation of the SOF of the AVP administration. The synchronized excitation of the SOE Special neurons by fi-fx stimuli elicit a negative field potential (NFP) in LSC. Following topical administration of 10  $\mu$ l 10<sup>-10</sup> M AVP dissolved in artificial cerebrospinal fluid (ACF), amplitude of the NFP increased and remained increased after wash-out of the prepara-tion with the control ACF. In more than 50% of the experiments the peptide-induced increase in magnitude of NFP lasted for be and the set of the mass-out of the peride. Des-glycinami-de AVP, and  $[pGlu^4,Cys^{\circ}]$  4-9 AVP, behaviorally acting fragments of AVP, also increased NFP in LSC. However,  $10^{-7}$  M concentrations of the peptides were needed to obtain the effect. These experiments demonstrate for the first time that in LSC, one of the extra hypo-thalamic target structure for AVP, the exogenous peptide hormone can elicit a long-term enhancement of the excitatory amino acid neurotransmission and suggest that this presumably postsynaptic action of AVP may be one of the functions of this peptide in LSC In addition, evidence accumulated so far suggests that for a full expression of these actions presumably the whole molecule of AVP is needed.

9.8 BOMBESIN DIRECTLY STIMULATES INSULIN SECRETION FROM A CLONAL LINE OF HAMSTER BETA CELLS. <u>S. Swope\* and A. Schonbrunn</u>\* (SPON: L. Levine). Dept. of Pharm., Harvard Med. School and Lab. of Toxicol., Harvard Sch. of Pub. Health, Boston, MA 02115. Bombesin (BBS), a tetradecapeptide originally isolated from

Bombesin (BBS), a tetradecapeptide originally isolated from frog skin, stimulates insulin secretion both  $\underline{in\ vivo}$  and in organ cultures. Furthermore, pancreatic neurones contain bombesin-like immunoreactivity. To determine whether BBS acts directly on pancreatic Beta cells, we have characterized its effects on insulin secretion by HIT cells, a clonal line derived by SV40 transformation of hamster islets (Santere <u>et al.</u>, 1981, PNAS, 78:4339). The addition of 100 nM BBS to HIT cells stimulated insulin release 20 fold by 30 seconds. The secretory rate returned to basal levels within 90 minutes. Treatment of HIT cells with 100 nM BBS elicited the secretion of only 1.04  $\pm$  .07 % (n = 2) of the total intracellular insulin stores were not depleted. The effect of BBS was dose-dependent with an ED50 of 0.54  $\pm$  .10 nM (n = 4). Structurally unrelated neuropeptides including secretin, VIP, TRH, substance P, neurotensin, CCK-octapeptide, and CBS value of the value protection. The relative potencies of these analogs indicated that the C-terminal octapeptide sequence in BBS is sufficient for potent stimulated insulin secretion. Maximal doses of glucagon (1  $\mu$ M) stimulated insulin secretion S.0  $\pm$  .8 fold (n = 3) in one hour and the effect of glucagon plus BBS was greater than the additive effect of the 2 peptides alone. Somatostatin, a recognized inhibitor of insulin secretion both in vitro and in vivo, blocked BBS stimulated release by 72  $\pm$  2% (n = 3) with an ID50 of 2.6 nM. In conclusion, these data show that physiological concentrations of BBS rapidly and directly stimulate insulin release by a clonal line of hamster BBS and cells. This system promises to be useful for investigating the mechanism by the BBS stimulated insulin secretion.

INTRACELLULAR STIMULATION EVOKES PEPTIDE RELEASE FROM A SINGLE, IDENTIFIABLE PEPTIDERGIC NEURON IN AN INSECT. Nathan Tublitz and James W. Truman. Department of Zoology, University of Washington, Seattle, WA 98195.

We have been investigating two cardioacceleratory peptides We have been investigating two cardioacceleratory peptides (CAPs) isolated from the ventral nerve cord(VNC) of the tobacco hawkmoth, <u>Manduca</u> <u>sexta</u>. The two CAPs are co-released into the haemolymph during adult wing-spreading behavior, causing an increase in heart rate that facilitates wing inflation. We report on the identification of the CAP-containing neurons utilizing a variety of methods, most directly by evoking release of CAP-like bioactivity via intracellular stimulation of a single, identified We report neurosecretory cell. The two CAPs are stored and released from the perivisceral

organs, the classic VNC neurohaemal release site in insects located on the segmentally arranged transverse nerve(TN). Previous work has established that each TN contains exons from two, morphologically distinct group of cells: four lateral cells with a single axon projecting to the ipsilateral TN, and five pairs of widline neurons, each wich a bifurcating axon that terminates in both ipsilateral and contralateral branches of the TN. Based on microsurgical and electrophysiological experiments, the lateral cells, previously shown to contain another peptide hormone, bursicon(Taghert, P.H., J. Exptl. Biol., 98:305), do not contain the CAPs.

Several lines of evidence suggest that the CAP-containing Several lines of evidence suggest that the CAP-containing neurons are restricted to three pairs of midline cells that differentiate post-embryonically during adult development. Neither CAP can be detected in the larval ventral nerve cord prior to the differentiation of these cells. Also, CAP accumula-tion in the ventral nerve cord closely parallels midline cell enlargement during adult development. Finally, intracellular stimulation of a single, identifiable midline neuron results in the release of detectable levels of protease-sensitive, CAP-like bioactivity. These data suggest that three neir of midline cells bioactivity. These data suggest that three pair of midline cells, which arise during adult development, contain and release the CAPs

(Supported by a NSF predoctoral fellowship and a National Research Service Award(GM-07108) to N.T. and NSF(PCM 7724878) and NIH(R01NS-13079) research grants to J.W.T.)

9.10 A SUBSTANCE P-LIKE PEPTIDE MODULATES SENSORY AND CARDIAC ACTIVITY IN LIMULUS. Jorge R. Mancillas and A.I. Selverston. Depts. of Neurosciences and Biology, Univ. of Calif. at San Diego, La Jolla, CA 92093.

The central nervous system of the horseshoe crab (Limulus p.) contains substance P-like immunoreactive cells arranged in pairs of bilaterally-symmetrical clusters distributed regularly throughout all ganglia posterior to the protocerebrum. distribution was studied using indirect immunocytochemical techniques and a monoclonal antibody. Six bilaterally-symmetrical pairs of clusters are located in the circumesophageal connectives (CEC's) and the subesophageal mass (SEM), were some individual scattered cells can also be seen. Each of the first 5 abdominal ganglia contains an anterio-lateral, a medial longitudinal and a medial posterior main of cell clusters. Subtance A like immenance in fiber pair of cell clusters. Substance P-like immunoreactive fibers leave through virtually all the ventral and dorsal nerves to

inervate peripheral targets. An abundance of stained terminals can be seen in the CEC, SEM and abdominal ganglia. Two of the substance P-like immunoreactive pairs of clusters in the CEC's seem to give rise to efferent fiber projections that leave through the 3rd and 4th dorsal nerves, enter the lateral

leave through the 3rd and 4th dorsal nerves, enter the lateral optic nerve halfway between the brain and the lateral eye, and innervate several components of the ommatidia. Synthetic substance P (10<sup>-1</sup> to 10<sup>-1</sup>m) injected subcorneally into the lateral eyes induces increases in the photoreceptors' sensitivity that are reversible, dose-dependent and mimic those that occur spontaneously in a circadian fashion (Barlow, J. Neurosci. 3:856). Substance P also alters the endogenous circadian rhythm in photosensitivity by increasing the amplitude of the nocturnal plateau, while injection of D-pro<sup>2</sup>, D-phe<sup>2</sup>, D-Trp<sup>2</sup> substance P in the afternoon retards the rise in sensitivity and reduces the nighttime levels. If the antagonist is applied after the nocturnal plateau has been reached, a short-term, reversible drop to diurnal levels is observed. data is consistent with an involvement of a substance P-like peptide in efferent-controlled circadian rhythms of photosensitivity. The 6 clusters in the CEC's and SEM may constitute a generalized, level-setting system with multiple targets, which can be driven by a circadian clock as well as by other systems responsible for integrated organismic responses.

A substance P-like peptide may have additional functions in Limulus, since: 1) Substance P-li fibers innervate arterial walls, where they may be involved in the regulation of blood flow, and 2) Substance P-li fibers, that may originate in the anterio-lateral clusters of the abdominal ganglia, innervate the heart, which is sensitive to the application of synthetic eucletance P substance P.

9.11 ACUTE REGULATION OF GANGLIONIC TYROSINE HYDROXYLASE ACTIVITY BY SECRETIN, VASOACTIVE INTESTINAL PEPTIDE AND PHI. N.Y. Ip and R.E. Zigmond. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

We have previously shown that stimulation of the preganglionic cervical sympathetic trunk leads to an acute increase in tyrosine hydroxylase (TH) activity in the rat superior cervical ganglion (SCG). This increase in enzyme activity is mediated in part by a nicotinic and in part by a non-cholinergic mechanism (Ip et al., Proc. Natl. Acad. Sci. <u>80</u>:2081, 1983). As a first step in an attempt to identify the transmitter responsible for this nonattempt to identify the transmitter responsible for this non-cholinergic effect, we screened thirteen neuropeptides at a concentration of 10  $\mu$ M for their ability to increase TH activity. Of these, secretin and VIP were effective, while angiotensin II, bombesin, bradykinin, cholecystokinin octapeptide, insulin, luteinizing hormone-releasing hormone, [D-Ala<sup>2</sup>, Met<sup>5</sup>] enkephalin-oride correction correctoring or hormone P produce amide, motilin, neurotensin, somatostatin and substance P produced no effects.

Secretin produced a significant increase in TH activity at 1 nM secretin produced a significant increase in TH activity at 1 m and a maximal elevation (3-fold) at 0.1  $\mu$ M. VIP produced a significant increase at 0.1  $\mu$ M and a near maximal effect (4-fold) at 10  $\mu$ M. The effects of these peptides were not altered by prior decentralization of the ganglia, by addition of hexamethon-ium (3 mM) and atropine (6  $\mu$ M), or by lowering the concentration of calcium in the medium to 0.1 mM. Several peptides with structural similarities to secretin and VIP were also exempted for their addition for a structure of the structure of the secret of the structure of the secret of the secre

Several peptides with structural similarities to secretin and VIP were also examined for their ability to increase TH activity. Glucagon, gastric inhibitory peptide and human pancreatic tumor growth hormone-releasing factor produced no effect at a concen-tration of 10 µM, while PHI increased TH activity. A significant increase was obtained at 1  $\mu M,$  and a near maximal effect (3-fold) was produced at 30  $\mu M$  PHI.

Carbachol, a cholinergic agonist, also increases TH activity acutely (Ip et al., J. Pharmacol. Exp. Ther. 223:280, 1982). To investigate whether there is any interaction between the cholinergic and peptidergic regulation of TH, we examined the ability of secretin to increase enzyme activity in the presence of a low concentration of carbachol (3 µM). At this concentration, carbachol produced no significant effect on TH activity by itself; however, it potentiated the response to secretin at all doses of secreting tested (1 nM to 1  $\mu$ M). The effect of VIP, examined only at 1  $\mu$ M, was also enhanced by the addition of carbachol.

These data indicate that ganglionic tyrosine hydroxylase activity can be regulated by secretin and the closely related peptides, VIP and PHI. We are currently examining whether any of these peptides mediate the non-cholinergic increase in TH activity following nerve stimulation. (USPHS Grants NS12651 and MH00162) 9.12 EVIDENCE FOR THE INVOLVEMENT OF CYCLIC AMP IN THE ACUTE STIMULA-TION OF GANGLIONIC TYROSINE HYDROXYLASE ACTIVITY PRODUCED BY

TION OF GANGLIONIC TYROSINE HYDROXYLASE ACTIVITY PRODUCED BY CERTAIN NEUROPEPTIDES. <u>R.E. Zigmond, C. Baldwin\* and N.Y. Ip</u>. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115. Tyrosine hydroxylase (TH) activity can be increased acutely in adrenergic neurons by a variety of stimuli. One of the mechanisms which may account for these increases in enzyme activity is the stimulation of a cyclic AMP dependent protein kinase resulting in the phosphorylation and the consequent activation of TH. We have previously reported that 8-bromo-cyclic AMP can increase TH activity in adult rat superior cervical ganglion (Ip et al., Proc. Natl. Acad. Sci. USA <u>80</u>: 2081, 1983). TH activity can also be increased by three neuropeptides--secretin, vasoactive intes-tinal peptide (VIP), and PHI. We have now further examined the involvement of cyclic AMP in regulating ganglionic TH activity and have investigated the possible role of this second messenger in mediating the effects of these neuropeptides. 8-Bromo-cyclic AMP produced a dose-dependent increase in TH

8-Bromo-cyclic AMP produced a dose-dependent increase in TH control of the second 30  $\mu M.$  Isobutyl methylxanthine (0.5 mM), a phosphodiesterase inhibitor, increased TH activity by about 2-fold.

Volle and Patterson (J. Neurochem. <u>39</u>:1195, 1982) recently reported that VIP can increase cyclic AMP levels in the rat superior cervical ganglion. We have investigated the ability of superior derividal gaugiton, we have investigated the authors of Sa number of peptides to alter cAMP levels in this tissue. The effect of each peptide was examined at a concentration of  $10 \ \mu\text{M}$ during a 10 min incubation, and cyclic AMP in the tissue and medium was measured by a protein binding assay. VIP, secretin and PHI increased cAMP levels while glucagon, human pancreatic tumor growth hormone-releasing hormone, substance P, angiotensin II, bradykinin and neurotensin produced no significant effects. The latter group of peptides had no effect on TH activity.

The data indicate that ganglionic TH can be regulated by intracellular cyclic AMP levels and raise the possibility that secretin, VIP and PHI increase TH activity by elevating cyclic AMP levels in this ganglion. Supported by USPHS grants NS 12651 and MH 00162.

10.1 Monoclonal antibodies against sodium channel.

H. Meiri, I. Zeitoun<sup>\*</sup>, H.H. Grunhagen<sup>\*</sup>, V. Lev-Ram<sup>\*</sup>, Y. Cohen<sup>\*</sup>, Z. Eshhar<sup>\*</sup> and J. Schlessinger<sup>\*</sup>. Dept. Physiol. Pharmacol. The Sackler Faculty of Medicine, Tel-Aviv Univ.69978 Israel, Univ. Saarland Homborg, Germany and the Weizmann Inst. of Sci. Rehovot. 76100 Israel.

The voltage dependent Na<sup>+</sup> channel plays an important role in the conduction of electrical impulses in various neurones. In order to investigate the location, dynamic properties and chemical nature of Na<sup>+</sup> channel we have generated monoclonal antibodies against it.

Mice were immunized with electroplax eel membrane fragments which are rich with sodium channels. The spleens of the immunized mice were fused with NS 1 myeloma cells according to published procedures. The resulting hybridoma cells were cloned and screened for the properties of their sec.eted antibodies.

Several hybridomas secreting antibodies with binding properties associated with the sodium channel were selected and subsequently grown for further characterization.

One clone denoted  $SC^{22-14}$  binds membrane from eel electroplax and from rat brain synaptosomes which are enriched with sodium channel. The binding of these antibodies is inhibited by Veratridine doubled by scorpion toxin but not effected by Tetrodotoxin. Moreover, these antibodies stain specifically nodes of Ranvier of single fibers in rat sciatic nerve when examined with Rhodamine labeled goat antimouse. Finally the antibodies block the action potential recorded from rat sciatic nerve and optic nerve. Preliminary voltage clamp studies imply that the antibodies block exclusively the inward sodium current of single axons without effecting pot asium or leakage current or membrane potential.

The second clone denoted SC-72-23 binds to the same enriched preparation of the sodium channel and its binding is blocked by either Tetrodotoxin, Veratridine or Scorpion toxin. These antibodies stain nodes of Ranvier of rat sciatic nerve and block the action potential of rat optic and sciatic nerve. The binding capacity of the third clone SC-79-17 is signifi-

The binding capacity of the third clone SC-79-17 is significantly decreased upon the addition of either Tetrodotoxin and veratridine to these samples. It also stains the nodes of Ranvier in rat sciatic nerve. It enlarged and prolonged the action potential of rat optic nerve.

potential of rat optic nerve. These clones and new ones are further analysed. However, it is already clear that we have generated arepertoire of antibodies against different parts of the sodium channel. These reagents will be used to visualize the distribution and dynamic properties of the channel molecules on viable cells using the methods of image intensification microscopy and fluorescence photobleaching 10.2 MOLECULAR MORPHOLOGY OF THE TETRODOTOXIN BINDING SODIUM CHANNEL PROTEIN FROM ELECTROPHORUS ELECTRICUS IN SOLUBILIZED AND RECON-STITUTED VESICLE PREPARATIONS. M.H. Ellisman, J.A. Miller\*, W.S. Agnew\*, T.J. Deerinck\*, D.B. Leong\*, R.L. Rosenberg\*, S.A. Tomiko\*. Department of Neurosciences, Laboratory for Neurocytology, UCSD, La Jolla, CA 92093 and Department of Physiology, Yale University, New Haven, CT 06510. Tetrodotoxin (ITX) has been used as a biochemical marker for following the purification of Na channel protein solubilized from eel electric organ in Lubrol-PX and sodium cholate. The purified macromolecules were examined by electron microscopy

Tetrodotoxin (TTX) has been used as a biochemical marker for following the purification of Na channel protein solubilized from eel electric organ in Lubrol-PX and sodium cholate. The purified macromolecules were examined by electron microscopy both after reconstitution into liposomes, and solubilized form in the two detergents. Vesicles were visualized either by negative staining or by the replication techniques of freeze-fracture and freeze-etching. In the fractured membranes derived from either reconstitution system, incorporated proteins appeared as ~100 Å diameter particles. Exposure of the vesicle true surfaces by freeze-etching and replication by rotary-shadowing revealed particulate protrusions when examined in stereo-electron micrographs. Thus, the freeze-fracture analysis reveals a relatively large and symmetrical intramembranous particle projecting slightly beyond the bilayer. These structures, which we estimate to be roughly cylindrical of ~100 Å diameter x 80 Å length (min.) were difficult to correlate with the distinctive and regular rod-shaped (40 Å x 170 Å) particles delineated by negative staining of purified Lubrol-PX solubilized protein (Ellisman et al., PNAS 79, 1982). In an effort to reconcile this discrepancy we examined material solubilized in both cholate and Lubrol using a battery of negative staining techniques at various pH's. Examination of the cholate preparations resulted in aggregation of material into grape-like clusters with doughnut structures. No rods of the sort seen earlier in the Lubrol preparations stained at lower pH were seen. Rather, the irregularly sized doughnuts appeared similar to solubilized acetylcholine receptor when it is spread on carbon-filmed grids. Lower pH staining, rod-like structures were seen. The rod-like structures in the cholate preparations resulted in aggregation of material into grape-like clusters with doughnut structures still apparent. After longer exposure to lowered pH staining, rod-like structures were seen. The rod-like structures in the cho

10.3 THE NATURE OF THE PEPTIDE WHICH FORMS THE TETRODOTOXIN-BINDING SITE OF THE SODIUM CHANNEL FROM <u>ELECTROPHORUS ELECTRICUS.</u> J.A. <u>Miller\* and W.S. Agnew\* (SPON: W.C. Wallace)</u>. Department of Physiology, Yale University School of Medicine, New Haven, CT 06510.

Tetrodotoxin (TTX) has been used as a biochemical marker for following the solubilization and purification of the voltageregulated sodium channel protein from the electric organ of <u>Electrophorus electricus</u>. The native protein has been purified in the non-ionic detergent Lubrol-PX and in the bile salt detergent sodium cholate. In the latter detergent the extracted TIX binding site is intrinsically less stable than in comparable extracts in non-ionic detergents; however, by carefully maintaining low temperatures throughout, by providing adquate ratios of stabilizing phospholipid and by saturating the binding site with TIX, it is possible to isolate an active protein with a high degree of purity. The protein isolated contains only a large (>260,000 daltons) peptide; no smaller peptides, either covalently or non-covalently linked, have been detected. This large peptide displays a variable degree of glycosylation as evidenced by marked electrophoretic microheterogeneity. Enzymatic digestion with endoglycosidases results in a limit digest which electrophoreses as a single well-defined band of 30% lower apparent molecular weight. This observation is consistent with an earlier analysis which determinations of the true molecular weight of either the complete molecule or the limit digest are not possible by sodium dodecyl sulfate (SDS) gel electrophoresis, as direct measurements reported here reveal binding of atypically high amounts of SDS. Aside from producing a greater yield of product of high purity, the use of cholate as the solubilizing agent for the protein permits a choice of methods for reconstitution into vesicles. This has allowed us to reconstitute the molecule rue integent weight and the protein pertein permits a choice of methods for reconstitute the molecule rue weight of find mutation and the protein to vesicles. This has allowed us to reconstitute the molecule rue.

tein permits a choice of methods for reconstitution into vesicles. This has allowed us to reconstitute the molecule into well-defined, unilamellar vesicles. These vesicles are suitable for future analysis of the functional properties of this purified protein. 10.4 EFFECTS OF BATRACHOTOXIN, VERATRIDINE AND SCORPION TOXIN ON NA CHANNELS IN LIFID BILAYERS. <u>B. Rudy</u>\* (SPON: J. Jacoby). Dept. Physiol., New York Univ. Med. Ctr., New York, NY 10016. Sodium channels were incorporated into black lipid membranes

Solum channels were incorporated into black lipid memoranes (BLM) from whole brain membrane vesicles placed in one of the solutions bathing the membrane (CIS side). The membrane vesicles were obtained from a sucrose gradient fraction of rat brain homogenates enriched in Saxitoxin ( $^{3}H-STX$ ) binding, i.e. 8-10 pmols/mg protein. The protein is incorporated into the BLM probably by fusion of the membrane vesicles with the bilayer. Single Na channels were recorded in this membrane in the presence of batrachotoxin (BTX), or Veratridine, with or without scorpion toxin. In the presence of BTX, the channels are similar to those described by Krueger, Worley & French (Biophys. J. 41: 142a, 1983) in PE:PS membranes except that the single channel conductance is slightly smaller (20 pS vs. 30 This is probably the result of differences in membrane pS). composition; negatively charged membranes will result in higher local Na concentrations. The channels are inserted always with the TIX binding site exposed to the CIS side. In the presence of veratridine the single channel conductance seems to be half that with BTX. The average open time for the channel is also smaller and its kinetics is slower than with BTX. These re-sults give an insight of why veratridine is much less effective than BTX in increasing the permeability of Na channel contain-ing cells or reconstituted vesicles. Addition of scorpion toxin to the solution induces a novel voltage and time depen-dent response. A much faster opening and closing of the channels appears minutes after the addition of the toxin but only when the membrane potential is positive on the CIS side. If the membrane potential is changed from +50 to -50 mV, the If the membrane potential is changed from +50 to -50 mV, the fast gating subsides after a short time to that observed in the absence of scorpion toxin. Returning the membrane potential to +50 mV allows the fast gating to reappear after a short delay. The time course of the appearance and vanishment of the gating induced by scorpion toxin are of the order of tens of seconds depending on the membrane potential. The sign and the time course of the voltage dependent effect suggest that it is re-lated to the binding and unbinding of scorpion toxin to specific binding sites (Catterall, J. Biol. Chem. 252: 8660, 1977). Because the fast gating may reflect the opening and closing of the inactivation gate, the inactivation gate becomes accessible to study at the single channel level in mem-branes where molecular studies are possible. Supported by NIH Grant GM26976 and BSRG SO7RR05-399-21.
MODULATION OF PHARMACOLOGICALLY INDUCED DEPOLARIZATION IN FROG 10.5 NERVE. <u>T.A. Rando</u>, <u>G.K. Wang</u> and <u>G.R. Strichartz</u>. Anesthesia Res. Labs., Brigham and Women's Hosp. and Harvard Medical School, Boston, MA 02132

The depolarizing actions of the sodium channel activator veratridine (VTD) and batrachotoxin (BTX) were measured in frog sciatic nerve by the sucrose-gap method. DC potentials were recorded in Ringer with 12mM TEA at pH 7.2, 20-22°C. VTD pro-duced a rapid depolarization which was readily reversible upon washing with Ringer. The BTX-induced depolarization had a much slower onset and was irreversible. The extent of the depolarization was concentration-dependent for both drugs with a maximal

depolarization being obtained at about 50  $\mu M$  VTD or 5  $\mu M$  BTX. To test whether the actions of these activators were affected To test whether the actions of these activators were affected by the state of the sodium channel, their effects were studied in nerves treated with <u>Leiurus</u> scorpion toxin (LQ) or chloramine-T (CT). Both reagents inhibit Na<sup>-</sup> channel inactivation. LQ increased the rate and extent of depolarization by both activa-tors. In contrast, CT had mixed effects. While CT did not increase the extent of depolarization by either activator, it did greatly increase the rate of BTX-induced depolarization. Little offect up acon on the rate of meru by ut the unumeral rate on washing was markedly decreased. A similar effect was seen when the nerve was stimulated at 1-10 Hz during activator treatment; the onset rates were increased, the extent of depolar-ization was unchanged, and the washout rate of VTD was decreased. The interactions between local anesthetics and Na<sup>+</sup> channel

activators were studied using lidocaine (LID). LID was a compet-itive inhibitor of VTD, reducing the potency of VTD in depolarizing the nerve. LD had no effect on the extent of the depolar-ization when present during BTX treatment or when applied to a Ization when present during BIX treatment or when applied to a nerve already depolarized by BIX. However, the presence of LID greatly slowed the rate of BIX-induced depolarization. We com-pared the potency of another local anesthetic, RAC 1091, to its stereoisomer, RAC 1091I, in their ability to repolarize a nerve depolarized by VTD; RAC 1091 was about 3 times as potent as RAC 1091I (which was comparable to their relative potencies in reduc-ing the compound action potential or bis sustant)

ing the compound action potential amplitude in this system). These results are consistent with a scheme wherein activators react most rapidly with "open" channels to stabilize that channel configuration. Thus, treatment that increase the probability of the open channel configuration (e.g. LQ, CT, stimulation) speed activator action, whereas local anesthetics may inhibit activator action by decreasing the fraction of channels in the open configuration and/or (as previously suggested by Huang et al., Biophys. J., 23:219, 1978) by competing directly with activators at a common binding site. The prevention of inactivation <u>per se</u> does not potentiate activator-induced depolarization.

10.7

EVIDENCE FOR INGREASED  $G_{N_B}$  IN THE SYMAPTIC REGION OF RAT SKELETAL MUSCLE. S.C. Kinnamon<sup>\*</sup>, J.H. Caldwell, & W.J. Betz. Dept. of Physiology, Univ. of Colorado Med. School, & Dept. of Nolec. & Cell. Biology, Kat'l. Jewish Hosp., Denver, CC. Action potentials recorded near the synapse in skeletal muscle have a higher maximum rate of rise ( $V_{max}$ ) than those recorded in extrajunctional regions (Nastuk & Alexander, Fed. Proc. 22:333, 1973; Thesleff et al. Acta. Physiol. Scand. 91:196, 1974). Based partly on this observation, Thesleff et al. suggested that voltage gated Na channels are relatively concentrated at the end plate region. However, the results could alternatively be interpreted as reflecting nonuniform passive cable properties of the membrane. In fact, recent studies in our laboratory suggest that Cl conductance (Gc1) is reduced in the end plate region, which alone could increase action potential  $V_{max}$  at that site. We therefore repeated measurements of  $V_{max}$  in normal saline, and compared then to measurements in low [Cl] solution (Cl replaced by isethionate; all experiments on rat lumbrical muscle). In normal saline,  $V_{max}$  was 43% greater near the end plate than in extrajunctional regions. In low [Cl] solution,  $V_{max}$  increased at both sites, and the <u>difference</u> was reduced to 28%. Thus, a reduced Gc1 at the end plate can accout for some, but not all of the difference in normal saline. In addition, we used a vibrating, extracellular microelectrode (Jaffe & Nuccitelli, J. Cell. Biol.

normal saline. In addition, we used a vibrating, extracellular microelectrode (Jaffe & Nuccitelli, <u>J. Cell. Biol.</u> 63: 614, 1974) to record a steady membrane current generated by bath application of veratridine (plus alpha bungarotoxin). This treatment caused a large inward current at the synaptic region, which was abolished by tetrodotoxin. The inward current percented in Cleffee solutions consistent with the Inward current at the synaptic region, which was abolished by tetrodotoxin. The inward current persisted in Cl-free solutions, consistent with the suggestion that Na channels are more concentrated at the end plate region. Finally, we measured the length of fiber over which an increased  $V_{\rm max}$  could be recorded; the results suggest that the increase is restricted to a region within 150-200 um of the end plate.

10.6 PHARMACOLOGIC EVIDENCE FOR SALTATORY CONDUCTION ALONG THE GOLD-FISH MAUTHNER AXON. <u>Paul G. Funch and Donald S. Faber</u>. Div. Neurobiology; Dept. Physiology; SUNY at Buffalo; Buffalo, NY 14214.

The Mauthner (M-) axon of the goldfish apparently lacks the The Mauthner (M-) axon of the goldish apparently lacks the typical node of Ranvier structures which are found along other vertebrate myelinated axons. Nevertheless, active sites spaced about 2.4 mm apart were discovered using electrophysiological techniques (Funch & Faber, J. Neurophysiol., 47:1214-1231, 1982), and our morphological studies of the oligodendrocytic sheath (Wood, Funch & Faber, Soc. Neurosci. Abstr., 9, 1983) have demonstrated that single sheath segments span the internodal region between the active sites. The experiments des-cribed here were designed to test the hypothesis that the active sites are the only regions of the M-axon which produce the inward sodium current necessary for action potential propagation.

Localized extracellular pressure ejections of tetrodotoxin (TTX; 100 µg/ml) from a microelectrode were made immediately adjacent to the M-axon sheath; this position was determined acjustic with result of the set of the voltage produced across the myelin sheath by the M-axon action potential. The size and spread of the TTX ejection was monitored visually by using Fast Green in the TTX solution as a marker. The duration of the ejection was limited so that the initial droplet of TTX was roughly 100 µm in diameter. The TTX ejections were effec-tive in rapidly blocking components of the M-axon's action potential only when they were made at the nodal regions (2.4 mm, 4.9 mm, and 7.0 mm caudal to the axon hillock-initial segment (AH-IS)). Beginning at the first active site caudal to the AH-IS, successive active sites were blocked with local TTX ejections and the effects on amplitude, maximal rate of rise (dV/dt), and spike duration (time from maximal dV/dt to minimal dV/dt) of the antidromic and orthodromic action potentials were The all-or-none changes in these parameters were assessed. consistent with the active site spacing, the space constant of the M-axon (5 mm), a safety factor of 6-7, and asymmetrical coupling of the M-axon to the soma-dendritic region (Funch &

Faber, vide supra). Thus, although the M-axon apparently lacks morphologically distinguishable nodes of Ranvier, it has clearly defined and functionally distinct nodes and internodes which support the saltatory conduction of impulses. (Supported by NIH Grant NS 17063.)

10.8 Ca-ACTIVATED K CHANNELS IN RAT BRAIN SYNAPTOSOMES. D.K. Bartschat and M.P. Blaustein. Dept. Physiol., Univ. Maryland Sch. Med., Baltimore, MD 21201 Modulation of potassium channel function has been implicated

Modulation of potassium channel function has been impricated in the regulation of neurotransmitter release from nerve terminals in vivo, but the small size of mammalian presynaptic nerve terminals has precluded use of electrophysiological abechniques to assess K channel activity. Accordingly, we used Rb efflux terminals has precluded use of electrophysiological abechniques to assess K channel activity. Accordingly, we used "Rb efflux (cf. Neurosci.Abstr.,6:572, 1980) as a probe for K permeability, P, (Hille, J.Gen.Phys.,61:669, 1973) in rat forebrain gynapticopies (cf. J.Membr.Biol.,50:287, 1979). After loading with "Rb at 30" c for 30 min. in physiological salt solution (PSS) containing 5K and 145Na, 50 µl aliquots were placed on pre-washed glass fiber filters (Schleicher and Schuell #25), and extrasynaptosomal "Rb was removed with five 2 ml washes of PSS. Efflux was initiat-ed with 2 ml of "reaction medium", frequently containing elevated K, decreased Na and/or drugs. Efflux was terinated after 1-20 sec be with 2 mi of reaction method, irreducintly containing elevation K, decreased Na and/or drugs. Efflux was terminated after 1-20 ser by rapid addition of 2 ml "stopping solution" containing 145 mM TEA<sup>+</sup> and 1 mM<sub>0</sub>BA<sup>+</sup>, agents known to block K channels. Suction was applied, and RB released into the filtrate was assayed by liquid scintillation methods. "Rb remaining in the synaptosomes appried, and Ko released into the tiltrate was assayed by liquid scintillation methods. Rb remaining in the synaptos was also measured, and Rb release was expressed as 7 total

Was also measured, and KD release was expressed as 7 total BB released for each time point. Rb efflux into 5K PSS was slow (0.1-0.27/sec); increasing K markedly stimulated efflux. Two components of K-stimulated In marketly stimulated efflux. We components of K-stimulated efflux were seen: a rapid component apparently inactivating in less than 1 sec (C<sub>2</sub>), and a slower component that remained linear for 5 sec (C<sub>2</sub>). Both were graded with increasing K<sub>0</sub>, but C<sub>f</sub> was much more dependent on external Ca (Ca) than was  $c_s^0$ . This suggested the presence of Ca-activated K<sup>0</sup> channels in the terminate terminals.

terminals. Three lines of evidence supported this view; a) More than 50% of the K-stimulated Rb efflux at short times was dependent on Ca in a concentration-dependent manner. La<sup>+</sup> abolished the stimulation by Ca . b) Rb efflux could be stimulated in 5K by addition of Ca + A23187. Neither agent alone was effective in 5K Ca + A23187 produced larger, more prolonged stimulation of Rb efflux in 75K than Ca alone. A23187 alone was without effect in 5K by between the stimulation of the stimulation o 75K. c) Membrane potential changes measured with the voltage sensitive dye CC, revealed that Ca + A23187 decreased fluorescent intensity (FI) in 5K, suggesting membrane hyperpolarization; this is expected if P, is increased. Ca or A23187 alone produced little change of KFI in 5K or 100K. Ca + A23187 produced little change of FI in 100K. The data are consistent with the presence of Ca-activated K channels in mammalian presynaptic nerve termin-als. Tracer flux measurements may yield insights into physiological and pharmacological properties of these channels in vitro. Supported by NS-16106.

PATCH-CLAMP STUDY OF CALCIUM-ACTIVATED POTASSIUM CONDUCTANCE IN 10.9 PANCREATIC ISLET CELLS. <u>D.L. Cook</u><sup>\*</sup> M. <u>Ikeuchi<sup>\*</sup>and W.Y Fujimoto<sup>\*</sup></u> (SPON: J. Miller). Dept. of Medicine and Physiology and Bio-physics, University of Washington and Seattle VA Med. Ctr., Seattle, WA 98108.

Glucose, the major physiological stimulus for insulin release, triggers a bursting pattern of membrane electrical activity in triggers a bursting pattern of membrane electrical activity in pancreatic islet cells similar to the pattern seen in molluscan pacemaker neurons. In islets, voltage-dependent  $Ca^{++}$  splking is superimposed on a "plateau" depolarization due to a slower, voltage-dependent current (also likely to be a  $Ca^{++}$  current) which triggers the spikes. Pacemaker-like depolarization (during the silent phase) and repolarization (during the plateau phase) trigger the onset and offset of the plateaus. Increasing glucose trigger the onset and offset of the plateaus. Increasing gluco changes the pacemaker to prolong plateaus and shorten silent phases so that a larger fraction of time is spent  $Ca^{++}$  spiking (the electrical correlate of glucose-dependent  $Ca^{++}$  uptake). *I* candidate pacemaker mechanism for which there is indirect evidence in islets is the  $Ca^{++}$  activated  $K^+$  conductance. To the To test this, we have voltage-clamped excised membrane patches of identified, cultured rat beta cells bathed symmetrically with KCl (140 mM), MgCl<sub>2</sub> (2 mM), HEPES (10 mM), EGCA (1 mM) and varying levels of free Ca<sup>++</sup>. We have identified a channel with a large unit conductance (216-235 pS at temp = 20-22C, n = 4) a large unit conductance (216-235 pS at temp = 20-22C, n = 4) which is activated as Ca<sup>++</sup> level on the cytoplasmic surface is raised from 1  $\mu$ M to 100  $\mu$ M. The response to Ca<sup>++</sup> occurs immediately (within 100 msec) and does not accommodate. The channel conductance is linear (over a <sup>+</sup>/- 80 mY range), and is not, itself, affected by Ca<sup>++</sup>. The channel is not activated by external Ca<sup>++</sup> but is activated by depolarization to positive potentials at low Ca<sup>++</sup> and is less steeply voltage sensitive at high Ca<sup>++</sup> levels where the channel is active even at negative control of Ca<sup>++</sup> calls proceese K<sup>++</sup> nign ta<sup>++</sup> levels where the channel is active even at negative potentials. CONCLUSION: Rat pancreatic beta cells possess K<sup>+</sup> channels which are activated by depolarization and by intra-cellular free Ca<sup>++</sup> as have been recently described in rat muscle and salivary gland. These channels may serve as pace-makers for glucose-dependent, bursting electrical activity in nancreatic islet cells pancreatic islet cells.

10.11 ACTIVATION OF A K<sup>+</sup> PERMEABILITY IN THE GH3 ANTERIOR PITUITARY CELL LINE BY THYROTROPIN RELEASING HORMONE. A.K. Ritchie\* (SPON: J.E. Blankenship). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Multinucleated cells (up to 50 µm in diameter) have been produced by fusion of cells from the GH3 anterior pituitary cell line with polyethylene glycol. These cells were used to study the electrophysiological response of this cell line to 50 nM thyrotropin-releasing hormone (TRH). One of the responses to TRH is a pronounced hyperpolarization accompanied responses to the Is a pronounced hyperpolarization accompanied by an increase in membrane conductance (Ozawa and Kimura, 1979, Proc. natn. Acad. Sci 76: 6017, 1979). The reversal potential of this response is -66mV and varies by 59 mV/decade change in external K<sup>2</sup> concentration, indicating that an increase in K ion permeability is largely responsible for the hyperpolarization. The response is inhibited by 0.5 mM

hyperpolarization. The response is inhibited by 0.5 mM quinine, 0.1 µM apamin and 20mM TEA-HCL. Single electrode voltage clamp studies of GH3 cells (< 20 µm in diameter) show that the TRH induced current flow is enhanced as the membrane potential is clamped to more contributed when the the section of the observation positive levels. This voltage dependence and the observation that the hyperpolarization is sensitive to agents which are known inhibitors of the calcium-activated K channel suggests that the TRH response may be mediated by activation of such that the TRH response may be mediated by activation of such channels. Voltage clamp experiments show that the Ca activated K current (I\_) in these cells is partially inhibited by 10mM TEA-HCl and completely inhibited by 20mM TEA-HCl, however, the effects of quinine and apamin on I\_c in these cells is still under investigation.

If the TRH induced hyperpolarization is due to Ic then The first induced hyperpolarization is due to be then response persists in Ca<sup>++</sup> free solutions and under conditions in which the voltage dependent Ca<sup>++</sup> channel is completely inhibited by 0.5 mM CdCl<sub>2</sub>. Consistent with this hypothesis is the observation by others that TRH causes a dramatic increase in  ${}^{+}$ Ca<sup>++</sup> efflux (but not influx) suggestive of a mobilization efflux (but not influx) suggestive of a mobilization ral stores of Ca  $^{++}$ . - 10.10 IN VITRO INNERVATION MODULATES A Ca-ACTIVATED K-CONDUCTANCE IN
  - IN VIEW INNERVATION MUDULATES A CAPACITATED A CONDUCTING ALL RAT MYOTUBES. B.A. Suarez-Isla and S.I. Rapoport. Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, NIH, Baltimore City Hospitals, Balto., Maryland 21010 USA We have shown (Suarez-Isla et al., Neurosci. Abstr., 8: 125, that the incidence of slow hyperpolarizing after-potentials (slow HAPs) decreases significantly in rat myotubes which are innervated in vitro by chick spinal cord neurons that form stable neuromuscular synapses but not after innervation with chick retinal neurons, which form transient synapses. The slow HAP is associated with an increased Ca-dependent K-conductance (Barrett et al., Dev. Biol. 82:258, 1981) and probably maintains spontaneous contractile activity before innervation in vivo, being suppressed during maturation.

. To investigate whether the decreased incidence of the slow HAP following innervation is due to modulation of a Ca-dependent Kconductance, we used an extracellular patch clamp technique to examine gating and kinetic properties of single Ca-activated K-channels ( $I_{\rm K}$  (Ca) channels) in <u>intact membrane patches</u> of control myotubes and myotubes cocultured with spinal cord neurons.

The I channels were active in control and cocultured myotubes, even in the absence of slow HAPs. They were in 80% of the patches tested. The single channel conductance equaled 110 pS. In a few cases, channels appeared in bursts followed by silent In a few cases, channels appeared in bursts followed by silent periods of seconds to minutes. Action potentials, evoked by a second intracellular electrode, transiently increased the probability of opening of the  $I_{K(C_{2})}$  channel. The fraction of time that a channel spent in the open state (f(V)) increased e-fold with 20 mV of depolarization for low levels of activity in control and cocultured myotubes. Shifts of about 30 mV along the voltage axis were observed in both cases. The voltage dependence of open and closed time-constants was similar in both types of cells. However, the current-voltage relation depended on innervation.  $I_{\mu(\alpha)}$  channels were blocked at lower holding potentials in  $I_{\rm K(Ca)}$  channels were blocked at lower holding potentials in cocultured myotubes and the I/V relation "rolled over" at about 440 mV, showing a clear negative conductance region. In control myotubes, "roll over" became apparent only beyond +75 mV of holding potential. A model of voltage dependent ion block of the channel (Woodhull, J. Gen. Physiol. <u>61</u>, 687 1973) indicates that the voltage sensitivity of the block is significantly increased in cocultured cells. These results indicate that neurons that for stable neuronuscular synapses  $\underline{in \ vitro}$  exert a neurons that form stable neuronuscular synapses  $\underline{in \ vitro}$  exert a neurotropic influence that is rapidly expressed as a change in the conductance properties of Ca-activated K-channels of muscle cells in culture. Further experiments with excised membrane patches are needed to test whether the neurotrophic effect has also affected the Ca sensitivity of the I conductances.

10.12 PURIFIED CATALYTIC SUBUNIT OF CYCLIC AMP-DEPENDENT PRO-TEIN KINASE CLOSES THE SEROTONIN-SENSITIVE POTASSIUM CHANNEL OF <u>APLYSIA</u> SENSORY NEURONS IN CELL-FREE MEM-BRANE PATCHES. J. S. Camardo\*, M. Shuster\*, S. A. Siegelbaum\*, C. M. Eppler\* and E. R. Kandel (SPON: L. Rowland). Center for Neuro-

C. M. Eppler\* and E. R. Kandel (SPON: L. Rowland). Center for Neuro-biology & Behavior, Dept. of Pharmacology, Columbia Univ., College of P & S, and N. Y. State Psychiatric Institute, New York, NY 10032. Serotonin induces a slow EPSP in the sensory neurons of <u>Aplysia</u> by closing a specific K<sup>+</sup> channel, which has been previously identified by single channel recording techniques (Siegelbaum et al., <u>Nature</u>, 229:413). The serotonin-sensitive (S) channel is selective for K<sup>+</sup> ions, open at the resting potential, voltage-independent and independent of intracellular calcium. Evidence from biochemical and eloctrophysiological expericalcium. Evidence from biochemical and electrophysiological experi-ments indicates that serotonin acts via cAMP-dependent protein kinase, but the molecular site of kinase action remains unknown. We now report preliminary experiments indicating that purified catalytic subunit of cAMP-dependent protein kinase (PKC) decreases the opening of the S channel in cell-free membrane patches. Single channel currents were recorded from inside-out membrane

single channel currents were recorded from inside-out membrane patches with the cytoplasmic surface of the membrane exposed to a 360 mK KCl, low Ca, bath solution. Two types of K channel currents with similar but not identical single channel conductances were recorded in these patches; a Ca, dependent, voltage-dependent K channel (I<sub>c</sub>), and the Ca<sup>++</sup>-independent, voltage-dependent K<sup>+</sup> channel (I<sub>c</sub>), and the Ca<sup>++</sup>-independent, voltage-independent S channel. Puri-fied catalytic subunit of protein kinase (kindly provided by E. G. Krebs, C. S. Rubin, and D. A. Walsh) was added to cell-free patches after pre-cautions were taken to assure that the enzyme had ready access to the patch. In three out of three experiments under these optimal conditions with patches that contained only S channels, the kinase (1-7.5 uM), in the presence of MgATP, caused a rapid (within 2-10 sec.) and pronounced decrease in S channel activity. After addition of PKC, the time-averaged patch current, <1, was reduced to  $10 \pm 4$  % of its control value. The effects of PKC were reversed after addition of calf alkaline phosphatase (293 units/ml) to the patch: < I > increased to 74  $\pm$  8 % of its control (pre PKC) level. In all three experiments subsequent application

control (pre PKC) level. In all three experiments subsequent application of PKC again reduced channel activity significantly. PKC shows some specificity for the S channel. In two experiments on patches containing only the  $Ca_1^{++}$ -dependent K<sup>+</sup> channel, PKC had no effect on channel activity, measured during exposure to either 100 uM  $Ca^{++}$  (where the channels were largely open) or 300-400 nM  $Ca^{++}$  (where the channels were largely closed). Our results indicate that the activity of the S channel, a sero-tonin-sensitive K<sup>+</sup> channel, can be regulated by a cAMP-dependent protein kinase. The ability of this enzyme to modulate channel activity in a cell-free system surgers that the substrate for kinase action is

in a cell-free system suggests that the substrate for kinase action is either the S channel or a regulatory molecule which remains attached to the membrane patch when it is withdrawn from the cell.

10.13 VOLTAGE-DEPENDENT SODIUM CONDUCTANCE IN AN INVERTEBRATE STRIATED MUSCLE. <u>W. Stühmer<sup>R</sup> and L.M. Schwartz</u>. Dept. of Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195. Many neurons, from both vertebrates and invertebrates, have been shown to use an influx of sodium to generate action potentials. This is also a feature of vertebrate skeletal muscles. In contrast, all invertebrate muscles examined to date use predominantly an influx of calcium to generate action potentials. At some point during evolution, there must have been selective pressures which favored the expression of sodium channels in straited muscles. We report here that in planktonic arrow worm (<u>Sagitta elegans</u>, phylum: Cheatognatha) that sodium constitutes the predominant charge carrier during depolarization. Using the 100se-patch voltage clamp (Stühmer & Almers, PNAS 79, 946-950, 1982) we characterized the inward current flowing in response to membrane depolarization. While technical constraints prevented us from performing ion substitution experim its, several lines of evidence suggested that this current flows through sodium channels. (1) These channels were voltage-dependent with peak transient currents flowing in response to depolarizations of 90 transfer currents from in response to depoint actions of 2 m W from a resting potential of approximately -70 mV. (2) The channels opened rapidly with maximal current flow occurring with in 0.4 ms at 4°C. (3) This channel showed voltage-dependent from rest. (4) This inward current was abolished by 500 nM TTX. These data suggest that <u>Sagitta</u> muscles use voltage-dependent sodium channels to generate action potentials. Thus sodium spikes in striated muscle can no longer be considered a purely chordate trait. Supported by USPHS grant #AM17803 to Prof. Wolfhard Almers and

DEVELOPMENT OF THE VISUAL SYSTEM: RETINOTHALAMIC PROJECTIONS

TOPOGRAPHY OF GANGLION CELL PRODUCTION IN THE CAT RETINA. 11.1 C. Walsh, E.H. Polley, and T.L. Hickey. Comm. on Neurobiology,
 U. of Chicago, Chicago, IL 60637, Depts. of Anatomy, Ophthalmology and Neurosurgery, U. of Illinois School of Medicine, Chicago, IL 60680, and School of Optometry/The Medical Center, U. of Alabama, Birmingham, AL 35294.

Ganglion cells in the cat's retina are formed as several rough, central-peripheral waves which overlap one another as cells are produced first for central retina and then for peripheral retina. Medium-sized cells are produced before large cells, and the smallest cells seem to be produced throughout the period of ganglion cell addition (Walsh et al, <u>Nature, 302</u>: 611, 1983). The present report is based on further analysis of retinae from 24 cats which received <sup>3</sup>H-thymidine between the 21st and 36th days of gestation (E21-E36), and then were killed 2-10 months after birth. Our earlier work contains procedural details.

While each cell class shows the same general pattern of addi-tion, it is best illustrated for alpha cells. The oldest alpha cells, labelled after 'H-thymidine injections on E25, lie mainly above the optic disc, scattered over a wide area extending nasally and superiorly from area centralis (a.c.). After injections at later ages (E26,77,29), the area covered by heavily labelled alpha cells expands superiorly, nasally, and inferiorly, while spreading only slowly temporally across the a.c. itself. In superior retina the region containing heavily labelled alpha cells is bounded temporally by a line running superiorly and temporally from a.c. This corresponds roughly to the raphe line, which separates gang-lion cells whose axons run inferior to a.c. from those with axons that run superior to a.c., towards the optic disc (Murakami et al, Br. Beh. Evol. 21: 67-113, 1982). Later injections (E31) labelled alpha cells near or below the temporal horizontal meridian (i.e., inferior and temporal to the raphe line) but no alpha cells nasal to the raphe line, or anywhere in the nasal retina except in the far periphery. Hence, retinal regions containing the oldest alpha cells are also the first regions to complete alpha cell production. Injections at later ages (E35, 36) did not label any alpha cells.

In the cat then, production of those ganglion cells which survive in the adult is in no way symmetrical about either the optic disc or area centralis. Nasal retina leads temporal retina, and superior leads inferior, in the production of each ganglion cell type. Cells in the area centralis are produced over an extended time period. Moreover, cells in the region near and below the horizontal meridian of temporal retina are produced quite late. (Supported by NIH grants EY-01338, GM-07281, and EY-02374).

11.2 GENESIS OF MORPHOLOGICALLY IDENTIFIED NEURONS IN THE DORSAL LAT-ERAL GENICULATE NUCLEUS OF THE CAT. <u>Peter F. Hitchcock\*1\*2 and</u> <u>T. L. Hickey1</u>. School of Optometry/The Medical Center, Univ. of Alabama in Birmingham, Birmingham, AL 35294<sup>1</sup> and The Division of Biological Sciences, Univ. of Michigan, Ann Arbor, MI 48109<sup>2</sup>. Neurons in the dorsal lateral geniculate nucleus (dLGN) of the cat can be placed into five morphological classes (1-5) and three physiological classes (X,Y,W), based on a variety of structural and functional characteristics. Recently, Friedlander, Lin, Stanford, and Sherman (J. <u>Neurophysiol.</u>, 46: 80-129, 1981) and Stanford, Friedlander, and Sherman (J. <u>Neurosci.</u>, 1: 578-584, 1981) have shown how the three physiological classes of neurons distribute among the five morphological classes. Utilizing <sup>3</sup>H-thymidine autoradiographic techniques, we earlier demonstrated the period of time during prenatal development when cat dLGN neurons, classified according to adult soma size and location, undergo their final cell division. Dorsal lateral geniculate nucleus neurons undergo their final cell division be-tween gestational days 22 (E22) and E32. Neurons generated early in this period are ultimately distributed throughout the dLGN and exhibit a full range of soma sizes. The purpose of the present work was to directly demonstrate the relationship between the time a dLGN neuron undergos tits

The purpose of the present work was to directly demonstrate the relationship between the time a dLGN neuron undergoes its final cell division and its adult morphology. This task was accomplished by combining  $^{3}$ H-thymidine labelling of dividing neurons with Golgi impregnation procedures, using a technique

neurons with Golgi impregnation procedures, using a technique developed in our laboratory. In this study, 2138 Golgi impregnated neurons were classified in the dLGNs of seven cats, each of which had received a single injection of <sup>3</sup>H-thymidine on one of the following gestational days, E24-E28 or E30. Of the 2138 neurons classified, 1517 were successfully resectioned and recovered. Of these, 385 (25.4%) were found to contain the <sup>3</sup>H label. In animals that had received an injection of <sup>3</sup>H-thymidine between E24-E28, dLGN neurons from each of the five morphological classes were found to contain <sup>3</sup>H label. In a cat that had been injected with <sup>3</sup>H-thymidine on E30, only class 3 and class 5 neurons were found to contain <sup>3</sup>H habel. These findings demonstrate that neurons from each of the five morphological classes were found to contain <sup>3</sup>H habel. morphological classes undergo their final cell division between E24-28 and, when combined with the structure/function relation-E24-28 and, when combined with the structure/function relation-ships described above, suggest that X, Y, and W cells in the cat's dLGN undergo their final cell division simultaneously, at least between E24 and E28. The morphological and physiological properties of dLGN neurons that do not undergo their final cell division until E30 may be more restricted. Supported by EY01338, EY03039 (CORE), RR05807, and EY07033.

DEVELOPMENT OF THE CORTICOGENICULATE PATHWAY IN THE CAT: AN ELEC-11.3 DEVELOPMENT OF THE CONTINUENT OF THE CATE AND ELEC-TRON MICROSCOPIC AUTORADIOGRAPHIC STUDY. A. J. Weber and R. E. Kalil, Neurosciences Training Program and Dept. of Ophthalmology, Univ. of Wisconsin, Madison, WI, 53706. Previous anatomical research has demonstrated a topographical-ly organized projection from the visual cortex to the lateral

electron microscopic studies suggest that corticogeniculate axon electron microscopic studies suggest that corticogeniculate axor terminals are a specific morphological class. In brief, these synaptic endings are characterized by their 1) round synaptic vesicles, 2) small size and 3) dark mitochondria, and therefore these profiles have been classified as RSD terminals (Guillery, <u>Z. Zellforsch.</u>, 96, 1969). At present, it is not known whether all corticogeniculate axons terminate as RSD profiles since degeneration methods usu-ally do not preserve the normal ultrastructure of terminals. In addition, our knowledge of the synaptic cranization of the cor-

addition, our knowledge of the synaptic c ganization of the cor-ticogeniculate system is limited to adult cats since this pathway has not been studied in younger animals with the electron microscope. In the present study, electron microscopic autoradio-graphy (EMAR) has been used to investigate the corticogeniculate

graphy (EMAR) has been used to investigate the correctingentate pathway in adult cats and to study its development. Thirty-five cats, ranging in age from newborn to adult, re-ceived large injections of <sup>3</sup>H-proline into visual cortex near the representation of the intersection of the zero vertical and hori-zontal meridians. Following survival periods of 24 to 36 hours, Topical meridians. Following survival periods of 24 to 36 hours, the cats were perfused with paraformaldehyde and glutaraldehyde, the lateral geniculate nuclei were removed in Imm parasagittal or coronal blocks, and embedded in epon-araldite. Five micron sec-tions from each block, processed for light microscopic autoradio-graphy, were used to localize the area of the LGN that was labeled anterogradely from visual cortex. Thin sections for EMAR were then cut from the most densely labeled region of laming A. At each age studied, labeled corticogeniculate terminals con-form to the RSD classification. Furthermore, corticogeniculate endings make synaptic contacts at birth that do not appear to differ from those seen in older kittens or adults. Thus, at all ages corticogeniculate axons terminate exclusively on dendritic processes and are always presynaptic. This suggests that the es-sential pattern of corticogeniculate synapses does not change during development.

during development.

The number of labeled terminals increases steadily during the The number of labeled terminals increases steadily during the first postnatal month and rapidly during the second. In all ani-mals, however, many unlabeled RSD profiles are seen in the im-mediate vicinity of labeled terminals. This result suggests that not all RSD profiles are cortical in origin. Supported by N.I.H. Training Grant 07507 (A.J.W.) and N.I.H. Grant EY01331 (R.E.K.).

11.5 PHYSIOLOGICAL SEGREGATION OF GENICULATE AFFERENTS IN THE VISUAL CORTEX OF DARK REARED CATS. <u>N.V.Swindale\*</u> and <u>M.S.Cynader</u> (SPON:A.Fröhlich). Dept. of Psychol., Dalhousie Univ., Halifax, N.S. B3H 4J1, Canada

In cats dark reared from birth, normal segregation of geniculate afferents to layer IV of area 17, as revealed by trans-neuronal autoradiography, fails to occur (Swindale, Nature,290,332,1981). In area 18 on the other hand, segregation Nature, 290, 332, 1981). In area 18 on the other hand, segregation appears normal (Swindale, Soc. Neurosci. Abstr. 8, 297, 1982). We took advantage of the relative unresponsiveness of cortical neurones in the visual cortex of dark reared cats to record from the population of geniculate axons in layer IV of area 17 and 18, with the intention of comparing the anatomical distribution of geniculate inputs with their physiological activity. In area 18 and parts of area 17, ocular dominance was measured by making numerous vertical neurotical content and sampling at depths

by making numerous vertical penetrations and sampling at depths between 500 and 800 um; in area 17 tangential penetrations were also made down the medial bank of the marginal gyrus, and histological reconstructions used to verify that the recordings were from layer IV.

Identification of activity evoked by moving or flashed spots criteria: 1) the responses followed flashes without habituation up to several Hz; 2) there was no selectivity for orientation or direction and 3) responses appeared first at at depth of about 500 um below the cortical surface and, in vertical penetrations, grew less strong below about 800 um. The evoked activity (measured by listening to an audio-monitor) was probably multi-unit since 1) individual units could rarely be resolved either aurally, or by looking at the oscilloscope trace; 2) the measured ocular dominance remained the same when the electrode advanced vertically through layer IV. We used this method to record the ocular dominance distribution in area 17 and 18 of dark reared

activity. In area 17 there were more binocular responses, but there were still many regions where responses could only be obtained from one eye. This has to be reconciled with the results of the other set of the still many regions where responses could only be obtained from one eye. This has to be reconciled with the results of trans-neuronal autoradiography which show that inputs from both eyes are present in all regions of layer IV. A tentative explanation would be that in some regions, geniculate afferents are physiologically silent i.e. some axonal branches fail to conduct impulses. In normal segregation conduction failure might precede the physical removal of axons: development in dark reared cats may perhaps be arrested between these two stages.

EFFECTS OF RETINAL GANGLION CELL BLOCKADE ON THE MORPHOLOGICAL DEVELOPMENT OF RETINGENICULATE SYNAPSES IN THE CAT. R. E. Kalil, M. W. Dubin, G. L. Scott\* and L. A. Stark\*. Dept. of Ophthalmology, Univ. of Wisconsin, Madison, WI, 53706, and Dept. of Molecular, Cellular and Developmental Biology, Univ. of Colo-rado, Boulder, CO, 80309.

rado, Boulder, CO, 80309. Synapses between retinal ganglion cells and neurons in the dorsal lateral geniculate nucleus (LGN) of the cat develop in an orderly sequence during the first two postnatal months (Kalil and Scott, <u>Soc. Neurosci. Abstr.</u>, 1979), and this sequence is largely unaffected by partial or complete visual deprivation (Kalil and Scott, <u>Soc. Neurosci. Abstr.</u>, 1981). Recently, it has been de-monstrated that impulse blockade in the retinogeniculate pathway there have been been be a second by solation of the second by during development leads to severe physiological abnormalities in the LGN (Archer et al., <u>Science</u>, 217, 1982). In the present ex-periments we investigated whether blocking retinal ganglion cell activity also affects the morphological development of retinogeniculate synapses.

Intraocular injections of tetrodotoxin (TTX), at a concentration known to block ganglion cell activity (Archer et al., op. cit.), were administered unilaterally to three cats. The injections were begun shortly after birth, and continued on alternate days for the next 7 to 8 weeks. The cats were then perfused with mixed aldehydes, and blocks of tissue from the A laminae of the LGN ipsilateral and contralateral to the injected eye were pre-pared for electron microscopy. Control tissue from two cats that received intraocular injections of citrate buffer only was also available

In comparison with retinogeniculate (RLP) terminals from control cats or from the normal eye of experimental animals, RLP terminals from the TIX treated eye display several abnormalities. First, terminal cross-sectional area and perimeter are reduced in size by about 50%. Second, these terminals make approximately size by about 50%. Second, these terminals make approximately 30% fewer contacts than normal, however the length of individual contacts is increased on average by 60%. Third, RLP terminals from the TIX treated eye make simple axodendritic contacts almost exclusively, and are found only rarely in complex encapsulated zones. By contrast, about 33% of all contacts made by normal RLP terminals are with vesicle filled profiles (F profiles) and one-third of normal RLP terminals are encapsulated. Taken together, these structural abnormalities show that reti-nogeniculate synapses in cats reared for two months with retinal ganglion cells silenced by TIX share many features in common with synapses in neonatal kittens. This result suggests that elec-trical activity plays an important role in the morphological de-

synapses in heuralar kitters. This result suggests that electrical activity plays an important role in the morphological development of synaptic patterns. Supported by N.I.H. grant EY01331 (R.E.K.) and grants from the N.S.F. and March of Dimes (M.W.D.).

11.6 PRENATAL DEVELOPMENT OF RETINOGENICULATE AXONAL ARBORIZATIONS IN THE CAT. <u>D.W. Sretavan and C.J. Shatz</u>. Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

In the development of the cat's retinogeniculate pathway, afferents from both eyes initially overlap and then segregate into distinct contralateral and ipsilateral regions within the lateral geniculate nucleus (LGN). Segregation begins by embryonic day 47 (E47) and is complete at birth 3 weeks later. Here, we examine the morphology of individual retinogeniculate arborizations (LGN) during this period.

Nine fetuses (E47-E64) and a 2-day-old kitten have been examined. The diencephalon was removed from the cranium and small crystals of HRP were inserted into the exposed optic tract. The tissue was bathed in oxygenated Ringer's solution in a slice chamber for six hours at 37° C. The tissue was fixed, sectioned in the horizontal

nours at 37 c. The tissue was fixed, sectioned in the horizonta plane at 100  $\mu$ m intervals, and reacted for HRP histochemistry. A total of 45 fibers have been reconstructed. In the younger fetuses (E47-E53), most axons, upon entering the LGN, turn sharply (>90°) and course anteromedially in straight trajectories. The simplest fibers are unbranched and end in trajectories. The simplest fibers are unbranched and end in growth cones. Slightly more complex fibers have many fine, short processes  $(10-30 \ \mu\text{m})$  arising from all portions of the axon. How-ever, the distal (furthest from the optic tract) portion of some axons is smooth and unbranched. Often fibers of different degrees of complexity are found next to each other. This arrangement may reflect the differential arrival and maturation of axons from retinal ganglion cells born at different times.

In older fetuses (E53-E55), significant arborizations are first seen. Fibers end in fan-shaped arbors consisting of radially directed branches roughly equal in length (100 µm); proximally affected branches foughly equal in length (100 µm); proximally the axon is smooth and unbranched. More complex fibers have elaborate, elongated arborizations (500 µm) but are restricted in width to less than 100 µm. Close to birth (EGS, EG4), arbors are even more highly branched and have a columnar shape similar to that seen in the adult (Bowling, D.B. and Michael, C.R., J. Neurosci., in press.). Most occupy the full thickness of an LGN layer while others arborize chiefly in the top or bottom half. However, unlike the adult, clusters of boutons are not seen and the width

of arborizations remains less than 100  $\mu\text{m}.$  These findings demonstrate that during the period of segregation, retinogeniculate axons are relatively simple in morphology and only begin to acquire complex, highly focused branching patterns towards the end of the period, shortly before birth. Furthermore, the absence of widespread branching throughout this period suggests that the retinogeniculate projection already possesses a significant degree of topography

(Supported by NIH Grant EY02858 and the McKnight Foundation.)

PHYSIOLOGICAL AND MORPHOLOGICAL DEVELOPMENT OF RETINOGENICULATE 117 AXONS IN KITTENS. <u>M. Sur, R.E. Weller and S.M. Sherman</u>, Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY 11794. We have studied the postnatal development of physiological and morphological properties of single retinal axons innervating the lateral geniculate nucleus (LGN) in kittens by using the intracellular HRP technique. At 3-4 weeks of age, most optic tract axons can be classified as either X or Y. Latencies to optic chiasm stimulation are shorter for Y-cell than for X-cell axons. However, nonlinear responses from Y-cells are often immature. Both X- and Y-cell receptive fields are large (often 4-5 times adult sizes) and lack antagonistic surrounds. Both X- and Y-cell ter-minal fields are morphologically different from their adult counminal fields are morphologically different from their adult coun-terparts. The X-cell terminal fields in lamina A or Al are slightly wider in 3-4 week old kittens than in adults (kitten: N=6, mean=167µm, range=120-240µm; adult: N=16, mean=140µm, range= 100-175µm; p=0.05). In contrast, the Y-cell terminal fields in the kittens are narrower than in adults (kittua: N=9, mean=188µm, range=160-260µm; adult: N=12, mean=293µm, range=220-410µm; p< 0.001). Most terminal boutons of both X- and Y-cell axons are small ( $<2\mu$ m), although some are medium-sized ( $2-5\mu$ m). Many boutons have filopodial extensions with growth cone-like appendages. By 8 weeks of age, receptive field sizes are comparable to adult Xand Y-cell fields, surrounds have developed, and Y-cell nonlinear responses are stronger and more stable. Four recovered X-cell axons have terminal widths of 120-180 $\mu$ m with a mean of 145 $\mu$ m. Two axons have terminal widths of 120-180um with a mean of 145µm. Two recovered Y-cell axons have widths of 160 and 330µm. Terminal boutons appear adult-like, with many small and medium-sized swell-ings. There are still a few boutons with filopodial extensions, and relatively few of the large, crenulated boutons that are com-mon in adult axons. At 12 weeks, receptive field properties of X-and Y-cell axons are indistinguishable from adult axons. Two re-covered X-cell axons have widths of 100 and 115µm, while 3 reco-word X-cell axons have midths of 100 and 115µm, while 3 recovered Y-cell axons have widths of 180, 185 and  $310\mu$ m. Terminal boutons appear adult-like in size and form.

Our conclusions must be qualified because of the possibility that we have sampled the most mature axons. Nonetheless, receptive field properties, terminal arbors, and individual boutons of X- and Y-cells appear to develop rapidly in kittens between 3 and 8 weeks of age. However, some X-cell axons at 3-4 weeks have terminal arbors that are broader than those seen in adults, whereas most Y-cell arbors are smaller at 3-4 weeks than in adults. This suggests that, during the critical period, a process of enlarge-ment of Y-cell arbors is concomitant with the pruning of exuberant connections made by immature X-cell arbors. Supported by USPHS Grants EY04712 and EY03038.

VISUAL RESPONSE LATENCIES AND CONTRAST SENSITIVITY FUNCTIONS IN 11.8 VISUAL RESPONSE LATENCIES AND CUMIRAST SENSITIVITY FUNCTIONS IN PRIMATE LGN AFTER MONOCULAR DEPRIVATION. <u>G. E. Irvin\*, M. A.</u> <u>Sesma, T. K. Kuyk\*, T. T. Norton and V. A. Casagrande</u>. Dept. of Physiol. Optics, School of Optometry/The Medical Center, Univ. of Alabama in Birmingham, Birmingham, AL 35294; Depts. of Anatomy and Psychology, Vanderbilt Univ. Nashville, TN 37232. We previously reported (Sesma et al. Soc Neurosci Abstr

Arlabama in brinningham, Brinningham, A. So294; Depts. of Anatomy and Psychology, Vanderbilt Univ. Nashville, TN 37232. We previously reported (Sesma et al., <u>Soc. Neurosci. Abstr</u>. '82) that Y-like and X-like cells in the LGN of galago appear to be unaffected by monocular deprivation as judged by measurements of encounter rate, latency to chiasm and cortical stimulation, receptive-field size, response to targets of appropriate standing contrast and phasic-tonic index. We have now extended these investigations to include visual response latencies and contrast sensitivity functions (CSFs) of single cells in the LGN of 5 adult greater galagos which received monocular lid suture for more than 14 mos. Response latencies were measured for small visual stimuli (1.0 log unit above threshold) centered in the receptive field. The results are comparable to those in normal galagos in that response latencies to both light onset and peak response were shortest for Y-like (mean, 51 msec onset; 91 msec peak), intermediate for X-like (mean, 65 msec onset; 120 msec peak), and longest for W-like cells (mean, 85 msec onset; 144 msec peak). Monocular deprivation did not affect the response latencies. There were no significant differences either between peak) and longest for w-like certs (mean, op more onset, erry msec peak). Monocular deprivation did not affect the response latencies. There were no significant differences either between the latencies of deprived and non-deprived cells in the deprived animals or between cells in deprived and normal animals. Thus, W-, X- and Y-like cells is capable of reaching the visual cortex at the same time as information carried by their non-deprived counterparts.

Limited CSF data showed that deprived Y-like and X-like cells responded similarly to non-deprived Y-like and X-like cells. For Y-like cells, the mean high spatial frequency cut-off (deprived Y-like cells, the mean high spatial frequency cut-off (deprived vs. non-deprived) was 0.8 c/deg vs. 0.9 c/deg and the peak sensi-tivity occurred at a mean spatial frequency of 0.2 c/deg for both the deprived and non-deprived cells. For X-like cells, the mean high spatial frequency cut-off was 0.9 c/deg (D) vs. 1.2 c/deg (ND) and the peak sensitivity occurred at a mean spatial fre-quency of 0.3 c/deg (D) and 0.4 c/deg (ND). When differences in the eccentricity of the sampled cells were considered, the aver-aged CSF values for the deprived animals were not significantly different from those found in normal galagos (Kuyk et al., <u>Invest. Ophthalmol. Vis. Sci. (Suppl.</u>), '83). These data provide additional evidence that monocular deprivation has very little effect on either Y-like or X-like cells in primate LGN. Supported by R01 EY02909, R01 EY01778, K04 EY00223, EY03039 (CORE), F32 EY05473 and F32 EY05680.

THE RELATIONSHIP BETWEEN AFFERENT LAMINAR DEVELOPMENT AND CELL THE RELATIONSHIP BETWEEN AFFERENT LAMINAR DEVELOPMENT AND CELL LAYER FORMATION IN THE LATERAL GENICULATE NUCLEUS (LGN). V. A. Casagrande and J. K. Brunso-Bechtold. Depts. of Anatomy and Psychology, Vanderbilt University, Nashville, TN 37232. Our previous work in tree shrew has shown that early eye removal prevents the formation of interlaminar spaces (ILSS) between the six LGN cell layers indicating that retinal input plays a key role in cell layer formation. Yet, some species exhibit more layers of retinal input than cell layers suggesting that other factors such as the development of extrartinal input that other factors such as the development of extraretinal input may be important. In order to investigate this further we studied the development of lamination of retinal input in relation to LGN ontogeny by injecting both eyes of 15 tree shrews with several combinations of tracers at different

Shrews with several combinations of tracers at different developmental stages. In the adult, spacing between retinal input to all six layers is not equivalent. Uncrossed and crossed input to layers 1 and 2, respectively, extends into the ILS leaving only a small label-free gap. In contrast, crossed and uncrossed input to cell layers 4 and 5 is confined to the cell layers as is the crossed input to layers 3 and 6. Unlike retinal input, extraretinal input in adults is concentrated within all ILSs except that collicular fibers avoid layers 1 and 2 and the ILS in between. At birth (P 0) when no cell layers are present retinal input reveals a similar but less distinct pattern than in adult. For example, retinal input to future layers 1 and 2 shows little, if any, space between them while input to the remaining future layers is separated by zones of lighter label. At that time, cortical input has not yet entered the LGN and collicular input is present but unlaminated. By P 5 retinal input exhibits a more distinct laminar pattern. At that stage, ILSs between cell layers have begun to form and corticogeniculate fibers show evidence of concentration within these forming ILSs. Finally, at P 16 when all cell layers are these forming ILSs. Finally, at P 16 when all cell layers are apparent, label from the retina shows a pattern indistinguishable from that of the adult.

The timing of the above events suggests several conclusions: First, retinogeniculate input is clearly laminated prior to the First, retinogeniculate input is clearly laminated prior to the formation of the ILSs and thus is in a position to influence their development. Second, cortical input begins concentrating in the ILSs at the time these are forming and thus may further this development. Finally, it is of interest that the unequal spacing of retinal input is weakest in the region (layers 1 and 2) lacking collicular input in the adult. (Supported by EY03881 and 1K04-EY00223). 11.10 NEONATAL DEVELOPMENT OF GAD IMMUNOREACTIVITY AND GAD+ SYNAPSES IN THE DORSAL LATERAL GENICULATE OF THE MONKEY: A LIGHT AND ELECTRON THE DORSAL LATERAL GENICULATE OF THE MONKEY: A LIGHT AND ELECTRON MICROSCOPIC ANALYSIS. M.P.Ogren, A.H.Hendrickson, & J-Y. Wu, Dept. Psych., MIT, Cambridge <sup>1</sup>A 02139; Dept. Ophth., Univ.Wash., Seattle WA 98195; Dept. Cell Biol., Baylor Sch. Med., Houston TX 77030. Our previous study of the dorsal lateral geniculate (dLG) in the adult monkey (Ogren et al '82, Hendrickson et al '83) described the morphology and distribution of neurons and synapses that con-tain comme eminobutysic social (d100), by immerspitceobenical stain

in the ing of an antiserum to the GABA-synthesizing enzyme, glutamic acid decarboxylase (GAD). We now report on the development of GAD

decarboxylase (GAD). We now report on the development of GAD reactivity and GAD+ synapses in the dl.G during the first postnatal month. The dlG of 3 normal macaque monkeys at 3 postnatal ages; 2 da, 2 wk, & 4 wk were prepared for light (LM) and electron (EM) microscopy. The synaptic development of the dLG was also examined with conventional EM in 3 other normal animals at similar ages. GAD reactivity in the LM is remarkably pale in the dLG at 2 da, and gradually increases in intensity at 2 and 4 wk. The number of GAD+ structures does not appear to change with age. Rather, the labeling is more faint so that higher magnification is required to visualize it at 2 da, and to a lesser extent at 2 wk. This impression is supported by EM analysis in these animals in which the full adult-like complement of GAD+ neurons, dendrites and synaptic terminals is easily detected at all ages. Dendritic labeling, however, is relatively more pervasive in the youngest animals. This suggests that the pale LM appearance of GAD in the dLG may be due suggests that the pale LM appearance of GAD in the dLG may be due to its more diffuse distribution within the reactive neurons at early ages, although the concentration of the GAD enzyme may also increase with age. By 4 wk GAD reactivity in the LM is crisp and robust and is visable at low magnifications as in the adult. Higher concentrations of GAD+ labeling in the laminar, particularly

the magnocellular zones is apparent at all ages. EM analysis shows another age related difference in frequency of synapses made by GAD+ synaptic terminals within the glomeruli. These are likely to be presynaptic dendrites because of their in-These are likely to be presynaptic dendrites because of their in-termediate position between retinal terminals and dLG dendrites in serial and triadic synapses. At 2 da the GAD+ terminals in glomer-uli are postsynaptic to retinal terminals, but are rarely presyn-aptic to dLG dendrites, so that serial and triadic synapses are correspondingly rare. Outside the glomeruli, GAD+ terminals engage in numerous simple synaptic contacts of all types reported for the adult. At 2 and 4 wk the frequency of GAD+ synapses within the glomeruli increases dramatically. This corresponds to our quantita-tive findings from conventional EM and a previous finding by Hamori et al '75. This result indicates that retinally driven GABA-ceric transmission of presynaptic dendrites in monkey dLG is GABA-ergic transmission of presynaptic dendrites in monkey dLG is immature at birth. DEVELOPMENT OF RETINAL PROJECTIONS TO THE AUDITORY AND SOMATO-11.11 SENSORY SYSTEMS. <u>D.O. Frost</u>, Sect. of Neuroanatomy, Yale Med. Sch., New Haven, <u>CT. 06511</u>

When the superior colliculus (SC) and dorsal nucleus of the lateral geniculate body (LGd) are ablated in newborn hamsters and alternative terminal space is made available in the ventrobasal (VB) or medial geniculate (MG) nuclei by ablation of their ascending afferents, optic tract (ot) fibers form permanent, orderly connections to VB or MG. Here we report that during normal dev-elopment retinofugal axons project transiently beyond the borders of the visual system, and that the abnormal adult projections to VB, but not MG, result from the stabilization of some of these exuberant juvenile connections. On the day of birth (day 0) and postnatal days 1,2,3,4,6 & 8,

normal hamster pups received intraocular injections (ca 1  $\mu$ 1) of 40% horseradish peroxidase or 2% HRP/wheatgerm agglutinin conju-gate.  $14\pm1$  h after injection the pups were perfused and sections of their brains were reacted by the TML procedure to visualize anterogradely labeled ot axons. Additional pups operated on day 0 so as to induce permanent retinal projections to MG and VB

received, at corresponding ages, similar injections contralateral to the operated side of the brain; they were processed as above. The retinal projections of normal day 0 hamsters are more mature than previously reported. Large numbers of terminating crossed retinofugal axons extend into LGd, the ventral nucleus of the lateral geniculate body (LGv), the pretectum, SC and the accessory optic nuclei. Some ot axons pass across LGd to form an Unequivocal projection to the neighboring dorsolateral region of VB, where ectopic projections are found in operated, but not in normal adults. The <u>normal</u> projections to VB persists on day 4, but not on day 8. In <u>normal</u> hamsters, no retinal projections to MG were seen at any age, although ot fibers pass over its The write seen at any age, although of There's pass over its surface. In <u>operated</u> hamsters, the normally transient retinal projection to VB persists indefinitely. In these animals, by day 2 the retina projects ectopicly to MG. Collectively, these results suggest that permanent retinal projections to VB are formed by the stabilization of a normally transient projec-

formed by the stabilization of a normally transient projec-tion, whereas projections to MG are rapidly induced <u>de novo</u>, as a result of neonatal surgery. Thus, different mechanisms operate in the formation of abnormal retinal projections to VB and MG. Additional new observations on <u>normal</u> day 0 pups include: 1) Uncrossed projections to LGd, LGv and the midbrain have al-ready begun to form. 2) The stratum opticum and the stratum gris-eum superficiale of SC have not yet differentiated. 3) Fascicles of retingueal fibure area candelly curveficially is Cit they of retinofugal fibers pass caudally superficially in SC; they descend into the subjacent tissue across the entire extent of SC. 4) The inferior colliculus receives a transient retinal projec-tion which is present on day 0 but disappears by day 4.

- 11.12 DENDRITIC REACTIONS TO EARLY POSTNATAL LESIONS IN THE CAT RETINA. U.Th. Eysel, L. Peichl\* and H. Wässle\*. Institute of Physiology, University of Essen and Max-
  - Planck-Institut für Hirnforschung, Frankfurt, F.R.G. In the normal cat retina the a-ganglion cell dendri-tic fields respect each others territories (Wässle et al., <u>Nature</u>, <u>292</u>:344, 1981). We investigated whether these territories remain fixed when the neighboring cells are destroyed by retrograde degeneration follow-ing retinal lesions. In adult cats neither  $\alpha$ - nor  $\beta$ cells change their dendritic territory after retinal lesions. This is shown in retinal whole mounts after re-trograde filling with HRP. Following lesions in early trograde filling with HRP. Following lesions in early postnatal life (3rd postnatal day) and several months survival  $\alpha$ - and  $\beta$ -ganglion cells with asymmetric dendri-tic fields are found. They extend their dendrites into the parts of retina which are free of ganglion cells due to retrograde degeneration. Similar results were re-ported after retinal lesions on the day of birth in rats (Perry & Linden, <u>Nature</u>, 297:683, 1982). A quantitative evaluation of acell changes was done in retinae stained with a neurofibrillar method where dendritic staining is superior to HRP material. Cells at the border of the region lacking ganglion cells have dendritic fields of region lacking ganglion cells have dendritic fields of normal size and ellipticity but they show conspicious morphological changes: dendrite diameters as well as dendritic density (number of dendrites per unit area) are larger in the part of the dendritic tree which lies in the ganglion cell-free region; many cells show skewed fields with dendrites pointing preferentially towards that region.

Inclus with dentities pointing preferentially cowards that region. In contrast to the lesions in adulthood the early lesions are made during a period of ocular growth. Asymmetric dendritic fields could therefore result from active dendritic growth or from distortions due to in-homogeneous growth of the retina. The denervated parts of retina expand less than adjacent normal parts during growth. This is revealed by area measurements and an increased density of horizontal cells which are also stained by the neurofibrillar method. Thus passive stretch of dendrites into the denervated area is very unlikely. An active shift of dendritic volume to that part of the dendritic field not competing with other dendritic territories seems to be the most probable ex-planation. This may be an effective way to contact more of the abundantly available presynaptic sites there without enlarging the dendritic territory as such. Supported by the Deutsche Forschungsgemeinschaft.

LEARNING AND MEMORY: ANATOMY I

12.1 FORMATION OF VISUAL DISCRIMINATION HABITS IN RHESUS MONKEYS AFTER INFERIOR TEMPORAL NEOCORTICAL LESIONS DURING INFANCY AND

 ADULTHOOD. J. Bachevalier\*, B. L. Malamut\* and M. Mishkin (SPON:
 C. Duncan-Johnson), Lab. Neuropsychol., NIMH, Bethesda, MD 20205. The storage and retention of experience depends on at least The storage and retention of experience depends on at least two qualitatively different processes served by two separate neural mechanisms: a memory system and a habit system (Mishkin et al, in <u>The Neurobiology of Memory</u>:1983). With regard to vision, the memory system appears to include both the anterior part of inferior temporal cortex (area TE) and limbic structures (Mishkin, <u>Phil. Trans. R. Soc. Lond., B298</u>:1982). In contrast, the habit system in vision does not depend on limbic structures, though it may involve area TE (Michaet et al. unpubliched date) though it may involve area TE (Malamut et al, unpublished data). To examine this latter possibility, we assessed the effects of area TE lesions on a test thought to be selectively dependent on the habit system. In addition, since this system is functional early in infancy, we compared the effects of TE ablations made in informer with those and the deltheter. infancy with those made in adulthood. Area TE was removed bilaterally in four newhorn monkeys and

four adult animals. A two-stage surgical procedure was performed in all infants at 1 week and 3 weeks of age and in one adult animal; the remaining 3 adults sustained a one-stage procedure. Seven unoperated infants, matched for age, and ten unoperated adults served as control animals. Effects of surgery on the concurrent discrimination learning were assessed postoperatively at the age of 3 months in Infant monkeys and after a 15 day recovery period in adults. In this task, a set of 20 pairs of easily discriminable objects (Set A) was presented once every 24 hours. The positive and negative objects within each pair, as well as the order of the pairs, remained constant across Well as the order of the pairs, remained constant across sessions. When the monkeys reached a criterion of 90 correct responses in 100 trials, they were trained on a second set of 20 new object pairs (Set B) in the same manner as before. In adult animals, unoperated monkeys learned each of the sets in an average of 10 sessions, whereas the operated animals required an average of 27 and 33 sessions to learn set A and set B, respectively. No difference was found between one- and two-stage operated adult animals. Like normal adults, the normal infants learned the two sets in an average of 16 and 7 sessions

learned the two sets in an average of 16 and 7 sessions respectively. By contrast, unlike operated adults, the infants with TE lesions were only slightly impaired in the acquisition of set A and, furthermore, were unimpaired in learning set B, performing as well as normal infants and adults. The findings support earlier data showing that habit formation proceeds at adult rates in early infancy and suggest that, although area TE is involved in the habit system in adults, neonatal ablation of this cortical area leads to significant functional sparing of the system. functional sparing of the system.

12.2 RESPONSES OF NEURONS IN THE INFERIOR TEMPORAL VISUAL CORTEX IN SHORT AND LONG TERM MEMORY TASKS. G.C.Baylis\* and E.T.Rolls (SPON: M.Calford). Dept. Exptl. Psychol., Oxford Univ., Oxford. England.

There is evidence that some neurons in the inferior temporal visual cortex (ITC) have activity related to the performance of a delayed matching to sample task. In this task the monkey must remember whether he has seen a particular stimulus in the preceding few seconds. To investigate the role of the ITC in memory, we have compared the activity of ITC neurons in the rhesus monkey in this relatively short term memory task with their activity in a task requiring memory over longer periods in which different, intask requiring memory over longer periods in which different, in-terfering, stimuli are seen. In the delayed matching to sample task, the stimuli were geometric shapes of one of four colors presented on a TV screen for is, separated by a delay of 2-5s. If the second stimulus matched the first, the monkey could lick to obtain fruit juice, and if not the monkey had to withold his lick to avoid obtaining saline. The longer term memory task was a serial recognition task in which 0-8 other stimuli intervened between the novel and familiar presentations of a stimulus with between the novel and familiar presentations of a stimulus, with each stimulus being shown only twice per day (Rolls et al, 1982). The monkey indicated which stimuli he recognized by licking on the familiar trials to obtain fruit juice. ITC neurons did not respond differentially to novel and fami-

liar visual stimuli if more than 1-2 stimuli intervened between the novel and familiar presentations of a given stimulus. Typi-cally the neurons which responded to the novel and not the familiar stimuli in the recognition task only did so if there were no intervening stimuli. A number of these neurons had cor-responding responses, on non-match trials, in the DNS task. Some responding respondes, on non-match triais, in the DNS task. Some other neurons responded to the familiar stimuli in the recogni-tion task (and had corresponding responses on match trials in the DMS task), but only responded in this way if the familiar pre-sentation of a given stimulus immediately followed its novel presentation. Thus it was found that the responses of ITC neurons which are relevant to the means means of these tracks (2) which are related to the memory aspects of these tasks (26 neu-rons in the present sample of 421 neurons) occur in relation to relatively short term memory aspects of these tasks, so that the longer term aspects of the memory required for this type of re-cognition appear to be processed in structures beyond the ITC

Cognition appear to be processed in structures beyond the fit (see Rolls et al, 1982). Of the total of 141 visually responsive neurons, including those with memory-related responses, 49 or 34.8% had activity which occurred selectively to some of the stimuli, often on the basis of color, shape or orientation but in some cases selectively to faces, and the remainder had responses which occurred to a broad range of the stimuli used in the tasks. Rolls ET, Perrett DI, Caan AW, Wilson FAW (1982) <u>Brain</u> 105: 611.

12.3 A FURTHER EXAMINATION OF THE MEDIAL TEMPORAL-LOBE STRUCTURES INVOLVED IN RECOGNITION MEMORY IN THE MONKEY, <u>E. A. Murray and</u> <u>M. Mishkin</u>. Lab. of Neuropsychology, NIMH, Bethesda, MD 20205. Monkeys with combined but not separate removal of the amygdaloid complex (A) and hippocampal formation (H) are severely impaired in visual recognition memory (Mishkin, <u>Nature</u>, <u>273</u>: 279, 1978). Since neither the A nor H lesion alone included substantial portions of the entorhinal cortex (Fnt), whereas the combined lesion included all of it, the results are also consistent with the possibility that either H+Ent or A+Ent lesions are sufficient to produce the severe memory deficit. To test these possibilities 9 cynomolgus monkeys were trained on visual delayed nonmatching-to-sample (DNMS) with trial-unique object. In this test, the mokey is trained to displace as the post of the severe is and the produce the severe is a since the post of the post of the severe is the post of the severe is the produce of the severe is the post of the post o

on visual delayed nommatching-to-sample (DNMS) with trial-unique objects. In this task, the monkey is trained to displace a baited sample overlying the central well of a three-well testing board and then, 10s later, to avoid this sa ple in favor of a completely novel object, both objects now overlying the lateral wells. On attaining the criterion of 90 correct responses in 100 trials, three animals each were given either H+Ent lesions or A+Ent lesions or kept as unoperated controls. After a two week rest period, the monkeys were retrained on DNMS to the same criterion as before or for a maximum of 2000 trials. They were then given a performance test in which: i) delays of 30s, 60s, and 120s were interposed between the sample presentation and test, in blocks of 100 trials each, and ii) lists of 3, 5, or 10 sample objects were presented successively prior to the choice tests, in blocks of 150 trials each.

The control monkeys showed perfect retention of the hasic task and averaged 93% correct responses on the performance test. Monkeys with H+Ent lesions were mildly impaired, requiring a mean of 317 trials to relearn the task and averaging 84% correct responses on the performance test. Monkeys with A+Ent lesions, by contrast, failed to reattain criterion; they achieved 81%, 82%, and 83% correct responses, respectively, in the last 100 trials of the 2000-trial training period. On the performance test, the animals averaged 60.5% correct responses, or about the same as that obtained by the A+H lesion group (rhesus) in the original study (Avg.=59.57). Since addition of the Ent lesion did not augment the recognition deficits produced by hippocampectomy alone, but

Since addition of the Ent lesion did not augment the recognition deficits produced by hippocampectomy alone, hut greatly exacerbated those of amygdalectomy alone, the Ent lesion appears to be equivalent to a hippocampectomy in this situation, presumably because it disconnects the hippocampus from the inferior temporal visual cortex. The results support the earlier conclusion that combined damage to the amygdaloid and hippocampal systems is necessary to produce a profound memory impairment in monkeys.

12.4 EFFECTS OF LIMBIC LESIONS ON PICTURE RECOGNITION VS. PICTURE DIS-CRIMINATION LEARNING IN MONKEYS. W. H. Overman, G. E. Ormsby\* and M. Mishkin. Psychology Dept., Univ. N. C. at Wilmington, Wilmington, N. C. 28406.

Following combined ablation of amygdala and hippocampus, monkeys show abnormally rapid forgetting on one-trial tests of both object recognition and object-reward association (Mishkin, Phil. Trans. R. Soc., London, E-298, 1982) although they show normal rates of learning two-choice object discriminations even when successive trials are separated by 24 hours (Malamut, et al., Neurosci. Abstr. 6:191, 1980). In the present study we sought to determine whether the same findings would be obtained in a semiautomatic version of the task utilizing photographs of objects instead of the objects themselves. Six rhesus monkeys with combined ablations of the amygdala and

Six rhesus monkeys with combined ablations of the amygdala and hippocampus (Group A+H) and unoperated controls (Group N) had been matched for performance on trial-unique delayed nommatchingto-sample (DNMS). Postoperatively, Group A+H required significantly more trials than Group N to relearn up to a 10 sec DNMS. At longer delays of 30, 90, and 180 seconds Group A+H performed at 76%, 62% and 64% correct while Group N performed significantly better at 89%, 88% and 80% correct. A second experiment in which delay intervals of various lengths were intermixed in daily test sessions revealed the same results as Experiment I. In Experiment III the animals were trained on three consecutive two-choice picture discriminations for 35 trials/day with 20 sec intertrial intervals. Group A+H learned all discriminations as rapidly as Group N, both learning to criterion in 3-4 sessions. In Experiment IV, both groups were trained on a concurrent visual discrimination in which a set of 20 pairs of slides were presented only once every 24 hours. The positive and negative slide in each pair, as well as the order of the pairs remained constant across sessions. Groups A+H learned in an average of 14 sessions (92 errors) which was not statistically different from Group N which learned in an average of 18 sessions (94 errors). The last two experiments demonstrate that the impairments previously seen in Group A+H were not due to either perceptual or general learning deficits. These results provide additional support for the view that the limbic system is necessary for one-trial visual recognition memory but not for visual discrimination habits acquired through repetition (Mishkin, et al., <u>Conf. Neurobiol. Learn</u>. <u>Memory</u>, McGaugh, et al., (Eds.), Guilford Press, N.Y., in press.)

 DISSOCIATIONS BETWEEN SKILL LEARNING AND VERBAL RECOGNITION IN AM-NESIA AND DEMENTIA. M. Martone\*, J.T. Becker, M. Payne\* and N. CA.

 CA.
 Butters. Psychology Service, Boston VA Medical Center, Boston, MA. 02130.

 Den
 Several previous studies (e.g., Cohen & Squire, <u>Science, 210</u>: e cir 

 07.
 1980) have shown that amensic patients with hippocampal ordition bippocampal ordinations.

207, 1980) have shown that annesic patients with hippocampal ordiencephalic lesions are impaired on tests of recognition memory (i. e.declarative knowledge) while retaining the capacity to acquire general skills (i.e. procedural knowledge). The purpose of the present study was to evaluate this separation of skill and recognition memory in a group of demented patients (Huntington's Disease patients) with known memory deficits due to basal ganglia lesions (Butters, et al., Adv Neurol., 23: 203, 1981). Ten patients with Huntington's Disease (HD), 8 amnesic patients with alcoholic Korsakoff's syndrome (AK) and 10 normal control sub-

Ten patients with Huntington's Disease (HD), 8 amnesic patients with alcoholic Korsakoff's syndrome (AK) and 10 normal control subjects (NC) were trained to read word triads which appeared as mirror images of themselves over 3 consecutive test days. Sixty triads, arranged in 3 blocks of 20 triads, were presented on each day. Half of the triads in each block occurred only once during the 3 test days (unique words) and half were repeated from block to block (repeated words). The time needed to read each triad was recorded. Pollowing the third day of testing, a recognition test consisting of 15 unique words, 15 repeated words and 30 distractor items was administered to each subject. Skill learning was assessed by analyzing the time needed to read the unique words. Verbal recognition was assessed in two ways: 1)by determining the difference in reading time between the unique and repeated words and 2)by performance on the recognition test.

Consistent with the previous results, both the NC and AK groups readily acquired the mirror reading skill, showing a steady decrease in the time needed to read the unique words both within and between test days. However, unlike the NC subjects, AK patients were impaired on recognition; that is, they did not read the repeated words significantly faster than the unique words nor were they able to identify the repeated words on the recognition test. In contrast to the AK patients, HD patients were impaired on the

In contrast to the AK patients, HD patients were impaired on the acquisition of the mirror reading skill: they did not show a steady decrease in reading time of the unique words over the 3 days and showed less improvement on the unique words from day 1 to day 3 than did the NC subjects. However their performance on both measures of recognition memory was equivalent to that of the NC subjects.

jects. This finding of a double dissociation between skill learning and recognition memory in HD and AK patients suggests that these two abilities are separable and may depend upon the integrity of the basal ganglia and limbic systems respectively. Supported by the VA Medical Research Service and NIAAA grant AA00187.

DEMONSTRATE PRESERVED LEARNING AND PETENTION OF SKILLS. <u>S. Zola-Morgan</u>, \* and <u>L.R. Squire</u>. V.A. Medical Center, San Diego, CA 92161 and Det. of Psychiatry, UCSD Sch. of Med., La Jolla, CA. The traditional view of the human amnesic syndrome has been that despite their impairments these patients can under some circumstances exhibit good learning and retention across long intervals. The best known examples of this observation come from the learning of perceptual-motor skills. During the last ten years, investigators have compiled a considerable group of tasks that are less clearly perceptual-motor, but that can clicit signs of retention in patients who by other indications are profoundly amnesic. A particularly good example is the demonstration that amenic patients improved their skill at learning to read mirrorreversed words over a three-day period and then retained the skill at a normal level three months later. These findings, among others, have suggested a distinction between skills, which are spared in huma amnesia, and information based on facts, or the outcomes of engaging in skills, which is impaired.

AMNESIC MONKEYS WITH CONJOINT HIPPOCAMPUS-AMYGDALA LESIONS

As part of efforts to develop an animal model of human amnesia, we have attempted to parallel the findings from human amnesia of preserved skill learning. Groups of monkeys with demonstrated amnesia were administered a series of tasks that appear to depend substantially on skill-learning.

We utilized two motor-skill tasks as well as two visual pattern discrimination tasks. The first motor-skill task required monkeys to learn to manipulate a fragile breadstick around a series of barriers without dropping or breaking it. The second required monkeys to learn to retrieve a candy lifesaver threaded onto a thin metal tube by moving the lifesaver around a right andle bend to the end of the tube. Monkeys with conjoint lusions of the hippocampus and the amygdala (HA=3) acquired each of the two motor skills over a period of several days at the same rate as normal control monkeys (N=3). Retention of the lifesaver motor-skill, after a one month interval, was the same for the HA and N groups. On acquisition and retention of the pattern disrimination task. HA monkeys were impaired only mildly if at all. Moreover, monkeys with lesions of the medial thalamus, an area that has been implicated in human ammesia also performed pattern discrimination tasks successfully. The relationship of pattern discrimination task is used to be a start of the discussed.

This demonstration of preserved learning and retention of skills in monkeys, who by other measures are amnesic, brings into correspondence the behavioral data from human amnesic patients and operated monkeys, and sets the stage for identifying precisely what brain structures must be damaged to produce ammesia.

- MEMORY FOR REMOTE PERSONAL AND PUBLIC EVENTS AFTER BILATERAL 12.7
  - MEMORY FOR REMOTE PERSONAL AND PUBLIC EVENTS AFTER BILATERAL MEDIAL TEMPORAL LOBECTOMY. Suzanne Corkin, Neal J. Cohen,\* and Harvey J. Sagar,\* Dept. Psychol., MIT, Cambridge, MA O2139. In characterizing differences between amnesias of different etiologies, one tack is to compare the duration of remote memory impairment. H.M., who underwent bilateral medial temporal lobectomy in 1953 for intractable seizures, is of particular interest because his retrograde amnesia appears to be temporally imited; it has been distinguished from the lock postricted amonts limited; it has been distinguished from the less restricted remote memory dysfunction documented in patients with Korsakoff's syndrome. Previous studies indicated that H.M.'s retrograde loss, though difficult to delineate precisely, was restricted to the 2 to 3 years immediately preceding the operation. New attempts to test the limits of his recall and recognition of both personal and Less the limits of first recall and recognition of both personal and public remote information suggest that the remote memory impairment, though still temporally limited, may be more extensive than had previously been reported. The results confirm a marked disorder from around the time of operation, and in addition reveal a milder deficit dating back to the time of onset of concepting of consults in 1002 of generalized convulsions in 1942. In tests of knowledge of public events, H.M.'s performance was

within the normal range for events from the 1940s and 1950s but inferior for the 1960s and 1970s. He was also normal in his ability to produce specific episodic memories, but the median age ability to produce specific episodic memories, but the median age of these episodes (44 years ago) was greater than that of any healthy age-matched control subject and derived exclusively from the period before his 17th year of life. When constrained to the period after his 16th year, he performed poorly and was inconsistent in dating his memories. In 1982, H.M. could still draw an accurate floor plan of the house in which he had lived for many years after his operation until 1974. He also recognized many years after his operation until 1974. He also recognized someone else's drawing of that floor plan when it was presented with foils. His recognition of photographs of relatives and family friends was generally good, except that he did not recognize a photograph of his grandfather as an old man, of himself and his mother on his 50th birthday in 1976, or of the woman who took care of him for several years in the late 1970s. H.M.'s memory for old tunes that had been hits during the period from 1920 to 1967 was poor. The few that he could name had been popular before 1955, except the "Children's Marching Song," which was a hit in 1959. Not only does H.M. have no recollection of his classmates when reunited with them at their 35th reunion. A number of them, however, recognized H.M. and recalled that he had had epilepsy. had epilepsy. Supported by grants MH 24433, RR 00088, MH 08280, and a grant from

IMPAIRMENT IN RECOGNITION MEMORY AFTER MAMMILLARY 12.9 BODY LESIONS IN MONKEYS. <u>R.C. Saunders</u> (SPON: C. Leonard),
 Dept. Exp. Psych., Univ. Of Oxford, Oxford, England.
 Despite a long history of clinico-neuropathological studies of patients

with Korsakoff's syndrome, the critical lesion responsible for the annesia has remained uncertain. Mammillary body (MB) pathology has been a consistent finding; however, it occurs usually in conjunction with pathology in the medial thalamus. The present study investigates whether lesions restricted to the MB produce a severe memory impairment in monkeys analogous to that described in amnesic patients. Amnesic patients are impaired in yes-no recognition and forced-choice

Amnesic patients are impaired in yes-no recognition and forced-choice recognition memory tasks. The present study tested cynomologus monkeys, in two analogous visual recognition memory tasks. First, they were trained pre-operatively on a running recognition memory paradigm, in which a series of complex pictures were presented in succession. The monkey had to make an instrumental response (yes) when a picture appeared for the second time or withhold the response (no) during its first presentation. The task was made more difficult by increasing the number of intervening stimuli between the first and second presentation of a or intervening stinut between the first and second presentation of a picture. Pre-operatively monkeys reached a high level of performance at the most difficult stage, with up to 14 intervening stimuli. They were then given a bilateral MB lesion; bilateral fornix (Fx) transection or a combined bilateral MB lesion; plus Fx transection or remained as unoperated control subjects (NC). The MB lesions and/or Fx transections and a subtratial effect on the monlewel performance in this task. had a substantial effect on the monkeys' performance in this task. They took significantly longer to relearn the task and in the final stage their performance was significantly worse than control animals. There were no differences in performance between lesions groups. Average performance scores for each group were: NC=91%; MB=76%; Fx=75%; MB+Fx=77%.

The same monkeys were then trained on a delayed non-matching to sample task similar to forced-choice recognition memory tests used with patients. All monkeys obtained a 90% criterion level of performance with a 15 sec delay between sample presentation and the retention test. The list of objects was then increased in two stages, to a list of 3 and next to 10. In stage 1, with a list of 3 objects, the retention tests of an object were presented in the reverse order to their initial presentation. Therefore, the retention interval varied systematically from 0 to 2 to 4 intervening items. In stage 2, with the list of 10 objects, the retention intervening items. In stage 2, with the list of 10 objects, the retention interval remained a constant 9 items. The performance of monkeys with MB lesions or Fx transections or both was again significantly worse than The lesions of the longer retention intervals. Performance in stage 2 of monkeys with:  $\overline{\text{MB}}$  lesions alone was 69% correct;  $\overline{\text{Fx}}$  transection 83%;  $\overline{\text{MB}}$  lesion+ $\overline{\text{Fx}}$  transection 75% and  $\overline{\text{NC}}$  86%.

The results indicate that lesions restricted to the MB can produce a severe recognition memory impairment in monkeys and suggests further that MB pathology in man may be sufficient to produce the severe amnesia seen in Korsakoff patients.

- 0F SEMANTIC AND LEXICAL KNOWLEDGE ACQUISITION IN AMNESIA. 12.8
  - Actions from of SEMANTIC AND LEXICAL KNOWLEDGE IN AMMESIA. John D. E. Gabrieli,\* Neal J. Cohen,\* and Suzanne Corkin (SPON: Michael Kuperstein). Dept. Psychol., M.I.T., Cambridge, MA 02139 The noted patient H.M. has exhibited global ammesia since undergoing bilateral resection of medial temporal-lobe structures in 1953. The present series of experiments demonstrates the role in 1953. The present series of experiments demonstrates the role of these structures in the acquisition of new semantic and lexical knowledge. Several tests assessed H.M.'s knowledge of 184 words added to the Merriam-Webster Dictionary in dictionary supplements published every five years since 1954. First, H.M. was asked to judge whether a string of letters constituted legitimate English words. Then, he was asked to recall or recognize from among four choices the definitions of the new words. H.M.'s recall (74 pts.; max=368) and recognition (51%) for the meanings of new words were far below normal, but still above chance. He performed especially poorly on words added to the dictionary since 1966. H.M. correctly judged 67% of the new words to be legitimate English words, which was inferior to his near-perfect judgement of old words. but in marked contrast to his low (10%) rate of false poorly ... correctly judgeo words, which was words, but in ma words, which was inferior to his near-perfect judgement of our words, but in marked contrast to his low (10%) rate of false judgements of nonwords as words. Lexical decision performance was at chance for items missed on the recognition test, suggesting that he does not have an autonomous lexical representation of new words whose meaning he does not know, despite his continued

words whose meaning he does not know, despite his continued exposure to these words over many years. We also demonstrated H.M.'s inability to learn new vocabulary words in a controlled laboratory setting. Subjects were presented with uncommon words whose definitions they could not produce. Each word was presented with a one-line definition for study, followed immediately by a test in which each word was to be matched with the appropriate definition. The test was administered repeatedly until subjects reached a criterion of correct matches for all words within a trial. Each word was then presented with a common synonym for study, followed immediately by a matching test; this procedure was repeated until subjects reached criterion. A final test required each word to be matched with incomplete sentence frames, until criterion was met. Twelve college students tested with 20 to-be-learned words required only college students tested with 20 to-be-learned words required only College students tested with 20 to-be-learned words required only 2.0, 1.1, and 1.2 trials to reach criterion on the definition, symonym, and sentence-completion tests, respectively. H.M. was tested with only 8 to-be-learned words. Still, he never reached criterion on any test despite 15 trials for each test on each of 4 consecutive days. The number of words matched correctly on 60 trials per test revealed no savings across tests; H.M. averaged 3.8/8, 3.8/8, and 4.4/8 words correct on the definition, synonym, and contact correctively. and sentence-completion tests, respectively. RECOGNITION MEMORY DEFICIT IN MONKEYS EXACERBATED BY ADDITION OF A MEDIAL THALAMIC LESION TO A PRE-EXISTING HIPPOCAMPAL LESION.

MEDIAL THALAMIC LESION TO A PRE-EXISTING HIPPOCAMPAL LESION. <u>H. Mahut, L. Rehbein<sup>\*</sup> and M.Moss</u>. Dept. of Psychol., Northeastern Univer., and Boston Univer. Sch. of Med., Boston, MA. Clinical evidence associates amnesia with damage to either lim-bic or diencephalic structures. In monkeys, hippocampal ablations impair memory assessed with a trial-unique delayed non-matching to sample (DNMS) recognition task (Mahut <u>et al., J. Neurosci., 2</u>: 1314, 1322). Mourosci. 2014. 1214, 1982). However, combined anygdalo-hippocampal ablations re-sult in a more severe deficit (Mishkin, <u>Nature</u>, <u>273</u>:297, 1978; Mahut <u>et al.</u>, <u>op. cit</u>.). One way to account for the synergistic effect of the combined lesion is to consider that 1. Amygdala project to medial dorsal and midline thalamic nuclei in the monkey (Porrino et al., <u>J. comp. Neurol.</u>, <u>198:121</u>, 1981) and 2. Damage to medial thalamus is implicated in clinical cases of amnesia (Teuber et al., <u>Neuropsychologia</u>, <u>6:267</u>, 1968; McEntee et al., <u>J. Neurol.</u> <u>Neurosurg. Psychiat</u>, <u>39:436</u>, 1976). The present experiment was designed to see whether the addition of a thalamic lesion to a pre-existing hippocampal lesion would result in as severe a memory loss as that which follows an amygdalo-hippocampal lesion.

Four rhesus macaques that had served as a normal control group from 3 mos to 6 yrs of age were trained on the DNMS recognition task 1 yr before surgery and re-tested pre-operatively. Three re-ceived bilateral hippocampectomies and H1 and H2, but not H3, had also moderate bilateral damage of inferotemporal cortex. Their post-operative performance declined from 90% to 62%-80% correct responses with 130 sec delays and to 61%-78% with 10-item lists, with H3 the least impaired of the three monkeys. The fourth monkey (MD) received a thalamic lesion which included near-total damage of mid and posterior parts of nMD, bilateral interruption of the fornix with degeneration of MMB, and unilateral damage of cin-gulate bundle, stria medullaris, midline and anterior nuclei: This monkey made 69% correct responses with 130 sec delays and 61% with 10-item lists. A similar decline in post-operative performance after an equivalent lesion was reported by Aggleton and Mishkin (Neurosci. Abstr., 8, 1982). Hippocampectomized monkeys then re-ceived a thalamic lesion and were re-tested with the same task. In all three, nMD was partially spared in its anterior and mid por-tions, with radical removals of the posterior extent. In all other respects, the lesion resembled that sustained by monkey MD. This time, performance declined to chance: 54%-58% correct responses with 130 sec delays and 47%-56% with 10-item lists.

These preliminary results suggest that the severe memory loss after anygdalo-hippocampal lesions may be attributed to the com-bined effects of direct damage to the hippocampus and a functional disruption, as a result of amygdalar damage, of a parallel memory system located in the medial dorsal thalamus.

12.11 THALAMIC AMNESIA: MATERIAL SPECIFIC DEFECTS ASSOCIATED WITH DORSOMEDIAL NUCLEUS INFARCTION. <u>F. Morrell</u>, <u>L. de Toledo-Morrell</u>, <u>\* L.R. Squire</u>, <u>L. Bieliauskas</u>, <u>\* E. Russell</u>\* <u>and J. Messer</u>, <u>\* Departments of Neurological Sciences</u>, Psychology, Radiology and Cardiology, Rush Medical College, Chicago, II. 60612 and Department of Psychiatry, UCSD, La Jolla, Ca. 92093

Although there are now several definitive reports of amnesia due to dorsomedial thalamic nucleus lesions, all previously reported cases have been studied long after establishment of the lesion. The present case allowed examination of the evolution of the amnesic syndrome correlated with serial CT scan changes.

The patient is a 53 yr old right handed woman who was studied intensively beginning 3 days after acute onset of a devastating amnesic syndrome. Initial CT scans revealed an area of infarction in the left dorsomedial nucleus of the thalamus. Prominent surrounding edema resulted in elevation of the frontal horn of the lateral ventricle and compression of the <u>right</u> dorsomedial nucleus. At that time, neurological and neuropsychological examination revealed frontal "release" signs, poor performance on the Wisconsin Card Sorting Test, decrease in word fluency, anomic aphasia and a severe amnesia for verbal, non-verbal and spatial material.

Six days after the infarct, all deficits for non-verbal and spatial material had cleared, frontal "release" signs had disappeared and card sorting performance was normal. A second CT scan 7 days after the infarct revealed complete resolution of the surrounding edema and persistence of a discrete lucency entirely replacing the left dorsomedial nucleus. The severe verbal memory deficit has remained. Remote memory tests also revealed generally poor performance.

The persistent deficits in this case are similar to those described in N.A. (Squire and Moore, <u>Ann. Neurol.</u>, <u>6</u>: 503, 1979). Our findings indicate that more widespread disturbance occurs if both thalamic nuclei are disabled as was the case during the early edematous phase. Our observations predict that a right sided thalamic lesion would show visual-spatial rather than verbal deficits (as recently shown by Speedie & Heilman, <u>Arch. Neurol.</u>, <u>40</u>: 183, 1983) and emphasizes the material specific nature of memory deficits in general.

12.13 OBJECT RECOGNITION IMPAIRED BY VENTROMEDIAL BUT NOT DORSOLATERAL PREFRONTAL CORTICAL LESIONS IN MONKEYS. <u>Mortimer Mishkin and</u> <u>Jocelyne Bachevalier</u>\*. Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Within the prefrontal region of the monkey, least is known functionally about the ventromedial cortex, an area to which the magnocellular division of nucleus medialis dorsalis (MDmc) and the anterior thalamic nuclei (AntN) project. Since MDmc and AntN are major thalamic targets of the amygdala and hippocampus, and since these limborthalamic pathways appear to be involved in memory functions (Mishkin, Phil. Trans. R. Soc. Lond., B298:1982), we tested whether the prefrontal targets of these two limborthalamic pathways might also he involved in memory. Nine cynomolgus monkeys were trained preoperatively in a

Nine cynomolgus monkeys were trained preoperatively in a trial-unique recognition task in which they were required to distinguish a completely novel object from a sample object presented 10 sec previously (delayed nonmatching-to-sample). After reaching a criterion of 90 correct responses in 100 trials, three monkeys each underwent bilateral lesions of either dorsolateral prefrontal cortex (DL), ventromedial prefrontal cortex (VM), or neither. DL lesions extended from the frontal pole to the depth of the arcuate sulcus, and from the ventral lip of the principal sulcus to the midline. VM lesions included middle and medial orbital cortex (targets of MDmc) as well as subcallosal and anterior cingulate cortex (targets of AntN). Postoperatively, all animals were retrained on the hasic recognition task to a 90% criterion. Animals that did not reatain the criterion in 1500 trials were given 500 additional trials with a correction procedure.

Monkeys with DL lesions were slightly impaired, reattaining the 90% criterion in an average of 230 trials as compared with 0 trials for the unoperated controls. In sharp contrast, the monkeys with VM lesions were severely impaired, failing to relearn the recognition task within the limits of testing and achieving an average of only 75 correct responses in the last 100 trials prior to correction training. With correction training, their performance improved to an average of 85% correct in the final 100 trials.

Comparison of these results in recognition memory with those obtained earlier on spatial delayed response (Prihram et al, J. <u>Comp. Physiol. Psychol.</u>, <u>45</u>:1952) suggests that: (i) presumably because of its connections with the limbo-thalamic pathways, ventromedial prefrontal cortex may be more important than dorsolateral prefrontal cortex in general memory processes and (ii) the classical delayed-response deficit after dorsolateral prefrontal lesions may represent a perceptual-mnemonic impairment in spatial functions rather than a strictly mnemonic one. 12.12 ACUTE LOSS OF AUTOBIOGRAPHICAL MEMORIES IN AN AMMESIC PATIENT WITH ALCOHOLIC KORSAKOFF'S SYNDROME. <u>N.Butters and L.S. Cermak.</u>\* Psychology Service, Boston VA Medical Center, Boston, MA 02130.

Recent studies have suggested that the retrograde of amnesia (RA) of alcoholic Korsakoff patients is related to two possible factors: (1)The alcoholics' failure to learn new information during their years of intoxification, and (2)An acute loss of (or access to) remote memories with the onset of Korsakoff's syndrome. To demonstrate that acute, extended losses of remote memories do occur in some amnesias, a single-case study of a scientist (Patient P.Z.) who developed alcoholic Korsakoff's syndrome three years following the publication of his autobiography was conducted. Since P.Z. must have had intimate knowledge of the information in his autobiography prior to his illness, any failure to recall this material could not be attributed to a deficit in original learning. In addition, P.Z. was administered tests of famous faces, public events and famous scientists from all decades between 1930 and 1980.

between 1930 and 1980. The results showed that P.Z., like other alcoholic Korsakoff patients, was severely impaired in his recall of public events and famous faces, with some sparing of very remote memories. On the test of autobiographical information, P.Z. could only recall facts from the first 25 years of his life. A similar temporallygraded RA was found in his recall of famous scientists, most of whom P.Z. had known on a professional and/or personal basis. These results suggest that P.Z.'s, and perhaps all Korsakoff patients', RA is due primarily to an acute and extended loss of old memories with the onset of Wernicke's encephalopathy. The fact that P.Z.'s loss of remote memories is temporally grade may indicate that information acquired during the past 20 years was less stable than facts learned 40 years previously. This weakness, and thus greater vulnerability, of recent memories my reflect the neurotoxic effects of long-term alcoholism. Supported by the VA Medical Research Service and NIAAA grant AA-00187.

12.14 AMNESIA FOLLOWING VENTROMEDIAL FRONTAL LOBE LESIONS. A.R. <u>Damasio</u>,\* <u>N.R.</u> <u>Graff-Radford</u>,\* <u>P.J.</u> <u>Eslinger</u> and <u>N.</u> <u>Surgery</u> (Div. Neurology (Div. Behavioral Neurology) and Medicine, Iowa City, IA 52242.

Although patients with rupture of anterior communicating artery (ACOA) aneurysms have been known to develop behavioral disturbances, the precise nature and anatomical underpinnings of the syndrome have not been elucidated. Here we describe a series of 5 patients with damage to the ventromedial frontal lobe as a result of ACOA aneurysm rupture. On the basis of CT scan analysis and of intraoperative reports and photographs, we localized damage to the orbitofrontal and basal forebrain regions, i.e. the gyrus rectus, the septal nuclei, the nucleus accumbens, the substantia innominata and related pathways, i.e. the precommissural fornix.

The initial stages of the disturbance were hallmarked by bizarre fabrications and an inability to distinguish between real and confabulated events (e.g. one patient thought he was a space commander at the time of the Columbia space shuttle; another described how she shopped in the Falklands Islands at the time of the war). As the early phase resolved, a more circumscribed memory disorder emerged. Impairment was especially prominent for anterograde and retrograde contextual memory. The beneficial effect of cuing suggested that retrieval rather than encoding was the major defect. The amnesia was accompanied by personality changes in the form of social disinhibition and mild elevation of mood. The syndrome was markedly worse in the bilateral cases but in both unilateral and bilateral varieties, the characteristics and magnitude of the syndrome make it distinguishable from that seen in patients HM, NA, DRB (herpes encephalitis) as well as in the alcoholic patients.

We hypothesize that damage to basal forebrain (a) disrupts function in the hippocampus, a structure with which it is reciprocally connected, and (b) blocks cholinergic innervation of widespread cortical regions. (Supported by a University of Iowa Faculty Scholar Award to ARD and Grant NS 06720-02 to PJE).

12.15 EFFECTS OF FOCAL BRAIN LESIONS ON SENSITIVITY TO FREQUENCY OF OCCURRENCE. M.L. Smith\* and B. Milner. Dept. of Psychology and the Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4. Automatic, as opposed to effortful, memory processes are

Automatic, as opposed to effortful, memory processes are those that draw minimal attentional capacity, occur without intention to remember and do not interfere with other ongoing activity (Hasher & Zacks, 1979). Studies with normal subjects have identified three types of information that are automatically encoded: spatial location, temporal order and frequency of occurrence. Smith and Milner (1981) have demonstrated an impairment in recall of spatial location after right temporal location that intert with Impairment in recall of spatial location after right temporal lobectomy that invaded the hippocampal region. Patients with right frontal lesions performed normally on this task but have marked deficits in the temporal ordering of recent events (Milner, 1982). The finding of different critical areas within the right hemisphere for the recall of these two types of utermined a information and use the offect

the right hemisphere for the recall of these two types of automatically encoded information led us to explore the effect of such lesions on the recall of frequency of occurrence. The study included patients with excisions of the left temporal (LT), right temporal (RT) or right frontal lobe (RF), and normal control subjects (NC). Lists of words or abstract designs, with the stimuli occurring 1,3,5,7 or 9 times, were presented. Each list was followed immediately by a frequency-estimation test comprising one example of each stimulus from the original list interspersed with four new stimuli. The public time, were such it is the number of times each item

estimation test comprising one example of each stimulus from the original list interspersed with four new stimuli. The subject was required to estimate the number of times each item had appeared in the first list. There were no differences between the groups on the verbal task. With the designs, all patient groups were impaired at frequency 9; however, the impairment appeared first and was most pronounced in the RF patients, who not only underestimated the number of times they had seen the designs, but also did not distinguish between the frequencies 5, 7 and 9. Although few RT patients had extensive hippocampal lesions, it was evident that such patients did not differ from those with little or no hippocampal removal. Thus, the right frontal lobe appears to be involved in the automatic encoding of frequency of occurrence be involved in the automatic encoding of frequency of occurrence as well as in recency discrimination. The negative findings for the right hippocampal region on these two tasks contrast with the demonstrated role of this region in the automatic processing of spatial location.

## CATECHOLAMINES: DOPAMINE RECEPTORS I

PARTIAL PURIFICATION OF D2 DOPAMINE RECEPTORS BY AFFINITY CHROMA-13.1 TOGRAPHY. <u>B. Chan\* and B.K. Madras.</u> (SPON: R.H. Ackerman), Psycho-pharmacology Section, Clarke Institute of Psychiatry, 250 College Street, Toronto, Ontario, canada M5T 1R8, and Department of

Street, Toronto, Ontario, canada M5T 1R8, and Department of Pharmacology, University of Toronto. Partial purification of the D<sub>2</sub> dopamine receptor has been achieved with isoelectric focussing (Davis et al, Lilly et al, Madras et al, Soc. Neurosci. Abstr. 7, 10, 1981). To further advance dopamine receptor purification, affinity chromatography of the receptor was performed using a derivative of haloperidol, dehydroxyamino-haloperidol (P. Seeman, H. Pieper, Washidth) History and the receptor was performed using a derivative H. Machleidt) linked to a Sepharose gel. The compound has a lower affinity for the receptor than haloperidol.

Canine striatum membranes were solubilized with digitonin and incubated with either butyrophenone-linked or unlinked gel. With prolonged exposure to either gel preparation, (16h at  $4^{\circ}$ C) the soluble material was depleted (95%) of receptor sites. After washing with buffer to remove non-specifically adsorbed proteins, the receptor was desorbed with a NaCl-spiperone solution. the receptor was desorbed with a NaCl-spiperone solution. The supernatant of the centrifuged gel was dialyzed overnight and assayed for receptor binding. Specific binding to the receptor was detected using <sup>3</sup>H-spiperone, 4 nM, and (+)-butaclamol, 1  $\mu$ M. Under optimal conditions 50-60% of the receptor and 10% or less of the protein was recovered from the gel. Unlinked gel, treated in an identical manner, yielded about 10% of the receptor after desorption. Preliminary data indicate that higher purification can be attained if the particulum purificial research of the receptor for the second to the receptor of the second to the second seco can be attained if the partially purified receptor is recycled through the gel. Affinity chromatography may prove to be a use-

ful method for dopamine receptor purification. Supported by grants from the Ontario Mental Health Foundation and the Bickell foundation.

13.2 D2 DOPAMINE RECEPTOR PURIFICATION USING <sup>3</sup>H-NCA: IDENTIFICATION OF A 40,000 DALTON BINDING PROTEIN. L.B. Lilly\*& P. Seeman (Spon: Y. Israel). Dept. Pharmacol., Univ. of Toronto, Toronto. Since <sup>3</sup>H-NCA (N-chlorethylnorapomorphine; Dr. C. Filer, NEN,

Boston) binds to more than one site, we have here used the iso-electric point of the  $D_2$  receptor (5.06; Lilly et al., Soc. Neurosci. Abstr. 7: 10, 1981) to isolate a single protein which Neurosci. Abs binds <sup>3</sup>H-NCA.

binds  $^{3H-NCA.}$ Canine striatal membranes prepared in  $Mg^{2+}$ -containing Tris-ion buffers were labelled with 50 nM  $^{3H-NCA}$  for 30 min at 30°C. The membranes were washed 3-5x until all free ligand had been removed, and solubilized with 1% digitonin; about 15% of the counts appeared in the soluble fraction. This material was introduced into a vertical isoelectric focusing column containing a pH 3-10 ordigate. Two biding needs result for a focusing a pH 3-10 gradient. Two binding peaks resulted from focusing, at pH 5 and pH 7.5. To determine if a single protein has been focused at pH(SDS-PACE) was performed. Crude soluble fraction and the pH 5 fraction were each incubated in 50 mM Tris, 2% SDS and 5% merfraction were each incubated in 50 mM Tris, 2% SDS and 5% mer-captoethanol prior to their application to a 10\% gel. The gel was subsequently sliced and counted. In the soluble fraction and under denaturing conditions, 3H-NCA labelled several proteins, including a prominent peak with a molecular weight of 40,000 daltons (see Fig.). In contrast, the column fraction appears to contain only a single 40,000 dalton peak. This peak may be the D<sub>2</sub> receptor; however, recent experiments using radiation inacti-vation have shown the intact receptor to have a molecular size of 123,000 daltons (Lilly et al., Mol. Pharm., in press, 1983); thus, the 40,000 dalton protein may be only a ligand-binding submit of the receptor.

DOPAMINE RECEPTOR TURNOVER RATES IN RAT STRIATUM ARE AGE-134 DEPENDENT. <u>S.E. Leff</u>, R. <u>Gariano's and Ian Creese</u>. Dep of Neurosciences, University of California, <u>San</u> Diego, of Medicine, La Jolla, CA 92093. Department School

Aging in rodents and primates is accompanied by non-uniform cerations in CNS structure and biochemical function which alterations affect behavioral and neurochemical responses to pharmacological treatment. We now report that after irreversible blockade with a dopamine receptor alkylating agent, N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ), CNS D-2 dopamine receptor turnover/recovery rates show an age-dependent decline. Male Sprague-Dawley rats (22-30 days or 9-12 months old) were injected with 8 mg/kg i.p. EEDQ eliciting 80-90% inhibition of D-2 receptor specific ["H]spiperone binding in membrane homogenates of striatum 4-6 hours postinjection. The recovery of ["H]spiperone binding activity after EEDQ blockade was dramatically faster for young rats (30 days old; t<sub>1</sub>, "2.5 days) compared to mid-life/mature rats (9-12 month old; t<sub>1</sub>, 2-4.5 days). Receptor levels were determined by saturation and Alxylation and during recovery were the results of alterations in Bmax values. Prolonged intracerebral treatment (11 hours) with the affect behavioral and neurochemical responses to pharmacologi-Prolonged intracerebral treatment (11 hours) with the values. values. Profonged intracerebrat creatment (11 nours) with the protein synthesis inhibitor, cycloheximide, indicates that receptor recovery rates are dependent upon protein synthesis. Radioreceptor assays of EEDQ activity from sera of injected rats indicate that EEDQ is rapidly catabolized in vivo. There-fore different rates of EEDQ metabolism could not account for fore different rates of EEDQ metabolism could not account for the age-differences in receptor recovery rates. The slower recovery rate we have observed in older rats may be consistent with a reported aging-related deficit in dopamine receptor up-regulation after chronic dopamine antagonist treatment in mice (Severson et al., Soc. Neurosci. Abstr. 5:11, 1979). These findings are consistent with clinical observations that older patients generally require lower doses of antipsychotic drugs for therapeutic effect and present a higher risk for the development of parkinsonian-like extrapyramidal side-effects to antipsychotic drugs. In preliminary, related experiments we find that chronic reserpine which leads to a dopamine receptor up-regulation markedly accelerates receptor recovery. In sum-mary we suggest that theories of CNS neurotransmitter receptor changes produced by pharmacological treatments, or in aging or diseased brains should now take receptor turnover rates into consideration and not rely solely on absolute level determina-tion for functional correlations. Supported by PHS MH32990 (I.C.), and NIMH Predoctoral Fellowship MH08918 (S.L.).

SODIUM IONS CONVERT BRAIN D<sub>2</sub> DOPAMINE RECEPTORS FROM HIGH TO LOW AFFINITY FOR DOPAMINE ACONISTS. <u>D. Grigoriadis\* & P. Seeman</u> (Spon: N. Wiener). Pharmacol. Dept., Univ. of Toronto, Toronto. Although it is known that guanine nucleotides lower the affin-

ity of brain dopamine receptors for dopamine, it has not yet been possible to obtain a single homogeneous population of low-affinity

The of blain dopamine receptors for dopamine, it has not yet been possible to obtain a single homogeneous population of low-affinity dopamine receptors. Huff & Molinoff, as well as Wreggett et al., for example, found that even in the presence of 300 µM GTP there still remained about 23% of the <sup>3</sup>H-spiperone binding sites which had high affinity for dopamine. We now report that 300 µM Gpp(NH)p in the presence of Na<sup>+</sup> converts the high-affinity receptors (D<sup>1</sup><sub>2</sub><sup>14</sup>) into a single population of sites with low affinity for dopamine agonists when done in the presence of ketanserin to pre-clude <sup>3</sup>H-spiperone from binding to scrotnergic sites. Rat brain striata were homogenized in sodium-free buffer (50 mM Tris-HCl, 5 mM KCl, 1.5 mM CaCl<sub>2</sub>, 4 mM MgCl<sub>2</sub>, 1 mM EDTA, 0.1% ascorbic acid, 12 µM nialamide). The tissue was pre-incubated for 10 min at 37°C, chilled, and added to incubation tubes con-taining 80 pM <sup>3</sup>H-spiperone and 50 nM ketanserin (final conc.); the contents were filtered after 45 min at 37°C. Specific binding was that inhibited by 1 µM (+)-butaclamol. The Fig. illustrates that in the absence of Na<sup>+</sup> the population of dopamine receptors con-sisted of 54% in the high-affinity state (Kp=20 nM) and 46% in the low affinity form (Kp=2 µM) for the aminotetralin ADTN. Howthe low affinity form ( $K_D^{=2}$  µM) for the aminotetralin ADTN. However, in the presence of 120 mM NaCl 75% of the receptors were  $D_L^{Low}$ . With high sodium (240 mM) 88% of the receptors were  $D_L^{Low}$ ,

ELEVATION OF  $D_2$  DOPAMINE RECEPTORS IN SCHIZOPHRENIA BRAIN. 135 P. Seeman, C. Ulpian<sup>\*</sup> and W.W. Tourtellotte<sup>\*</sup>. Pharmacology Dept., Univ. of Toronto, Canada; Wadsworth Hospital, Los Angeles.

Although it had been originally shown that the binding of Although it had been originally snown that the origing of  ${}^{3}$ H-neuroleptics to dopamine receptors in schizophrenic brain was elevated by 30% to 100% (Refs. 1-3), we have recently found that both the K<sub>D</sub> and the density (B<sub>max</sub>) of binding sites for  ${}^{3}$ H-spiperone depend on the final concentration of tissue protein (Ref. 4). Thus, we re-studied the  $K_D$  and density of D<sub>2</sub> receptors in schizo-phrenic putamen (P), caudate nucleus (C) and nucleus accumbens (A), using a final tissue concentration of less than 1 mg of (a), using a final final control of respective final final final final final final final final set of the final set of the final set of the density of D<sub>2</sub> dopamine receptors was approximately double the control value The Fig. shows data for tissues from Toronto (squares) and Los Angeles (circles). It is now essential to examine a larger Angeles (cricles). It is now essential to commune a larger series of post-mortem tissues, particularly from patients who had been actively schizophrenic but who had not been medicated with

13.7 THE BRAIN D2 DOPAMINE RECEPTOR DIFFERS FROM THE PITUITARY D2 RECEPTOR, AS DETECTED BY (-)3PPP.

Susan R. George, Masayuki Watanabe\* & Philip Seeman. Dept. of Pharmacology, Univ. of Toronto, Toronto, Canada, M5S 1A8. Although D2 dopamine receptors in brain and pituitary have hitherto been considered identical, we now report that it is possible to differentiate them by means of (-)N,n-propyl,3-(3-hydroxy -phenyl)-piperidine or (-)3PPP.

-phenyl)-piperidine or (-) 3PPP. In the complete absence of Na<sup>+</sup>, (-) 3PPP inhibited the binding of 200 pM 3H-spiperone to porcine anterior pituitary in two phases, 30% with high affinity  $(D_{\rm High}^{\rm High})$ , and 70% with low affinity  $(D_{\rm 2}^{\rm OW})$ as is typical of dopamine agonists. In the presence of 100 mM Na<sup>+</sup>, (-) 3PPP detected only a single population of  $D_{\rm 2}^{\rm LoW}$  sites, indicat-ing conversion of  $D_{\rm 1}^{\rm High}$  to  $D_{\rm 2}^{\rm LoW}$  Na<sup>+</sup>; guanne nucleotides (GN) also did the same. In calf caudate, using excess ketanserin to occlude  $^{3H}$ -spiperone binding to serotonergic receptors, (-) 3PPP detected only a single population of  $D_{\rm 2}$  sites, whether in the absocclude <sup>An</sup>-spiperone binding to serotonergic receptors, (-)3PP detected only a single population of  $D_2$  sites, whether in the abs-ence or presence of Na<sup>+</sup>. The affinity of (-)3PP for the  $D_2$  sites was increased by Na<sup>+</sup>, but unaffected by GN, both effects, we found, being typical of antagonists. Data for (+)3PP in brain and pituitary were similar to that described for (-)3PPP in pituitary. Thus, as shown in the fig., the addition of Na<sup>+</sup> to pituitary results in the conversion of  $D_2^{High}$  sites detected by (-)3PPP into  $D_2^{LOW}$  sites, and an enhancement of the affinity of (-)3PPP for  $D_2$ sites, in brain, suggesting that hoth enantiomers of 3PPP are agon- $D_2^{(3)}$  sites, and an enhancement of the affinity of (-)site  $z_2$ sites in brain, suggesting that both enantiomers of 3PPP are agon-ists in pituitary, while in caudate, (+)3PPP is an agonist and (-)3PPP an antagonist. The opposite effects of Na<sup>+</sup> and GN on (-)3PPP provide the first evidence that the molecular properties of brain and pituitary receptors may differ.

NEUROLEPTICS EXHIBIT NONCOMPETITIVE EFFECTS AT DOPAMINE 13.8

NEUROLEPTICS EXHIBIT NONCOMPETITIVE EFFECTS AT DOPAMINE RECEPTORS. Jonathan E. Freedman<sup>1</sup>, Robert J. Gould<sup>2</sup> and Solomon H. Snyder<sup>2</sup>. <sup>1</sup>Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06508, and <sup>2</sup>Depts. of Neuroscience, Pharmacology and Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. We have studied the kinetics of radioligand binding to various classes of dopamine receptor binding sites in rat corpus striatum membrane homogenates. D<sub>1</sub> receptor sites were labeled with the novel ligand <sup>3</sup>H-fluphenazine, which binds about 80<sup>7</sup> \* to D<sub>1</sub> sites and 20<sup>7</sup> \* to D<sub>2</sub> sites, with a pharmacologic profile resembling that of <sup>3</sup>H-cis-flupenthixol, but with an improved signal-to-noise ratio (2000 cpm specific binding, specific binding 80<sup>7</sup> \* of total binding). <sup>3</sup>H-Spiperone was used for D<sub>2</sub> receptor sites, while D<sub>3</sub> and D<sub>4</sub> high affinity agonist sites were labeled with <sup>3</sup>H-apomorphine. The rate of dissociation of <sup>3</sup>H-ligands was accelerated in the presence of certain nonradioactive drugs, suggesting more

The rate of dissociation of  $^{3}$ H-ligands was accelerated in the presence of certain nonradioactive drugs, suggesting more than one class of binding sites. The dissociation of  $^{3}$ H-apomorphine was markedly enhanced by butyrophenones, while  $^{3}$ H-spiperone dissociated faster in the presence of dopamine. This indicates the existence of two distinct sites on dopamine receptors: a butyrophenone site and a dopamine recognition site which interact allosterically. Phenothiazines also accelerate  $^{3}$ H-fluphenzation discociation. But wrophences accelerate

Minimum and the determinant of the second s

NEUROLEPTIC RECEPTOR LABELING IN VIVO WITH [<sup>11</sup>C]SPIROPERIDOL. C. D. Arnett<sup>\*</sup>, J. S. Fowler<sup>\*</sup>, A. P. Wolf<sup>\*</sup>, J. Logan<sup>\*</sup> and R. R. MacCregor<sup>\*</sup> (SPON: L. Giron). Department of Chemistry, 13.9

Brookhaven National Laboratory, Upton, NY 11973. A model was developed and evaluated for the external detection of specific neuroleptic receptors in living brain using positron emission transaxial tomography (PETT) and the neuroleptic spiroperidol radiolabeled with the positron-emitting nuclide carbon-11. Pretreatment with nonradioactive butaclamol was used to differentiate the specifically bound pool of radioactivity from nonspecifically bound and free pools. The time course of each of these three pools over 60 min was determined in rats by an  $\underline{ex}$  vivo experiment requiring killing of the animals at various times after injection and homogenization and rapid filtration of brain regions to separate bound pools from the free pool (Arnett, C. D., et al., <u>J. Neurochem</u>. <u>40</u>: 455-459, 1983). The proper choice of dose and timing for in vivo PETT studies was made on the basis of the results of this study.

Taking advantage of the short half-life of carbon-ll (20 min), this model was applied to PETT studies in baboons by using a double injection paradigm of [ $^{11}C$ ]spiroperidol with an intervening injection of a high dose of a nonradioactive neuroleptic to block specific receptors. Pretreatment with the pharmacologically inactive (-)-butaclamol served as an injection control and allowed the normal distribution of  $[^{11}C]$ spiroperidol among the three brain pools. A high dose of (+)-butaclamol given after the decay of most of the radioactivity from the first [<sup>11</sup>C]spiroperidol injection effectively blocked the specific  $[^{-v}]$ spiroperiod injection effectively blocked the specific receptors and allowed the subsequently administered second dose of  $[^{11}C]$ spiroperidol to distribute only to the nonspecifically bound and free pools. PETT scans taken after the second dose were subtracted from those taken after the first dose (normalizing for dose differences) to produce an accurate map of neuroleptic receptors in vivo.

These results demonstrate the successful application of this approach to the PETT mapping of neuroleptic receptors in live baboons. The proper choice of a highly selective drug for the intervening blocking dose can allow differentiation of  $[^{11}C]^-$ Intervening blocking dose can allow differentiation of  $[-c]^{-1}$  spiroperidol binding to D-2 dopamine receptors, serotonin receptors, etc. Using different radioligands, this paradigm should be applicable to PETT studies of other types of receptors as well. This model demonstrates the potential utility of  $[^{11}C]^{-1}$  spiroperidol and PETT for mapping neuroleptic receptors in the human brain.

13.10 THE D-2 DOPAMINE RECEPTOR IN THE INTERMEDIATE LOBE OF THE RAT PITUITARY GLAND REGULATES THE SYNTHESIS OF PROOPIOMELANOCORTIN AND MELANOTROPHIC HORMONES. <u>M. Beaulieu, M.E. Goldman, T.E.</u> <u>Cote\* K. Miyazaki\* and J.W. Kebabian\*</u>. Experimental Therapeutics Branch, NINCDS, NIH, Betnesda, MD 20205. The intermediate lobe of the rat pituitary gland is innervated by deperimental for the rat pituitary gland is intervated by deperimental for the rat pituitary gland is intervated by deperimental for the rat pituitary gland is opertained by the provide the part of th

by dopaminergic neurons originating in the brain. A post-junctional D-2 dopamine receptor occurs upon the melanotrophs, the cells synthesizing the prohormone, proopiomelanocortin (POMC)

the cells synthesizing the pronormone, prooplomelanocortin (PMC) and processing it into several molecules ressembling  $\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH). This D-2 receptor is stimulated by bromocriptine (CB 154) and blocked by spiroperidol (SPIRO). In vivo treatment of male Sprague Dawley rats with CB 154 (10 mg/kg/d; 2 d) lowers the content of messenger RNA (mRNA) directing the synthesize POMC by 60%, diminishes the capacity of the IL to synthesize  $\alpha_{\alpha}$ SNG+like molecules by 65% and blocks the of the IL to synthesize POMC by 60%, decreases the capacity of the IL to synthesize  $\alpha$ -MSH-like molecules by 65%, and blocks the secretion of  $\alpha$ -MSH-like peptides from the IL. Furthermore, prolonged treatment with CB 154 causes the IL to atrophy and diminishes the IL content of  $\alpha$ -MSH-like molecules by 70%. Because a similar number of IL cells are retrieved from enzymatic dispersions of vehicle- and CB 154-treated animals, it seems probable that the CB 154 treatment is decreasing the capacity of

acch melanotroph to synthesize α-NSH-like molecules. In vivo treatment of male Sprague Dawley rats with SPIRO (10 mg/kg b.i.d; 1 d) increases the IL content of mRNA directing POMC mg/kg bild, full increases the capacity of the IL to synthesize both POMC and  $\alpha$ -MSH-like molecules from the IL. Furthermore, treatment with SPIRO prevents the inhibitory effects of CB 154 upon POMC and  $\alpha$ -MSH synthesis.

The present data demonstrate that the capacity of the IL to The present data demonstrate that the capacity of the IL to synthesize POMC and  $\alpha$ -MSH-like peptides is variable and is regulated by the D-2 dopamine receptor. Dopamine released from nerve terminals in the IL stimulates the D-2 receptor and thereby keeps the synthetic capacity of the IL submaximal. CB 154 stimulates the D-2 receptor and further decreases the synthetic capacity of the IL. SPIRO blocks the D-2 receptor, thereby removing this inhibitory constraint; this accounts for the observed stimulatory effects of CB 154. 13.11

COMPARISON OF ESTROGEN AND HALOPERIDOL ON THE ELEVATION OF PROLACTIN SERUM LEVELS AND THE INCREASE IN DENSITY OF THE STRIATAL DOPAMINE RECEPTORS. Robert E. Hruska. Dept. of Biochemical Pharmacology, State University of New York, Buffalo, NY 14260. Prolactin (PRL) serum levels are elevated by the administration of either estrogen or haloperidol (HAL). Several groups have also reported that either estrogen or HAL administration will increase the density of the striatal dopamine (DA) receptors. This suggested a link between the two treatments. Interestingly, it appears that each of these treatments has diminished effects on striatal DA receptor density in rats which are hypophysectomized (Hypox), and hence have no PRL available. This led to the postulation that a pituitary factor, namely PRL, was involved in the regulation of striatal DA receptors. When PRL was chronically administered to intact and Hypox male rats, it was able to increase the density of the striatal DA receptors in both cases, although Hypox rats required a larger dose of PRL. Importantly, although Hypox rats required a larger dose of PRL. Importantly, the pituitary does not appear to be necessary for the maintenance of the striatal DA receptors, since Hypox rats have a normal

the pituitary does not appear to be necessary for the maintenance of the striatal DA receptors, since Hypox rats have a normal density and affinity of these receptors. Further studies have indicated that the regulation of striatal DA receptors by PRL is complex. Male, adult rats were injected s.c. with 17B-estradiol valerate at doses from 15-500  $\mu$ g/rat. At various times afterward the rats were decapitated, trunk blood collected for PRL measurements, and the striatal tissue prepared for DA receptor measurements. There was a time-dependent relationship between the elevation in serum PRL levels and the elevation in the striatal DA receptor density. While PRL serum levels were maximally elevated at two days, the receptors were maximally elevated at four to six days. By ten days the elevated density of receptors had subsided to non-significant levels, while the serum levels remained significantly elevated above control levels. Therefore, the increase in striatal DA receptor density produced by estrogen administration may depend on the novelty of the increase in PRL levels or on the rise of serum PRL levels. These observations also suggest that the regulation of striatal DA receptors appears to be different after chronic HAL treatment compared to chronic estrogen treatment. After estrogen, PRL levels remain elevated while the receptor density remutes of a striatal DA receptors appears to be different after chronic HAL treatment control levels. After HAL the levels of PRL return to control levels while the receptor density remains elevated. HAL also acts directly on striatal DA receptors and therefore may act via more than one merchanism. The alavation in serum PRL level and levels while the receptor density remains elevated. HAL also acts directly on striatal DA receptors and therefore may act via more than one mechanism. The elevation in serum PRL levels and striatal DA receptor density also appeared to be related to the dose of estrogen used. Maximal effects on both parameters, at six days after injection, were obtained by the 60 µg/rat dose of estrogen. Therefore, the modification of striatal DA receptors by PRL is multifaceted. (Supported by PMAF Res. Starter Grant.)

13.12 THE POSSIBLE ROLE OF 2-HYDROXYESTRADIOL IN THE DEVELOP-MENT OF ESTROGEN-INDUCED STRIATAL DOPAMINE RECEPTOR HYPERSENSITIVITY. J.K. Clopton\* and J.H. Gordon. Dept Pharmacology, Univ Hith Scis/The Chicago Med Sch, N. Chicago, IL 60064. Several reports have indicated that the administration of estrogen will result in the dupler period of the dupler strongen will

result in the development of a striatal dopamine receptor hypersensitivity. result in the development of a striatal dopamine receptor hypersensitivity. However, all of these reports use non-physiologic (i.e. pharmacologic) doses and/or paradigms, thus posing the question of the physiologic relevance of these observations. In the first experiment we confirmed our previous observations of a biphasic response in dopamine receptor sensitivity following estradiol benzoate (EB) in doses of 10, 30 and 100  $\mu$ g/kg. The first phase, seen at 24 hrs after the last dose of EB, was a dose related suppression of dopamine receptor sensitivity. The second phase was the development of a dopamine receptor hypersensitivity which was quantit-ated 72 hrs after the last dose of EB, and was only seen following the two higher doses of EB. These data thus confirm our previous work and support the hypothesis that the development of a dopamine receptor hypersensitiv-ity following EB may be a pharmacologic phenomenon.

In the second experiment 2-hydroxyestradiol (2-OHE) was administered to In the second experiment 2-hydroxyestradiol (2-OHE) was administered to ovariectomized rats in doses of 0.3, 1.0, 3.0, 10.0, 30.0 and 100.0  $\mu$ g/kg for 3 days and apomorphine-induced stereotypy was quantitated at 24 and 72 hrs after the last dose. Doses of 2-OHE of 1.0  $\mu$ g/kg or greater produced a striatal dopa mine receptor hypersensitivity at both 24 and 72 hrs after the last injection. The threshold dose for 2-OHE was between 0.3 and 1.0  $\mu$ g/kg, while the threshold dose for EB was between 10 and 30  $\mu$ g/kg. Thus only 3% or less of the injected EB would need to be converted to 2-OHE for this matchedite to modiate the downlow moder of the hypersensitivity metabolite to mediate the development of the hypersensitivity. Some reports have suggested that the enzyme responsible for the

some reports have suggested that the enzyme responsible for the conversion of estrogen to catecholestrogen is a microsomal enzyme. In the third experiment we administered piperonyl butoxide (PBO) a microsomal enzyme inhibitor in an attempt to block the development of the estrogen-induced dopamine receptor hypersensitivity. PBO, 400 mg/kg, was administered 4 hrs prior to the administration of a single dose of estradiol (3, 10, 30 and 100  $\mu$  g/kg). Animals were then tested for apomorphine-induced stereotypy at 24 and 72 hrs after the injection of the estradiol. The administration of PBO shifted the dose response curve to the right, with the PBO treated animals showing about a 100 fold decrease in sensitivity to estradiol. Studies of the <u>in vitro</u> metabolism of <sup>3</sup>H-estradiol indicated a significant reduction in radioactivity in the catechol fraction for the statistic provides the statistic provide following the administration of PBO.

These studies indicate that the two responses seen in striatal dopamine receptor sensitivity following the administration of the 2-0HE metabolite and the similar of the similar of the similar of the similar of the administration of the 2-0HE metabolite and the attenuation of the estradiol-induced response in PBO treated animals all uncontext that the other administration of the 2-0HE metabolite and the attenuation of the estradiol-induced response in PBO treated animals all suggest that the estrogen-induced striatal dopamine receptor hypersen-sitivity may be mediated by the catechol metabolites.

13.PO

ROLE OF AMBIENT ANIONS IN RELIEVING SEROTONERGIC ANXIETY IN A NORCATIONIZED ENVIRONMENT. A.J. Giannini, R.L. Gilliland, R.H. Loiselle\* and <u>M.C. Giannini.\*</u> Psychiatry Dept., Northeastern Ohio Universities College of Medicine, Rootstown, OH 44222.

Twelve male students were placed in a highly stressed learning situation. During this sixty-minute period heart rate rose from 70.5/min. to 80.1/min. No differences were seen in platelet serotonin levels measured before and after the learning situation. Repetition of this paradigm with the same students in a highly anionized environment resulted in a change in heart rate from 71.6/min. to 74.2/min. Again no differences were seen in platelet serotonin levels measured before

seen in platelet serotonin levels measured before and after one hour of ionization. These findings are different than those reported by Kreuger (19) who found stress to be associated with a rise in serotonin. Olivier's (19) work also noted that atmospheric anions would lower serotonin levels and that these levels would be inversely related to physiological parameters of anxiety. The above results would suggest, there-fore, that the role of anions in relieving anxiety may be independent of serotonin.

13.PO POSSIBLE ROLE OF THE DA-2 RECEPTOR IN PHENCYCLIDINE PSYCHOSIS. A.J. Giannini, S.M. Kalavsky, R.H. Loiselle,\* M.C. Giannini,\* and W.A. Price.\* Psychiatry Dept., Northeastern Ohio Universities College of Medicine, Rootstown, OH 44222. Previous treatment of phencyclidine (PCP) psychosis in our department has demonstrated the greater efficacy of dopaminergic blockers relative to opiates, benzodiazepenes, physostigmine and hydroxyzine (Castellani & Giannini a,b; Giannini & Castellani; Giannini & Price). The role of DA-1 and DA-2 receptors in this type of psychosis was tested as described below. Twelve patients were seen in acute PCP psychosis. On a random basis six were treated with chlorpromazine (CPZ), a predominantly DA-1 blocker, and the remainder with haloperidol, a predominantly DA-2 blocker. Two equivalent dosages of either CPZ or haloperidol were injected at 20-minute intervals. Patients were then rated on a BPRS by a blind observer. All twelve responded equally well on anxiety, excitement and tension scales. Haloperidol-treated patients responded in a significantly better fashion on conceptual disorganization (p > .05) and hallucination scales (p > .05). These preliminary results suggest a role for the DA-2 receptor in PCP psychosis.

13.PO DIFFERENTIAL CHANGES IN RAT BRAIN DOPAMINE AND SEROTONIN PRECEPTORS AFTER CHRONIC TREATMENT WITH TYPICAL AND ATYPICAL ANTI-PSYCHOTIC DRUGS. <u>Tyrone Lee and Siu Wa Tang</u>. Psychopharmacology Unit, Clarke Institute of Psyciatry, Toronto, Canada M5T 1R8. The blockade of central dopamine receptors has been proposed to be the major action of antipsychotic drugs such as haloperidol or chlorpromazine in controlling psychotic symptoms. Chronic administration of typical antipsychotic drugs is known to induce

administration of typical antipsychotic drugs is known to induce dopamine receptor supersensitivity in the central nervous system. In order to demonstrate if the atypical antipsychotic drugs share this same action, brain dopamine receptor numbers were measured in rats chronically treated with haloperidol, loxapine, clozapine or sulpiride. Serotonin receptor numbers were also measured for comparison.

Adult male Wistar rats (175-200 gm) were treated with once Adult male Wistar rats (175-200 gm) were treated with once daily i.p. with haloperidol (5 mg/kg), loxapine (5 mg/kg), cloza-pine (30 mg/kg) or sulpiride (100 mg/kg) for 28 days. Control rats received equivalent volume of vehicle. Forty-eight hours after the last injection animals were sacrificed and striatal and frontal cortigal homogenates were prepared for receptor binding assays using 'H-spiperone. Dopamine receptor ( $D_2$ ) was defined by 10 uM sulpiride and serotonin receptor ( $S_2$ ) was defined by 50 nM mianserin. Receptor density ( $B_{max}$ , in femtomoles/mg protein) and affinity ( $K_D$ , in nM) were determined by Scatchard analysis. The results are as follows:

DBUC	DOPAMINE (D2) RECEPTOR			SEROTONIN (S2) RECEPTOR		
DRUG	Bmax	%control	N	Bmax	%control	N
Control	460+49☆	100	4	412+33	100	3
Haloperidol	657+31	143**	3	464+12	113	3
Loxapine	484+43	105	6	167+15	41***	5
Clozapine	476+38	104	4	218+64	53	3
Sulpiride	$547 \pm 16$	119	6	346 <u>+</u> 31	84	5

P**<**0.01, Student'

"Mean  $\pm$  5.E; "PCO.02, "ACCOUNT Student's to test. Chronic exposure to haloperidol in the rat increased the density of dopamine (D<sub>2</sub>) receptors (43%) but caused no significant change in the number of serotonin (S<sub>2</sub>) receptors. Loxapine, clozapine and sulpiride did not cause any significant change in dopamine and suppride did not cause any significant change in dopamine receptors but loxapine alone induced a significant reduction in serotonin receptor number (59%). No significant difference was observed in receptor affinities among the different drug groups. Our present data suggest that not all neuroleptics induce an increase in dopamine receptor number on chronic administration.

Loxapine, on the other hand, appeared to potently affect the serotonin system and this unique property so far is known to occur only with antidepressant drugs. (Supported by the Research Fund of the Clarke Institute).

MULTIPLE <sup>3</sup>H-SPIPERONE BINDING SITES DEFINED BY KETANSERIN IN RAT 13.PO FRONTAL CORTEX: REGULATION BY ENDOGENOUS SEROTONIN, NEUROLEPTICS AND ANTIDEPRESSANTS. Daiga M. Helmeste and Siu Wa Tang. Psycho-pharmacology Unit, Clarke Institute of Psychiatry, Toronto, Ont., CANADA M5T 188.

NADA M5T 1R8. Ketanserin, a putative S<sub>2</sub>-serotonin antagonist, has recently  $_{3}$ Retainserin, a putative S2-serotonin antagonist, has recently the second to specifically define the S2-serotonin component of  ${}^{3}_{\rm H}$  spiperone binding and as a specific tritiated label for S2-serotonergic sites. We have discovered that a ketanserin baseline (100 nM) defines more than one  ${}^{3}_{\rm H}$ -spiperone site in the rat frontal cortex [Kd1 (nM)=0.3, B<sub>max1</sub> (fmol/mg.protein)=300; Kd2=5, B<sub>max2</sub>=600]. [Examination of  ${}^{3}_{\rm H}$ -ketanserin binding to rat frontal cortex [1 uM methyaering back into a serveral definition of the serveral de (1  $\mu M$  methysergide baseline) also revealed multiple binding sites]. To determine which of the  $^3 H\text{-}spiperone$  labelled sites are under serotonergic control, changes in binding sites were examined after chronic drug treatments which enhance (d-fenfluramine; 2.5 mg/kg i.p., twice daily for 28 days) or decrease sectorin release (PCPA 300 mg/kg, i.p. for first and last 3 c ys, 100 mg/kg every second day for days 4 to 18). These were compared to other treatment groups consisting of acute [single or double (2 days) injs., 48 hr before] administration of the antidepressants mianserin, amoxapine and imipramine or the neuroleptics haloperidol, thiothixene, per-

Marked changes in receptor density ( $m_{ax}$ ) were observed in the 0.3nM K<sub>d</sub> <sup>3</sup>H-spiperone site, as follows (expressed as percentage of controls): chronic d-fenfluramine (50% of control); chronic PCPA (155%); acute mianserin, 10 mg/kg, (57%); acute loxapine, 5 mg/kg, (6%); acute amovapine, 10 mg/kg, (7%), dotter to approx, mg/kg, (6%); acute amovapine, 10 mg/kg, (78%). Other groups showed no significant changes. This 0.3nM Kd  $^{3}$ H-spiperone site can also be preferentially labelled using a 50nM mianserin baseline.

The ability of mianserin to acutely down-regulate the 0.3nM  $\ensuremath{\mathsf{K}_{\mathrm{d}}}$ site does not seem to be dependent on intact serotonin stores since chronic PCPA pretreatment did not prevent the mianserin induced down-regulation. The ability of mianserin, loxapine and amoxapine to acutely down-regulate the 0.3nM Kd site did not seem to be related to their high affinities for this site, since S2-serotonin antagonists with similar affinities [cinanserin or ker-anserin 10 mg/kg] had no effects on this site, either in terms of acutely blocking the mianscrim effect or in charging the numbers of this site by themselves.

The above data suggests that the 0.3nM  $K_{\rm d}$   $^3H\text{-spiperone}$  site is a serotonergic receptor and that its density can be acutely altered by certain compounds used in the treatment of the major psychos -08.

AGONIST INDUCED DECREASES IN AGONIST AFFINITY AT DOPAMINE

AGONIST INDUCED DECREASES IN ACONIST AFFINITY AT DOPAMINE RECEPTORS. J. J., Klein\*, A. C. Andorn\*, K. R. Kohægan\* (SPON: V. Rowland). Dept. of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106. The  $C_{50}$  of dopamine at  $\Im$ -spiroperidol receptors in rat striatum is 2840 +/- 357.0 nM (N=5) when obtained in competition studies using a 15 min incubation and 0.2 nM  $\Im$ -spiroperidol, 0.01 mM ascorbate,  $\Im$ -4 mM Na-Hepes, and 0.20 +/- 0.05 mg protein. However, at an incubation time of 60 min the  $1C_{50}$  of dopamine is shifted to the right by 2 orders of magnitued to 100,000 +/- 0.0 nM (N=5). Preincubating the tissue for 60 min in the presence of 10 uM dopamine and using this tissue in 55 min study results nM (N=5). Preincubating the tissue for 60 mm in the presence of 10  $\mu$ M dopamine and using this tissue in a 15 min study results in an IC<sub>50</sub> of 180,000 +/- 50,000 nM (N=2). (The contribution of the dopamine in the preincubate was corrected for). Preincubation of tissue in buffer alone does not change the IC<sub>50</sub> at 15 min. The addition of pargyline to the preincubation step does not change the results observed at either 15 or 60 min. These findings suggest that agonist can induce decreases in the affinity of the receptor for agonist while sparing antagonist affinity. Such findings are not inconsistent with physiologically relevant recep-tors, as agonist induced desensitization is well known in other receptor systems (Harden, T. K., Su, S. Y., Perkins, J. P., J. Nuc. Res.5:99, 1979). Cyc.

Interestingly, the IC<sub>50</sub> of dopamine at a 60 min incubation is the same as its IC<sub>50</sub> using a 15 min incubation, but having 100  $\mu$ M Gpp(NH)p present in the assay. Further study will determine agonist induced changes in agonist affinity procede mechanisms similar to or distinct from guanyl nucleotide induced decreases in  $^{3}\text{H}\text{-spiroperidol}$  binding in rat striatum.

- GUANYL NUCLEOTIDE INDUCED LOSSES OF ANTAGONIST BINDING AT HIGH 13.PO GUANYL NUCLEOTIDE INDUCED LOSSES OF ANTAGONIST BINDING AT AIG AFFINITY DOPAMINE RECEPTORS. A. C. Andorn\*, K. R. Kohagan\*, J. L. Klein\*(SPON:M.E. Maguire).Dept. of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106. Guanyl nucleotides induce a loss of high affinity <sup>3</sup>H-spiroper-Guanyl nucleotides induce a loss of high affinity  ${}^{3}H$ -spiroperidol binding in rat striatum as seen in rate association studies in the presence of 100  $\mu$ M Gpp(NH)p. The loss in binding is also seen in rate dissociation studies. These are biphasic in the absence of Gpp(NH)p (tiz rapid = 0.1 min; tiz Slow=31.5 +/ 9.4 min N=3). In the presence of Gpp(NH)p these studies are monophasic with tiz= 0.1 min (N=3). Saturation studies show that in the absence of Gpp(NH)p, at least two affinity states for  ${}^{3}H$ -spiroperidol are present with  $K_{D}$ =8.7+/-1.7mM,  $B_{max}$ =15.9+/-17.3 fmol/mg,  $K_{D2}$ =0.25+/-0.14nM,  $B_{max}$ = 183.3+/-23.0 fmol/mg protein (N=4). The same studies in the presence of 100  $\mu$ M Gpp(NH)p indicate that only one affinity state is present with an apparent K<sub>D</sub> of 0.16 +/- 0.02nM and  $B_{max}$  of 223.0 +/- 62.8 fmol/mg protein (N=3), corresponding to the lowest affinity state observed in the absence of nucleotide. The effects of guanyl nucleotide are blocked by
  - corresponding to the lovest affinity state observed in the abse of nucleotide. The effects of guanyl nucleotide are blocked by the addition of 3.4 mM Mg<sup>++</sup>, are reversible, and are not produced by 100  $\mu$ M ATP. Some of these results are similar to the effects of guanyl nucleotide on <sup>3</sup>H-agonist binding in the opiate receptor system (Blume, A. J., Proc. Mat. Acad. Sci. 75: 1713, 1978). However, the results presented here demonstrate 1713, 1978). However, the results presented here demonstrate clear effects of guanyl nucleotides on <sup>3</sup>H-antagonist binding.

AFFERENT AND EFFERENT CONNECTIONS OF THE CLAUSTRUM OF TREE SHREW AND RAT. Teresa L. Neal\* and Russell G. Carey. Div. of Neurobiol., Barrow Neurol. Inst., Phoenix, AZ 85013.

In both tree shrew and cat the dorsal claustrum is recipro-cally connected with the visual cortex and, in particular, with area 17 (Carey et al., 1979; LeVay & Sherk, 1981). Consensus concerning subcortical connections of the claustrum in these species, however, has been highly elusive. Studies in the cat have tended to doubt the existence of such projections whereas results in the tree shrew (Carey & Bear, 1979) indicate their existence. The purpose of the present study was two-fold: first, to verify the existence of these projections by making injections directly into the tree shrew thalamus as well as in the claustrum; and second, to determine whether the pattern of connections observed in cat or tree shrew is representative of

the pattern found in a third mammal, the Long-Evans rat. After injections of WGA-HRP into the tree shrew claustrum, labeled cells and terminals in the thalamus are primarily lo calized within the lateral intermediate nucleus (Li) and the nuclear region embedded within the external medullary lamina (EML). Small electrophoretic injections into the same thalamic regions werify the existence of these reciprocal connections. After these injections a focus of moderate terminal activity is found in the same general area of the claustrum that projects to area 17. However, the pattern of retrogradely labeled cells from these injections is dissimilar. These labeled cells predominently lie on the outside margin of the claustrum and tend to encapsulate the nucleus for considerable distance. Thus it appears that a separate zone exists that projects to the thalamus that does not receive a projection from visual cortex.

thalamus that does not receive a projection from visual cortex. The pattern observed in the rat however is distinct from that of either the tree shrew or the cat. First, as reported for the cat, there is only minimal evidence for subcortical connections. More important, however, is the finding of only limited connections with area 17. Only the cortical region that lies medial to area 17 (area 18M) has dense reciprocal connections with the claustrum. Cortical regions lateral to 17 do appear to receive a moderate projection from the claustrum but do not annear to project to the claustrum. Furthermore. but do not appear to project to the claustrum. Furthermore, after injections into the claustrum of the rat, the terminal activity is found maximally in the infragranular layers of 18M and not in the granular layers as is the case for tree shrew and cat. Similar to that of the other species, the reciprocal projection originates from cells of layer VI. Supported by NIH Grant EY03641(RGC) and funds from EPI-Hab

Phoenix, Inc.

14.2 THE CORTICO-CLAUSTRAL LOOP IN MONOCULARLY DEPRIVED AND STRABISMIC CATS. <u>David J. Perkel\* and Simon LeVay</u>, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The dorsocaudal (visual) claustrum receives a convergent input from several visual cortical areas and projects back to them. The normal cat most claustral neurons are about equally responsive to stimulation of either eye (Sherk & LeVay, J.Neurosci. 1:93). We have examined the effects on the visual claustrum of two condi-tions that are known to affect the eye preference of cortical neurons.

In 2 monocularly deprived (MD) cats (lid-sutured at 3 weeks) all claustral units responded only to stimulation of the expe rienced eye. Presumably this reflected the change in the ocular dominance of the cortical cells projecting to the claustrum. In one MD cat an injection of  ${}^{3}\text{H}\text{-proline}$  was made into the visual claustrum. Autoradiography showed a normal return projection to claustrum. Autoradiography showed a normal return projection to visual cortex, including area 17: the terminals were distributed in an even, non-columnar fashion. This implies that cortical oc-ular dominance columns for the deprived and experienced eyes both receive a claustral input that is driven only by the experienced eye. To test whether the cortico-claustral loop might be involved in suppressing cortical responses to the deprived eye, the ocular and after ablation of the visual claustrum with an injection of kainic acid. There was no change: both before and after the abla-tion responses to the deprived eye were confined to small regions in or just above layer 4. Thus the cortico-claustral loop does not suppress deprived-eye responses, at least in long-term deprivation. One strabismic cat was studied (both lateral recti cut at 3

weeks). When paralyzed it was cross-eyed by 17°. In the cortex (area 17) most cells were monocular and were grouped into sharplydefined columns. In the claustrum most neurons were still binocular, but the proportion of cells driven strongly or exclusively by one eye (OD groups 1,2,6 & 7) was much higher (468) than in normal cats (158). Cells dominated by one or the other eye were randomly mixed - strabismus did not cause the appearance of ocular dom-inance columns in the claustrum. As in normal cats, binocular claustral cells generally had a similar preferred orientation in the 2 eyes, and cells with similar orientations were grouped together. Although there was some breakdown of binocularity in the claustrum, no doubt reflecting that seen in the cortex, our results suggest that binocular convergence at the claustral level is com-paratively resistant to strabismus. The results also indicate that the development of matching orientations in the left- and right-eye fields of claustral neurons does not require normal binocular vision, at least after 3 weeks of age. (Supported by NIH EY-1960)

14.3 COURSE AND STRUCTURAL ORGANIZATION OF GENICULOCORTICAL AND CORTICO-FUGAL PATHWAYS IN WHITE MATTER OF THE RAT VISUAL SYSTEM. W. R.

COURSE AND STRUCTURAL ORGANIZATION OF GENICULOCORTICAL AND CORTIO-FUGAL PATHWAYS IN WHITE MATTER OF THE RAT VISUAL SYSTEM. W. R. Woodward and B. M. Coull\*. Dept of Neurology, Oregon Health Sciences Univ, Portland, OR 97201. We previously reported that geniculocortical and corticofugal fiber pathways are segregated within white matter of the rat visual system (Woodward & Coull, 1982). Geniculocortical fibers are localized in the external stratum, whereas corticofugal fibers run in the internal sagittal stratum of the medullary substance. These observations were extended, and the course and organizational structure of these fiber tracts within white matter were examined. The entire geniculocortical and corticofugal fiber tracts were visualized by autoradiography 24 hours after focal <sup>3</sup>H proline and <sup>3</sup>H fucose injections into dorsal lateral geniculate nucleus (dLCM) or into striate cortex. Subcortical white matter in rat is approximately 300 um wide. Geniculocortical fibers coalesce into a 100 µm wide band lateral to the ventricle and project to cortical targets in the external stratum, whereas corticofugal fibers course diagonally across the white matter and project to subcortical targets as a 150 µm wide band in the internal sagittal stratum. The two fiber tracts are separated from near the visual cortex to adjacent to the lateral ventricle. Neuronal degener-ation studies following kainic acid lesions of dLCN or visual ation studies following kainic acid lesions of dLCN or visual cortex confirm these findings. Geniculocortical and corticofugal fiber tracts appear quite

Geniculocortical and corticofugal fiber tracts appear quite different in white matter in both orthograde transport and neuronal degeneration studies. When sectioned in the coronal plane geniculocortical fibers appear as a continuous, unbroken band, whereas corticofugal fibers appear as a series of ellipsoid fascicles. We considered the possibility that the fascicles repre-sent cylindrical bundles of corticofugal fibers projecting through the coronal plane at an oblique angle. Two consequences of this assumption are (1) the minimum diameter of a fascicle is equal to the cross-sectional diameter of that bundles and (2) horizontal and vertical components of the angle that bundles form with the coronal plane can be calculated. The bundles are estimated to be 22.5  $\mu$ m in diameter, and the horizontal angle increases and the vertical angle decreases for progressively more lateral bundles vertical angle decreases for progressively more lateral bundles in the white matter. The latter prediction is consistent with the course of corticofugal fibers which initially project laterally and downward before turning rostrad. Geniculocortical and corticofugal fiber organization within

white matter has important implications for neurophysiology and for neurodevelopment.

BRANCHING OF SINGLE AXONS FROM THE LATERAL GENICULATE NUCLEUS AND LATERALIS FOSTERIOR TO THE VISUAL CORTEX IN THE NEONATAL RAT. L.K. Laemle and S.C. Sharma. Dept. of Anatomy, UMDNJ-NJ. Med. Sch., Newark, N.J. 07103 and Dept. of Ophthalmology, N.Y. Md. Sch., Valhala, N.Y. 10595 The advent of techniques which permit double label-ing of individual CNS neurons has demonstrated that a single axon may bifurcate thus innervating both halves of the brain. This phenomenon has been demonstrated in the visual pathway of the adult rat, where some ganglion cells in the temporal quadrant of the retina project to both ipsilateral and contralateral lateral genizulate nucleus (LGN) (Jeffrey et al, 1981). In the present study we ask whether axonal branch-ing is restricted to retinal ganglion cells, or wheth-er this is a more general phenomenon in the visual pathway. The problem was approached by the use of double retrograde labelling with fluorescent dyes. Twenty-seven neonatal rats, gaes 3 days to 7 days were used in this study. Injections of 5% true blue or 5% fast blue were placed in the right visual cortex (areas 17, 18, and 18a); 30 minutes to 72 hours later 1% nuclear yellow was injected into the homologous area of the left hemisphere. Animals were sacrificed 8 hours to 24 hours following injection with nuclear yellow. Total survival from the time of injection with true blue or fast blue was 24 to 96 hours. Retrogradely labeled neurons were located in the LGN and in the nuclues lateralis posterior (LP). Small injections in area 17 resulted in restricted areas of Iabeled neurons in the LGN (dorsalis) and restricted label in LP. Large injections resulted in labeling of the entire LGN and LP. Examination of these nuclei revealed a predominance of single-labeled neurons which were labeled retrogradely from the ipsi-lateral cortex. Scattered among jpsilaterally labeled cells were occasional neurons single-labeled from the contralateral cortex. Double labeled neurons were ob-served in both the LGN and LP, and were more prev

in the latter nucleus.

The present study demonstrates that single cells in the LGN and LP of the neonatal rat project bilaterally upon the visual cortex. This provides another mechan-ism for duplication of visual information at the level of the visual cortex. Supported by NIH grant 1 RO1 EYO4107-01A1 (LKL) and EYO1426 (SCS).

CONTRALATERAL CORTICAL PROJECTIONS TO VISUAL THALAMUS IN THE CAT. 14.5 Berman and B. R. Payne. Depts. of Anatomy and Physiology/ Biochemistry, The Med. Coll. of Pennsylvania, Phila., PA 19129.
 Efferent pathways from visual cortical areas to subcortical

structures are mainly ipsilateral. However, in recent years a number of studies have shown that, in the cat, there are projections from visual cortical areas to a number of contralateral subcortical structures, including the claustrum, caudate-putamen, thalamic intralaminar nuclei, pretectum, superior colliculus and pontine nuclei. Many of these contralateral projections, such as to the superior colliculus, are retinotopically organized. In our continuing studies of crossed corticofugal projections, we now describe a substantial projection from visual cortical areas to certain nuclei of the contralateral visual thalamus.

Cortical projections to subcortical regions were traced with tritiated amino acids injected into extrastriate visual cortical areas of cats. After survival times of two or seven days, sec-tions of the brain were cut and prepared for autoradiography. Silver grains were observed, as expected, over the targets of visual cortical projections in the ipsilateral midbrain and thalamus. In addition, silver grains were seen overlying the tectal and posterior commissures and a number of contralateral thalamic and midbrain structures. In the thalamus, the label was heaviest over the lateral-posterior nuclear complex with the greatest density of silver grains over the presumed border between the lateral and interjacent subdivisions of this complex. Less dense label was observed over the posterior nuclear complex and rostral pulvinar.

All regions of the thalamus, which receive projections from contralateral visual cortical areas contain neurons which respond to visual stimuli and express well ordered maps of visual space. Comparison of the crossed corticothalamic terminal regions with published maps of the thalamus suggests that the crossed cortical projections are to parts of the thalamus representing visual space in the vicinity of the vertical meridian. This suggests that the contralateral cortical projections to the thalamus and superior colliculus are both organized in a retinotopic fashion The presence of retinotopically organized crossed corticothalamic projections indicates that one hemisphere influences the response properties of cells in contralateral thalamus. This influence, however, is likely to be confined to representations of visual space close to the division of the two hemifields. In addition, the crossed corticothalamic pathway may provide a non-callosal route by which visual information can be transferred from one hemisphere to another.

Spatial contrast sensitivity: effects of peripheral field 14.7 stimulation during monocular and dichoptic viewing. R.T.

Marrocco and M. Carpenter\*. Institute of Neuroscience, Univ. of Oregon, Eugene, OR. 97403. We have used a radial grating as a peripheral field stimulus surrounding a 2 deg target. The grating was seen in the same eye or the eye opposite to that seeing the central target. A central 2 deg. aperture assured that the radial grating did not encroach on the 2 deg stimulus. The task of 3 experimentally a foveally viewed, 2 deg, counterphasing sine wave grating target to threshold. In half the trials the radial grating was rotating at 5 deg/sec, while in the other half it was stationary. In each condition the contrast threshold change, if any, was taken as the difference between contrast settings for the

stationary minus the moving radial grating conditions. Our results showed that movement of the peripheral radial grating caused a decrease in the contrast thresholds for monocular and dichoptic viewing conditions. A shift of 0.6 to 0.8 log units was seen for monocular conditions and a shift of 0.4 to 0.6 log units was seen for dichoptic viewing. The size of the shift was dependent on the target grating spatial frequency. Low spatial frequencies were affected to a greater extent for the dichoptic paradigm than the monocular. The reverse was true for high spatial frequencies. Thus, the curve for contrast sensi-tivity appeared to be shifted to lower peak spatial frequencies for the dichoptic paradigm.

for the dichoptic paradigm. The changes in contrast thresholds for monocular viewing can be explained by lateral spatial interactions in the retina or lateral geniculate nucleus. However, since the effective visual stimulation of the visual pathway is equivalent for both paradigms at or beyond the point of binocular convergence (i.e., striate cortex), the residual effect in the dichoptic paradigm is thought to reflect the action of a feedback pathway to subcortical visual centers. Supported by NSF grant ENS 82-07531.

EXCITATORY NATURE OF CORTICOFUGAL PROJECTION UPON 14.6 LATERAL GENICULATE AND THALAMIC RETICULAR NUCLEI, AS EVIDENCED BY CRYOGENIC BLOCKADE OF RAT VISUAL CORTEX. Yukihiko Kayama, Akira Shosaku\* and Robert W. Doty<sup>1</sup>. Institute of Higher Nervous Activity, Osaka University Medical School, Osaka 530, Japan.

The function of the corticofugal projection to the dorsal lateral geniculate nucleus (LGNd) has frequently been studied using inactivation of the visual cortex (VC) by cooling. However, the reported effects have been complex and/or equivocal. Thus we reexamined the question in a lissence palic species where VC can readily be fully and reversibly inactivated. The skull overlying visual areas 17,18 and 18a was removed in urethane-anesthetized rats, which were immobilized and artificially ventilated. Inlet and outlet tubes in an acrylic wall surrounding this opening permitted rapid application and removal of chilled or body temperature saline to the intact dura mater within this opening. Unit recording showed drastic curtailment of VC which this period. So set of cooling onset, and complete recovery within similar time upon start of rewarming. With 1-min cooling of VC, temperature at LGNd was unaltered, but background activity was significantly reduced in about half the neurons sampled. The effects were somewhat less striking on activity evoked by electrical stimulation of the optic chiasm (OX) or photic stimulation of plotted receptive fields. Although an occasional unit might become interpreter in the signal and occasional and ingit occasional and ingit occasion in the signal and the signal a (vTRN), identified by their characteristic discharge to single electrical pulses applied to OX, were much more consistent and profound. Background activity was depressed in all 32 units observed, versus 12 of 22 units comparably studied in LGNd. VC cooling diminished responses to electrical or photic stimulation in about 80% of vTRN units. Thus, the continuous control which the VC seems to exert upon vTRN is significantly more powerful than that upon LGNd. In no case, for either LGNd or vTRN, were excitatory effects obtained by inactivation of VC, and it is therefore concluded that the normal influence of the latter and it is therefore concluded that the normal influence of the latter upon these nuclei is uniformly excitatory. The projection of VTRN into the LGNd has repeatedly been demonstrated, anatomically and physiologically, to be inhibitory. Thus, in removing a tonic excitatory input to vTRN, inactivation of VC causes a disinhibition of LGNd which, to some degree, may counterbalance the disfacilitation which the latter also suffers from the loss of VC input. <sup>1</sup>Fellow of the Japan Society for the Promotion of Science.

CELLS OF ORIGIN OF THE CORTICOCOLLICULAR PROJECTION IN THE CAT. 14.9 Anatomy, Tulane University Medical School, New Orleans, La. 70112. The laminar distribution and the specific cell type(s) of the corticotectal projection were examined by placing injections of wheat germ agglutinin-horseradish peroxidase (WGA-HRP) within the superior colliculus of the cat and processing the tissue for tetramethylbenzidine reaction product (Mesulam '78). WGA-HRP positive neurons are found primarily within visual cortical areas 17, 18, 19, 21A, the ectosylvian visual area (EVA), the splenial visual area (SVA) and the suprasylvian areas (i.e., AMLS, ALLS, PMLS, PLLS, DLS and VLS). Labeled neurons are also found within area 7, the insular cortex and the cingulate cortex. The majority of labeled neurons are located within layer V; however, a substantial number of labeled neurons are observed within layer IV, with a few scattered cells located within layer VI. Labeled revenues restricted to layer V are found only within area 7 and the EVA. Within the insular and cingulate cortices, labeled neurons are also present within the supragranular layers; i.e., layers II and III. The shape, size and number of labeled neurons vary considerably among different cortical areas. For example, while the predominant labeled cell type is pyramidal within all areas examined, labeled stellate-like cells are also seen primarily within areas 17, 18, DLS and VLS. The lateral suprasylvian areas contain the part hotorecome conviction of labeled neuronidal contain the most heterogeneous population of labeled pyramidal cells, ranging from the smallest to the largest and exhibiting a great variety of different cell shapes. The insular and cingulate cortices contain only small to medium-sized labeled pyramidal neurons within the supragranular as well as the infragranular layers; within area 7, only medium-sized pyramidal cells are labeled. These data are not in agreement with the traditional view that the cortical projection to the superior colliculus originates only from pyramidal neurons located in layer V. In fact, these results clearly demonstrate that the cells of origin of the corticocollicular projection are not confined to any single cortical lamina or cell type. RECEPTIVE FIELD PROPERTIES OF CORTICOTECTAL CELLS IN VISUAL 14.10 AREAS 1 AND 2 OF THE RABBIT. T.G. Weyand and H.A. Swadlow. Dept. Psychology, U-20, University of Connecticut, Storrs, CT

The receptive field properties of neurons which project to the superior colliculus (CT cells) from visual cortical areas 1 and 2 (V1, V2), were studied in the awake, unparalyzed rabbit. 1 and 2 (V1, V2), were studied in the awake, unparalyzed rabbit. CT cells were identified by antidromic activation following electrical stimulation of the superior colliculus. Antidromic latencies in V1 (median = 2.29 msec) and V2 (median = 2.14 msec) were quite similar. Receptive field properties of CT cells in V1 (27 cells) and V2 (12 cells) were classified according to the scheme of Murphy and Berman (J. <u>Comp. Neurol.</u>, 188: 401, 1979). The primary feature distinguishing CT cells in V1 from those in V2 was receptive field size; the mean receptive field diameter (major axis + minor axis/2) of CT cells was  $4.6^{\circ}$  in V1 and  $25.0^{\circ}$ in V2 (6 < 001) In other respects the recentive field arometrics (major axis + minor axis/2) of CT cells was  $4.6^{\circ}$  in V1 and 25.0° in V2 (p <.001). In other respects the receptive field properties were remarkably similar. Twenty-four CT cells (16 in V1 and 8 in V2) were classified as complex, and 5 of these displayed end-stopping. Thirteen neurons (10 in V1 and 3 in V2) were movement neurons and 6 of these displayed end-stopping. Two neurons (1 in V1 and 1 in V2) were obviously directional but were not orienta-tion selective. Sharp orientation tuning was not observed among any complex CT cells and 9 of 13 of these cells displayed little, if any, spatial summation. While most CT cells would respond to stimuli over a broad range of velocities, some cells would respond nearly to stimuli maving  $\frac{10}{20}$  (see while other cells

stimuli over a broad range of velocities, some cells would respond poorly to stimuli moving < 10 /sec while other cells responded poorly to stimuli moving > 30 /sec. Ninety-three additional cells were classified in V1 (78 cells) and V2 (15 cells). Although 42 simple cells were observed in V1, none were CT cells. On several occasions, a simple cell was found between two CT cells in a single penetration. With the exception of CT cells and a special type of movement cell, neurons in V2 were very difficult to reliably drive with visual stimulation. These results suggest that the CT cells in each representation project information about the identical visual events; the only difference being that the individual V2 CT cell has access to a larger region of the visual field than each V1 CT cell.

14.11 THE LATERAL SUPRASYLVIAN CORTICOTECTAL PROJECTION IN CATS. R.L. EGAL\* & R.M. BECKSTEAD (Spon: D.A. Keefer), Dept. of Anat., Univ. of Virginia Schl. of Med., Charlottesville, VA 22908. The lateral suprasylvian area (LS) of the cat cortex has a significant influence on the visual responsiveness of neurons in the deep layers of the superior colliculus (SC) and appears to be the deep layers of the superior colliculus (SC) and appears to be necessary for the normal performance of some visually guided tasks. In an earlier abstract (Segal <u>et al.</u>, Neurosci. Abstr., <u>8</u>:191.3, 1982), we showed by the retrograde transport of wheat germ-HRP (WGA-HRP), that all portions of the LS project to the deep layers of SC. To confirm and extend these findings, we used the anterograde transport of either <sup>3</sup>H-amino acids (for autoradio-graphy) or WGA-HRP from single zones of LS, or a combination of these two tracers from various LS zones. Examination of terminal distributions in SC in several such cases indicates both an areal and a laminar organization of the LS projection to SC.

Tracer deposits within any zone of the LS (anterior and poster-ior subdivisions of the medial and lateral banks and the dorsal and ventral subdivisions of the caudal suprasylvian sulcus) result in an intracollicular distribution of labeled axons that is typic-ally most concentrated in the stratum opticum (SO) with an irregular and progressively diminishing amount of label both dorsally in the superficial gray layer (SC) and ventrally in the intermediate gray layer (IG). The densest concentration of terminal labeling occurs in the dorsal SO after injections along the medial bank of the LS and is located more ventrally in SO after injections along the lateral bank. Similarly, the lateral bank projection tends to be biased preferentially toward IG and the medial bank towards SG. An outstanding exception to this general feature, is that labeled axons from the approximate border region of the anterior and post-erior subdivisions of the lateral bank of the LS reach IG and the deep gray and white layers of SC as well as the lower portion of so.

The areal distribution within SC presents a more complex pattern than the laminar organization. The anterior subdivision of the medial bank projects primarily to the rostral two thirds of the lateral SC. The posterior subdivision can be further sub-divided into rostral and caudal portions, which project respect-ively to the caudal and the rostral SC. The posterior subdivision of the lateral bank can be further subdivided into rostral, intermediate and caudal portions with the rostral and caudal portions mediate and caudal portions with the Postral and caudal portions projecting to the <u>rostral</u> SC and the intermediate portion project-ing to the <u>caudal</u> SC. In a single case involving the caudal LS (dorsal and ventral subdivisions), the label is confined to the rostral SC. Curiously, all regions of the LS project to the lateral two thirds of the SC, but only the posterior subdivision of the lateral bank appears to project to the medial SC. Supported by NIH Grant NS 11254.

14.12 Y-CELL INPUTS TO THE LATERAL SUPRASYLVIAN AREA: A SUBSTRATE Y-CELL INPUTS TO THE LATERAL SUPRASYLVIAN AREA: A SUBSTRATE FOR Y-INDIRECT INFLUENCE ON THE DEEP SUPERIOR COLLICULUS. David M. Berson\* (SPON: J.T. McIlwain), Section of Neurobiology, Div. of Biol. and Medicine, Brown University, Providence, RI 02912 Retinal Y-cells provide excitatory input to most cells of the cat's deep collicular layers by way of a polysynaptic pathway involving the visual cortex (Berson and McIlwain, J. Neurophysiol. 47, 1982; Berson, Soc. Neurosci. Abstr. 8, 1982). Results of the present study indicate that the posteromedial lateral suprasylvian area (PMLS) may relay some of this indirect Y-cell influence. influence.

Cats were anesthetized with ketamine, nitrous oxide and/or Cats were anesthetized with ketamine, nitrous oxide and/or barbiturates and, in some instances, also paralyzed and artificially ventilated. Units recorded in the medial inter-laminar nucleus (MIN) of the lateral geniculate complex could be activated antidromically by electrical stimulation in ipsilateral PMLS (latencies 0.4 - 1.4 ms; n=12). The same cells could also be driven orthodromically from the optic disk (OD) and optic chiasm (OX) at latencies comparable to those previously reported for geniculate Y-cells (OD: 1.2 - 2.1 ms,  $\bar{X}$ = 1.7 ms, n=8; OX: 0.9 - 1.4 ms,  $\bar{X}$ = 1.2 ms, n=10). Units in PMLS could be driven by OD and OX shocks, often at latencies short enough to suggest monosynaptic input from

Units in PMLS could be driven by OD and OX shocks, often at latencies short enough to suggest monosynaptic input from geniculate Y-cells (OD:  $1.9 - 7.2 \, \text{ms}, \bar{X} = 4.2 \, \text{ms}, n=42; OX: 1.6 - 6.3 \, \text{ms}, \bar{X} = 3.8 \, \text{ms}, n=42).$  For 95% of cells (40/42), responses following OD and OX shock differed in latency by less than 0.9  $\,\text{ms}$ , indicating involvement of rapidly conducting (>25  $\,\text{m/s}$ ) Y-cell axons. Units in PMLS could be activated antidromically from the superior colliculus (latency 0.5 - 6.4  $\,\text{ms}, n=32$ ), and some of these could also be driven orthodromically with OD-OX latency differences characteristic of Y-cell influence. These results indicate that some cells in PMLS projecting to the superior colliculus receive Y-cell input, probably via MIN. Since deep tectal cells are activated at short latencies by electrical stimulation in PMLS (Berson and McIlwain, submitted), it is proposed that the prominent indirect Y-cell influence observed previously in the deep tectum is mediated, in part at least, by a pathway through MIN and PMLS.

14.13 EXCITATORY AND INHIBITORY INFLUENCES OF STRIATE AND EXTRASTRIATE

EXCITATORY AND INHIBITORY INFLUENCES OF STRIATE AND EXTRASTRIATE CORTEX ON SUPERIOR COLLICULUS CELLS. K. Ogasawara\*, J.G. McHaffie\* and B.E. Stein. (Spon: R. Clemo) Dept. Physiol & Biophys, Medical College of Virginia, Richmond, VA 23298. Visual Corticotectal projections originate from areas 17-18 and the posterior suprasylvian cortex (PSSC). The present experiments were initiated to determine whether their influences on superior colliculus (SC) cells were similar. Thirty adult cats were used in these studies. Each was anesthetized with a single dose of sodium pentobarbital (35 mg/kg), then paralyzed and artificially respired with N<sub>2</sub>O (75%) and O<sub>2</sub> (25%). Once a cell ifn the SC was isolated, its receptive field was mapped and its response properties were determined. The optimal stimulus was then presented 16 times successively, and evoked dis-charges were counted and displayed as rasters and histograms. One of the cortical areas (e.g. PSSC) was then deactivated by cooling it to 12C with a cooling probe, and the same tests were repeated. The area was then rewarmed and the tests were run once again. The entire series was repeated with the second area (eg 17-18) cooled and then rewarmed. The majority of the cells studied had recep-tive fields within the central 30° of the visual field. Regardless of the cortical area cooled, binocular cells (2/22). The loss of normal cortical input to SC cells was apparent as a depres-sion of the responsiveness of these cells during cortical cooling, and was most dramatic on SC cells that were both binocular and di-rectionally selective. Deactivation of area 17-18 profoundly de-pressed all (n=41) the superficial lamina (stratum opticum and above) cells studied. However, cooling PSSC affected only 60% of these cells and did so by producing only a slight response decre-ment. On the other hand, all deeper layer cells (n=29) were prothese cells and did so by producing only a slight response decre-ment. On the other hand, all deeper layer cells (n=29) were pro-foundly depressed by cooling PSSC, but none was obviously affected by cooling 17-18.

by cooling 1/-18. In a second series of experiments, area 17-18 or PSSC remained cooled while visually responsive SC cells were sought in 62 elec-trical penetrations. Comparatively few responsive superficial layer cells were encountered when 17-18 remained cooled (n=2) and few deeper layer cells were found when PSSC remained cooled (n=4). Yet the cells that were visually responsive during cortical cooling exhibited response depression when cortex was rewarmed. This con-

Yet the cells that were visually responsive during cortical cooling exhibited response depression when cortex was rewarmed. This con-firms earlier speculations that at least some SC cells normally re-ceive suppressive corticotectal influences. From a functional standpoint, the present study suggests that superficial layer cells depend upon excitatory and/or inhibitory inputs primarily from 17-18, whereas deeper layer visual cells de-pend upon corticotectal inputs from PSSC but not from 17-18. Supported by Grants EY04119 and BNS-8209857.

ALTERATIONS OF RESPONSE PROPERTIES IN THE CAT ACCESSORY OPTIC SYSTEM FOLLOWING VISUAL CORTEX LESIONS. Keith L. Grasse and Max S. Cynader. Dept of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1. 14.15 Scotia, Canada B3H 4J1.

The response properties of cells in the lateral (LTN) and dorsal (DTN) terminal nuclei of the accessory optic system (AOS) were examined in 14 cats which underwent unilateral visual cortex ablation. Following decortication, single units in the LTN and DTN ipsilateral to the cortical lesion no longer showed the high degree of binocular convergence characteristic of the intact anidegree of binocular convergence characteristic of the intact ani-mal. Instead LTN and DTN units became almost completely dominated by the contralateral eye. In addition, responsivity of LTN and DTN cells to high stimulus velocities was abolished by removal of cortical input. This decrement in high velocity response was evident in both the excitatory and the inhibitory components of the velocity response profile. While decortication did not reduce the incidence of direction selective units in either the LTN or the DTN the distribution of preferred and non-preferred direct the DTN, the distribution of preferred and non-preferred direc-tions was dramatically altered in the LTN, and to a lesser extent in the DTN. In the LTN, this change in distribution of preferred and non-preferred directions was expressed as a reduction in the incidence of LTN cells which displayed maximal excitation for upward stimulus motion. In contrast to the distribution of direc-tion selective LTN cells observed in normal cats, where approximately equal numbers of upward and downward preferring units were found, most LTN units recorded in the decorticate animals pre-ferred downward-directed stimulus motion. In the DTN of the decorticate cat, the majority of direction selective units still preferred horizontal (temporal-masal) stimulus motion as in the intact preparation, but the overall distribution of preferred directions displayed a significant downward-going vertical com-ponent when compared to normal. Other response properties, such as receptive field size and position in visual space, or preference for large textured stimuli, appeared unaffected by cortical lesions.

The results of these experiments, together with anatomical in-vestigations which have demonstrated that the visual cortex provides a large and diffuse afferent projection to the cat AOS (Berson and Graybiel <u>Neurosci</u>, 5:2203, 1980, Marcotte and Updyke <u>Brain Res.</u>, 242:205, 1982), strongly suggest that cortical input to the cat AOS plays a highly significant role in the formation of response properties of cells in the LTN and DTN. In particular, the visual cortex provides a major source of ipsilateral eye input, high velocity responses, and upward direction selectivity for the AOS nuclei examined in these experiments.

## CORTEX AND CORTICO-SUBCORTICAL RELATIONSHIPS I

15.1 DIFFERENCES IN THE SPATIAL ORGANIZATION OF MITRAL AND TUFTED CELL INTRINSIC AND EFFERENT CONNECTIONS IN THE HAMSTER. <u>T.A. Schoen-</u> feld and F. Macrides. Worcester Foundation for Experimental Biolfeld and F. Macrides. Wor ogy, Shrewsbury, MA 01545. ōgy,

ogy, Shrewsbury, MA 01545. Classes of output neurons in the main olfactory bulb (MOB) are known to differ morphologically in several ways, including in (a) the length, laminar distribution, symmetry and degree of branching of dendrites, (b) the degree and distribution of intrinsic axon collaterals, and (c) the distribution of axonal projections to different regions of the olfactory cortex. We recently discovered some additional morphological distinctions among MOB output neur-ne and their interioric and contral circuits. Some additional morphological distinctions among MOB output neur-ons and their intrinsic and central circuits, using axonal trans-port of wheat germ agglutinin-HRP. External and middle tufted (Te and Tm) cells were found to make intrinsic axonal connections that project topographically and reciprocally between medial and later-al sectors of the MOB. To our knowledge, this is the first report of extensive intersector connections intrinsic to the MOB. The deeper-lying, internal tufted (Ti) and mitral cells do not appear to make such intersector connections; their intrinsic interactions are dominated by intrasector lateral and reciprocal synaptic con-tacts between their dendrites and the processes of interneurons. The Te cells were found to be the only class of output neuron to project no further caudally than pars externa (pE) of the anterior olfactory nucleus. Moreover, efferent projections to pE by Te cells, and possibly by the other output neurons awell, are topo-graphically organized. A topographic pattern in turn is seen in the efferent projections of pE to homotopic sectors of the contra-lateral MOB. In contrast, the long-projecting axons of mitral and Ti cells appear to collateralize in widely dispersed regions of alfactory overter without a cloar score records transpresed. Tateral MUB. In contrast, the long-projecting axons of mitral an Ti cells appear to collateralize in widely dispersed regions of olfactory cortex without a clear sector-to-sector topography. Thus, superficial (Te and Tm) cells engage in extensive intra-bulbar and, through projections to pE, interbulbar axonal projec-tions that appear roughly analogous to associational and commis-sural projection systems in neocortex arising principally from superficial pyramidal cells, whereas the axonal connections of door (mitral and Ti) colls are demiated by long projections to deep (mitral and Ti) cells are dominated by long projections to extrabulate of a construction of the set of the projection of the long neocorticofugal systems that arise principally from deep pyramidal cells. Such similarities to neocortical organization belie the characterization of the olfactory bulb as a "simple" cortical system. We propose that the mitral and tufted cells and their intrinsic and central circuits may be organized as functionally defined parallel pathways.

15.2 GRID PATTERN OF LAYER V EFFERENT NEURONS OF MOUSE BARREL FIELD CORTEX. J.E. Crandall, M. Korde\* and V.S. Caviness, Jr. Dept. Neurol. and Dept. Neuropath., M.G.H. and E.K. Shriver Ctr., Boston, MA 02114

Topologically ordered efferent systems with multiple, widely separated targets arise from layer V of parietal and frontal fields, corresponding to SI and MI representations of rodent neocortex. The present study is an analysis in the adult mouse of the relative distribution of cell bodies of origin of multiple systems efferent from these cortical regions. The analysis is based upon serial 50 um sections in the tangential plane following injections of HRP into selected target regions (superior colliculus, pons and cervico-medullary junction). For each system, efferent neurons labelled retrogradely by transport of HRP are mapped as registered with outer, middle and inner areal thirds for each of barrels 2-4 in rows C and D of the posterior medial barrel subfield (PMBSF) or SI representation of the parietal cortex and within an equivalent area of the MI representation of the frontal cortex.

Neurons are distributed uniformly throughout layer V in these areas of cortex. Efferent neurons labelled retrogradely with areas of cortex. Efferent neurons labelled retrogradely with HRP in both fields represent no more than 5-20% of the total population of the layer. In general nearest neighbors of labelled cells are not labelled by this method. In MI cortex labelled neurons are distributed diffusely among the nonlabelled neurons. In the PMBSF cortex, by contrast, labelled cells efferent to each subcortical target area are in register preferentially with the periphery or wall not the center or hollow of the bergel hollow of the barrel.

The set of observations suggests that layer V is an efferent mosaic where the mosaic units are single rather than groups of cells. In the barrel field, neurons of subdiencephalic projection are distributed in a grid pattern which appears to be the complement to the specific thalamic afferents relaying sensory information from the contralateral mystacial vibrissal pad.

OPTICAL MONITORING OF NEURON ACTIVITY IN RAT SOMATOSENSORY AND 15.3

OPTICAL MONITORING OF NEURON ACTIVITY IN RAT SOMATOSENSORY AND VISUAL CORTEX. H.S. Orbach, L.B. Cohen, A. Grinvald, and R. Hildesheim<sup>\*</sup>. Dept. of Physiology, Yale Univ. New Haven, CT 06510, and Dept. of Neurobiology, Weizmann Inst., Israel. We investigated the use of voltage sensitive dyes to monitor neuron activity in rat cortex. The fluorescence from 96-124 areas of cortex stained with styryl or oxonol dyes was measured simultaneously by projecting an image of the cortex onto a diode array. To reduce noise from movements related to the heart beat the trials were triggered by the electrocardiogram and the re-sults of a trial without a stimulus were subtracted from the results of the preceeding trial with a stimulus. The figure illustrates the outputs from a portion of the array from a measurement from somatosensory cortex stained with dye

The figure illustrates the outputs from a portion of the array from a measurement from somatosensory cortex stained with dye RH414 (similar to RH237, Grinvald et al., 1982). 128 trials were averaged. Each element received light from a 450x450 µm square area of cortex. The whisker Al was moved by 20 degrees at the time of the square pulse in the lower left trace. A ball-electrode recording is shown in the lower right trace. The transient increases in fluorescence, which we presume to repre-sent the average depolarization of the membranes imaged on the individual detectors, are localized in the middle of the field. The central responses are both larger and faster than responses on surrounding detectors. The diameter of the area that includes all signals that are greater than 50% of the largest signal was about 1800 µm in this experiment, larger than the diameter of the anatomical barrel measured at layer IV. When two whiskers, Al and D4 were stimulated, the areas of cortical response were clearly distinguishable. It was also possible to measure signals of similar size

FEATURES OF THE ORGANIZATION OF MACAQUE MONKEY VISUAL 15.5 CORTEX DEMONSTRATED WITH MONOCLONAL ANTIBODY CAT 301. S.H.C. Hendry, S.J. Hockfield, R.D.G. McKay and E.G. Jones. James L. O'Leary Division of Experimental Neurology and Neurological Surgery and McDonnell Center, Washington University School of Medicine, St. Louis, MC 63110 and Cald Series University School of Medicine, St. Louis, MO. 63110 and Cold Spring Harbor Laboratories, Cold Spring Harbor, NY 11724

Using a monoclonal antibody, CAT 301, generated against a homogenate of aldehyde-fixed cat spinal cord, we have identified a patchy distribution of labeled neurons in areas 17 and 18 of cynomolgus monkeys (Macaca fascicularis) that can be correlated with certain aspects of cortical organization. CAT 301 positive neurons in area 17 form densely stained bands in

layers IVB and VI. Other layers contain fewer cells. Both pyramidal and non-pyramidal cells are labeled. Within layers IVB and VI, patches, 100-300 microns in diameter, of closely clustered, heavily labeled neurons are separated by gaps containing fewer, more lightly labeled cells. The gaps vary in width from 150-500 microns. Most patches in layer IVB line up radially with those of layer VI. Smaller patches of labeled cells are present in layers II and III and many of these, particularly in layer III, also line up with the patches in the deeper layers. In the dorsal lateral geniculate, cells only in the magnocellular layers are heavily labeled by CAT 301.

In three monkeys ocular dominance columns were labeled either by monocular enucleation followed by cytochrome oxidase (CO) histochemistry or by monocular injection of 2mCi of <sup>3</sup>H-proline followed by autoradiography. The CAT 301 positive patches in layers IVB and VI of the three animals are associated with the middle of both ipsilateral

of the three animals are associated with the middle of both ipsilateral and contralateral eye dominance columns. Patches or "blobs" of CO staining in layers II and III are also related to CAT 301 positive patches. The CO patches in layers II and III ine up radially with CAT 301 positive patches of layers IVB and VI, and deep in layer III many CO patches and CAT 301 positive patches are coextensive. The relationship between CO patches and CAT 301 positive patches in the more superficiel layers is being investigated.

The relationship between CO particles and CAT soft positive particles in the more superficial layers is being investigated. In area 18 large (approximately 1mm) and small (200-300 microns) patches of CAT 301 positive neurons are present in layers III and V. The patches of labeled neurons overlap with most CO positive patches present in area 18 and at the 17/18 border.

These data suggest one or more as yet uncharacterized antigens recognized by a monoclonal antibody may be associated with neurons

receiving certain afferent inputs and with certain classes of physiologically distinct neurons in areas 17 and 18 of macaque monkeys. Supported by Grants NS17556, NS18040 and NS10526 from the National Institutes of Health and McDonnell Center for Studies of Higher Brain Function.

DIFFERENTIAL DISTRIBUTION OF NEURONS IMMUNOREACTIVE TO 154 MONOCLONAL ANTIBODY CAT 301 IN THE MAMMALIAN CEREBRAL CORTEX. E.G. Jones, R.D.G. McKay, S.J. Hockfield and S.H.C. Hendry. James L. O'Leary Division of Neurology and Neurological Surgery and McDonnell Center for Studies of Higher Brain Function, Washington Harbor Laboratories, Cold Spring Harbor, NY 11724. The distribution of neurons immunoreactive to a monocl

monoclonal The distribution of neurons immunoreactive to a monoclonal antibody, CAT 301, made by immunizing mice with aldehyde-fixed cat spinal cord was studied in the cerebral cortex of rats, guinea pigs, cats and macaque monkeys. Immunocytochemically labeled cells are present in all cortical areas, but the number of labeled cells varies markedly from species to species and area to area. In cat and monkeys the largest populations of CAT 301 positive cells are present in the primary motor area (area 4), the first somatic sensory area (SI) and the primary visual area (area 17). In most areas, CAT 301 positive cells are densely clumped in only 2 or 3 layers but the layers involved vary from one area to another. Because of the differences in the number and laminar distribution of CAT 301 positive cells, boundaries between many areas are readily apparent.

Several observations suggest that certain populations of cortical neurons are preferentially recognized by CAT 301: (1) laminar distribution of labeled versus unlabeled pyramidal cells suggests that neurons projecting to some targets are labeled but those projecting to other targets are not. Furthermore the vast majority of corticospinal neurons in monkey SI and area 17 and 18, suggesting a relationship to particular afferent systems; (3) differences among areas in the numbers of CAT 301 positive neurons suggests that the relevant antigen or antigens may be present on subsets of pyramidal and non-pyramidal cells with particular functional characteristics. Supported by Grants NS17556, NS18040 and NS10526 from the National Institutes of Health and McDonnell Center for Studies of

Higher Brain Function.

PERISTRIATE INPUT TO THE ENTORHINAL CORTEX FROM RETROCALCARINE 15.6 REGIONS IN THE MONKEY. C.L. Barnes, G.W. Van Hoesen and S.K. Itaya. Depts. of Anatomy and Neurology, Univ. of Iowa, Coll. of Med., Iowa City, IA 52242.

Med., Iowa City, IA 52242. Physiological studies have shown that hippocampal neurons respond to visual stimulation. It is likely these are mediated largely via cortical pathways that relay in the entorhinal cortex (area 28), the major source of cortical afferents to the hippocampal formation. Several potential multisynaptic pathways have been demonstrated anatomically in the monkey, and involve such structures as the amygdala, perirhinal cortex (area 35) and the posterior parahippocampal region (area TF). All receive input from the visual association cortices, such as areas TE and OA. and send afferents to the entorhinal and subjcular cortices. the posterior parahippocampal region (area IF). All receive input from the visual association cortices, such as areas TE and OA, and send afferents to the entorhinal and subicular cortices. We report here a more direct visual input to the entorhinal cortex in the monkey that arises from the cortex in the mouth of the calcarine fissure and the retrocalcarine peristriate area along its upper bank. These observations were made after ex-posing the ventromedial temporal cortex via a lateral surgical entry into the middle cranial fossa, and injecting horseradish peroxidase (HRP) into the entorhinal cortex. The tissue was processed according to Mesulam's tetramethyl benzidine proce-dure. In these experiments, neuronal labeling in the peri-striate cortex was confined largely to area OB, although neurons were observed in area OA, dorsal and ventral to the calcarine fissure. The labeling in area OB was located topographically in the anteriormost part of the calcarine fissure at levels coinci-dent with the end of the hippocampus and the formation of the atrium of the lateral ventricle. It involved cortex in the depths of the fissure, along its upper bank and its dorsal continuation along the medial surface of the hemisphere where it adjoins cingulate area 23 and dorsal area OB. In these loca-tion labeled neurons were deture within locar study confirmed its characterization as area OB. In these locations labeled neurons occured at variable depths within layer III, with only a few labeled neurons in other laminae. Despite the location of labeled neurons within the calcarine fissure, several factors mitigate against considering this cortex area OC or 17. First, it fails to meet the relevant cytoarchitectural criteria, second, it does not contain the pattern of cytochrome oxidase staining characteristic of area OC, and, third, it does oxidase staining characteristic of area OC, and, third, it does not receive direct lateral geniculate input as judged by the anterograde transneuronal transport of wheat germ agglutinin conjugated to HRP after intravitreal injections. Thus, the results represent a new and direct source of visual input to the entorhinal cortex from area OB. The anterior location of neu-rons in the calcarine region suggest a role in function related to peripheral vision. (Supported by Grant NS 14944 to G.W.V.H.)

PROJECTIONS TO THE FRONTAL CORTEX FROM THE POSTERIOR PARIETAL 15.7 PROJECTIONS TO THE FROMTAL CORTEA FROM THE POSTERIOR PARIETAL REGION IN THE RHESUS MONKEY. <u>M. Petrides and D. N. Pandya</u>. Dept. of Psychology and the Montreal Neurological Institute, McGill Univ., Montreal, Canada and V. A. Medical Center, Bedford and Boston Univ. Sch. of Med., Boston, Mass. A detailed examination of the projections to the frontal cortex from various subdivisions of the posterior parietal cortex in the phasus monkey has been carried out with the autocadiarphic tech

rhesus monkey has been carried out with the autoradiographic tech-nique. The results showed that the superior parietal lobule (rostral and caudal area PE) projects to the dorsal part of area 6. This projection extends from the border of areas 4 and 6 to the caudal bank of the upper branch of the arcuate sulcus (AS). The projections from the medial parietal cortex (areas PEc and PGm) are similar to those of the superior parietal lobule but they tend to concentrate in the more rostral part of dorsal area 6. Both the superior parietal lobule and the medial parietal cortex are connected with a discrete part of the medial surface of the frontal lobe that appears to correspond to the supplementary motor area. The more ventral part of the medial parietal cortex also

projects to area 8 in the concavity of the AS. The projections to the frontal lobe from the inferior parietal lobule (IPL) are somewhat more complex. The anterior part of the Inducte (IFE) are somewhat more complex. The anterior part of the IFE (area FF) projects to the ventral area 6 including the caudal bank of the lower branch of the AS, to the ventral area 46 below the sulcus principalis, and to a part of the cortex of the frontal operculum. The middle IFL (areas PFG and PG) projects to the ventral part of area 46 as well as to area 8. The projections ventral part of area 46 as well as to area 8. The projections directed to the ventral bank of the sulcus principalis appear to originate primarily from the more lateral parts of this region, whilst those directed to the part of area 46 lying below the sulcus principalis and to area 8 seem to originate from the more dorsal part of areas PFG and PG including the adjacant cortex lying in the lower bank of the intraparietal sulcus. The pos-teriormost IPL (caudal PG and area OPT) is connected with both

teriormost IPL (caudal Po and area OPI) is connected with both dorsal and ventral area 46 as well as dorsal area 8. The present investigation also showed that the frontal polar cortex (area 10) and the orbital frontal cortex do not receive projections from any of the subdivisions of the posterior parietal cortex.

DOUBLE LABELING OF PARAHIPPOCAMPAL EFFERENTS TO THE CINCULATE 15.8 GYRUS AND PARIETO-OCCIPITAL CORTICES IN THE MONKEY USING FLUO-RESCENT TRACERS. D.R. Brady, C.L. Barnes and G.W. Van Hoesen. Depts. of Anatomy and Neurology, Univ. of Iowa Coll. of Med., Iowa City, IA 52242.

The cortices of the posterior parahippocampal area (TF and TH) give rise to axons that terminate in all classes of cortex (allocortex, e.g., subiculum; periallocortex, e.g., ento-rhinal cortex; proisocortex, e.g., areas 23 and 24; isocortex, e.g., areas 7 and 19). Our aim has been to ascertain whether the neurons that underlie this connectional diversity are segregated into separate populations or whether this is sustained by axon collateralization from individual neurons. To initiate this, we have studied the posterior parahippocampal projections to the cingulate gyrus (proisocortical areas 23 and 24) and to the parieto-occipital area (isocortical areas 7 and 19) using both single and double labeling strategies. In five monkeys, tritiated amino acids (<sup>3</sup>H-leucine, lysine and proline) were injected into areas TF and TH and the brains were processed injected into areas TF and TH and the brains were processed for autoradiography. In four complementary experiments the retrograde tracers horseradish peroxidase (HRP) and fast blue were injected singly into either areas 23 and 24 or into areas 7 and 19. Lastly two monkeys received injections of two retro-grade tracers, with fast blue injected into areas 23 and 24, and nuclear yellow into areas 7 and 19. Survival time for the autoradiographic and fast blue experiments was 7 days, while a 2 days equivalent to areas 10 and nuclear valles while a 2 day survival was used for HRP and nuclear yellow. The single labeling experiments using tritiated amino acids, The single labeling experiments using tritiated amino actus, HRP and fast blue yielded complementary results and verified the fact that posterior parahippocampal areas TF and TH project to both the cingulate gyrus (areas 23 and 24) and to the parieto-occipital cortices (areas 7 and 19). The cells of origin for these projections were found in layers III, V and VI of areas TF and TH. An overall topographic difference was observed in double labeling experiments such that cingulate projections arose from more medial parahippocampal locations while the projections to the parieto-occipital area arose more laterally. However, over-lap was observed between the two. Of interest was the fact that a population of double labeled neurons that project to both the cingulate gyrus and the parieto-occipital area was observed the cingulate gyrus and the parieto-occipital area was observed in the vicinity of the region of overlap. In view of the fact that the lateral parts of the posterior parahippocampal area are isocortical, whereas the more medial parts are more pro-isocortical or "limbic" in structure, it is tempting to spec-ulate that via axon collateralization distinct populations of cortical neurons form an interface between both struc-turally and functionally diverse parts of the cortex. (Supported by Grant NS 14944 to G.W.V.H.)

PARAHIPPOCAMPAL PROJECTIONS TO POSTERIOR AUDITORY ASSOCIATION 15.9 PARAHIPPOCAMPAL PROJECTIONS TO POSTERIOR ADDITORY ASSOCIATION CORTEX (Tpt) IN THE MONKEY. D. Tranel\*, D.R. Brady, G.W. Van Hoesen, and A.R. Damasio\*. Depts. of Anatomy and Neurology, Univ. of Iowa Coll. of Med., Iowa City, IA 52242. Area Tpt is a distinctive cytoarchitecturally-defined part of the multiple of the second second

the auditory association cortex located at the confluence of the lateral and superior temporal sulci in the superior temporal gyrus. Lesions of this area in humans cause the distinctive and well-known language disturbance termed Wernicke's aphasia. In addition, area Tpt has been found to be significantly larger in the left hemisphere, a finding consistent with its role in lang-uage processing. A comparable area Tpt has been identified in uage processing. A comparable area Tpt has been identified in the rhesus monkey. The acquisition of language depends, in all likelihood, on the appropriate locking of associations between auditory information and information from other modalities (e.g., visual, somatosensory), in what may be best described as a language-devoted memory process. Considering the central role of the hippocampal system in memory, we hypothesized that direct anatomical pathways between regions of the hippocampal system and the auditory association contex must exist and are probably and the auditory association cortex must exist, and are probably demonstrable in even non-human primates. The brains of eight rhesus monkeys that had injections of tritiated amino acids (3Hleucine, lysine and proline) in various parts of the parahippo-campal gyrus (areas 28, 35, TF and TH) were studied. Using autoradiography, it was observed that both areas TF and TH pro-ject to the anterior auditory association cortices, but the more medial parts of the posterior parahippocampal cortices, includ-ing area TH, have extensive projections that course posteriorly to nearly the entire lateral extent of area Tpt. This observation was complemented by using the fluorescent retrograde tracer fast blue. Following the injection of this substance into area Typt, labeled neurons were observed in the medial part of the posterior parahippocampal cortices, and particularly, in area TH. This result is of some interest, since it has been shown that area TH in the monkey receives a major hippocampal output from the subicular cortices. Thus, along with previous results demonstrating superior temporal projections to the hippocampal cortices, our findings complete a reciprocal pathway that mediates a direct structural coupling between higher-order auditory association cortices and temporal structures known to play a role in memory. (Supported by Grant NS 14944 to G.W.V.H. & A.R.D.)

PRIMATE PREFRONTAL CORTEX PROJECTS TO THE REGION OF THE LOCUS 15.10 COERULEUS AND DORSAL RAPHE. Arnsten, A.F.T., Schwartz, M.L. and <u>Goldman-Rakic</u>, P.S.. Section of Neuroanatomy, Yale Medical School, 333 Cedar St., New Haven, CT 06510 The monoaminergic projections from brainstem to cortex have

the molecular interpretation of the rodent and primate. In contrast, the possibility of a reciprocal descending cortical projection to monoamine nuclei has been addressed less frequently. The substan-tia nigra appears to receive a widespread cortical innervation, (eg Br. Res. 117:423-435, 1976), whereas studies of cortical afferents to the locus coeruleus (LC) and midbrain raphe nuclei in the rat indicate that cortical projections to these monoamine nuclei may be restricted to the prefrontal cortex (PFC) (J. Comp. Neurol. 178:1-16, 1978; Br. Res. 122:229-242, 1977). We examined this issue further in the rhesus macaque by injecting anterograde tracers into PFC (principal sulcus and dorsomedial cortex) and nonPFC (parietal association cortex) areas. Injections of HRP or tritiated amino acids into the PFC areas resulted in anterograde labeling of the pontine central gray in the vicinity of the LC and the dorsal raphe. The labeling was densest at the anterior level of the ipsilateral LC, particularly surrounding the more ventrally-located cells. The projection extended medially to the dorsal raphe and ventromedially into the central superior raphe, but strikingly avoided the dorsal tegmental nucleus of Gudden. More posteriorly, the labeling became sparse and was present medial to the compact LC in a region where LC dendrites have been observed. Labeled fibers could be followed only as far as posterin levels of the LC, indicating that the PFC fibers terminated in the pontine central gray and were not in passage to more caudal areas of the brainstem. A contralateral projection to the LC-raphe region was also observed but was less dense than that to the ipsilateral central gray.

In contrast to the results with PFC areas, injections into the parietal association cortex did not result in anterograde labelng of the LC-raphe region. As parietal cortex shares most other PFC terminal fields, this negative finding is notable and sup-portive of a selective PFC innervation of the LC-raphe region.

Immunocytochemical analysis of the PFC terminal field revealed met-enkephalin- and Substance P-reactive fibers. These peptide neurons have been shown to synapse on LC cell bodies and dendrites in the rodent (Br. Res. 160: 387-400, 1979). Thus it is possible that the PFC influences LC neurons through indirect actions on peptide interneurons. The results from these anterograde tracing and immunocytochem-

ical experiments provide a morphological basis for PFC regulation of brain monoamine activity in the primate. Supported by MH38546, MH00298 and MH08641.

15.11 DISTRIBUTION OF THE NEURONS OF ORIGIN OF THE CORPUS CALLOSUM AND ANTERIOR COMMISSURE IN THE MARMOSET MONKEY (Callithrix jacchus). Marc L. Jouandet, Laurence J. Garey, and Hans-Peter Lipp. Institute of Anatomy, Unversity of Lausanne, Switzerland. The distribution of the neurons of origin of the great cerebral commissures of the marmoset monkey was investigated by means of Horseradish peroxidase (HRP) histochemistry. Large quantities of HRP were injected unilaterally throughout one cerebral hemisphere in order to label as many commissural neurons as possible in the contralateral hemisphere. The distribution of these labeled neurons was charted with the aid of a semi-automatic computer micro-scope. Six adult monkeys were used in this investigation: three were normal when subjected to the HRP injection operation; three others first underwent complete commissurotomy of the corpus callosum (CC), leaving the anterior commissure (AC) intact. Thus the

losum (CC), leaving the anterior commissure (AC) intact. Inus the three normals provided information on the origins of both the CC and the AC, whereas the three callosotomized monkeys allowed study (of the origins of the AC alone. All CC and AC neurons in the marmoset are pyramidal shaped. No columnar pattern is discernable for either the CC or the AC neur ons; rather, these cells are densely and continuously distributed in the various lamina tangential to the cortical surface. Except for layer I, all cortical layers can possess commissural cells. The laminar distribution of these neurons varies according to cortical region. The cortical field of origin of the AC of the marmoset is similar to that in the rhesus monkey (layer III pyramidal neurons in an extensive temporal neocortical field; Jouandet and Gazzaniga, 1979). Significantly, there exists in the marmoset a progressive reversal in quantitative predominance between supraand infragranular commissural neurons proceeding from the temporal pole, through the occipital cortex, through the parietal and into the frontal cortex. The predominance of infragranular neurons in portions of the parietal and frontal cortices of the marmoset dif-fers greatly in organization from the prevailing laminar pattern seen in the cat. In the cat, commissural neurons present in Seen in the cat. In the cat, commissing neurons present number over supragranular layers almost invariably predominate in number over the commissural neurons in the infragranular layers (Jouandet, Lachar, and Garey, in preparation). The major acallosal zones are found in the primary visual cortex, and the fore and hindlimb representations of the somatosensory cortex. Correlations between representations distributions and provide due door the detteen commissural neuron distributions and previously described cytoarchetectonic areas are not obvious.

COCHLEA

POTASSIUM-INDUCED CHANGES IN THE LEVELS OF ENDOGENOUS AMINO ACIDS OF GUINEA PIG PERLIVIER, <u>G. L. Jenison and R.P. Bobbin</u>, Kresge Hearing Research Laboratory of the South, Dept. of Otorhinolaryngology, L.S.U. Medical Ctr., New Orleans, 70119 Among those studies intended to characterize the afferent neurotransmitter produced by cochlear hair cells, several have attempted to detect a stimulus-induced release of putative amino acid candidates in perilymph. Sound has proven effective only in elevating levels of  $\beta$ -alanine, and a  $\gamma$ -aminobutyrate-like substance (D.G. Drescher, ARO Midwinter Abstr. #116, 1982), however, neither  $\beta$  -alanine nor  $\gamma$  -aminobutyrate have any significant effect on cochlear potentials when delivered to perilymph. Therefore, we have chosen to examine the depolarizing influence of elevating potassium levels on the concentration of amino acids to perilymph.

Guinea pig cochleae were perfused with artificial perilymph (s. tympani + s. vestibuli, 2 µL/min.) through ports cut in their basal turn, after occlusion of the cochlear aqueduct. Trials began with a 40 minute perfusion period, during which natural perilymph was replaced with artificial perilymph. natural perilymph was replaced with artificial perilymph. Samples were then collected during sequential perfusions of artificial perilymph containing 5 mM KCl (NORMAL), then 50 mM KCl (HIGH K<sup>+</sup>) and finally 5 mM KCl (NORMAL). Amino acid levels for each sample were then determined by Dr. R. Thalmann of Washington U. School of Medicine using OPA derivatization followed by HPLC coupled with fluorescence detection.

Preliminary results (n=6) indicate significant (P(0.01)) increases in four primary amine peaks which temporally correlated with the perfusion of HIGH K<sup>+</sup>. In all four cases, baseline concentrations were reestablished with subsequent perfusion of NORMAL. Glutamate levels rose from a mean baseline concentration of 0.41  $\mu$ M to a mean peak value of 0.68  $\mu$ M within 20 minutes after exposure to HIGH K<sup>+</sup>. Concentration increases were also noted for aspartate (0.23 + 0.38  $\mu$ M) and tryptophan (0.74 + 1.27  $\mu$ M) within 30 minutes after exposure to HIGH K<sup>+</sup>. The fourth peak, consisting of the three co-eluting compounds: taurine,  $\gamma$ -aminobutyrate and  $\alpha$ -aminobutyrate (R. Thalmann et al., Laryngoscope, 92: 321, 1982), increased by about 60% within the first 20 minutes of exposure to HIGH K<sup>+</sup>. Unlike glutamate, however, this peak continued to grow over the following 10 minutes to approximately twice its original value. All other amino acids identified either decreased in concentration or remained unchanged. In view of the above mentioned co-elution problem, modified separation techniques capable of resolving relative taurine,  $\alpha$ -and  $\gamma$ -aminobutyrate concentrations are currently being employed. [Supported by N grants NS-06575, NS-16080, NS-07058 and NSF grant BNS-8118772].

16.2 RESPONSE PROPERTIES OF SINGLE COCHLEAR AFFERENT NEURONS ALTERED BY RAISED PERLLYMPHATIC MAGNESIUM CONCENTRATION. J.H. Siegel and E.M. Relkin\*. Auditory Physiology Lab./ Dept. of Neurobiology BY RAISED PERILYMPHATIC MAGNESIUM CONCENTRATION. J.H. Siegel and E.M. Relkin<sup>\*</sup>. Auditory Physiology Lab./ Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201. Divalent calcium antagonists of presynaptic transmitter release such as Mg<sup>++</sup>, Co<sup>++</sup> and Mn<sup>++</sup> have been shown to inhibit

spontaneous and sound-evoked activity of single cochlear affer-ent neurons (Robertson and Johnstone, <u>Pflugers Archiv.</u> <u>380</u>:7-12, 1979). We have developed a technique for continuously perfusing scala tympani while simultaneously recording from single units Scala sympanic while simultaneously recording from single units in the eighth nerve of adult chinchillas (Siegel and Relkin, <u>ARO Abstracts</u>, <u>6</u>:49-50, 1983). We are using this system to study mammalian synaptic transmission <u>in vivo</u>. Raising the magnesium concentration in the perfusate to <u>6</u> mM while holding calcium constant at 1.5 mM elevates single-unit threshold at all frequencies of the accustic stimular and reducer frequencies of the acoustic stimulus and reduces spontaneous activity to near zero. The maximum discharge rates are also reduced. Preliminary results from PST histograms for tone-burst show a greater reduction of the onset than the stimuli steady-state response, at a given stimulus level, with increased magnesium concentration. The change in shape of the PST response with elevated magnesium is thus quite similar to the effect of reducing the level of the acoustic stimulus when the perilymph contains normal calcium and magnesium concentrations. All these effects are fully reversible on return to control perfusate.

Our observations that cochlear microphonics and ear-canal acoustic distortion products are substantially unaltered by elevated magnesium suggest that the principal effect is on the presynaptic release of transmitter by the hair cell. Interspike presynaptic release of transmitter by the hair cell. Interspike interval histograms are evaluated to investigate possible ef-fects on the excitability of the postsynaptic neuron. This system thus appears to be well suited to the study of synaptic mechanisms in a sensory organ where a controlled and graded stimulus can be delivered and extracellular fluid composition can be varied effectively. 16.3 THE IMPORTANCE OF MEASUREMENT ERROR ON PARAMETER ESTIMATION FOR MODELS OF COCHLEA ELECTROANATOMY. B. N. Sabowitz\*, A. E. Hubbard\* and D. C. Mountain\* (SPON: M. Feldman). Depts. Otolaryngology, Biomedical Engineering, Electrical,Systems and Computer Engineering. Boston University. Boston, MA, 02215.

Computer Engineering. Eccard MA, 02215. Modeling of cochlear electroanatomy is of interest both as an aid to understanding cochlear electrophysiology and as a tool to predict current flows resulting from cochlear prosthetics. Parameters for these models are calculated from experimental measurements which are subject to a variety of potential errors. The present study examines the sensitivity of the model parameters to measurement error.

The measurement error. Johnstone et al. (1966) presented experimental data which allowed calculation of parameters for a purely resistive cross-sectional model of the cochlea. A review of this model and a sensitivity analysis of the determination of each resistance branch due to errors in voltage measurements will be presented. Results indicate that even for reasonable measurement errors (< 5%), derived values can vary by 100 % or more. In addition, simulations account for the occasional result of negative resistance branches as reported by Johnstone et al. The sensitivity of this model to voltage measurement errors sheds doubt on the ability to characterize parameters accurately unless measurements are performed in a judicious fashion. If one assumes that the measurements are highly accurate and that measurement errors are the result of damage caused by moving electrodes, the model allows one to predict the sequence in which electrodes may be placed in order to maximize the accuracy of derived model parameters.

16.5 THE RELATION BETWEEN THE ENDOCOCHLEAR POTENTIAL AND THE SPONTANEOUS DISCHARGE RATE OF AUDITORY NERVE FIBERS IN THE CAT FOLLOWING FUROSEMIDE ADMINISTRATION. <u>William F. Sewell</u>. Eaton-Peabody Laboratory of Auditory Physiology, Massachusetts Eye and Ear Infirmary and Harvard Medical School, Boston, MA. 02114

The intravenous administration of furosemide produces concomitant decreases in the endocochlear potential and in the spontaneous discharge rate of auditory nerve fibers. By simultaneously measuring the endocochlear potential and auditory nerve spontaneous discharge rate in the same ear, following an intravenous injection of furosemide, the quantitative relation between the endocochlear potential and the spontaneous discharge rate was established.

Following furosemide administration the logarithm of the spontaneous discharge rate was proportional to the endocochlear potential. The slope of this logarithmic relation increased as a function of the characteristic frequency of the fiber. The slope of the logarithmic relation is steeper for fibers with "medium" spontaneous discharge rates (0.5 - 12 spikes per second) than for fibers with "high" spontaneous discharge rates ( >18 spikes per second). Among "high" spontaneous rate fibers, there is no strong correlation between the slope and the spontaneous discharge rate of the fiber.

The decrease in the spontaneous discharge rate in auditory nerve fibers is interpreted as follows: (1) the injection of furosemide causes a decrease in the endocochlear potential; (2) a decrease in the endocochlear potential produces a linearly related decrease in the membrane potential of the hair cell; and (3) the rate of release of transmitter quanta decreases logarithmically with a change in the membrane potential of the hair cell, which decreases the rate of occurrence of action potentials in VIIIth nerve fibers. 16.4 HYSTERETIC EFFECTS IN THE COCHLEAR MICROPHONIC,

A HISTERETIC EFFECTS IN THE CONTERNANT (ROCPHONIC), D. C. Mountain, A. E. Hubbard, and T. A. <u>McMullen</u> (SPON: R. Holub). Depts. of Otolaryngology, Biomedical Engineering, and Electrical, Systems, and Computer Engineering, Boston University, Boston, MA 02215. The cochlear microphonic (CM) recorded from

The cochlear microphonic (CM) recorded from scala media of both gerbils and guinea pigs was studied for various sound pressure levels. The data was plotted as Lissajous figures with the xaxis corresponding to estimated basilar membrane displacement. At low and moderate sound pressure levels the resulting curves were similar to the transducer transfer characteristics reported by Hudspeth and Corey (Proc. Natl. Acad. Sci. USA, 74: 2407-2411, 1977) for frog saccular hair cells. A linear region about the origin and asymmetric saturation were noted. For higher input levels a pronounced hysteresis appeared. The major finding is that the negative-going slope of the CM becomes significantly steeper than the positive-going slope. The positive-going slope appears to be more sensitive to sound level than the negative-going slope. Qualitatively, the findings were identical in both species. Computer simulations of several alternative

In both species. Computer simulations of several alternative models will be compared to the experimental data. These models include the effects of two populations of hair cells, effects of cochlear electro-anatomy, and transducer-channel opening and closing times.

16.6 ORGANIC ACIDS ATTENUATE COCHLEAR EFFECTS OF FUROSEMIDE. L.P. Rybak, C. Whitworth\*, L. Wright\* and T. Morizono\*. Depts. of Surgery and Pharmacology, SIU School of Med., Springfield, IL 62708

A number of epithelial systems concerned with fluid transport possess organic acid pumps powered by aerobic metabolism. Such systems include kidney, eye, liver and choroid plexus. It is unknown whether the cochlea has an organic acid pump to control the local fluid balance.

the local fluid balance. Furosemide is an ototoxic loop diuretic which is actively taken up by an organic acid pump in the renal tubule (Odlind, B., J <u>Pharmacol Exp Ther</u> 208:515, 1979). Its mechanism of ototoxicity is unknown. The possibility exists that furosemide ototoxicity may be mediated in part by an organic acid uptake system in the cochlea. The purpose of this series of experiments was to investigate the effect of several inhibitors of organic acid transport on furosemide ototoxicity.

Transport on furoscenide ototoxicity. Chinchillas weighing 400-600 gm were divided into several groups. Each animal was anesthetized with ketamine 45 mg/kg IM followed by pentobarbital 30 mg/kg IM. A femoral vein was cannulated for drug administration. Cochlear function was monitored by placement of a microelectrode into the scala media through the basilar membrane to continuously monitor the endocochlear potential (EP) over several hours. Control animals received 0.5 ml of normal saline IV followed in thirty minutes by furosemide 25 mg/kg IV. Experimental animals were similarly transport inhibitor in the same volume as the controls followed by furosemide.

by furosemide. A series of organic acid transport inhibitors significantly reduced the EP decline produced by furosemide. Probenecid (50 mg/kg) was more effective than novobiocin (50 mg/kg). Diatrizoate (150 mg/kg) was the least effective in altering the furosemide related drop of the EP. An inhibitor of organic base transport, N-methylnicotinamide (50 mg/kg) had no effect on the furosemide-induced drop of the EP. These findings suggest that at least part of furosemide ototoxicity may be mediated by organic acid transport. 167

inner-hair-cell (IHC) and outer-hair-cell (OHC) The

The inner-hair-cell (IHC) and outer-hair-cell (OHC) subsystems in the cochlea and the brainstem. D.O. Kim, Dept. of Physiol. & Biophys., Washington University Medical School, St. Louis, MO 63110 Comparative neuroanatomy of IHC and OHC of the mammalian cochlea has been well documented: (1) They have prominent differences in their morphology; (2) They are selectively innervated in distinct ways by distinct neural populations for both afferent and efferent innervations; and (3) There are about four times as many OHCs as IHCs but the OHCs receive only about 5% of the total afferent neurons. Functional roles played by the IHC and OHC have not been well understood, and the marked underrepresentaion of the OHC in the afferent neural populations has been particularly puzzling. We propose and review evidence for the following set of hypotheses: (1) There are two distinct auditory subsystems in the cochlea-bundle (OCB) neurons of Warr (1978) with axons projecting to the IHC region, and (b) the "OHC subsystem" consisting of OHCs and neural populations receiving input from IHCs; This subsystem includes the large OCB neurons of Warr with axons synapsing on OHCs; (2) The OHC has active bidirectional transduction mechanism in the stereocilia and cuticular plate region which reduces the net mechanical damping of Corti's organ, even to negative damping under certain conditions; and (3) The function of the OHC subsystem is to actively enhance the net mechanical damping of Corti<sup>1</sup>s organ, even to negative damping under certain conditions; and (3) The function of the OHC subsystem is to actively enhance and control the sensitivity and tuning of the motion of the whole Corti's organ by regulating release of mechanical energy in the "motor function" of OHC, thereby confering high sensitivity, sharp tuning and wide dynamic range to the IHC subsystem through which the auditory information is channeled to the higher centers of the auditory system. [Supported by NIH grant RO1-NS-18426]

PREFERENTIAL LABELING OF COCHLEAR HAIR CELLS FOLLOWING 16.8 INCUBATION WITH H<sup>3</sup>-GLUTAMINE. <u>I.R. Schwartz and A.F. Ryan\*</u>, Div. of Head & Neck Surgery, UCLA Sch. of Med., Los Angeles, CA

90024, Div. of Otolaryngology, UCSD Sch. of Med., La Jolla, CA 92093 & Research Service, VA Med. Ctr., San Diego, CA 92161. Identification of the afferent transmitter between cochlear hair cells (HC) and VIIIth nerve dendrites remains a major unresolved problem in cochlear physiology. Evidence that aspartic acid (ASP) or glutamic acid (GLU) is the transmitter is inconclusive, but evidence for other candidates is also equivocal. To further evaluate the role of ASP & GLU in afferent transmission, light and electron microscopic autoradio-graphic investigations of the amino acid uptake systems in the graphic investigations of the amino acid uptake systems in the in vivo gerbil cochlear preparation have now been extended to seventeen  $H^3$  or  $C^{14}$  labeled putative transmitters and related compounds with special emphasis on amino acids related to the metabolism of GLU. The methods used are described in Schwartz & Ryan (Hearing Research 9, 185-200, 1983). Of the compounds tested, only glutamine (GLM) produced pronounced preferential labeling of cochlear HCs. Immediately after CLM incubations label was also found over efferent terminals beneath HCs, over satellite cells around spiral ganglion neurons and to a lesser extent over spiral ganglion

ganglion neurons and to a leaser extent over spiral ganglion neurons themselves. Vestibular HCs were unlabeled even though label was present over adjacent supporting cells. The accumulation of label in cochlear HCs following incubation with glycine, alanine and proline is only slightly greater than the labeling of surrounding cells in the organ of Corti. By contrast, labeling of HCs was less than that of surrounding tissues after taurine incubations. D- & L-GLU, D- & 1-ASP, GABA, histidine, ornithine, arginine,  $\alpha$ -keto glutaric acid, methionine, choline and muscimol produced no preferential labeling of HCs. At the light microscopic level afferent terminals did not appear labeled with any compound tested.

GLM uptake could play an important role in afferent synaptic transmission by providing transmitter precursor and/or by clearing the synaptic cleft of a transmitter predursor and/or by clearing the synaptic cleft of a transmitter breakdown product. It seems unlikely that GLM itself is a transmitter. However, in addition to possible transmitter related roles, it may also serve as a major substrate for HC metabolism. Supported by NINCDS grants NS09823, NS14503, NS14945, RCDA NS00176 to A.F.R. and by the Research Service of the Veterans

Administration.

PREFERENTIAL GLUTAMINE UPTAKE BY COCHLEAR HAIR CELLS: CHANGES IN 169

PREFERENTIAL CLUTAMINE UPTAKE BY COCHLEAR HAIR CELLS: CHANCES IN INTRACELULAR DISTRIBUTION WITH INCREASING SURVIVAL TIME. A.F. <u>Ryan\* and I.R. Schwartz</u> (SPON: B. Pfingst). Div. of Otolar-yngology, UCSD Sch. of Med., La Jolla, CA 92093 and Div. of Head & Neck Surgery, UCLA Sch. of Med., Los Angeles, CA 90024. Cochlear hair cells in the gerbil preferentially accumulate the amino acid glutamine, as described in the companion abstract. To determine the fate of incorporated label, both pulse duration and survival time were varied in a light microscopic, autoradiographic study.

graphic study. Following pulse durations of 20 min, with immediate cold rinse and fixation, inner hair cells (IHCs) showed a marked preferen-tial labeling when compared to supporting cells of the organ of Corti. The label was evenly distributed throughout the cell, penetrating even the stereocilia, and did not appear to be pre-ferentially located in any cytoplasmic organelles at the light microscopic level. The outer hair cells (OHCs) were also uni-formly labeled, although to a lesser extent than the IHCs. Preferential labeling of structures which we have previously shown to accumulate a variety of other amino acids (Schwartz and Rvan: Rvan and Schwartz: Hearine Res., 9:1736185. 1983). such Ryan; Ryan and Schwartz; <u>Hearing Res.</u>, <u>9</u>:173&185, 1983), such as the cochlear efferents and spiral ganglion satellite cells, was also noted.

A similar, though more intense, pattern of labeling was noted after 40 min pulse duration. However, label in IHCs tended to be heavier at the apical pole of the cell, and in mitochondria. Label in OHCs tended to be in the subsurface cisternae (SSC) and in mitochondria. Spiral ganglion neurons showed a greater degree of labeling, relative to satellite cells, than after a 20 min pulse.

Following a 20 min pulse, cold perilymph rinse, and survival times of 30-120 min, label distribution changed markedly. With increasing survival time, IHC label shifted to the apical pole and, to a lesser extent, to the basal end of the cell. Label tended to be in mitochondria at 30-60 min survival times, but not at 120 min. In the OHCS, with increasing survival time, label was localized to the SSC. As with the IHCs, label was associated with mitochondria only with 30-60 min survivals. Disappearance of label from the cochlear efferents and the satellite cells surrounding the spiral ganglion neurons was more rapid than from the hair cells. Relative labeling of the spiral ganglion neurons in-creased, and preferential labeling of VIIIth nerve fibers in the modiolus was apparent at the longest survival times.

The kinetics of label distribution in hair cells are consis-tent with uptake of a transmitter precursor, with subsequent transformation into a different amino acid or peptide. (Supported by NINCDS grants NS14945, NS14503 and NS09823, RCDA NS00176 to A.F.R., and by the Research Service of the VA.)

16.10 IMMUNOCYTOCHEMICAL LOCALIZATION IN THE GUINEA PIG ORGAN OF CORTI AFTER PERIPHERAL EFFERENT LESIONS. J.A. Rubio\*, R.A. Altschuler, B. Kachar, F. Eckenstein\* and J. Fex. Lab. Neuro-otolaryngology & Lab. Neuropath. & Neuroanat., NINCDS, NIH, Bethesda, MD 20205 and Max Planck Institute, Martinsreid, Germany.

We have previously shown immunoreactive labelling in olivocochlear efferents in the organ of Corti using antisera against methionine enkephalin, choline acetyltransferase, aspartate aminotransferase and glutaminase. In this study peripheral lesions of the efferents were made and the organ of Corti was examined immunocytochemically both to confirm these findings and to determine if any non-efferent fibers or terminals are also labelled.

200-350 g. female NIH strain guinea pigs were pre-medicated with a mixture of atropine sulphate and chlorpromazine hydro-chloride injected intramuscularly. Thirty minutes later ketamine hydrochloride was given intraperitoneally, with additional sodium pentobarbital often added to maintain the anesthesia level. A tracheostomy was then performed and ventilatory support given with a small animal respirator. Under aseptic conditions a posterior cranectomy was performed under a Zeiss operating microscope. Dura was incided and retracted medially. The parafloccular lobe of the cerebellum was then aspirated. Facial, vestibular and cochlear nerves were identified. Using a fine stapes hook, the vestibular nerves were avulsed at the internal auditory meatus, taking care not to lesion the auditory nerve or the internal auditory artery which lies between the nerves. Four to eight weeks after surgery, animals were fixed by vascular perfusion and immunocytochemical pro-cedures carried out on the cochlea using antisera against methionine enkephalin, choline acetyltransferase and glutaminase.

In the cochlea ipsilateral to the lesion, no specific immunoreactive labelling was seen with antisera to methionine enkephalin or choline acetyltransferase. With antisera to glutaminase, in the cochlea ipsilateral to the lesion, immuno-reactivity was observed by the bases of inner hair cells, though less was seen than in the contralateral, non-lesioned cochlea. This remaining immunoreactivity may be in the dendrites of spiral ganglion cells, whose cell bodies and terminals show glutaminase-like immunoreactivity.

16.11 TYPE 2 SPIRAL GANGLION CELLS IDENTIFIED BY GLUTAMINASE-LIKE IMMUNOREACTIVITY AND NEUROPILAMENT STATN. A.M. Schwartz, R.A. Altschuler, R.J. Wenthold, and J. Fex. Lab of Neurootolaryngology, NIH, NINCOS, Bethesda, MD 20205, and Lab of Neurophysiology, Univ. Wisc., Madison, WI 53706.

The spiral ganglion of the guinea pig contains two morphologically distinct cell types. Type 2 spiral ganglion cells characteristically are smaller than type 1 cells, are unmyelinated, and have an abundance of neurofilaments within their cytoplasm. They are often but not exclusively located in the periphery of the ganglion in groups of two or three. In immunohistochemical studies, using antisera to glutaminase, which has been proposed as a marker for aspartergic/glutaminergic neurons, some spiral ganglion cells in the guinea pig were noted to lack immunoreactivity. These nonimmunoreactive cells had many characteristics of type 2 cells, but it was not possible to def. itively identify them as such based solely on the immunohistochemistry. Therefore we took 10 µm cryostat sections of guinea pig cochlea and using indirect immunofluorescent techniques, reacted them first with antisera to glutaminase. After fluorescence photomicrography, the coverslip was removed and the same sections were restained with the Palmgren silver stain. With this silver stain, type 2 spiral ganglion cells appear darker than type 1 cells because of the abundance of neurofilaments in their cytoplasm. We see a close correspondence between cells with decreased glutaminase-like immunoreactivity and the darker staining type 2 cells in the Palmgren sections. We have thus identified a subpopulation of spiral ganglion cells based on their immunohistochemical basis for future work on these two different cell types. 16.12 STAPEDIUS MUSCLE MODULATION OF AMPLITUDE AND PHASE OF COCHLEAR POTENTIALS IN AVES: PHYSIOLOGICAL AND HISTOLOGICAL EVIDENCE, S. Allen Counter. The Biological Labs., Harvard University, Cambridge, MA. 02138.

Aves, unlike mammals, possess only one middle ear muscle, the stapedius. This muscle, which is innervated by a branch of the facial nerve, is exceptional in the respect that it alone exerts its effects on an entire physiological system, viz. the middle ear as well as on intracranial pressure. Electromyograms from the m. stapedius, inner ear microphonic potentials (MPs) and 8th nerve responses were studied during activation of the m. stapedius in Aves in order to determine the muscle's role in phase and ampli-Aves in order to determine the matched stole in phase and any stole in phase and any stole in the control state were  $200 \,\mu$  V and were linear (on a log-log scale) over a range of 40-100 dB SPL. Tension levels of 50-400 mN in the m. stapedius caused a reduction of up to 20 dB in the MP amplitude, depending on the sound frequency. Both phase shifts and Luce, the change of the sound requires. Each phase and to outra-lateral cochleas during m. stapedius contraction. Intractanial MPs were out of phase at the contralateral car by  $180^{\circ}$  at low fre-quencies (<1 KHz) and approximately 2 i at higher frequencies. quencies (<1 km<sup>2</sup>) and approximately 2% at might here existing the avian m. Stapedius is a fast muscle with fast type (11, 11<sub>12</sub>, 11<sub>123</sub>) fibers of essentially uniform diameter (19 Am). Teased fibers revealed en plaque endings, well developed sarcomeres, and a dense investment of both sarcoplasmic reticulum and transverse tubules. Preliminary evidence on embryo and early hatchlings suggest sensory pathology following m. stapedial deprivation.

16.14 AFFERENT INNERVATION OF OUTER HAIR CELLS IN THE ADULT CAT: AN HRP STUDY. D.D. Simmons<sup>4</sup> and M.C. Liberman<sup>4</sup> (SPON: D.K. Ryugo). Depts. of Anat. and Physiol., Harvard Med. School; Eaton-Peabody Lab., Mass. Eye and Ear Infirmary, Boston, MA 02114.

Recent morphological studies of the adult cat cochlea have concluded that afferent neurons of the spiral ganglion can be divided into at least two morphologically distinct types: type I neurons giving rise to radial fibers (RFs) which synapse exclusively with inner hair cells (HCs) and type II neurons giving rise to outer spiral fibers (OSFs) which synapse with outer hair cells (OHCs) (Speendlin, H., <u>Arch. Klin. Exp. Ohren Nasen Kehlkopfheilkd. 200:</u> 275, 1971; Kiang, et al., <u>Science 217</u>: 175, 1982). Data on RFs suggest that there may be significant differences in innervation patterns between the neonate and the adult, between the base and the apex of the cochlea, and between the fibers contacting opposite sides of IHCs (Liberman, M.C., <u>Hearing Res. 3</u>: 45, 1980). Compared to our current understanding of RFs we know little about the morphology of the OSFs. Most of the anatomical data concerning the innervation of the OHCs has been based on Golgi-stained material from neonatal animals.

The OSFs in the adult cochlea can be darkly labeled following extracellular injections of horseradish peroxidase (HRP) in the cochlear nerve trunk (Kiang et al., ibid.). This technique was used in the present study to produce the Golgi-like filling of OSFs necessary to study their innervation patterns. OSFs in the adult cochlea were found to pass unbranched through the IHC region, cross the tunnel of Corti along its floor, and spiral in a basal direction for at least 0.2 mm before sending branches to the OHCs. Many OSFs had branches which end in terminal swellings among the supporting cells well beneath the OHCs.

HRP injections were positioned in the nerve bundle so as to label CSFs innervating OHCs in different cochlear regions, exploiting the similarity of the tonotopic organization for the central axons of CSFs and RFs. Several morphological features of the CSFs were found to vary systematically with cochlear location. For example, toward the apex (the low-frequency region) of the cochlea, OSFs traverse longer distances, have more collaterals, innervate more OHC rows, have fewer branches terminating on structures other than OHCs, and have larger diameters and larger terminal boutons. Possible functional significance of these anatomical features will be discussed. 17.1

IN VITRO TISSUE CULTURE MODEL FOR STUDY OF AGENTS CAPABLE OF AFFECTING ADULT CNS RECENERATION. <u>A. Leon, R. Dal Toso\*, S. Maz-zoni\*° and G. Toffano</u>. Fidia Research Laboratories, Department of Biochemistry, Abano Terme, Italy and °Divisione Neurologica, Ospedale per gli Infermi, Faenza, Italy. Fetal neuronal tissue culture techniques are increasingly being utilized for the identification and study of growth-promot-ing environmental factors or pharmacological agents capable of positively influencing adult CNS neuronal regenerative capabili-ties. They also allow for analyses of the occurrence of toxic or specific growth-inhibiting environmental influences during chron-ic adult degenerative neuropathological diseases. Serumless specific growth-inhibiting environmental influences during chron-ic adult degenerative neuropathological diseases. Serumless dissociated fetal mesencephalic cells in culture were therefore utilized as a controlled model system for the study of factors capable of determining regeneration/degeneration of CNS dopa-minergic (DA) neurons. In particular, fa.ilitatory effect of monosialoganglioside CM<sub>1</sub> on dopaminergic regeneration in vivo (Toffano, G. et al., <u>Brain Res., 261</u>:163-166, 1983) and the possible occurrence of specific dopaminergic growth inhibiting agents in sera obtained from patients suffering from Parkinson's disease were investigated. The results obtained indicate thet: disease were investigated. The results obtained indicate that: 1. whereas the survival of serumless mesencephalic dopaminergic

disease were investigated. The results obtained indicate that: 1. whereas the survival of serumless mesencephalic dopaminergic cells is highly dependent on the cellular density seeded, their dopaminergic maturation (measured as specific H-DA uptake) is specifically affected by the presence of their target striatal cells. Such data are in accord with those already reported by Prochiantz A. et al. (<u>Nature</u>, 293:570-572, 1981) and Di Porzio U. et al. (<u>Nature</u>, 288:370-373, 1980). 2. The presence of GM<sub>1</sub> molecules on the neuronal cell surface, either endogenous or following stable insertion of exogenous molecules, affects neurite outgrowth and dopaminergic maturation of fetal mesencephalic cells. Addition of GM<sub>1</sub> at concentrations ranging from 10<sup>-5</sup> to 10<sup>-7</sup> M increases the proportion of neurite bearing cells and neurite length of co-cultured mesencephalic striatal cells. CM<sub>1</sub> doubles H-DA uptake in mesencephalic cells and the effect is additive to that produced by striatal target cells. In contrast GM<sub>1</sub> antiserum produces a marked decrease of both neurite extension and H-DA uptake. 3. Addition of sera obtained from all male or female patients considered suffering from Parkinson's disease (15 patients, 40-60 years of age) impedes DA cell maturation regardless of the pre-sence of optimal target support. The inhibitory effect is depend-

sence of optimal target support. The inhibitory effect is depend-ent on the concentration of sera (maximal concentration 1:50 dilution) and appears to be correlated with the severity of the disease. The sera are totally ineffective in modifying GABAergic maturation of striatal cells. Control sera obtained from normal subjects are totally without effect.

The relevance of such data will be discussed.

17.4 DEGENERATION AND REGENERATION-ASSOCIATED POLYPEPTIDES IN RAT PERIPHERAL NERVE. <u>H.W. Muller\*, M.J. Ignatius and E.M. Shooter</u>. Dept. of Neurobiol., Stanford Univ. Sch. of Med., Stanford, CA94305.

Non-neuronal sheath cells in rat sciatic nerve responded to denervation by the sequential induction of several new polypeptides which were secreted into the distal nerve stump. We were able to identify at least 7 specific denervation-induced proteins with apparent molecular weights from 37,000 (37k) to 45,000 (45k) and isoelectric points between 5.2-5.4. The appearance of these proteins correlated well with periods of axonal degeneration and re-generation. However, the time-course of induction as well as the rates of synthesis and disappearance of these proteins in nerve segments distal to injury were dependent on the particular type of nerve injury applied to initiate degeneration.

(i) When degeneration was initiated by a nerve crush leading to axotomy and subsequent axonal regeneration, the synthesis and in 3-6 days post-injury prior to the induction of any of the other proteins. Despite a decreasing rate of synthesis during the folproteins. Despite a decreasing rate of synthesis during the foi-lowing weeks the 45k remained at a high concentration in the nerve for approx. 4 weeks until at 7-8 weeks after the crush it had slowly disappeared. A 37k protein (Skene and Shooter, PNAS, 1983, in press) was maximally induced at 1 week post-crush and appeared in the distal stump approx. 2 weeks after the 45k. The 37k remained at a high concentration for 2-3 weeks before it rapidly decreased to background levels.

(ii) In a transected sciatic nerve where axonal regeneration into the distal stump was prevented the same set of soluble pro-teins was induced and synthesized at similar rates as in (i), thus indicating that the induction of these proteins is not under regulation of regrowing axons.

(iii) When a segment of sciatic nerve was separated by excision from its neuronal input and from its target cells the time-course and rate of synthesis as well as the concentration of the denervation-induced proteins in the isolated piece of nerve was sig-nificantly altered. The initial high rate of synthesis of the 45k was maintained for several weeks and this polypeptide remained at high concentration in the nerve sheath for at least 6-7 weeks post-excision. However, the 37k did not accumulate in the isolated nerve segment in detectable amounts for 10 weeks suggesting a role for the target in the maintenance of 37k synthesis.

The other degeneration-induced proteins besides the 45k and 37k were less prominent and their rates of synthesis and accumu-lation generally resembled that of the 45k throughout the experiments.

17.3 REGENERATION IN THE LARVAL LAMPREY: AN HRP STUDY.

R. E. Coggeshall and B. N. Christensen. Depts. of Anatomy and Physiology & Biophysics Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

Recent experiments on lamprey suggest that regeneration of giant reticulospinal axons is often incomplete or inappropriate (Wood and Cohen, Science, 1979). This is in spite of the fact that the lamprey appears to regain its normal swimming behavior following spinal section. It has been suggested (Selzer, J. Physiol. 1978) that the return of coordinated swimming movements following spinal section are due to reinnervation of motor neurons via polysynaptic pathways. Both of these reports concluded that regenerating axons do not extend more than a few ities of reticulospinal neurons, both "giant" and "non-giant" by examining the number of labelled cells found in the brain after application of HRP to the cut end of the cord from 0.5 - 1.5  $\mbox{cm}$ caudal to spinal crushes made up to four months previously. Two other series of animals were done. In one, we determined the number of brainstein neurons projecting to the dorsal fin region of the spinal cord when HRP was applied to the cut end of the cord at the level of the first dorsal fin. In the second, we crushed the spinal cord 1 cm rostral to the first dorsal fin and then applied HRP to the cut end of the spinal cord 1 cm caudal to the lesion. The latter tested for the possibility that HRP could label cells within the brainstem by a route other than axonal transport along descending spinal axons. By four months following spinal cord crush our animals re-

gained normal swimming behavior. A large number of reticular neurons were labelled including some of the giant cells which give rise to the giant axons descending the length of the cord. In four animals without lesions, the number of non-giant cells labelled in the brainstem was 171 (+ 73.3 S.E.) and the number of giant cells was 8 ( $\pm$  2.1 S.E.). In 9 animals transected 4 months previously, the number of labelled non-giant neurons was 57.6 (± 30.6 S.E.) and the number of giants was 3.8 (± 2.2 S.E.). Although there is more than a 50% reduction in the number of labelled cells in the experimental animals, it is clear that a large number of cells located in the brainstem send axons across the lesion for a distance of at least 1.5 cm. These results indicate that some axons regenerate for long distances past a transection and thus behavioral recovery may depend on these axons reaching their original synaptic sites. Second, since a large population of non-giant reticulospinal neurons regenerate axons past the transection, these cells, rather than the giant cells, may be responsible, at least in part, for the behavioral recovery. Supported by grants NS14429, 10161 and 17039 from the NIH.

EARLY CALCIUM DEPENDENT INCREASE OF TRANSGLUTAMINASE ACTIVITY IN 17.5 THE RAT SUPERIOR CERVICAL GANGLION AFTER POSTGANGLIONIC NERVE INJURY. <u>G. M. Gilad and V. H. Gilad</u>\*. Isotope Department, Weizmann Institute of Science, Rehovot, Israel.

As early as 2h after postganglionic nerve injury an increase in ornithine decarboxylase (ODC) activity occurrs within parent sympathetic neurons of the superior cervical ganglion (SCG). This sympaticitie neurons of the superior certain ganginon (Stof). This increase in ODC activity is rapid and transient, and is most probably due to a transient accumulation of new enzyme molecules. The increased ODC activity reflects an enhanced polyamine biosynthesis which is required for the survival of the injured neurons(Gilad and Gilad, Brain Res., in press). Intracellular transglutaminase (TG) is an enzyme which catalyzes the covalent binding of diamines (e.g. putrescine), or polyamines to glutamine residues on peptide chains and thereby may lead to the formation of crosslinks between adjacent polypeptide chains. In The present study therefore we sought to determine: (a) whether TG activity is present in the SCG and if so, is it activated by calcium (Ca)? and (b) whether TG activity is altered in the SCG after axonal injury and if so, is it dependent on Ca fluxes? The activity of TG was found to be present in homogenates of rat SCG (65.5±6.5 pmol [<sup>3</sup>H]putrescine bound/h/mg protein) and had an absolute requirement for Ca in the assay mixture. When the enzyme activity was measured at different times (15min to 7h) after unilateral postganglionic nerve crush, an increase of 175.5±8.5 percent (p=0.001) was detected by 30min postoperative in the ipsilateral SCG as compared to contralateral or In the polarized of controls. Such an increase was not observed before or after 30min postoperative. Application in vivo, of a saline (0.9% NaCl) solution containing verapamil  $(2\pi M)$  - an inhibitor of Ca. fluxes across membranes of excitable tissues - completely of Ca. fluxes across memoranes of excitable tissues - completely prevented the observed increase in TG activity. The effect of verapamil could be reversed by addition of CaCl (10mM) to the applied solution. We conclude that: (a) within minutes after postganglionic nerve injury, put rescine dependent and Ca activated TG activity is briefly enhanced in the corresponding SCG, and (b) the enhanced for activity is dependent une Co fluxes correspond (b) the enhanced TG activity is dependent upon Ca fluxes across membranes proximal to the injury site. The results imply that changes in Ca fluxes, which may be triggered by axonal injury, are essential for the observed increase in TG activity, the earliest biochemical change so far reported in the region of the parent nerve cell body. -Supported by a grant from the Muscular Dystrophy Association.

SELECTIVE REINNERVATION OF LIMB MUSCLES BY REGENERATING FROG MOTOR AXONS. <u>Susan L. Powell\*</u> and <u>Monte Westerfield</u> (SPON: B. Gordon-Lickey). Institute of Neuroscience, Univ. of Oregon, 17.6 Eugene, OR 97403.

We have examined the selectivity of reinnervation of limb muscles by the regenerating axons of frog spinal cord motoneurons following axotomy when the ventral root was crushed or cut. Two factors that might direct regeneration were investigated. 1) Do external factors in the nerve guide the regenerating axons? 2) Do the central connections of motoneurons from limb sensory neurons signal which muscles they should reinnervate? The anatomical pattern of reinnervation was assayed by retro-

grade labeling after injection of HRP into individual muscles. The functional pattern of reinnervation by motoneurons was assayed by intracellularly recording antidromic activation of motoneurons upon stimulation of single muscle nerves, and the pattern of central connections between muscle sensory and motor neurons was determined by recording synaptic potentials elicited by stimulation of appropriate peripheral nerves. Our results demonstrate that:

1) Motoneurons randomly reinnervate limb muscles if the a) notoneutons fancomy remains the provided by cutting.
 a) On the other hand, if the ventral root is crushed, moto-

neurons selectively reinnervate their old targets. This difference may suggest that alignment of the nerve sheath is required for proper regeneration.

3) Motoneurons reform appropriate connections with muscles (after crushing the ventral root) even when their sensory innervation is absent due to removing the dorsal root. Supported by the NSF, NIH, MRF, and the Sloan Foundation.

<sup>3</sup>H-URIDINE INCORPORATION IN NORMAL AND AXOTOMIZED IMMATURE 17.7 HAMSTER FACIAL MOOR NEURON IN MOUNTAL AND ANDIONIZED IMMAIONE Dept. of Anatomy, University of Illinois, Chicago, IL 60680.

A common feature of the axon reaction in mature peripheral motor neurons is increased RNA synthesis, reflecting the anabolic and regenerative nature of the response to injury. Immature hamster facial motor neurons do not survive axotomy as do mature hamster facial neurons. The capacity to survive axotomy as to market hamster facial neurons. The capacity to survive axotomy is gradually acquired over the first two postnatal weeks. This temporally coincides with the early period of maturation of the neuron's protein biosynthetic apparatus, including the nucleoli which are sites of rRNA synthesis and processing. A study of  ${}^{3}\text{H-uridine}$ incorporation was undertaken to determine how RNA synthesis is altered in facial neurons axotomized during the period when they cannot, or have a reduced capacity to, sustain a regenerative response.

Facial nerves of fetal and early postnatal hamsters were severed by electrocautery and by cutting, respectively, with the unoperated sides serving as control. Animals were sacrificed at times varying from 17 hours to 4 days after injury. One hour prior to killing by perfusion fixation, <sup>3</sup>H-uridine (3µCi/g body wt) was injected into each animal. Brain-stems were processed WD/ WBS injected into each animal, brain-stems were processed for light microscope autoradiography, Somal area, nuclear area and grain number per unit area cell body were averaged per facial nuclear group. Statistical analysis was by 2-way ANOVA

nuclear group. Statistical analysis was by 2-way ANOVA. Axotomy in fetal hamsters (14 days in utero) resulted in a significant decrease in grain density 17 hours after injury, even though uridine incorporation remained high. Significant changes in grain density were not observed after axotomy in the postnatal ages examined. Mean somal area decreased significantly in neurons axotomized at 4, 7, and 9 days and examined after 2, 2 and 4, and 4 days respectively. Nuclear area, however, did not change. Thus, immature hamster facial neurons do not increase RNA synthesis to meet the demands of regeneration. Injured neurons from fetal hamsters show a large, rapid decrease in RNA synthe-sis. Since it appears that these neurons synthesize RNA at a high level normally. the pronounced effect of axotomy stems from in-

level normally, the pronounced effect of axotomy stems from interrupting a highly active process. In contrast, injured neurons from early postnatal animals continue to synthesize RNA at normal How early postaval animals continue to synchesize and at homai levels through the postoperative times examined. This correlates well with the gradually increasing capacity of these neurons to survive injury as they mature. The decrease in somal area after axotomy can be interpreted as an interruption of the rapid growth that accompanies neuronal maturation and suggests that synthesis of structural proteins necessary for growth may be significantly altered during this period.

A TIME COURSE STUDY OF AXOTOMY-INDUCED CHANGES IN RNA SYNTHESIS AND NUCLEOLAR MORPHOLOGY IN IMMATURE AND MATURE HAMSTER FACIAL

NEURONS. <u>Kathryn J. Jones and Arthur LaVelle</u>. Department of Anatomy, University of Illinois, Chicago, Illinois, 60680. We have previously observed that diffuse chromatolysis, cell We have previously observed that diffuse chromatolysis, cell swelling and increased protein synthesis characteristic of the <u>adult</u> response to axotomy do <u>not</u> occur in the <u>15-day</u> postnatal neuron. This differential response to axotomy has been temporally correlated with the development, mainly <u>after</u> 15 days, of an intranucleolar body (INB) consisting of ribonucleoprotein (RNP) particles. Axotomy induces dispersion of this INB in the adult by 4 days postoperative (dpo). In this study we examined the initial effects of externs or RNA metabolics. effects of axotomy on RNA metabolism and on nucleolar morphology in neurons undergoing the two different modes of reaction.

Adult and 15-day old hamsters were subjected to axotomy of the right facial nerves, with the left sides serving as controls. At 1/2, 1, 2 and 4 dpo, some of the animals were injected subout-aneously with 3H-uridine 1 h prior to sacrifice via perfusion-fixation and the brains processed for routine light microscope autoradiography. The remainder of the animals were sacrificed and processed for routine EM. The number of grains per unit area cell body, in 2 µm sections, were averaged per animal. The areas of nucleolar profile tracings from 1 µm Epon-embedded sections were calculated using a BioQuant Image Analyzer. All data were analyzed using 2-way ANOVA. Cytomorphic changes in nucleolar substructure were assessed by EM. In the 15-day neurons, no changes in uridine uptake after

axotomy were noted throughout the time course studied. Nucleolar morphology and size were also unaffected by axotomy at 15 days. the adult neurons, axotomy induced a transient increase in In the adult neurons, axotomy induced a <u>transient</u> increase in uridine uptake at 2 dpo, with return to <u>control</u> levels by 4 dpo. This increase in RNA synthesis at 2 dpo coincided with the onset of nucleolar swelling, with an initial "loosening" of the fibrillar portion of the nucleolus and with an incipient disper-sion of the INB granular material. Nucleolar area remained significantly higher at 4 dpo when the INB was totally dispersed. Intranucleolar bodies are thought to be storage sites for

ribosomal precursors. Their absence in normal 15-day and in axo-tomized adult neurons reflects the increased metabolic activity associated with both growing neurons and with regenerating adult neurons. Since it has been shown that the level of protein syn-thesis remains increased in these adult neurons for a prolonged time after injury, it is surprising that there is such a short spurt of elevated RNA synthesis after axotomy. Although a later increase in RNA synthesis cannot be excluded, we feel that the stored RNP particles in the INB contribute to and meet the initial metabolic demands placed on these cells by axotomy.

FLAT, WHOLE-MOUNT NERVE PREPARATIONS: A USEFUL TOOL FOR STUDYING PATTERNS OF REGENERATING AXON OUTGROWTH. Y. Geinisman and M.T. Shipley, Dept. of Cell Biol. & Anat., Northwestern Univ. Med. Sch., Chicago, IL 60611 and Dept. of Anat. & Cell Biol., Univ. of Cincinnati Col. of Medicine, Cincinnati, OH 45267.

Present techniques for experimental analyses of regenerating axon outgrowth distal to the site of axotomizing injury have serious limitations. For example, the actual outgrowth distance cannot be measured for individual axons without their entire course reconstruction from numerous histological or ultrathin sections, which is difficult, if not impractical. Further, the direct differential examination of all axonal subpopulations that elongate at fast, intermediate or slow rates is impossible, since only one subpopulation of the fastest growing axons can be direct-ly studied by axonal transport and pinch test techniques. To cirunvent these limitations, we have developed a method which is based on the use of flat, whole-mount nerve preparations. In young adult rats, the right sciatic nerve (SN) is crushed,

and HRP (Sigma VI, 40% solution) is injected into the region of cell bodies of spinal motoneurons innervating the musculature of the right hind limb. Rats are perfused 16-24 h later, the SN is dissected out and the epineurium removed. The SN is flattened between two glass slides, removed, then reacted (floating) with TMB, mounted on a micro slide, counterstained with neutral red, dehydrated and coverslipped. At 16 h after the crush, all HRP dehydrated and coversipped. At ion after the clush, all nh labeled axons are found proximal to the crush zone. By 2 days, HRP labeled axons are observed crossing the crush zone and passing peripheral to it; the distance between the crush site and axon tips is progressively increased at 4 and 6 days. Many axon tips are enlarged and mark a distinct leading edge of several waves of outgrowing axons. In each wave, both single labeled axons and axonal bundles can be traced along their entire undulating course. The flat SN preparations have also been stained for acetylcholin-esterase and reacted with antitubulin antibodies. With both techesterase and reacted with antitubulin antibodies.

niques, outgrowing axons can be clearly visualized. It appears, therefore, that flat, whole-mount preparations of regenerating nerves can be useful for obtaining: (1) accurate esregenerating nerves can be useful for obtaining; (1) accurate es-timates of the rate of regenerating axon elongation by measuring the outgrowth distance of individual HRP labeled axons over time after axotomy; (2) values of the "initial delay" of outgrowth by assessing the time, necessary for regenerating labeled axons to reach the nerve segment just distal to the lesion site; and (3) information concerning the nature of axonal subpopulations that elongate at different rates by employing histochemical, immunocytochemical and electron microscopic techniques. Moreover, virtu-ally any staining method applicable to floating or mounted histo-logical sections should work well in these preparations. Supported by NIH AG-03410, NS-18490 and NS-19730.

NON-SELECTIVITY OF AXONAL REGENERATION IN THE OCULOMOTOR NERVE 17.10 OF GOLDFISH. S.S. Scherer, Division of Biological Sciences, The University of Michigan, Ann Arbor, MI 48109

I have reinvestigated the guestion of whether the extraocular muscles of goldfish are selectively reinnervated by regenerating axons of the oculomotor nerve. Using the retrograde transport of horseradish peroxidase (HRP), I have mapped the motor pools of extraocular muscles that were innervated by normal or regene-

of extraocular muscles that were innervated by normal or regenerated oculomotor nerves. HRP was injected into either the left superior rectus (SR) (N=3), medial rectus (MR)(N=1), inferior rectus (IR)(N=1), or inferior oblique (10)(N=2) muscle in 7 normal animals. After 4 days survival, the animals were perfused, and their brains sectioned transversely at 40-50 um. The sections were reacted with diaminobenzidine, and counterstained with neutral red. Labeled and unlabeled motoneurons were plottec with the aid of a camera lucida. As in other teleosts, the motor pools of the MR, TR, and TO were in the ipsilateral (left) tegmentum of tralateral (right) side. tralateral (right) side.

I similarly mapped the motor pool of the left SR in 4 animals whose left oculomotor nerve had been sectioned intracranially 17 (N=2) or 65 (N=2) days before. Labeled cells were found in 3 of the 4 brains; none were found in one brain (65 d). Most of the labeled cells were found in the ipsilateral tegmentum, in positions that corresponded to the motor pools of the MR, IR, and IO, but some labeled cells were found in the contralateral tegmentum, in the position that corresponded to the motor pool of the SR.

Two explanations could account for the wider distribution of labeled motoneurons in lesioned animals: (1) reinnervation of the SR was non-selective, or (2) regenerating axons selectively reinnervated the SR, but the intraorbital diffusion of HRP was reinnervated the SR, but the intraorbital diffusion of HRP was more pronounced than in normal animals, and led to the labeling of the other motor pools. The second explanation seems unlikely since the orbital contents were not directly involved in the approach used to transect the oculomotor nerve. Furthermore, behavioral experiments in progress show that animals have ab-normal eye movements after the transected oculomotor nerve has regenerated, which is consistent with the hypothesis that rein-nervating is non colocting. (Supervised the SC S nervation is non-selective. (Supported by EY07022 to S.S.S. and EY00168 to S.S. Easter, Jr.)

17.12 NEUROMUSCULAR PROPERTIES DURING CLAW REGENERATION IN ALPHEID SHRIMP. <u>P.J. Stephens and J.M. Leferovich</u>\*. Department of Biology, Villanova University, Villanova, PA. 19085.

The dimorphic claws of snapping shrimp consist of a smaller pincer claw and a larger snapper claw. In Alpheus californiensis the structural dimorphism is accompanied by a profound asymmetry in the properties of the closer muscle. The closer muscle in the snapper claw is composed of a near uniform population of slow fibers, while the pincer claw closer has two different types of muscle fibers. Analysis of sarcomere length and myofibrillar adenosinetriphosphatase (ATPase) activity revealed that a central band of fast fibers is located along the longitudinal axis of the muscle and intermediate-type fibers are situated on the dorsal and ventral margins. The closer muscle in each claw is innervated by two

excitatory motor axons. The fast closer exciter (FCE) subplies all closer muscle fibers whereas the slow closer exciter (SCE) makes functional connections only with fibers in the central portion of the muscle. In the pincer claw, injection of dye through the recording microelectrode demonstrated that muscle fibers supplied by only the FCE are fast, while those innervated by both excitatory axons are intermediate-type fibers. Thus there is a close matching between the innervation pattern of the SCE and the regional distribution of different fiber types in the pincer claw closer muscle. These data are consistent with the hypothesis that nerve-muscle interactions take place during development.

We have made observations on the closer neuromuscular system during regeneration of the pincer claw. Upon emergence of the claw from its limb bud, analysis of sarcomere length and ATPase activity revealed that the closer muscle is composed of a near homogeneous population of fast fibers. During the ensuing intermolt period the muscle fibers on the dorsal and ventral margin of the closer differentiate from fast to intermediate-type fibers. Examination of the innervation patterns of the two Thus the innervation patterns of the values of claw regeneration the peripheral fields are similar to those in fully developed claws. Thus the innervation patterns of the two excitatory motor axons are established before muscle differentiation, suggesting that any trophic interactions must proceed from nerve to muscle.

This work was funded by grants from the National Science Foundation (BNS 13196) and the Whitehall Foundation.

ABNORMAL PHYSIOLOGICAL PROPERTIES OF REGENERATING SENSORY AXON 17.11

ABNORMAL PHYSIOLOGICAL PROPERTIES OF REGENERATING SENSORY AXON TERMINALS IN THE CORNEA. <u>Andrew J. Rozsa, Roger W. Beuerman,</u> Brett Dupuy\*, and Darrell L. Tanelian. LSU Sch. of Med., Dept. of Ophthalmology, LSU Eye Center, New Orleans, LA 70112. Our previous report (<u>Neurosci. Abst.</u>, 8:300, 1982) presented anatomical descriptions of the recorganizational process of epi-thelial axon terminals following various types of experimental wounds in the cornea. Collateral sprouting from intact terminals overlapped temporally the primary degeneration of the original terminals. In turn, the early collateral sprouts degenerated in 7-10 days and a second generation of regenerative neurites ap-peared. These latter neurites originated from the tips of the severed axons. The electrophysiological studies presented here sought to correlate the functional features of degenerating and regenerating corneal axon terminals to the morphological changes regenerating corneal axon terminals to the morphological changes described previously.

Twenty-three albino rabbits (2-3 kg) were anesthetized with urethane (1.5 g/kg) and placed in a head holder. The periorbital uretnahe (1.5 g/kg) and placed in a head holder. The periorbial skin was retracted and the conjunctiva was secured over a stain-less-steel ring to ensure a stable preparation. Action poten-tials were recorded conventionally from dissected axon bundles of the long ciliary nerve. Circular (4 mm dia) wounds were produced by scraping the corneal epithelium with a scalpel. In post-operative preparations exceeding 24 hrs, distinct wound margins were near-orwed by tranships domarcative.

were preserved by trephine demarcation. We examined two conditions: first, the immediate effects or response to acute injury; and second, the initial phase in the restoration of sensory competence to the corneal epithelium. The restoration of sensory competence to the corneal epithelium. The following neuronal activity and response characteristics were noted: 1) the generation of spontaneous abnormal patterns of neural impulses in unstimulated corneal nerves that are normally quiescent; 2) the replacement of the modality specificity of corneal nerves by a generalized responsiveness to all forms of stimulation; and 3) the prolonged excitation of sensory nerves denoted by after discharges that outlasted the duration of the stimulation. The area of tissue confined within the wound margins displayed a zone of absolute sensory loss; this area was surrounded by a narrow peripheral zone of partial sensory loss. The biophysical specificity of terminals was reestablished after 24 hrs, although the hyperexcitability to stimulation persisted 24 hrs, although the hyperexcitability to stimulation persisted for the duration of the post-operative period investigated (7 days). We hypothesize that the ectopic neural activity and responsiveness characteristics that follow corneal injury are neural substrates for acute pain. Collateral sprouts appear to possess sensory functions; however, their overreaction stimulation is probably the neural substrate for hyperpathia. (Supported by USPHS grants EY04074 and EY07073, NEI). to

17.13 LAMININ IN REACTIVE SCHWANN CELLS. LIGHT- AND EM IMMUNOLOCALI-ZATION IN TRANSECTED RAT SCIATIC NERVES. <u>A. Bignami, N.H. Chi\*</u> and D. Dahl. Spinal Cord Injury Research, Brockton-West Roxbury VA Medical Center, and Department of Neuropathology, Harvard Medical School, Boston, MA.

Laminin is an extracellular noncollagenous matrix glycoprotein present in all basement membranes so far investigated. Laminin is produced by several cell lines and promotes the adhesions of is produced by several cell lines and promotes the adhesions of cells to a substratum in vitro. The expression of laminin by early astrocytes in primary dissociated cultures of newborn murine brain has been reported recently (Liesi et al., J Cell Biol. 96:920, 1983). Immunofluorescnee with laminin antisera revealed a striking change in the localization of this protein in rat sciatic nerve as a result of Wallerian degeneration. In rat sciatic nerve as a result of Wallerian degeneration. In normal sciatic nerve, the staining was confined to the endoneurium and the same was also found to be true during the first days of degeneration. On day ll endoneurial tubes were not more identified in the distal stump of crushed nerves and of nerves that had been transected and tightly ligated to prevent regeneration. In both crushed and ligated nerves proliferating Schwann cells forming the cell-bands of Büngner were intensely laminin positive. As indicated by double-labeling experiments, laminin and neurofilament antisera revealed similar but not identical staining patterns in crushed nerves, thus suggesting a identical staining patterns in crushed nerves, thus suggesting a close relation between laminin and regenerating axons. Crushed nerves had recovered their normal appearance 3 weeks after operation while anti-laminin reactivity was markedly decreased in li-gated nerves probably as a result of fibrosis. The localization of laminin in reactive Schwann cells was confirmed by immuno-peroxidase labeling at the EM level. Schwann cell cytoplasm engulfing myelin breakdown products and surrounding regenerated axons was intensely stained. No reaction product was present in axons. Supported by NIH grant NS13034 and by the Veterans Administration.

RELEASE OF FAST-TRANSPORTED PROTEINS FROM REGENERATING NERVE. 17.14 Bruce Tedeschi<sup>\*</sup> and David L. Wilson. Dept. of Physiology & Biophysics, Univ. of Miami Sch. of Med., Miami, FL. 33101.

Biophysics, Univ. of Miami Sch. of Med., Miami, FL. 33101. The secretion of axonally transported proteins from intact nerve was reported (Hines & Garwood, Brain Res., 125:141, 1977) but not confirmed (Tedeschi et al, Brain Res., 125:141, 1977) but not confirmed (Tedeschi et al, Brain Res. 211: 175, 1981). In the present study, we have demonstrated the secretion of a subset of rapidly transported proteins from regrowing axons in previously-crushed frog sciatic nerve. To study secretion from axons, proteins in DRG were labeled <u>in vitro</u> with <sup>35</sup> S-methionine. After axonal transport, any released proteins were collected in the bath of a small chamber surrounding the sciatic nerve at its crush site. The released material was subjected to 2-dimensional polyacrylamide gel electrophoresis and the pattern of labeled, released poly-peptides detected with Kodak XAR film. The results showed that: (1) A specific subset of rapidly transported proteins is released f.om axons at the crush site; (2) Nost proteins that are rapidly transported and released

(2) Most proteins that are rapidly transported and released from axons are different from those synthesized and released by It is a surrounding cells in the sciatic nerve; (3) One exception is a glycoprotein, designated B14 (Mr = 30,000 to 40,000daltons, pl = 5 to 6), which also is released from a number of

other fissues in a variety of organisms. The release from axons appears to represent a physiological process because (1) the release is selective, (2) no release is seen during the first 24 hours after nerve crush, and (3) the release continues to occur for weeks after damage, while axon regrowth is occuring. The release may be associated with new membrane addition in the growing axons. The role of the released proteins is not known. (Supported by NSF grant BNS 81-17817, NIH grant NS18263 and NIH training grant NS07044.)

RELEASE OF NON-NEURONAL PROTEINS FROM REGENERATING NERVE. <u>David L. Wilson and Bruce Tedeschi</u>\* (SPON: L. Dribin.) <u>Dept. of Physiology & Biophysics</u>, Univ. of Miami Sch. of Med., 17.15 Dribin.) Miami, FL 33101

Mamm, FL 35101 We have examined the proteins that are synthesized in and released from non-neuronal cells in the frog sciatic nerve after nerve damage.

Frog sciatic nerves were unilaterally crushed with forceps. The uncrushed contralateral nerves served as controls. At 1 to 28 days following damage the frogs were sacrificed, and the sciatic nerves were removed and desheathed. In small chambers, sciatic nerves were removed and desheathed. In small chambers, various parts of the previously-crushed nerve (proximal to crush, crush site, distal to crush) or control nerve were incubated in a bath containing frog Ringers and <sup>25</sup>S-methionine. Following labeling (3-7 hours), the material released into the baths was subjected to 2-dimensional polyacrylamide gel electrophoresis and the polypeptides detected with Kodak XAR film. For quantitative analysis, selected gel regions corresponding to polypeptide spots on the film were cut out and counted in a liquid scintillation counter.

One protein, designated B14 (Mr = 30,000 to 40,000 daltons, pI = 5 to 6), was found to be released in greater amounts from crush and distal nerve regions than from proximal regions of damaged nerve or control nerve. This increase was not seen initially (1 to 3 days post-crush) suggesting a possible association with the regeneration process. It is interesting that this protein, B14, is the one protein which we have found to be both a rapidly transported protein released from axons and a non-neuronal protein released from the cells surrounding axons in the sciatic nerve. The relevance of the present findings to reorganization of an injured nerve is not known. (Supported by NSF grant BNS 81-17817, NIH grant NS18263 and NIH training grant NS07044.)

FUNCTIONAL AND ANATOMICAL CONSEQUENCES OF NEONATAL INFRAORBITAL NERVE DAMAGE IN RAT. M. Math\*, A. Brown<sup>\*</sup> M.F. Jacquin and R.W. Rhoades. UMDNJ-NJSOM & RMS, Piscataway, NJ 08854. The infraorbital (IO) nerve's innervation of the mystacial vibrissae and its central representations at the various levels of the trigeminal (V) neuraxis have been used by numerous investigators to examine the central nervous system response to neonatal peripheral damage. Surprisingly, with only a few exceptions, the effects of neonatal IO damage upon organization in the V ganglion and brainstem have not been examined in detail. We have used a combination of Electronmicroscopic, HRP tracing

and single unit recording techniques to assess the consequences of neonatal section of the IO nerve in rat. In normal adult rats (N=4) the IO nerve contained from 17,480 - 22,259 myelinated and 12,088 - 15,851 unmyelinated Electronmicroscopic examination of this V branch in a neonatally lesioned adult animal revealed only 5,260 myelinated and 2,747 unmyelinated axons.

Single unit recording from the ophthalmic-maxillary portion of the V ganglion also demonstrated substantial effects of this manipulation. In normals, 44% of the 96 units recorded were responsive only to deflection of the whiskers while in the lesioned rats only 13% of the 64 cells tested were activated by such stimulation. Moreover, 31% of the cells in the lesioned rats responded tonically to a noxious pinch or deep pressure while only 12% of the units recorded in the normal ganglia yielded such responses. In spite of these changes in single unit response characteristics, the normal topographic organization of the ganglion was maintained in the lesioned rats. Transganglionic HRP transport was used to examine the

innervation of the brainstem by the normal and regenerate IO nerve. In the normals, somal clusters resembling the barrels or barreloids were not visible. In the brainstem, however, barrelike aggregates of HRP labelled terminals could be seen in principalis, interpolaris, caudalis and the first cervical segment. In the lesioned animals, the number of V ganglion cells labelled by HRP application to the IO nerve was substantially reduced and the terminal distribution in the brainstem for this V branch was also markedly abnormal. Transganglionic transport from the regenerate IO nerve indicated an almost exclusive projection to the marginal layer of the medullary and rostral cervical dorsal horn.

NERVE REGENERATION IN A SUPRAMAXIMAL GAP. L. J. Stensaas. Dept. of Physiology, Univ. of Utah Sch. of Med., Salt Lake City, UT 84108. 17.17

Nerve regeneration in a supramaximal gap following severance of a nerve and removal of the distal stump depends on the growth and development of the regenerating unit. The regenerating unit (RU) consists of a small open-end perineurial sheath surrounding a cluster of axon sprouts and reactive Schwann cells. Axons and Schwann cells within the unit originate from single myelinated parent fiber in the proximal stump which grow out into the connective tissue matrix of the lesion accompanied by the new perineurial sheath. During the process of regeneration the RUS display a maturation gradient in which the more proximal RUS display a maturation gradient in which the more proximal axons are larger, more numerous and become myelinated early while those situated distally are smaller, unmyelinated and few in number. Thus, maturation of most cellular components of the RU occurs even in the absence of nerve union with the distal stump. Each of the many RUS enverging from the proximal stump maintains its individuality within the lesion by virtue of the rapid concomittant development of the perineurial sheath from mitotically active Schwann cells near the tip of the re-generating axons. Depending on the location and orientation of the units, they collectively give rise to three structures appended to the proximal stump: 1) the nerve regenerate. In addition to changes in the size and number of RUS along the maturation gradient of the nerve regenerate of a 21-day prepara-tion, remarkable changes occurred in the connective tissue matrix of the regenerate. Such changes were most conspicuous matrix of the regenerate. Such changes were most conspicuous near the "front" of regenerating axons where RUs were incompletely ensheathed by perineurial cells. The changes included a dense collagen network within which there were numerous hyperplastic fibroblasts and capillaries. The fact that such reactive tissue developed ahead of the nerve re-generate implies that factors elaborated within the RUs were liberated from the open, distal end of the regenerating units and served to stimulate cells in the connective tissue through which the regenerating axons will pass. With time a progres-sive deposition of dense (epineurial) collagen developed around RUs in the nerve stump and epineurial regenerate. The presence of a dense connective tissue matrix in the "capsule" of the long term terminal and epineurial regenerate may contribute to the development of a painful neuroma.

MORPHOLOGICAL ASSESSMENT OF MYELINATION OCCURRING IN ADULT PERIPHERAL NERVES REGENERATING THROUGH A SILICONE CHAMBER. J.M. LeBeau\*, F.M. Longo\* and M.H. Ellisman. (SPON: J.D. Hat-ton) Laboratory for Neurocytology, Department of Neurosciences, University of California, San Diego, School of Medicine, La Jolla, CA 92093. 17.18

A model system in which peripheral nerve regenerates across a 10mm gap between cut ends of the nerve regenerates described (Lundborg, Longo and Varon, <u>Brain</u> <u>Res. 232</u>:157-161, 1982). This system involves suturing 2 mm of the proximal and distal stumps of transected rat sciatic nerve into a 14 mm long sil-icone tube. Since regeneration and myelination occur somewhat separated in the intervening 10 mm space, this system provides a natural gradient of changes across the chamber representing a natural gradient of changes across the chamber representing the sequence of axon-Schwann cell interaction. This sequence has been examined with light and electron microscopic tech-niques, including freeze-fracture EM. Migration of vascular endothelial and Schwann cells from both ends of the cut nerve follows the development of an acellular matrix that spans the follows the development of an acellular matrix that spans the length of the chamber. Axonal outgrowths of the proximal nerve stump then invade the chamber. Axonal growth cones appear to associate with the Schwann cell surface. Several millimeters behind the advancing growth cone, multiple lamellar processes of the Schwann cell surround the axons. New nodes of Ranvier are defined before the lamellar processes of the encircling Schwann cell begin to compact into myelin. These are defined by the subaxolemmal densification, observed in thin sections, and clusters of axolemmal particles, observed by freeze-fracturing. The internodal spacing is short, similar to that observed for nodal spacing of early development and other regenerating systems. The newly formed nodes are normal in appearance, however, the annulus of heterogeneously sized par-ticles, characteristic of the nodal zone of the axon, is prom-inent. REGENERATION OF STRETCH RECEPTORS IN RAT MUSCLE. D. C. Quick\* 17.19

 RECENERATION OF STRETCH RECEPTORS IN RAT MUSCLE. <u>D. C. Quick\*</u>
 and S. L. Rogers\* (SPON: W. R. Kennedy). Dept. of Anatomy,
 Univ. of Minnesota, Minneapolis, MN 55455.
 In traumatized muscles, the muscle fibers undergo a process
 of degeneration and regeneration (B. M. Carlson, 1978, Physiol.
 Bohemoslov. 27:387). Histological studies have shown that muscle spindles are also capable of regeneration (S. L. Rogers, in press, Devel. Biol.). Nerve fibers are known to be present in regenerated spindles but their functional status has been uncertain. We undertook electrophysiological studies of regenerated rat muscles to determine whether functional stretch receptors could be found (see also D. C. Quick & S. L. Rogers, in press, Neurosci.).

One extensor digitorum longus muscle from each rat was traumatized by devascularization and injection of Marcaine; the contralateral muscle served as a control. After 2-4 months, the muscle nerve was tested for afferent electrophysiological activity as the regenerated muscle was stretched. Sensory units could be found in nearly every muscle tested, and could often be localized by probing the belly of the muscle. The responses in some units resembled those of normal muscle spindles, but the responses of most regenerated units were very rapidly adapting and many were only transiently sensitive to stretch stimuli. In addition, the inter-spike intervals were often highly irregular. We therefore conclude that regenerated muscle spindles can regain functional activity, but their response properties are abnormal for at least 4 months in rats. These results suggest that the criteria for evaluating the success of a muscle graft or transplant should include a consideration of whether the muscle can participate in sensory-dependent processes, including tone control, initiation of reflexes and kinesthesia.

This work will be extended to cats in order to study single regenerated muscle spindles in vitro and to make direct correlations between histological and electrophysiological data from individual spindles. (Sponsored by a grant from the National Science Foundation.)

- THE SYNTHESIS AND AXONAL TRANSPORT OF GLYCOPROTEINS IN AXOTOMIZED FROG NEURONS FROM ANIMALS MAINTAINED AT 15°C AND 25°C. Marino De Leon and Richard C. Carlsen, Department of Human Physiology, University of California, Davis, CA 95616. Previous studies in our laboratory have shown that axotomized spinal neurons in the frog do not undergo a cell body response when the animals are maintained at 15°C. In contrast, spinal neurons in frogs kept at 25°C show cell body changes beginning 5-6 days after injury. Injured neurons in 15°C animals initiate regenerative sprouting despite the absence of cell body changes, but regenerative growth is abortive and injured motoneurons do not reinnervate their former target muscles. The purpose of the 17.20 but regenerative growth is abortive and injured motoneurons do not reinnervate their former target muscles. The purpose of the present study was to compare injury-induced changes in the synthesis and axonal transport of glycoproteins in frogs kept at  $15^{\circ}C$  or  $25^{\circ}C$ . Glycoproteins are a major constituent of axon structure and have been shown to be increased during regenera-tion of peripheral nerves. Experiments were performed on Northern Rana pipiens maintained at either  $15^{\circ}C$  or  $25^{\circ}C$ . The synthesis and axonal transport of  $H^3$ -fucose labeled glycopro-teins were determined in vitro at room temperature  $(21^{\circ}C)$ . Synthesis and axonal transport of  $H^{o}$ -rucose labeled glycopro-teins were determined in vitro at room temperature (21°C). Isolated ganglia were incubated with  $H^{3}$ -fucose for 4 hours. Axonal transport continued for 18 hours and transported glyco-proteins collected at a ligature (normal nerve) or at the tran-section. At the end of this first transport period a second ligature out of the period of the terminal to the section. At the end of this first transport period a second ligature was placed around the nerve 1.0 cm proximal to the first collection point and incubation continued for 6 hours. Glycoprotein accumulation distal to the second ligature was used as a measure of axonal "turnaround". Experiments were performed at 4,7,12 and 29 days after axotomy in 25°C frogs, and at 14,21 and 36 days after axotomy in 15°C animals. The general features of injury-induced changes in glycoprotein synthesis and transport were as follows: a)  $\ln$  25°C frogs; fast anterograde transport of glycoproteins by axotomized cell bodies also increased by 40-50%. Late anterograde transport increased by 20% and "turnaround" of glycoproteins in injured nerves was approximately 250% greater than in ligated control nerves. b) In 15°C Frogs; the pattern of synthesis and transport in injured nerves Frogs; the pattern of synthesis and transport in injured nerves was the opposite of that occurring in 25°C nerves. Axotomized 15°C nerves synthesized and transported about 50% less glycopro-15% nerves synthesized and transported about 50% less glycopro-tein than control nerves. There was no apparent difference in synthesis and transport by control nerves from 15°C or 25°C animals. We conclude that one feature of the signal initiating the cell body response to axotomy is an induction of increased glycoprotein synthesis and transport, and that this induction is required to support continued growth and maturation of regenerating axons (Supported by NIH NS15065).
- FORSKOLIN ACTIVATION OF ADENYLATE CYCLASE IN VIVO STIMULATES SENSORY NERVE REGENERATION. <u>Suzanne L. Kilmer\* and Richard C.</u> <u>Carlsen</u>. Department of Human Physiology, University of Cali-fornia, School of Medicine, Davis, CA 95616. The previous demonstration of an increase and redistribution of adenylate cyclase activity in injured nerve suggests that an increase in neuronal cyclic AMP concentration could play a role in portionary approaching. We have determined that accu-17 71

increase in neuronal cyclic AMP concentration could play a role in peripheral nerve regeneration. We have determined that accu-mulating adenylate cyclase activity was translated into a two-fold increase in cyclic AMP concentration in the regenerating nerve stump, coincident with the initiation and elongation of regenerative sprouts. We sought to magnify the role of cyclic AMP in regeneration by using Forskolin, a robust activator of adenylate cyclase, to produce an additional increase in neuronal cyclic AMP in situ. Forskolin in vitro produced an approximately 40-fold greater elevation in neuronal cyclic AMP than an equi-molar (10-5) concentration of isoproterenol. The increased (10-5) concentration of isoproterenol. molar The increased cyclic AMP concentration was sustained for at least 60 minutes in the continued presence of Forskolin. Sensory nerve regeneration, the continued presence of Forskolin. Sensory nerve regeneration, measured by axonal transport of radioactive proteins to the most distal point of regenerative growth, was compared in Forskolin-treated and saline-treated frogs. Injection of Forskolin, in situ, using several patterns of application had a significant stimulatory influence on sensory nerve regeneration in freeze-lesioned sciatic nerves of Rana pipiens. Neurons in treated frogs regenerated at a rate 38% faster than their paired con-trols, 2.71 mm/day and 1.95 mm/day, respectively. The time to initiation of regenerative growth was not affected. In contrast. initiation of regenerative growth was not affected. In contrast, reinnervation of the gastrocnemius muscle by motor nerves was not reinnervation of the gastrocnemius muscle by motor nerves was not enhanced. The degree of reinnervation was determined by com-paring the tension produced by stimulating the nerve to that produced by direct stimulation of the whole muscle. Forskolin and saline-treated motoneurons reinnervated the muscle at the same post-injury day (21) and recovery of nerve evoked twitch and tetanic tensions occurred at the same rate. This contrast in the Forskolin effect on sensory and motor nerve regeneration does not support a role for Forskolin at the site of axonal growth, or the possibility that Forskolin may enhance regeneration by serving as support a role for Forskolin at the site of axonal growth, or the possibility that Forskolin may enhance regeneration by serving as a general metabolic stimulant. Instead, the positive effect on sensory regeneration suggests that Forskolin may act at injured cell bodies in dorsal root ganglia. The inability of Forskolin to cross the blood-brain barrier would exclude it from contact with axotomized motoneurons. These observations suggest that a increase in cyclic AMP concentration in axotomized cell bodies may stimulate processes involved in regenerative axonal growth. (Supported by NIH Grant NS 15065)

AN IMPROVED METHOD UNMASKS HIDDEN POLYNEURONAL INNERVATION AT 17.22 FROG NEUROMUSCULAR JUNCTIONS. A.A. Herrera. Dept. Biological Sciences, Univ. of Southern California, Los Angeles, CA 90089. Focal polyneuronal innervation (P1) is the convergence of 2 or more presynaptic axons to the same postsynaptic site. It is com-monly observed at developing vertebrate skeletal neuromuscular monly observed at developing vertebrate skeletal neuromuscular junctions and, in frogs, persists throughout adulthood. In 16 nor-mal adult <u>Rana pipiens</u> sartorius muscles, 102 of 639 endplates tested (16%) showed PI. The incidence was variable, ranging from 5 to 35% in muscles from different batches of frogs and in experi-ments done at different times of the year. The incidence of PI, however, was consistently enhanced in reinnervated muscles. In 10 frogs tested 67-107 d after the left sartorius nerve was crushed near its entrance to the muscle the incidence of PI was 40% (118/ 295), significantly higher than normal (P<0.0002). These measure-ments were made by careful application of the conventional method of estimating PI: Muscles stretch d to 1.1x rest length were immersed in the minimum concentration of curare (2-4 x  $10^{-6}~\text{M})$  nemersed in the minimum concentration of curate (2-4 x 10 m) ne-cessary to block twitching and attempts were made to subdivide the intracellularly recorded endplate potential (EPP) by varying the amplitude, polarity, and duration of a stimulus applied to the nerve. Since spontaneous miniature EPPs, the smallest units of transmitter release, are never seen under these conditions, this method will obscure very weak inputs and therefore underestimates PI.

A new method of determining PI uses high concentrations of formamide to block excitation-contraction coupling (J. Cell Biol maining to brock excitation contraction coupling (J. Cell Biol. 78,782). Muscles were exposed to 2M formamide in Ringer for 17-22 min at 7°C. This depolarizes muscle fibers to an average resting membrane potential of about -60 mV, a desirable feature that tends to block the generation of muscle fiber action potentials. Minia-ture EPPs were seen at all endplates with resting potentials more negative than -40 mV. In 6 reinnervated sartorius muscles so treated, 46 of 62 endplates examined (74%) showed PI, a level significantly higher than in curare (40%, P<0.0002). In two individual reinnervated muscles, the same groups of endplates were tested both in currare and after formamide treatment. Formamide re-vealed higher PI in both (curare 49 and 39%, after formamide 89 and 63%, respectively). Of the 28 endplates with PI seen after formamide treatment in these 2 muscles, 7 had inputs whose EPP averaged less than 3.5 mV in amplitude and showed quantal fluctuations. Three of these occasionally failed to release upon nerve stimulation. I hypothesize that the increased PI seen in reinnervated muscles after formamide treatment is due to the enhanced detectability of very weak polyneuronal inputs. Supported by grants from USPHS (NS18186) and MDA.

- IMPLANTED ELECTRODES FOR MONITORING ACTION POTENTIALS IN 17.23 REGENERATING CAT NERVES. <u>C. Krarup\* and G.E. Loeb</u>, Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205. The <u>in situ</u> study of conduction along regenerating and
  - constricted nerve fibres requires the use of near-nerve electrodes because of the low amplitude responses and high threshold to because of the low amplitude responses and high timesholes ratio and a fixed spatial relationship of the electrodes to the nerve, stranded stainless steel wires,  $100 \ \mu\text{m}$  in diameter, were sewn implanted around the tibial and sciatic nerves of cat. The leads Implanted around the tibial and sciatic nerves of cat. The leads were placed subcutaneously and connected to a socket secured to the back of the animal. Nerve action potentials were recorded by electronic averaging using a tripolar electrode configuration (Stein, R.B., et al., <u>Brain Res</u>. 128:21-38, 1977). The six independent leads spaced along each cuff allowed the local conduction velocity to be calculated from the responses recorded simultaneously at two independent tripolar sites. The amplitude of the normal compound nerve action potentials ranged from 3 to 2000 w/ depending on stimulation and recording site. of the normal compound nerve action potentials ranged from 3 to 7000  $\mu$ V depending on stimulation and recording site. The evoked muscle action potential (10 - 30 mV) was recorded via a bipolar surface patch electrode implanted on the fascia of plantar muscles; a distal sensory branch of the plantar nerve could be activated via this electrode. The implanted electrodes remained stable over many months. Conduction along <u>regenerating</u> fibres in the tibial and plantar nerves after crush was examined weekly in -lightly anestnetized animals. Four weeks after crush the action potential was 0.5  $\mu$ V (0.25 percent of normal), conducted at 10 m/s '(10 percent of normal), and had a 10-fold increase in threshold (2 - 3 ma). Within 100 days after crush, the conduction velocity (1) percent of normally, and has a to-fold increase in circlesofd - 3 ma). Within 100 days after crush, the conduction velocity along sensory and motor fibres increased to about 60 percent of normal. In other animals the tibial nerve was <u>constricted</u> by placing a silastic cuff 1 mm in diameter around the nerve. Thi This placing a silastic cuff 1 mm in diameter around the nerve. This caused 40-60 percent slowing in distal conduction velocity. In the most severely affected nerves the conduction velocity proximal to the constriction evoked by distal stimuli was 50 percent slowed as well, suggesting selective survival of small fibres. In less affected nerves the proximal velocity was normal, indicating survival of large fibres with slow conduction velocity and presumably smaller caliber distal to the lesion (Baba, M., et al., 54:197-208, 1982.)

Implanted electrodes are sensitive enough to record the action potential from regenerating nerve fibres and remain stable over many months. Distal to a constriction consistent with nerve fibre atrophy. Distal to a constriction, conduction was slowed

17.24 AXON-MYELIN ANOMALIES REVEALED BY DIAMINOBENZIDINE REACTION WITH INTRA-AXONAL HORSERADISH PEROXIDASE. R.J. Preston\*, J.D. Kocsis and S.G. Waxman. (Spon: M. Weinrich) Dept. of Neurology, Stanfo Waxman. Stanford Univ. Medical Sch. and Veterans Admin. Med. Ctr., Palo Alto, CA 94304.

In studies of rat sciatic nerve, including samples from normal and demyelinated nerve and nerves with experimentally induced neuromas, the DAB reaction with HRP-filled axons differentiated myelinated vs nonmyelinated fibers and also seemed to provide a myelinated <u>Vs</u> nonmyelinated ribers and also seemed to provide a sensitive light-microscopic indication of aberrant axon-myelin structure. Central ends of 1-2 cm segments of desheathed nerves were soaked in HRP (Sigma VI; 3% in Kreb's soln.) <u>in vitro</u> for 1-2 hrs. at 5°C. Nerves were rinsed and stored in Kreb's for 12-45 has (5°C) prior to glutaraldehyde fixation (5%;5 hrs;5°C), PO, buffer rinse (pH 7.4; containing 0.2M sucrose; 12-18 hrs; 5°C) and processing with 3,3'-diaminobenzidine tetrahydrochloride (0.05%) and  $H_{2O_2}(0.06\%)$ . Reacted nerves were examined in glycerol or after Vestopal embedding. In normal nerves, reaction product (RP) was continuously distributed in small diameter nonmyelinated fibers, but was mostly limited to nodal and paranodal axon of myelinated fibers where it formed a  $6-12 \ \mu\text{m}$  long rod centered at the node and extending into adjacent paranodal areas. Internodal and continuous staining of myelinated fibers was less frequent and often in superficial fibers possibly damaged by dissection. How-ever, when nerves were frozen whole or freeze-sectioned prior to DAB processing, continuous RP reliably occurred in myelinated Howfibers. In nerves with fibers demyelinated by loose ligature, RP appearance depended on location. Beneath and 0.6-1.5 mm central to the ligature, both normal and abnormal RP distribution occurred in myelinated fibers. The latter extended for 25-90  $\mu m$  or more, sometimes asymmetrically about nodes and other times without apparent node or myelin profiles. More centrally, normal nodes pre-valled and nodal sprouts were more frequent. In segments ending in neuromas, few or no rormal nodes occurred within 2.5 mm of the terminal stump, and only scattered medium and large diameter fibers had continuous RP despite numerous stained axons in this core ofter foreging. More centrally, neared head large zone after freezing. More centrally, normal nodal RP was less prevalent than distributions showing; densely stained nodes with extensive symmetric or asymmetric spread of RP to adjacent inter-nodes; extensive stained axonal regions with one or both adjacent paranodes absent or thinned; occasional nodal sprouts and many fine, varicose nonmyelinated processes. We cannot presently specify the mechanism through which this histochemical procedure may differentiate normal and abnormal axon-myelin relationships, but we expect that the procedure will be useful for light microscopic study and for focusing ultrastructural study of pathological tissue. Supported by the National Multiple Sclerosis Society and the Veterans Administration.

17.25 MYO-INOSITOL UPTAKE IN REGENERATING SCIATIC NERVES OF MICE. D.E. Matsumoto and R.M. Gould. Dept. of Anatomy, Howard Univer-sity Coll. of Med., Washington, D.C. 20059 and New York State Inst. for Basic Res. Ment. Retard., Staten Island, N.Y. 10314. It has been shown that myo-inositol, when injected into sciatic nerves, is incorporated into phosphoinositides by normal axons and Schwann cells, and that CDP diacylglyceride:inositol transferase, the terminal enzyme involved in de novo synthesis of phosphatidyl inositol, is present in axons (M.H. Kumara-Siri and R.M. Gould, Brain Res. 186:315, 1980). In the present study, myo-inositol uptake was examined in regenerating nerves. To initiate regeneration, sciatic nerves of anesthetized adult mice were unilaterally crushed with fine-tipped forceps and, after survivals of 2,3 or 5 days, the nerves were injected (under halothane anesthesia) with 75 to 100  $\mu\rm Ci$  of (3H) myo-inositol. Glass micropipettes were used to make multiple injections at lo-cations which were proximal and distal to the crush site. After 1 or 2 hr postinjection survival, the anesthetized animals were perfused with formaldehyde-glutaraldehyde fixative, the nerves removed, washed, osmicated and processed for embedment in epoxy resin. Semithin and thin sections of nerves were processed for autoradiography at the light and electron microscopic (EM) In autoradiographs of nerves with 2 or 3 days postcrush levels. survivals, the level of labeling was low except for an accumula-tion of grains in the region immediately proximal to the crush. In nerves with 5 days postcrush survival, the regenerating neur-ites have crossed the crush site and entered the distal portion of the nerve. The labeling pattern is correlated with the presence of the neurites so that the grain density is highest around the crush site and in the distal part of the nerve where regenerating axons occur, and the labeling is low in more proximal regions, and the general level of labeling is greater than that observed in specimens with 2 days survival. In EM autoradiographs, the neurites, including growth cones, had the highest labeling of all the structures in regenerating nerves. The processes of Schwann cells were also labeled to some extent, but grains rarely occurred over the nucleus and degenerating myelin. Examination by thin layer chromatography of lipid extracted from Examination by thin layer chromatography of lipid extracted from regenerating nerves established that injected (3H) myo-inositol was incorporated into phosphoinositides. The evidence therefore indicates that in the early stage of regeneration axons are the predominent site where myo-inositol is incorporated into phospho-lipids. This study was supported by NIH Biomedical Research Support Grant 5807RR05361 and NIH Crant NS 16305.

REINNERVATION OF SKELETAL MISCLES AFTER SCIATIC NERVE TRANSECTION AND REPAIR. S.S. Deshpande\*<sup>1</sup>, N.H. Goldberg\*<sup>2</sup>, C.K. Meshul<sup>1</sup>, F.K. Toy\*<sup>2</sup>, K.S. May\*<sup>2</sup>, R.T. Smoot\*<sup>2</sup> and E.X. Albuquerque<sup>1</sup> (SPON: T. Oh). Depts. of <sup>1</sup>Pharmacol. and Exp. Ther. and <sup>2</sup>Surgery University 17.26 of Maryland School of Medicine, Baltimore, MD 21201.

Reinnervation of the fast extensor digitorum longus (extensor) and slow soleus muscles after nerve crush (J. Gen. Physiol. 61:1, 1973) or after blockade of axonal transport by batrachotoxin (Brain Res. 225:115, 1981) occurs at old endplates (EP). This study deals with the innervation of the extensor and soleus muscles after transection of sciatic nerve and after its immediate surgical repair. The sciatic nerve was cut 30 mm from its entry surgical repair. The sciatic nerve was cut 30 mm from its entry into the extensor muscle in Wistar female rats (200 g). Immediate microneurorrhaphy with 3-5 epineural sutures (10-0 nylon) was performed. At intervals up to 8 months, the regeneration in the nerve and reinnervation of muscles were studied using electrophysiologic and light and electron microscopic (EM) electrophysiologic and light and election microscopic (EM) techniques. At 8 days after surgery, the extensor and soleus muscles showed 20% attrophy and were denervated as shown by membrane depolarization, absence of spontaneous miniature endplate potentials (mepps) or nerve-evoked muscle action potentials (AP). EM of EP disclosed absence of nerve terminals and presence of Schwann cell growth over junctional folds. At 2 weeks, extensor and soleus muscles were depolarized by 25-30 mV. The proximal nerve segment had grown through the lesion site but apparently had not made functional synapses in the muscle. By 22 days, the muscles were still depolarized by 25 mV, but mepps with low frequency (0.16 vs 3.2 Hz in control) and amplitude (0.4 vs 0.5 mV in control) were recorded indicating reinnervation. Nerve stimulation evoked APs with low rates of rise and amplitude. No stimulation evoked APs with low rates of rise and amplitude. No muscle reinnervation was observed 22 days after nerve transection alone. At 50 days, the muscles showed complete repolarization, no signs of denervation and EM of EPs at 6 weeks showed normal EPs. At 8 months after nerve repair the soleus muscle still showed 45% atrophy. Although sensory function was established between 2-3 weeks after the operation, motor ability, particularly that of digital extension, had not been regained even at 8 months. Up to day 30, daily subcutaneous injection of CM 1 ganglioside (50 mg/kg) was ineffective in enhancing reinnervation after nerve repair. It is likely that, whereas regenerating axons after crush infurv use old conduits (endoneurial tubes) for reinnervation in a injury use old conduits (endoneurial tubes) for reinnervation in a precise fashion to bring complete functional recovery, the same axons after nerve transection and immediate repair could be misdirected to old or newly formed endoneurial tubes during the process of regeneration. (Supported by USPHS Grant NS-12063 (EXA) and Bressler Research Fund (NHG).)

THE EFFECTS OF MSH/ACTH PEPTIDES ON FAST AXONAL TRANSPORT IN RAT SCIATIC NERVE. L. Crescitelli\*, °K.L. Keim and F.L. Strand, Dept. Biology, New York University, N.Y., N.Y., 10003 and "Dept. Pharmacology I, Hoffmann-La Roche Inc.,Nutley, N.J.,07110. MSH/ACTH peptides are known to improve neuromuscular function [Strand, et al. Pharmacol Biochem Behav, 5: 179, 1976] and to promote the regeneration of peripheral nerve [Strand and Kung, Peptides 1: 135, 1980] in rats. To determine if peptide-induced changes in axonal transport (AT) were in part respons-ible for the previous findings, we studied the downflow rate of fast AT in intact rats treated with either MSH/ACTH 4-10 or MSH/ACTH 4-9 Met( $0_2$ )<sup>D</sup>D-Lys [ie, ORG 2766] and in hypophysectom-ized (hypox) rats. Male Sprague-Dawley rats (225-325 gm; N=4 to 6) were used. Following treatment, a dorsal laminectomy was performed and 4 x 1 microliter injections of 3H-leucine (5 mCi/ml) were applied into the ventral horn of the 4th and 5th lumbar segments. Four hours later the animals were killed and perfused with 10% phosphate buffered formalin. The sciatic nerve was excised and divided into 3mm segments, and solubil-ized in Soluene 350 at 50°C for 18 hrs; the samples were counted for 3H at 35% efficiency for 10 min. We determined the downflow AT rate in intact control rats to be 414 ± 16 mm/24 hr. This corroborated the findings of others [eg, 410 mm/24 hr; 0chs, Science, 176: 252, 1972]. In rats treated for 7 days with 10  $\mu$ /g/kg/day of MSH/ACTH 4-10 the fast AT rate was 416 ± 14 mm/24 hr. A fast AT rate of 412 ' 3 mm/ 24 hr was determined in gats tgeated for 7 days with 1,  $\mu$ /Kg/day of MSH/ACTH 4-9 Met ( $0_2$ )<sup>10</sup>-Lys<sup>5</sup>. From 12-16 day hypox animals, a fast AT rate of 405 5 12 mm/24 hr was found. Thus, neither an excess of MSH/ACTH peptides, those reported to be neurotropic in many other experiments, nor the absence of circulating 17.29

a fast AT rate of 405  $\pm$  12 mm/24 hr was found. Thus, neither an excess of MSH/ACTH peptides, those reported to be neurotropic in many other experiments, nor the absence of circulating endogenous MSH/ACTH peptides, as evidenced from experiments in hypox animals, affected fast AT. However, more recent experiments indicate that MSH/ACTH 4-10 may alter AT in regenerating nerves. While the fast AT rate was not altered by nerve-crush in rats treated with peptide, the area under the AT curve (dpm x mm nerve) suggests an in-crease in the apparent amount of 3H-leucine incorporated pro-tein present in sciatic samples from treated rats. That MSH/ACTH fragments might increase the amount of protein trans-ported in regenerating nerves would support the concept that improvements in neuromuscular function and regeneration could be caused by such peptides. be caused by such peptides.

FIBER ELONGATING FACTOR(s) ORIGINATED FROM THE GOLDFISH BRAIN: 17.27 FILLARACTERITATION AND PURIFICATION Y. Mizrachi\*, Y. Kimhi\*, M. Rubinstein\*+ and M. Schwartz (Spon: I. Ginzburg). Depts, of Neurobiology and Virology\*, The Weizmann Institute of Science, Rehovot 76100, Israel.

We have recently shown that goldfish brain contains factors that enhance neurite outgrowth from regenerating retinal explants. Two of these were purified and further characterized

Two of these were purified and further characterized. Crude preparation was obtained by collecting the 100,000g super-natant of homogenized goldfish brain. Several peaks of activity were separated by chromatography on a Sephadex G-100 column. Among them, two distinguishable low molecular weight substances (range of 5,000-10,000 daltons) could be detected by differences in their properties: One, designated SNEF (substrate neurite elongation factor) was found to exert its effect after preadsorption onto a poly-L-lysine treated substratum. A second, designated DNEF (di-fusible neurite elongation factor) could not exert a significant effect when preincubated with the substratum. Whether this is caused by poor adsorption or "substratum-inactivation" is being investigated.

The ability of SNEF to exert an effect while being adhered, was employed to determine the nature of this peptide factor; we found that phytohemagglutinin, adsorbed onto plates, precoated with SNEF, inhibited the capability of SNEF to promote neurite outgrowth. This inhibition could be reversed by an addition of N-acetylglucose amine. The results suggest that this factor has an exposed sugar moeity

With respect to activity in situ, we found that DNEF accelerated regeneration associated processes. Thus, a single injection of 6-100 fraction (10  $\pm$ g/eye) performed simultaneously with a crush of the optic nerve shortened the period required for expres-sing neurite outgrowth in vitte (extensive outgrowth was observed Solution was earlier than the regular schedule post injury). The DNEF fraction was further purified by HPLC, yielding a component of a very high specific activity  $(10^7 \text{ fold enriched in terms of specific})$ activity relative to the crude preparation). The relation between the two factors is currently being examined.

TRANSIENT PROPERTIES OF MECHANORECEPTIVE AFFERENTS DURING REINNERVATION OF THE GLABROUS SKIN OF THE HUMAN 17.30 HAND

The technique of percutaneous microneurography was

The technique of percutaneous microneurography was used to record single unit activity from 64 mechanore-ceptive afferents during the early stages of reinner-vation (between 6 and 13 months postoneratively). The results were obtained from 13 patients who had suffered complete transsection, with subsequent repair, of the median or ulnar nerves. No functional connections were detected in another 4 patients examined at earlier postoperative (4-6 mos.) times. Three types of mechanoreceptive (RA, SAI, SAII) and many unidentified units innervating deep tissues, but no Pacinian corpuscle units were found. Most receptors were in the palm and proximal parts of the fingers, consistent with the poor clinical recovery of the pa-tients', and in contrast to distributions in normal subjects. The sampling distribution of afferents also resembled that seen in patients with poor recovery exa-mined three or more years after surgery'. Additionally, response thresholds and discharge characteristics were comparable to those of afferents studied three or more comparable to those of afferents studied three or more years after nerve repair, and similar to normal<sup>1</sup>. However, two abnormalities not previously seen in humans were encountered. Firstly, multiple receptive fields innervated by single afferents (RA, SAI) and complex receptive fields (SAI) were found in plotting fields at 10X von Frey hair threshold. Secondly, some SAI (3/14) and deep (5/22) units fatigued easily, showing a much decreased responsiveness to mechanical stimuli repeated with interstimulus intervals of 4-8 seconds. Normal af-ferents and those studied long after nerve repair sho-wed no such fatigue to similar stimuli.

These abnormal properties are considered to reflect the active process of regeneration. It is suggested that the fatigue may be due to structural or metabolic alterations of the outgrowing axon. The disappearance of multiple receptive fields when regeneration is com-plete may be due to coalescing of separate fields or retraction of peripheral sprouts.

17.31 AGE-RELATED CHANGES IN THE STIMULATION OF THE REGENERATION OF THE HYPOGLOSSAL NERVE BY TESTOSTERONE. W.H.A. Yu. Department of Anatomy, Mount Sinai School of Medicine, New York, N.Y. 10029.

10029. By quantitating the hypoglossal neurons labeled retrogradely by horseradish peroxidase (HRP) injected into the tongue, we have shown that administration of testosterone propionate (PP) accelerated the regeneration of the hypoglossal nerve in young adult rats (Exp. Neurol. 77:129, 1982; 80:in press, 1983). In the present study I have investigated whether regeneration of the hypoglossal nerve could be similarly influenced by TP in pre-pubertal rats. Three and 4 weeks old rats of both sexes were used. After unilateral hypoglossectomy under anesthesia, half of the rats in each experimental group were injected with 2 mg TP on every third day, and the other half with the oil vehicle alone. The rats were killed at the 11th, 13th, and 15th post-operative day, respectively. Twenty-four hours prior to killing, 50 ul of 10% HRP solution was injected into the midline of the tongue. The total numbers of HRP labeled neurons in both hypoglossal nuclei were counted in each rat. The number of labeled cells in the lesion side was expressed as a percentage of that of the intact side and referred to as "the percentage regeneration". The percentage regeneration increased two folds between the 11th and 15th post-operative day. In 3-weeks old rats no difference in the percentage regeneration of 4-weeks old rats treated with TP was significantly greater than that in the control group at the first 2 post-operative periods. These data indicate that the responsiveness of the hypoglossal neurons to testosterone administration during regeneration is age dependent. The hypoglossal neurons of adult rats were shown to take up and retain radioactively labeled androgens into their nuclei (Sar and Stumpf, Science, 197:77, 1977). The ability of testosterone to accelerate nerve regeneration in mature but not in immature rats may be correlated with the level of androgen receptors in the neurons. 17.32 EFFECT OF EXTRACELLULAR MATRIX COMPONENTS ON THE REGENERATION OF ADULT SENSORY NEURONS IN CULTURE. Jean R. Wrathall, Department of Anatomy, Georgetown University, Washington, D.C. 20007.

The regeneration of peripheral neurons in vivo occurs in association with nonneuronal cells of the PNS and extracellular matrix (ECM) components produced by these cells. The importance of factors produced by PNS nonneuronal cells in neural regeneration has long been postulated but the mechanisms involved have not been determined. Studies on the regeneration of adult neurons in culture may be used to investigate these mechanisms.

The regeneration of adult sensory neurons in culture appears to be dependent upon the presence of PNS nonneuronal cells and is maximal upon co-culture of neurons with a mixture of Schwann-like and fibroblastic cells (Wrathall, J. Cell Biol. 95:92a, 1982). In the present experiments, neuron regeneration was studied in the absence of nonneuronal cells per se, but in the presence of types of ECM components produced by PNS nonneuronal cells.

Dorsal root ganglia from adult mice (9-12 months old) were dissociated with collagenase and the sensory neurons seeded at low densities (6,000 viable neurons/dish) onto 35mm tissue culture Petri dishes previously coated with type I collagen, type IV collagen, laminin or combinations of collagen and laminin. As controls, replicate cultures were prepared with neurons seeded onto uncoated dishes and onto monolayer "cell beds" of mixed adult PNS nonneuronal cells (cell line SNCT). The number of neurons that attached and the percentage that had regenerated neurites was determined 24 hours later. The percentage of neurons that regenerated neurites varied with the substrate according to the following progression: type I collagen ↓ tisue culture Petri dish < type IV collagen < type I collagen + laminin < laminin < type IV collagen + laminin < mixed nonneuronal cells

With the combination of ECM components tested that appeared optimal (type IV collagen + laminin) almost 60% of the attached neurons regenerated neurites as compared to about 5% on type I collagen and 70% on a living cell bed of mixed PNS nonneuronal cells. Thus ECM components appear to have a significant effect on the regeneration of adult neurons in culture. Those components associated with basal lamina (type IV collagen and laminin) appear to stimulate regeneration to a significant degree. Whether the stimulatory effect of living nonneuronal cell beds on neurite regeneration is due, at least in part, to their production in culture of these ECM components, is currently being investigated.

The purified type IV collagen and laminin used in these experiments were a generous gift of Drs. Hynda Kleinman and George Martin.)

17.33 ANALYSIS OF PROTEINS RELEASED BY NERVE SHEATH CELLS DURING DEVELOPMENT. G. Jackson <u>Snipes\*</u>, J. H. <u>Pate Skene</u>, and John <u>A.</u> <u>Freema</u> (SPON: L. <u>Aulsebrook</u>). <u>Dept.</u> of Anatomy, Vanderbilt Univ. Sch. of Med., Nashville, TN 37232, and Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA, 94305.

Molecules released by nerve sheath cells have been assigned many roles including tropic, trophic, growth inhibiting, maintenance and structural. We have undertaken a time course study to indentify interesting proteins released by nerve sheath cells from the time of birth to adulthood in rats. We have also compared proteins released by the central optic nerve sheath with the peripheral sciatic nerve glia. During the developmental period examined in this study, most myelin-forming cells will complete their final cell division. These experiments were performed essentially as described by Skene and Shooter (PNAS, in press). Briefly, the nerves were excised, washed in phosphate byffered saline, incubated in nutrient media containing S-methionine. Labelled proteins in the supernatant were trichloroacetic acid precipitated and analysed on 2-dimensional o'farrell gels visualized by flourography.

Among the interesting proteins released by optic or sciatic nerve sheath cells are proteins with molecular weights of 37 kilodaltons (kd), 51kd, 54kd, 47kd, and 75 kd. The 37kd protein is expressed at high levels in the neonate optic and sciatic nerves, but its synthesis is greatly reduced in adult nerves. These proteins co-migrate with a protein identified by Skene and Shooter as being induced in sheath cells following a nerve crush. The 51 and 54 kd proteins were found only in the sciatic nerve and could not be detected until about 2 weeks after birth. The synthesis of these proteins has been reported to be greatly reduced following nerve injury. The optic nerve releases a 47kd protein which, like the 51 and 54 kd proteins of the sciatic nerve, is expressed at maximal levels in the adult animal. The 75kd protein, which exhibits pronounced microheterogeneity, is found in both neonatal optic and sciatic nerves, but has not been detected in either the normal or regenerating adult nerves.

75kd protein, which exhibits pronounced microheterogeneity, is found in both neonatal optic and sciatic nerves, but has not been detected in either the normal or regenerating adult nerves. Thus, we conclude that nerve sheath cells in different functional states secrete different proteins. Neonatal sheath cells release proteins different from those of adult sheath cells. Sheath cells in the peripheral and central nervous system secrete proteins that are qualitativley similar (but not identical) to each other. The pattern of secreted proteins is also different between developing neonatal and regenerating adult sciatic nerves. We are presently preparing monoclonal antibodies against some of these proteins so that we may begin to answer questions on their function.

17.34 REGENERATION OF A SENSORY AND A MOTOR NERVE. <u>Chung Bii</u> Jenq\* and Richard E. Coggeshall. Marine Biomedical Institute and Neurosciences Graduate Program and Dept. of Anat. and Physiology and Biophysics, University of Texas Medical Branch. Galveston. Texas.

Branch, Galveston, Texas. Previous work concerning axonal regeneration in peripheral nerves concentrated on the myelinated fibers. Since the majority of axons in peripheral nerves are unmyelinated, these fibers should also be considered. Young adult (200-500 gm) male rats were anesthetized by nembutal (intraperitoneal injection 35mg/Kg). The right

Young adult (200-500 gm) male rats were anesthetized by nembutal (intraperitoneal injection 35 mg/Kg). The right sciatic nerve was transacted 2-3mm distal to the ischial tuberosity. Stumps of the severed nerve were reapproximated within a silicone tube. A stitch through the epineurium and the wall of the tube was made to secure the approximation.

The rats were sacrificed 8 weeks postsurgery by perfusion with aldehydes in cacodylate buffer. After perfusion, the nerve to the medial gastrocnemius (NMG), a typical somatic motor nerve, and the sural nerve (SN), a typical somatic sensory nerve, were removed and processed for EM embedding.

All myelinated and unmyelinated axons of the NMG or SN were counted. The data are presented in Table 1. Note that in NMG, numbers of both myelinated fibers and unmyelinated fibers from the operated side are always greater than those from the unoperated side whereas in SN, the unmyelinated fibers are less on the operated side. The differences are significant (p<.05).

The present study suggests that myelinated and unmyelinated fibers behave differently in our regeneration paradigm. We presume that a greater understanding of these differences may be useful in consideration of function and therapy.

THE EFFECT OF TRIFLUOPERAZINE ON ACETYLCHOLINE RECEPTOR 181 SYNTHESIS IN CULTURED CHICK MYOTUBES. <u>M. Schneider\*, B.H.</u> <u>Shieh\*, L. Pezzementi\*, and J. Schmidt</u>. Department of Biochemistry, S.U.N.Y. Stony Brook, Stony Brook, N.Y. 11794.

> Acetylcholine receptor appearance rate in the presence of the phenothiazines trifluoperazine and chlorpromazine was measured in cultured chick myotubes by means of  $^{125}$ abungarotoxin. At drug concentrations of 5 to 10 x  $10^{-6}$  M, receptor appearance rate was significantly enhanced while receptor half-life, cellular protein, net protein synthesis rate, and acetylcholinesterase levels were not similarly affected. The phenothiazine sulfoxides were less potent by over an order of magnitude. Drug combination experiments revealed that receptor stimulation caused by phenothiazines, like that due to local anesthetics and blockers of voltage-gated sodium and calcium channels, is overcome by low concentrations of ryanodine, but, unlike that seen with lidocaine and tetrodotoxin, is insensitive to membrane depolar-ization with 20 mM KCl. The drug sensitivity of the trifluoperazine effect resembles that observed with D-600, suggesting that phenothiazines may block a voltage-gated suggesting that phenothazines may block a voltage-gated calcium channel and thereby stimulate receptor synthesis. At concentrations of 3 x  $10^{-5}$  M and above, both trifluoper-azine and chlorpromazine inhibited receptor synthesis and caused myotube contracture and cell loss, presumably due to release of calcium from the sarcoplasmic reticulum. These results lend support to the role of calcium as an Intercellular messenger in receptor synthesis regulation, but render unlikely the notion that calmodulin serves as the calcium receptor in this signaling pathway.

AGE-DEPENDENT CONVERSION OF SYNAPTIC PROPERTIES AT THE CRAYFISH 18.2 NEUROMUSCULAR JUNCTION THROUGH ALTERED MOTONEURON ACTIVITY. <u>G.A. Lnenicka</u> and <u>H.L. Atwood</u>, Department of Physiology, University of Toronto, Toronto, Ontario, Canada.

Crustacean tonic and phasic motoneurons have synaptic properties which are in accordance with their functional requirements. Phasic axon synapses produce large EPSPs which depress rapidly during repetitive stimulation. Tonic axon synapses generally produce smaller EPSPs which are more resistant to fatigue. order to test whether neural activity plays a role in the devel-opment of these properties, tonic activity was imposed upon a phasic motoneuron. The phasic "fast" closer excitor of the crayfish claw was chronically stimulated through an implanted elec-trode, and the population response of its neuromuscular synapses monitored via a recording electrode in the closer muscular synapses monitored via a recording electrode in the closer muscle. The fast excitor was stimulated for two weeks, two hours per day at 5 Hz, while the contralateral control claw was left unstimulated. After conditioning, the fast excitor initial EPSP amplitude (measured during 0.1 Hz stimulation) and the EPSP depression dursubset of closer muscle fibers. A comparison of the conditioned and control fast excitor synapses demonstrated that in sexually immature juvenile crayfish, conditioning produced a 40% decrease in the initial EPSP amplitude, and a 9-fold increase in synaptic endurance (ratio of EPSP amplitude after 30 minutes of stimula-tion at 5 Hz to initial EPSP amplitude). In large adult crayfish this regime of stimulation produced no decrease in the initial EPSP amplitude and only a 2-fold increase in synaptic endurance. Measurements of muscle fiber input resistance, and membrane time constant indicate that changes in the EPSP produced by condition-ing reflect changes in the amount and pattern of transmitter re-The effect of chronic stimulation upon the juvenile fast excitor synaptic properties has been found to persist for at least 7 days after the end of the conditioning regime.

/ days after the end of the conditioning regime. Fast excitor synapses in recently hatched crayfish produce small EPSPs which facilitate during repetitive stimulation. Dur-ing growth, these synapses gradually develop into the high output depressible synapses found in the adult. Preliminary measure-ments of fast excitor activity in free-moving crayfish indicate that the fast excitor is more active in small crayfish. It appears that the development of the phasic synaptic properties during errorth available to accounce to a decrement of the cationity of the growth could be a response to a decrease in the activity of the motoneuron, and imposed activity reverses or halts this change in synaptic function. This neuromuscular system should allow a cellular analysis of the influence of activity upon synaptic type, and the consolidation of synaptic properties during maturation.

HYPERTHERMIA-AND PENTYLENETETRAZOL-INDUCED NEONATAL SEIZURES 18.3 FACILITATE KINDLING IN THE ADULT RAT. M.F. Gilbert and D.P. Cain. Dept. of Psychology, U. Western Ontario, London, Ont. N6A 5C2

Facilitation of electrically kindled seizures has been demonstrated in adult rats following a series of subconvulsive injections of Pentylenetetrazol (PTZ) (Cain, D., <u>Pharm.Biochem.Behav.</u>, 17:1111,1982). A decreased threshold to PTZ seizures following neonatal treatment with hyperthermia (HYP) (McCaughran, J. & Schetcher, N., <u>Epilepsia</u>,23:173,1982), and an increased suscepti-bility to HYP-induced seizures as a result of neonatal PT% convulsions has also been demonstrated (McCaughran, J. & Manetto, C., Exp. Neurol.,79:287,1983). The present study investigated the effects of seizures induced by HYP and PT% at various ages upon seizure

susceptibility in the adult using the kindling model of epilepsy. A single seizure was induced in young rats at lor 10 days of age with HYP or PTZ. A multiple seizure condition consisted of 3 seizures at 1, 3, and 5 days of age. Animals were left to mature and at 90 days of age or more were implanted with teflon-coated nichrome wire electrodes in the amygdala or pyriform cortex. One to two weeks postoperatively, afterdischarge (AD) threshold was deter-mined, and thereafter a 1 sec train of square wave pulses at 200µA and 60 Hz was delivered daily in a standard kindling paradigmuntil 3 stage 5 generalized scizures were observed. Generalized scizure threshold was determined 2 weeks after the last seizure.

A significant facilitation in amyqdaloid kindling was observed in the single HYP ( $\overline{X}{=}8.8~\rm{ADS})$  and PTZ ( $\overline{X}{=}8.1~\rm{ADS})$  conditions at 1 day of age relative to saline injected and handled controls  $(\vec{X}{=}13.8~{\rm ADs})$  . No further facilitation was evidenced in the multiple seizure conditions (X=8.8 and 10.1 ADs for HYP and PTZ, respectively). A similar facilitation was evidenced for pyriform cortex kindling following a single PTZ seizure at 1 day of age  $(\widetilde{X}{=}6,6~vs,~8,6~ADs$  for controls). No differences were found in AD or generalized seizure threshold between any of the groups.

This facilitation, however, appeared to be age limited. Animals receiving a single PTZ scizure at 10 days of age did not differ from controls in amygdaloid kindling rate ( $\overline{X}$ =12.8 vs. 13.8 ADs for controls). These results cannot be attributed to differences in the length or severity of the seizures between age groups as PTZ seizures in 10 day olds were longer and as severe as those observed in 1 day olds. In addition, similar kindling rates were observed in the HYP and PTZ conditions even though PTZ seizures were always of a much longer duration and frequently involved a tonic component never observed during HYP-induced convulsions. Similarly, multiple seizures did not result in any further facilitation in kindling rate. This age specific increase in seizure susceptibility therefore is believed to reflect a proclivity for neuroplasticity in the developing organism, rather than brain damage induced by neo-natal convulsions. (Supported by a NSERC grant to D.P.C.)

NEUROMUSCULAR BLOCKADE WITH BOTULINUM TOXIN DECREASES THE 18.4 INCORPORATION OF SODIUM CHANNELS INTO SKELETAL MUSCLE.

INCORPORATION OF SODIUM CHANNELS INTO SKELETAL MUSCLE. L. Bambrick<sup>\*</sup>, T. Gordon and J. Baumgold. Dept. of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T66 2H7. The density of extrajunctional acetylcholine receptors (ejAChR) in skeletal muscle is regulated by the motor neuron during devel-opment, denervation and reinnervation. Studies using neuromuscular blocking agents to interfere with junctional transmission (Lavoie, P.-A., et al., Exp. Neur., 54, 148, 1977) or electrical stimula-tion of denervated muscle (Linden, D.C. and Fambrough, D.M., Neurosci., 4, 527, 1979) indicate that this effect is, at least in part, mediated by the nerve-reveased substance.

The present study was undertaken to determine whether nerve-mediated activity may regulate the density of the voltage-sensi-tive channel (Na-channel), which is another integral membrane tive channel (Na-channel), which is another integral membrane protein, and further whether incorporation of Na-channels and ejAchR are regulated reciprocally. Na-channel density increases during development (Sherman, S.J. and Catterall, W.A., J. Gen. Physiol., 80, 753, 1982) and declines following denervation (Barchi, R.T. and Weigle, J.B., J. Physiol., 295, 383, 1979) in contrast to the direction of change in ejAChR density. To discrim-inate between the effects of nerve-evoked muscle activity and of a possible nerve released factor on Na-channels, experiments were performed using botulinum toxin (BoTx). BoTx is a neuromuscular junction blocker which acts presynaptically to prevent the release of ACh while not disrupting the terminal, interfering with axonal transport or directly affecting the muscle. Sprague Daley rats at different stages of development received subcutaneous injections of BoTx into one leg. The experimental and

Sprague Daley rats at different stages of development received subcutaneous injections of BoTx into one leg. The experimental and control contralateral leg muscles were removed at various days following treatment. The presence of ejAChR was assayed by using the contractile response to exogenously applied ACh as a measure of ACh sensitivity. The muscles were subsequently homogenized and Na-channels assayed using 3H-saxitoxin (3H-STX) a Na-channel specific neurotoxin. The number of ACh receptors was assayed using 1251-labelled  $\alpha$ -bungarotoxin ( $1251-\alpha$ BTX). The affinity constants (Kd) and maximum bindings ( $B_{max}$ ) were determined by a Scatchard analysis as well as from a direct hyperbolic fit of the data. The effect of BoTx in all ages was to concurrently decrease Na-channel numbers and increase ACh sensitivity. The Kd of the bindings was unchanged. Our results indicate that nerve evoked activity mediates the incorporation may be reciprocally related to the decreased incorporation of ACh receptors into the extrajunctional membrane. membrane.

18.8

RAPID REMODELLING OF NEUROMUSCULAR JUNCTION DURING SHORT-TERM 18.5 DISUSE. Fahim, M.A. and Robbins, N. Anatomy Dept., Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Disuse in adult neuromuscular junctions (NMJs) leads to rapid changes (within 3-5 days) in neuromuscular synaptic physiology (review; Robbins, <u>Trends in Neurosci</u>, p. 120, 1980). Therefore, it was of interest to investigate whether junctional structure was correspondingly modified. In an experimental disuse model, we employed a recently developed technique for obtaining large num-bers of single fibre NMJs for topologic examination by scanning electrom wire experimental discussion of the structure o bers of single fibre NMJs for topologic examination by scanning electron microscopy (SEM). Disuse was achieved by pinning the ankle and knees of male 150-180 g Sprague-Dawley rats, a proce-dure known to cause instant and long-lasting disuse of about 90% (Fischbach & Robbins, J. Physiol. 201, 305, 1969). After 3,5,7 and 10 days, muscles were removed and prepared for SEM (Fahim et al., J. Neurocyt. 12, 13, 1983) and light microscopy. In soleus muscles, the motor endplate appeared as a smooth, slightly elevated, elliptical 'raised area' into which the synap-tic clefts were etched. After only 3 days of disuse, the primary clefts became more frequently rounded in shape rather than linear channels, although the areas of the primary cleft and of the

channels, although the areas of the primary cleft and of the 'raised area' were unchanged. Corresponding to the rounded shapes, 'raised area' were unchanged. Corresponding to the rounded shapes quantitative measurements of primary clefts showed a significant increase of the ratio of perimeter to center line length at 3,5 and 7 but not at 10 days of disuse. The changes may have receded either because of loosening of the pin, circumferential atrophy compressing the folds, or to some adaptation. Atrophy of about 20% was noted at 3-7 days and of 36% at 10 days. In a pilot study of 5 day disused muscles, using the zinc iadide crime method to view the prime to the part of the part of

iodide osmium method to visualize nerve terminals, there was enlargement of the nerve terminal area and most frequently, ultraenlargement of the nerve terminal area and most frequently, ultr terminal sprouting. Although nerve sprouting has been observed after total disuse obtained by various drugs (Brown, <u>Ann. Rev.</u> <u>Neurosci. Abst. 4</u>, 17, 1982), this is the first report of nerve terminal sprouting in disuse obtained without drug or nervemuscle injury.

The SEM changes after 3-7 days of disuse differ from those seen after total TTX-induced disuse (Labovitz et al., <u>Neurosci. Abst.</u> 8, 755, 1982) where the 'raised area' is considerably reduced. Thus, "physiological" disuse, which is never complete, may differ in its consequences from that of artificial total disuse.

In conclusion, endplates undergo rapid structural remodelling in response to diminished activity. The presynaptic nerve termi-nals may be more plastic, exhibiting growth, while the postsynap-tic structures undergo distortion. This work was supported by NIA grant AG 00795 and NS 18694.

REGIONAL BRAIN 2-DEOXYGLUCOSE UPTAKE DURING PERFORMANCE OF A 18.7 LEARNED REACHING TASK. Jannon L. Fuchs, Sandra M. Bajjalieh\* Cheryl A. Hoffman\* and William T. Greenough. Dept. of Psycho Dept. of Psychology, University of Illinois, Champaign, IL 61820.

Regional brain activity in rats performing a learned reaching task was studied using  $\lfloor^{14}C\rfloor$  2-deoxyglucose autoradio graphy. The reaching task has previously been used as a model learning system for investigating changes in brain RNA and protein chemistry (Hydén & Eghazi, 1964; Hydén & Lange, 1968). Recently, pyramidal cell apical dendritic branching was found to increase in the motor cortex forelimb area contralateral to the trained paw (Larson & Greenough, 1981). The present study was carried out to localize brain areas metabolically activated during the reaching task in order to provide a basis for further detailed anatomical and metabolic studies.

Fifteen male hooded rats were trained to reach through a hole in their plexiglass training cage for small pieces of food placed on a platform just outside the cage. A transparent cage partition was placed next to the hole so that the rat could only reach food using its initially non-preferred paw. As a consequence of the partition placement, the rat was positioned such that only the partition pretent, the fat was positioned such that only one eye could view the food in the reaching situation. Animals were trained in 2 sessions per day (total l hr.) for 7 days. On the 8th day, subjects were injected i.p. with  $[^{14}C]_{2-deoxyglucose}$  (5  $\mu$ Ci/1009). The post-injection survival period lasted as long as the subjects kept reaching (usually for 35-55 minutes). Littermate controls (N=7) received the same treatments but were not trained, and were given either free access to food or no food during the post-injection period.

Increases in 2-deoxyglucose uptake were observed in the hemisphere contralateral to the reaching paw in areas including primary motor and sensory forelimb regions of cerebral cortex, and in prefrontal cortex, dorsal column nuclei, and caudate-Uptake in the ipsilateral hemisphere resembled that of putamen. controls in these regions. On the side contralateral to the eye which could view the food, increased label was observed in the superior colliculus and lateral geniculate nucleus. The asymmetry in superficial layers of superior colliculus was rats which performed the learned reaching task under very dim red light.

SHORT AND LONG TERM SYNAPTIC STRUCTURAL CORRELATES OF ACTIVITY AND EFFICACY CHANGE IN RAT HIPPOCAMPAL SLICES. W. T. Greenough and F.-L. F. Chang. Depts. of Psychol. and Anat. Sci. and Neur. and Behav. Biol. Prog., Univ. Illinois, Champaign-Urbana, IL 61820. Lee et al. (J. Neurophysiol., 1980, 44:247) reported increased density of shaft synapses and reduced variation in spine shape measures in hippocampal CAI shortly after potentiating stimulation of Schaffer collateral afferents. However, their activity con-trols received less stimulation than the LTP preparations. We have further studied structural correlates of 1) long term potentiation (LTP), 2) equivalent low frequency synaptic activity, 3) tiation (LTP), 2) equivalent low frequency synaptic activity, 3) continuous high frequency synaptic activation which did not pro-duce LTP, and 4) synaptic inactivation by high  $Mg^{+2}/low$  Ca<sup>+2</sup> incubation, in subfield CAl in the <u>in vitro</u> hippocampal slice, and have examined the persistence of changes at 10-15 min, 2h, and 8h after stimulation. After potentiating stimulation (6 trains at 100 Hz for 1 s or 200 Hz for 0.5s), compared to an equivalent number of low frequency stimuli (1 Hz for 600s), there were increases in numbers of shaft and sessile synapses (synapses on stubby, headless spines). This suggested 1) an increase in the number of shaft synapses onto inhibitory interneurons and/or 21 number of shart synapses onto initiation on pyramidal neurons ana/or y/ involving initial formation of shaft synapses and a transition from shaft, to sessile to spine synapses. Postsynaptic spine heads also assumed a rounder shape, as indicated by decreases in spine perimeter to area ratios, contact lengths, and the percent-age of 'cup' shaped spines. There was no effect of potentiating stimulation on bouton or spine areas. After continuous high fre-quency synaptic activation (40 Hz or 100 Hz for 10 min), which produced no apparent LTP, there were no changes in synapse numbers or spine head shape parameters. However, in contrast to effects of LTP there was an increase in bouton mitochondrial area and a marginal increase in bouton area compared to the low frequency condition. Inactivation did not affect any of these measures. LTP associated increases in numbers of shaft and sessile synapses persisted over an 8h incubation period, while the effect on spine shape disappeared after 2h. Physiologically-demonstrable LTP per-sisted over the 8h period. Effects of continuous high level activation on mitochondrial and bouton areas were even more transient, disappearing 2h after stimulation. These findings 1) confirm previously reported effects of poten-

tiating stimulation on synapse numbers and spine shape, 2) in dicate that spine shape changes are not necessary for the main-tenance of LTP, and 3) indicate that continuous high frequency activation which does not produce LTP has different (and non-per-sisting) effects from potentiating stimulation. (Supported by NSF BNS-8216916 and NIH ST32 GM7143)

A (1\*C)-2-DEOXYGLUCOSE STUDY IN THE ADULT RAT SOMATOSENSORY COR-TEX FOLLOWING ACUTE AND CHRONIC DEAFFERENTATION. <u>W.D.</u> <u>Dietrich,</u> <u>R. Busto\*, M.D. Ginsberg</u> and <u>D.W. Smith\*</u>. Cerebral Vascular Disease Research Center, Departments of Neurology and Anatomy, University of Miami School of Medicine, Miami, Florida 33101. Previous quantitative histochemical studies demonstrated that chronic sensory deprivation produces changes in the activities or certain enzymes related to energy metabolism in individual bar-rels of the posteromedial barrel subfield (PMBSF) (Dietrich, et al., J. <u>Neurosci.</u> 2:1608-1613, 1982). Surprisingly, enzyme ac-tivities in barrels associated with intact whiskers were <u>increased</u> significantly over control values, apparently the re-sult of an increased utilization of the intact sensory periphery by the animals. In the present investigation, we have examined chronic sensory deprivation produces changes in the activities of by the animals. In the present investigation, we have examined the effects of deafferentation on the somatosensory cortex of adult rats to ascertain whether increased metabolic activity in this cortex could account for the previously reported enzymatic changes. Deafferentation was produced in experimental animals by first plucking all the large whiskers on one side of the face and next cauterizing the corresponding hair follicles. Following 1, 2, 5, 10 and 15 days post-whisker removal,2-DG studies were performed according to the method of Sokoloff et al. for the deter-

A (14C)-2-DEOXYGLUCOSE STUDY IN THE ADULT RAT SOMATOSENSORY COR-

mination of local cerebral metabolic rates for glucose (LCNRG). Glucose utilization was reduced in the contralateral barrel subfield 1, 2, 5 and 10 days post-whisker removal, with the largest decrease occurring at 1 day (approximately 698 of sham-operated control values). Following this period, there was a progressive recovery of LCMRG at each subsequent time period. In contrast, an increase in LCMRG was demonstrated in the ipsilateral barrel subfield at selective time periods with the largest increase occurring at 5 days post-deafferentation. Isolated areas of high glucose utilization within the region of the PMRSF were apparent in groups of 3 to 5 overlaying the approximated region of lamina IV. Quantitative analysis of these individual re-gions demonstrated LCMRG to be approximately 130% of sham-operated controls. In contrast, increased glucose utilization in the region of the barrel subfield could not be demonstrated in 15-day animals.

The present findings demonstrate that following permanent re-moval of all the large whiskers on one side of the face, a transient increase in glucose utilization occurs in the PMBSF associated with the intact set of whiskers. The results are thought to be indicative of an increased utilization of the intact sensory periphery under these conditions. Finally, these results demon-strate that following a sustained period of decreased or incre-ased stimulation, there is an apparent readjustment of the level of glucose utilization in the affected brain region. NUMERICAL DENSITY OF SYNAPSES IN NEUROPIL OF OCCIPITAL CORTEX OF 15.9 RATS REARED IN COMPLEX, SOCIAL, OR ISOLATED ENVIRONMENTS. Anita M. Turner\* and William T. Greenough (SPON: C. L. Prosser). Depts Psychol. & Anat. Sci., and Neur. & Behav. Biol. Prog., Univ. Ill-Depts. inois, Urbana-Champaign, IL 61820.

Quantitative studies of Golgi-stained tissue have indicated that neuronal dendritic fields are more extensive in the visual cortex of rats reared in complex environments (EC) than in rats reared socially (SC) or individually (IC) in standard laboratory cages. While it has been widely assumed that this was associated with an increased number of synapses, reported synapse numbers per unit area, uncorrected for size, have been lower in EC than in IC rats (e.g., Diamond <u>et al.</u>, <u>J. Neurosci. Res.</u> 1:109, 1975). Our results, using stereological calculations, conflict with this prior work. Members of 11 littermate triplet sets of male Long prior work. Members of 11 littermate triplet sets of male Long Evans hooded rats were reared in EC (grouped in a large cage with daily toy changes and daily exposure to a playbox), SC (paired in stainless steel hanging cages),or IC (individually in hanging cages) environments from 25 to 55 days of age. Micrographs repre-senting a total area of 236  $\mu^2$  (final mag., 41,786X) were ran-domly taken from each of layers I, III and IV of area 17, exclud-ing cell bodies and blood vessels, from lead citrate-uranyl ace-tate stained sections from each of the 33 animals. All synapses exhibiting presynaptic vesicles and an asymmetric postsynaptic density were included. Swnapse density was estimated by the methdensity were included. Synapse density was estimated by the meth-of of DeHoff (DeHoff & Rhines, eds., <u>Quantitative Microscopy</u>, Mc-Graw-Hill, 1968). Synapses were treated as discs of infinite thinness. Results, below, indicate slightly higher overall synaptic density in EC  $\underline{vs}.$  SC rats, with IC values below these groups. aptic density in EC vs. SC rats, with IC values below these groups. Calculations using a number of other published formulae for volume density, including methods which correct the size distribution (Coupland, <u>Nature</u> 217:384, 1968), provide directionally equivalent results, although absolute values differ. Calculation of neuron densities, which will allow estimation of the number of synapses per neuron, is in progress. (Supported by NSF BNS 8216916 and U. Ill. Res. Bd.)

DEVELOPMENTAL CHANGES IN ACETYLCHOLINESTERASE IN NORMAL AND MED 18.10 MUSSE MUSCLE. C.G. Reiness and J. Yeakley\*. Dept. of Biology, Pomona College, Claremont, CA 91711. We have investigated the effects of the hereditary motor end-

We have investigated the effects of the hereditary motor end-plate disease (med) on the development of the molecular forms of acetylcholinerterase (AChL) in mouse muscle. This mutation exists in two alleles, med and med<sup>J</sup> which cause progressive muscle weak-ness and death of the mice by 3 (med) or 5 (med<sup>J</sup>) weeks of age. AChE forms from the biceps brachi in uscle, which is severely affected by the disease, were separated by velocity sedimentation on linear sucrose gradients. Globular forms that sedimented at approximately 105, 65 and 45 (the  $G_4$ ,  $G_2$ , and  $G_1$  forms; Bon et al. PNAS <u>76</u>, 2546 (1979) were present. In normal littermates of af-fected mice, the fraction of total AChE in the 10S peak increased from 102 at day 10 to a plateau of 30% at day 20. A concomitant from 10% at day 10 to a plateau of 30% at day 20. A concomitant decrease in 4-65 forms from 50% to 30% of the total suggested that they were converted to 105 AChE. AChE profiles of med<sup>J</sup> mice were indistinguishable from those of normal littermates until 14d of age (about 4d after symptoms of the disease are first detectable). Thereafter, med<sup>3</sup> mice had relatively less 10S and more 4-6S AChE than unaffected mice. Med mice were similar ex-

more 4-65 AChE than unaffected mice. Med mice were similar ex-cept that they deviated from normals at an earlier age, and the 45 (but not 65) form virtually disappeared by 19d of age. Asymmetric 165 ( $A_{12}$ ) and 135 ( $A_8$ ) forms were also present in biceps brachii. The proportion of 165 AChE in normal muscle was constant at about 3545%. Despite a 50% reduction in AChE spe-cific activity in med<sup>J</sup> mice, the mutation did not have a selective effect on 165 AChE as it did on the 105 and 4-65 forms.

All forms reappeared after inactivation of AChE in situ with DFP. DFP. Thus persistence of these forms in the muscle represents (at least partly) continued synthesis rather than maintenance of molecules existing prior to the onset of the disease. The effects of denervation for 7d were similar to those of the

med<sup>J</sup> mutation. There was a decline in relative amounts of 10S  $\overrightarrow{\text{AChE}}$  while 16S remained prominent. We thus conclude that the effects of the med<sup>1</sup> mutation on AChE

in mouse biceps brachii muscle are similar to those of denervation. The muscle remains innervated throughout the course of the disease, indicating that some factor other than presence of the nerve must regulate AChE. Neither denervation nor onset of the disease results in the selective loss of the endplate specific 16S AChE. Therefore expression of this form does not require continuous innervation in mouse muscle.

18.11 PAW PREFERENCE AND TRAINING IN CATS WITH ADULT OR NEONATAL REMOVAL OF ONE CEREBRAL HEMISPHERE. <u>J.W. Burgess and J.R.</u> <u>Villablanca</u>. Mental Retardation Research Center, Departments of Psychiatry and Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.

In continuing studies on recovery of function and brain reorganization, we examined paw preferences after ablation of the left telencephalon (hemispherectomy) in neonatal (4-18 days impairs posture and movement of the right (contralateral) limbs. Paw preference was evaluated with a 10-30 cm string manipulandum, passed alternately through L or R visual fields to elicit directed paw responses in 5-20 min testing sessions. Prior to two months of age, no limb preference was apparent, but after this age hemispherectomized kittens used the impaired this bias was more marked than in neonatal-hemispherectomized cats (p<.001) or intact adults (p<.001). This abnormal paw preference showed plasticity to motor training in both age groups. By presenting the string stimulus repeatedly to the affected side, adult-lesioned animals were induced to respond with the Side, adult-residue animals were induce to respond with the impaired limb, and gradually reversed their marked preference for the non-impaired paw. In later unbiased testing, they reponded more with the affected limb than did untrained animals  $(p^{<},01)$ . Directed paw use was also tested in a more complex food-retrieval paradigm: food-deprived cats were presented with the interior of pay. a box containing food accessible only with the impaired paw. Neonatal-lesioned animals (N=4) mastered retrieval in 1 trial either spontaneously or with brief restraint of the non-impaired paw. Adult-lesioned cats required significantly more trials (mean=7.57) to use the impaired limb (p<.001), and could do so only with continuous restraint of the non-impaired paw, exten-sive food deprivation, and at least 1 month of postsurgical recovery. However, after initial mastery, both groups retained proficiency in the task. Overall, these results show that ab-normal paw preference resulting from hemispherectomy in cats shows increased recovery if: 1) lesions are sustained neonatal-ly, or 2) appropriate motor training is administered. Concomitant studies of underlying anatomical mechanisms are presented in a companion abstract. (supported by USPHS HD-05958 and HD-04612).

18.12 EARLY MONAURAL DEPRIVATION IN THE RAT INDUCES REORGA-NIZATION OF THE PATTERN OF METABOLIC ACTIVITY IN THE (SPON: J.G.Richards) Friedrich Miescher-Institut P.O.Box 2543, 4002 Basel, Switzerland,

Local metabolic activity in the central auditory system of the albino rat was assessed after free field auditory stimulation with 20 kHz sweeps, 5s/sweep for 45 minutes, using [I4-C]-2-deoxyglucose autoradiogra-phy. Autoradiograms were analysed using a Leitz-ASBA computerized image analysing system.

In the normal mature rat a high level of metabolic activity was observed bilaterally in all brainstem and mesencephalic auditory nuclei. The stimulus used did not markedly increase metabolic activity in the medial geniculate body (MGB) and cortical areas. Acute unila-teral ear block induced a dramatic decrease of activi-ty in the ipsilateral cochlear nuclei (CN), contralateral lateral lemniscus (LL) and inferior colliculus (IC). Metabolic activity in the contralateral superior olivary complex (SOC) was only slightly reduced. Rats of II-I2 days old were raised with the left

ear blocked until 25, 35 or 50 days old and were then presented with the auditory stimulus either with the left ear still blocked, with both ears ears open or with the left ear open and the right ear blocked. No modification of the pattern of metabolic activity was observed as compared to normal and acute controls in the CN,SOC,LL,MGB and cortex. However, in the IC cont ralateral to the ear blocked a complex pattern of chan-ges was observed. In the central and caudal parts of this nucleus, a 30% decrease of activity in the medioventral region was seen after bilateral stimulation, while a 15% increase of activity was observed in the central and dorso-lateral part. In the frontal region of the nucleus an overall IO% decrease of activity was seen. These changes were already present in 25 day old rats and longer periods of deprivation did not induce any further alterations. No changes in mitochondrial enzymes (cytochrome C oxydase) or structural elements (tubulin, microtubule associated proteins MAPI & MAP2, neurofilaments and synaptic membrane proteins) were apparent using enzymatic and immune staining techniques. Further studies will be required to evaluate the mechanisms underlining the observed metabolic plasticity.

DEVELOPMENT OF THE IPSILATERAL RETINO-COLLICULAR 19.1 PROJECTION IN THE GOLDEN HAMSTER, R. Insausti, C. Blakemore, and W.M. Cowan. The Salk Institute, P.O. Box 85800, San Diego, CA 22138; University Laboratory of Physiology, Oxford, England; and Dept. of Anatomy, University of Navarra, Spain

In most rodents that have been studied, there is, in the immediate postnatal period, an extensive projection from the retina to the ipsilateral superior colliculus, which later becomes restricted to the rostral part of the colliculus unless the contralateral eye is removed at, or shortly after, birth. We have analyzed the time course of the restriction of this projection in golden hamsters and, using a variety of retrograde labeling procedures, have determined the cells of origin of the early extensive retino-collicular projection, and their fate after unilateral enucleation on the day of birth.

From a series of brains of animals in which wheat germ agglutinin-conjugated horseradish peroxidase (WGA-HRP) was injected into one eye at different ages, it is evident that the ipsilateral retino-collicular projection is distributed across the entire ro. ro-caudal extent of the colliculus by the day of birth, and that it begins to withdraw from the caudal part of the colliculus towards the end of the first postnatal week. By day 12 or 16 it is reduced to its adult form, being restricted to the rostral pole of the colliculus. Retrograde labeling experiments with WGA-HRP or the fluorescent dyes Fast Blue, True Blue or Nuclear Yellow, indicate that the early-formed ipsilateral projection arises from ganglion cells that are scattered across most of the retina; however, as the projection within the colliculus becomes progressively restricted, its cells of origin come to be located predominantly in the inferior temporal quadrant of the retina. That this restricted distribution of the cells of origin of the projection is due to retinal ganglion cell death has been established by experiments in which True Blue was injected into the colliculus of one side on the day after birth in normal hamsters and in animals in which the contralateral eye was removed. Retinal whole mounts prepared when these animals were killed on day 16, showed a clear difference in the two groups: in the normal animals the labeled ganglion cells were essentially limited to the inferior temporal retina, whereas in the enucleated animals many were found widely scattered across the retina as in neonatal animals. Taken together these findings deross the return as in neoratal annuals. Taken logenter these that and a sin neoratal annuals. Taken logenter these that a diffuse origin within the retina; (ii) that its restriction during the first two weeks postnatally is due to the selective death of ganglion cells in the central and nasal parts of the retina; and (iii) that this cell death is dependent upon the integrity of the input from the controlateral eye. THE IPSILATERAL RETINAL PROJECTION TO THE SUPERIOR COLLICULUS IN 19.2 THE RABBIT: RE-EXAMINATION OF DEVELOPMENT AND OF ENUCLEATION

THE RABBIT: RE-EXAMINATION OF DEVELOPMENT AND OF ENUCLEATION EFFECTS. L.H. OStrach, K.L. Chow and J.W. Crabtree\*. Dept. of Neurology, Stanford University, Stanford, California 94305. A re-examination of the ipsilateral retinal projection to the superior colliculus (SC) in dutch-belted rabbits has revealed significant new information about the pattern and size of this projection during postnatal development and following unilateral enucleation. Rabbits aged 1, 6-7, 10-11 days, and adults received unilateral intraocular injections of 3H-proline. After appropriate survival times the animals were perfused with 10% forma-lin and the brains were frozen sectioned at 60  $\mu$ . Complete series lin and the brains were frozen sectioned at 60  $\mu$ . Complete series of sections were identically prepared, exposed and developed to demonstrate the autoradiographically labelled retinal projection. Animals enucleated either at day 1 or as adults were identically prepared. Reconstruction of the entire surface area of the SC, dorsal view area of the ipsilateral projection to the SC and length (anterior-posterior extent) of both the entire SC and the ipsilateral projection were based on dark-field camera lucida drawings of every section. In normal animals from day 1 to adult ace increases in SC

In normal animals from day 1 to adult age increases in SC surface area (138%) and length of SC (41%) were observed. Significantly, the area occupied by the ipsilateral projection and its length also increased (110% and 62% respectively); thus, the proportional area of SC receiving ipsilateral retinal inputs

and its length also increased (110% and 62% respectively); thus, the proportional area of SC receiving ipsilateral retinal inputs was unchanged during postnatal development. After 2-6 months survival, animals enucleated on day 1 showed expected decreases in SC surface area (37%) and length of SC (14%). However, the area occupied by the ipsilateral projection and its length was the same as in normal adults. Animals enuclea-ted as adults showed smaller decreases in SC surface area (16%) and SC length (6%) and the area and length of the ipsilateral projection were similar to normal adult values. In all cases the ipsilateral projection occupied approximately the rostral 1/3 of the SC and appeared wedge-shaped with a broad base aligned with the lateral margin of the SC. The present results show that the ipsilateral retinal projec-tion to the SC in rabbits is organized into its adult pattern at birth and develops to retain a constant proportional distribution within the SC. Furthermore, this pattern and distribution are not altered by enucleation. Additional data obtained from normal and enucleated fetal rabbits will be present findings provide a more thorough and accurate representation of the ipsilateral retinal projection in the rabbit than has been previously report-ed (Ostrach et al., Invest Ophthal Vis Sci 20:(Suppl): 73, 1981). ed (Ostrach et al., <u>Invest Ophthal Vis Sci 20:(Suppl): 73, 1981)</u>. VISUALLY GUIDED AVOIDANCE BEHAVIOR BY RATS WITH EXPANDED IPSI-LATERAL PATHWAYS. G. C. Midgley (SPON: R. C. Tees) Dept. of Psychology, Mount Allison Univ., Sackville, N. B. EOA 3CO Canada. This study is part of an investigation of the plasticity of ipsilateral retinal connections to visual structures. Unilateral 19.3 eye removal in infancy results in the development of new retinal connection and a different pattern of connections in the visual system of the rat. When small pieces of food or large objects approach the rat from the peripheral visual field they misdirect their initial head turn and behave as if the new visual pathways have aberrant connections (Midgley, 1981). Misdirected head turns could be the direct result of aberrant connections. However, it is also possible that the animals were attempting to avoid the visual stimuli. To test this notion we directly examined the visually guided avoidance behavior of rats with expanded ipsi-lateral visual pathways. If the pathways have aberrant con-nections then the rats should also misdirect their avoidance responses

The visually guided behavior of Albino rats with expanded ipsilateral visual pathways was made entirely dependent upon the ipsilateral connections by severing the contralateral visual tract. They were trained to run between two goal boxes and visual stimuli that elicited avoidance responses from intact animals were presented in each of 4 quadrants of the visual field. The rats' avoidance responses were video-taped and an analysis of the relationship between the stimulus position, analysis of the relationship between the stimulus position, initial head turn and the direction that the animal ran was conducted. The success of the contralateral optic tract lesion and expansion of the ipsilateral retinal pathway was verified by the injection of horseradish peroxidose (5 ml, 40% solution) in the intact eye and microscopic analysis of the ipsilateral and contralateral control of the ipsilateral and contralateral superior colliculus.

The visually guided avoidance behavior of the rats with expand-ed ipsilateral pathways was appropriately directed and except for very small stimuli presented in the extreme peripheral visual field could not be distinguished from that of the normal rat. The misdirected approach response of these animals may in fact represent and attempt by the animal to avoid visual stimuli. The size and nature of the new subcortical pathways may result in a significant reduction of visual acuity. Reduced acuity would, in turn, result in avoidance of visual stimuli that the intact animal would recognize as food. These findings suggest that the new connections are not aberrant but, appropriate, and perhaps a plastic and adaptive response to neonatal visual damage.

AN AUTORADIOGRAPHIC ANALYSIS OF CELL GENERATION AND DEATH IN THE HAMSTER RETINAL GANGLION CELL LAYER.  $\underline{D.R.}$ 19.4 Sengelaub, R.P. Dolan\*, and B.L. Finlay. Department of Psychology, Cornell University, Ithaca, N.Y. 14853 At birth, the distribution of cells in the hamster retinal ganglion cell

layer is uniform across the retinal surface. Cell number increases through postnatal day 5, after which a substantial amount of cell loss surface, it is greatest in the peripheral retina. In order to determine if this greater peripheral cell loss is a product of retinal position or time of cell genesis, the initial number of cells, spatial distribution of cells, and relative loss of cells by generation day was studied using tritiated

thymidine. Following timed matings, pregnant females were injected with  ${}^{3}$ H thymidine (5 uCi/gram body weight) on embryonic days 9-14 (E15 = day of birth). Pups were injected individually (20 uCi/grm) for postnatal injections on days 1-3. Animals were killed on either postnatal day 4 (prior to the period of maximal cell degeneration), on days 5 or 6 (the period of maximal observable degeneration), or at adulthood. After autoradiography processing, counts of labelled live and degenerating cells were made from horizontal sections through the retinal ganglion cell layer. The hamster retinal ganglion cell layer is generated from embryonic day 10 through postnatal day 3, with the number of cells labelled being small and decreasing with injections after postnatal day 1. Cell generation has two peaks on E12 and E14. The spatial distribution of labelled cells varies with injection day and shows evidence of both a temporal-to-nasal and a center-to-periphery progression. E10 injections label 32% more cells at the temporal margin of the retina than at the nasal margin, and 22% more centrally than peripherally. Injections on postnatal day 1 (day of birth) label 25% more cells nasally than temporally and 113% more cells peripherally than centrally. Migration into the ganglion cell layer of cells generated on E13 or later continues through postnatal day 6, increasing the number of labelled live cells from postnatal day 4 to day 6 for these cohorts. For cells labelled on E10 through E12, numbers of labelled live cells decrease over this same period.

The ratio of labelled degenerating cells to live cells is equal for all prenatal injections, indicating that no prenatal cohort is subject to more cell loss than any other. Injections after postnatal day 1 label few degenerating cells. Rates of cell loss are always relatively higher in the periphery than the center for each cohort, regardless of the spatial distribution of the cells in that cohort.

These results indicate that it is retinal position and not time of cell genesis that determines the probability of cell survival.

19.5 TEMPORAL RETINA IS PREFERENTIALLY REPRESENTED IN THE EARLY INNERVATION OF THE SUPERIOR COLLICULUS IN HAMSTERS. Kenneth C. Wikler, Judy I. Raabe\*, and Barbara L. Finlay. Department of Psychology, Cornell University, Ithaca, N.Y. 14853 The hamter ratios chours distinct spatial patterning of neurographics

HAMSTERS. Kenneth C. Wikler, Judy I. Raabe\*, and Barbara L. Finlay. Department of Psychology, Cornell University, Ithaca, N.Y. 14853 The hamster retina shows distinct spatial patterning of neurogenesis (Sengelaub, Dolan, and Finlay, 1983). To determine if the spatial distribution of the first retinal cells to reach their targets is the same as the spatial distribution of the early generated cells in the retinal ganglion cell layer, the brachium of the superior colliculus was filled with horseradish peroxidase (HRP) during the early stages of tectal innervation.

innervation. The hamster retinal ganglion cell layer is generated from embryonic day 10 to postnatal day 3 (E-15/ day of birth = postnatal day 1). The tectum develops its mature retinal innervation pattern from embryonic day 14 to postnatal day 12. HRP gel was placed in the transected brachium of the superior colliculus in neonatal hamsters (n = 5) on the day of birth in order to label initial ingrowing axons. Retinal ganglion cells were examined under light microscopy for evidence of retrograde labelling (TMB reaction product). The retina contralateral to the HRP placement was densely and non-uniformly labelled on the day of birth. More cells were labelled in the temporal retina compared to nasal retina. A discrete lack of HRP backfill in the extreme temporal periphery of the contralateral eye and a corresponding label in the extreme temporal retina ipsilateral to the injection were observed. In order to determine whether the pattern of innervation of the

In order to determine whether the pattern of innervation of the superficial gray layer of the tectum is similar to that of the brachium, unilateral HRP placements in the superficial gray layer of the hamster superior colliculus were made on the day of birth (n=3). Although labelling of the contralateral eye was less dense than that seen with brachial placements the same temporo-nasal spatial gradient of HRP label was evident.

Our results demonstrate that at birth a substantial number of retinal fibers have reached the brachium rostral to the tectum, with temporal retina having a larger representation than nasal retina. The pattern of innervation of the superficial gray layer is a sparser version of the pattern of representation in the brachium. Early representation of the retina in the brachium as revealed by HRP is similar to but more pronounced than the temporal to nasal gradient in retinal neurogenesis. Frost, So, and Schneider (1979) have demonstrated that the rostral portion of the tectum is the first area of the tectum innervated by the retina. This study indicates that the rostral part of the tectum is preferentially and appropriately innervated by temporal retina. Supported by NSF BNS 79 14941.

19.6 CHANGES IN THE PROJECTION OF THE NUCLEUS ISTHMUS TO THE TECTUM WITH RETINOTECTAL COMPRESSION IN GOLDFISH. A.A. Dunn-Meynell<sup>\*</sup> and S.C. Sharma. Department of Ophthalmology, New York Medical College, New York 10595.

It is well established that following removal of a portion of the optic tectum in teleosts, retinal fibers reorganize their tectal projection so that all ganglion cells project to the tectal remnant. The experiments described here were performed to examine whether tectal efferents from other areas of the brain could show a similar plasticity. The projection of the nucleus isthmus on to the optic tectum in goldfish was investigated.

In each of a group of goldfish the normal isthmo-tectal projection was examined by making a localized injection of horseradish perioxidase (HRP) into the dorsal surface of the optic tectum. Three days later each animal's brain was sectioned and reacted to reveal retrogradely transported HRP in the cells. Isthmal cells which contained HRP were thereby shown to send their fibers to the region of the tectum in which the injection was made. After an injection in the caudalmost tectum labelled cells were observed in the dorsal portion of the nucleus isthmus. Following a rostral tectal injection, labelled cells were seen in the ventral isthmus. An injection in the mid-dorsal tectum labelled cells midway between the dorsal and ventral poles of the isthmus. The dorso-ventral isthmal axis was thus shown to project caudo-rostrally along the optic tectum in goldfish.

The dots of the first and a shown is shown and the shown is shown and the project caudo-rostrally along the optic tectum in goldfish. Retinotectal compression was induced in a group of goldfish by removal of the caudal half of the optic tectum and crushing of the contralateral optic nerve, followed by 6 or more months of recovery. Compression of the visual field was verified in a sample of these fish by using electrophysiological mapping of the retinotectal projection. The fish were given HRP injections in the mid dorsal tectum (near the cut edge of the tectum). Following the injection, labelled cells were seen in the dosal nucleus isthmus. This pattern of labelling was very similar to the pattern observed in controls which had received caudal tectal injections. It therefore appears that the isthmal cells previously projecting to the caudal tectum project after retinotectal compression to the caudal edge of the hemi-tectum, displacing the isthmal cells previously projecting there.

displacing the isthmal cells previously projecting there. We conclude from these experiments that there is a topographically organized projection from the nucleus isthmus on to the tectum in goldfish and that this projection may reorganize to maintain a normal topographic projection after tectal surgery. This provides evidence of regeneration and plasticity of neurons in the central nervous system in adult fish. Supported by grant NEI 01426

ISTHMOTECTAL CONNECTIONS IN LARVAL AXOLOTLS: DISCREPANCY BETWEEN ELECTROPHYSIOLOGICAL AND ANATOMICAL RESULTS. <u>S.B. Udin</u> and <u>M.D. Fisher\*</u>, Div. Neurobiology; SUNYAB; Buffalo, NY 14214. The nucleus isthmi (NI) is the primary relay for the frog's ipsilateral visuotectal projection; information is transmitted between the tecta via the crossed isthmotectal pathway (Gruberg, E.R. & S.B. Udin, J. <u>Comp. Neurol.</u>, <u>178</u>:487-500, 1978; Grobstein, P. <u>et al</u>, <u>Brain Res.</u>, 156:117-123, 1978). In axolotls, electrophysiological methods have detected ipsilateral visuotectal activity only in animals which have been induced with thyroxine to metamorphose but not in animals in their normal larval state (Stirling, R.V. & K. Brandle, <u>Dev.</u> <u>Brain Res.</u>, 5:343-345, 1982). In order to determine whether the crossed isthmotectal pathway develops during metamorphosis, as the electrophysiology suggests, or whether it is present but undetected in the larval state, we have investigated the structure and connections of the axolotl NI using horseradish peroxidase (HRP).

peroxidase (HRP). The anuran NI is characterized by (1) input from the tectum on the same side of the brain, (2) output to both tecta, (3) intense staining for acetylcholinesterase (AChE). Using injections of HRP into the tectum of axolotls, we have confirmed that there is a region in the axolotl's isthmus, caudoventral to the tectum, where HRP fills cell bodies bilaterally and also fills a restricted region of the nearby lateral neuropil unilaterally. The labelled cells send their dendrites into the tecto-recipient region of the lateral neuropil. AChE staining of HRP-labelled sections shows that the HRP-labelled region of the neuropil also stains heavily for the presence of AChE.

Thus, the larval axolotl <u>does</u> have a crossed isthmotectal projection which could relay ipsilateral visuotectal information. In order to investigate why such activity has not been detected electrophysiologically, we labelled crossed isthmotectal axons by injecting HRP into the NI of larval axolotls. The anterograde filling showed that isthmic axons do enter the opposite tectum but that they arborize only in the extreme rostrolateral margin. We offer three possible explanations for the apparent discrepancy between the electrophysiological and anatomical results: (1) the extreme lateral position and small extent of the crossed projection may have made it inaccessible for electrophysiological recording; (2) the synaptic connections in the NI may be immature and/or non-functional prior to metamorphosis; or (3) the terminal arborizations of the crossed projection may be too sparse to be detected by conventional extracellular recording methods. (Supported by NIH Grant EY034070 to S.BU.) 19.8 NORMAL DEVELOPMENT OF <u>XENOPUS</u> OPTIC TECTUM AND THE EFFECT OF OPTIC FIBER INNERVATION ON CELLULAR MIGRATION AND LAMINATION. <u>S. M. Royer and P. Grant</u>. Department of Biology, University of Oregon, Eugene, Oregon 97403. While investigating the rules ordering retino-tectal connec-

While investigating the rules ordering retino-tectal connections during development, we studied normal development of lamination and synaptogenesis in the <u>Xenopus laevis</u> tectum and investigated the effect of unilateral enucleation on these processes. To study the timing and pattern of lamination, we prepared a normal developmental series and one in which the left eye was re-

normal developmental series and one in which the left eye was removed at stages 26-31 (before any tectal innervation by retinal axons). For light microscopic analysis, toluidine blue-stained, serial semi-thin sections of plastic-embedded embryos and tadpole brains were used. For ultrastructural analysis, vhole embryos or isolated brains were prepared using standard techniques.

Serial scale-time sections of public-embedded embryos and tachole brains were used. For ultrastructural analysis, whole embryos or isolated brains were prepared using standard techniques. The optic tecture of the frog is a laminated structure, consisting of 9 alternating fibrous and cellular strata. In <u>Scenopus</u> tacholes lamination begins at about stage 47 with the appearance of a few cells in layer 8 in rostral tectum, long after the arrival of retinal fibers at stages 33-40. Lamination proceeds rostro-caudally, and the pattern of 9 layers is apparent in the rostral tectum by about stage 50 and appears later in more caudal regions.

In unilaterally enucleated tadpoles, the initial stages of lamination are similar in both tectal lobes, although the right tectum receives no optic fiber innervation. As reported for <u>Rana</u> <u>pipiens</u> (kollros, J. Exp. Zool., 123:153, 1953), the thickness of the outer layers (7-9) of the right tectum, however, is later reduced, especially that of layer 9. Comparison of the ultrastructure of layer 9 confirms its reduced development on the nonimmervated side. The neuropil is thinner and is characterized by fever terminal processes and synaptic contacts and an abundance of shall axons and extracellular space. At the ultrastructural level, differences between control and experimental tecta are much less apparent at early stages than during metamorphosis, when the reduced development of layer 9 is most pronounced. Even in the same embryo ultrastructural differences in neuropil organization are more apparent in the more mature rostral regions than in caudal regions.

These results suggest that early migration of tectal cells and the initiation of lamination are unaffected by the absence of optic fiber input. In later development, however, the absence of optic fiber innervation leads to a significant disorganization of the layer 9 neuropil.

19.9 COMPETITION AND THE FORMATION OF EYE-SPECIFIC RETINOTECTAL BANDS IN GOLDFISH. <u>A.S. Mednick and A.D. Springer</u>. Dept. of Anatomy, New York Medical College, Valhalla, N.Y. 10595

When one tectal lobe is ablated, the severed optic nerve fibers regenerate to the remaining ipsilateral tectal lobe and displace some of the existing retinotectal fibers from the contralateral eye. The foreign fibers from the ipsilateral eye form rostrocaudally oriented tectal bands of innervation that interdigitate with bands that represent the native fibers from the contralateral eye (Springer, A.D. & Cohen, S.M., <u>Brain Res.</u>, 225:23, 1981). Such fish (Group 1) had either the native or foreign fibers labeled with tritiated proline after bands had formed and the percent of the remaining tectal surface that was occupied by each set of fibers was determined. The foreign fibers covered 27% while the native fibers covered 73% of the remaining tectum. This difference existed over the entire tectum. In addition, the native fibers occupied 50% or more of the tectum in 95% of the transverse tectal sections examined, while the foreign fibers occupied 50% or more of the tectum in only 5% of the sections.

A second group of fish (Group 2) had one tectal lobe ablated and, in addition, the ipsilateral optic nerve was crushed at the same time. Thus, both optic nerves were regenerating and reached the remaining tectal lobe at about the same time. For this group, the foreign fibers increased their coverage to 42% and the native fibers decreased their coverage to 58% of the rostral 3/4 of the tectum. Thus, the foreign fibers in Group 2 increased their projection by 56% relative to Group 1 and covered an additional 15% of the tectum. The native fibers in Group 2 decreased their projection by 21% relative to Group 1 and covered 15% less of the tectum. There were no differences between Groups 1 and 2 for the caudal 1/4 of the tectum. Furthermore, the foreign fibers occupied 50% or more of the tectum in 26% of the sections, a five-fold increase over Group 1.

These results indicate that temporal factors are important in the formation of eye-specific bands. Foreign fibers are least successful in displacing the native fibers when the native fibers already occupy the tectum, but become more successful when they and the native fibers are both regenerating and simultaneously competing to occupy the tectum. Increased competitive success in the foreign fibers, however, is restricted to the rostral 3/4 of the tectum.

- 19.10 EVIDENCE FOR MOVEMENT OF TERMINAL ARBORS OF AXONS FROM RETINAL GANGLION CELLS IN THE TECTUM OF FISH. Anne C. Rusoff. Oklahoma State University. Stillwater, OK 74078.
  - Oklahoma State University, Stillwater, OK 74078. The retina and the tectum of adult fish both add new neurons as the fish grows. New ganglion cells form a complete annulus at the peripheral margin of the retina (Johns, P.R. J. Comp. Neurol. <u>176</u>: 343-358, 1977); however, new tectal cells--the synaptic targets of these ganglion cells--form only a horseshoe in the tectum; there are no new neurons added at the rostral pole of the tectum (Raymond, P.A. and Easter, S.S. Jr. J. Neurosci., in press). The terminal arbors of the ganglion cells must, therefore, continually shift caudally, if the map of the retina is to remain centered on the tectum.

ganglion cells must, therefore, continually shift caudally, if the map of the retina is to remain centered on the tectum. I have used 3 species of perciform fish, the kissing gourami, the green sunfish and the rainbow cichlid, to demonstrate anatomically that the map of the retina does remain centered on the tectum. These perciform fish have a ribbon-shaped optic nerve in which axons are very clearly segregated by age (Scholes, J.H. Nature 278: 620-624, 1979). All the axons from a given annulus of retinal ganglion cells are together in a band across the ribbon. The youngest axons (from the most peripheral annulus) are at one edge of the nerve and the oldest axons (from the most central annulus) form the band at the opposite edge of the nerve. I inserted a pipette coated with horseradish perceided (HRP) into optic nerves in these fish, damaging just axons of a given age and filling only these axons with HRP from their cell bodies in the retina to their terminal arbors in the tectum. I prepared the retinas as whole mounts to demonstrate the positions of the cell bodies of the axons filled with HRP-reaction product; I also prepared the tecta as whole mounts. The tecta were used to demonstrate the positions of the axons as they crossed the tectum and the positions of their terminal arbors from an annulus of ganglion cells centered on the optic disc formed an annulus on the tectum, and this annulus was centered on the tectum, not skewed toward rostral tectum. This result was obtained in fish two months old to one year old even though the tecta from the young fish were only about half as long (measured from rostral to caudal) as the tecta from the older fish. These preparations provide visible evidence that terminal arbors of axons from ganglion cells shift caudally on the tectum as the fish grows. (Supported by NH grant R01-EVO3666.)

19.11 TRAJECTORIES OF REGENERATING FIBERS IN THE OPTIC PATHWAY OF COLDFISH. S.M. Fraley and S.C. Sharma. Department of Ophthalmology, New York Medical College, Valhalla, NY 10595. The optic pathway of normal goldfish is highly organized such that fibers from different retinal sectors are discretely localized in the nerve, tract and bracium and thus follow an orderly course en route to the tectum. In the present study, horseradish peroxidase (HRP) labelled regenerating fibers from a selected retinal sector were traced in order to determine whether their course deviates from the normal trajectory.

Selected returns sector were viated in order to determine whether their course deviates from the normal trajectory. The optic nerve of adult goldfish (7-10 cm, snout to tail base) was crushed until the fibers within their sheath were labelled with HRP 4-12 months after nerve crush. The retina was exposed, fibers located at the 12 o'clock retinal position were severed, and 30% HRP in 1% DMSO-phosphate buffer solution was applied to the cut area. All surgery was performed under anesthesia with MS-222. The optic pathway was reacted with benzidine dihydrochloride 4 days later to reveal HRP label. The fibers were followed through the intact wholemount optic pathway and in 40u sectioned material.

In normal animals, dorsal retinal fibers remained closely adjacent to each other throughout the nerve and thus were localized in only a small portion of the total nerve area. All these fibers entered the ventrolateral tectum via the ventral optic tact and ventral brachium. In contrast, regenerating dorsal retinal fibers were distributed throughout the nerve. A large proportion of these fibers coursed into the ventral aspect of the optic tract and projected to the ventral brachium. Fibers which entered into the dorsal portion of the optic tract maintained their course and thus entered the dorsal brachium.

The data indicated that regenerating fibers followed a relatively straight trajectory through inappropriate areas of the optic pathway and thereby entered the tectum via the incorrect brachia. The size of the deviant population may thus be randomly determined by the number of fibers which become deflected as they pass through the site of nerve crush during regrowth.

19.12 CYTOLOGY AND FIBRE PATTERN IN THE FISH OPTIC NERVE AND TRACT A. Maggs\* and J.H.Scholes (SPON: M. Brown ). MRC Cell Biophysics Unit, Kings College London, 26-29 Drury Lane, London WC 2, England.

Newly extending retinal axons in growing lower vertebrates pass through various sharply defined cytological domains on the way to the optic tectum. Two of these are the optic nerve and the optic tract, and the boundary between them, in teleost fish at least, appears to coincide with an important change in the retinotopic layout of the visual afferents, related to the final disposition adopted by their terminals in the tectal map. In the fish optic nerve, growing axons are usually constrained to track in a single tightly packed fascicle, from which satellite cells are excluded. In the optic tract, however, they are free to spread out in a sparse array among glia and older myelinated fibres. A conspicuous cytological distinction between these two domains in the visual pathway is that, in the optic nerve, astrocytes are hypertrophied and their cytoplasmic intermediate filament protein is a dominant component of the polypeptide spectrum of the tissue, only sparsely represented in the tract. I'e have made and characterised an antiserum against this protein to study by immuno- and conventional anatomical methods the the relation between optic fibre patterns and the distribution of astrocytes and other satellite cells in the visual nathway.

SYNAPSE FORMATION IN DOUBLY INNERVATED TECTA OF GOLDFISH. 19.13 Mark J. Airhart\* and Jeanette J. Norden (SPON: G. C. Palmer). Department of Anatomy, Vanderbilt University School of Medicine, Nashville, TN 37232

It has been reported that removal of one tectal lobe in gold-fish results in hyperinnervation of the remaining tectum (Levine and Jacobson, <u>Brain Res.</u>, 1975; Springer and Cohen, <u>Brain Res.</u>, 1981). It has also been shown, using light microscopic tech-niques, that initially the projections from the two eyes to the remaining single tectal lobe appear to be completely overlapping. Over time, however, the projections from the two eyes segregate into eye-specific termination bands, similar to those reported for 3-eyed frogs (Constantine-Paton and Law, <u>Science</u>, 1978), and following optic tract deflection in goldfish (Meyer, <u>Develop</u>. <u>Brain Res.</u>, 1983). In the present study, we have examined the neuropil of doubly innervated tecta in goldfish using electron microscopy to determine if regenerating retinal fibers form synapses at a time when the projection from the two eyes overlaps. Doubly innervated tecta were created by ablating one tectal lobe and positioning the distal end of the severed optic tract and brachia against the rostral pole of the remaining tectum. The induced ipsilaterally projecting fibers and terminals were It has been reported that removal of one tectal lobe in gold-

and Drachla against the rostral pole of the remaining tectum. The induced ipsilaterally projecting fibers and terminals were labeled by injecting HRP (50%, aqueous) intravitreally (4 days before sacrifice) and by injecting the nerve (2 days before sacrifice). Animals were sacrificed at times ranging from 26-112 days, and their brains processed according to standard protocols. Sections (50 and 200 µm) were cut on a vibratome and alternate sections were reacted for HRP using tetramethylbenzi-dine for light microscopy and diaminphenziding for aloctmon dine for light microscopy and diaminobenzidine for electror microscopy.

Four animals in which a continuous ipsilateral projection ex-tending throughout the rostro-caudal and medio-lateral axes of the tectum have been examined. In these cases, regenerating ipsilateral fibers and terminals overlapped in their distribu-tion with the same tectal laminae as the normal, contralaterally projecting retinal fibers and terminals. In addition, labeled ipsilateral retinal synapses could be identified in the stratum opticum and through the stratum fibrosum et griseum superficiale across the entire tectum. These results indicate that induced ipsilateral retinal fibers do form synapses at a time when the projections from both eyes overlap. This implies that a dynamic reordering of fibers and synapses from both eyes must occur during the subsequent formation of eye-specific bands. Supported by PSH Grants EY05567 (AMA) and EY03718 (JJN).

SEGREGATION AND DENSITY OF SYNAPSES IN EYE-SPECIFIC TERMINATION BANDS IN THE TECTA OF 3-EYED FROGS. Jeanette J. Norden and Martha Constantine-Paton. Dept. of Anatomy, Vanderbilt University School of Medicine, Nashville, TN 37232, and Dept. of Biology, Princeton University, Princeton, NJ 08540. Transplantation of an eye primordium to an embryo host in Rana produces frogs with three eyes, two of which innervate a single tectum in alternating bands (Constantine-Paton and Law, 1978). In these animals, each of the eyes has approximately the same 19.14

In these animals, each of the eyes has approximately the same number of retinal ganglion cells and in the doubly innervated number of retinal ganglion cells and in the doubly innervated tectum the supernumerary and normal eyes appear to equally divide the available neuropil. Our previous quantitative analysis of the number of synapses in the tecta of 3-eyed frogs, however, indicated that the total number of synapses in singly and doubly innervated tecta was approximately equal, indicating that super-numerary and normal eyes projecting to a single tectum make significantly fewer synapses (Norden and Constantine-Paton, 1982). We are currently examining synapses within eye-specific termination bands of doubly innervated tecta after double labeling at different developmental stages to determine 1) if supernumerary and normal eyes initially form the same number of synapses; and 3) if there is any time during development at which the supernumerary eye appears to be at a competitive disadvantage

synapses; and 3) if there is any time during development at which the supernumerary eye appears to be at a competitive disadvantage in terms of the number of synapses. To date, we have examined approximately 35,000 um<sup>2</sup> of the superficial tectal neuropil of one Stage XV tadpole who showed eye-specific bands following injection of HRP into the supernumerary eye and 3H-proline into both normal eyes. Using quantitative EM, some HRP-labeled "profiles" could be identified in all areas of the superficial neuropil in the double intervented tecture but users list domaining and the superficience of the supernumeration of the superficience of UPO labeled doubly innervated tectum, but very high densities of HRP-labeled profiles could be seen only within the supernumerary eye's termination zone. Furthermore, while it was extremely rare to see termination zone. Furthermore, while it was extremely rare to see a labeled synapse within the normal eye bands, approximately  $25^{\circ}$ of all synapses present in the supernumerary eye bands were labeled. While these results are preliminary, they indicate that in the tadpole there is a strict 'segregation of synapses from the two eyes within doubly innervated tecta. Furthermore, in this animal, there was no consistent difference between the total number of synapses in the supernumerary and normal eye bands. We are currently examining the tecta of 1 and 8-mo. post-metamorphic 3-eyed frogs to see if this strict segregation and equal density of synapses in eye-specific bands is a consistent finding in older animals. older animals.

19.15 MORPHOLOGY OF RETINAL AXONAL TERMINAL ARBORS IN THE GOLDFISH

MORPHOLOGY OF REIINAL AXONAL TERMINAL ARBORS IN THE GOLDFISH TECTUM. C.A.O. Stuermer. Div. Biol. Sci., U. Mich., Ann Arbor, and Max Planck Institut, Tuebingen, W. Germany. Crystals of HRP were inserted into the optic nerve of 7 cm fish. Three days later the fish were perfused with saline. The tectal lobes were removed, reacted with DAB for 1 hr, then fixed, dehydrated, cleared, whole mounted under Permount, and coverslip-ped for light microscopic examination. Labeled axons and termi-

ped for light microscopic examination. Labeled axons and termi-nal arbors (TAs) were drawn through a camera lucida. TAs occur in three sizes: small (c. 80x100 um), large (c. 150x 200 um), and giant (c. 200x300 um). The larger dimension is always oriented rostrocaudally in central tectum, or parallel to the tectal edge in peripheral tectum. The diameter of the axons enlarges 4-6X at the origin of the TA and divides into numerous branchlets studded with varicosities and synaptic bou-tons. Small TAs, from axons no greater than 0.5 um diameter, are the most numerous. Large TAs originate from axons of c. are the most numerous. Large TAs originate from axons of c. 1-1.5 um diameter, and are less frequent. Giant TAs, from axons of c. 2.5-3 um, are the least numerous. This three-class distri-bution of axon diameters and TA dimensions correlates with the

bution of axon diameters and TA dimensions correlates with the three size classes of retinal ganglion cells. TAs contribute to two distinct layers in SFGS, superficial (50 um wide) and deep (20 um wide), which correspond with Graf-stein's F3 and F4, respectively. F3 has mostly small TAs super-ficially and all three sizes more deeply. F4 consists almost exclusively of large TAs. In any column perpendicular to the tectal surface, the major branches of all TAs in both layers are oriented similarly. The orientation of a TA's initial segment and the long dimen-

oriented similarly. The orientation of a TA's initial segment and the long dimen-sion of the TA may be similar or different, depending on the tectal location. Centrally, TAs originate from long, caudally directed, extrafascicular axons derived from short fascicles in rostral tectum. Here, the long dimension of the TA is parallel to its initial segment. In peripheral tectum, TAs emerge from short, centrally directed extrafascicular axons derived from peripheral fascicles. Here, the TA's initial segment and its long dimension are perpendicular. These observations are consistent with a detailed model of retinotectal growth, which we have described elsewhere, based on

retinotectal growth, which we have described elsewhere, based on Gaze's hypothesis of sliding connections. (Supported by DFG Stu 112 to the author and EY-00168 to S.S.

BINDING OF EXOGENOUS LECTINS TO DEVELOPING CHICK OPTIC TECTUM. S. E. Raiguel (Spon: R. E. Marc) Univ. of Texas Grad. School of Biomedical Sci., Dept. of Visual Sciences. Houston, TX 77025 Embryonic chick optic tecta were examined for lectin-binding capacity during development. Chick embryos at 8, 12, and 18 days of incubation were perfused with ethanol-acetic acid (95:5, v:v) and the brains fixed overnight in this fixative, dehydrated and embedded in paraffin. Eight-micron sections were deparaffinized, rehydrated and incubated 20 min. with the following fluorescein-isothiocyanate-conjugated lectins: Concanavalin A (Con A), Doli-chos biflorus agglutinin, peanut agglutinin, Ricinus communis agglutinin I, soybean agglutinin, Ulex <u>europaeus</u> agglutinin, and wheat germ agglutinin (WGA) (Vector Laboratories). Fluorescence was observed only in sections incubated with Con A and WGA, and could be eliminated by preincubation of the lectin with the ap-propriate hapten sugar (10 mM α-methyl-d-mannopyranoside or N-acetyl galactosamine, respectively). Fluorescence was most in-tense at day 8 and diminished in progressively older embryos. Although WGA staining was more pronounced, similar distributions were seen for WGA and Con A: labeling of the fibrous layers of the stratum grisium et fibrosum superficiale, of the ependymal cell layer, and of the large cell bodies of the stratum grisium centrale. In the earliest embryos, what appeared to be radial glial cells bound WGA in a broad cental lamina. Although differ-ent planes of section were used to examine different tectal axes, no regional variation in staining intensity could be seen which might indicate the presence of gradients of glycocnjugates such as have been proposed to serve as marker substances during dev-elopment. These data suggest that such markers, if present, are not preserved by this fixation procedure, and hence may con-sist of glycolipid, or are simply present in such low concentra-tions as to be undetectable by these methods.

tions as to be undetectable by these methods.

19.17 Intermediate Filament Proteins in the Goldfish Visual Pathway. Wolfgang Quitschke\* and Nisson Schechter. Department of Psychiatry and Behavioral Sciences, SUNY at Stony Brook, New York 11794.

Biochemical events associated with axonal outgrowth and regeneration can be investigated in the goldfish visual pathway. An analysis of the goldfish optic nerve by two dimensional gel electrophoresis indicated that a predominant cluster of proteins (58K daltons) is composed of components of neuronal and noneuronal origin (Brain Res. 258 (1983) 69-78). The concentration of the proteins of neuronal ( $ON_{2}$ ) and  $ON_{2}$ ) is directly linked to optic nerve degeneration and regeneration while the concentration of the other proteins ( $ON_{2}$  and  $ON_{2}$ ) remains stable during the process. These proteins are distinct from myelin, actin and tubulin preparations. Since they can not be classified among the most common structural proteins the proteins.

The proteins were analyzed with respect to several known characteristics associated with intermediate filament proteins. The results are as follows: Proteins ON<sub>1</sub> and ON<sub>2</sub>, which are synthesized in the retina, are transported via the slow phase of axonal transport. Differential phosphorylation is observed among the components of the cluster both <u>in vivo</u> and <u>in vitro</u>. Furthermore, phosphorylation of proteins  $ON_1$  and  $ON_2$  discusses a posttranslation modification during axoplasmic transport. Proteins  $ON_1-ON_2$  are exclusively present in cytoskeletal enriched fractions which are insoluble in nonionic detergents. Finally, the proteins from this fraction can be reconstituted into typical 10nm intermediate filament structures as shown by electron microscopy.

Cytoskeletal preparations of rat optic nerve and goldfish optic nerve were compared by one dimensional gel electrophoresis. The rat optic nerve contains glial fibrillary acid to protein and nonneuronal vimentin in addition to the neurofilament triplet. A typical mamalian neurofilament triplet is not detected in the goldfish optic nerve while the major cytoskeletal constituent is the 58K band which is indistinguishable from vimentin in the rat optic nerve (this work was supported in part by a BBSC grant RRO5736).

## DEVELOPMENT OF MOTOR SYSTEMS

CORTICAL PROJECTIONS TO REDUCED TARGETS. <u>M. E. Goldberger and</u> <u>B. S. Bregman</u>. Dept. of Anatomy, The Med. Coll. of Pennsylvania, Phila., PA and Univ. of Maryland, Sch. of Med., Baltimore, MD. 20.1 We showed previously (1) that spinal cord hemisection in new-born cats has diverse effects on motor function. Sparing of function is observed in some aspects of motor behavior but not in others. The present studies indicate that the anatomical sequellae are also diverse. In adult cats having had C1-3 hemisection as newborns and unoperated controls, the sensorimotor cortex (contra-lateral to hemisection) was either injected with HRP-WGA or ablated for degeneration studies. HRP and degeneration methods gave the same results. We examined cortical projections to the damaged side of the spinal cord and to two brainstem nuclei whose development was altered by the neonatal lesion; the magnocellular red nucleus (MgRN) and the dorsal column nuclei (DCN). MgRN cells were axotomized, while the gracile, cuneate and external cuneate, (ECN) nuclei were deafferented. After neonatal hemisection the corticospinal tract takes an aberrant route around the lesion, enters the grey matter, forms a small fasciculated pathway that descends through the base of the dorsal horn to lumbar levels and subserves the sparing of tactile placing. In controls, cortical projections occupy all of the MgRN but are densest ventrolateral-ly. Dorsomedial to MgRN a dense termination is seen in nuclei in and around the periaquaductal grey (PAG; e.g. interstitial, Darkschewitch). After neonatal hemisection, the MgRN undergoes massive retrograde degeneration during development. The cortical projection to the area of the MgRN which has few remaining (usually small) cells is greatly decreased or absent. The projec-tion to the adjacent PAG region appears normal. The control cortico-DCN projection is dense ventrally at the base of the gracile and cuneate, sparse in the cell nest regions dorsally but does not enter the adjacent ECN. Neonatal hemisection causes shrinkage and cell loss of the DCN due to deafferentation and the cortico-DCN projection is extremely dense both at the base and among the cell nests. In addition, an abnormal projection courses laterally, near the floor of the IVth ventricle to reach medial groups of ECN cells. In contrast to the corticorubral pro-jection which was absent, the cortico DCN projection expanded. Thus the response of developing cortical afferents to the reduc-Axotomy-induced retrograde degeneration (MgRN) of target neurons may inhibit development of afferents; denervation (or the trans-neuronal reduction it induces) may stimulate that development.

Supported by NIH NS16629, NS19259 and NSF BNS 241775, and the Office of Mental Health of the Commonwealth of Pennsylvania. <sup>(1)</sup>Bregman and Goldberger, Science <u>217</u>:553-555, 1982.

20.2 DEVELOPMENT OF PLACING REACTIONS IN SPINAL CATS. <u>G. A. Robinson</u>, <u>C. T. Leonard and M. E. Goldberger</u>. Dept. of Anatomy, The Med. Coll. of Pennsylvania, Phila., PA 19129.

Cats display hindlimb locomotion after spinal transection at 12-14 days of age, providing evidence for a spinal pattern gen-erator for locomotion (SPGL). Cats transected as adults, however, show poor locomotion, suggesting an age related sparing of func-tion, i.e. an 'infant lesion effect.' We examined the development of placing reactions, hopping and treadmill locomotion in normal kittens and those with spinal transections (Tl3) at 3 ages: 1 day postpartum (1 DPP), 11-17 DPP, and as adults. Placing reactions postpartum (1 DPP), 11-1/ DPP, and as adults. Placing reactions were examined using a force transducer to record the force of stimulation required to elicit placing. Placing was elicited by stimulating the dorsal, ventral, medial or lateral surfaces of the hindpaw. Responses were scored relative to those obtained in the normal adult. The 3 spinal preparations and the normal kittens differed quantitatively in the stimulus strength required to eli-cit, and in the execution of, placing. For example, backward plac-ing in normals began in the first week as a low threshold, flex-ion-only response and developed to a low threshold weight-bearing response after approximately 1 month. The 1 DPP group showed low response after approximately 1 month. The 1 DPP group showed low threshold backward responses but they never matured past flexion. Transection at or after 11 days abolished backward placing responses. Lateral placing developed differently from backward. Normals, after a brief period of low threshold, partially weightbearing responses developed fragmented responses such as simple flexion which finally matured to low threshold weight-bearing placement by 1 month of age. The 1 DPP group developed low thresh-old weight-supporting lateral placement by 2 weeks of age. Later-al placement in the 11-17 DPP group and in the chronic adult preparation was elicited by strong proprioceptive stimuli only and did not mature to the point of providing weight support. These data suggest that the spinal networks underlying the SPCL also share responsibility for placing reactions and are consis-tent with the development of locomotion in spinal cats. In both cases, the earlier the lesion was made the more sparing of function occurred. One possible explanation for these age-related differences might be the failure of neonatally spinalized cats to develop an adult level of inhibition. Thus, the SPGL would be suppressed more in an adult-transected cat. We therefore hypothesized that pharmacological blockade of inhibitory influences would result in facilitation of locomotor performance. Prelimi-nary data suggests that i.p. administration of bicuculline facilitates treadmill locomotor performance in the chronic adult spinal cat but not the chronic neonatal operates (tested as young adults). This suggests that transection in the adult may reveal the normally developed inhibitory influence which fails to develop completely in the 1 DPP group. Supported by NIH16629&NSF BNS241775.

DEVELOPMENT AND RECOVERY OF FUNCTION IN NEONATALLY BRAIN DAMAGED 20.3 CATS. C. T. Leonard, G. A. Robinson, M. E. Goldberger. Dept. Anatomy, The Med. Coll. of Pennsylvania, Phila., PA 19129. Interest in the 'infant lesion effect' (i.e. greater recovery from CNS damage in the neonate vs. the adult) led our laboratory to examine various behavioral and neurological parameters of motor function in kittens receiving sensorimotor (SM) cortical ablations on the day of birth (neonatal operates; NO's). The NO's were first on the day of birth (neonatal operates; NO's). The NO's were fir compared with normal developing littermates and after reaching maturity, with adult cats receiving similar cortical ablations (AO's). Testing included: placing responses, with thresholds measured with a force transducer; monopedal hopping and locomo-tion, analyzed by kinematics. Our data indicate that neonatally brain damaged kittens differ in their development from normals and also differ in their response to damage when compared with AO's. The NO's exhibit a prolonged period of reflex maturation when compared with normal littermates but all reflexes follow a normal progression of emergence. NO's exhibit fewer deficits the when compared with normal littermates but all reflexes follow a normal progression of emergence. NO's exhibit fewer deficits than AO's. AO's fail to recover tactile placing and exhibit obvious locomotor deficits. In contrast, NO's do exhibit tactile placing (an example of neurological sparing) and show only subtle loco-motor deficits. For example, kinematics reveal that abnormal increases in hip extension occur at the end of stance phase  $(E_3)$  but this is compensated for by an increase in total limb flexion velocity. We refer to this type of behavioral compensation as masking of a deficit. Masking is seen in both AO's and NO's. How-ever, the deficit (hip hyperextension) is greater in the AO's and the compensation less effective.

Preliminary neuroanatomical studies, using conjugated Horse-radish Peroxidase (HRP/WGA) and Fast Blue fluorescence, indicate the presence, in normal one day old kittens of a widespread, diffuse uncrossed corticothalamic (CT) efferents. In addition, numerous fibers cross through the massa intermedia. With time, there is a gradual decrease in the CT efferent system along with a concomitant increase in thalamic localization. Removing left SM cortex, at birth, appears to preserve, in part, the widespread CT efferent system of the right unablated cortex. This increased projection is not seen in AO's. Results confirm the greater plasticity of the neonatal nervous system and suggest two possible mechanisms underlying the 'infant lesion effect': 1) Greater masking of deficits utilizing movements which differ from those of an intact animal; and 2) Sparing of neurological function in the developing animal. Difference in organization and sparing of the corticothalamic system is one example of the neuroanatomical differences between AO's and NO's which may account for the observed behavioral sparing but this remains to be investigated. Supported in part by a grant from United Cerebral Palsy Educ.

MOTONEURON PROPERTIES FOLLOWING MOTOR REINNERVATION IN CAT MEDIAL GASTROCNEMIUS. <u>R.C. Foehring</u>, <u>G.W. Sypert</u> and <u>J.B. Munson</u>. Dept. of Neuroscience, Univ. of Fla. Coll. of Med., Gainesville, 20.5 FL, 32610.

Electrical properties of motoneurons (MNs) innervating the cat medial gastrocnemius are closely related with the type of muscle unit innervated (Fleshman <u>et al.</u>, <u>J. Neurophys.</u> 46). We used intracellular recording techniques to determine if the normal correspondence between MN and muscle unit properties is reestablished 8-10 months following self-reinnervation. These data were obtained from 10 normal and 4 reinnervated cats (all values  $\pm$  SEM):

Motor Unit Type:	FF	FI	FR	S
% of Population				
Reinnervated(n)	44% (33)	4% (3)	21% (16)	25% (19)
Normal(n)	54% (43)	8% (6)	23% (18)	15% (12)
Conduction Vel.(m/s)				. ,
Reinnervated	96 ± 1	94 ± 5	96 ± 2	85 ± 2
Normal	99 ± 2	$100 \pm 2$	97 ± 2	83 ± 2
Rheobase(nA)				
Reinnervated	24 ± 0	18 ± 3	$12 \pm 1$	4 ± 1
Normal	21 ± 2	17 ± 1	10 ± 1	6 ± 1
Input Resistance(MΩ)				
Reinnervated	0.5 ± 0.2	0.7 ± 0.3	0.9 ± 0.1	$1.2 \pm 0.1$
Normal	$0.6 \pm 0.1$	0.8 ± 0.1	$1.0 \pm 0.6$	1.8 ± 0.1
AHP Half Decay(ms)				
Reinnervated	20 ± 1	23 ± 1	22 ± 1	43 ± 3
Normal	18 ± 1	17 ± 2	22 ± 1	41 ± 4

MN properties were generally appropriate for each unit type. To determine whether there were individual mismatches between MNs and muscle units, MN type was determined by the methods of Zengel et al. (ms. submitted). Briefly, cells with AHP 1/2 decay time <30ms were designated Slow, while cells with AHP 1/2 decay time <30ms were designated Slow, while cells with AHP 1/2 decay time <30ms were designated Fast. MNs were further subdivided by calculating rheobase/input resistance: FF>18>FR>7. FI MNs are not identifiable by this technique. The normal conclusion showed 5 identifiable by this technique. The normal population showed 5 mismatches by these criteria (6.8%, excluding FI units). The reinnervated population showed 6 mismatches (12.8%, excluding 3 reinnervated population showed 6 mismatches (12.8%, excluang 3 FI MNs and 6 MNs not making functional connections). <u>Conclusions</u>: Following 8-10 months reinnervation, MNs exhibit normal electri-cal properties and usually innervate appropriate muscle units. We are uncertain of the extent to which this is due to the MN converting muscle fibers, the converse, or competition among MNs for individual muscle fiber connections. Supported by NIH grant NS 15913, the MRS and RERDS of the VA, and the W.L. Gore Co.

THE DEVELOPMENT OF CORTICOSPINAL PROJECTIONS IN THE OPOSSUM, 20.4

T. Cabana\* and G.F. Martin. Dept. of Anatomy, School of Medicine, The Ohio State University, Columbus, Ohio 43210. It has been suggested that the development of the cortico-spinal tract in the rat involves the production of excess prospinal tract in the rat involves the production of excess pro-jections and the subsequent elimination of inappropriate ones (Bates & Killackey, '80; Ivy & Killackey, '81; Stanfield et al, '82): in newborn rats, nearly all neocortical areas are retro-gradely labelled by injections of fluorescent markers into the pyramids or the spinal cord. The adult pattern of cortical labeling is none the less achieved by the end of the second week. In the opossum, cortical fibers do not grow into the cord until about 30 days after birth (42 days after conception) (Martin et about 30 days after birth (42 days after conception) (Martin et al, '80). We took advantage of that fact to investigate possible sequences and mechanisms in the development of corticospinal systems. In pouch young opossums, the origin of corticospinal fibers was determined by retrograde tracing (horseradish perox idase, Nuclear Yellow) and their terminations were studied using the orthograde transport of HRP. Cervical placements of markers in 30 day old opossums labelled

cortical neurons only in presumptive parietal areas of the motorcortical neurons only in presumptive parietal areas of the motor-sensory cortex. One week later, labeling was found in cortical areas known to innervate the cord in the adult animal ("trunk-limb" area), but also in other regions such as the "face" area of parietal cortex, the preorbital, cingulate and insulo-temporal cortices; labeling was rare in frontal and peristriate-striate areas. Such labeling could be demonstrated until at least post-natal day 65. During that period of development, injections of HRP into either the parietal or the preorbital cortex (assessed by the pattern of retrograde labeling in the thalamus) labelled axons as far as the fourth thoracic segment of the cord where axons as far as the fourth thoracic segment of the cord where they distribute to laminae III to VII. Occipital injections did they distribute to laminae III to VII. Occipital injections did not produce spinal labeling. In the adult opossum, corticospinal fibers supply generally comparable areas (Martin & Fisher, '68). By postnatal day 80, retrograde labeling had "disappeared" from all but motor-sensory cortex, but it was still present in the "face" area. This was still the case in a weaned, four month old

opossum, but not in adults. Our data indicate that: 1) corticospinal projections in the opossum arise initially from areas which provide them in the adult, 2) additional areas of cortex subsequently contribute to spinal projections which are eventually eliminated, 3) there exist species differences as regard the scope and duration of transient projections and 4) the development of corticospinal success in the openeum is relatively protracted. Supported hy systems in the opossum is relatively protracted. Supported by BNS-8068675.

REINNERVATION OF MUSCLE RECEPTORS BY CUT AFFERENT FIBERS. J. B. Munson, W. F. Collins, III, and L. M. Mendell. Dept. of Neuro-biology and Behavior, SUNY, Stony Brook, NY 11794. We investigated the specificity with which afferent fibers of the cat's medial gastrocnemius (MG) muscle reinnervate muscle 20.6

Boloigy and benavior, Sunt, Stony brook, NY 11/94. We investigated the specificity with which afferent fibers of the cat's medial gastrocnemius (MG) muscle reinnervate muscle receptors during peripheral nerve regeneration. Using sterile procedures, MG muscle nerve regeneration. Using sterile procedures, MG muscle afferents (penetrated in dorsal root filaments) were determined from their responses during muscle stretch and contraction. Using criteria of Gregory, et al. (J. Physiol. 331), we categorized 42 MG receptors as follows: spin-dles (n = 20); tendon organs (GTO; n = 5); contraction receptors (CR; n = 3); high threshold (HT; n = 6); not connected (NC; n = 8). To classify afferent fibers, we electrically stimulated each one individually (Honig et al., J. Neurophysiol. 49) and noted the averaged field potential generated in the MG motoneuron pool. Spindle afferent fibers can generate a field potential in the motoneuron pool consisting of a terminal potential (TP) and focal synaptic potential (FSP; Munson & Sypert, J. Physiol. 296). In control cats fast spindle afferent fibers (288m/s) reliably evoked an FSP whereas slow ones (<79m/s) did not when the recording microelectrode was placed in the MG pool close to the afferent fiber entry level. This difference parallels the weak projection of slow compared to fast spindle afferents to the motor pool (Sypert et al., J. Neurophysiol. 44; Luscher et al., ibid. 42). One control GTO (of 10) produced a tiny FSP in the MG pool; the other 9 produced none. After muscle reinnervation, central projections were studied for 32 of the 42 characterized muscle afferents. Ten of 17 fibers supplying spindles produced <7m/s. Fibers innervating GTOs or CRs ("in series" behavior) produced no FSP (7/8) or a very tiny FSP (1/8). Four (of 7) NC fibers gener-ate an FSP. No HT afferent generated an FSP. We conclude: (1) after 6 months some afferents had not reinnervating muscle spindles was much higher than that reinnervating GTOS (20, vs. 5) in keeping acter 6 months some alterents had not reinnervated muscle recep-tors; (2) the number of afferents reinnervating muscle spindles was much higher than that reinnervating GTOS (20 vs. 5) in keeping with the normal numbers of spindles and GTOS; (3) fibers reinner-vating spindles and GTOS had central projections similar to those in control cats. At present we cannot determine whether this apparent re-establishment of almost normal specificity results from selective reinnervation of muscle receptors by afferent from selective reinnervation of muscle receptors by afferent fibers, or whether adjustments occur in the muscle or the spinal Cord to bring center and periphery into register. Supported by NIH grants NS15913(JBM), NSO6407(WFC) & NS14899 & NS16996(LMM).

DOWN REGULATION OF GLYCINE RECEPTORS IN RESPONSE TO 20.7

DOWN REGULATION OF GLICINE RECEPTIONS IN REPORTS IN A CONSETONE TO MOTONEURON INJURY. A. Rotter, C. Schultz\* and A. Frostholm\*. Department of Pharmacology, College of Medicine, University of California, Irvine, Irvine, CA 92717 Several quantitative studies have shown that axotomy of the hypoglossal nerve results in a loss of synaptic contacts on hypoglossal motoneurons. Our own studies have established that mouse hypoglossal motoneurons. Our own studies have established that mouse hypognosai nuclei have high concentrations of glycine receptors. The receptors were labeled with  $[^{3}H]$  strychnine, a potent glycine antagonist, the binding of which to mouse brain sections can be demonstrated autoradiographically. We have used this method to study the effect of axotomy on the number of glycine receptors in the hypoglossal nucleus. axotomy on the number of grycine receptors in the hypoglossal nucleus. The present results are based on a total of 6 adult male and female C57BL/6J mice in which the hypoglossal nerve was cut on only one side of the neck. After 7-9 days the animals were anesthetized with ether, the brains removed, mounted on cryostat chucks and frozen in dry ice. Coronal sections 20  $\mu$ m thick, were prepared for autoradiography. The highest levels of binding were observed in the spin<sup>1</sup> cord and brain stem; binding levels progressively decreased rostrally along the brain axis. In binding levels progressively decreased rostrally along the brain axis. In coronal sections of the lower brain stem, several structures were densely labeled. These included the reticular formation, cuneate and gracile nuclei, and most prominently, the hypoglossal nuclei. The labeling over the hypoglossal nucleus was distributed throughout the neuropil. The cytoplasm and nuclei of the large hypoglossal neuronal somata were unlabeled. The density of the silver grains fell abruptly at all the boundaries of the hypoglossal neuropil. This clear demarcation was abolished if sections were incubated in the presence of 1 mM glycine. We examined the hypoglossal nerve. A marked decrease in the intensity of [34] trycphine binding was observed. Since the perver arises almost or [3H] strychnine binding was observed. Since the nerve arises almost exclusively from the ipsilateral hypoglossal nucleus and the two nuclei lie immediately adjacent to each other on either side of the midline, the opposite nucleus may be used as a control in the same coronal section. A comparison of grain densities over the nuclei on the operated and comparison optimized of the function of the hypoglossal nerve resulted in a decrease of at least one half of the number of  $[^{3}H]$  strychnine binding sites in the axotomized of nucleus.

Several studies have shown that many of the effects of axotomy are reversible if the hypoglossal axons are allowed to regenerate and reestablish neuromuscular contacts. Our preliminary observations on mice showed that in cases where the hypoglossal nerve regenerated, binding of  $[^{3}\mathrm{H}]$  strychnine in the hypoglossal neuropil had also returned to normal levels. This dependence of the receptor upon the establishment of peripheral neuromuscular contacts raises the possibility that the metabolic events required to produce receptors are influenced by factors which originate in the target tissue.

PATTERNS OF FAST AND SLOW MUSCLE FIBERS IN EMBRYONIC CHICK 20.8 MUSCLES INNERVATED BY FOREIGN MOTONEURONS, M. W. Vogel\* and L. Landmesser. Biology Dept., Yale University, New Haven, Conn. 06511 and Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, CT 06268 In the chick hindlimb there is a characteristic pattern in the

distribution of fast and slow muscle fibers within individual muscles, as revealed by myosin ATPase staining. For example, the anterior medial portion of the iliofibularis contains predominately slow myotubes, the posterior lateral portion, predominately fast.

To determine what role, if any, the innervation plays in the development of such characteristic myosin ATPase staining patwe caused a variety of hindlimb muscles to be innervated by foreign motoneurons. This was accomplished by rotating about the a-p axis either the lumbosacral neural tube at St 15-16, or the limb bud at St 17-18. We then determined the myosin ATPase staining characteristics of muscles in embryos ranging in age From embryonic stage 36-44. For some muscles, we also recorded EMG activity patterns and/or labeled their motoneurons with retrogradely transported HRP.

In the majority of cases (80/85 muscles examined in 15 limbs) the overall pattern of fast and slow myotubes was essentially normal. From this we conclude that either the pattern is intrinsic to the limb and unaffected by the source of innervation up to St 44, or that when fast and slow motoneurons are presented up to St 44, or that when last and slow motoneurons are presented with a muscle containing both fiber types, they selectively innervate the appropriate region. The latter possibility is supported by several exceptions to our general finding. In these cases (5/85), changes in fiber type composition of individ-ual muscles were observed, suggesting that the pattern of fast and slow myotubes can be altered at the stages studied. This could result from motoneurons either altering the staining property of individual myotubes, or favoring the development of one type of myotube. The low frequency with which such changes were observed may be explained by the fact that under the experimental conditions used, muscles would have been likely to be innervated by mixtures of both fast and slow motoneurons. We are therefore attempting to produce additional evidence for changes by experi-mental designs which force motoneurons to innervate myotubes of the wrong type. Supported by NIH Grant NS 19640.

#### CONTROL OF POSTURE

PARTITIONING OF CAT POSTERIOR THIGH MUSCLES INTO TWO GROUPS BASED 21.1 Don EMG ACTIVITY DURING JUMPING. F. E. Zajac, W. S. Levine\* and D. Dungan\*. Univ. of Maryland, Palo Alto VA Med. Ctr. and Mech.

D. Dungan\*. Univ. of Maryland, Palo Alto VA Med. Ctr. and Mech. Eng. Dept., Stanford Univ., Stanford, CA 94305. In our study of maximum height jumps a theoretical result in-dependent of the musculo-skeletal model used to represent hindlimb dynamics is that each muscle ought to be either maximally activat-ed (on) or inactivated (off) during propulsion once the heals loose contact with the around. Second ficelly, eland eight enterpresent ed (on) or inactivated (off) during propulsion once the nexts loose contact with the ground. Specifically, single-joint extensor and flexor muscles ought to be on and off, respectively, through-out this 2nd propulsion phase. While double-joint muscle activa-tion should also be binary in this epoch, its on-off timing depends on model details. Be binary in this epoch, its on-off thing depend on model details. Intramuscular EMCs (Fig. 1) were recorded from 4 adult cats trained to jump from a force-plate to touch cotton balls suspended about 2.5m above the platform. Comparison of fil-tered EMCs occurring in the maximal jump with those seen in other jumps and movements suggests that on-off activity does exist in the 2-debaard for the table of 6.44 Jumps and movements suggests that on-off activity does exist in the 2nd phase. EMGs prior to heel-off (lst phase) can vary in both timing and amplitude from one maximal jump to another, con-sistent with the variability seen in ground reaction forces during this phase (Zajac, F.E. et al., J. Exp. Biol.) 91:73, 1981). Based on their EMC pattern posterior thigh muscles can be grouped into

those which only facilitate hip extension (semimembranosis anterior [SMa], biceps anterior [BA] and adductor femoris [AF]) and those which also act to flex the knee (semitendinosus [ST], biceps posterior[BP] and gracilis [GR]). Data from submaximal jumps acquired during training indicate that the double-joint group contributes to 1st phase propulsion in the maximal jump as evident by the occurrence of the first peak in vertical force (Fig.1, top), though quite high jumps are possible with-out this participation. Activity level in the single-joint group and in vastis lat-eralis (VL) is in accord with jump height. Calculated length trajectories show that activity from each posterior thigh muscle studied occurs just before and during its shortening and ceases with onset of length-ing. The partitioning of posterior thigh muscles into groups based on their activation patterns during jumping is thus in agreement with such partitioning based on origin-insertion geometry. (Supported by NIH NS 117662).

21.2

INTRALIMB COORDINATION DURING PAW SHAKE RESPONSES IN THE HINDLIMB OF CAT. D.M. Phillips\* and J.L. Smith. Neuromotor Control Lab., Dept. Kinesiology, UCLA, Los Angeles, CA 90024. Paw shake responses (PSR) are the most rapid cyclic movements observed in cats involving simultaneous movements of the hip, knee and ankle. Intralimb coordination of PSR may be different from slower cyclic movements such as locomotion and scratching reflect-ing differences in the limb dynamics. The purpose of this study was to identify the PSR intralimb coordination in unrestrained and restrained hindlimb. restrained hindlimb.

restrained hindlimb. Data from 4 cats spinalized at T-12 as adults was collected 1-3 mos following spinalization. EMG sampled from selected flexors and extensors at the hip, knee and ankle included ilio-psoas (IP), gluteus medius (GM), adductor magnus (AM), posterior biceps (PB), vastus lateralis (VL), lateral gastrocnemius (LG) and tibialis anterior (TA). Cycle durations (CD) defined as the interval between successive LG burst onsets were determined, and the onset time for each muscle was expressed as a percent of the average CD. PSR were elicited by wrapping tape around the hind-paw, and in some trials knee and ankle movements were restricted by a plaster cast at 115° and 100°, respectively. In the unrestrained limb the average CD was 97 ms during 12 when CDD between the surface of an extension

cycles/PSR. Intralimb coordination consisted of an extensor synergy which included the coactivity of extensors at the hip and ankle (GM, AM, PB, LG), followed by a mixed synergy initiated at 57% of the CD which included coactivity of the ankle flexor (TA) and knee extensor (VL). The onset of the hip flexor (IP) was outof-phase with the extensor and mixed synergies occurring at 33% of the average CD.

of the average CD. Mechanical perturbation restricting knee and ankle movements resulted in an increased CD of 120 ms and a reduction in the num-ber of cycles/PSR to 8. The extensor synergy was unaltered; how-ever, the coactivity of TA/VL was disrupted in 3 animals. In all cats, the TA remained reciprocolly active relative to the extensor synergy, although its onset was delayed to 73% of the CD. The VL exhibited two abnormal patterns: an absence of activity or a shift in onset resulting in coactivity with hip and ankle extensors. The IP activity was delayed in its onset to 42% of the CD. PSR coordination is characterized by an extensor synergy at the hip and ankle followed by a mixed synergy at the knee and ankle.

hip and ankle followed by a mixed synergy at the knee and ankle. Perturbation by ankle-knee immobilization disrupts the mixed synergy especially the knee extensor suggesting that the dynamics of the moving limb may be necessary for consistent VL participa-tion in the mixed synergy. Supported by NIH grant NS 16333.

INTERSEGMENTAL DYNAMICS OF THE PAW SHAKE RESPONSE. 21.3

INTERSEMENTAL DINAMILS OF THE PAW SHAKE RESPONSE. M. G. Hoyx, R. F. Zernicke, and J. L. Smith. Dept. Kinesiology, UCLA, Los Angeles, CA 90024. Angular motion of the cat hindlimb during the paw shake response (PSR) is determined by muscle activity and the dynamic mechanical interactions between the linked limb segments. The mechanical interactions between the linked limb segments. The relative contribution of each force component to the resultant joint torque is important in understanding PSR control, because only active muscle force represents the direct participation of the CNS in movement dynamics. The purpose of this study was to quantify the role of the active musculature and passive mechanical dynamics in the PSR.

dynamics in the PSR. PSR were elicited in the chronic spinal cat by applying tape to the hindpaw; limb motion was filmed (200 f/s). Hip, knee, ankle, and metatarsophalangeal joints were digitized from projected film frames. Displacement-time data were smoothed and differentiated (Hatze, H., J. Biomech., 14:13, 1981) to provide linear and angular kinematics. The leg and paw were modeled as a planar, 2-segment rigid-body system. Body segment parameters were obtained, and kinetic equations of motion (Putnam, C., J. Biomech., In Press) were formulated to yield knee and ankle joint torques as functions of generalized muscle moments at the knee and ankle, angular acceleration and angular velocity of the leg angular angular acceleration and angular velocity of the leg, angular acceleration and angular velocity of the paw, linear acceleration of the knee, and gravity.

A PSR consists of a sequence of 8-13 flexion-extension cycles with an average cycle duration of  $79 \pm 6$  ms. During the first half of a cycle, the knee flexes and the ankle extends; joint actions reverse in the second half of the cycle. These joint har of a cycle, the knee releasing the anxie exceeds the difference of the actions are consistent with the muscle synergy reported by Koshland and Smith (Neurosci. Abst., 1983). The range of motion of the ankle  $(56 \pm 7')$  was greater than that at the knee  $(35 \pm 5')$ . Peak knee extension and flexion were  $100 \pm 3'$  and  $68 \pm 2'$ , and ankle values were  $173 \pm 1'$  and  $116 \pm 6'$ . Knee joint maxima preceded ankle joint maxima by 5-10 ms. The ankle angular velocities in flexion (-2584  $\pm$  429'/s) and in extension (3085  $\pm$  306'/s) were greater than the corresponding values at the knee (-1388'/s and 1232'/s). Torque data demonstrate that passive mechanical interactions are especially important at the knee joint, while ankle joint torque is dominated by muscle moment. The segmental angular velocities and gravity contribute relatively little to the resultant joint torques of the PSR. The formulation of the kinetic equations of motion permits a detailed examination of the intersegmental dynamics of the PSR and highlights the capacity of the lumbosacral cord to generate and coordinate appropriate.

the lumbosacral cord to generate and coordinate appropriate muscular moments to compensate for passive dynamic segmental interactions. Supported by NIH NS 16333.

RESPONSES LATERAL. GASTROCNEMIUS 21.5 OF INNERVATION SUBCOMPARTMENTS AND SOLEUS TO PAIRED PERTURBATIONS OF POSTURE. D.S. Rushmer, J.M. Macpherson, D.C. Dunbar\*, and C.J. Russell. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209.

The stereotyped nature and the timing characteristics of EMG responses to controlled perturbations of stance suggest that they might be programmed within the central nervous system.

We have studied this possibilty by recording from the four innervation subcompartments of the lateral gastrocnemius and from the soleus muscles of awake behaving cats. Animals stood on an hydraulic posture platform and were subjected to two posture perturbations presented closely in time. The first perturbation was always a drop of support from beneath a single limb, evoking the "diagonal support response" described by Coulmance et al (<u>Exp Brain</u> <u>Res 37</u>:265,1979). The second perturbation, presented at Res 37:265,1979). The second perturbation, presented at latencies of 10-100 msec following the first, consisted of the drop of support from beneath the diagonal pair of limbs loaded as a result of the first perturbation. This second perturbation required the animal to change the strategy of postural response while it was still responding to the first perturbation. Drop of a single limb evoked stereotyped EMG responses

which were different depending upon the role in the postural response of the limb containing the recorded muscles. There were also differences between the response characteristics of the lateral, medial and intermediate innervation subcompartments on the one hand, and those of soleus on the other. Responses of the distal subcompartment, which contains a higher proportion of slow fibers than the other three, contained elements of both response types.

Responses to the second perturbation strongly suggested central programming of postural responses, since in many cases, EMG responses which were appropriate for the first perturbation but not for the second, continued to be observed even though the recorded limb was not subjected to the force changes evoked by the first perturbation. The timing characteristics of this programming are different for soleus and the four innervation subcompartments. Supported by NIH grant #SO7 RR 05593-15 and Good Samaritan Hospital and Medical Center

INTRALIMB COORDINATION OF THE PAW SHAKE RESPONSE: A MIXED FLEXOR-21.4 EXTENSOR SYNERGY. G.F. Koshland and J.L. Smith. Lab. of Neuro-motor Control, Dept. Kinesiology, UCLA, Los Angeles, CA 90024.

Two movements, locomotion and scratching, known to be gene-erated within the lumbosacral cord follow a strict synergy of alternating flexor-extensor activity across all hindlimb joints. The paw shake response (PSR) also elicited in the chronic spinal The paw shake response (PSR) also elicited in the chronic spinal cat, has a mixed synergy in which the knee extensors and ankle flexors are coactive. The purpose of this study was to determine whether this mixed synergy is typical of the PSR intralimb coordination of the normal, spinal and deafferented spinal cat. PSR were evaluated in 4 cats, 1 mo prior to and 1-3 mos after cordotomy at T-12; and in one spinalized cat, PSR recovery was collected to the prior to and the prior t

followed 1-4 mos after unilateral deafferentation  $(L_4-S_2)$ . PSR Individual sector initiation of the sector initiation (L2-5). Sector initiation (L2-5), sector in the usual manner by wrapping tape around the paw; however, in the deafferented limb, PSR were obtained from tactile stimuli applied to the lateral thigh. ENG from the vastus latera-lis (VL), tibialis anterior (TA) and lateral gastrocnemius (LG) was analyzed for burst and cycle durations (CD, defined as the interval between LG burst onsets). Intralimb synergies were determined by the onset latencies of the VL and TA, normalized to percent of CD.

to percent of CD. The mixed synergy of the VL and TA coactivity was common in all preparations. In the normal cats, the two muscles had onset la-tencies of 64% ( $\pm$ 7) and the mean CD was 96 ms ( $\pm$ 9) over 8 cycles/ PSR. In the spinalized cats, VL and TA onsets were similar at 54% of the cycle and the mean CD was 85 ms ( $\pm$ 8) over 11 cycles/PSR. In 21% of the 38 deafferented PSR recorded, the VL and TA were co-active at 86% of the cycle. This coactive pattern was not observdefine a lower of the recovery period and was associated with CD of this cat's normal PSR (114  $\pm 24$  ms). Earlier in the recovery, two other synergies were seen in which VL onset shifted as the onset of TA remained stationary at 86% of the PSR cycle. In one synergy, associated with PSR with longer cycles (158  $\pm$ 39 ms), the VL was coactive with the LG, while in the other synergy, the VL onset occurred at 93%, midway between the TA and LG and was as-sociated with shorter cycles (123 +12 ms).

Our results suggest that PSR and its mixed synergy of ankle flexor and knee extensor coactivity is centrally generated. Thus, the lumbosacral cord may contain more than one, or a facultative network of unit generators to coordinate different intralimb synergies. Supported by NIH grant NS 16333.

POSTURAL CORRECTION IN FELINE AND HUMAN SUBJECTS DURING BOTH QUADRUPEDAL AND BIPEDAL STANCE. <u>D.C. Dunbar\*, F.B. Horak, J.M.</u> Macpherson, D.S. Rushmer, and C.J. Russell. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, 21.6

Sciences institute, wood sama tan nospital a nearest estat, Portland, OR 97209. The use of the domestic cat as an experimental model for understanding human motor control evokes the issue of the degree to which a quadruped can legitimately serve as an archetype for a biped. This study addressed the problem as it pertains to investigating CNS mechanisms underlying postural maintenance by analyzing EMG activity, force changes, and segmental adjustments.

segmental adjustments. Cat and human subjects stood both quadrupedally and bi-pedally on hydraulic platforms that disturbed posture by suddenly translating the subjects either anteriorly (headwards) or posteriorly (tailwards). The EMG activity and force changes of cats standing quad-rupedally and human subjects standing bipedally during both anterior and posterior translations were comparable to those reported previously by Rushmer, et al. (Exp. Brain Res., 50:45, 1983) and Nashner (e.g., Exp. Brain Res., 26:59, 1976), respectively. Postural responses of feline subjects standing bipedally were, in general, in accord with the patterns seen in human bipeds and the responses in quadrupeds. Thus, during anterior translations, bipedal cats corrected for backward sway by activating muscles on the anterior aspect of the hindlimbs whereas quadrupedal human subjects whereas quadrupedal human subjects activated muscles on the posterior aspect. The patterns were reversed during posterior translations. Bipedal cats rotated mostly at the ankles, less at the hips, and stiffened the knees, human quadrupeds used the hips and M-P joints while stiffening the knees and ankles. Furthermore, as in cats, muscle coactivity converted the human forelimbs into supportive struts while the hindlimb corrected posture. Variations appeared to be attributable principally to differences in limb morphology and to inexperience at adopting these postures.

These findings suggest that postural responses in feline and human subjects are determined primarily by the mechanical conditions of bipedalism and quadrupedalism combined with the conditions of bipedalism and quadrupedalism combined with the particular linear dimensions and musculoskeletal designs of <u>Felis</u> and <u>Homo</u>. Thus, the CNS in feline and human subjects appear very similar physiologically, both systems dependent upon plasticity and adaptability to meet the specific require-ments of a given posture. It is concluded, therefore, that cats provide an excellent experimental model for understanding CNS control of human posture.

POSTURAL BEHAVIOR OF INTACT CATS STATICALLY TILTED. 21.7 E. Fava\*, F. Lacquaniti\*, C. Maioli\*, G. Marini\* M.L.Sotgiu\* and C. Terzuolo. IFCN-CNR, Milano,20131 ITALY.

Cats were trained to stand freely on a platform statically tilted at various angles (up to ± 30° from the horizontal) in the sagittal plane. Strain-gauges measured the normal components of the reaction forces at each paw. Geometrical parameters of the body posture (limb lengths, joint angles and head inclination) were obtained from photographs. The only requirements for trial acceptance were the maintenance of lateral simmetry in weight distribution and the fact that standard deviation of the forces recorded at each paw did not exceed a fixed value.

For all tilt angles of the platform, cats exhibited a remarkably consistent postural behavior, whose main features were: 1) the projection of the center of gravity on the support surface was approximately constant (about halfway the distance between foreand hindpaws); 2) the distance between proximal joints and paws, and the orientation in space of both fore- and hindlimbs were also approximately constant; 3) head position instead varied widely from trial to trial, but it did not affect the postural parameters mentioned above.

On the basis of the described results, we argue that the process of postural regulation minimizes the changes in torques required for joint stabilization at different tilt angles. In fact, as long as limbs act as struts to support the animal's weight, no leverage is required in addition to that necessary for the maintenance of posture on a horizontal surface.

Notice that the observed behavior does not conform to that predicted on the sole basis of labyrinth and neck reflexes, as they are usually described (i.e. reciprocal flexion-extension at fore- and hindlimbs). Rather, it must be governed by the whole array of sensory information available to the animal.

POSTURAL ALTERATIONS FOLLOWING VIBRATION IN THE TENDO-ACHILLES: 21.9 A STUDY IN THE CALF MUSCLES OF ELDERLY SUBJECTS. M. E. Melnick, D. Biggs\*, S. Zilber\* and J.B. Redford\*. Department of Physical Therapy Education, Univ. of Kansas College of Health Sci, Kansas City, KS 66103

Falls in the elderly are a major medical problem. The purpose of this study was to quantitate posture in elderly as compared with young subjects and to determine the response to vibration applied over the triceps surae. The H-reflex was also studied to see if it was correlated with stance and the reaction to vibration. The differential response in these parameters would give clues of the nature of equilibrium changes with aging and direction for future studies and treatment. Volunteers over the age of 68 with no overt neurologic symptoms or complaints of gait disorders were given a brief evaluation. Using standard recording techniques, latency of response and peak-to-peak amplitude of the H-reflex were measured in each leg. For the postural assessment, the subjects were asked to stand comfortably on a stabilograph connected to an X-Y plotter which traced any shifts in center of gravity (COG). Stability was tested with and without vibration and with eyes open and closed during repeated 30 sec epochs. Vibration (150 cycle/sec) was applied simultaneously to both triceps surae muscles. The X-Y plotter was adjusted so that tracings were obtained before, during and after vibration epochs. The results were compared to those from young volunteers 20-40 years old. COG measurements showed the following significant differences between the two groups: increase in lateral sway at rest in the elderly (20mm in elderly; 13mm in young, p=0.05); a decrease in response to vibration in the elderly (10mm vs 24mm, p < 0.01); a decrease to variability in the elderly (jounn vs 24mm, p < 0.01); a decrease in variability in the elderly. There was no change in response in either group between eyes open or eyes closed conditions. The H-reflex showed a tendency toward an increase in latency and decrease in amplitude in the elderly subjects but was not correlated with postural adjustments. These data suggest that there may be a decreased response to peripheral carecary inthat there may be a decreased response to peripheral sensory in-put in the elderly. The elderly subject may then increase postural rigidity for support, making the elderly less able to respond flexibly to changes in walking surface. ORIENTATION EFFECTS ON THE TENDON JERK REFLEX. B. Myklebust, G. Gottlieb, G. Agarwal. Dept. Physiology, Rush Medical College, Chicago, IL 60612. The role of body tilt in soleus (SOL) motoneuron excitability has been studied in normal adults by correlating H-reflex amplitude with head position (1,2). The effects are attributed to vestibular influences, but results are attributed to vestibular influences, but results are contradictory, and inter- and intra-subject variability are significant.

We assessed the effects of body tilt on the stretch reflex by use of tendon jerks. Subjects were restrained on a Circolectric bed with a parachute harness; head and limb positions were controlled. Tendon taps were applied at a range of tilts from vertical (0 deg), horizontal supine (-90 deg), (+120 deg). The force of hammer tap was measured with a strain gage mounted on the hammer head. SOL EMGs were recorded with surface electrodes.

The ratio of mean peak-to-peak SOL amplitude to mean hammer force was computed for 10 to 20 taps at each body tilt. This ratio was greatest from 0 to 90 deg, and it was depressed in the supine positions (up to -90 deg) and in tilts greater than +90 deg. Thus it appears that outside the range of normal functional body attitudes, the gain of the tendon jerk reflex is depressed. This supports

an argument that tonic vestibular input maintains the excitability of the stretch reflex arc in body tilts characteristic of normal posture. However, uncontrolled exteroceptive input, poor correlations between hammer force and ENG amplitudes, and inter- and intra-subject variability suggest the need for further study. 1) C. Chan, R. Kearney: Neuroscience Letters 33: 333-338, 1982. 2) I. Aiello, G. Rosat, G. Serra, V. Tugnoli, M. Manca: <u>Exper. Neurol.</u> 79: 10 26 1002

21.10 MODULATION OF H REFLEX EXCITABILITY BY LATERAL TILT. C.W.Y. Chan and M.A. Dalzell\*. School of Physical & Occupational Therapy,

McCill University, Montreal, Quebec, Canada, H3G 1Y5. In a previous report (Chan, C.W.Y. & Kearney, R.E., <u>Neurosci</u>. Lett., <u>33</u>:333, 1982), we demonstrated that the H reflex amplitude reached a minimum when the head was near vertical, and often increased as a sinusoidal function of whole head-body rotations in the sagittal plane. The present study extends this work to map changes in soleus motoneuronal pool (MNP) excitability due to lateral tilt.

Subjects were blind-folded and fixed to a modified circo-Subjects were blind-folded and fixed to a modified circo-electric bed by means of partial casts for the neck and legs, and straps around the body and arms. A sling and saddle system held the body firmly in place. Static lateral head-body tilt was achieved by rotating the bed in random steps of 30°, to a maximum of 90° on either side of the vertical. Variability in soleus MNP excitability was measured with the H reflex technique. At each test position 25° responses upper proceeded on applyed to deter test position, 25 responses were recorded and analyzed to deter-mine the mean and standard deviation of the peak-to-peak amplimine the mean and standard deviation of the peak-to-peak ampli-tude of H and m waves. These values were then compared with those obtained in the control position (30° ipsilateral) immedi-ately before, and 1 min after, each change in head position. If there were significant changes in (1) the pre- and post-test con-trol H values, and (2) the test and control m responses, the trial was rejected. The mean H reflex amplitude per test posi-tion was then normalized with respect to pre- and post-test con-trol values and plotted as a funciton of head position.

1 major and 2 minor patterns of response emerged: (1) In 10 of 17 subjects studied, the H reflex was progressively facilitated With increasing amount of ipsi- and contra-lateral tilt. (2) In 3 subjects, it was facilitated by ipsilateral tilt but inhibited by contralateral tilt. (3) In the remaining 4 subjects, it was inhibited by ipsi- and contra-lateral tilt. Furthermore, the ob-served H reflex data could be described by a sinusoidal function

Served H reflex data could be described by a sinusoidal function in 15 of 17 subjects, with 81-99% of the variance accounted for. The 3 patterns of H reflex modulation by lateral tilt repre-sented real inter-subject differences, as the data from the same subjects were reproducible. Since the effect of rapidly adapting cutaneous receptors were minimized by waiting 1 min before each recording, our results could be attributed mainly to otolithic

afferents whose unit recording showed similar behavior (Fernendez, C. & Goldberg, J.M., <u>J. Neurophysiol.</u>, 32:996, 1976). In conclusion, we have demonstrated that the soleus MNP excit-ability in man is often facilitated by ipsilateral tilt, a behavior that is consistent with the asymmetric tonic labyrinthine reflex described in decerebrate cats.

ADAPTATION OF THE SOLEUS H-REFLEX IN MAN TO STANDING ON INCLINED SURFACES. J.S. Frank\* (SPON: A. Baylor). Dept. of Kinesiology, Univ. of Waterloo, Waterloo, Ontario, Canada, N2L 3G1. 21.11 Passive movement of the ankle joint in man has been shown to modify soleus motoneuron excitability (Mark et al., <u>Exp. Brain</u> <u>Res.</u>, <u>6</u>:130, 1968; Robinson et al., <u>J. Neurol., Neurosurg.</u> <u>Psychiat.</u>, <u>45</u>:699, 1982). Since this may be important to the control of upright posture, this investigation examined the influence of ankle joint position on soleus H-reflex excitability in man when standing on inclined surfaces. Eleven subjects were required to stand for 2 min. on 4 upward-inclined (5, 10, 15 and 20° dorsiflexion) and 4 downward-inclined (5, 10, 15 and 20° plantarflexion) surfaces. Surface emg recorded over the right plantarliexion) surfaces. Surface emg recorded over the right soleus and tibialis anterior muscles and H reflexes were elicited to the soleus muscle by stimulation of the posterior tibial nerve. The stimulus intensity was adjusted to evoke an H reflex of approximately half the maximum amplitude, as well as a small M wave. H reflexes were elicited at 15 sec. intervals while the subject stood alternately on a flat surface and then on inclined surface. A total of 8 reflex measures were averaged for each inclined surface.

Of the ll subjects examined only 6 subjects showed a stable M wave which was used to verify constant stimulating conditions across the testing conditions. The results of these subjects are presented in the graph below. H-reflex amplitude is expressed as a percent of the maximum M response for each subject. All as a percent of the maximum in response for each subject. All subjects revealed no change in reflex excitability during dorsi-flexion of the ankle of up to 15°. There was a depression of reflex excitability at 20° which was accompanied by tibialis anterior muscle activity. Plantarflexion of the ankle when stand-ing on downward inclined surfaces revealed a progressive increase In of downand includes and access revealed a progressive increase in reflex excitability for 3 subjects and a progressive decrease in reflex excitability for 3 other subjects. These results differ from those reported for passive rotations of the ankle and suggest a different control of soleus motoneuron excitability with changes in ankle joint angle in standing man than non-standing man.

TWO DISTINCT STRATEGIES FOR STANCE POSTURE CONTROL: ADAPTATION TO ALTERED SUPPORT SURFACE CONFIGURATIONS. F.B. Horak and L.M. <u>Nashner</u>. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, OR 97209. Biomechanical models of the standing human predict two strategies for adjustment of the center of body mass with respect to the base of support: 1) "Ankle strategy", a pattern of muscular contractions with which the body moves as a flexible inverted pendulum about the ankles by exerting torque against the support surface and 2) "Hip strategy", rapid flexion and extension of the hips moves the center of body mass by exerting a shear force rather than torque against the surface. This study examines how the width of the support surface influences the choice of postural strategy and how these strategies interact. these strategies interact

surface influences the choice of postural strategy and how these strategies interact. Equilibrium was perturbed by platform translations in the anterior-posterior direction in 9 subjects standing alterna-tively on a normal surface and on a narrow beam which limited the ability of their ankles to exert torque. The width of the support surface was varied with respect to the amplitude of the perturbations such that the center of body mass disruptions were within and beyond the boundary of the "ankle strategy". EMG activity from six trunk and leg muscles revealed two distinct synergic patterns available for stance control, each with a consistent temporal sequence and strength ratio of proximal and distal synergist activity. On the normal support surface, a distal-to-proximal muscle activation sequence was associated with a rapid increase in ankle torque and approxi-mate in-phase coupling of the ankle and hip joints. In situations in which torque production by the ankles was limited, a hip strategy was used involving a directionally opposite muscle synergy in a proximal-to-distal sequence leading to rapid rotation of the trunk about the hips. Laten-cies of initial muscle activation for both the ankle and hip strategies were 75-100 ms suggesting automatic control. In trials immediately following a change in the width of the trials immediately following a change in the width of the support surface the changes in strategy were often made gradually with a progressive shift toward proportionately less gradually with a progressive shift toward proportionately less of the inappropriate strategy and more of the appropriate one. In some individuals, the shift was complete after 5-20 trials, while in others a small mixture of the two strategies remained under all circumstances. During adaptation to novel surfaces, normal subjects exhibited a specific interaction between the ankle and hip strategies such that the muscle synergies associated with each were activated sequentially rather than simultaneously.

21.13 VISUALLY MEDIATED FEEDBACK CORRECTIONS DURING ISOMETRIC FORCE TRACKING IN HUMANS. P.J. Cordo. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland,

OR 97209. It is generally accepted that voluntary movements may be modified during the course of their execution provided that the total duration exceeds sensory feedback processing times. Although the role of somesthetic feedback in the production of

Although the role of somesthetic feedback protessing times. Although the role of somesthetic feedback in the production of adjustments to ongoing movements is presently undefined, visually-mediated modifications to movement trajectories have been demonstrated. The present study was undertaken to provide a more complete characterization of the properties of visually-mediated adjustments to a simple voluntary motor activity. Eleven standing subjects supported at the chest and under the right elbow produced isometric force tracking responses to step stimuli. The right wrist was placed in a cuff attached to a vertical shaft such that force exerted on this manipulandum was produced exclusively by the elbow musculature. Two horizontal lines were displayed on an oscilloscope screen in front of the subject: 1) a stationary reference line and 2) a "tracking" line representing the mathematical difference between the stimulus voltage and the force produced on the manipulandum. The subject's task was to respond to a sudden upward displacement of the tracking line by exerting force on the manipulandum in the flexor direction in order to return the tracking line to prescible. the manipulandum in the flexor direction in order to return the tracking line to the reference line position as quickly and accurately as possible. During sequences of 80 trials, the stimulus amplitude was randomly varied between limits requiring force responses of 2-12 kg. In 40 trials, the tracking line was unexpectedly extinguished within 10 ms of the onset of the subject's response. The stimulus amplitude, the force response of the subject and the electromyographic activity of the biceps brachii, brachioradialis, triceps brachii and posterior deltoid muscles was recorded. muscles was recorded.

By comparing average responses in the 40 trials with continuous visual feedback and the 40 trials where visual feedback was interrupted, the appearance of visually-mediated adjustments was determined to occur between 200-300 ms after response onset. Examination of single, selected trials revealed the occurrence of individual adjustments, beginning as revealed the occurrence of individual adjustments, beginning as early as 180 ms following response onset. Analysis of elec-tromyographic recordings demonstrated the participation of flexor muscles in these visually-mediated corrections for both overshoots (decreased activity) and undershoots (increased activity). The extensor muscle (triceps) co-contracted with the flexor musculature and, therefore, was not directly involved in the production of force adjustments. 21.14

FEEDFORWARD CONTROL OF POSTURE IN NORMAL ADULTS <u>S.</u> <u>D. Lucy\*, C. L. Riach\*, and K. C. Hayes\*.</u> (SPON: J. P. Girvin) Dept. Physiology, Fac. Med. Univ. Western Ont. Ontario N6G 1H1 It is well documented that activity in postural muscles, such as erector spinae, precedes upper limb movements in man and that this feedforward control of posture aids in the maintenance of truncal stability. Little is known, however, of the mechanisms by which posture aids in the maintenance of truncal stability. Little is known, however, of the mechanisms by which this is accomplished, or the exact functional interpretation. The present study was designed to determine whether or not this muscle activity induced reliable shifts in the center of pressure (CP) of ground reaction forces in the 600 msec immediately preceding voluntary arm movements. Consideration was also given to the relationships between preparatory excursions in CP and the altered location of CP introduced by the torques transmitted through the musculo-skeletal system during arm motion. Healthy adults (n=32) stood quietly on a strain-gauged force-platform (AMTI OR-6) and generated a series of self initiated rapid straight arm raises (right arm). CP excursions were derived from the orthogonal force and moment of force signals and were sampled (A/D), at 512 Hz. Onset of arm movement was determined from an Endevco 7264-200 accelerometer secured to the wrist. 21 of the subjects exhibited determined from an Endevco 7264-200 acceleronmeter secured to the wrist. 21 of the subjects exhibited clear evidence of preparatory shifts in CP in the lateral direction. 22 showed evidence of preparatory CP excursions in the fore-aft direction although these-were less distinct and more variable. For the lateral CP shifts two distinct phases were evident, an early change, commencing 400-500 msec prior to arm acceleration (38%) and a later change <150 msec prior to arm motion (61%). These preparatory CP deviations were always to the left of midline; the CP excursions concurrent with arm acceleration were always to the right. These results provide evidence that the preparatory muscle activity leads to definite shifts in CP prior to arm movement (as distinct from an increase in stiffness without CP excursions) and that these are appropriate for offsetting the imbalancing torques resulting from arm motion that are trans-mitted through the kinematic linkage. mitted through the kinematic linkage.

- POSTURAL SWAY IN SUBJECTS WITH CEREBELLAR ATAXIA, <u>K. C. Hayes\*, J. D. Spencer\*, S. D. Lucy\* and C. L.</u> <u>Riach\*.</u> (SPON: W. F. Brown) Dept. Physiology, Fac. Medicine, Univ. Western Ont., London, Ontario N6G IH1 The periodic fluctuations in location of the center of pressure of ground reaction forces during quiet standing ie postural sway, have been investi-gated in ten subjects with cerebellar ataxia. Of these subjects, 2 were diagnosed with Freidriech's Ataxia, 2 with Multiple Sclerosis, 1 chronic alcohol abuse and the remainder with brainstem or cerebellar infarcts, stroke or degenerative conditions. Subjects stood with feet parallel, and positioned 6 cm apart on a stable strain-gauged force-platform (AMTI OR-6) for a period of 20 seconds. They were derived from orthogonal force anu moment of force signals sampled (A/D) at 51 Hz. In the E0 condition cerebellar subjects demonstrated increased sway (pc.05) in both the fore-aft (RMSy= 7.37mm ± 1.23 [S.E.]) and lateral direction (RMSy= 8.1mm ± 1.43) when compared to age matched normal subjects (n=66). With EC the sway values in the fore-aft direction increased (RMSy= 9.26mm ± 1.36 and RMSy, = 7.57mm 21.15 when compared to age matched normal subjects (n=66). With EC the sway values in the fore-aft direction increased (RMS $_y$  = 9.26mm ± 1.36 and RMS $_x$  = 7.57mm ±2.0) yielding Romberg quotients ranging from  $R_y$  = 92% to 350% and  $R_x$  = 35% to 154%. Two subjects were unable to maintain equilibrium with EC. Power spectral analysis of the CP excursions of normal subjects, using a Fast Fourier Transform, indicated the principal energy to be <1Hz, with peaks generally occurring <.2Hz. Three of the cerebellar patients revealed prominent peaks in the spectrum between occurring <.2HZ. Three of the cerebellar patients revealed prominent peaks in the spectrum between 1-3HZ in the fore-aft direction; others exhibited spectra that were essentially normal apart from the general increase in power.
- BIOMECHANICAL CORRELATIONS OF POSTURAL MUSCLE ACTIVITY. 21.16
  - W. G. Friedli\*, M. Hallett and S. R. Simon\*. Gait Laboratory, Children's Hospital Medical Center and Neurology Section, Brigham and Women's Hospital; Harvard Medical School, Boston, MA 02115. When a standing human subject makes an arm movement muscles throughout the entire body participate. Muscle activity in the trunk and legs precedes the arm movement and is highly specific for different tasks. Presumably this muscular activity has sig-nificance for posture, defined as maintainance of the body seg-ments in appropriate relationship to each other and stabilization of balance. The purpose of the present study was to understand the precise functional consequences of this postural muscular activity.

Normal human subjects standing on a force plate made bilaterally symmetric elbow flexion and extension movements (focal movements). For some movements subjects were free-standing and for others they were strapped to a rigid wall behind them. Vertical and fore-aft translational forces as well as center of foot pres-sure were measured from the force plate. Body motions were de-rived from high speed cinematography.

For movements made when free-standing, analysis of the postural instabilities revealed that the principal problems are those of fore-aft translational force and rotational force in the saggital plane. Sources of postural perturbation are (1) muscular forces arising from the muscles moving the limb which also act on the body and (2) the momentum of the moving limb. Our data show the former to be more significant. Hence for flexion movements the dynamic perturbation is a forward translational force and clock-wise (viewing the body from the right) rotational force; for extension movements the perturbations are oppositely directed. The fore-aft translational forces seen by the platform during the The tore-aft translational forces seen by the platform during the movement are backward for flexion and forward for extension. Postural agonist muscles for a flexion movement are the erector spinae, hamstrings and triceps surae which produce counterclockwise force; postural agonist muscles for an extension movement are rectus abdominus, quadriceps and tibialis anterior which produce clockwise force. Actual movement of body segments is small and property of forces from the forced movement movement are produced by the force force force force for the forced movement movement is small and property of forces from the forced movement movement. reflects interplay of forces from the focal and postural movement. Movements made with the subject strapped to a rigid wall have less movements made with the subject strapped to a right with have less need for compensation and reduced postural force was seen. Verti-cal forces seen by the platform appear to reflect changes in con-ter of footpressure and do not seem directly compensatory. We conclude that a princinal function of postural muscle ac-tivity seen in association with a focal movement is to compensate for the rest between the second secon

for the most destabilizing dynamic forces produced by the movement.

MODULATION OF POSTURAL RESPONSES DURING PREPARATION FOR VOLUNTARY 21.17 MOVEMENT. M.H. Woollacott, M. Bonnet; K. Yabe\*. Département de Psychobiologie Expérimentale, CNRS-INP 3, 31 chemin J. Aiguier 13009 Marseille, France.

During preparation for voluntary movement, processes occur at a variety of levels within the nervous system, which facilitate the speed and/or accuracy of the task to be performed. The following experiments were designed to determine if the postural regulatory system, which is activated in advance of a voluntary movement as a function of the direction of movement, is modulated by prepara-The following

a function of the direction of movement, is modulated by prepara-tory processes, either in a <u>global</u> fashion, or more specifically, in relation to the <u>direction</u> of the prepared movement. Electromyograms (<u>EMC's</u>) were recorded from the gastrocnemius medialis (CM) and soleus (S) muscles of the right leg while stand-ing subjects performed a reaction time (RT) task involving pushing or pulling on a handle with the right hand. A warning signal gave advance information about the direction of the arm movement to be performed. Modulation of postural were avoirability by preparperformed. Modulation of postural muscle excitability by prepar-atory processes was tested by rotating the right ankle joint to elicit a GM and S stretch reflex, randomly, at different times during the 1.5 sec. preparatory period: 100, 300 and 500ms before the response signal. The amplitude of EMG activity recorded after the stretch was measured in terms of 2 successive components: M1 (40-60ms) and M2 (60-80ms). Each series of trials consisted of randomly distributed control trials, advance information push, advance information pull, and no advance information (NAI) trials. 6 subjects were tested.

 Statistical analysis of EMG amplitude (ANOVA) showed that the preparatory effects were different for the 2 muscles: GM showed a generalized facilitation, MI and M2 being more strongly facilita-ted for pull than for push trials; 2) The time course of stretch response modulation during the second half of the preparatory period was different for the 2 muscles, an increasing facilitation being observed in GM only; 3) Significant interaction between advance information conditions and response components were shown

for CM and S muscles; 4) These EMG response moduz G lations were emphasized in faster RT performers (N = 3, see figure). Thus, when A0 standing subjects know in advance the direction of 20 rapid arm movement, direction specific preparatory changes of the stretch reflex response appear in both PULL ipsilateral GM and S muscles.

DEVELOPMENTAL ASPECTS OF POSTURAL CONTROL IN CHILDREN. A. 21.18 Shumway-Cook and M.H. Woollacott, Dept. of P.E. and Inst. of

Neuroscience, University of Oregon, Eugene, Oregon 97403. The development of neural mechanisms underlying postural control is critical to the acquisition of complex motor skills and requires the maturation of two potentially separate, though inter-active processes: 1) those responsible for organizing muscles and joints into appropriately coordinated response patterns, and 2) those responsible for ensuring that responses remain consistently centext dependent, by integrating and acting upon redundant and

centext iependent, by integrating and acting upon redundant and sometimes conflicting sensory inputs to the postural control system. This study compared central nervous system organizational pro-cesses underlying balance in children of 3 age groups: 15-31 mos., 4-6 yrs., and 7-10 yrs., using a moveable platform capable of antero-posterior (A-P) displacements or dorsi-plantarflexing rotations of the ankle joint. A servo system capable of linking platform rotations to A-P sway angle allowed disruption of ankle joint inputs, to test the effects of incongruent sensory inputs on response patterns. Surface electromyography was used to quantify latency and amplitude of the castrocommus homstrines, thial is latency and amplitude of the gastrocnemius, hamstrings, tibialis anterior, and quadricers muscle responses. Cinematography provided biomechanical analysis of sway motion.

biomechanical analysis of sway motion. While directionally specific postural response synergies to A-P perturbations were present in the youngest children tested, re-sponse durations were longer than in adults and did not adapt to changing contexts. Transitions from immature to mature response patterns did not occur in a linear fashion, but showed stage-like properties. Variability in latency and amplitude relations between synergic muscles was low in the 15-31 mo. group, large in 4-6 yr. group, and subsequently decreased in the 7-10 yr. old, as responses acquired adult characteristics. Motion analysis in con-junction with FMC data success that in the 4-6 yr. old, the lack junction with EMG data suggests that in the 4-6 yr. old, the lack of tight temporal coupling between distal and proximal muscles was less efficient in minimizing inertial lag associated with mass of trunk and thigh and resulted in a motion of the knee joint. Results from balance tests under altered sensory conditions (eyes closed and/or ankle servoed) suggested that 1) with development a shift in controlling inputs to posture from visual dependence to more adult-like dependence on a combination of ankle joint and more adult-like dependence on a combination of ankle joint and visual inputs occured in the 4-6 yr. age group; 2) the ability to resolve multi-modal sensory conflict in balance control was not present in the 15-31 mo. old, emerged in the 4-6 yr. old, and reached adult form in the 7-10 yr. old. It is proposed that the age 4-6 is a transition period in the development of posture control. At this time the nervous system 1) uses visual-vestibular inputs to fine tune ankle-joint proprioception in preparation for its increased importance in posture control; and ?) fine tunes the structural organization of the postural synergies themselves.

VISUAL, VESTIBULAR AND VOLUNTARY CONTRIBUTIONS TO HUMAN HEAD STABILIZATION. N. Wereleys, D. Guitton, R.E. Kearney, B.W. Peterson. Montreal Neurological Institute and Biomedical Engineering Unit, McGill University, Nontreal, Canada, and Northwestern University, Chicago. We have investigated the ability of humans to stablize their heads in space and assessed the influence of mental set and the relative importance of visual and vestibular cues. Subjects were fixed firmly to the chair of a turntable facing a screen on which was projected a target spot. A 'gunsight' spot generated by a small projector fixed to the head provided feedback of head position. Four conditions were studied. 1) Gunsight (GU), subjects were instructed to stabilize the head in space by superimposing the 'gunsight' spot on the fixed target spot while the chair position was displaced according to a random pattern with a bandwith from 0 - 1 Hz. 2) Imagined gunsight (IGU), identical to (1) except that the subject was blindfolded and so had to imagine the target position. 3) Mental arithmetic (MA), subjects did mental arithmetic while the chair was displaced. 4) Visual tracking (VT), subjects were instructed to track the target spot white the Chair was fixed and the target spot driven to follow the chair displacement trajectory used in conditions 1,2 and 3. In GU normal subjects stabilized their head position extremely well (mean HEAD/CHAIR gain = .95). Significant stabilization in MA (mean gain (mean = .68) than for GU. The inpulse response functions (IRF) for GU had two distinct components: one near the origin and the other at about 250 ms. The infield position of turntable precluded a definitive statement regarding this peak. Nevertheless it tended to have a similar amplitude in GU and IGU and to be greatly reduced (402) in MA. This result suggests voluntary control of neck mechanics. The infield peak suffict short latency mechanics (inertia, prediction, vestibulo-collic, cervico-collic). The limited bandwith of our turntable precluded a def

OCULOMOTOR SYSTEM: MECHANICS AND PSYCHOPHYSICS

EFFECTS OF LIGHT AND DARK ENVIRONMENTS ON PRIMATE FIXATIONAL EYE MOVEMENTS. <u>D. Max Snodderly</u>. Eye Research Institute, 20 Staniford Street, Boston, MA 02114. 22.1

Many studies of the primate visual system compare behavioral performance during light and darkness. This is often done to eliminate visual influences on oculomotor performance or to compare the properties of photopic and scotopic systems. I have compared the fixational eye movements of two <u>Macaca</u> <u>fascicularis</u> monkeys when performing the fixation task devised by <u>Wurtz</u> under two illumination conditions: The fixation target was presented either with the room lights on, creating a background adjacent to the spot of 1 cd/m<sup>2</sup> or the fixation target was presented in total darkness.

For each trial, mean eye position was calculated for the last half second as a measure of eye position during the trial. Eye position at the end of dark trials was higher than at the end of

position at the end of dark trials was higher than at the end of light trials for both monkeys. Between-trial scatter of eye position was also greater on the vertical meridian in the dark than in the light. A human subject tested under the same condi-tions did not show this deterioration of performance in the dark. When one examines the movements of the eye within the trials, the performance of the monkeys and the human subject is more com-parable. In the dark, all subjects made fewer but larger fixa-tional saccades than in the light. I interpret this to mean that stimulation of the peripheral retina during fixation increases the frequency of fixational saccades.

VISUAL SUPPRESSION DURING VERGENT EYE MOVEMENTS. K.A. Manning\* 22.2 and L.A. Riggs (SPON: F. Volkmann). Hunter Laboratory of Psychology, Brown University, Providence, RI 02912.

Vision is known to be impaired near onset of saccadic eye movements. This suppression of vision, which is usually called saccadic suppression, appears to arise through central, neural processes when tested under appropriate conditions. We now provide evidence that suppression is associated with non-saccadic eye movements in human subjects, vergent movements. Visual suppression was measured psychophysically in 3 observers during convergence and divergence. Subjects executed 2 degree vergent movements by fixating alternately a near or far point under bright, Ganzfeld viewing conditions. A two-alternative, temporal, forced-choice procedure was used to measure subjects' sensitivity to brief, full-field decrements in illumination that occurred 1) at onset of vergent movements, and 2) during steady fixation. All subjects showed roughly 0.5 log unit suppression during convergent and divergent movements.

We conclude that saccades are not the only eye movements accompanied by visual suppression. Since visual suppression is present during convergence and divergence, suppression appears to arise as a corollary to initiation of an eye movement. Supported by EY-03169

HUMAN SACCADES ARE VERY CONJUGATE. J.L. McFarland\*, A.F. Fuchs, C.R.S. Kaneko and J. Wallman. Depts of Physiology & Biophysics and Psychology, and Regional Primate Research Center, Univ. of Wash-ington, Seattle, WA 98195; Dept. of Biology, City Univ. of New York, New York, NY 10031. 22.3

For saccades to be conjugate, agonist motoneurons must be activated nearly simultaneously and with similar discharge patterns. Although the motoneuron pools innervating vertical extraocular muscles are all located in the mesencephalon, the motoneurons for horizontal gaze lie in both the pons and the mesencephalon. Recent electrophysiological studies suggest that for vertical saccades, information is probably delivered simul-taneously over parallel pathways, while for horizontal saccades, first signals impinge on abducens motoneurons and then internuclear neurons relay these same signals to medial rectus motoneurons in the mesencephalon.

To investigate whether these differences in pre-motoneuronal To investigate whether mess differences in pre-motionary circuitry are reflected as differences in the trajectories of conjugate horizontal and vertical saccades, we measured the movements of both eyes simultaneously and independently using the scleral search coil technique. Two human subjects made 5°, 10°, and 20° horizontal, vertical and oblique saccades between stationary targets. Saccade amplitude, duration, peak velocity, onset time, and time-to-peak velocity were determined.

Both horizontal and vertical saccades had virtually identical timing and trajectories in the two eyes. On the average, the two eyes started together (within our 1-msec measurement error), moved the same dis-tance (average difference of less than 0.2°), ended together, and attained the same peak velocity. Both eyes reached maximum velocity simultane-ously during all vertical and small horizontal saccades. During the larger (20°) horizontal saccades, however, the adducting eye reached peak velocity 2.5 to 4.0 msec, on average, before the abducting eye.

Since the saccades of each eye are essentially indistiguishable, we uggest that the extraocular muscles of each eye must receive virtually identical and simultaneous neural inputs during horizontal and vertical saccades.

Our data are in contrast with those of previous binocular electro-oculographic studies (White <u>et al.</u>, J. Opt. Soc. Am. 52:210, 1962; Miyoshi <u>et al.</u>, Ann. N.Y. Acad. Sci. <u>374</u>:731, 1981) in which significant differ-ences between the timing and trajectories of horizontal saccades in the abducting and adducting eyes were observed. (Supported by NIH Grants RR00166 and EY00745.)

HORIZONTAL AND VERTICAL COMPONENTS OF OBLIQUE SACCADES ARE TEMP-22.4 NORTLY COUPLED IN HUMANS AND MONKEYS. W.M. King, Dept. of Physiology, Univ. Rochester Med. Ctr., Rochester, NY 14642, S.G. Lisberger, Dept. Physiology, UCSF, San Francisco, CA 94143, and A.F. Fuchs, Dept. of Physiology & Biophysics and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195.

The trajectories of purely horizontal or vertical saccades are stereotyped, and are characterized by approximately linear relationships between amplitude and duration, and between ampli-tude and velocity (ADV relationships). For example, in humans, a 5 deg saccade typically has a duration of 35 msec and a peak velocity of 200 deg/sec whereas a 20 deg saccade has a duration of 70 msec and a peak velocity of 400 deg/sec. Most saccades, however, are oblique with differently sized horizontal and ver-tical components. Previous studies in humans (T. Bahill and L. Stark, Arch. Ophthal. 1977) suggested that oblique saccade ADV relationships. In contrast, studies in cat (C. Evinger et al., Exp. Br. Res. 1981; D. Guitton and G. Mandl, Vis. Res. 1980) suggested temporal coupling of oblique saccade components with failure to obey separate ADV relationships.

We have examined this issue in humans and in monkeys using an electromagnetic search coil to obtain accurate measurements of horizontal and vertical eye movements. In some animals, single unit recordings from short lead burst neurons and abducens moto-neurons were obtained to corroborate the behavioral evidence.

Consistent with the cat studies, our data demonstrate strong temporal coupling between the horizontal and vertical components of oblique saccades. The duration of the smaller component is stretched to nearly equal the duration of the larger component. Consider, for example, an oblique saccade with a 5 deg horizontal and a 20 deg vertical component. Using the typical values given above, the duration of the 5 deg component would be nearly 70 msec instead of 35 msec. Quantitatively, our results may be summarized by two relationships: First, <u>component duration</u> is linearly related to the <u>polar</u> or <u>vector amplitude</u> of the sac-cade. This relationship is a generalized amplitude-duration function valid for the components of a saccade in any direction. Second, <u>component peak velocity</u> is linearly related to <u>component</u> <u>average</u> velocity (defined as component amplitude divided by component duration). This relationship implies that a single peak velocity - vector amplitude function does not exist for oblique saccades.

Our results suggest that the premotor circuits producing the horizontal and vertical components of saccades are centrally coupled.

22.5 ALEXANDER'S LAW: DOES IT REALLY INTERFERE WITH THE VESTIBULO-OCULAR REFLEX (VOR)? D. A. Robinson, D. S. Zee, A. H. Holmes\*, T. C. Hain\* and L. F. Rosenberg\*. Depts. Ophthalmology and

Neurology, The Johns Hopkins Univ., Baltimore, MD 21205. In 1912, G. Alexander observed that the intensity of spontanevestibular nystagmus decreased with gaze in the direction of the slow phases and increased in the other direction. In 1982, Doslak et al. (<u>Ann. Otol. Rhinol. Laryngol.</u>, 91: 316) showed this occurred with caloric nystagmus in normals and intensity can be defined as slow-phase eve velocity. Does this mean that centri-

defined as slow-phase eye velocity. Does this mean that centri-petal slow phases are more compensatory than centrifugal? To test this possibility, we rotated four subjects at 0.5 Hz, 30 deg/sec peak velocity. With a visible target straight ahead, gains of the VOR (eye velocity/head velocity) were 0.914 ± 0.024. At 25 deg left and right, gains decreased to about 0.787. This decrease on eccentric gaze is a new finding but there was no dif-ference between left and right peak ere velocity. The decreased of the velocity is the decreased of the velocity is the decreased of the velocity. ference between left and right peak eye velocity; no Alexander's law. When subjects imagined a target in the dark, all gains drop-ped by about 4% but again there was no Alexander's law. During rotation at a constant velocity (30 deg/sec) in the dark, subjects could suppress quick phases by imagining a target on the chair or on the wall. In the latter case it was necessary to imagine a target about 30 deg ahead and track it well into the other direction creating a giant, 60 deg, slow phase 2 sec long. In ei case there was no consistent evidence for Alexander's law. We did find Alexander's law during per- and post-rotatory In either

nystagmus. Gains measured using initial eye velocity were low (0.437) because subjects were concentrating on maintaining gaze

(0.437) because subjects were concentrating on maintaining gaze left or right periodically. Thus, mean initial eye velocity was 13.1 deg/sec. It rose or fell by 14.5% on 25 deg eccentric gaze in the quick-phase or slow-phase direction respectively. In all the cases without Alexander's law, subjects suppressed normal nystagmus by attending to a real or imagined target. We felt that when quick phases are allowed to rapidly and repeatedly change are norition it is impossible to form the mergent of such change gaze position it is impossible to form the percept of such a target. We suggest that the normal VOR is opposed by a parallel pathway normally used to cancel the VOR. The percept of an earth-fixed target drops the gain of this path to zero so that VOR gain is 1.0. The percept of a chair-fixed target raises it to 1.0 so that VOR gain is 0.0. Without a percept (e.g. mental arithmetic), the parallel gain goes to a default value near 0.5 so that VOR gain is also near 0.5. Under these conditions, nystagmus occurs, gains are low, and Alexander's law appears. We still do not know why it occurs but we can state that it only appears in situations where the VOR is not or cannot be used to assist in attending to the percept of a target.

POST-SACCADIC EYE STABILITY REQUIRES A COMPLEX, ACTIVE POST-SACCADIC INNERVATION. <u>H. P. Goldstein\* and D. A. Robinson</u> (SPON: E. Young). Wilmer Institute, The Johns Hopkins University, Baltimore, MD. We recently reported that after averaging data from nearly

We recently reported that after averaging data from nearly identical horizontal saccades in the monkey, the abducens motoneuron firing rate consistently showed a slow decay to the steady state level for saccades where the unit burst ("on saccades") as well as for saccades where the unit paused ("off saccades"). This decay, with a major time constant of about 90 msec, lasted hundreds of msec after the end of the saccade even though the eye remained stationary in the orbit. From analysis of the dynamic orbital properties one can deduce that this "pulse-slide-step" (and "pause-slide-step") innervation is required to hold the eyes steady after a saccade. To have consistency of neural and mechanical data in a single species we measured the mechanical dynamics of the passive orbital tissues in the monkey thereby extending previously

species we measured the mechanical dynamics of the passive orbital tissues in the monkey thereby extending previously determined data from humans and cats. Monkeys were anesthetized and the horizontal recti detached in one eye. That eye was displaced and then quickly released; the returning time course measured with the magnetic eye coil technique. The time course showed an initial fast, 20 msec time constant decay followed by a clouer decay with a major time constant decay followed by a slower decay with a major time constant of about 170 msec. Mathematical analysis shows that the force needed to maintain the change orbital tissues at a fixed position after an abrupt change in position is an exponentially decaying force with a time constant of 90 msec. While dynamic relationships exist between discharge rate and muscle force, we still feel that the long, post-saccadic drifts in firing rate are part of a programmed command (vision being too late to assist) preventing stress-relaxation of orbital tissues from creating eye drift. We have carried this further by simulating a more realistic nonlinear model on a digital computer. Both theory and simulation show that if the brain fails to compensate for these slower decays the eye would drift at velocities in excess of 10 deg/sec, a rate which would preclude clear vision after a saccade. We further suggest that patients with post-saccadic drift anomalies may correctly match the pulse and step, but not correctly match the slide to that pulse and step. (This work supported by NIH grants EY07047, EY01765, and EY00598.)

A RESTRICTED MAIN SEQUENCE FOR PURKINJE IMAGE RECORDINGS OF VERTI-22.7 CAL SACCADES. J.R. Hotson, K. Dehnad\*, E.B. Langston\*, A. Owe B.W. Brown\*, Dept. Neurology and Div. Biostatistics, Stanford Owen\*, University and Santa Clara Valley Med. Ctr., Stanford 94305 and San Jose 95128, Ca.

The main sequence parameters of saccades provide quantified measurements of the saccade systems. This method has mainly e mined horizontal saccades because studies of vertical saccades mined norizontal saccades because studies of vertical saccades are limited by techniques that are insensitive, inaccurate, or invasive. These technical limitations may explain the paucity of studies of the vertical saccade system. Purkinje image recordings using the SRI eyetracker can measure vertical saccades, however the recording range is limited to +/-

9 deg arc, and there is a lens overshoot artifact that interferes with amplitude and duration measurements. This recording approach however is particularly sensitive and records eye movement in the same range as most naturally occurring saccades. For these rea-sons, we used Purkinje image recordings to develop a restricted subject and provide a method for accurate comparative studies of the human vertical saccade system. The peak velocity and amplitude was plotted for 1-15 deg arc

vertical saccades excluding glissades and overlapping saccades. Saccade displacement rather than amplitude was measured to omit Saccade displacement rather than amplitude was measured to omit the lens overshoot artifact. Dynamic overshoot is not prominent in vertical saccades and thus position displacement gives an ap-proximation of saccade amplitude. A power law (Log Vel= $\alpha + \beta$  Ampl) with and with-and an exponential law (Log Vel= $\alpha + \beta$  Ampl) with and with-out quadratic terms were tested for best fit of the plots. These models were compared in 8 control subjects by plots of residuals, the standard deviation around the linear regression, and a quadra-tic regression coefficient. A power law gave a better fit than an exponential law for this restricted region of the main sequence that lacks an asymptote. Adding a quadratic term did not signifi-captly improve the model

that lacks an asymptote. Adding a quadratic term did not significantly improve the model. Next tested was the ability of Log Vel=  $\alpha$  +  $\beta$  Log A to discriminate between control subjects and patients with Huntington's Disease and Joseph Disease. These diseases may selectively slow vertical saccades. A comparison of the estimated peak velocity at 10 deg arc amplitude (Vp10), the scattergram of the slope, and intercept of the linear regressions, and the plot of the standard deviation about the regression (SDreg) were used as tests of discriminated equally between 8 control subjects and 9 patients with 83% of the observations in the patients and none of the control subjects falling below a discrimination boundary (Vp10-5.9 or 365 deg arc/sec). SDreg separated only 44% of patient measurements but when combined with Vp10 further enhanced its discrimination to 89%.

STRETCH RECEPTOR AFFERENTS FROM EXTRAOCULAR MUSCLES IN THE SEMI-LUNAR GANGLION OF THE RAT. W. J. Daunicht\* (SPON: W. Lichten-steiger). Div. Biocybernetics, Univ. Duesseldorf, D-4000 Dues-22.8 steiger). Div. seldorf, F.R.G.

In order to investigate the functional role of proprioception from extraocular muscles (EOM) in eye movements of mammals, the rat was chosen as a model. In a first basic study the presence of EOM stretch receptors was demonstrated in this animal, and sensitivity and dynamic properties of receptor impulse rate in relation to passive eye movements were determined. Single unit activity was recorded in anesthetized albino

relation to passive eye movements were determined. Single unit activity was recorded in anesthetized albino rats, while EOM were passively stretched using an electromagne-tic puller with position feedback. The impulse rate modulation was studied in response to sinusoidal stretching with frequen-cies f between 0.01 and 10 Hz and amplitudes between 140 and 355 µm corresponding to 2.7 to 6.8 deg of eye rotation. Units responding specifically to passive stretch of EOM were found in the ganglion semilunare, but not in the mesencephalic trigeminal nucleus (mes V). The activity was not correlated to touch of surrounding tissue or movement of the jaw. The major-ity of afferents had a very high sensitivity S, e.g. at 1 Hz an average of 200 imp/s/mm corresponding to 10.5 imp/s/deg of eye rotation; others had a lower sensitivity, e.g. at 1 Hz an aver-age of 30 imp/s/mm corresponding to 1.6 imp/s/deg. In the range between 0.1 and 10 Hz the sensitivity increased by 6.8 dB/decade. Such a behavior could be described by the relation  $S \sim f^{K}$  with k = 0.34, predicting a constant phase lead of 31 deg in case of linearity. Experimentally a constant 34 deg phase lead was found. At frequencies below 0.1 Hz the sensitivity plots flat-tened out and the phase lead tonded to decrease. The static order neurons was confirmed by horseradish peroxidase injections into EOM. Only the ophthalmic subdivision of the ipsilateral ganglion semilunare (besides the corresponding oculomotor nuc-leus) contained labelled neurons, but never the mes V. Up to 18 first order neurons per muscle were found. It is concluded that rats are suitable to study the function

Is first order neurons per muscle were found. It is concluded that rats are suitable to study the function of EOM proprioception and that the high sensitivity of their stretch receptors enables them to monitor eye movements with high precision. Dynamic properties and distribution of sensitivities are consistent with findings at primary and secondary endings at cat hind limb muscle spindles. In a next step it is planned to study the afferent activity in the alert animal.

22.9 ELECTRICAL ACTIVITY OF MUSCLE FIBERS OF RAT EXTRAOCULAR MUSCLES. D. J. Chiarandini, E. Stefani and J. Davidowitz\*, Depts. of Ophthal. and Physiol. and Biophys., New York Univ. Med. Ctr., New York, NY 10016 and Dept. Physiol., Center for Advanced Studies, I.P.N., Mexico D.F. 14 Extraocular muscles (EOMs) of mammals have two types of muscle

fibers, singly and multiply innervated (SIFs and MIFs). These are intermingled in two muscle layers, the global and orbital. Global MIFs (diameter: 15-25  $\mu$ m) have poorly delineated myofibrils generate tonic tension, are polyneuronally innervated and lack action potentials. They show, instead, Na-dependent graded responses or slow peak potentials (SPPs) (1-5). Orbital MIFs (diameter: 5-15 µm) have a morphology that varies from large ill-defined myofibrils toward the ends of the fibers to small well defined myofibrils in their middle region (6). Their contractile properties are unknown. In inferior rectus muscles of rat, we have found in vitro that orbital MIFs are polyneuronally innervated by 2-5 axons. These axons usually have a threshold of innervated by 2-5 axons. These axons usually have a threshold of 0.3-2.0 V which is comparable to that of axons to SIFs but lower than that of axons innervating global MIFs (3-10 V). Measurements of the membrane time constant, using a bridge circuit, show that it is 7 msec in orbital MIFs, larger than in orbital SIFs (3 msec) but much smaller than in global MIFs (150 msec). The input resistance of orbital MIFs is about 14 MΩ, higher than in orbital SIFs (20 MΩ). Nerve stimulation of orbital MIFs evokes compound and the patential with in protecting which is most of a triprer stimulation of orbital MIFs evokes compound the patentials which is protected with the patentials which is most ease do not triprer stimulation of the patentials which is not the patentials which was a stimulation of the patentials which is the patentials which is patentials which we have the patentials which is patentials which was a stimulation of the patentials which is patentials which was a stimulation of the patentials which is patentials which is patentials which is patentials which was a the patentials which is patentials which is a patential which is patentials which was a stimulation of the patentials end-plate potentials which in most cases do not trigger action potentials, even if the fibers have a normal resting potential (RP). However, action potentials were recorded in some orbital MIFs. In global MIFs with a normal RP, nerve stimulation evokes compound end-plate potentials which do not trigger action potentials but which, if large enough, can elicit SPPs. These results demonstrate that in EOMs the contraction of most MIFs is due to graded, non-conducted depolarizations. Moreover, the differences in the threshold of the motor axons, passive electrical properties and ability to fire action potentials, indicate that orbital and global MIFs are functionally different. AN INEXPENSIVE EYE-MOVEMENT MONITOR USING THE SCLERAL SEARCH COIL 22.10 TECHNIQUE. <u>R.S. Remmel</u>, Department of Physiology and Biophysics, University of Arkansas Medical Sciences, Little Rock, Ar 72205.

The magnetic search coil method for measuring eye movements was developed by D.A. Robinson (IEEE Trans. Bio-Med. Eng., BME-10 developed by D.A. Kobinson (LELE Frans. Blo-Med. Eng., BME-10 (1963) 137-145) and offers very low error, drift and noise. In an animal a coil of wire of 1-3 turns can be surgically implanted either under or adjacent to the four recti muscles. A contact lens containing the coil can be used with humans. The subject is placed inside horizontal and vertical oscillating magnetic fields, which induce voltages in the scleral coil which are proportional to the sine of the eye angle.

Our two pairs of Helmholtz coils are 51 cm in mean diameter and spaced 51 cm apart. Each coil has 5 turns of #16 wire wound on a plywood frame. The pairs of coils are in series and have an inductance of 80  $\mu$ H. The field is uniform to 1% out to 2.5 cm from the center, a distance appropriate for a cat's eye.

The horizontal field coils are driven by square waves at 50 KHz and the vertical ones at 75 KHz. These frequencies are derived from one master oscillator and are phase-locked. This 2:3 ratio of frequencies means that the 50 KHz and the 75 KHz square waves have no ODD harmonics in common (a square wave has only odd harmonics). The field-coil amplifiers use common switching transistors and supply 30 V p-p to the coils. No tuning nor other adjustments are needed.

The output of the scleral coil is (0.00035 AN  $\sin\!\theta)$  volts. where A is the area in sq. cm., N is the number of turns and  $\theta$  is the eye angle.

The scleral-coil amplifier is made from three fast operational The scieral-coil amplifier is made flow the fast operational amplifiers. This signal and its inverse are connected to the two contacts of a single pole-double throw switch (made from MOS-FET transistors); this switch is operated by the 50 KHz signal to accomplish phase-sensitive demodulation for the horizontal channel Next come a 3-pole filter, a D.C. amplifier and a 1-pole filter, Next come a 3-pole filter, a D.C. amplifier and a 1-pole filter, which eliminate the carrier frequencies. The filter network has a rise time (10% to 90%) of 1.2 msec. An identical circuit is pro-vided for the vertical channel. The amplifier has a noise level of 0.32 µV at the input (after demodulation). The gain is 7000 (D.C. output/p-p input). Gain and offset controls are provided. For a typical one-turn coil of 2 cm diameter, the sensitivity is 0.13 V/deg. The amplifier noise is then equivalent to 1.0 min. of angle. The circuit consumes 0.68 A from each of two 15 V regu-lated supplies and costs less than \$300 to build. Supported by NSF Grant ISP-8011447. Mr. Bob Waldron assisted.

SPECIFICITY OF SMOOTH PURSUIT EYE MOVEMENT DYSFUNCTIONS IN SCHIZO-22.11

SPECIFICITY OF SMOOTH PURSUIT EYE MOVEMENT DYSFUNCTIONS IN SCHIZO-PHRENIA. P.S. Holzman\*, C. Solomon\*, S. Levin, C. Waternau\*. Mailman Res. Cr., McLean Hosp. and Harvard U., Belmont, MA 02178. Smooth pursuit eye movements (SPEM) are disrupted in 50-80% of schizophrenics (SZ's) (review in Lipton et al., 1983). The eye tracking disruption (ETD) consists of saccadic intrusions and of saccadic smooth pursuit tracking (Levin et al., 1983). The pre-viously reported prevalence of ETD in 50% of SZ's relatives, and data from twin studies showing a high concordance of ETD (r=.77) in MZ twins, but not in DZ twins (r=.39), discordant for schizo-phrenia (Holzman et al., 1977, 1978, 1980) suggest that ETD may represent a biological marker for vulnerability to schizophrenia. ETD are also present, however, in 30-50% of patients with major affective disorders, primarily manic depressive psychosis (MDP) (Shagass et al., 1974; Lipton et al., 1980). The appearance of ETD in many organic disorders also indicates that in themselves they are not pathognomonic to SZ. To establish the trait status of ETD in schizophrenia would therefore require evidence that they are prevalent in families of SZ's but not in families of MDP's. We present here such evidence. 80 SZ and 46 MDP subjects fulfilling DSMIII and St. Louis

diagnostic criteria were tested. All were receiving medications at the time of testing. 59 parents from 34 families were also tested. Parents from the two groups did not differ in age. Eye-

tested. Parents from the two groups did not differ in age. Eye-movements were recorded binocularly in the horizontal plane with the electrooculographic technique. Target characteristics and scoring methods were as described in Levin et al. (1981). As in previous studies, 59% (47/80) of the SZ's and 41% (19/46) of the MDP's had ETD. A chi-square test was not significant. In contrast, 34% (13/38) of the parents of SZ's, as compared to 10% (2/21) of the parents of MDP's showed ETD. When counting the number of families with ETD, 55% (12/22) of SZ families had ETD but only 17% (2/12) MDP families had it. The probability that a parent or a family of a SZ offspring has ETD is significantly higher than the corresponding probability for a MDP parent or higher than the corresponding probability for a MDP parent or family. The significant predictive variable for the parent's eye tracking quality is the offspring's diagnosis rather than eye tracking status. There were no differences between ETD patterns in the records of parents or of patients. The data replicate a previous report of ETD in 34% of SZ relatives and 11% of non-SZ relatives.

The results suggest that ETD represent a trait-related disorder in SZ but not in MDP. Although they characterize only a subgroup of SZ's, ETD now appear to be a biological marker that transcends surface symptoms of this psychiatric condition.

OCULOMOTOR FUNCTION IN ALCOHOLIC KORSAKOFF'S SYNDROME 22.13 R.V. Kenyon\*, J.T. Becker, H. Hermann, & N. Butters.(SPON:C.Oman Man-Vehicle Lab., Mass. Inst. of Tech., and Boston Univ. Sch. Med.

Patients with alcoholic Korsakoff's syndrome are described as having both memory and perceptual deficits. Although the amnesic syndrome has been well studied, only a few researchers have focused on the perceptual abnor-malities in this disorder. The perceptual changes include a failure at visual scanning and contour analysis may reflect a problem with eye movements rather than with higher-order processing.

The purpose of the present experiment was to investigate the oculomotor functions of patients with alcoholic Korsakoff's syndrome. Four patients and one nonalcoholic age-matched syndrome. Eye movements were monitored with an infra-red detection system and both saccadic and smooth pursuit movements were studied. The results of the study suggest that patients with

The results of the study suggest that patients with Korsakoff's syndrome have significant oculomotor abnormalities. First, their latency to begin a saccadic eye movement is significantly longer than that expected for individuals in their age group. In contrast, small corrective saccades were generated with normal latency. Second, the overall saccadic velocity in two of the four of the patients was significantly slower than the norm. Third, the qualitative aspects of the saccades were unusual. Two patients had significant numbers of hypometric saccades and saccadic intrusions during fixa-tion. Fourth, the gain of the smooth pursuit system was lower than normal. lower than normal.

These data suggest that significant abnormalities remain even as long as seven years after the onset of the disorder. These changes appear to be consistent with the patient's known damage to the cerebellum and to the frontal cortex functional system.

SMOOTH PURSUIT AND FIXATION IN THE PARENTS OF SCHIZOPHRENICS 22.12 L. Whicker, Jr.\*, L.A. Abel and L.F. Dell'Osso. Ocular Mo Lab, V.A. Med. Cntr. and Dep't of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106 Ocular Motor

In the past decade a large body of work has grown up concerning ocular motor function in schizophrenics. Abnormalities of smooth pursuit were described in patients and in their relatives smooth pursuit were described in patients and in their relatives. Early work postulated an actual defect in the pursuit pathways of schizophrenics and their relatives, but the methodologies used were crude and qualitative. More recent work on patients using quantitative recording techniques has shown poor fixation and tracking, but questions of interpretation have left it unclear as to whether an actual defect in pursuit exists or if poor track-ing might be attributed to impaired attention. Of particular interest would be documentation of an abnormality in the clinic-ally normal relatives of schizophrenics, using quantitative ocu-lographic techniques. We therefore studied the fixation and smooth pursuit of 8 parents (6 F, 2 M) of schizophrenic patients admitted to the Psychiatry Service of the VA Medical Center. The subjects' mean age was 61.9 (s.d.=7.64); all subjects denied hos-pitalization for psychiatric reasons or use of neuroleptic drugs. None showed evidence of loose associations or illogical thought None showed evidence of loose associations or illogical thought during interviews.

Subjects were instructed to "hold their eyes still" or "stare at a spot" for two minutes. One subject's square wave jerk (SWJ) frequency lay outside the published normal range; he also had some incidence. Pursuit of ramp targets at 5, 10, 20 and 40 deg/s showed that all patients could produce normal gains; <u>pursuit per</u> so was not impaired. SWJ persisted during pursuit, but at a low-er frequency. In 3 subjects at 5 deg/s, however, frequent sac-cades off-target were seen. These were usually jumps ahead of the spot; the subject would then wait for the target to reach his eye position and resume tracking. This occurred in spite of fre-quent and enthusiastic verbal encouragement. Such "anticipatory saccades" might be mistaken for SWJ. Thus, actual smooth pursuit and fixation were intact in all subjects and SWJ were within normal limits in 7/8, but a tracking pattern consistent with an attentional impairment was seen in 3/8. Such an abnormality in apparently normal relatives of psychiatric patients merits further study.

22.14 OCULAR AND MANUAL MOVEMENTS TO VISUAL AND AUDITORY TARGETS, J.D. Fisk\* and J. A. Mather\* (Spon: M. A. Goodale), Psychology Department, The University of Western Ontario, London, Canada N6A 5C2.

Orientation to sensory stimuli often involves the coordinated interaction of a number of muscle groups, but the manner in which the central nervous system achieves this coordination remains unclear. If the processing of sensory information is mediated by neural substrates common to a number of motor sys-tems one would expect parallels in the performance of these systems. The present study compared the performance of the ocular and manual motor systems in a task which required sub-jects to orient quickly and accurately to a peripheral stimulus. Subjects looked and pointed to targets on a screen that were presented at 10° and 20° to the left and right of a cen-tral fixation target. Eye movements were recorded by DC electrooculography. Arm movements were restricted to rotation about a point directly in front of the subjects, and were recorded via a linear potentiometer. Visual targets were 1° diameter LEDs. Auditory targets were a train of clicks at 50 Hz and 70 Db. Blocks of trials were run with either 200 ms (short) or 5 s (long) target durations. The latency to initi-ate movement of the eyes and hand was lower when the target duration was short. This suggests that the processing time for both motor systems was affected by a common factor. The dura-tion of movement of the eyes and hand was also lower for short targets. This result may reflect the use of additional neural systems which modify the motor output on the basis of sensory information obtained during the production of the movement. Changes in target modality from visual to auditory also affected the eye and hand movements similarly. With visual targets the latency to initiate movement and the error of final position of both the eyes and hand were lower for the 10° targets. In contrast, the latency and error with auditory targets were lower for the more eccentric 20° targets. The similarity of the effects of changes in the stimulus parameters suggest that a common neural substrate may underlie the analysis of sensory information for both systems. The relatively large decrease in accuracy of eye movements to auditory as opposed to visual targets demonstrated the specialization of the ocular Visual targets demonstrated the specialization of the ocular motor system for orientation to visual stimuli. However, the findings of this study suggest that the sensorimotor informa-tion for orienting to a periphral stimulus may be integrated by processes common to the ocular and manual motor systems. This research was supported by Grant #T199Al from the Natural Sciences and Engineering Research Council of Canada to Dr. J. Mather A. Mather.

NON-VISUAL CONTROL OF FINGERTIP POSITION IN SPACE: THE USE OF 22.15

NON-VISUAL CONTROL OF FINGERTIP POSITION IN SPACE: THE USE OF RETINAL VERSUS OCULOMOTOR REFERENCE INPUTS. <u>0.Bock\*and R.Eckmiller</u> (SPON: W.H.Zangemeister). Div. of Biocybernetics, Univ. of Düsseldorf, D-4000 Düsseldorf, FRG. Pursuit of visual targets by the tip of the right index finger was studied in 10 healthy human subjects. Visual cues on fingertip position were excluded by a horizontal panel below eye level, re-stricting possible sources of position information to propriocep-tion and efference copy. A mechanical device restrained arm move-ments such as to assure fingertip motion along a horizontal arc (45 cm radius, center between axes of eye rotation) just below the cylindrical screen (45 cm diameter) for visual target display. Static characteristics were studied by asking the subjects to point at stationary targets appearing in a random order at eccen-tricities between 25 deg left and right (experiment S). For dynamic characteristics subjects pursued a visual target (15' diameter) moving sinusoidally at different amplitudes (20, 10, and 5 deg) and frequencies from 0.1 to 1.2 Hz (experiment D). In both experiments subjects either fixated a point straight ahead (SR,DR: target position monitored as retinal eccentricity), or pursued the target with the eyes (S0,D0: target position monitored as <u>c</u>cular position plus eventual retinal error). In experiment S subjects typically pointed past the targets. The amount of past-pointing was rather constant for a given subject (s.d. 1 to 2 deg) with individual means ranging from 6 deg left to 6 deg right. However, when pointing to two successive targets, the amplitude of fingertip movement corresponded well to target distance (with a slight tendency to overshoot at small and undershoot at large eccentricities). No unequivocal difference

target distance (with a slight tendency to overshoot at small and undershoot at large eccentricities). No unequivocal difference

undershoot at large eccentricities). No unequivocal difference between SR and SO was detected. In experiment D the gain of fingertip movement strongly depen-ded both on stimulus amplitude and frequency. In DR the gain at 20 deg stayed close to 1 dB up to 0.3 Hz and then fell to -2 dB at 1.2 Hz. With decreasing amplitude DR gain increased and a distinct peak formed at 0.3 Hz. This peak reached 4.5 dB at 5 deg amplitude, i.e. the finger overshoot the target by 70%. In D0 the gain at 20 deg was 0.5 dB below DR and changes with decreasing amplitude upon cimilar but loce departie. Curther increased in the

gain at 20 deg was 0.5 dB below DR and changes with decreasing amplitude were similar but less dramatic, further increasing the gap to DR. The peak at 0.3 Hz reached in DO only 2.5 dB at 5 deg amplitude, i.e. the finger overshoot the target by 30%. Our results indicate that different reference sources clearly modify the control of fingertip position in space: if a retinal rather than oculomotor signal is available at low stimulus ampli-tudes and frequencies, fingertip motor program deviates most from target movement. As a next step, in an inverse set of experiments, dependence of oculomotor control on non-visual reference inputs of fingertip position will be studied.

22.16 CONTRIBUTION OF VISUAL FEEDBACK TO THE CONTROL OF DIRECTIONAL AIM-ING IN ADULTS. C. Bard, M. Fleury and J. Paillard. Physical Activity Sciences Laboratory, Laval University, Quebec, G1K 7P4, Canada. CNRS Marseille, France. The manipulation of movement speed in directional aiming tasks and of available visual information at specific moments during lime transitions the identification of specific moments during

The manipulation of movement speed in directional aiming tasks and of available visual information at specific moments during limb trajectory allows the identification of visual afference moda-lities and the determination of their role in visuo-motor correc-tion. The aim of this study was to investigate directional aiming accuracy according to movement speed and visual feedback. Eight adults participated in the experiment. The subject, holding a joy stick, performed an horizontal  $\alpha$  mextension in a sagittal plane toward luminous targets at 0°, 10°, 20° or 40° of eccentricity in the right visual field. Twenty trials (5 repetitions for each target) were administered. For each trial, RT and MT of the arm, angular errors in aiming, eye and head latencies were measured. The independent variables were: condition of feedback, with vi-sual feedback, without visual feedback, with initial feedback and with terminal feedback, and movement speed. Results showed that aiming accuracy deteriorates independently of movement speed when movement is performed in an open-loop condition. For all feedback conditions, accuracy is better in slow aiming. For all feedback and .wovement speed conditions, aiming accuracy deteriorates with target eccentricity. Relative spatial error increases according to target eccentricity. Whatever feedback condition, or movement speed, ocu-lar latency does not vary. Head latency (HL) significantly dimini-shes in fast aiming - XF = 415 msec, XS = 468 msec, but does not vary according to other experimental conditions. Hand reaction time (RT) significantly diminishes in fast aiming; it also varies according to target eccentricity. Two main conclusions can be drawn from these results. (1) With the present directional aiming task, whatever the movement speed, performance deteriorates when subjects work in an open-loop condition, compared to other feed-back conditions. This confirms that even in fast aiming the sporting the hypothesis that certain correction could originate from peripheral vision. (2 limb trajectory allows the identification of visual afference modathesis that the motor system is more susceptible of imprecision, than the information processing system, when speed and therefore strength applied to the system are increased.

### EXCITABLE MEMBRANES AND SYNAPTIC TRANSMISSION: INVERTEBRATE STUDIES

ON THE MECHANISM OF PRESYNAPTIC INHIBITION. R.M. Glantz, L.T. Wang and B. Waldrop Biology Dept., Rice Univ., Houston, TX 77251 A previous report (Glantz, Neurosci. Abstr. 7:251, 1981) describes the features of presynaptic inhibition at the excitatory synapses between as-cending and descending interneurons in the crayfish brain. Briefly, the 23.1 EPSP in descending interneurons is diminished by 30-60% as a consequence of concurrent stimulation of cephalic sensory nerve roots. This stimulation elicits polysynaptic, depolarizing IPSPs in ascending interneuron terminals. The IPSP amplitude is 3-5 mV and is associated with a 30% increase in the terminal input conductance and a reversal potential of 12 mV above rest. Here we report on the geometry, passive, and active characteristics of the ascending cell terminals. The results imply that the passive shunt hypothesis of presynaptic inhibition is probably incorrect. The terminal region is actively invaded by the axonal spike. This

conclusion follows from a comparison of action potentials in axons and terminal arborization of ascending cells, summarized below:

			Sensitivity		
	Ampl. (mV)	Overshoot (mV)	Threshold current (nA)	to applied current (mV/nA)	Half width (ms)
Axon	97.8 <u>+</u> 7.8	24.9 <u>+</u> 8.0	7.1 <u>+</u> 3.8	2.1 <u>+</u> 1.0	0.9 <u>+</u> .2
Term.	97.5 <u>+</u> 12.9	22.7 <u>+</u> 8.0	4.3+2.5	1.8 <u>+</u> 0.2	1.8 <u>+</u> .4

The passive cable properties of the terminal region have been calculated on the basis of measurements of input resistance, membrane time constant, and physical dimensions derived from Lucifer Yellow injections. The varicosities (presumed sites of transmitter release) of the terminals are 0.1 to

cosities (presumed sites of transmitter release) of the terminals are 0.1 to 0.3  $\lambda$  from the active recording sites. If the intervening neurite is electrically passive then the decremented time integral of the impulse, calculated for the varicosity, will be about 96% of the active spike value. IPSPs in the terminal increase the terminal input conductance by 30% but decrease the spike amplitude by only 5%. The spike half-width is not affected. If an electrically inactive varicosity is subjected to an IPSP the calculated spike time integral will diminish by about 5%. For transmit signals (150 Hz) the length constant ( $\lambda_f$ ) is 0.71 times the d.c. length constant. The IPSP conductance increase diminishes  $\lambda_f$  by about 25%. The effect on the peak spike amplitude will still be small however because the electroting distance to the varicosity is short and the input impedance in electrotonic distance to the varicosity is short and the input impedance in the terminal arbor is greater than that of the principal neurite. We conclude that the passive shunt hypothesis of presynaptic inhibition is probably not sufficient to account for the observed attenuation of EPSPs associated with presynaptic IPSPs.

A COMPARISON OF THE EFFECT OF TEMPERATURE ON CELL R15 PACEMAKER ACTIVITY IN THE <u>IN SITU</u> AND EXCISED ABDOMINAL GANGLION OF <u>APLYSIA</u>. <u>S.N. Treistman and G.M. Bablanian</u>. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545. The bursting pacemaker activity (BPA) seen in cell R15 of <u>Aplysia</u> is endogenous to the cell, and biophysical studies have identified some of the ionic currents which are important to its generation. The BPA recorded from R15 in the excised abdominal ganglion is lost when the cell is cooled below 12°-14°. Since R15 appears to play an important role in osmoregulation, radical changes in the output of this cell as a function of environmental temperature would be expected to have significant effects upon the animal's ability to osmoregulate. The present study was under-taken to determine whether in the intact animal, R15 exhibits the same temperature sensitivity as in the excised ganglion, or whether the effect of temperature upon R15's biophysical properwhether the effect of temperature upon R15's biophysical proper-ties are moderated by either synaptic inputs or factors in the hemolymph. The abdominal ganglion containing cell R15 was exposed by a small incision in the dorsal body wall, prinned to a platform, and impaled. The sides of the incision were pulled above the level of surrounding sea water preventing loss of hemolymph. thermistor placed adjacent to the ganglion recorded hemolymph temperature, while a thermometer recorded changes in sea water temperature, while a thermometer recorded changes in sea water bath temperature. In order to compare the temperature sensitivity of the cell in situ and in vitro, the sea water temperature sur-rounding the intact animal was first lowered, and the strength of BPA was monitored as a function of hemolymph temperature. The ganglion was then removed from the animal, cell R15 was reimpaled, and the temperature was changed to match that previously induced in the intact preparation. In no case did we find an increased resistance to loss of BPA when the intact animal was compared with the isolated ganglion. In fact, when differences between the in situ and in vitro cell were encountered, they showed that suppres-sion of BPA occurred at even warmer temperatures in the in situ cell. These results led us to examine whether the ganglion might be protected from rapid cooling when the animal is exposed to be protected from rapid cooling when the animal is exposed to cooled sea water. Such a mechanism does appear to exist. The hemolymph temperature adjacent to the abdominal ganglion was monihemolymph temperature adjacent to the abdominal ganglion was moni-tored while the sea water surrounding the animal was chilled. Cooling of the hemolymph proceeded along an exponential time course with a time constant of 128.2 minutes. However, when the circulatory system of the animal was disrupted by severing the aorta, reexposure of the animal to the same temperature conditions resulted in a significantly faster (p<0.001) cooling rate with a time constant of 50.0 minutes. Thus, although R15's thermosensi-tivity is present in the whole animal, it is buffered from trans-ient temperature change by a previously undescribed mechanism. ient temperature change by a previously undescribed mechanism.

THE EFFECT OF R15 HYPEKPOLARIZATION ON HEMOLYMPH COMPOSITION IN INTACT <u>APLYSIA</u>. <u>G.M. Bablanian\* and S.N. Treistman</u> (SPON: L. Kennedy). Worcester Foundation for Experimental Biology, 23.4

INIACI APLYSIA. G.M. <u>Bablantan</u><sup>\*</sup> and S.N. Ireistman (SPON: L. Kennedy). Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545. R15, a bursting pacemaker cell in <u>Aplysia</u>, is thought to be a neurosecretory cell concerned with osmoregulation. We have used an intact preparation of <u>Aplysia</u> to correlate the activity in R15 with changes in the ion and metabolite concentration in the hemo-lymph, possibly related to its osmoregulatory role. The abdominal ganglion was exposed through an incision in the dorsal body wall, begins or constant in burst and circulation intact. In previous lymph, possibly related to its osmoregulatory role. The abdominal ganglion was exposed through an incision in the dorsal body wall, keeping synaptic inputs and circulation intact. In previous experiments, we have established that R15 shows bursting pacemaker activity (BPA) in the intact preparation, and that BPA is inhibited by a dilution of the sea water surrounding the animal. For the present studies, R15 was hyperpolarized for 30 min and hemolymph samples were taken at subsequent time points. The samples were analyzed for  $K^+$ , Na $^+$ , ammonia, and amino acid composition. We found that  $K^+$  rose from 11.7  $\pm$  0.5 mM to 13.2  $\pm$  0.3 mM in the 2.5 hours after inhibition of R15. This rise of 12.8  $\pm$  1.7% was statistically significant, and was not found in control experiments in which R15 was impaled but not hyperpolarized or in which other cells were hyperpolarized. Na $^+$  values were added or in the 3 di not produce this rise. Amino acid analysis revealed large changes in the amino acid composition of R15. Not all amino acids were affected. The largest changes were as 36% rise in taurine, a 211% rise in lysine, a 253% rise in glutamic acid, and a 252% rise in histidine. All values are obtained by comparison with controls. These results demonstrate wide-ranging physiological effects from a relatively short period of hyperpolarization in a single neurosecretory cell. secretory cell.

SODIUM PUMP INHIBITION AND DEPOLARIZATION IN HYPOXIC 735 HYPERPOLARIZING L<sub>2</sub>-L<sub>2</sub> NEURONS OF <u>APLYSIA</u>. <u>Philip E. Coyer</u>. Department of Neurology and the Neurosciences Program, University of Alabama in Birmingham, Birmingham, Alabama, 35294.

Members of an identifiable group of pacemaker neurons are known to hyperpolarize in response to hypoxia (Coyer et al., J. exp. Biol. <u>102</u>, 1983). A tenable hypothesis which has been raised concerning this boservation is that low oxygen conditions stimulate the sodium pump through alterations in the (ATP)/(ADP)(Pi) ratio and glycolytic feedback mechanisms. Presumably, continued production of ATP resulting from this mechanism augments the sodium pump and accounts for the in-creases in intracellular potassium ions associated with membrane hyperpolarization. To test this hypothesis, 10 experiments were conducted on hypoxic hyperpolarizing members of the  $L_2-L_2$  neurons of the <u>Aplysia</u> abdominal ganglion. Measurements of membrane potential and intra-cellular potassium ion activities were made under control (normoxic), experimental (hypoxic), and return to control (reoxygenation) conditions to verify that hypoxia and normoxia results in reversible changes for neurons. Subsequently, a pressure micro-ejection pipette filled mM sodium iodoacetate, a glycolytic inhibitor, was inserted into these neurons. these 10 neurons. Membrane potential was also recorded from the ejection pipette to insure that the same neuron was impaled with both variable durations were delivered to the system thus expelling the sodium iodoacetate into these neurons. The sodium salt was chosen since increases in intracellular sodium are known to stimulate the pump and result in membrane hyperpolarization. Providing iodoacetate inhibited glycolytic feedback mechanisms as is known, the response of these neurons to hypoxia should have been just the opposite as that observed for normal cells. The irreversible depolarization of these same 10 cells, which were observed to hyperpolarize during hypoxia under normal conditions (no injection), substantiated that glycolytic feedback mechaconditions (no injection), substantiated that glycolytic feedback mecha-nisms were operative under normal conditions in which there was augmentation of the sodium pump. These mechanisms were inoperative under iodoacetate injected conditions in which the pump was not augmented. The results coupled with those obtained for hypoxic depolarizing neurons of the  $R_3R_{13}$  group suggest that metabolic dif-ferences and the pump dependence of the membrane potential account for the differential selectivities of the nerve cells to hypoxia. Supported in part by NINCDS NS 08802.

AN ANTICALMODULIN DRUG, W-7, INHIBITS THE VOLTAGE-DEPENDENT CALCIUM CURRENT IN <u>PARAMECTUM CAUDATUM</u>. <u>T.M. Hennessey and</u> <u>C. Kung\*</u>. Lab. of Molec. Biol. and Dept. of Genetics, Univ. of Wisc., Madison, Wisc. 53706. W-7, N-(6-aminolesyl)-5-chloro-1-naphthalene sulfonamide, is a potent encipeleredulin drug. The Dr the current part drug 23.6

potent anticalmodulin drug. The  ${\tt ID}_{5\,0}$  , the concentration of drug which inhibits half of the calf-brain calmodulin-dependent phosphodiesterase activity, is 30  $\mu$ M. Its C-5-dechlorinated analog, W-5, is much less effective (ID<sub>50</sub> = 240  $\mu$ M). These drugs are not specific for calmodulin, however (Schatzman <u>et al.</u>, BBA <u>755</u>:144-147. 1983).

The duration of backward swimming of <u>Paramecium caudatum</u> when transferred into a solution with 20 mM K<sup>+</sup> (a behavioral measure-ment of the Ca-channel activity) was reduced from 50 sec to 25 sec by the addition of 20  $\mu$ M  $_{\rm P7}$  or 150  $\mu$ M  $_{\rm P5}$ . Backward swimming was completely blocked by 150  $\mu$ M  $_{\rm P7}$  or 400  $\mu$ M  $_{\rm P5}$  within 1 sec. These effects could also be reversed within 1 sec after washing the cells out of the drugs. These drugs inhibit the voltage-dependent  $Ca^{2+}$  current in a

concentration-dependent and reversible manner. This current is responsible for the Ca-action potentials and the backward swimming of <u>Paramecium</u>. The inward  $Ca^{2+}$  current, induced by step responsible for the Ca-action potentials and the backwird swimming of <u>Paramecium</u>. The inward  $Ca^{2+}$  current, induced by step depolarizations controlled by a voltage clamp, was isolated after blocking the K<sup>+</sup> outward currents with internal Cs<sup>+</sup> and external TEA<sup>1</sup>. The isolated Ca<sup>2+</sup> current was reduced to half by 40 uM of W-7 or 150 µM of W-5. The voltage at which the maximal inward current is seen was also shifted by 10-15 mV less negative by 150  $\mu M$  of W-7. Under the voltage-clamp conditions used (4  ${\rm :M}$  K<sup>+</sup>, 1 mM Ca<sup>2+</sup> bath, 2 M KCl electrodes) none of the other voltagedependent currents (Kung and Saimi, Ann. Rev. Physiol. 44:519-534, 1982) were significantly affected, even at drug concentrations which suppressed over 90% of the Ca<sup>2+</sup> current. The Ca<sup>2+</sup>dependent  $K^+$  current was also decreased by these drugs, presumably due to the lowered internal Ca<sup>2+</sup> concentration expected of the reduced Ca<sup>2+</sup> current.

This system may be used to study the mechanism of action of W-7 excitable membrane and to screen other potential Ca-channel blockers.

CA DIFFUSION MEASURED DIRECTLY IN APLYSIA NERVE CELL BODIES. 23.7 CA DIFFUSION MEASURED DIRECTLY IN AFFISIA NERVE CELL DOFF. D. Tillotson\* and E. Nasi\* (SPON: P. Nasi). Dept. of Physiology, Boston Univ. Sch. Med., Boston, MA 02118. The properties of intracellular Ca<sup>++</sup> regulation allow Ca<sup>++</sup> to

function so effectively in the triggering of a variety of physi-ological mechanisms. In general, the resting internal Ca is held to extremely low levels (<10-7 M) offering the possibility held to extremely low levels (<10<sup>-7</sup> M) offering the possibility of a wide dynamic range for transient changes in internal Ca<sup>++</sup> with cell activation. We have studied the mechanism(s) that handle the Ca<sup>++</sup> transients which occur with membrane Ca<sup>++</sup> channel activation in nerve cell bodies. After Ca<sup>++</sup> crosses the cell membrane it is not freely diffusible. The Ca<sup>++</sup> buffering machinery provides, as a function of its Ca<sup>++</sup> binding, a resist-ance to free diffusion. The extent to which Ca<sup>++</sup> mobility within the cytoplasm is slowed by this resistance is directly related to the strength of the buffer. We have directly measured the diffusion rate of iontonboretically injected Ca<sup>++</sup> related to the strength of the buffer. We have directly measured the diffusion rate of iontophoretically injected Ca<sup>++</sup> using the Ca<sup>++</sup> sensitive dye Arsenazo III. This was accomplished by severely restricting the cytoplasmic region sampled by the AIII light probe system (accepting probe diameter 30u). A standard Ca<sup>++</sup> injection (400na, 100msec) was delivered and the absorbance change produced within a discrete region was measured. The measuring system, and hence the measuring region, was then moved in 10µ steps with respect to the injecting electrode tip and the injection was repeated. With the Ca injector tip positioned near the cell membrane, the diffusion coefficient was measured to be in the range of 40 - 170  $\mu^2/sec$ , which is above the value estimated for squid axon.

LIQUID SCINTILLATION STUDIES OF CALCIUM MOVEMENTS IN MYOEPITHELIAL 23.8 CELLS. J.E. Chaffee\* and M. Anderson. Department of Biological Sciences, Smith College, Northampton, MA 01063.

Sciences, Smith College, Northampton, MA 01003. The myoepithelial cells that make up the proventriculus of the marine polychaete worm <u>Syllis spongiphila</u> generate calcium action potentials which are associated with contractions. Each cell has a central, noncontractile core which contains membrane-bound vesicles of crystalline material; the predominant elements within the vesicles are Ca and P. Experiments using <sup>45</sup>Ca were performed to investigate the uptake of Ca by the whole cells and by the vesicles. Proventriculi were exposed to artificial sea water (ASW) containing a concentration of <sup>45</sup>Ca of about 20 µCi in 200 µL, rinsed 30 m in Ca-free ASW containing 10 mM La, and solubilized in a 10% deoxycholate solution. Samples were counted in a Beckman LS 7500, and protein content was determined by Lowry analysis of separate samples of the solubilized tissue. Proventriculi equili-brated ≥60 m after dissection and then exposed to 45Ca for periods brated 260 m after dissection and then exposed to  $^{42}$ Ca for periods ranging from 5 to 60 m reached a saturation level after 15 m of about 1.7 x 10<sup>-10</sup> mM Ca per µg protein (n=17). Ca uptake of control (exposed to  $^{45}$ Ca for 15 m. n=6) proventriculi was compared to that of proventriculi stimulated pharmacologically by 5 x 10<sup>-4</sup> M carbamylcholine chloride (Carb, n=10) during the 15 m exposure to  $^{45}$ Ca and to that of one proventriculus stimulated electrically to elicit action potentials ( $^{1/m}$ ) during the 15 m exposure to  $^{45}$ Ca. The Ca influx of the Carb-stimulated proventriculi was about double and that of the electrically stimulated proventricul solubilized tissue through millipore filters (0.2 µm pore size). solubilized tissue through millipore filters (0.2  $\mu$ m pore size). Scanning electron micrographs of the filtered material showed spheroids similar in size (0.5 - 1.0  $\mu$ m) to those seen in trans-mission electron micrographs, suggesting that the filtered material consisted of vesicles. Vesicular uptake was variable with Carb stimulation:  $\frac{45}{2}$ Ca in the vesicles of control proventri-culi was 5.7  $\pm$  1.7% that of the whole cells (n=5) while that of Carb-stimulated proventriculi was 11.3  $\pm$  6.7% (n=8). Vesicular uptake of proventriculi stimulated electrically (n=6) did not differ from controls except in one preparation (13.5%) allowed to rest 60 m after stimulation prior to solubilization. This result suggests that time is resulted for the labelled Ca to enter the suggests that time is required for labelled Ca to enter the vesicles. (Supported by NIH Grant NS12196 to M. Anderson).

LOCALIZATION OF A K<sup>+</sup>-DEPENDENT INHIBITORY SYNAPSE IN LEECH CNS 23.9 J. Yang and A.L. Kleinhaus. Dept. Neurology, Yale U. Sch. of Med., New Haven CT. 06510.

In leech segmental ganglia (<u>Macrobdella</u>), stimulation of the neurons sensitive to pressure (P-cells) evoked K<sup>+</sup>-dependent inhibitory synaptic potentials on cells of unknown function (Nut cells) (Kleinhaus & Brand, Comp.Biochem.Physiol. 70A, 1981). Recently, Carnevale and Johnston (J. Neurophysiol. 47, 1982) described a method for characterizing remote synapses by recording at the soma. The method, based on an analysis of a generalized 2-port electrical network is independent of any specific geometrical electrical network is independent of any specific geometrical assumptions and characterizes the synapse by two steady-state coupling coefficients  $K_{12}$  (soma-to-synapse) and  $K_{21}$  (synapse-to-soma). The coefficients are estimated experimentally from 1) post-synaptic potential  $(V_{pSP})$  vs post-synaptic cell membrane po-tential  $(V_m)$  and 2) apparent reversal potential recorded at the soma  $(V_{rev})$  vs -RT/F in {K}. Given  $K_{12}$  and  $K_{21}$ , the normalized electrical distance of the synaptic location can be obtained for properties coupled and the potential reversion solution is a state of the synaptic any specific electrical model of the post-synaptic ell. We have applied this method, in conjunction with the transient analysis of lumped-soma short cable model parameter estimation (Jack & Redman, J.Physiol. 215,1971), to determine the location of P-Nut inhibi-tory synapse. Specific branching patterns and homogeneous membrane were assumed to allow the representation of the Nut cell as a lumped-soma short cable model.

a lumped-soma short cable model. From 29  $V_{rev}$  determinations made at seven K<sup>+</sup> concentrations (2 - 25 mM), a value of K<sub>12</sub>=.80+.06 was obtained. A lower bound of K<sub>21</sub>=.104+.062 was estimated from 4 measurements of  $V_{psp}$ vs  $V_m$  in normal (4mM) K+. The electrotonic response of Nut cells to a brief hyperpolari-zing current injection showed a rapid initial phase (t<30ms) followed by a linear decay phase (40ms<t<70ms) on a log V vs t plot. Log 'tV plot showed an early decay with time constant simi-lar to the detormined free the log V conclusion and better phase lar to that determined from the log V analysis and a later phase with slower decay. These results are consistent with the response of a lumped-soma short cable model with an open-circuit termination. Transient analysis done on 6 Nut cells gave electrical model parameters of (mean+SEM): membrane time constant=80.7+5.8 ms, D.C. cable-to-some conductance ratio=10.8 $\pm$ 5.0, and normalized length of the equivalent cable=.73 $\pm$ .11. Based on these calculations the inhibitory synapse was localized

at 0.52 length constant away from the soma. The relatively large value of  $K_{12}$  and smaller  $K_{21}$  as well as the inconsistency in the synaptic location calculated from these two steady-state coupling coefficients suggest that the synaptic contact occurs on a fine branch of the axonal arborization or on a specialized synaptic spine.

23.10 FINE STRUCTURE OF SYNAPSES AND SYNAPTOSOMES FROM SQUID (LOLIGO PEALII) OPTIC LOBE. G.D. Pappas, N. Haghighat\* and R.S. Cohen Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, 60612.

Cephalopod optic lobes are a well-known source of cholinergic endings (Dowdall and Whittaker, J. <u>Neurochem. 20</u>:921, 1973). In order to utilize this property for subsequent analyses of cholinergic mechanisms of synaptic transmission in the CNS, we cholinergic mechanisms of synaptic transmission in the CNS, we describe the ultrastructure of the entire optic lobe of the squid (Loligo peali) and relate the morphology of synaptosomes derived from the optic lobe to endings in the intact tissue. Previously, Cohen (J. Comp. Neurol. 147:399, 1973) presented a description of the fine structure of the outer nuclear and plaxiform layer (photoreceptor region) of the squid optic lobe; however, we have included, in addition to these regions, a morphological study of all other layers, including the medulla, indicating the different structural features of the synaptic junctions themselves and classifying these terminals into distinct morphological types. In the cortex, both chemical and electrical junctions were found, the former being the main kind, showing two basic forms. The first was an invaginated synapse, appearing only between presynaptic bags and spines which may showing two basic forms. The first was an invaginated synapse, appearing only between presynaptic bags and spines which may originate from the trunks of amacrine cells of the outer granular layer. The width of the postsynaptic thickening was less than that seen in typical mammalian synapses. A clustering of vesicles is seen in the presynaptic process, particularly around the junction, in distinction to those more evenly distributed vesicles seen in the rest of the terminal. The second obvious basic form of junction was that of a typical chemical synapse, found in almost all layers except the upper portion of the first radial layer. Here, too, paramembranous densities were thinner than those found in typical mammalian synapses, even when stained with E-PTA to enhance their contrast. Synapses in the medulla were predominantly of the synapses, even when stained with E-PTA to enhance their contrast. Synapses in the medulla were predominantly of the second type, although a few photorecepter endings extended to this region as well. The different types of terminals observed in the intact squid optic lobe corresponded to the different types of endings recognized in a synaptosome fraction derived from these lobes. Because of its high content of cholinergic endings and distinct synaptic types, the squid optic lobe may provide an interesting and viable model for the purification of cholinergic synaptosomes and synaptosomal plasma membranes for the elucidation of cholinergic mechanisms of transmission in the central nervous system. Supported by NIH grants NS 15889 and NS 16610 and NSF. 23.11 SYNAPTIC ORGANIZATION IN THE CARDIAC GANGLION OF THE AMERICAN LOBSTER. P. M. Morganelli\* and R. G. Sherman. Dept. of Zool., Miami Univ., Oxford, OH 45056. The nerve terminals in the cardiac ganglion of Homarus americanus are situated in regions of neuropil which are invested by glia. Each neuropil region con-tains several terminals representing from one to three different types., Seven different types of nerve ter-minal were distinguishable by transmission electron minal were distinguishable by transmission electron microscopy. Four form chemical synapses (Types 1, 2, 5 and 6) and three represent neuroscoretory neurons (Types 3, 4 and 7). Type 1 is the most frequently ob-served and occurs in both pacemaker and follower cell served and occurs in both pacemaker and follower cell regions. These terminals are packed with spherical, clear-cord vesicles (CCV) of 40-50 nm diameter, with a few dense-cored vesicles (DCV) of 70-130 nm inter-spersed. Type 5 terminals are a special case of Type l which form symmetrical synapses with Type 1 ter-minals. Type 2 terminals occur in the follower cell region and contain flattened CCV (17-27 X 30-160 nm) with a few DCV (100 nm) interspersed. Type 6 ter-minals occur near to pacemaker somata, contain mostly spherical CCV (40-80 nm), but also some DCV (100 nm), and have a granular cytoplasm. Based on vesicle morphology, Types 1, 5 and 6 are presumed to form excitatory synapses, while Type 2 is presumed to be inhibitory. inhibitory.

Inhibitory. The three types of neurosecretory terminals show no release site morphology. Type 3 terminals occur in both follower and pacemaker regions, and contain a large number of both spherical CCV (30-40 nm) and DCV (70-120 nm). Type 4 terminals occur in the pacemaker region and contain primarily DCV, but also some CCV. Type 7 also has been seen only in the pacemaker region, and some of these terminals lie close to pacemaker commata. They possess a placemaker population of somata. They possess a pleomorphic population of CCV (40-90 nm) along with many DCV (100 nm). The axoplasm of Types 4 and 7 is granular.

Axoglial synapses have been observed in a few in-stances, involving nerve terminals that contain mostly spherical CCV (30-40 nm) and a few DCV (100 nm). spherical CCV (30-40 nm) and a rew DCV (100 nm). Electrotonic junctions were seen in the follower cell region. The nerve terminals involved were spherical processes of 4-5 um diameter which were situated in close apposition to one another. In these cases, regions were apparent where fusion of adjacent plasma membranes had taken place.

EXPOSURE AND ISOLATION OF FUNCTIONAL, SYNAPTICALLY CONNECTED NEURONS OF THE MOTOR NERVE NET OF A JELLYFISH. 23.12 P. A. V. Anderson. C. V. Whitney Laboratory and Department of Physiology, University of Florida, St. Augustine, FL 32084. The motor nerve net of the jellyfish <u>Cyanea capillata</u> is a two dimensional network of neurons that innervates the swimming musculature. The neurons are bioolar and are connected by chemical

musculature. The neurons are bipolar and are connected by chemical synapses. The cable properties of the neurons and the arrangement of the synapses are such that a microelectrode in the soma of a cell will record all that occurs in the synaptic terminal. Because the synapses are structurally symmetrical, and apparently functionally so, each terminal alternately serves a pre- and post-synaptic function. Since two synaptically linked cells can be impaled simultaneously, this preparation affords the opportunity for intracellular recordings from pre- and postsynaptic terminals.

The neurons lie between the cell bodies and muscle tails of the myoepithelial cells that form the bulk of the tissue. The myoepithelial cells are connected by septate desmosomes and, consequently, constitute a diffusion barrier and limit access to the neurons. A technique has been developed whereby these epithelial cells can be removed, with minimal damage to the neurons. The neurons remain in place and attach to the underlying, transparent mesoglea. The result is a preparation that very much resembles a nerve tissue culture preparation. Individual neurons retain their normal appearance and form connections with one another. The number of nerve cells remaining in place depends on the severity of the stripping procedure and, by carefully controlling the variables, the result can be an almost intact nerve net, widely separated single cells or synaptically connected, paired cells. In the saline prepared following an analysis of the free ion content of the mesoglea, In the saline the cells retain their normal resting potentials and produce normal action potentials. Furthermore, the synapses continue to function quite action potentials. Furthermore, the synapses continue to function duite normally and in preparation that contain large numbers of neurons activity will spread over wide areas and activate any muscle remaining at the edges of the preparation. By supplementing the saline, these preparations can be maintained in good condition for several days. Under these culture conditions, neurons damaged during isolation produce growth cones and appear to reform connections with other neurons. Because the cells remain in contact with a native extracellular matrix. the mesoglea, the preparation can almost be considered as an <u>in vivo</u> tissue culture preparation. The advantages offered by this preparation to the study of the

synapses are numerous. Most important is the unrestricted access, but because the cells and their synapses remain functional, it may be possible to apply the patch clamp/whole cell voltage clamp technique and quantify the currents involved in synaptic transmission. (Supported by NSF Grant BNS 82-0949)

# TRANSMITTERS IN INVERTEBRATES

24.1 ISOELECTRIC FOCUSING AND IMMUNOBLOT STAINING of DROSOPHILA

ISOELECTRIC FOCUSING AND IMMUNOBLOT STAINING of <u>DROSOPHILA</u> CHOLINE ACETYLTRANSFERASE. P. <u>M. Salvaterra, G. D. Crawford\*</u> and <u>L. Correa\*</u>. Division of <u>Neurosciences</u>, City of Hope Research Institute, Duarte, CA 91010. We have recently shown purified <u>Drosophila melanogaster</u> cho-line acetyltransferase (ChAT, E.C. 2.3.1.6) consists of three major structurally related polypeptides with molecular weights of 67K, 54K and 13K daltons after SDS gel electrophoresis (Slemmon et al., in <u>press</u>). In contrast to this complex poly-peptide composition, gel filtration or sucrose gradient centri-fugation of native enzyme shows only a single symmetrical activity peak at 67 K daltons. From these results, it is likely that the enzyme activity exists in two forms: a single polypep-tide with a molecular weight of 67K daltons and a non-covalent complex of the 54K and 13K dalton polypeptides. Consistent with tide with a molecular weight of 67K daltons and a non-covalent complex of the 54K and 13K dalton polypeptides. Consistent with this structural model is the observation of two enzyme activity forms noted after isoelectric focusing of homogenates or par-tially purified ChAT from wild type (Oregon R or Canton S) on thin layer polyacrylamide gels. Also supporting this structural model is the observation that monoclonal anti-<u>Drosophila</u> ChAT antibodies stain both the 67K and 54K dalton polypeptides in an immunoblotting procedure. These antibodies are directly inhi-biting and probably bind determinants at or near the active site of the enzyme (Crawford, G.D. et al., J. <u>Biol. Chem., 257</u>:3853, 1982). We have also examined the isoelectric focusing pat-terns of two temperature-sensitive presumed structural gene mutants of ChAT described by Greenspan and Hall (J. Comp. terns of two temperature-sensitive presumed structural gene mutants of ChAT described by Greenspan and Hall (J. Comp. Physiol., 137:83, 1980). The Chats<sup>1</sup> mutant has only one pI form coincident with the higher pI form of wild type, while Chats<sup>2</sup> has two pl forms, both slightly different from wild type. Monoclonal anti-ChAT antibodies react with the Ch ts mutant forms to directly inhibit their activity in a manner similar to reaction with the wild type form. This suggests that the determinant(s) are preserved on the mutant forms. Interestingly, immunoblots of partially purified Chats<sup>1</sup> show antibody staining of only one polypeptide at 67K daltons. Supported by NS18858.

Lukowiak\* (SPOY CHOLINERGIC RECEPTORS IN THE APLYSIA GILL. 24.2 CHOLINERGIC RECEPTORS IN INE APLISIA OILL. <u>9. metso.</u>, J.I. Goldberg\*, J.P. Edstrom\* and K. Lukowiak\* (SPON: B. MacVicar). Departments of Chemistry and Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1. Several lines of evidence suggest that acetylcholine (ACh) is a putative neurotransmitter in the Aplysia gill involved in the multium of contractile babayior. Althouch receptor

a putative neurotransmitter in the <u>Aplysia</u> gill involved in the regulation of contractile behavior. Although receptor mechanisms have been characterized in other <u>Aplysia</u> tissues, the cholinergic pharmacology of the <u>Aplysia</u> gill has not been detailed. The perfused gill, isolated from the abdominal ganglion (CNS), exhibits periods of spontaneous phasic movements which are mimicked by infusing the neuropeptide FMRFamide (EC<sub>50</sub>, 0.1  $\mu$ M), dopamine (DA) (EC<sub>50</sub>, 1  $\mu$ M) and membrane-permeable analogues of cyclic AMP through the gill. The effects of ACh and several cholinergic agonists and anatgonists on quiescent, spontaneously-active and pharmacologically-activated wills were examined. At ant gonists on quiescent, spontaneously-active and pharmacologically-activated gills were examined. At concentrations greater than 1  $\mu$ M, ACh rapidly elicited a slowly developing tonic contraction of the afferent vein that reversed immediately upon washout. This effect was observed on both quiescent and active preparations. At concentrations less than I why ACh perfusion resulted in a reduction of gill tone. The excitatory effect of ACh (10  $\mu$ M) was reduced 70% and 60% by the muscarinic antagonists atropine (10  $\mu$ M) and hexamethonium (10  $\mu$ M), respectively. The ACh-evoked contraction was potentiated

2.5-fold when curare (10  $\mu M$ ) was co-infused. Perfusion of carbachol (10  $\mu M$ ) did not mimic the excitatory effects of ACh. In fact, at all concentrations examined (1-100 "M), carbachol influcion reduced baseline tension, the amplitude of spontaneous contractions and those evoked by FNRFamide and DA. Contractile movements elicited by perfusion of p-chlorophenylthio-cyclic ANP were dramatically reduced when carbachol (10 "M) was added to the perfusate. Further addition of curare (10 ).M) reversibly blocked carbachol inhibition of the cyclic AMP-evoked contractions.

These findings suggest that excitatory (muscarinic) and inhibitory (nicotinic) cholinergic receptors are involved in the regulation of gill contractile behavior by ACh.

DOPAMINE REDUCES ARSENAZO III ABSORBANCE CHANGE DURING DEPOLARI-ZATION OF BURSTING NEURON. <u>D. V. Lewis, W. A. Wilson</u>, Lab. of Neurophysiology, Depts. of Pediatrics and Pharmacology, Duke University, Durham, N.C. 27710. The bursting neuron R15 of <u>Aplysia</u> california exhibits a 24.3

The bursting neuron RIS of <u>Aplysia</u> californica exhibits a voltage sensitive calcium conductance. Using the calcium indica-tor, Arsenazo III, increases in cytoplasmic calcium have been observed during voltage clamp depolarizations activating the persistent slow inward current (SIC). Dopamine applied to RIS blocks the bursting, eliminates the negative slope resistance region of the current voltage curve and hyperpolarizes the cell. One explanation for the effect of dopamine would be blockade of the SIC user redisted by calcium and if dopamine the SIC. If the SIC were mediated by calcium and if dopamine blocks the SIC, then dopamine should block voltage dependent calcium influx. We have monitored calcium influx into R15 by calcium influx. We have monitored calcium influx into RI5 by injecting Arsenazo III intracellularly and measuring absorbance changes of the cell using two fiber optic probes to deliver light to and collect light from the cell. When absorbance changes were very small, signal averaging was used to enhance the signal to noise ratio. The absorbance changes were measured only in the soma in early experiments by placing the fiber optics on either side of the exposed soma. Increased Arsenazo III absorbance side of the exposed soma. Increased Arsenazo III absorbance (indicating increased cytoplasmic calcium activity) occurred during the SIC activated by 10 sec voltage clamp steps from -50mV to between -35 and -25mV. Bath applied dopamine, which clearly eliminated negative slope resistance, did not reduce the Arsenazo absorbance changes. In another series of experiments, the fiber optics were placed immediately below the soma, transilluminating the pedicle of neuropil containing the proximal axon of R15. The axon can be seen to fill with dye when the soma is injected with Arsenazo III. Absorbance increases can be detected in the axon during the small depolarizations presumably due to calcium influx into the axon. Dopamine reduces these absorbance rises in into the axon. Dopamine reduces these absorbance rises in contrast to its lack of effect on somatic calcium influx. To demonstrate that voltage control of the axon was not altered by demonstrate that voltage control of the axon was not altered by dopamine application, a second microelectrode was used to monitor voltage changes in the axon. We hypothesize that dopamine reduces voltage sensitive calcium influx into the proximal axon and that this effect may contribute to the loss of negative slope resis-tance seen with dopamine. An effect of dopamine on axonal but not somatic calcium conductance is consistent with local iontophoretic application of dopamine being effective on the axon but not on the soma (Ascher, P., J. Physiol. 255:173, 1972).

DOPAMINE AND SEROTONIN IN LIMAX FEEDING: DISTRIBUTION AND META-BOLISM. S. J. Wieland, H. Zaininger\*, E. G. Jahn\*, and A. Gelperin. Department of Biology, Princeton University, Prince-ton, New Jersey 08544 and Bell Laboratories, Murray Hill, New 24.4 Jersey 07974.

Both dopamine and serotonin produce profound effects on neural elements of the feeding control system in <u>Limax maximus</u>. To characterize the roles of neurons which contain these monoamines, we mapped the location and projection of aminergic neurons in the cerebral and buccal ganglia, endogenous levels of precursors, the

amines, and their possible metabolites. Histochemistry for catecholamines and serotonin revealed fluorescent amine products in all three lip nerves of the cerebral ganglion and the cerebral-buccal connective. Simultaneous retrograde labeling with the red fluorescent dye propidium iodide showed lip-projecting dopaminergic neurons clustered next to nonamine containing neurons projecting out the same nerve. The buc-cal ganglia contained several small amine fluorescing neurons and the buccal roots all contained several fluorescent fibers.

Quantitation by MPLC-EC of endogenous dopamine and serotonin showed 2.4 ( $\pm$  1.09 SEM, n=6) pmols dopamine and 2.18 ( $\pm$  0.23 SEM, n=6) pmols serotonin in the pair of cerebral buccal connectives, compared to 133 ( $\pm$  3.6 SEM, n=29) pmol dopamine and 91 ( $\pm$  3.2 SEM, n=29) pmol serotonin in the cerebral and 32 ( $\pm$  5.8 SEM, n=9) SEM, n=29) pmol serotonin in the cerebral and 32 ( $\pm$  5.8 5km, n=9) pmol dopamine and 14 ( $\pm$  2.5 SEM, n=9) pmol serotonin in the buc-cal ganglia. The subesophageal ganglia contain 303 ( $\pm$  13.1 SEM, n=19) pmol dopamine and 191 ( $\pm$  9.9 SEM, n=19) pmol serotonin. Accumulation of 3H-dopamine and 3H-serotonin during incubation with 3H-tyrosine and 3H-tryptophan indicates both monoamines were With 3H-tyrosine and 4-tryptophan indicates both monoamines were actively synthesized from their respective amino actids. Incubation with  $\alpha$ -methyl-p-tyrosine selectively blocked <sup>3</sup>H-dopamine accumulation without interfering with <sup>3</sup>H-serotonin accumulation, and conversely, p-Cl-phenylalamine selectively blocked <sup>3</sup>H-serotonin synthesis. These results suggest dopamine and serotonin are synthesized through the same pathways as in the vertebrates. While a-methyl-p-tyrosine blocked <sup>3</sup>H-dopamine accumulation over a 24 hour period, total endogenous levels of dopamine did not decline over the same period in the presence of this blocker, even with the addition of benztropine, which blocks dopamine re-uptake in the vertebrate CNS. This suggests that either re-uptake by <u>Limax</u> is not blocked by benztropine, or that multiple pools of dopamine may exist with very different turnover rates.

Results of neurophysiological experiments testing the effects of dopamine synthesis and re-uptake blockers on the neural control system for feeding will also be discussed. Supported in part by NSF Grant BNS 8005822.

STUDIES OF CATECHOLAMINE NEURONS IN <u>APLYSIA</u>: LIGHT AND ELECTRON MICROSCOPY. <u>Ronald S. Goldstein<sup>\*</sup></u>, (SPON: M. Klein) Center for Neurobiology & Behavior, College of Physicians & Surgeons of Columbia University and The New York State Psychiatric Institute, New York, N.Y. 10032. The cell biology and ultrastructure of serotonergic, cholinergic, histaminergic and peptidergic neurons have been studied in <u>Aplysia</u>. Formaldehyde and glyoxylic acid-induced fluorescence have shown that catecholamine neurons exist in <u>Aplysia</u>, but their small size and apparent rarity have prevented their identification for further study. The FaGlu catecholamine histofluorescence method of Furness

The FaGlu catecholamine histofluorescence method of Furness and colleagues (Histochemistry 57:285) was modified for use in Aplysia tissue. Wholemounts and sections of juvenile and adult and peripheral tissues were examined. ed cerebral ganglia, 70-80 positive In serially ganglia and peripheral tissues were examined. In serially sectioned cerebral ganglia, 70-80 positive neurons were observed, many in clusters of 10-20 cells. This is 10 times as many cells as were found using glyoxylic acid, because of improved preservation of structure with the FaGlu method. It should now be easy to find these clusters in live ganglia and, in conjunction with intracellular marking, this technique should facilitate the future identification of catecholamine neurons in <u>Aplysia</u>. Catecholaminergic processes were densely packed in localized

portions of the neuropil of all central ganglia. Many of the axons were smooth, some were seen to bear fine varicosities. axons were smooth, some were seen to bear fine varicosities. In contrast, serotonin has been shown by immunocytochemical studies in this laboratory (<u>Neuroscience</u>, in press) to be both widespread throughout the neuropil and to form an extensive plexus of fibers and varicosities in the cell body layer of the ganglia.

technique, which produces wa ed ultrastructural The FaGlu water-insoluble allowed fluorophores. also studv of catecholaminergic neurons in <u>Aplysia</u>. In the electron microscope, catecholaminergic neurons were seen to contain large numbers of 70-80 nm dense cored vesicles, in contrast to The vesticles found in sectonergic neurons receiving the same treatment. Since the FaGlu technique can be combined with radioautography, studies of the specificity of transmitter metabolism and association of transmitter with subcellular organelles that have been performed on serotonergic and histaminergic neurons in <u>Aplysia</u> can now be extended to catecholaminergic neurons as well catecholaminergic neurons as well.

SEROIONIN-, PROCTOLIN-, AND BOMBESIN-LIKE IMMUNOREACTIVITY: 24.6 Dept. Neurobiol., Harvard Med. School, and Dept. Zoology, U. of Wyse, Massachusetts, Amherst, MA 01003.

Neurons immunoreactive to serotonin and to the peptides proc-Neurons initialized by the localized by fluorescence microscopy of 20  $\mu$  cryostat-sectioned Limulus tissues. Methods followed Beltz and Kravitz (J. Neurosci. 3:585-602, 1983). Serotonin-like immunoreactivity (SLI) occurs in a consistent pattern in the CNS. In the brain, somata with SLI are associated with the central body and with the patternel body In the brain, somata with SLI are associated with the central body and with protocerebral neuropil (Chamberlain et al., Neurosci. Abstr., this volume). Clusters of somata with SLI are associated with each of the fused prosonal ganglia forming the circumesopha-geal ring: five pairs of pedal (thoracic) ganglia and paired chilarial and opercular ganglia. Serotonin-immunoreactive fibers ennesh the neuropil of each of these regions and of the optic medulla and optic lamina. Serotonin immunoreactive cells and fibers place optic in each of the obtained (circumesopha-geal ring) and optic lamina. fibers also occur in each of the abdominal (opisthosomal) ganglia. Peripheral nerves, heart, cardiac ganglion, and gut appear to lack SLL

Proctolin. Somata exhibiting proctolin-like immunoreactivity (PLI) occur in the central body of the brain, in chilarial and opercular ganglia at the posterior end of the prosomal circumesophageal ring, and in abdominal ganglia. Fibers with PLI ramify sparsely within neuropil of protocerebral, pedal, chilarial, and abdominal ganglia. The corpora pedunculata and optic lobes appear to lack PLI. Peripherally, fibers with PLI occur in the cardiac ganglion and in muscle layers of the gut,

areas in wich proctolin enhances muscle contraction. Bonbesin. Bonbesin-like immunoreactivity (BLI) appears con-fined to a few (2-4) neurons with somata in the central body of the brain. Fibers with BLI are rare within the CNS itself, but an extensive meshwork of processes with BLI surrounds the circumesophageal ring of fused prosonal ganglia. These processes appear to end in hemolymph space under the sheath. No BLI

appears to end in neurorympin space under the sheath. No BLI appears in abdominal ganglia, heart, cardiac ganglion, or gut. These results demonstrate that specific Limulus neurons have serotonin-like, proctolin-like, and bombesin-like immunoreacti-vitias. The anatomical distribution of distributions of distrib vities. The anatomical distributions of these neurons suggest that serotonin and proctolin (or a proctolin-like peptide) act as transmitters or local modulators in the nervous system; that proctolin may act locally at the heart and gut; and that bombesin (or a bombesin-like peptide) is released into hemolymph from superficial endings and acts as a neurohormone. Supported by NIH grants to E.A. Kravitz.

24.7 LOCALIZATION OF SEROTONIN-LIKE IMMUNOREACTIVITY IN THE LIMULUS PROTOCEREBRUM. S. C. Chamberlain, B.-A. Battelle and G. A. <u>Wyse</u>. Syracuse Univ., Syracuse, NY 13210; NEI, NIH Bldg. 6, Rm 224, Bethesda, MD 20205; and Univ. Mass., Amherst, MA 01003. Neurons with serotonin-like immunoreactivity (SLI) were localized using a primary serum anti-serotonin-bovine serum albumin conjugate antibody from rabbit, a fluoroscein-conjugated antirabbit IgG secondary antibody, and fluorescence microscopy. Both cryostat and vibratome sections of 4% paraformaldehyde fixed tissue were used. Preabsorption of the primary antibody with 500 µg/ml synthetic serotonin creatinine sulfate did not completely block staining, however, remmant staining was rare, and in repeated control experiments formed an apparently random

and in repeated control experiments formed an apparently random subgroup of the stained population. The neuropils of the visual lamina, medulla, and ocellar ganglion all contain small-diameter beaded fibers with SLI; however no immunoreactive somata were observed in the adjacent

however no immunoreactive somata were observed in the adjacent ganglion cell layers. The neuropil of the central body contains a sparse network of fibers with SLI which arise from a band of large-diameter fibers along its medial edge. The somata of these neurons lie within the curve of the central body. The central neuropil of the protocerebrum is richly invested with fibers with SLI, some of which arise from somata in the protocerebrum and some of which may come from other parts of the circumesophageal ring. No fibers with SLI were observed in any of the optic nerves.

Somata with SLI are found in four distinct places in the protocerebrum: i) Within the curve of the central body (20-50 somata); ii) A small lateral cluster of cells between the corpora pedunculata and the central neuropil (4-9 somata); iii) A posterior midline ganglion (7-12 somata); and iv) a small ventral cluster of cells within the corpora pedunculata (3-4 somata). This last group of neurons gives rise to a small number of beaded fibers which innervate a glial strand in the center of the ipsilateral corpora hemisphere. Supported in part by NEI grants. 24.8 EVIDENCE FOR PROCTOLIN-LIKE SUBSTANCES IN THE CENTRAL NERVOUS SYSTEM OF THE LEECH. <u>C. Li\* and R. L. Calabrese</u>. The Biological Laboratories, Harvard University, Cambridge, MA 02138. The neuropeptide proctolin has been described in many arthropods. With immunohistochemistry on whole mount preparations, we have found cells with proctolin-like immunoreactivity (PLI) in the ganglia of the leech (<u>Hirudo medicinalis</u>). Three different anti-proctolin antisera were used; a similar staining pattern was seen with all of the antisera. Two to four bilaterally symmetric pairs of cells with PLI appeared in the anterior packets of segmental ganglia 1-20; an unpaired medially located cell with PLI appeared only in ganglia 5-7. Two fixatives (4% paraformaldehyde and Bouin's fixative) and two antibody labelling techniques (indirect immunofluorescence and peroxidase-antiperoxidase procedure of Sternberger) were tried; the same results were always obtained. Staining could be eliminated by addition of synthetic proctolin to antisera. This work provides strong evidence that proctolin or proctolin-like substances exist in these cells.

Homogenates of leech ganglia showed proctolin-like activity as measured by the bioassay of 0'Shea and Adams (Science 213: 567, 1981). In this assay, proctolin causes an increase in the frequency of myogenic contractions of the locust leg extensor muscle. We estimate by this method that there are approximately 0.27 femtomoles of proctolin or proctolin-like substances per midbody ganglion. These assay results corroborate our work with the antisera and further indicate the presence of proctolin or proctolin-like substances in these cells. Physiological experiments are planned to study the possible function of these cells.

We wish to thank the Taghert/Goodman, Schwartz/Siwicki/ Kravitz, and Bishop/O'Shea groups for generously donating their anti-proctolin antisera. The bioassays were kindly done by O'Shea and colleagues.

Supported by NSF grant BNS-8121551.

24.9 SEROTONIN AND OCTOPAMINE AFFECT WALKING AND OPTOKINETIC RESPONSES IN CRAYFISH. <u>Stacey J. Arnessen® and Richard F. Olivo</u>. Dept. Biological Sci., Smith College, Northampton MA 01063. Recent work shows that serotonin and octopamine modulate the

Recent work shows that service, and the optimized and the crayfish's posture and escape response, and that octopamine modulate the crayfish's swimmeret beating. We investigated the effects of these amines on two responses that are normally enhanced by spontaneous arousal: locomotion and the optokinetic response.

Crayfish were suspended above a floating foam rubber ball on which they could walk freely, and were surrounded by a striped drum that oscillated sinusoidally to elicit continuous eye movements. Leg and claw movements were detected by a video camera and column-scan digitizer (Olivo & Thompson 1982, Soc. Neurosci. Abstr. <u>§</u>: 735); eye movements were measured by a wire wand and capacitative transducer. Each experiment began with a control period of about 1 hour, during which spontaneous periods of active walking and enhanced eye movements alternated with quiescent periods. We then injected 1 mg (or occasionally more) of one of the amines into the pericardial sinus, and recorded its effects and the subsequent recovery during the next 5 to 6 hours. Records on FM tape were processed by computer to yield walking activity and the peak-to-peak amplitude of eye movements (relative optokinetic gain).

Injection of serotonin (at the arrows in the figure) invariably suppressed spontaneous walking and eliminated the optokinetic response. Recovery began after several hours.

24.10 THE SEROTONERGIC INNERVATION AND MODULATION OF THE STOMATOGASTRIC GANGLION OF DECAPOD CRUSTACEANS. B.S. Beltz, E. Marder, S. Hooper\*, J.S. Eisen, R. Flamm\*, and R. Harris-Warrick. Neurobiol., Harvard Med. Sch., Boston, MA 02115; Biol., Brandeis Univ., Waitham, MA 02254; and Neurobiol and Behavior, Cornell Univ., Ithaca, NY 14853.

Univ., Waltham, MA 02254; and Neurobiol and Behavior, Cornell Univ., Waltham, MA 02254; and Neurobiol and Behavior, Cornell Univ., Ithaca, NY 14853. Serotonin serves as a neurotransmitter and neuromodulator in invertebrate and vertebrate nervous systems. The stomatogastric ganglion (STG) of decapod crustaceans is a well-studied central pattern generator that could provide a model system for examining the effects of amines on neuronal circuits. Therefore, we analyzed the distribution and physiological effects of serotonin in the stomatogastric system of three species of decapod crustaceans (Cancer irroratus, Homarus americanus, and Panulirus interruptus). Serotonin-like immunoreactivity was mapped in whole mounts of the complete stomatogastric system using the method of Beltz & Kravitz (J Neuroscience 3: 585-602, 1983). Staining was seen in the neuropile of the commissural ganglia of all three species. Furthermore, in Cancer and Homarus, but not in Panulirus, serotonin-like immunoreactivity was found (1) in fiber tracts connecting the commissural ganglia and the stomatogastric ganglion, (2) in a densely staining neuropile within the stomatogastric ganglion, and (3) in fibers in the motor nerves lasio contain several brightly staining bipolar neurons. Endogenous serotonin levels in extracts of STG from all three species were measured by High Performance Liquid Chromatography (HPLC). Serotonin levels (fmoles) were as follows: Cancer, 350+230 (n=7); Homarus 811-310 (n=5); Panulirus, not detectable (< 5) (n=4). Concentrations of serotonin than comparable regions in Cancer and Homarus. However, bath application of serotonin (10<sup>-5</sup>M to 10<sup>-4</sup>M) produced alterations of motor output in isolated STG of all three species. Dramatic increases in the number of lateral pyloric (LP) action potentials/burst were usually seen and the cycle frequency was usually reduced. In <u>Cancer</u>, and occasionally in the other species. Fortonin (10<sup>-5</sup>M to 10<sup>-4</sup>M) produced alterations of motor output in solated STG of all three species. Can

ORCHESTRATING BEHAVIORS: A CENTRAL MODULATORY ROLE OF OCTOPAMINE 24.11 THE LOCUST. Sompong Sombati\*. {SPON: G. Streisinger}, Inst. of Neuroscience, University of Oregon, Eugene, OR 97403 The locust metathoracic ganglion contains a cluster of

about 30 dorsal unpaired (DUM) neurons. Some are confined to the CNS, of unknown functions, others have axons terminating near skele-tal muscles. These neurons tend to fire intensely, when the animal is disturbed. They synthesize and release octopamine (OA) which blocks intrinsic rhythmicity and potentiates neuromuscular transmission. All have central branches, some of which may exert effects on central synapses. Possible central actions were test-ed by iontophoresis of OA into discrete regions of neuropil known to be associated with various behaviors. The fast extensor tibiae (FETi) motorneuron (MN) makes cen-

tral excitatory connections with many flexors tibiae MN's. This is necessary for co-contraction of antagonistic muscles prior to is necessary for co-contraction of antagonistic muscles prior to a locust jump. Intracellular recordings were made from identi-fied flexor MN's, while simultaneously antidromically stimulating FETi and iontophoresing OA on flexor neuropil. This potentiated the central transmission from FETi to flexor MN's by potentiated the central transmission from FETi to flexor NN's by up to 100%. FETi spikes then, elicited spikes in flexor NN's, creating "fictive" co-contraction phase. OA effect outlasted the cessation of iontophoresis by about 1 min. Some DUM neurons showed similar effects on these pathways when intracellularly stimulated.

defined locations. OA iontophoresis In 3 generated long-lasting bouts of rhythmic motor activity. One site caused long-lasting bouts of rhythmic motor activity. One site caused flexing/extending of the tibia at about 1 Hz, resembling that seen in walking or running. At another, flight rhythm of the flight muscles on both sides was evoked with a frequency of about 10 Hz. This lasted up to 25 min. The activity duration was dose-dependent. Simultaneously, the respiratory rate was also increased. At a different location, OA could increase the respiratory rate, independent of flight activity.

The experiments were repeated on the last abdominal ganglion of the female locust, known to contain the central pattern generator for oviposition digging (Thompson, <u>Soc. Neurosci.</u> <u>Abstr.</u> Vol.8, 1982). The activity is inhibited by higher centers and can be released by severing the connectives, stimulation of which can re-inhibit the activity. OA iontophoresis into a spec-ific neuropil region during oviposition, inhibited the behavior as did stimulation of the severed connectives. These observed effects of OA are consistent with the idea

OA may be released centrally when the animal is disturbed. This may orchestrate the appropriate expression of behaviors for an escape, in this case, by enhancing running, jumping or flying while suppresing conflicting behaviors such as oviposition. (Supported by NSF Research Grant BNS 82-41884 to Dr. G. Hoyle)

CALCIUM/PHOSPHOLIPID-DEPENDENT PROTEIN PHOSPHORYLATION IN APLYSIA 24.13 NEURONS. <u>S.A. DeRiemer, L.K. Kaczmarek, K.A. Albert, and</u> <u>P. Greengard</u>. Dept. of Pharmacology, Yale Univ. Sch. Med., <u>P. Greengard.</u> Dept. of Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510. Electrical stimulation of the bag cell neurons of <u>Aplysia</u>

generates a long-lasting afterdischarge triggered by a rise intracellular cAMP and associated with changes in the phosphorylation state of at least two proteins (BCI and BCII). Evidence indicates that calcium entry, as well as cAMP levels, may regulate bag cell electrical activity and protein phosphorylation. We have previously shown that a calcium-calmodulin dependent protein kinase very similar to one found in the mammalian brain exists in the Aplysia nervous system. second class of calcium-dependent protein kinase regulated by phospholipids (Ca/PS-PK, C kinase) has also been found in both phospholipids (Ca/PS-PK, C kinase) has also been found in both vertebrate and invertebrate nervous systems (Kuo et al., PNAS 77:7039, 1980). We have now determined that an enzyme of this type exists in the <u>Aplysia</u> nervous system. Protein phosphorylation was examined in cell free preparations of the <u>Aplysia</u> nervous system using SDS-PAGE. Homogenates were also fractionated by centrifugation at 100,000xg to yield particulate and cytosolic fractions. Addition of phosphatidyl serine (50 mg/ml) and 1,3 diolein (5 mg/ml) to cytosolic fractions in the presence of calcium caused an increase in phosphate incorporation presence of calcium caused an increase in phosphate incorporation into protein bands with M\_'s of 87K, 72K, 59K, 48K, 38K. These proteins were not phosphorylated upon addition of calcium plus calmodulin. In particulate fractions additions of Ca-PS plus diolein had little or no effect beyond that of calcium alone, presumably due to the presence of endogenous lipids. In addition to observing endogenous substrates for Ca/PS-PK, we found that to observing enougenous substrates for Ca/FS-FK, we found that <u>Aplysia</u> nervous system homogenates could phosphorylate an  $M_F$  87K protein purified from mammalian brain. This protein appears to be a specific substrate for Ca/PS-PK. An increased phosphorylation of this protein was observed in crude homogenates and in particulate and cytosolic fractions in the presence of calcium PS and diole in excepting that Ca/PS-PK is present in calcium, PS and diolein suggesting that Ca/PS-PK is present in membranes and in cytosol.

Calcium entry into <u>Aplysia</u> neurons may therefore activate at least two distinct phosphorylating enzymes,  $Ca/CaM \ PK$  and Ca/PS-PK, with differing substrate specificities. We are now determining whether protein substrates for Ca/PS-PK change their phosphorylation state during or after a bag cell afterdischarge.

24.12 HISTAMINE UPTAKE IN THE OPTIC LOBE OF THE LOCUST: AUTORADIOGRAPHIC STUDIES. <u>Michael S. Elias</u> and Peter D. <u>Evans.</u> ARC Unit of Insect Neurophysiology and Pharmacology, <u>Dept.</u> of Zoology, University of Cambridge, Downing Street,

Evans. ARC Unit of Insect Neurophysiology and Pharmacology, Dept. of Zoology, University of Cambridge, Downing Street, Cambridge, CB2 3EJ. U.K. The retina and optic lobe of the locust, (<u>Schistocerca</u> <u>americana gregaria</u>), contain very high levels of endogenous histamine, as well as the enzymes necessary for the biosynthesis and metabolism of histamine (Elias, M.S. and Evans, P.D., J. Neurochem, 1983, in press). The presence of a histamine uptake system, of potential use in the inactivation of histamine, was therefore investigated. Locust optic lobes and retinge were incubated in

Locust optic lobes and retinae were incubated in physiological saline containing (2,5-H)-histamine  $(21.5 \ \mu\text{M}, 4.64 \ Cl/mmol)$  for two hours at 21° C. At the end of the incubation >90% of the radioactivity in the tissue was present incubation >90% of the radioactivity in the tissue was present as histamine. Tissues were then processed for conventional light microscope autoradiography and covered with Kodak AR-10 stripping film. Dense accumulations of silver grains were seen in several regions of the optic lobe. Grains were most highly concentrated along the medial border of the medulla neuropil and around the entire periphery of the lobula. Small aggregations of grains were occasionally seen immediately medial to the basement membrane situated between the retina and lamina. No significant accumulations of grains were present within the retina or the neuropil zones of the were present within the retina or the neuropil zones of the lamina, medulla or lobula.

Along the medial border of the medulla histamine appeared to be taken up into cell bodies, though it was unclear whether the cells were glia or neurons. To resolve this question further autoradiographic experiments were carried out at the electron microscope level (method of Salpeter, M.M. and Bachmann, L. J. Cell Biol. 22: 469, 1964). E.M. auto-Bachmann, L. J. Cell Biol. 22: 409, 1964). E.R. auto-radiographs showed histamine-accumulating cells along the medulla border to exhibit characteristics of electron density and morphology typical of glial cells. Labelled histamine was present within both glial cell bodies and their processes. In the region surrounding the neuropil of the lobula histamine was concentrated within fine glial processes wrapped around neuronal cell bodies and their axons. No neurons or axons showed any accumulation of silver grains above background.

These results are in concordance with previous studies showing the active glial uptake of amino acid and biogenic amine putative neurotransmitters. They suggest that glial cells may play a role in the inactivation of histamine released as a neurotransmitter or neuromodulator in the optic lobe of insects.

FUNCTIONAL MORPHOLOGY OF THE ATRIAL GLAND AND THE LARGE FERMAPHRODITIC DUCT OF APLYSIA CALFORNICA. S. D. Painter, R. A. Zuckerman\*, G. T. Nagle and J. E. Blankenship. Marine Biomedical Institute, Univ. Tx. Med. Br., Galveston, TX 77550. The atrial gland (AG) is located in the distal end of the large

hermaphroditic duct (LHD) of the reproductive tract of A cell discharge and egg-laying activity, and it has been suggested that these peptides are released into the blood during copulation to ensure that the animal will subsequently lay eggs. Yet the AG appears to be an exocrine gland, secreting into the lumen of the LHD rather than into the hemocoel. Its secretions have, therefore, also been ascribed a prostatic, lubricating or pheromonal function.

To gain insight into the possible functional roles of the AG we have examined the structure of the LHD in serial thick and thin sections during various phases of reproductive activity. The duct is complex, composed of two functionally separate compart ments which can be easily distinguished: the red hemiduct (RHD) and the white hemiduct (WHD). They form two separate, though closely apposed, ducts near the base of the accessory genital mass (ACM). They fuse, about 1 cm from the ACM, to form a single duct bisected by a tissue septum. This septum becomes a series of typhlosoles in the distal duct which keep the compartments functionally, if not physically, separate. The AG arises as a small group of cells adjacent to the RHD on a minor typhlosole The gland rapidly enlarges and assumes a more peripheral position; the RHD coordinately regresses and assumes a more central position. Large vesicles (d =  $1-2\mu$ ) in the AG columnar epithelial cells stain immunocytochemically with monoclonal antibodies directed against biologically active AG peptides.

The egg cordon passes through the RHD and in close proximity to the AG; it is not associated with the WHD. In contrast, the penis and sperm (both homotypic and heterotypic) pass through the WHD and are never in direct contact with either the RHD or the AG. Occasionally, stray sperm and unpackaged eggs are also observed in the WHD, presumably in transit to the gametolytic gland for destruction. These observations suggest that the AG is unlikely to be involved in male copulatory functions. Since it contains peptides that can induce egg release and is intimately associated with the oviduct, it is more likely that the atrial gland is involved in the female function of egg laying. - 24.15 HIGH-PRESSURE LIQUID CHROMATOGRAPHY ANALYSES OF GANGLIA EXTRACTS FROM INSECT AND SNALLS. M.K. Leung\*, G.B. Stefano, P. Assanah\* and W. Burrowes\*. (Spon: E. Catapane) Depts. Chemistry and Biological Sciences, SUNY/College at Old Westbury, New York 11568 Previous studies have demonstrated the presence of mammalian-like opioid mechanisms in various invertebrate nervous systems. Recently, Met-and Leu-enkephalin and the heptapeptide Met-enkephalin precursor in ganglia extract of M. edulis have been isolated by high-pressure liquid chromatography (HPLC) and identified by amino acid sequence determination. Similar HPLC analyses were used in the study of ganglia extracts of insect (Leucophaea maderae) and snail (Helix aspersa). Ganglia from these organisms were extracted separately in the cold with 0.5M acetic acid in the presence of phenylmethylsulfonyl fluoride and pepstation A. High molecular weight pro ains and lipids were removed from the extracts by trichloroacetic acid precipitation and ether extraction respectively. The extracts were lyophilized and redissolved in 10 mM acetate fuffer pH4·0. They were then subjected to HPLC analyses on a Brownlee RP-300 reverse-phase column (4·6 X 250 mm) using the acetate buffer with a 2-propanol linear gradient of 5-25% in 15 min. The results showed the presence of peptide with the same Rt as authentic Met-enkephalin in extracts of both organisms. The level of this peptide in the insect extract is about 2X higher than that in the snail. This is in direct correlation with earlier studies demonstrating higher Met-enkephalin binding in L. maderae ganglia than in snail. Identification of this peptide is now in progress. The results also showed that little or no peptide with Rt similar to Leu-eukephalin was detected in either ganglia extract. Supported by NIH-MBRS Grant RR 08180
- 24.16 THE DISTRIBUTION AND ACTIONS OF A FMRFamide-LIKE PEPTIDE. <u>H. K. Lehman<sup>\*</sup></u> (SPON: M. J. Greenberg). C. V. Whitney Marine Laboratory, Rt. 1, Box 121, St. Augustine, FL 32084.

FMRFamide-like peptides occur in the tissues of the snail, <u>Helix</u> <u>aspersa</u>. They have been characterized by HPLC, radioimmunoassay and bioassay. In addition, the major peptide has been characterized by its amino acid composition. The physiological role for no FMRFamide peptide is known. Therefore, I have been examining the tissue distribution of the major FMRFamide homolog in <u>Helix</u> as an approach to possible sites of release and action.

Twenty-three tissues in <u>Helix aspersa</u> were extracted and purified by HPLC, and the concentration of FMRFamide-like peptide was estimated with sensitive (0.1 pmole) radioimmuno- and bioassays. These tissues were also examined by immunocytochemical methods. The immunoreactive FMRFamide-like peptide has a wide but uneven distribution throughout the digestive, reproductive, circulatory, secretory and nervous systems. Tissues with greater than 20 nmoles of immunoreactivity per gram wet weight include the penis-vas deferens complex, the subesophageal and cerebral ganglia, the collar, and the tentacles. Nerves and nerve varicosities are enriched in these tissues, particularly in the muscle layers; cell bodies were only found in the ganglia. Tissues with lesser amounts of immunoreactive FMRFamide (2-15 nmoles) include the digestive tract, salivary glands, ventricle and auricle, and portions of the female reproductive tract. Nerve fibers are only sparsely distributed in all of these tissues; cell bodies were observed in regions of the digestive tract. The notion that activity should be correlated with distribution was

The notion that activity should be correlated with distribution was tested by examining the effects of purified extracts, FMRFamide, and FMRFamide analogs on the contractility and rhythmicity of those muscular organs in <u>Helix</u> which had been shown to contain immunoreactive FMRFamide. A correlation seems to occur: the richly innervated penis is about ten times more sensitive to these peptides than is the less innervated crop; and the radula retractor muscle, which seems to contain no FMRFamideric like pontide like non-tracting is a purposed.

I suggest that the <u>Helix</u> FMRFamide-like peptide is a neuromuscular effector; but further experiments are needed to determine if it is primarily a transmitter or modulator.

24.17 L-GLUTAMIC ACID, A POSSIBLE NEUROTRANSMITTER TO THE <u>APLYSIA</u> ANTERIOR AORTA. M. Sawada,\* D. Gibson and D. McAdoo. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX. 77550.

L-Glutamic acid is a strong candidate to be an excitatory neurotransmitter in the vertebrate central nervous system and at the arthropod neuromuscular junction. Observations that arteries of the marine gastropod <u>Aplysia</u> are very sensitive to L-glutamate led us to systematically characterize the effects of L-glutamate on muscle fibers in the <u>Aplysia</u> anterior aorta. Iontophoretically applied L-glutamate caused depolarizations at only 14% of the sites penetrated, indicating that there are highly localized regions of sensitivity to L-glutamate on muscle fibers in the <u>Aplysia</u> artery. Muscle fibers were insensitive to iontophoretically applied D-glutamate. Responses to iontophoretically applied glutamate desensitized very rapidly. The L-glutamate antagonist, 2-amino-4-phosphonobutyric acid antagonized the responses to iontophoretically applied L-glutamate and EJPs in the anterior aorta. Iontophoretically applied L-glutamate caused strong conductance increases at the sensitive spots on the muscle fibers. Bath applied L-glutamate also depolarized anterior aorta muscle fibers. However, this response did not desensitize, was not blocked by 2-amino-4-phosphonobutyric acid, and was not accompanied by a significant change in membrane conductance. Thus bath applied and iontophoretically applied L-glutamate appear to act on the muscle fibers by different mechanisms. The observations reported here make L-glutamate a strong candidate to be an excitatory neurotransmitter to mollsucan circulatory muscle. Supported by DHEW NS 13311 and NS 11255. 24.18 BEHAVIORAL AND ELECTROPHYSIOLOGICAL RESPONSES TO 5'-AMP INDICATE CRUSTACEANS HAVE EXTERNAL CHEMORECEPTORS RELATED TO INTERNAL PURINERGIC RECEPTORS OF VERTEBRATES. W.E.S. Carr\*, C. D. Derby, P. L. Linser\*, R. A. Gleeson\* and B. W. Ache\* (SPON: L. A. Wilkens). C. V. Whitney Laboratory of University of Florida, St. Augustine, FL 32084

In vertebrate animals, adenosine and its non-cyclic nucleotides are known to function as transmitters and/or modulators in brain, heart and elsewhere. Using both behavioral and electrophysiological procedures, we have found that both a shrimp and a spiny lobster have external chemoreceptors for the nucleotide, adenosine 5'-monophosphate (AMP). Moreover in both cases, structure-activity relationships and the effect of an antagonist indicate these chemoreceptors have marked similarities to internal purinergic receptors.

to internal purinergic receptors. Behavioral matrice back to internal purinergic receptors. Behavioral studies in the shrimp show that AMP is a potent chemoattractant. Response increases with dose up to 10  $\mu$ M and then declines at higher concentrations. AMP is about 150 times more effective than ADP. ATP and adenosine are not attractants. The response is antagonized by theophylline. Bioassays of about 30 substances structurally related to AMP reveal that the integrity of both the adenine and the ribose phosphate moieties are required for maximal activity. However, the integrity of the ribose phosphate is of special importance since most modifications here completely inactivate the molecule. These results suggest the shirmp has external chemoreceptors similar to the P<sub>1</sub>-type (= R-type) purinoceptors found in vertebrate tissues.

Recordings from single olfactory cells in the antennule of the spiny lobster reveal the existence of receptor cells with the type of specificity implied by the behavioral studies. The potency sequence in these cells is AWP > ADP > ATP >> adenosine. The response to AWP is antagonized by theophylline. Further studies of the structure-activity relationships of these cells are in progress. Also in progress are studies of AMPbinding to receptors on excised sensilla from antennules of the spiny lobster.

Collectively, our studies indicate that crustaceans may serve as valuable model systems for studying purinergic receptors, as well as several other receptor types, at levels bridging the gap from behavior to electrophysiology to receptor characterization.

EVIDENCE FOR GABA AS AN INHIBITORY NEUROTRANSMITTER IN THE LEECH. 24.19 

thesize GABA from glutamate, indicating the presence of the enzyme glutamic acid decarboxylase (GAD). In addition, 30-35 identifiable neurons per ganglion accumulate exogenous <sup>3</sup>H-GABA by a high affinity uptake system.

The presence of GAD activity and specific accumulation of GABA by a reproducible set of neurons suggest that GABA may be a transmitter in the leech. In order to test this possibility we identified two pairs of the GABA-accumulating neurons, and are studying the pharmacological and physiological properties of the synapses they make on other neurons. We identified two of the GABA-accumulating neurons as the

We identified two of the GABA-accumulating neurons as the inhibitory motor neurons, cells 1 & 2, which innervate the longi-tudinal muslces in the body wall. The inhibitory motor neurons were identified electrophysiologically, filled with Lucifer Yellow and incubated in  $^{3}\text{H-GABA}$ . Autoradiographic processing reveals both Lucifer Yellow and silver grains in the same cell body. Lucifer Yellow itself does not cause neurons to accumulate CARBA because pointer mechaneous cause neurons to accumulate GABA, because neither mechanosensory cells nor excitatory motor neurons which have been filled with dye accumulate  $^{3}\mathrm{H}\text{-GABA}$ .

The inhibitor of the dorsal longitudinal muscles, cell 1, makes intraganglionic synapses onto the excitatory motor neurons of the dorsal longitudinal muscles, cells 3, 5 & 7. Intracellular stimulation of cell l produces a hyperpolarization in cell 3 accompanied by increase in membrane conductance. Bath application of GABA (100  $\mu m$ ) in normal Leech Ringer (1.5 mM Mg) causes a rapid hyperpolarization in cell 3 and an increase in membrane conductance. The original membrane potential and conductance are rapidly recovered when GABA is replaced by normal Ringer. 15 mm Mg<sup>++</sup>, which is sufficient to block the synapse between cell 1 and 3, does not block the response to bath-applied GABA. Therefore it is likely that GABA is acting directly on cell 3.

The response to bath-applied GABA is blocked by muscimol (100  $\mu$ m), a rigid analog of GABA. Nipecotic acid (100  $\mu$ m), another GABA analog, also induces a hyperpolarization in cell 3.

another GABA analog, also induces a hyperpolarization in cert -In summary, identified inhibitory motor neurons accumulate GABA, and their inhibitory effect on other neurons is mimicked by GABA. Muscimol appears to be an antagonist and nipecotic acid appears to be an agonist for the GABA response. Supported by NIH training grant CM 07048, & NIH NS14410.

# TRANSMITTER IMMUNOCYTOCHEMISTRY

25.1

IMMUNOCYTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN DEVELOPING RAT SPINAL CORD. P.E. Phelps, R.P. Barber\*, G.D. <u>Crawford\*, P.M. Salvaterra, and J.E. Vaughn. Division of Neuro-</u> sciences, City of Hope Research Institute, Duarte, CA 91010. The specificity of an immunocytochemical method for identifying cholinergic neurons with a monoclonal antibody to choline acetyl-transferase (ChAT), the synthesizing enzyme for acetylcholine, has been demonstrated in the adult rat CNS (Houser et al., <u>Brain</u> <u>Res.</u> 266:97-119). This method has been used to identify cholin-ergic neurons in developing cervical spinal cord of rat pups ranging in age from 1-28 days postnatal (dpn), as well as in adult specimens. The postnatal development of four types of ChAT-positive neurons, motoneurons, and three previously unidentified

adult specimens. The postnatal development of four types of ChAT-positive neurons, motoneurons, and three previously unidentified groups of cholinergic cells, has been studied. Large and small motoneurons (MNs) in newborn rats contained a moderate amount of ChAT-positive reaction product in their somata, dendrites, and axons. The intensity of ChAT-positive staining increased by 8 dpn, and was near adult levels by 14 dpn. Intensely ChAT-positive MN dendrites formed prominent bundles in specimens 14 dpn and older. Large MNs in adult spinal cord received synapses from ChAT-positive terminals. A few similar structures were located on MN's at birth and increased substantially in number by 8-11 dpn.

synapses interpositive terminals. A few similar structures were located on MN's at birth and increased substantially in number by 8-11 dpn. The most intensely ChAT-positive group of neurons in 1-5 dpn specimens were named partition cells because they occupied a region extending from the central canal to an area just dorsal to the lateral MNs, and thereby formed a division between dorsal and ventral horns. These partition cells were medium to large in size and had 5-7 primary dendrites that displayed mediolateral and rostrocaudal orientations. Axons of these cells could be traced into the ventral funiculus, MN pools and the ventral commissure. Another ChAT-positive cell group encircled the central canal. Although detectable at birth, processes of these small, central gray cells were not well delineated until 14 dpn, and were intensely ChAT-positive by 21 dpn. The fourth group of ChAT-positive neurons was located in the dorsal horn (liaminae III-IV and adjacent to the dorsal columns). These cells were present at early ages, but it was not until 11-14 dpn that their dendrites could be observed to project dorsally into laminae II III. A band of ChAT-positive punctate structures also was promi-nent in lamina III of adult dorsal horn, but was not detectable III. A band of ChAI-positive punctate structures also was promi-nent in lamina III of adult dorsal horn, but was not detectable until 14 dpn in developing spinal cord. By 21-28 dpn, the density of this band gradually approximated that observed in adult specimens. This study is being extended to include embryonic stages of development. All four ChAT-positive neuronal groups described above have been identified as early as embryonic day 17. Supported by USPHS Grant NS18449.

DISTRIBUTION OF CHOLINE ACETYLTRANSFERASE POSITIVE NEURONS AND. TERMINALS IN HIPPOCAMPUS. D. A. Matthews, P. M. Salvaterra, G. D. Crawford\*, C. R. Houser and J. E. Vaughn. Division of Neurosciences, City of Hope Research Inst., Duarte, CA 91010. It is generally accepted that the septohippocampal pathway is the sole source of cholinergic innervation to the hippocampus. However, some confusion persists regarding the distribution of cholinergic terminals and the source of the residual choline acetyltransferase (ChAT) activity that persists following septal lesions. This is due, in part, to a lack of information about the <u>cellular</u> localization of ChAT, the synthesizing enzyme for acetylcholine and a definitive cholinergic marker. Therefore, a monoclonal antibody to ChAT has been used to study cholinergic structures in normal rat hippocampus and in hippocampus deprived of its septal innervation. Small numbers of previously undetected ChAT-positive (ChAT+) 25.2

of its septal innervation. Small numbers of previously undetected ChAT-positive (ChAT+) neuronal somata were found scattered throughout the septotem-poral extent of the hippocampus. They were most common in stra-tum lacunosum-moleculare of regio superior, but were also found in various layers of the dentate gyrus and occasionally in the remaining hippocampal laminae. In electron micrographs, ChAT immunoreactivity was most often observed within synaptic vesicle-laden profiles that did not exhibit definitive synapses. However, some ChAT+ profiles formed asymmetric synapses with small dendrites or spines, and other possible synapses were either symmetric or of an intermediate type. Light microscopy demonstrated that ChAT+ terminal fields were organized in discrete bands and laminae. Pronounced bands were observed: discrete bands and laminae. Pronounced bands were observed: 1) immediately superficial to stratum granulosum, 2) deep to stratum pyramidale, and 3) on the border between stratum stratiating by an late, and 3) of the border between stratam gyrus, ChAT+ staining was pronounced in the hilus at the tem-poral levels, but only moderate staining occurred in the anterior hilus and throughout the molecular layer. A close correspondence was observed in the density and distribution of correspondence was observed in the density and distribution of ChAT+ terminals and acetylcholinesterase staining. Electrolytic lesions of the medial septal nucleus had no effect on ChAT+ somata, but virtually abolished the ChAT+ laminar pattern and eliminated all but occasional small patches of ChAT+ terminals. These results confirm that the vast majority of hippocampal cho-linergic terminals originate either from medial septal neurons or from fibers of passage. The newly observed intrinsic neurons can account for at least some of the ChAT activity remaining after septal lesions, and they apparently also contribute to the cholinergic innervation of the hippocampus. Supported by USPHS Grant NS18858.

CHOLINERGIC NEURONS IN RAT CEREBRAL CORTEX IDENTIFIED BY IMMUNO-CYTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE. C.R. Houser, G.D. Crawford\*, P.M. Salvaterra and J.E. Vaughn. Division of Neurosciences, City of Hope Research Inst., Duarte, CA 91010. Choline acetyltransferase (ChAT), the synthesizing enzyme for acetylcholine and a definitive marker for cholinergic neurons, has been localized immunocytochemically in sensory-motor regions of rat cerebral cortex with a monoclonal antibody to ChAT. The specificity of the monoclonal antibody and immunocytochemical methods has been demonstrated previously in several well charac-terized cholinergic systems (Houser, C.R. et al., Brain Res. 266: 97, 1983). ChAT-positive punctate structures and fine fibers with periodic varicosities were distributed in a loose network through-out the cortex. Some of these fibers were continuous with posi-tively stained fibers in the white matter underlying the cortex, many of which presumably originate from subcortical cholinerigic 25.3 many of which presumably originate from subcortical cholinerigic neurons. ChAT-positive fibers appeared to be rather evenly distributed throughout all layers of motor cortex, but a slight laminar pattern was evident in sensory cortex, where lower densities of fibers were observed in regions of granule cell densities of fibers were observed in regions of granule cell aggregates in layer IV. Electron microscopy demonstrated that ChAT-positive reaction product was concentrated in small vesicle-filled profiles throughout the cortex, and these structures were occasionally observed in continuity with lightly-stained axons. Although many of the vesicle-filled profiles did not exhibit definitive synaptic junctions in single thin sections, some of these profiles formed synaptic contacts, and preliminary findings suggested that they were of the symmetric type. ChAT-negative dendrites of various sizes were the most common postsynaptic elements of these synapses. In addition to fibers, <u>ChAT-positive cell bodies</u> also were present in cortical layers II-VI, and were most numerous in layers II-III. These somata were small in size (12-18µm in major diameter) and exhibited the characteristics of nonpyramidal neurons. The majority of ChAT-positive neurons were bipolar in form, displaying vertically-oriented dendrites that often extended across several cortical layers. ChAT-positive neurons with multipolar and bitufted dendritic patterns also were observed, but were less common than bipolar forms. Electron

observed, but were less common than bipolar forms. Electron microscopy confirmed the presence of ChAT-positive reaction product within the cytoplasm of small neurons. These neurons received both symmetric and asymmetric synapses on their somata and proximal dendrites, and such observations support their identification a neurons. Thus the identification as nonpyramidal, intrinsic neurons. Thus the present findings indicate that there is an intrinsic source of cholinergic innervation of the cerebral cortex in addition to previously described extrinsic sources. Supported by USPHS Grant NS18858.

25.5 ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL CHARACTERIZATION OF CHOLINERGIC NEURONS IN THE RAT BRAIN. D. M. Armstrong, Y. Kress\*, and R. D. Terry\*. Department of Neuropathology, Albert Einstein College of Medicine, Bronx, NY 10461. The electron microscopic immunocytochemical localization

of choline acetyltransferase (ChAT), the acetylcholine biosynthetic enzyme, was employed to examine the ultrastructural morphology and synaptic interactions of cholinergic neurons in the nucleus of the diagonal band of rat brain.

The details of the production and characterization of monoclonal antibodies to ChAT have been described (Levey et al., <u>J. Neurosci.</u>, 3:1-9). Antisera were localized by the peroxidase-antiperoxidase method in 50um Vibratome sections of brains fixed by vascular perfusion with a mixture of ice cold 4% paraformaldehyde and 0.15% glutaraldehyde in 0.1M phosphate buffer phosphate buffer.

Electron micrographs were taken throughout the horizontal Electron micrographs were taken throughout the horizontal and vertical limbs of the nucleus of the diagonal band. In all regions, peroxidase immunoreactivity for ChAT was distributed throughout the cytoplasm of selectively labeled neuronal perikarya and processes. The cholinergic neurons have a prominent nucleolus, infolded nuclear membrane, and numerous cytoplasmic organelles. The majority of the labeled processes were dendrites which contain ribosomes, microtubules, and mitochondria. Within labeled dendrites peroxidase immunoreactivity was distributed throughout the cytoplasm with somewhat dense accumulations associated with microtubules and mitochondria. Labeled dendrites were postsynaptic to unlabeled axon terminals characterized by microtubules and mitochondria. Labeled dendrites were postsynaptic to unlabeled axon terminals characterized by postsynaptic to unlabeled axon terminals characterized by numerous small clear vesicles. In addition to asymmetric synapses with unlabeled axon terminals, labeled dendrites often formed membranous appositions with other labeled dendrites and/or perikarya. The relative absence or paucity of ChAT-labeled axons or axon terminals may reflect that the majority of these cells are projection neurons or technical limitations such as accessibility of the applied antisera to the enzyme in axon terminals. We conclude that in the nucleus of the diagonal band, reaction product for ChAT was distributed throughout the cytoplasm of selectively labeled neuronal perikarya and dendrites which formed synaptic contacts with unlabeled axon terminals.

Contacts with unlabeled axon terminals. This work was supported by U.S.P.H.S. grant NS-02478 and The McKnight Foundation.

A COMPARISON OF THE DISTRIBUTION OF CHOLINE ACETYLTRANSFERASE AND A COMPARISON OF THE DISTRIBUTION OF CHOLINE ACETICITRANSFERASE AND TYROSINE HYDROXYLASE IMMUNOREACTIVITIES\_IN RAT RETINA. F. Eqken-stein<sup>#</sup>, R.W. Baughman, M.V. Sofroniey and J. Thibault<sup>\*</sup>. Har-vard Medical School, Boston MA 02115; University of Oxford, Ox-ford, England; <sup>\*</sup>College de France, Paris, France. The neurotransmitter synthesizing enzymes, choline acetyl-transferase (ChAT) and tyrosine hydroxylase (TH) represent specific markers for cholinergic and catecholaminergic neurons, enzymetry in the state of the

respectively. We have studied the distributions of these enzymes in the rat retina with immunohistochemical methods. The specifithe TH-antiserum with purified TH. For ChAT, a previously characterized antiserum was used and the staining pattern was characterized antiserum was used and the staining pattern was confirmed with two different monoclonal antibodies to ChAT. The ChAT-antiserum labelled numerous small (10 mioron diameter) neu-rons in the amacrine and ganglion cell layers with similar numbers of cells in each layer. These cells lay immediately ad-jacent to the inner plexiform layer (IPL). Laminae 2 and 4 (of 5) in the IPL showed strong staining for ChAT, probably representing cholinergic terminals. Confirmation of the stained representing cholinergic terminals. Contribution of the stathed neurons as amacrine cells awaits identification, in the same sec-tion, of the ganglion cells by retrograde labelling. TH-immunoreactivity was found in large neurons (>20 micron diameter) present in the amacrine cell layer, and very rarely, in the gan-glion cell layer. These cells were over 10x less numerous than the ChAT-positive cells. In the IPL, a dense plexus of fibers and varicosities was stained in Lamina 1 and a low density was seen in lamina 3; occasional labelled processes were also ob-served in the outer plexiform layer. The present results are in good agreement with previous studies on the localization of good agreement with previous studies on the localization of specific neurotransmitter uptake. The immunohistochemical tech-niques used here, however, make possible simultaneous double staining for different antigens. In addition, these techniques may permit study of the synaptic connections of the neurons described here, in particular, the cholinergic neurons, at the electron microscopic level.

25.6 A COMPARISON OF THE DISTRIBUTION OF CENTRAL CHOLINERGIC NEURONS A COMPARISON OF THE DISIRIBUTION OF CENTRAL CHOLINERGIC NEURONS AS DEMONSTRATED BY ACHE-PHARMACOHISTOCHEMISTRY AND CHAT-IMMUNO-HISTOCHEMISTRY. <u>K. Satoh, D.M. Armstrong and H.C. Fibiger</u>, Div. Neurological Sciences, Univ. British Columbia, Vancouver, B.C.; Dept. Neuropathology, Albert Einstein College of Medicine, Bronx,

NY. Pharmacohistochemistry for acetylcholinesterase (AChE) has been introduced as a neuroanatomical tool to detect perikarya in the CNS that may be cholinergic. In the present study, the reliabili-ty of this modified histochemical method in identifying choliner-gic cell bodies was assessed. Complete series of frontal sections of the mit broin end coincil conductor proceed either for AChE gic cell bodies was assessed. Complete series of trontal sections of the rat brain and spinal cord were processed either for AChE histochemistry 4-8h after systemic administration of diisopropyl-fluorophosphate (DFP, 2.0 mg/kg) or for choline acetyltransferase (ChAT) immunohistochemistry (Levey et al., <u>J.Neurosci.</u>, <u>31</u>,1983). The AChE-rich and ChAT-containing cell bodies were mapped on an atlas of the brain and the spinal cord, and a detailed comparison of these two cell populations was conducted with respect to their morphology and topographical distribution.

morphology and topographical distribution. The present observations revealed an excellent correspondence between the distribution of ChAT-containing and intensely stained AChE cells in many regions of the CNS. In the forebrain, these regions include the striatum, nucleus accumbens, olfactory tubercle, medial septum, nucleus of the diagonal band, lateral proptic region and nucleus basalis magnocellularis. Very simi-lar distributions were also seen in hindbrain and spinal cord structures; i.e. somatic and visceral efferent cranial nerve nuclei (III-VII, IX-XII), ventral horn and intermediomedial zone of the spinal cord midprain and notine termentum (nedunculononof the spinal cord, midbrain and pontine tegmentum (pedunculopon-tine nucleus, laterodorsal tegmental nucleus). ChAT-immunoreac-tivity and a high content of AChE were also observed in perikarya located in restricted areas of the reticular formation in the

Dower brain stem. Distinct incongruencies between the results of the two techniques were noted in several regions which contained cells that were stained intensely for AChE but where there was an absence of ChAT-containing neurons. These areas were the lateral hypothala-mus, subthalamus, locus coervieus, flocculus (cerebellum), nucleus raphe magnus, some regions of the bulbar reticular formation and the nucleus cervicalis lateralis. In no instance did we observe an area that contained ChAT-positive cells but which lacked AChErich perikarya. According to both histochemical techniques no cholinergic cell bodies are located in the cerebral cortex, hippocampus, nuclei of the amygdala, dorsal diencephalon, and the cerebellar nuclei.

The present observations indicate that AChE-pharmacohisto-chemistry can be used as a reliable method to detect cholinergic neurons in many, but not all regions of the CNS.

DIRECT IMMUNOCYTOCHEMICAL METHOD VISUALIZES GLUTAMATE IN PYRAMIDAL CELLS AND GABA IN INTERNEURONES IN THE CEREBRAL NEOCORTEX. 0.P. Ottersen\*, F-M. Haug\* and J. Storm-Mathisen\* (SPON: European Neuroscience Association). Anatomical Institute, University of Oslo, Karl Johansgt. 47, Oslo 1, Norway. A direct and specific method for visualizing amino acids in tissue sections has long been needed. Radioactive amino acids ta-hon up ifto hprain tiggen and to the output of ED 65% on 25.7

tissue sections has long been needed. Radioactive amino acids ta-ken up into brain tissue are retained to the extent of 50-65% on fixation by glutaraldehyde (G). Recently we showed that amino ac-ids thus fixed can be visualized immunocytochemically (Nature, 301, 1983, 517-520). Here we use this method to study the cellular localization of glutamate (Glu) and GABA in the cerebral neocor-tex. Briefly, antisera against Glu or GABA fixed to bovine serum albumin by G were raised in rabbits and purified by immunosorbent chromatography. The sera showed good specificities in a model system in which various amino acids and peptides fixed to brain proteins were visualized under conditions similar to those used for processing fixed tissue sections. Vibratome sections (20-100

proteins were visualized under conditions similar to those used for processing fixed tissue sections. Vibratome sections (20-100 um) were cut from rat or mouse brain, perfusion fixed with 5% distilled G in NaPi buffer, and processed with the PAP method. The GABA-antiserum stained nonpyramidal perikarya and bouton-like structures. The perikarya were mostly stellate and showed no clear lamination. The terminals were often in contact with un-stained pyramidal perikarya and dendrites. These results agree closely with published data on the immunocytochemical localizaclosely with published data on the immunocytochemical localiza-tion of GAD, and with the notion that a population of nonpyra-

midal cortical neurones is GABA-ergic. The Glu-antiserum stained pyramidal perikarya (which are be-lieved to send Glu-ergic axons to various cortical and subcortical Ineved to send Giu-ergic axons to various cortical and subcortical targets). Dendrites could often be followed through several corti-cal layers. The intervening neuropil was moderately stained. If the tissue was poorly perfused or the fixation delayed until after slicing in isotonic sucrose, cell bodies and dendrites were un-stained, but the neuropil contained boutonlike stained structures.

stained, but the neuropil contained boutonlike stained structures. Both antisera stained the nuclei, as well as the cytoplasm, of immunoreactive somata, indicating that the nuclear membrane is penetrable to the amino acids. None of the sera visualized glial perikarya, consistent with the notion that in these cells Glu and GABA are rapidly converted to glutamine. Preimmune sera, sera raised against aldehyde treated wheat germ agglutinin, or immune sera preabsorbed with antigen-bearing Sepharose beads, produced only weak, diffuse staining. This represents the first direct demonstration of Glu and GABA in neocortical neurones. The present approach should be applica-ble also to other free amino acids

ble also to other free amino acids. Supported by NAVF.

MEDULLARY RAPHE NUCLEI IN THE PRIMATE: A COMBINED CYTOARCHITECT-URAL, IMMUNOCYTOCHEMICAL AND QUANTITATIVE STUDY. <u>R. M. Bowker</u>, New York State Psychiatric Institute and the Department of Anatomy and Cell Biology, Columbia University, 722 West 168th Street, New York, New York 10032. The medullary raphe nuclei play important roles in modulatingvarious sensori-motor and autonomic functions within the nervous system, as well as different aspects of the sleep-arousal continium. In recent years immunocytochemical studies have demonstrated the presence of many services and peptidergic neurons within these raphe nuclei. In the present study, the distributions of chemically-identified neurons were determined in distributions of chemically-identified neurons were determined in relationship to the cytoarchitectural borders of the medullary raphe nuclei of the primate. The transmitter specific neurons were then quantitatively analyzed at the various levels of the raphe nuclei in terms of the relative population of neurons. In the non-human primate (squirrel (<u>Saimiri sciureus</u>) and rhesus (Macaca mulatta) monkeys) the brainstems were serially sectioned at 20 um with every fourth section being stained for Nissl substance and the remaining tissue sections being processed for immunocytochemistry, employing the avidin-biotin method of Hsu et al (1981). The cytoarchitecture of the medullary raphe nuclei immunocytocnemistry, omprogram al (1981). The cytoarchitecture of the medullary raphe nuclei wereadapted from the descriptions of Olszewski and Baxter (1954) and Taber et al (1960). Quantitative analyses of chemically specific and non-specific neurons were performed at nine different levels of raphe nuclei. In the medulla of the non-human primate raphe obscurus, the nucleus raphe magnus and the nucleus raphe pallidus. The latter cell group appears to be a relatively small paintaus. The latter cell group appears to be a relatively small component, or absent, in primates in comparison to other animal species. Nucleus raphe obscurus is composed of small and medium sized neurons, while the more anterior nucleus raphe magnus contains large and giant sized cells. A few large and giant neurons can beseen caudally in nucleus raphe obscurus. The nucleus raphe pallidus in squirrel monkeys is located at anterior levels of the inferior olive and appears to be comprised of a small, but homogeneous, cell group. Serotonin immunoreactive neurons were localized in each of the three raphe nuclei, but were not evenly distributed throughout each cell group. The serotonin cells are concentrated in the nucleus raphe obscurus and raphe pallidus. Quantitative data revealed that the percentages of serotonin immunoreactive neurons decreased in a caudal to rostral direction within the raphe nuclei at each of the nine levels. These data indicate that the serotonin-like neurons in the medullary raphe represent only a small fraction of the total raphe cell populationand suggest that in the primate, other transmitter agents may have a role in modulating the different raphe functions. (Supported byNS19379-01).

25.9 ON THE SEROTONIN INNERVATION OF THE RAT PITUITARY INTERMEDIATE LOBE. E. Mezey, Cs. Leranth, E. Friedman, D. T. Krieger, M. J. Brownstein, M. Palkovits, (Spon: W. W. Alberts). NIMH, LCB, NIMH, LCB, Palkovits . (Spon: W Bethesda, Md.20205.

Serotonin containing nerve fibres and terminals were detected in the rat pituitary intermediate lobe (IML) by light and electron microscopic immunohistochemistry. Transecting the pituitary stalk caused a marked (50%) decrease in IML sero-tonin (5-HT) and 5 - hydroxyindoleacetic acid (5-HTAA) content and degeneration of the majority (5-HIA) content and degeneration of the majority of the 5-HT positive nerve terminals in the IML. This indicates that most of the 5-HT containing nerve fibres in the IML come from the central nervous system. To locate the cell bodies that give rise to these fibers, we measured 5-HT in the IML after performing several surgical procedures: 1) transection of the ascending axons from the raphe nuclei, 2)total hypothalamic deafferentation or 3)electrolytic or mechanical lesions of the dorsomedial nuclei. Some animals underwent both 2) and 3) above. The effects of dorsomedial nucleus lesions and destruction of fibers from the raphe nuclei seemed to be additive; combining lesions 2) and 3) had the same effect as stalk transection -a 50% fall in 5-HT content. This result and our others indicate that tha 5-HT in IML nerve endings is provided by cells in the midbrain raphe and hypothalamic dorsomedial nuclei. 29.10 PROJECTION FROM THE AREA POSTREMA TO THE PARABRACHIAL NUCLEI. A NEW SEROTONERGIC PATHWAY. <u>A.J. Lança\*and D. van der Kooy</u> (Spon: P.A. McMullen) Inst. of Histol. and Embr., Univ. of Coimbra, Portugal and Neurobiol. Res. Group, Dept. of Anatomy, Univ. of Toronto, Canada M5A 1A8. The area postrema (AP), is a circumventricular organ classic-ally reported as a neurop-poor structure. However, there have

ally reported as a neuron-poor structure. However, there have been recent reports of efferent projections of this region to the parabrachial nucleus (PBN) and the dorsal division of the nucleus tractus solitarius, as well as direct neuronal inputs from the vagus nerve and the hypothalamus to the AP. The AP has also been suggested as a chemoreceptor area for intracerebro-ventricular and blood-born information (because of its weak blood-brain barrier). The identification of the neurotransmitter present in the projection to the PBN (the main efferent pathway of the AP) was investigated. A combined retrograde tracing-immunofluorescent technique was used to identify the relation-ships between the cellular population projecting to the PBN and the serotonin immunoreactive population of the AP in rats. retrograde fluorescent tracer True Blue was injected in the The parabrachial region and 3 days later the animals were perfused. In some rats pargyline was injected 2 hours before perfusion. Sections were processed for serotonin immunofluorescence.

Under the fluorescent microscope three different groups of cells were identified in the AP. First, True Blue positive cells (up to 250/section) that project to the PBN were observed distributed throughout the AP. Second, in the pargyline (MAO-inhib-itor) treated animals a high number of serotonergic cells (125/ section) was observed distributed throughout the AP. However, there was a slight tendency for a heavier distribution of sero-tonin immunoreactive cells in the dorsal two thirds of the AP. Third, double labelled cells were also seen. 20% of the True Blue labelled cells projecting to PBN were serotonin immunoreac-tive. 39% of serotonin immunoreactive cells were retrogradely labelled with True Blue. Thus a new serotonergic pathway from the area postrema to the parabrachial nucleus is described. The results suggest an active role played by serotonergic neurons in the transmission and modulation of chemical and visceral sensory input.

25.11 AN IMMUNOHISTOCHEMICAL AND ELECTRONMICROSCOPIC STUDY OF SEROTONIN NEURONAL ORGANIZATION IN THE DORSAL RAPHE OF THE MONKEY. <u>S.E. Kapadia.\* N.C. de Lanerolle and C.C. LaMotte</u> (Spon: E.E. Manuelidis). Sections of Gross Anatomy, Neurosurgery, and Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510. The PAP method of Sternberger was used with an antibody to a

The PAP method of Sternberger was used with an antibody to a 5-HT-BSA conjugate in order to identify serotonin neuronal structures in the dorsal raphe. Ultrathin serial sections revealed heavily immunostained 5-HT perikarya (18x22 um). Their nuclei showed multiple deep indentations. The cells had several mitochondria, a well formed Golgi body, and numerous RER cisternae, some in conspicuous laminar stacks. Dense cored vesicles (DVC) and lysosomal bodies were usually present. Immunoreactivity was intense in the cytoplasmic matrix. Outer membranes of mitochondria, RER and DCV were also stained. The immunoreactive beaded axonal varicosities contained round vesicles (18-35 nm) with large numbers of DCV (50-90 nm). Clusters of 5-HT unmyelinated ( $0.2-1.2 \times 0.3-1.2$  um) and myelinated ( $0.8-1.6 \times 0.8-2.8$  um) fibers were also observed. These 5-HT fiber bundles may provide evidence for the origin of both myelinated and unmyelinated fiber tracts from 5-HT somata within the dorsal raphe.

The 5-HT somata and dendrites were post synaptic to a variety of unlabelled terminals. These terminals contained (1) round vesicles (18-25 nm) and many small DCV (30-50 nm), or (ii) round vesicles (18-30 nm) with large DCV (90-110 nm), or (iii) small round vesicles (18-25 nm) with or without flattened vesicles. Simple synapses of these three terminal types with 5-HT structures were common. Two specialized relationships of unlabeled terminals and 5-HT targets were also observed: (i) 5-HT somatic and dendritic spines occasionally associated with crest synapses. (ii) 5-HT dendrites as the final postsynaptic element of a series of unlabeled synaptic terminals. Also observed was a 5-HT dendritic profile in apposition with another 5-HT dendritic profile, showing paramembranous thickening at the site of contact. This form of "dendritic bonding" was seen as part of a larger group of terminals and dendrites. This variety of terminals presynaptic to 5-HT structures suggests that several neuronal systems, perhaps with different neurochemicals, may modulate the 5-HT raphe neurons.

Occasionally, a 5-HT terminal was presynaptic to a 5-HT dendritic process. This relationship may be the anatomical basis for the physiological observation that 5-HT can inhibit 5-HT neurons. (Supported by NIH grant NS 13335). 25.12 COMBINED IMMUNOCYTOCHEMISTRY AND AUTORADIOGRAPHIC RETROGRADE AXONAL TRACING FOR IDENTIFICATION OF SEROTONERGIC RAPHE PROJECTION NEURONS. L. G. Isaacson\*, D. A. Steindler\* and B. K. Trosko\* (SPON: W. M. Falls), Department of Anatomy, Michigan State University, E. Lansing, MI 48824.

A technique combining unlabeled antibody PAP immunocytochemistry and autoradiographic retrograde axonal tracing has been utilized for identification of serotonin-containing raphe projection neurons. Unilateral pressure injections (0.2 µl) of wheat germ agglutinin (WGA), N-[acetyl-<sup>3</sup>H] (1.5 mCi/mg, 0.4% protein w/v, New England Nuclear) were stereotaxically placed within the caudate/putamen, thalamus, or hippocampus of six adult Hsd(ICR)BR white mice. Survival times ranged from 24-36 hours. One hour prior to sacrifice, the mice were injected with the MAO inhibitor pargyline (4 mg/ml, 75 mg/gm). Following cardiac perfusion with 4% formaldehyde, brains were removed, blocked and embedded in paraffin. Sections were cut at 4-5 µm in the coronal plane, mounted on gelatinized slides, dried and then incubated in antiserotonin antiserum (1:100 dilution) for 24-48 hours at 4°C. They were subsequently processed using the PAP methods of Sternberger and a glucose oxidase-diaminobenzidine histochemical procedure. These sections were dried, coated with Kodak NTB-2 nuclear emulsion and exposed for 4-16 weeks at 4°C. As a control, sections were treated exactly as above, replacing primary antiserum with normal rabbit serum.

Immunoreactive, serotonin-containing cells were characterized by brown, granular reaction product within the somata and dendrites. Serotonin neurons were distributed throughout the dorsal raphe, median raphe, raphe pontis, magnus and obscurus similar to that described by Steinbusch (<u>Neurosci</u>. 6:557-618, 1981). No immunoreactivity was observed in control sections. Retrogradely labeled raphe projection neurons were identified by the presence of numerous silver grains over their somata and proximal dendrites. Double labeled neurons, exhibiting both immunoreactivity and autoradiographic retrograde labeling, were identified as serotonergic projections neurons. For example, serotonergic raphe-striatal projections neurons were distributed mainly within the rostral portions of the dorsal and median raphe nuclei. A few projection neurons, labeled from the striatal injection, stained negative for serotonin. These neurons most likely represent a smaller non-serotonergic raphe-striatal projection previously described (Steinbusch et al., Neurosci, Lett. 19:137-142, 1982).

Smaller hol-seroconerge raphe-scillatal projection previously
 described (Steinbusch et al., Neurosci. Lett. 19:137-142, 1982).
 The transmitter-specific neuronal tracing method described here
 utilizes immunocytochemistry in combination with WGA, N-[acetyl-3H] axonal tracing. The high degree of sensitivity displayed by
 both of the labeling methods affords a permanent and accurate
 means of identifying neurotransmitters of projection neurons.
 Supported by NIH Grant NS-15931.

25.13 LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMISTRY OF A DOPAMINE AND CYCLIC AMP-REGULATED PHOSPHOPROTEIN (DARPP-32) IN RAT BRAIN. C. C. Ouimet, H. C. Hemmings, Jr.\* and P. Greengard. Dept. Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510. DARPP-32, a dopamine and cyclic AMP-regulated phosphoprotein

DARPP-32, a dopamine and cyclic AMP-regulated phosphoprotein with an apparent molecular weight of 32,000, has been studied in the brain by light and electron microscopic immunocytochemistry. The results suggest that DARPP-32 is enriched in a subclass of neurons that receive a dopamine input, and that it is absent from dopaminergic neurons themselves. Biochemical evidence (Walaas and Greengard, 1983) that the phosphorylation of DARPP-32 is regulated by dopamine and by cyclic AMP suggests that the DARPP-32 neurons belong to that subclass of dopaminoceptive cells possessing the D1 receptor. The indirect immunofluorescence technique was used for light

The indirect immunofluorescence technique was used for light microscopy and the peroxidase-anti-peroxidase technique of Sternberger was used for both light and electron microscopy. Antiserum specificity was demonstrated by immunoblotting and immunoprecipitation methods, and method specificity was shown by the lack of staining produced by appropriate control sera. DARP-32 immunoreactivity was very strong in neuronal cell bodies and dendrites in those brain regions that are enriched in dopaminergic nerve terminals: caudatoputamen, nucleus accumbens, olfactory tubercle, bed nucleus of the stria terminalis, and portions of the amygdaloid complex. Within the caudatoputamen, immunoreactivity was present in medium size (10-15) µm diameter) neuronal cell bodies and in dendrites, spines and axons. A small number of nerve terminals in the caudatoputame were also immunoreactive and these typically formed synapses upon neuronal elements that were likewise immunoreactive. In parasagittal sections, immunoreactive fiber bundles were traced from the caudatoputamen to the globus pallidus, entopeduncular nucleus, and pars reticulata of the substantia nigra, and within these regions, the labeled axons gave rise to immunolabeled nerve terminals. In the pallidal areas, and in the pars reticulata of the substantia nigra, indigenous cell bodies and dendrites were not immunolabeled. In the pars compacta of the substantia nigra and in other dopaminergic nuclei, immunoreactivity was never detected in neuronal cell bodies or dendrites.

DARPP-32 immunoreactivity may be an effective marker for neurons (or a subset of neurons) in which the action of dopamine is mediated through cyclic AMP and its associated protein kinase. In addition, DARPP-32 immunoreactivity will enable the identification of both the afferent and efferent neurons with which the DARPP-32-containing neurons interact. (Supported by USPHS Grants MH-17387 and NS-08440.) 25.14 DOPAMINERGIC NEURONES IN RAT DORSAL ROOT GANGLIA. Jack Price\*. (SPON:J.P.Brockes) MRC Neuroimmunology Programme, Dept. of Zoology University College London, Gower Street, London WClE 6BT, UK.

(SPON:J.P.Brockes) MKC Neuroimmunology Programme, Dept. of 200109 University College London, Gower Street, London WCLE 6BT, UK. The sensory neurones of the dorsal root ganglia (DRG) can be classified on the basis of a number of criteria. Classically, a distinction has been drawn between 'large light' and 'small dark' cells (see Lawson <u>et al</u>, Cell Tiss. Res. 153:399-413 1974) and more recently sub-populations of the latter have been characterised on the basis of their peptide content (e.g. somatostatin- or substance P-containing) or the presence of fluoride-resistantacid-phosphatase (FRAP).

We have recently shown a sub-population of small DRG neurones to be dopaminergic in the rat (Price & Mudge, Nature 301:241-243 1983). This conclusion was drawn from immunohistochemical data which demonstrated that these cells stain with an antibody which specifically binds the enzyme tyrosine hydroxylase (TH: Joh <u>et al</u>, Proc. natl. Acad. Sci. USA 76:509-513 1979) but not with another antibody which reacts with dopamine-*B*-hydroxylase (Geffen & Jarrott Handbk. Physiol. 15:521-571 1978). Further, the glyoxylic acid fluorescence method of De La Torre (J. Neurosci. Meths., 3: 1-5 1980) was used to show that these neurones synthesised and stored catecholamine, hence demonstrating the immunohistochemically-identified TH to be active.

These TH<sup>+</sup> sensory neurones have a number of interesting features. Firstly, they are found in DRG L5, L6 and S1 and in no other spinal ganglia. Secondly, they are not found in animals younger than 9 days of age. As rat DRG neurones become postmitotic between embryonic days 10 and 14, the most likely explanation for this late development of the catecholaminergic phenotype is that the neurones have switched to dopamine from another neurotransmitter.

The question arises as to how these putative dopaminergic neurones fit into classifications of DRG neurones described hereto. Their size (16-20 um diameter) suggests they are of the 'small dark' variety and this is supported by the observation that they do not stain with RT97, a monoclonal anti-neurofilament antibody (Wood & Anderton, Biosci. Rep. 1:263-268 1981) which only stains 'large light" cells. However, they are smaller than the substance P-, somatostatin- or FRAP-containing cell populations, and studies in which alternate serial sections were stained with anti-TH and an anti-substance P serum, or anti-TH and FRAP, showed that most, if not all,  $TH^+$  cells contain no substance P or FRAP. Similar studies with other anti-peptide sera are in progress. (I would like to thank the Medical Research Council for

- MAPPING OF HISTAMINE-IMMUNOREACTIVITY IN THE CENTRAL NERVOUS 25.15 MAPPING OF HISIAMINE-IMMUNUKALITYITT IN THE CENTRAL MERVOUS SYSTEM OF THE RAT. A.H. Mulder and H.W.M. Steinbusch (SPON: P. Luiten). Dept. Pharmacology, Medical Faculty, Free University, Van der Boechorststr. 7, 1081 BT Amsterdam, The Netherlands. A variety of neurochemical and neurophysiological data support the candidacy of histamine as a neurotransmitter in the central nervous system. However, thus far only limited evidence for the presence of histaminergic neurons is available, due to the lack of appropriate histochemical techniques. Here, we report on the development of a new immunohistochemical method and its application for the visualization of histamine in the rat brain. Procedures: Antibodies to histamine were raised in rabbits by immunization with a BSA-histamine or Haemocyanine-histamine conjugate. Optimum coupling conditions were established based upon retention studies using brain slices incubated with radiolabelled histamine. Untreated rats or rats pretreated with fauto-labelled histamine. Untreated rats or rats pretreated with either colchicine and L-histidine, or 5,7-dihydroxytryptamine (5,7-DHT) or 6-hydroxydopamine (6-OH-DA) were used. Ten yum thick cryostat sections from different brain regions were obtained after a perfusion fixation with 4% paraformaldehyde and subsequently processed for immunofluorescence. <u>Characterization of the anti-</u> bodies: Immuno-inhibition tests, using conjugate-complexes to the catecholamines and serotonin, revealed no crossreactivity towards any of the monoamines (MA). Staining was not abolished after preany of the monoamines (MA). Staining was not abolished after pre-treatment with the neurotoxins 5,7-DNT and 6-OH-DA. A negative staining was observed in nuclei containing MA other than hista-mine, i.e. the substantia nigra (DA), the locus coeruleus (NA) or the nucleus raphe dorsalis (5-HT). Distribution: A dense inner-vation of histamine-immunoreactive varicose fibers was observed throughout the median eminence, especially in the lateral parts of the external and internal zone. These fibers run through the infundibulum stalk into the pars nervosa of the pituitary. A fairly large number of histaminergic fibers were seen in the nucleus hypothalamicus posterior and rostrally in the tractus diagonalis of Broca. Scattered fibers were found in the nucleus periventricularis hypothalami and thalami, the nucleus paraventri-cularis hypothalami, the amygdala, the subfornical region and in the periaguaductal grav. Weakly stained perikarya were demon-strated in the caudoventrolateral part of the hypothalamus. Strongly fluorescent mast cells were detected at the basal surface of the hypothalamus. In summary: the Immunohistochemical method developed in this laboratory appears to be specific for histamine and opens the possibility of a complete mapping of histaminergic neurons in various species. It should be emphasized, however, that the fixation procedure needs further improvement for a better retention of histamine in brain regions with low levels of this monoamine.
- Is such classification of nerves as 'cholinopeptidergic' and 'adrenopeptidergic' more appropriate than that of 'cholinergic', 'adrenergic' and 'peptidergic' in the autonomic ganglion? Hisatake kondo\* Department of anatomy, Niigata University School 25.16

Hisatake kondo\* Department of anatomy, Niigata University School of Medicine, Niigata, 951, JAPAN The fine structural characteristics of substance P (SP), somatostatin (SRIF), vasoactive intestinal polypeptide (VIP), enkephalin (BNK) and gastrin releasing peptide (GRP) have been revealed by the immunoelectron microscopic analysis with the PAP method in the celiac ganglion of guinea pigs and rats. SP and SRIF nerve fibers are characterized by abundant small clear vesicles mixed with a few large granular vesicles and the immunoreaction product appears in the axoplasm as well as the core of the large granular vesicle. VIP, ENK and GRPnerve fibers, on the other hand, are characterized by considerably numerous large granular vesicles mixed with small clear vesicles and the immunoreaction product is confined to the core of the large vesicles although their axoplasm appears slightly darker than the control. The small clear vesicle is free of the immunoreaction in either of the five peptide-con-taining nerve fibers. Each of the five peptide-fibers forms axo-dendritic, axo-somatic and some axo-axonic synapses with its own proportions of the three synapses. The immunopositive granular vesicles are usually located away from the synaptic sites in either of the five peptide fibers. Serial section analysis of conventionally processed blocks of

serial section analysis of conventionally processed blocks of the same ganglia revealed that neuronal profiles containing considerably numerous large granular vesicles are often in cytoplasmic continuity with those containing small clear vesicle predominantly. The latter has conventionally been regarded as cholinergic type in the autonomic nerves.

cholinergic type in the autonomic nerves. All these findings suggest that there are two types of nerve fibers in the autonimic ganglion in terms of vesicle population; the one with single varicosities containing small clear vesicles predominantly, and the other with a varicosity containing large granular vesicles predominantly and another containing small clear vesicles predominantly. SP and SRIF fibers belong to the former type and VIP, ENK and GRP fibers belong to the latter type. It is further suprescription that both two twose of fibers are declinerging type and Vir, has and GRP TIPERS belong to the latter type. It is further suggested that both two types of fibers are cholinergic. This infers that neuropeptides are not present in neuronal entity different from classical cholinergic and adrenergic nerves, but that the co-exstence of peptides and classical transmitters is more likely in the autonomic ganglion.

25.17 A NEW TECHNIQUE FOR THE DETERMINATION OF IMMUNOHISTOCHEMICAL

A new recharged for the Determination of Immonoristochemical SPECIFICITY. <u>Cathrine A. Sasek and Robert P. Elde</u>. Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455. Determination of immunohistochemical specificity is most commonly attempted using absorption controls, cross-reactivity studies and radioimmunoassay (RIA). These tests are seriously commonly attempted using absorption controls, cross-reactivity studies and radioimmunoassay (RIA). These tests are seriously limited in that they characterize the <u>antiserum</u> for its ability to recognize presently characterized <u>antigens</u>. The method outlined below was developed in order to characterize the <u>anti-gens</u> revealed in a tissue section by immunohistochemical methods. This method has also been designed to account for changes in antigenicity during fixation. Since fixation has been shown to have a major effect on antigenicity, this is an important factor to consider in testing for specificity. Antiserum raised against synthetic FMRF-NH<sub>2</sub> was used to deve-lop this technique since, in addition to staining cells within pancreatic islets and cells and fibers throughout the nervous system, it has been shown to recognize a whole family of peptides in cross-reactivity studies. These include pancreatic polypep

in cross-reactivity studies. These include pancreatic polypep-tide (PP), neuropeptide Y (NPY) and peptide YY (PYY). However, as in all immunohistochemical reactions, the molecular nature of the antigens in the tissue section is unknown. Fresh brain and pancreas were homogenized and extracted in IM acetic acid. Small pancreas were homogenized and extracted in IM acetic acid. Small molecular weight peptides were collected after gel filtration (Ultrogel AcA 54, IM acetic acid), desalted with XAD-2 resin and grossly separated according to molecular weight by gel filtration (Biogel P6, 3M acetic acid). Fractions were vacuum dried and reconstituted in small volumes of IM acetic acid and methanol (1:1). Reconstituted fractions as well as synthetic peptides were subjected to thin layer chromatography on cellulose acetate (butanol, 4: acetic acid, 2: H<sub>2</sub>O, 2). The chromatogram was fixed with paraformaldehyde vapors (80°C in vacuo, 1 hr.) and processed according to the DAP technique using anti\_EMEF\_NH0 as the primary according to the PAP technique using anti-FMRF-NH2 as the primary antiserum.

In the chromatograms immunostained peptides of pancreatic In the chromatograms immunostained peptides of pancreatic extracts, for example, did not show the same migration pattern as synthetic NPY, PYY, avian PP, and FMRF-NH2. Thus it is likely that the peptide produced by the rodent pancreas and recognized with FMRF-NH2 antiserum has a different sequence than previously characterized members of this family of peptides. This method should prove to be generally applicable in identifying the physico-chemical nature of low molecular weight antigens recognized by immunohistochemical techniques. It additionally has the advantage of not requiring special equipment and of allowing for the use of different solvents to seperate struc-turally similar peptides. Supported in part by DA 02148.

LOCALIZATION OF SEROTONIN AND PEPTIDE NEUROTRANSMITTERS IN THE 25.18 VENTRAL MEDULLARY RETICULAR FORMATION IN THE RAT. J.A. Andrezik, S.G. Remington\*, and R.H. Ho. Department of Anatomical Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190 and Department of Anatomy, The Ohio State University, Columbus, OH 43210.

The reticular nuclei of the rostral ventral medulla (VMRF) are important areas influencing analgesia, respiration and cardio-vascular reflexes. VMRF is composed of nucleus paragigantocellularis lateralis (PGCL), and nucleus gigantocellularis, pars alpha,  $(GC\alpha)$ . Serotonin, enkephalins, and other peptides have been reported in the VMRF. As a sequel to normal anatomical studies, we ported in the VMKP. As a sequel to normal anatomical studies, we reacted the rostral medulla with antisera to serotonin (5-HT), substance P (SP), methionine enkephalin (ME) and neurotensin (NT). The location of the primary antibodies was visualized in frozen sections using the indirect PAP method of Sternberger. Adsorption controls indicated the specificity of staining.

Antiserum to 5-HT labels neurons mainly in  $CC\alpha$  throughout its entire extent and a few neurons in PCCL. In both cases some of these are large triangular neurons. Numerous reactive terminals punctuate the PGCL neuropil, more than in  $GC\alpha$ . PGCL contains more neurons that react with SP antiserum than

react with 5-HT antiserum. Most of these are medium-sized neurons or spindle shaped neurons. Some large triangular neurons and or spinale snaped neurons. Some large triangular neurons and neurons close to the ventral surface react with anti-SP serum, in-dicating possible coexistence of SP and 5-HT within the same neuron. Terminals labeled with SP antiserum are found throughout the PGCL and GCa, but the number of labeled terminals is quite striking in the lateral PGCL.

Antiserum to ME labels some neurons in GCa, mainly in the lateral portion at caudal levels. PGCL contains many labeled cells - medium-sized triangular and small round neurons. At the level of the rostral inferior olive, there is a tightly packed group of neurons (15-20 in number) at the ventrolateral border of  $GC\alpha$ , which stains intensely with the anti-ME serum. More rostral, at the level of the facial motor nucleus, most of the cellular labeling is found in  $GC\alpha.\ PGCL$  is densely packed with labeled

terminals throughout its extent. Antiserum to NT labels large round and medium-sized triangular

Antiserum to NI labels large round and medium-sized triangular neurons only in the caudal PGCL. There is sparse terminal label-ing in the midportion of PGCL, but it is not dramatic. Antisera to 5-HT, SP, ME and NT label, for the most part, different populations of neurons in discrete areas of VMRF. There is, however, some overlap of terminal labeling in VMRF. We pro-pose that there are local interactions between aminergic and postidoric elements in VMRF and we are currently investigating peptidergic elements in VMRF and we are currently investigating the anatomy of these systems at the ultrastructural level. Sup-ported by NIH Grants #NS-16868 (JAA) and #NS-10165 (RHH).

radioimmunocytochemistry with  $^{3}\mathrm{H}\text{-}\mathrm{Biotin}$ 25.19

S.P. Hunt and P.W. Mantyh (SPON: D. Bousfield). MRC Neurochemical Pharmacology Unit, Medical Research Council Centre, Medical School Hills Road, Cambridge CB2 2QH, UK. The high affinity of radiolabelled biotin for the glycoprotein avidin has been exploited in the design of techniques which can be used as a semiquantitative alternative to the peroxidase-anti-peroxidase (PAP) method or as a second marker system in combination with immunoperoxidase techniques. Tissue prepared by standard immunocytochemical protocols is exposed to primary anti-body for 48-72 h followed by incubation with biotinylated protein A or antirabbit immunoglobulin and then incubation with a complex of  ${}^{3}\mathrm{H}\text{-biotin}$  and avidin. Tissue is subsequently prepared for autoradiography and dipped in liquid emulsion (Ilford K5 or L4) for light or electron microscopy; or apposed to LKB ultrofilm for semiquantitative analysis. Using these techniques it has been possible to visualise a large number of antigens in animal and human nervous tissue including avian pancreatic polypeptide (APP), enkephalin (ENK), substance P (SP), glutamic acid decarboxylase (GAD), tyrosine hydroxylase (TH) and somatostatin (SOM). Large

(GAD), tyrosine hydroxylase (TH) and somatostatin (SOM). Large areas of human brain have been scanned and differences in amounts of bound antibody quantified. Electron microscopy indicated that silver grains reflecting bound substance P antibody were largely over axon terminals and double labelling studies using <sup>3</sup>H-biotin in combination with immunoperoxidase markers confirmed the coexistence (APP/TH and APP/SOM) or lack of coexistence (SP/SOM, ENK/SOM) of a number of antigens in the peripheral and central nervous system. As a specific test of this semiquantitative removed 48 h post-mortem. One leg had been amputated 24 months prior to death. A loss of substance P from the affected side had previously been noted using immunoperoxidase techniques (Hunt S.P. et al., Lancet 1:1082, 1982). Analysis of LKB film exposed S.P. et al., Lancet 1:1082, 1982). Analysis of LKB film exposes to  ${}^{3}\text{H-biotin}$  labelled tissue for 24 h and using computerised microdensitometry indicated a loss of 50% of the immunoreactive for that little recover substance P on the affected side, suggesting that little recovery of central peptide levels occurs following section of the peri-pheral process of the sensory neuron. We are currently exploring the potential of the technique for quantifying peptide changes in a variety of degenerative disorders of the human brain including Parkinson's and Alzheimer's disease and Huntington's Chorea.

COLLOIDAL GOLD AND PEROXIDASE AS ULTRASTRUCTURAL MARKERS FOR 25.20 SIMULTANEOUS LOCALIZATION OF TWO NEUROTRANSMITTER ANTIGENS IN THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS. <u>Anthony N. van den Pol</u>, Section Neurosurgery, Yale Univ. Sch. Med. New Haven, Ct. 06510. Postembedding immunostaining with colloidal gold adsorbed to

immunoglobulins or protein A was combined with peroxidase (PAP or biotin/ avidin) immunostaining to allow simultaneous identification of two putative neurotransmitter antigens in different neurons. Combinations of primary antibodies against peptides, transmitters, and enzymes localized in somata or processes in rat hypothalamic paraventricular nucleus were tried,

processes in rat hypothalamic paraventicular inclusions were then, including neurophysin, glutamic acid decarboxylase, tyrosine hydroxylase, somatostatin, ACTH, Substance P, and serotonin. After aldehyde fixation thick vibratome sections were stained with the first primary antibody (e.g.,anti-ACTH) and subsequent series of immunoreagents; horseradish peroxidase was used as the final marker with diaminobenzidine as the substrate. After embedding in plastic, thin sections were cut and treated with hydrogen peroxide and then immersed in the second primary (e.g., anti-neurophysin) which was subsequently localized with either anti-neurophysin) which was subsequently localized with either goat anti-rabbit IgG or protein A adsorbed to 5,10,or 20 nm colloidal gold particles. These procedures allowed simultaneous viewing with electron microscopy of two different sets of neurons, one labeled with peroxidase and the other with gold particles. Peroxidase labeling was found throughout the axonal or perikaryal cytoplasm of labeled neurons. Colloidal gold particles were found in highest concentrations over neurosecretory vesicles were found in highest concentrations or neuroscience of the method of the second second terminals. Gold particles were found in quantities up to 125 times greater over neurosecretory vesicles than over an equal cross-section area of cytoplasm with an anti-neurophysin serum; areas on electron micrographs were determined with a stereological point count methodology. Colloidal gold was also used for pre-embedding Count methodology. Collocal gold was also used to pre-emoteding immunocytochemistry; with appropriate dilutions gold was an effective marker for light microscopy. Intensification for light microscopy could be achieved with a FITC-conjugated IgG directed against the collocal gold adsorbed IgG. Grain density of gold with ultrastructural analysis of sections immunostained prior to plastic embedding was 10 times greater in labeled perikaryal cytoplasm than in the nucleus or in adjacent neuropil. Controls cycoplasm than in the hudreus of in adjacent neuropil. Controls with deletion of primary antiserum, adsorbtion with the homologous antigen, or substitution of an unrelated primary IgG were negative. Cross-reactivity of the first set of immunoreagents with the second set was negligible. The combination of colloidal gold and peroxidase immunocytochemistry allows simultaneous identification of both pre- and postsynaptic neuronal elements in a single thin section, or of two antigens in the same cell.(Supported by NIH NS16296 and NS10174.)

# CYCLIC NUCLEOTIDES

PURIFICATION OF THE STIMULATORY AND INHIBITORY GUANINE NUCLEOTIDE 26.1 REGULATORY UNITS OF BOVING CEREBRAL CORTICAL ADENVLATE CYCLASE. <u>E.J. Neer, and L.G. Wolf\*</u>. Cardiovascular Division, Brigham and <u>Women's Hospital and Harvard Medical School</u>, Boston, MA 02115 USA.

Hormone or neurotransmitter receptors either stimulate or inhibit the adenylate cyclase from bovine brain. Their actions on the enzyme are mediated by two distinct guanine nucleotide binding regulatory proteins, one of which  $(N_S)$  mediates stimulation of the adenylate cyclase catalytic unit (C) while the other  $(N_i)$  mediates inhibition.

inhibition. We have purified both these regulatory proteins from bovine cerebral cortex. The activity of  $N_S$  is measured by its ability to stimulate a preparation of solubilized C which has been separated from  $N_S$  as described by Strittmatter, S. and Neer, E.J. (PNAS(1980)77,6344). The cholate solubilized  $N_S$  was purified by a modification of the method of Sternweis et al (J.Biol.Chem (1981)256,11377) for rabbit liver. The final specific activity was 2µmol cAMP/mg/min. By SDS polyacrylamide gel electrophoresis, the purified preparation contains a peptide of 52,000 daltons and, in lesser quantity, one at 45,000. Like  $N_S$  purified from rabbit liver, the brain  $N_S$  is associated with a 35,000 dalton peptide which does not, itself, have the ability to stimulate C. The 52,000 dalton protein can be phosphorylated by a protein kinase

which does not, itself, have the ability to stimulate C. The 52,000 dalton protein can be phosphorylated by a protein kinase which copurifies with N<sub>3</sub> activity. N<sub>1</sub> is identified by the fact that it can be [32P]ADP-ribosylated by pertussis toxin. The labelled polypeptide has a molecular weight of 40,000. Like N<sub>3</sub>, it is associated with a 35,000 dalton protein which is not modified by the toxin. The availability of purified components of adenylate cyclase from cerebral cortex now allows further characterization of their structure and function. Supported by NIH grant AM19277 and American Cancer Society Grant 87.380.

SYNAPTIC MEMBRANE ADENYLATE CYCLASE GTP-BINDING PROTEIN SPECIFI-CALLY INTERACTS WITH RAT BRAIN TUBULIN. <u>C.M. O'Callanan,\* R.J.</u> <u>De Lorenzo and M.M. Rasenick</u> (SPON: S.A. Shefner). Dept. of <u>Neurology</u>, Yale University School of Medicine, New Haven, CT 26.2 06510.

Activation of hormone-responsive adenylate cyclase involves Activation of hormone-responsive adenylate cyclase involves association among several membrane-associated components: the hormone receptor, the Guanyl nucleotide binding subunit (G-Unit) and the catalytic moiety. Recent studies (<u>Nature</u> <u>294</u>:560, 1981; <u>Neurosci. Abs. 12</u>:344, 1982) suggest that cytoskeletal elements might affect coupling among the rat cerebral cortex adenylate cyclase components. Colchicine or vinblastine augment adenylate cyclase activation by Gpp(NH)p or NaF but not Mn<sup>++</sup> suggesting that the locus of their effect membranes are incubated with colchicine or vinblastine and subsequently washed, a 42,000 dalton GTP binding protein is specifically eluted. The above results suggest that tubulin might serve as a

The above results suggest that tubulin might serve as a possible "anchor" for some adenylate cyclase G-Units. In order possible allow for some adenyate cyclase G-onts. In order to further explore this hypothesis, three cycle polymerized-depolymerized rat brain tubulin was added to synaptic plasma membrane under conditions where tubulin incorporates into artificial membrane (BBA 647:270, 1981). This resulted in a tubulin-concentration dependent inhibition of Gpp(NH)p or NaFactivated adenylate cyclase. Tubulin exerted this effect at a variety of Gpp(NH)p or NaF concentrations while Mn<sup>++</sup> acti-Variety of GpD(NH)p or NAF concentrations while Mn<sup>-1</sup> acti-vated ademylate cyclase was unaffected by tubulin addition. These tubulin effects were noted only in adenylate cyclase from nervous tissue. Treatments which deplete synaptic memorane tubulin both increased the effects of tubulin addition and generally improved Gpp(NH)p and NAF activation of adenylate cyclase.

cyclase. When G-Unit was covalently labelled with  $(^{3}H)$ P3-4-Azidoanilido P1-5' GTP (AAGTP) and passed over a tubulin affinity column, labelled material bound to the column and was eluted with increasing NaCl concentrations. This procedure resulted in an enrichment of M<sub>r</sub> 42,000 AAGTP labelled protein. SDS gel electrophoresis of synaptic membrane associated proteins followed by tubulin hybridization indicates that M 42,000 AAGTP labelled that  $M_r$  42,000 AAGTP labelled protein may specifically interact with rat brain tubulin.

These data are consistent with a hypothetical G-Unit -Tubulin association within the neuronal plasma membrane. It is possible that neuronal cytoskeletal dynamics modulate hormoneresponsive adenylate cyclase.

Supported by AFOSR Grant #LQ81-183.

ACTIVATION AND INHIBITION OF SYNAPTIC MEMBRANE ADENYLATE CYCLASE BY MULTIPLE GTP BINDING PROTEINS. <u>M.M. Rasenick and R.L. Malina</u> Dept. of Neurology, Yale Univ. Sch. Med., New Haven, CT 06510. 26.3 Malina\*.

GTP or hydrolysis-resistant GTP analogues (e.g. guanylylimididiphosphate - Gp(NH)p)promote stable activation of rat synaptic membrane adenylate cyclase (AC) which persists subsequent to washing of membranes. This stable activation is time, temperature and Gpp(NH)p concentration dependent, and is thought to reflect the coupling of the AC catalytic moiety with the GTP binding regulatory subunit (G-unit).

We find that "stable" AC activation by Gpp(NH)p is subject We find that "stable" AC activation by Gpp(NH)p is subject to further augmentation by subsequent incubation of membranes with Gpp(NH)p. This phenomenon depends upon multiple exposure to Gpp(NH)p and subsequent washing and not upon total Gpp(NH)p incubation time. Furthermore, if low (<luM) Gpp(NH)p concentra-tions are present during AC assay, inhibition of "stable" Gpp(NH)p AC activation results. Colchicine, which is thought to promote David (Nature 204, 560, 102). Science 210, 56, 1022) brain AC coupling (Nature 294: 560, 1981; Science 219: 65, 1983) augments both the increase and the decrease in "stable" AC acti-vation. Binding studies with (4H)Gpp(NH)p reveal that although (3H) Gpp(NH)p binding is relatively stable to washing, about 50% readily exchanges with unlabelled GTP analogues. Treatment of (3H) Gpp(NH)p-labelled membranes with colchicine, which may favor formation of G unit (astablic complexed distributes (3H) formation of G-unit/catalytic moiety complexes, diminishes (3H) Gpp(NH)p exchange.

The photoaffinity GTP probe (3H)P3-4-azidoanilido P1 5' GTP The photoaffinity GTP probe (3H)P3-4-azidoanilido P1 5' GTP (AAGTP) was employed to ascertain whether activation and inhibi-tion of AC might be controlled by separate GTP binding proteinsand if their GTP binding varied under conditions of Gpp(NH)p orNaF-activation, or Gpp(NH)p-dependent inhibition. Three AAGTPbinding proteins, Mr 42,000, Mr 40,000 and Mr 35,000 respectively,were observed. Conditions for competition of AAGTP label (priorto photolysis) were different for the Mr 40,000 and Mr 42,000proteins. It is hoped that extensions of these studies willprovide inside in the the mechanism of activation and inhibition.provide insight into the mechanisms of activation and inhibition of neuronal adenylate cyclase.

RECEPTOR-MEDIATED MODULATION OF GTPase ACTIVITY BY 26.4 NEUROTRANSMITTERS IN RAT STRIATUM. M.C.Olianas and P.Onali. Inst.Pharmacology & Biochem. Pathology and Inst. Pharmacology, University of Cagliari, 09100 Cagliari.Italy.

In synaptic plasma membranes of rat striatum neurotransmitters which affect adenylate cyclase activity stimulate a high affinity GTPase. Acetylcholine (Ach) inhibits adenylate cyclase and increases GTP hydrolysis via muscarinic receptors. Chronic acetylcholine sterase inhibition by diisopropylfluorophosphate(DFP) administration results in desensitization of muscarinic inhibition of striatal adenylate cyclase. The ma-ximal decrease of basal enzyme activity elicited by Ach is reduced by 40-50% in membranes of DFP treated inhibition of adenylate cyclase is associated with a proportional decrease of the maximal stimulation of in inhibiting adenylate cyclase  $(3.5~\mu\text{M})$  and in stimulating GTPase (1 µM) are slightly increased (two-three fold) by DFP treatment. Occupancy of striatal dopamine (DA) receptors by DA causes activation of adenylate cyclase and GTPase. At maximal concentrations of each agonists (100 µM) the stimulation of GTPase by DA is additive with that elicited by Ach. When the DA-activated adenylate cyclase increases after unilateral lesioning of the nigrostriatal pathway with 60HDA, the DA-stimulated GTPase activity becomes supersensitive. The supersensitivity is characterized by 80% increase of the maximal GTPase activation by DA with no significant changes of the  $\mathbb{RC}_{50}$  of DA (1.8 $\mu$ M)These results indicate that alterations of the central neurotransmission in vivo elicit changes in the responses of GTPase to neurotransmitters which parallel those of adenylate cyclase.

DIFFERENTIAL MODIFICATION OF THE INHIBITORY EFFECTS OF GTP, 26.5 GPP(NH)P AND GTPYS ON FORSKOLIN-STIMULATED ADENYLATE CYCLASE.

GPP(NH)P AND GTPyS ON FORSKOLIN-STIMULATED ADENYLATE CYCLASE. M.M. Smith\* and T.K. Harden. Dept. of Pharmacology, Univ. North Garolina Sch. Med., Chapel Hill, NC 27514. Opiate, alpha2, and muscarinic receptor-mediated inhibition of adenylate cyclase (AC) apparently occurs through an inhibitory guanine nucleotide regulatory protein (N<sub>i</sub>). We have previously reported that relatively low concentrations of N-ethylmaleimide (NEM) blocks inhibitory coupling of these three receptors to AC in membranes from NG108-15 neuroblastoma x glioma cells, without affecting receptor-mediated stimulation. Experiments have been carried out to determine if the effect of NEM occurs at the level of N<sub>i</sub>. Forskolin-stimulated AC activity is inhibited in a concen-tration-dependent manner by guanine nucleotides, and this effect has been proposed to be an expression of N<sub>i</sub> activity (J. Biol. tration-dependent manner by guanine nucleotides, and this effect has been proposed to be an expression of N<sub>1</sub> activity (J. Biol. Chem. <u>257</u>:14723, 1982). In membranes from NG108-15 cells, for-skolin-stimulated AC was inhibited by GTP, Gpp(NH)p, and GTPyS by 35%, 50%, and 50%, respectively. The corresponding  $K_{0.5}$  values were 300 nM, 10 nM, and 3 nM. Subsequent to NEM treatment, GTP stimulated, rather than inhibited, forskolin-stimulated AC acti-vity. The concentration effect curve for NEM-induced blockade of the inhibitery activity of CTP, we the came of for NEM-induced the inhibitory activity of GTP was the same as for NEM-induced Interimitation activity of GIP was the same as for NEM-induced blockade of alpha2, opiate, and muscarinic receptor-mediated inhi-bition of AC. In contrast to the effect of NEM on GTP-mediated inhibition, the inhibitory effects of Gpp(NH)p and GTPyS were not affected by NEM.

These results have been confirmed in another cell line, the cyc<sup>-</sup> mutant of S49 lymphoma cells, which apparently expresses N but lacks the stimulatory guanine nucleotide regulatory protein but lacks the stimulatory guanine nucleofide regulatory protein, G/F. GTP, Gpp(NH)p, and GTPyS inhibited basal and forskolin-stimulated AC activity of cyc<sup>-</sup> membranes with efficacies and poten-cies similar to those observed in NG108-15 membranes. NEM pre-treatment resulted in increased basal and forskolin-stimulated ac-tivities, but had no effect on 10 mM Mn<sup>++</sup>-stimulated activity. NEM blocked the inhibitory effect of GTP on forskolin-stimulated AC activity with the same concentration effect curve as was seen in NG108-15 membranes, but had no effect on Gpp(NH)p- or GTPyS-mediated inblition mediated inhibition.

These data are consistent with three conclusions: 1) NEM blocks inhibitory coupling of receptors to AC by an effect distal to the receptor-N, interface. II) Gpp(NH)p- and GTP $\gamma$ S-mediated inhibition of forskolin-stimulated AC are not equivalent to GTPmediated inhibition. III)  $\rm N_{1}$  mediates a tonic inhibition of AC as evidenced by the increase in activity in NEM pretreated cyc^ membranes. Supported by GM29536 and an Established Investigatorship of the American Heart Association.

CALMODULIN-STIMULATED ADENYLATE CYCLASE ACTIVITY IN BOVINE RETINA. 26.6 N. Muirhead\*, G. Treisman\*, P. Simpson\*, and M.E. Gnegy. Dept. Pharmacology, Univ. of Michigan Med. Sch., Ann Arbor, MI 48109 Ca<sup>2+</sup> and calmodulin (CaM)-stimulated adenylate cyclase (AC) has

its greatest activity in brain although AC in a few other tissues such as pancreas are slightly responsive to CaM. Retina is a CNS tissue with the advantage of having limited types of neurons and being responsive to varied lighting conditions. Retina also has a relatively pure population of dopamine (DA) D-1 type receptors that stimulate AC activity and that are responsive to changes in lighting. We find a high level of CaM-stimulated AC in retina lighting. with activity comparable to that of cerebral cortex. In addition, the ability of CaM to stimulate in bovine retina was responsive to lighting conditions in the same manner as DA stimulation of AC.

CaM-stimulated AC was found in both rat and bovine retina. AC was measured in retinal particulate preparations (27,000 x g) that were washed twice in a buffer containing 1.2 mM EGTA. Maximal stimulation was achieved by 5  $\mu$ g/0.2 ml (1.4  $\mu$ M) CaM. Stimulation was dependent upon CaM and was biphasic as a function of Ca<sup>2+</sup>. Maximal stimulation occurred at an effective Ca<sup>2+</sup> concentration of AC was stimulated a maximum of 5.5-fold in rat and 7-fold

in bovine retinal membranes. Stimulation of bovine AC by CaM was altered by the lighting conditions under which the retina was dissected. The sensitivity of AC to CaM was greatest when retinas were dissected under a red safety light in a darkroom. The apparent Ka  $(K_{\rm a}^{\rm app})$  for CaM was Sately light in a darkholm. The apparent Ka  $(K_{\rm a}^{\rm pp})$  for can was 40 nM and the apparent Vmax  $(V_{\rm a}^{\rm pp})$  was 184 pmol/min/mg protein. When retina was dissected under fluorescent lights the  $K_{\rm a}^{\rm app}$  for CaM was 80 nm and the  $V_{\rm max}^{\rm app}$  was 174 pmol/min/mg protein. In contrast, the lowest activity was found when the retinas were dissected in dim light. The  $K_{\rm a}^{\rm app}$  for CaM-stimulated AC was 141 nM and the  $V_{max}^{\rm app}$  was 103 pmol/min/mg protein. These results were duplicated when retinas were dissected under red light and then incubated in an oxygenated Krebs Ringer Buffer for 30 min in red, fluorescent or dim lighting. Lighting effects on DA-stimulated AC paralleled that of CaM-stimulated AC. In contrast, stimulation of AC by guaryl nucleotides was not affected by lighting. Under all of the lighting conditions CaM could increase the  $v_{\rm max}^{\rm ADP}$  of the DA-stimulated AC activity. This work is significant because there is a high activity of CaM-stimulated AC in retina and it can be physiologically regulated by light in a manner similar to that for DA-stimulated AC.

CALMODULIN-STIMULATED ADENYLATE CYCLASE ACTIVITY IS INCREASED IN 26.7 STRIATUM FROM CHRONIC HALOPERIDOL TREATED RATS. <u>G. Treisman\*,</u> <u>N. Muirhead\* and M.E. Gnegy</u>. Dept. Pharmacology, Univ. MI Med.

Sch., Ann Arbor, MI 48109 Chronic dopamine (DA) receptor blockade with haloperidol (HAL) results in behavior supersensitivity to dopaminergic agonists. We have previously shown that chronic HAL treatment results in a biochemical supersensitivity of striatal adenylate cyclase (AC) to DA. This change was accompanied by an increase in the endogenous  $Ca^{2+}$ -binding protein, calmodulin (CaM) in HAL membranes. In vitro CaM increased DA sensitivity of striatal AC. CaM directly activates AC in striatal membranes in a  $Ca^{2+}$ -dependent manner. We investigated whether factors that are known to affect the striatal AC beyond the DA receptor, CaM and guanyl nucleotides, have altered responses in DA supersensitive animals.

We and others have shown that two components of AC are present in striatal membranes, a CaM-stimulated component and a CaM-insensitive component. We first examined whether the CaM-stimulated AC activity was altered by chronic HAL. Male Sprague-Dawley rats were injected with 1 mg/kg HAL s.c. for 10 days and then withdrawn for 3 days. Control rats were injected s.c. with 0.1 ml vehicle (VEH). CaM-stimulated AC activity was measured in a striatal particulate preparation (27,000 x g) washed twice with buffer containing 1.2 mM EGTA. Membranes from HAL-treated animals were 3-fold more sensitive to CAM than the VEH-treated controls. Thi was demonstrated by a significant shift in ED50 from 300 ng in VEH-membranes to 100 ng in membranes from HAL animals.

Guanyl nucleotides are required for DA-stimulation of AC activity. We found previously that the CaM-stimulated component could be selectively activated by low GppNHp concentrations, but The productive of the caM-sensitive activity is stimulated by high GppNHp or GTP. We therefore examined the effect of guanyl nucleo-tides on striatal AC in VEH- and HAL-treated rats. We found that membranes from HAL animals showed nearly twice the activation by a low concentration of GppNHp (0.2 µM) than controls; 97% stimulation versus 56% stimulation. This concentration selectively activates the CaM-sensitive AC fraction. Stimulation by GTP and high concentrations of GppNHp, on the other hand, did not differ significantly in membranes from HAL- and VEH-treated animals.

These results demonstrate that chronic blockade of the DA receptor results in an increase in CaM-stimulated AC activity as well as an increase in the DA-stimulated AC activity. This may This may be due to a selective change in a CaM-sensitive component of striatal AC activity. Supported by MH36044-02. 26.8

CHOLINERGIC RECEPTOR-MEDIATED INHIBITION OF FORSKOLIN STIMULATED ADENYLATE CYCLASE IN THE INTACT HUMAN FIBROBLAST: DIVALENT CATION EFFECTS. R.H. Lenox<sup>1</sup>, D.A. Van Riper<sup>1\*</sup> and M. Absher<sup>2\*</sup>. <sup>1</sup>Neuro-science Research Unit, Dept. Psychiatry and <sup>2</sup>Dept. Medicine, Univ. of Vermont College of Med., Burlington, VT 05405 Regulation of adenylate cyclase (AC) enzyme system involves the interaction of multiple protein components including a catalytic subunit, a guanine nucleotide binding protein and a hormone recep-tor. Cholinergic inhibition of AC via a muscarinic receptor has been demonstrated in a number of tissues and cell types. Forskolin (FSK), a diterpine, has been shown to stimulate AC activity in (FSK), a diterpine, has been shown to stimulate AC activity in

tor. Chollhergic inhibition of AC via a muscarinic receptor has been demonstrated in a number of tissues and cell types. Forskolin (FSK), a diterpine, has been shown to stimulate AC activity in both intact cell and broken membrane preparations by an apparent direct interaction with the catalytic subunit. Ions and guanyl nucleotides can modulate AC activity in cell membrane preparations independent of interaction with hormone specific cell-surface receptors. Recently, Hoffman et al. (BBRC, 1981) reported that manganese (Mn++) could preferentially uncouple the  $a_2$  adrenergic receptors. Recently, Hoffman et al. (BBRC, 1981) reported that manganese (Mn++) could preferentially uncouple the  $a_2$  adrenergic receptor mediated inhibition of AC in human platelet membranes. As part of our investigation of receptor regulation of AC activity in intact human cells, we have initiated a series of studies examin-ing divalent cation effects in cultured human diploid fibroblasts which possess muscarinic receptors that inhibit AC activity in re-sponse to cholinergic stimulation. Human fetal lung fibroblasts (IMR-90) were cultured in Minimal Essential Medium with 10% Fetal Bovine Serum. 10<sup>5</sup> cells were see-ded into 35 mm culture dishes in 3.0 ml medium and incubated at 37°C in 5% C0<sub>2</sub>·95% air. At stationary phase cultures were labeled for one hour with 2 µCi [<sup>3</sup>H]adenine. Buffers for cation studies were supplemented with varying concentrations of either magnesium (Mg++), calcium (Ca++) or Mn++. The enzyme reaction was initiated by the addition of FSK ± carbachol and terminated after 10 min at 37°C. The [<sup>3</sup>H]cAMP formed was isolated using a modification of the sequential chromatography method of Salomon et al. (ACNR, 1979). Incubation dependent increase in CAMP production. Basal CAMP accumulation was unchanged by concentrations of Mg++ or Ca++(0.01-10 mM), but did increase in the presence of 1.0-10 mM Mn++. FSK stimulated cAMP accumulation was enhanced in the presence of high-er concentrations dependent antagonism of th activity.

ASCORBIC ACID DECREASES [<sup>3</sup>H]-DOPAMINE BINDING IN STRIATUM WITHOUT INHIBITING DOPAMINE-SENSITIVE ADENYLATE CYCLASE. <u>David W. Schulz\*</u> Mark H. Lewis, John Petitto\* and Richard B. Mailman (SPON: C. Mitchell). Biological Sciences Research Center and Depts. of 26.9 Psychiatry and Pharmacology, University of North Carolina School of Medicine, Chapel Hill, NC 27514

of Medicine, Chapel Hill, NC 27514 Ascorbate, which occurs in high concentration in cells of neural crest origin (e.g., the CNS and adrenal), is a chemical messenger candidate. One of the first non-biosynthetic biochemical effects ascribed to ascorbate in the CNS was its ability to inhibit dopamine stimulated adenylate cyclase (DA-ACase) in homogenates from striata of Long Evans rats (J. <u>Neurochem.</u> 28:663, 1977). Because of the importance of changes in *CAMP* concentrations in vivo, we investigated this phenomenon further. An improved adenylate cyclase assay based on reverse phase preparative high performance liquid chromatography (HPLC) (Schulz and Mailman, J. Neurochem. submitted) was used. After the usual incubation, the reaction is stopped by addition of SDS, heating, addition of 4.5% ZnSO<sub>4</sub>-10% Ba(OH)<sub>2</sub>, and centrifugation. The supernatant is subjected to automated preparative HPLC using a Waters Z-Module with a 10  $\mu$  C<sub>18</sub> reverse phase cartridge, and 0.15M sodium acetate-20% methanol (pH 5.0) mobile phase. The presence of nonradioactive cAMP in the enzyme incubation mitture allows the use of UV (254nm) monitoring to trigger fraction collection (via Isco FOXY® with Peak Separator) automatically. Using this method, we were unable to detect any inhibition of DA-ACase by ascorbate at concentrations as high as IMM, although 5.68 mM ascorbate inhibited basal adenylate cyclase activity by ca. 30% while not inhibitory effects of ascorbate on dopamine-stimulated adenylate cyclase occurred when using striatal homogenates from Sprague-Dawley or Long-Evans rats, or N.C. Roard of Health mice. However, ascorbate was found to decrease stimulated adenylate cyclase occurred when using striatal homogenates from Sprague-Dawley or Long-Evans rats, or N.C. Roard of Health mice. However, ascorbate was found to decrease significantly the binding of  $[{}^{3}H]$ -dopamine to striatal membranes. Thus, it appeared that the sites binding  $[{}^{3}H]$ -dopamine that are affected by ascorbate are unlikely to be the same ones coupled to adenylate cyclase. This hypothesis was supported by our finding that the profile of DA-ACase inhibition by cis-flupenthixol is unaltered in the presence of 5.68 mM ascorbate. Interestingly, as has been reported, 5.68mM ascorbate did not affect the binding of  $[{}^{2}H]$ -gpiperone to these striatal membranes. Although ascorbate may play a neuromodulatory role, it does not appear that its effects are mediated through effects on cAMP biosynthesis.

MODULATION OF CYCLIC AMP STIMULATED SLOW INWARD CURRENT IN A BURSTING NEURON BY A CALMODULIN ANTAGONIST, pH;, AND Ca<sup>++</sup>. <u>Rhanor Gillette and Daniel J. Green</u>. Neural and Behavioral Biology Program, Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801. Food stimuli induce prolonged and endogenously sustained burst episodes in feeding command neurons, the ventral white cells (VWCs), of the carnivorous marine snail <u>Pleurobranchaea califor-nica</u>. Such burst episodes drive multiple cycles of vigorous feeding motor output. The neuromodulatory action of appetitive chemosensory pathways on the VWCs is mimicked by treatments that elevate intracellular cyclic AMP (<u>J. Neurosci.</u>, in press; <u>J.</u> <u>Comp. Physiol</u>. 146:461), which is the presumed natural regulation of VWC excitability. Cyclic AMP potentiates a slow inward cur-rent that sustains the burst episode (Green and Gillette, this volume). We previously showed that the action of cyclic AMP is itself mimicked by the effects of treatments that slightly ele-vate intracellular pH and by the effects of the anti-calmodulin Phenothiazine drugs (<u>J. Neurophysiol</u>. 49:509; <u>Brain</u> Res., in press). These agents may act through Ca<sup>++</sup>-activated, pH sen-sitive phosphodiesterase activity (<u>Brain Res.</u>, in press). In order to assess the effects of those agents on cyclic AMP action, we measured the slow inward current response to iontophoretic pulses of 0.2 M cyclic AMP (pH 7.4) 5-10 seconds long caused a initial steep rise in inward current which peaked several seconds after the pulse and declined slowly over 30-60 seconds. Ionto-phoretic currents were adjusted to give a replicable response (I-2 nA peak) far below the cell's maximum. While the rate of rise, time to peak and peak amplitude of the response were stable over long periods, the period of decline was less stable. This over long periods, the period of decline was less stable. This last may reflect dephosphorylation processes in cyclic AMP regu-

last may reflect dephosphorylation processes in cyclic AMP regulation of inward current. The calmodulin blocker trifluoperazine, and intracellular alkalinization by 15 mM NH<sub>4</sub><sup>+</sup> salines both caused marked increases in rate of rise, time to peak, and peak amplitude of the cyclic AMP current response. Conversely, prolonged depolarization, spike discharge and attendant Ca<sup>++</sup> influx for 1-2 minutes caused reductions in those parameters of cyclic AMP responsiveness.

responsiveness. These data suggest that Ca<sup>++</sup> influx contributes to burst termination in part through regulation of cyclic AMP levels. These data are also consistent with the action of a Ca<sup>++</sup>-calmodulin activated PDE in mediating the effects of phenothiazines, pH and Ca<sup>++</sup>. Supported by NSF BNS 79-18329 to R. G. and PHS 5T32 GM07143 to D.J.G.

POSSIBLE ROLE OF CYCLIC GMP AND CYCLIC AMP IN MEDIATION OF MUSCA-26.11 POSSIBLE ROLE OF CYCLIC GMP AND CYCLIC AMP IN MEDIATION OF MOSCA-RINIC RESPONSES IN XENOPUS OOCYTES. N. Dascalt I. Lotant Y. Oron\* and Y. Lass. Dept. Physiol. Pharmacol., Sackler Sch. Med., Tel Aviv University, Ramat Aviv 69978, Israel. Acetylcholine (ACh) and other muscarinic agonists evoke a com-

Any University, Ramat Aviv 69978, Israel. Ariv University, Ramat Aviv 69978, Israel. Acetylcholine (ACh) and other muscarinic agonists evoke a com-plex response in <u>Xenopus</u> oocyte membrane, which consists of four components: a transient inward current, Dl, followed by a slow prolonged inward (D2) or/and outward (H) currents, accompanied by large current fluctuations (F). At high (usually=1µM) ACh con-centrations H is obscured by D2. The response components may be separated pharmacologically and on the basis of a seasonal vari-ation. Dl, D2 and F result from changes in Cl<sup>-</sup> conductance, H is a K<sup>+</sup> current. Dl and H are partially mimicked by extracellularly applied cyclic GMP (cGMP) and its analogs and inhibited by exter-nal cyclic AMP (cAMP) analogs (Kusano K., Miledi R., & Stinnakre J., J.Physiol., <u>328</u>:143(1982); Dascal N. & Landau E.M., Life Sci., <u>27</u>: 1423(1980); Dascal N. & Landau E.M., Proc.Natl.Acad.Sci.JUSA, <u>79</u>: 3052; Dascal N., Landau E.M. & Lass Y., in preparation). CGMP was injected intracellularly, by pressure, through a mic-ropipette, while the oocyte was voltage clamped using other two micropipettes. Injection of 0.6--10 pmoles of CGMP into the cells evoked large outward current accompanied by a conductance incre-ase and having reversal potential of -85 to -96 mV, which is clo-se to the K<sup>+</sup> equilibrium potential. This H-like response was in-hibited by external tetraethylammonium (TEA; 40mM) and thus was concluded to represent a K<sup>+</sup> current. Higher doses of CGMP elici-ted outward currents with less negative reversal potentials (-52 to -75 mV) or inward current superimposed on the plateau of the outward current evoked earlier by a lower cGMP dose.F-like cur-rent. When ACh was applied at the peak of CGMP-liduced H-like response, Dl and D2 were enlarged while H was suppressed. Exter-nally applied phosphodiesterase inhibitors reduced D1, D2 and H. Intracellular cAMP level decreased following ACh application by about 30%, with a kinetics which parallelle

ADRENALECTOMY MODIFIES NEUROTRANSMITTER-STIMULATED CYCLIC AMP 26.13 ACCUMULATION IN HIPPOCAMPAL SLICES. A.L. Harrelson<sup>\*</sup> and B.S. McEwen, The Rockefeller University, New York, NY 10021, and W. Rostene, INSERM, U.-55, Paris 75571 France (SPON: G.Dohanich). The hippocampus is the principal CNS target site for gluco-corticoid hormones. In order to more closely link steroid hormone action on hippocampus to events involving neurotransmitters, we have investigated the effects of adrenalectomy on the ability of various neuroactive substances to stimulate cyclic AMP (cAMP) accumulation in slices of rat hippocampus. Male rats 8-10 weeks old were bilaterally adrenalectomized under ether anaesthesia. Four to six days later, animals were decapitated, the brains were rapidly removed, and dissected hippocampus cut twice on a McIl-wain tissue chopper at  $325\mu$ m. Slices were pre-incubated in Krebs-Ringer buffer (pre-equilibrated with oxygen) for 60 min. at 37°C in a shaking water bath, then aliquoted into incubation tubes. After 12 minutes of stimulation with the appropriate agonist, the incubation was stopped with 10% TCA. After ether against, the introduction was storped with row taken the inding assay. Where indicated,  $30\mu$ m ZK 62,711 (Schering AG) was included in the incubation medium to inhibit phosphodiesterase activity.

Basal cAMP values were not different between adrenalectomized (Adx) and sham-operated or intact controls. Hippocampal slices (Adx) and sham-operated or intact controls. Hippocampal slices from Adx rats showed greater cAMP accumulation than controls with vasoactive intestinal peptide (VIP) at both 10nM and 100nM (levels of 315 pmoles cAMP/mg protein vs. 183 pmoles/mg protein for con-trols, p < 0.005, Student t-test). When ZK 62,711 was added to the medium, similar results were obtained. Cyclic AMP accumula-tion stimulated by isoproterenol (10µM) was increased in Adx rats (23.5 vs. 16.4, p < 0.005). There was no significant difference when slices were stimulated with adenosine, prostaglandin E1, forskolin, and with 30µM norepinephrine + 5µM propranolol (a protocol used to stimulate  $\alpha$ -receptors). Histamine-stimulated cAMP accumulation tended to be less in Adx rats. We conclude cAMP accumulation tended to be less in Adx rats. We conclude that adrenalectomy changes the response of hippocampal adenylate cyclase to several putative neurotransmitters; furthermore, the Adx effect is not due to a general increase in adenylate cyclase activity, since other adenylate cyclase agonists show no change after Adx, and the effect of one agonist (histamine) appears to change in the opposite direction. Future studies will examine the effects of steroid replacement in Adx animals, the biochemical mechanism responsible for the increase in cAMP accumu-lation, and the extent to which these changes are seen in other brain regions which concentrate glucocorticoids to a lesser extent than hippocampus.

26.12

THE ROLE OF CYCLIC AMP IN ADENOSINE-EVOKED SLOW POTASSIUM CURRENT IN XENOPUS OCYTES. I. Lotan\*, N. Daskal\*, Y. Oron\*, S. Gelerstein\*, S. Cohen\* and Y. Lass. (SPON: Z. Wollberg). Dept. Physiol. & Pharmacol., Sackler Sch. Med., Tel-Aviv University, Ramat Aviv 69978, Israel. The membrane of Xenopus laevis oocytes exhibits a complex response to application of adenosine: i) an early transient inward current (H) carried by C[ ii] a slow, steady outward current (H) carried by K' iii] a slow C1 inward current (D2), usually masked by H. The adenosine induced H current is selectively inhibited by theophylline. The potency sequence of purinergic agonists in eliciting the H-response is: 5'-N-ethylcarboxamide - adenosine > adenosine = AMP > ADP = ATP (Lotan I., Dascal N., Cohen S. and Lass Y., Nature, 298:572, 1982). The data suggest that the H response is mediated through the activation of a purinergic receptor belonging to R., or P. type which is supposed to exert its physiological effects through elevation of intracellular injection of 0.15-5 pmole cAMP (applied iontophoretically or by pressure) caused a dose-dependent outward K current similar to the adenosine induced H-response. Intracellularly injected AMP was almost ineffective even at very high doses. The adenosine induced H-response. Intracellularly injected AMP was almost ineffective even at very high doses. The adenosine induced H-response induced the calcularly and intracellularly applied phosphodiestrase inhibitors, which by themselves evoked a moderate outward K current, strongly enhanced the cAMP response. Intracellularly and intracellularly applied phosphodiestrase inhibitors, which by themselves evoked a moderate outward K current, strongly enhanced the call response intracellularly applied phosphodiestrase inhibitors (theophylline and IBMX) enhanced the cell response to adenosine. Preliminary

applied phosphodiestrase inhibitors (theophylline and IBMX) enhanced the cell response to adenosine. Preliminary measurements of cAMP showed an increase by 20-300% following adenosine application. These results suggest that the adenosine-induced K conductance increase in Xenopus oocytes membrane is mediated by elevation of cAMP level.

A CORTICOSTERONE SYNTHESIS INHIBITOR (METOPIRONE) RAPIDLY UP

REGULATES NORADRENALINE STIMULATED CYCLIC AMP FORMATION IN

HIPPOCAMPUS IN VIVO. V.J. Roberts and R.L. Singhal\*. Department of Pharmacology, University of Ottawa, Ontario, Canada. K1H 8M5 Beta adrenergic stimulation is known to produce a number of biochemical responses such as gluconeogenesis in liver and lipolysis in adipose tissue. These effects are mediated via adenylate cyclase stimulation and require the «permissive» effect of corticosterone (CORT). Recent evidence suggests that CORT modulates noradrenergic mechanisms in the brain as well. Mobley and Sulser (Nature, 286: 608, 1980) reported an increase in noradrenaline (NA) stimulated cyclic AMP (cAMP) production in rat frontal cortex 2 weeks following bilateral adrenalectomy. We reported (Neurosci. Abs. 93.8, 1982) a similar effect in rat hippocampus. In addition, we demonstrated that treatment with a CORT synthesis inhibitor (Metopirone) resulted in a substantial increase in NA-stimulated cAMP production in rat hippocampus. Tolerance to this effect developed within one week. Metopirone had no significant effect on the cAMP generating system in vitro. In order to characterize this modulation further the time course of the effect was examined and various in vitro manipulations were performed. Male Wistar rats (200 g) received a 50 mg/kg i.p. injection of Metopirone 1, 2 or 4 hours prior to sacrifice. Control animals received an equal volume of the vehicle (40%propylene blycol in water). The hippocampi from 3 rats were pooled and sliced. The slices were pre-incubated for 20 min then incubated for 40 min in the presence of ('H) adenine to lable ATP stores. Adenylate cyclase was stimulated by the addition of 0, 1, 10 or  $100\mu$  NA for 10 min. For in vitro experiments agents were added to and remained in the medium during all incubations (Total time = 1 hr). While Metopirone treatment had no significant effect on cAMP production after 1 hour, a significant elevation in NA-stimulate cAMP formation did occur 2 hours following In order to characterize this modulation further the time course in NA-stimulated cAMP formation did occur 2 hours following Metopirone treatment. A slight but non-significant elevation remained at 4 hours. This effect parallels the CORT synthesis inhibiting effect of Metopirone as determined by serum CORT levels. The addition of CORT to the incubation medium did not nevels. The addition of GAR to the incubation meanum dia not modify CAMP production in hippocampal slices from treated animals. In addition, two in vitro CORT antagonists, 11-Deoxycortisol and progesterone, did not alter CAMP production in hippocampal slices from control animals. A longer incubation may be necessary to observe an effect. While we have hypothesized a direct modulation of CORT on NA-stimulated cAMP production, the in <u>vitro</u> data underscores the possibility that the observed increase in cAMP formation may be due to secondary changes such as increased ACTH levels. (Supported by grants from the OMHF and the MRC).

26.15 THE EFFECTS OF MUSCLE MEMBRANE ACTIVITY AND NERVE-CONDITIONED MEDIA ON CAMP and CGMP LEVELS IN CULTURED MOUSE MYOTUBES, J.A. Powell\*, L.J. Standish\* and E.S. Swearengen\* (SFON: D. Fambrough). Clark Science Center, Smith College, Northampton, MA 01063. Cyclic nucleotides have been implicated in the mechanism by which both muscle activity and neurotrophic factors modulate the metabolism of acetylcholine receptors in skeletal muscle (Betz, H. and Changeux, J., Nature, 278: 748, 1979; Powell, J.A. and Glenn, C. J. Cell Biol., 95: 357a, 1982). We have investigated both the short and long term effects of muscle activity on cyclic nucleotide levels in cultured mouse myotubes. Short term activity was \* monitored by initiating contractions in quiescent muscle (12 mM K\* or TTX treated) by addition of serum-free medium (normal K\*, 5 mM). Cultures were harvested at short intervals up to 120 min. Cyclic nucleotides were extracted from homogenates and measured by a radio immune assay. Long term activity was monitored in active or quiescent (TTX or high K\* treatment) muscle maintained in complete medium for 1 to 8 days. Long term muscle activity had little effect on cAMP steady-state levels relative to that in quiescent muscle. However, CCMP concentrations were elevated 1.5 to 5 fold in active muscle. Short term muscle activity produced a coordinate surge (up to 14 fold of "quiet" steady-state levels), peaking at 5-30 min following onset of contractions, and returning near to "active" steady-state levels by 120 min.

The short and long term effects of action potential generation on cyclic nucleotide levels in dysgenic (mdg/mdg) muscle (which fires action potentials in the absence of contractions) were similarly assayed. Changes in cyclic nucleotide levels were modulated in the membrane-active dysgenic muscle in an equivalent fashion to that observed in normal, active, contracting muscle.

Neurotrophic effects were assessed by measuring cyclic nucleotides in normal and dysgenic cultures maintained for several days in media conditioned by nerves (14 day spinal cord cells) or mature muscle. No significant differences were found in cAMP levels in muscle treated in these two ways, while nerve-conditioned medium produced a two fold elevation in CGMP levels relative to levels in myotubes maintained in muscle-conditioned medium.

In summary, our findings suggest that 1) the influence of muscle activity on cyclic nucleotide levels is mediated via action potential generation and that both cAMP and cCMP are transiently increased by brief periods of such activity, and 2) cGMP is relatively more affected by, and therefore involved in, the longer term effects of either membrane activity or neurotrophic influence.

(Supported by grants from NIH 16681 and the Smith CollegeBlakeslee Fund.)

26.16 MUSCARINIC CHOLINERGIC RECEPTOR-MEDIATED REDUCTION IN CYCLIC AMP ACCUMULATION OCCURS BY TWO MECHANISMS IN A SINGLE CELL. L.I. Tanner\* and T.K. Harden. (SPON: R.L. Glasser) Neurobiology Program and Dept. Pharmacology, Univ. North Carolina, School of Medicine, Chapel Hill, NC 27514.

Cline, Chapel Hill, NC 2/514. Activation of muscarinic cholinergic receptors (MR) results in a decrease in PGE\_-stimulated cyclic AMP accumulation in intact WI-38 fibroblasts (R.W. Butcher, J.Cyclic Nucleotide Res. <u>4</u>:411, 1978). The purpose of the present study was to further characterize the mechanisms responsible for this MR-mediated decrease in cyclic AMP levels. The MR agonist oxotremorine (OXO) inhibited PGE<sub>1</sub>- and isoproterenol-stimulated cyclic AMP accumulation by 60-70% in intact cells. This effect appeared to be due in part to activation of phosphodiesterase (PDE) since in the presence of the PDE inhibitor 3-isobuty-1-methylxanthine, MR-mediated inhibition was reduced to 40%. Similar results were obtained with another PDE inhibitor, Ro20-1724. Direct evidence for MR-mediated activation of PDE was obtained. That is, in the presence of OXO the rate of degradation of cyclic AMP was increased from 0.24 min<sup>-1</sup> to 0.50 min<sup>-1</sup>. This effect of OXO was blocked by a PDE inhibitor.

In addition to PDE activation, OXO also decreased cyclic AMP accumulation by inhibition of adenylate cyclase (AC). The evidence for this effect was two-fold. First, the effect of MR activation in intact cells was only partially attenuated by maximally effective concentrations of a PDE inhibitor. Second, MR-activation inhibited PDE<sub>1</sub> - and isoproterenol-stimulated AC activation of MR of WI-38 fibroblasts reduces cyclic AMP accumulation by an activation of PDE as we have demonstrated previously in 1321N1 human astrocytoma cells (MOI. Pharmacol. 22:310, 1982) and by inhibition of AC as has been demonstrated through a common population of MR or through separate MR subtypes remains to be determined. Supported by GM-29556 and Established Investigatorship of the American Heart Association.

26.18 A NEW PHOTOACTIVATED cAMP ANALOGUE AND ITS EFFECT ON THE SLOW INWARD CURRENT IN HEART. J. Nerbonne, J. Nargeot, and H. A. Lester. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Technology, Pasadena, CA 91125. Previously, we reported that the photolabile analogue of cAMP, o-nitrobenzyl cAMP, could be utilized to produce step changes in intracellular cAMP in heart (Nargeot et al., Proc. Natl. Acad. Sci. 80, 2395-2399 (1983)). In voltage-clamped, TIX-treated atrial trabeculae from bullfrog, this compound is physiologically inert at concentrations up to 100  $\mu$ M. Flashinduced concentration jumps of CAMP increase the slow inward current (carried principally by calcium ions). The amplitude of the effect is dependent on the absolute magnitude of the cAMP concentration jump: at 30  $\mu$ M o-nitrobenzyl cAMP, a single light flash produces a cAMP jump of 0.75  $\mu$ M, increasing the slow inward current by 50%. The increase is linear with time and the effect reaches a maximum in 30-40 sec. In very stable preparations, a 2% increase in the slow inward current can be detected within 150 msec after the light flash.

In order to extend the useful concentration range of intracellular cAMP jumps accessible with this methodology, we have designed and synthesized 3,4-dimethoxy-6-nitrobenzyl cAMP. We find that this new photolabile analogue, under the same experimental conditions used for o-nitrobenzyl cAMP, releases cAMP with twice the efficiency of the parent compound. The chemical reactions leading to photorelease for this derivative are complete within at most 5 msec. In voltage-clamped bullfrog atria in the absence of light, this derivative causes no change in the amplitude or the waveform of the slow inward current at concentrations up to 120  $\mu$ M. A single light flash in the presence of 50  $\mu$ M 3,4-dimethoxy-6-nitrobenzyl cAMP, however, increases the amplitude of the slow inward current is linear with time for the first 10 sec and the response reaches a maximum in 20-25 sec. Simultaneous measurements of the phasic contraction show that a light flash results in a threefold increase in the phasic tension over 20-25 sec (agreeing with the time course and the magnitude of the effect on the slow inward current). The response latency following single light flashes as well

The response latency following single light flashes as well as experiments employing the 3,4-dimethoxy-6-nitrobenzyl ester of cGMP will be discussed.

26.17 INVOLVEMENT OF CYCLIC NUCLEOTIDES IN AMINE AND PEPTIDE MODULATION OF THE <u>LIMULUS</u> HEART. <u>J.R. Groome\* and W.H. Watson</u>, <u>III</u> (SPON: S. Reingold). Dept. of Zoology, UNH, Durham, NH 03824.

The neurogenic heart of the horseshoe crab (Limulus polyphemus) is a simple system modulated by several amines and the pentapeptide proctolin (Watson, W.H., Augustine, G.J., Peptides, 3:485, 1982). Dopamine has positive inotropic and chronotropic effects on the heart (Augustine, et al., J. <u>Neurobiol.</u>, 13:61, 1982); proctolin only increases the strength of heart contractions (Watson, et al., J. <u>Exp. Biol.</u>, 103:55, 1983). The extraordinary <u>in vitro</u> viability of the <u>Limulus</u> heart coupled with the presence of large identifiable neurons in the cardiac ganglion have facilitated determination of the site of action of these compounds. However, the molecular mechanisms underlying their action remains uncertain. The slow onset and long duration of the effects produced by dopamine and proctolin suggests that cyclic nucleotides play a role in this process. Several experiments utilizing radioimmunological, pharmacological, and electrophysiological techniques have provided direct evidence for this hypothesis.

proctolin suggests that cyclic nucleotides play a role in this process. Several experiments utilizing radioimmunological, pharmacological, and electrophysiological techniques have provided direct evidence for this hypothesis. Levels of CGMP increase transiently in cardiac muscle following application of 10<sup>-6</sup>M proctolin (10-fold increase) or 10<sup>-5</sup>M dopamine (5-fold increase); while ganglion cGMP levels are not markedly affected. Dopamine also appears to increase levels of cAMP in the ganglion as well as in the muscle. Pharmacological elevation of intracellular cyclic nucleotide levels elicits a change in the cardiac rhythm that mimics the effect of dopamine application. Forskolin, an activator of

Pharmacological elevation of intracellular cyclic nucleotid levels elicits a change in the cardiac rhythm that mimics the effect of dopamine application. Forskolin, an activator of adenylate cyclase (Seamon et. al., <u>PNAS</u>, <u>78(6)</u>:3363, 1981) increases the rate and amplitude of heart contractions in a dose-dependent manner (threshold, saturation). Forskolin  $(10^{-0}M)$ ) also increases the burst frequency of the isolated ganglion 80%, probably as a result of its action on the pacemaker cells. IBMX (3-isobutyl 1-methyl xanthine), an inhibitor of phosphodiesterase, also increases contraction amplitude and rate. It is approximately two log units less potent than Forskolin.

These findings indicate that cyclic nucleotides are involved in amine and peptide modulation of the <u>Limulus</u> heart and confirm previous reports that dopamines act directly on the cardiac ganglion neurons while proctolin exerts its effects on the cardiac muscle.

ELECTROPHYSIOLOGICAL AND BIOCHEMICAL CORRELATES OF DEVELOPMENTAL LEAD TOXICITY IN RAT RETINA. <u>D.A. Fox and D.B. Farber</u>. College of Optometry, Univ. Houston, Houston, TX and Jules Stein Eye Instit., UCLA Sch. Med., Los Angeles, CA. Low-level developmental lead (Pb) exposure produces toxic amb-26.19

Low-level developmental lead (Pb) exposure produces toxic amb-lyopia in adult rats with greater spatial vision deficits observed under scotopic (rod-mediated) than photopic (cone-mediated) lum-inance conditions (Fox and Wright, Neurosci. Abs. 8:81,1982). <u>In</u> <u>vitro</u> electrophysiological studies, in isolated bullfrog retinas, reveal that low-level Pb depresses the amplitude of the rod, but not cone, photoreceptor potential (Fox and Sillman, Science 206: 78,1979). To determine if rod and/or cone photoreceptors were pre-ferentially altered in adult rats following developmental Pb ex-posure, electroretinographic (ERG) and retinal cyclic nucleotide metabolism studies were conducted. Female Long-Evans hooded rats were exposed to Pb (or no Pb) from parturition to weaning (days 0-21) via the milk of dams drinking 0.2% Pb acetate solution (or water). ERGs were recorded in anesthetized rats at 4 levels of luminance, scotopic to photopic, and the V-log I relationships were determined. The a-wave amplitude, which represents the photo-receptor response, was decreased 35% under photopic conditions receptor response, was decreased 35% under photopic conditions and greater than 50% under scotopic conditions. The b-wave was and greater than 50% under scotopic conditions. The b-wave was decreased 20% under photopic conditions and over 35% under sco-topic conditions. Thus, the ERG data reveals a preferential rod-mediated effect of Pb. Next we investigated, in litter-mates, whether there were changes in the retinal CGMP system (mainly as-sociated with rod photoreceptors) and/or the CAMP system (mainly as-sociated with cone photoreceptors) related to the ERG effects. In vivo, Pb caused cGMP levels in dark-adapted and light-adapted retinas to increase 40% and 25%, respectively, above controls whereas CAMP levels remained unchanged. Light-activated cGMP-phosphodiesterase (PDE) showed similar kinetics in control and Pb exposed tissue, but the Vms of the latter was decreased. At exposed tissue, but the V<sub>max</sub> of the latter was decreased. At 10<sup>-4</sup>M substrate, cGMP-PDE was inhibited 40%. In Pb-retinas, guanylate cyclase was activated by 20%. To verify the effects of Pb on cyclic nucleotide enzymes we performed in vitro retinal studies with adult control retinas incubated with different con-Scuales with adult control retinas included with different con-centrations of Pb. In vitro, a dose-response inhibition (10-40%) of cGMP-PDE occurred with 10<sup>-6</sup> to 10<sup>-4</sup>M Pb. Guanylate cyclase was activated 120-250% by 1 to 5 X 10<sup>-4</sup>M Pb. Thus, the in vivo ef-fects were confirmed in vitro. The effects of Pb on the retinal cGMP system show that developmental Pb exposure selectively dis-verte and between this result is consistent with the cump system show that developmental polexposure selectively ans-rupts rat rod photoreceptors. This result is consistent with the preferential rod-mediated deficits we observed in this study with the ERG and in previous electrophysiological and psychophysical studies in adult rats following developmental Pb exposure. Sup-ported by ES 03183 (DAF), EY 02651 and RCDA EY 00144 (DBF).

26 PO MORPHINE: A NEW SITE OF ACTION IN PURINE NUCLEOSIDE PATHWAYS. M.L. Cohn, M. Cohn, J. Larrinaga\*, D. J. Wooten\*, J. Samora\* and G. Fernandez\*. Dept of Anesthesiology Research, C.R. Drew Med Sch,

Los Angeles, CA 90059. In 1977, we reported the potent central analgetic properties of the dibutyryl analog of guanosine 3':5' monophosphate (dbcGMP). Although morphine has been shown to increase cGMP concentrations in rat brain structures and rat brain slices, the relationship between the pharmacologic actions of morphine and brain levels of cGMP is not well understood. Based on our analytical evidence which increasingly suggested that in addition to cGMP, one or several of its metabolic products may be involved in the biochemical processes regulating analgesia, we investigated here the effects of morphine on cGMP metabolism. Sprague-Dawley male rats were divided into three groups. Rats of control and second group were injected IP with saline 0.9% and morphine (1.7mg/kg) respec-tively and sacrificed 2 hrs later. Rats of third group were adtively and sacrificed 2 hrs later. Rats of third group were ad-dicted to morphine (100mg/kg--in slow releasing preparation of Collier et al., 1972) injected SC once a day for 2 days and sacrificed on 3rd day. Brain slices were incubated in tonometer at  $37^{\circ}$ C with Krebs-Ringer bicarbonate/glucose buffer, pH 7.35, a constant flow of  $0_2/CO_2$  (20:5) and 2.90 x 10-1 mM of standard cGMP. Sequentially withdrawn aliquots of incubation mixture were analyzed by high performance liquid chromatography (HPLC). In control rats, primary metabolic products user CMP analyzed by high performance liquid chromatography (HPLC). In control rats, primary metabolic products were GMP, guanosine (GUS), guanine, xanthine, and inosine. After the first 10 min of incubation, cGMP catabolism resulted in accumulation of GUS, sug-gesting that GUS nucleoside phosphorylase may be a regulatory enzyme and that, like adenosine, GUS may be active in physiolo-gical processes. Appearance of inosine on chromatograms agreed with our earlier reports of GMP reductase activity in rat brain slices. In IP merbine treated price accention of a GUS. slices. In IP morphine treated rats, concentrations of GUS were significantly increased over control values at the 30 and 60 min significantly increased over control values at the 30 and 60 min of incubation. Most striking, however, were GUS concentrations in rats addicted to morphine with accumulations 2 to 3 fold higher than control values at 30 and 60 min of incubation. In both groups of rats treated with morphine CGMP metabolism resulted in accumulation of inosine. Morphine ( $1.46 \times 10^{-2}$  mM) added to in-cubation of brain slices of untreated rats, with CGMP as sub-strate, produced GUS and inosine accumulations similar to those observed in rats treated IP with morphine. Noticeable also are our findings that morphine ( $1.46 \times 10^{-2}$  mM) added to incubation of standard GUS with GUS nucleoside phosphorylase resulted in ac-cumulations of GUS which were significantly increased over con-trol values. Therefore, the inhibition of GUS nucleoside phos-phorylase by morphine in rat brain slices was reproduced in a GUS incubation mixture containing the enzyme preparation. Supported by NIH/MBRS Grant No. RR0809-11.

26.PO DIFFERENT EFFECTS OF ADENOSINE ON CYCLIC AMP REGULA-TION IN RETINA AND BRAIN. K.M. Campau<sup>\*</sup>, D.A. Kinscherf<sup>\*</sup>, and J.A. Ferrendelli (SPON: D.B. McDougal, Jr.). Dept. of Pharmacology, Washington Univ. Med. Schl., St. Louis, MO 63110. Adenosine is a well known regulator of cyclic AMP levels in mammalian brain. This nucleoside increases cyclic AMP levels several fold and also greatly enhances the stimulatory effect of norepinephrine on cyclic AMP concentrations in incubated slices of brain. Indirect evidence suggests that adenosine is a major factor non-epinepinnie on cyclic AMF concentrations in incubated slices of brain. Indirect evidence suggests that adenosine is a major factor regulating levels of cyclic AMF in brain, in vivo. This study was carried out to determine whether adenosine has similar effects on cyclic AMF in mammalian retina.

Normal retinas were obtained from young adult C57BL/6J mice Normal retinas were obtained from young adult C57BL/63 mice. Animals were either light- or dark-adapted for one hour, killed by decapitation, and their retinas removed in the light or under dim red light illumination. The isolated retinas were then preincubated in buffer containing 120 mM NaCl, 5 mM KCl, 1.8 mM CaCl<sub>2</sub>, 0.8 mM MgSO<sub>4</sub>, 26 mM NaHCO<sub>3</sub>, 0.9 mM NaH<sub>2</sub>PO<sub>4</sub> and 10 mM glucose saturated with 95% O<sub>2</sub>-5% CO<sub>2</sub> at 37° for 30 min. Following this the tissue was exposed to various agents or other conditions, as indicated below; then the buffer was removed and the tissue was indicated below; then the buffer was removed and the tissue was treated with trichloroacetic acid and analyzed for cyclic AMP concentration

Isobutylmethylxanthine (IBMX) (1 mM), dopamine (100  $\mu M$ ), and norepinephrine (100  $\mu M$ ) all increased levels of cyclic AMP 1 - 2fold in normal light-adapted retina, but adenosine (100  $\mu$ M) had no effect. The combination of adenosine with norepinephrine with or without IBMX also failed to demonstrate a stimulatory effect of adenosine on cyclic AMP levels. Adenosine, however, did slightly augment dopamine-induced elevations of cyclic AMP levels in the presence of IBMX in light-adapted retinas. In dark-adapted reti-nas IBMX increased cyclic AMP levels more than those in lightadapted retinas, and dopamine caused an additional elevation. Adenosine did not affect any of these changes. Dopamine in com-bination with IBMX increased levels of cyclic AMP almost 40-fold in dystrophic (receptorless) retinas, but adenosine had no effect in this tissue either. In contrast to the findings in retina, adenosine (100  $\mu$ M) increased levels of cyclic AMP 6 - 10-fold in slices of stri-atum from C57BL/6J mice. This effect was inhibited by IBMX and augmented by norepinephrine and dopamine.

These results demonstrate that adenosine has little or no effect on cyclic AMP levels in incubated mouse retina and suggest that adenosine-sensitive adenylate cyclase is absent in this tissue. results indicate that regulation of cyclic AMP levels in brain is under different control than that in retina. Supported, in part, by USPHS Grant EY-02294. The

- 26.PO A SUPPRESSION OF DARK IBMX-ENHANCED CYCLIC AMP LEVELS OF INCU-A SUPPRESSION OF DARK IMMX-ENHANCED CICLIC ANP LEVELS OF INCU-BATED MOUSE RETINAS BY 5-METHOXYTRYPTAMINE. A.I. Cohen. Dept. of Ophthalmology, Washington Univ. Med. Sch., St. Louis, MO 63110. When incubated C57BL/6 mouse retinas were exposed to 1 mM IBMX, cyclic AMP levels rose 6.4 fold over those of control ret-inas in IBMX-free medium for dark-adapted, dark-incubated retinas Has in 1954 free mediam for light-adapted, light-incubated retinas, but only 4.5 fold for light-adapted, light-incubated retinas. However, if the medium included 10  $\mu$ M - 100  $\mu$ M 5-methoxytryptamine (5 MTA), dark cyclic AMP levels were held to values identical to those obtained with light-adapted, light-incubated retinas in IBMX media with or without 5 MTA. No effect on dark cyclic AMP levels in IBMX medium was obtained with 100  $\mu M$  serotonin, melatonin, or 5-methoxytryptaphol. In addition, when dark-incubated retinas which lack rod photoreceptors were used from dark-adapted The second secon well-known more vigorous production of cyclic AMP. SOME STEROID HORMONE CONCENTRATING CELLS IN THE MEDIAL BASAL HYPO-THALAMUS (MBH) AND ANTERIOR FITUITARY CONTAIN **6**-ENDORPHIN OR DYNORPHIN. J. I. Morrell, J. McGinty<sup>1</sup> and D. W. Pfaff. The Rockefeller University, New York, NY 10021. <sup>4</sup>East Carolina University, School of Medicine, Greenville, NC. Steroid hormone receptors located in particular brain and pitu-itary cells may be involved in the regulation of the genome of these cells, ultimately resulting in altered protein production. Steroid autoradiography has revealed the number and distribution of steroid hormone concentrating cells; immunocytochemistry has revealed the number and distribution of cells containing endose revealed the number and distribution of cells containing endogenous opiates. These distributions overlap. Levels of endogenus opiates in brain and pituitary vary over the estrus cycle, and in response to steroid hormones, including estradiol (E2) and dexamethasone (dex). We applied the combined steroid autoradiographic-immunocytochemical method (Morrell & Pfaff, Methods in Enzymology, 1983) to ask the question: Do E2 or dex concentrating cells contain endogenous opiates?

cells contain endogenous opiates? Eighteen adult, (9 colchicine pretreated,  $50\mu g/2\mu l$ , I.C.V.) ovariectomized, adrenalectomized female rats were given either . $8\mu g/250g$  of  ${}^{3}H-E_{2}$  (S.A. 100Ci/mM) or  $10\mu g/100gm$   ${}^{3}H-dex$  (S.A. .38Ci/mM) I.P.; 1-2 hrs later perfused with saline, then 4% para-formaldehyde. After a 24 h 30% sucrose soak, the tissue was fro-zen in freon chilled by nitrogen, and steroid autoradiograms were prepared. After exposure times of 2 to 12 months the autoradio-runn var photochogelocae fined end immenutable immenutable immenue the fit of the second secon prepared. Alter exposure times of 2 to 12 months the autorado-grams were photodeveloped, fixed and immunocytochemistry was car-ried out on the autoradiograms using primary antibodies to  $\beta$ -endorphin or dynorphin (gifts of R. Benoit, Salk Inst.; L. Terenius, Uppsala, Sweden) and either the PAP or ABC method with DAB for visualization. As expected, using the combined method we found many E2 concentrating cells in the MBH; many  $\pmb{\beta}$ -endorphin and The many dynorphin containing neurons were also found in the MBH, in-cluding within the arcuate and the region lateral to it, but ven-tral to the ventromedial nucleus. Of the  $\beta$ -endorphin containing neurons, about 4% concentrated E2; about 6% of the dynorphin conneurons, about 4% concentrated E2; about 6% of the dynorphin con-taining neurons concentrated E2. In the anterior pituitary, a few cells that contained  $\beta$ -endorphin concentrated E2. This is in con-trast to the results from the anterior pituitary of animals admin-istered  $\beta$ -dax; may  $\beta$ -endorphin containing anterior pituitary cells concentrated dex.

These data are consistent with the hypothesis of a genomic effect of E<sub>2</sub> on a particular subset of MBH neurons that produce endogenous opiates. In the anterior pituitary dex decreases the levels of pro-opiomelanocortin (POMC) m-RN4 (Schachter et al., Endo., 110: 1442-4). This regulation could result from the stematic product of the statement of the statemen torid acting thru autoradiographically localizable nuclear recep-tors in POMC-producing pituitary cells. Supported by HD 16327.

27.3 PROTEIN CARBOXYL METHYLATION IN POSTERIOR PITUITARY LOBE OF SALT

PROTEIN CARBOXYL METHYLATION IN POSTERIOR PITUITARY LOBE OF SALT TREATED, PITUITARY STALK SECTIONED AND BRATTLEBORO RATS. J.M. Saavedra and Y. Kloog\*. Section on Pharmacology, Lab. of Clinical Science, NIMH, Bethesda, Md. 20205, USA. Enzymatic methylation of free carboxyl groups of proteins is catalyzed by protein carboxyl-0-methyl transferase (E.C.2.1.1.24) Enzyme activity and levels of endogenous methyl acceptor pro-teins are very high in the posterior pituitary gland. Protein carboxyl methylase was postulated to play a role in the neuro-secretory process, which involves the exocytotic release of neurohypophyseal peptides and their corresponding neurophysins. Although neurophysins are good substrates for protein carboxyl Although neurophysins are good substrates for protein carboxyl methylase <u>in vitro</u>, the actual methylation of proteins in pos-terior pituitary has not been demonstrated. The Brattleboro rat is derived from the Long Evans strain, and presents genetic deficits in the formation of vasopressin and

presents genetic deficits in the formation of vasopressin and neurophysin-associated vasopressin. Homozygous Brattleboro rats are unable to synthesize these peptides and show a chronically increased stimulation of the hypothalamo-neurohypophyseal axis. Alterations in protein carboxyl methylation are selectively pres-ent in the posterior lobe of homozygous Brattleboro rats. Pos-terior lobe homogenates from male homozygous Brattleboro rats in-cubated in the presence of the natural methyl donor, S-adenosyl-L-methionine, show higher protein carboxyl methylase activity (+40%) and lower endogenous methyl acceptor protein capacity (-80%) than control heterozygous Brattleboro or Long Evans rats. This latter change is correlated with decreased methylation of This latter change is correlated with decreased methylation of proteins of a molecular weight of approximately 11,000, similar to that of neurophysins, as determined by polyacrylamide gel electrophoresis.

electrophoresis. Whole posterior pituitary lobes from control rats can enzymat-ically form protein carboxyl methyl esters using methionine as a precursor. At least six proteins are methylated in the intact posterior lobe. Among these is neurophysin, identified by its characteristic properties: molecular weight, [<sup>35</sup>S]-cysteine labelling, disappearance after salt loading or pituitary stalk section and low levels in homozygous Brattleboro rats. In addi-tion to neurophysin, four other still unidentified proteins are methylated in the hypothalamo-hypophyseal nerve endings, as in-dicated by their disappearance after pituitary stalk section. These results indicate that genetically (Brattleboro model) or experimentally induced (salt loading) stimulation of the neurohy-

experimentally induced (salt loading) stimulation of the neurohy-pophyseal tract result in specific alterations in posterior pitu-itary protein carboxyl methylation. Our results support the hypothesis of a role for protein carboxyl methylation in the neuro-secretory activity of the posterior pituitary, probably related to a modulation of the exocytotic release process in this organ.

INTERMEDIATE FILAMENTS OF THE NEONATAL AND ADULT HUMAN PITUITARY: 27.2 AN IMMUNCHI STOCHEMICAL STUDY WITH ANTI-NEUROPILAMENT AND ANTI-GLIAL FILAMENT MONOCLONAL ANTIBODIES. J.Q. Trojanowski, D. Gordon\* M.A. Obrocka\* and V.M.-Y. Lee\*. Div. of Neuropathology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19147. Normal pituitary glands from adults and neonates were obtained at autoney and immersion fixed in either Powing fixed in or in

at autopsy and immersion fixed in either Bouin's fixative or in 4% mercuric chloride/8% formaldehyde. After paraffin embedding, affixed to glass slides. Sections were prepared from each pituitary and affixed to glass slides. Sections were deparaffinized, endogenous peroxidase activity was quenched with methanol/hydrogen peroxide and monoclonal antibodies which recognize either neurofilament (NF) or glial filament (GF) proteins were applied to each section. Immunoreactive NF or GF were then localized using the peroxidase anti-peroxidase immunohistochemical method. Peroxidase was visualized with diaminobenzidine as the chromogen in medium containing imidazole and hydrogen peroxide. Sections lightly counterstained with hematoxylin were dehydrated, cover slipped and examined. Controls included sections incubated with supernatant from un-fused parent mouse myeloma cultures and similarly prepared sections of normal rat cerebellum treated with the same monoclonal antibolies or mouse myeloma supernatant. Immunoreactive NF was present as linear or punctate profiles in the neurohypophysis, present as linear or punctate profiles in the neurohypophysis, consistent with an intra-axonal localization and was more promi-nent in adults compared with neonates. Only rarely were similar profiles observed in the adenohypophysis and there was no un-equivocal immunoreactive NF in perikarya of the neuro- or adeno-hypophysis. In adult, but not in neonatal pituitaries, large extracellular "blobs" of immunoreactive NF were seen in the neuro-hypophysis. In munoreactive GF was present in the cell bodies and processes of only a small number of neurohypophysela cells, in some cells lining cysts of the residual pars intermedia and only occasionally in astrocyte-like profiles of the adenohypophysis of adult pituitaries. In neonatal pituitaries, immunoreactive GF was adult pituitaries. In neonatal pituitaries, immunoreactive GF was localized to the cells of the neurohypophysis and only rarely was it present in cells lining cysts of the residual pars intermedia. It was never seen in cell bodies of the the adenohypophysis. GF containing "blobs" were less common in the adult neurohypophysis than NF containing "blobs" and none were seen in the neonatal pituitaries. We conclude that the adult and neonatal pituitary contains both NF and GF and that the addit and heomatal pitutary contains both NF and GF and that they are differentially distri-buted. The "blobs" containing immunoreactive NF or GF in the posterior pituitary of normal glands may reflect a limited capa-city to degrade externalized GF and NF by elements of the neurohypophysis.

PRODUCTION OF MONOCLONAL ANTIBODIES USING SUPRAOPTIC, PARAVEN-TRICULAR AND NEUROHYPOPHYSIAL MEMBRANES AS IMMUNOGENS. C.M. P. C.M. Paden and S.J. Hapner\*. MT 59717 Dept. of Biology, Montana State Univ., Bozeman,

Monoclonal antibodies which recognize cell-type-specific antigens have great promise as probes of neuronal development. We have employed membranes prepared from rat neurohypophysis and supraoptic (SON) and paraventricular (PVN) nuclei as immunogens in an attempt to develop monoclonal antibodies for use as markers of cell surface antigens of hypothalamic neurosecretory cells.

The neurohypophysis (and intermediate lobe) were dissected from unperfused, decapitated adult Holtzman albino rats. SON and PVN tissues were removed from 200  $\mu$  cryostat sections of unfixed brain using a 400  $\mu$  Palkovits punch. All tissues were homogenized in a hypotonic Tris buffer and a crude membrane pellet obtained. In various experiments, BALB/c mice were immunized with 100 to 200  $\mu g$  of membrane protein suspended in Freund's Complete Adjuvant ip one or more times. After a period of one to 3 months, mice received either (a) a final ip boost injection, (b) an iv boost, or (c) spleens were removed and splenocytes activated in vitro with whole membrane or detergent extracts (R.A. Luben et al., <u>Science 218</u>, 887, 1982). Four days later splenocytes were fused with NSI mye loma cells and plated into 48 culture wells (G. Galfre and C. Mil-stein, <u>Methods in Enzymology 73</u>, 1981). Immunocytochemical screening for antibody production was done on rat pituitary and hypothalamic sections (Zamboni's fixed) with FITC conjugated sheep anti-mouse immunoglobulins sera.

A total of 23 positive wells have been obtained from 5 fusions. Three monoclonal hybridoma lines have been isolated from these, producing antibodies which stain (1) tissue throughout the neurohypophysis and median eminence, (2) myelin and (3) cytoplasm of scattered neurons throughout the brain. Among the hybridomas being cloned, some secrete antibodies which appear to stain the neurohypophysis and cytoplasm of magnocellular neurons in the SON, or cytoplasm in both the SON and PVN. While further immunocytoor cyclopizam in both the solv and rvw. While full the fu However, the majority of our antibodies recognize cytoplasmic an-tigens. We are trying different membrane extraction procedures to increase the production of antibodies to cell-surface molecules. Increase the production of antibodies to cert-surface molecules. Second, a citvation in vitro is much more effective than in vivo boosts with our immunogens. Two fusions using in vitro stimulated splenocytes have produced 20 of the 23 positive wells. This technique offers great advantages when immunizing with small amounts of protein containing many antigenic substances. 27.5 ULTRASTRUCTURE OF VENTROMEDIAL HYPOTHALAMIC NUCLEOLI AND NUCLEI REVEALED BY ENZYME DIGESTIONS IN DE-EMBEDDED THIN SECTIONS. S. K. Chung\*, R. S. Cohen and D. W. Pfaff. Dept. of Anatomy, Univ. of Illinois Health Sci. Center, Chicago, IL and Rockefeller Univ., NY. Estrogen affects ventromedial hypothalamic (VMH) nerve cell nucleoli in ovariectomized rats, causing an increase in the number of protuberances associated with nucleoli (Cohen & Pfaff, Soc. Neurosci. Abst., 2:531, 1982). Ultrastructural examination of these protuberances revealed dense aggregations of material, separated from the nucleolus by a narrow gap, penetrated by strands of electron-dense material that seem to be connected to the main portion of the nucleolus. Previous ultrastructural studies indicated increased synthesis of a secretory product in estrogen-activated neurons (Cohen & Pfaff, Cell Tiss. Res., 217:451, 1981), possibly associated with greater wRNA synthesis in the nucleolus. Here we describe the morphological and chemical nature of the nucleolus. Here we describe the morphological and chemical nature of the nucleolus. I explore the nuclear matrix in VMH nerve cells of ovariectomized, estrogen-treated rats. Based on sodium tungstate staining (Takeuchi, J. Electron Microsc., 30:150, 1981), which differentiates between RNA- and DNA-containing structures in epon-embedded thin sections, the dense aggregated material was shown to contain DNA. Since epon interferes with enzyme digestion, as well as obscuring the visualization of fine filaments, other hypothalamic tissue was embedded in polyethylene glycol (PEC) (Wolosewick, J. Cell Biol., 86:675, 1980), a water-misible wax, thin sectioned, and de-embedded before enzyme digestion. Pepsin did not alter significantly the morphology of the nucleolus nor its associated structures. However, treatment with RMAse and pepsin reduced the density of the nucleolus solus astructures and opersin reduced the density of the nucleolus. Stereo viewing of the de-embedded sections shows that the nucleolu

- 27.6 AN INTERACTION BETWEEN HYPOTHALAMIC SLICES INCUBATED IN VITRO. P. Cobbett\* & G. I. Hatton (SPON: ENA). Neuroscience Program and Psychology Dept., Michigan State University, E. Lansing, MI 48824.
  - Bychology beft, includent barrel and an energy in the lattice in vertice of the second in the second second

The DCI of Dehydrate males incubated with Control males was 0.475 (n=30 injections) which is significantly ( $\mathbf{X}^2$ =10.487, p<0.01) greater than that recorded previously for Dehydrate males incubated alone (DCI=0.121, n=31). In contrast the DCI of Dehydrate females incubated with Control females (0.263, n=33) was not significantly different to that of Dehydrate female slices incubated alone (0.229, n=30).

These data indicate that dye coupling of magnocellular neurons in a slice can be dependent on its "incubation partner" slice type and this interaction is sex dependent. The underlying cause of this phenomenon is not clear but may in part be the differential levels of 1) sex steroid hormones in the brain of males and females, and 2) other steroid hormones in the brain of normal and dehydrate animals.

This research supported by NIH Grant NS 16942.

27.7 DYE COUPLING IN THE <u>IN VITRO</u> HYPOTHALAMUS: DEPENDENCE ON SEX AND HYDRATION STATE. G. I. Hatton & P. Cobbett\* Neuroscience Program and Psychology Dept., Michigan State Univ., E. Lansing, MI 48824. To achieve sufficient release of hormone in conditions of high demand, homotypic magnocellular neurons of the hypothalamus must be coordinated. Such coordination might be achieved by electrotonic coupling which is indicated by dye coupling. We have investigated the incidence of dye coupling of magnocellular neurons in vitro in the paraventricular nucleus of male and female rats to determine whether the incidence of coupling is sex dependent and is affected by dehydration (one stimulus of hormone scertion). Slices were prepared from 30-90 day old animals given water (Control) or 2% NaCl (Dehydrate) for 8 days prior to sacrifice. The slices were incubated in an oxygenated medium of 310 mOsmol./kg. (310 medium) or 340 mOsmol./kg. (340 medium): these are similar to the plasma osmolalities of normal and dehydrate animals respectively. Male and female slices were incubated separately, as were control and Dehydrate slices. Neurons in the magnocellular region of the PVN were injected with Lucifer Yellow CH using appropriate precautions to prevent artefactual dye-filling of neurons and incorrect counts of dye coupling. Fixed, cleared slices were amined microscopically using epifluorescence to determine the number of filled neurons. In 310 medium, Control males had a DCI of 0.333 (n=35 injective) where the total number of dye filled neurons.

In 310 medium, Control males had a DCI of 0.333 (n=35 injections) whereas the DCI of Control females was 45% lower (0.162, n=30) indicating a different basal incidence of coupling between males and females. The DCI of Dehydrate females was 0.229 (n=30) in 310 medium and 0.367 (n=24) in 340 medium: these are increases of 25% and 102% respectively compared to the basal (Control) coupling index. Thus dehydration in vivo probably increases coupling but this increase is more completely maintained in vitro if the "dehydration" is also maintained. In contrast the incidence of dye coupling in males was decreased following in vivo dehydration. The DCIs were 0.121 (n=31) and 0.261 (n=20) in Dehydrates incubated in 310 and 340 media respectively. Thus even if dehydration increases coupling in vivo, it is not sustained in vitro under the conditions tested.

These data indicate that the incidence of dye coupling is dependent on sex and in vivo and in vitro "hydration states". The underlying causes of these differences are not known but may be related to steroid hormone concentrations. In addition the argument that dye coupling is a real phenomenon and not an artefact of incubation is supported by these data.

27.8 CYSTEAMINE DEPLETES PROLACTIN, BUT DOES NOT ALTER THE STRUCTURE OF PROLACTIN-CONTAINING GRANULES. <u>L.A. Weinstein<sup>#</sup> and D.M.D.</u> Landis (SPON: J.J. Halperin) Neurology Service, Massachusetts General Hospital, Boston, MA 02114 Systemic administration of cysteamine (mercaptoethyl amine)

Systemic administration of cysteamine (mercaptoethyl amine) causes a profound, dose-dependent depletion of prolactin in the rat anterior pituitary as assessed by radioimmunoassay (RIA) and by bioassay. Similar reversible depletion occurs in cells of dispersed pituitary cell cultures, and assay of the culture medium shows that the depletion is not caused simply by release of cell content. Cysteamine has no effect on purified prolactin in solution, and so its effect appears to occur within cells. To assess the mechanism of cysteamine action, we have examined the ultrastructure of rat anterior pituitary 1, 2, and 4 bours of the section administration of cysteamine (300mg/kg) and

To assess the mechanism of cysteamine action, we have examined the ultrastructure of rat anterior pituitary 1, 2, and 4 hours after systemic administration of cysteamine (300mg/kg), an interval during which prolactin levels are very low, and again at 24 hours, when levels have climbed to the normal range. Lactotropes initially were identified by comparison with observations made by previous investigators. Qualitative and quantitative studies showed no significant change in the appearance and number of secretory granules or lysosomes during the interval of prolactin depletion.

appearance and number of secretory granules or lysosomes during the interval of prolactin depletion. Lactotropes were also identified by light and electron microscopic immunocytochemical techniques (ICC), using a primary antiserum supplied by the National Hormone and Pituitary Program. No change in the pattern of prolactin-like immunoreactivity was detected at 1, 5, and 24 hours after systemic injection, in contrast with the depletion detectable by RIA. At low dilutions (1:400) most immunoreactivity was present over large secretory granules, but with more highly diluted antisera (1:2000-4000) the rough endoplasmic reticulum stained as well. Usually, staining of granules was of variable intensity in a single cell. Omission of primary antiserum or preabsorption with prolactin eliminated staining.

We suggest that cysteamine alters prolactin structure only in the microenvironment of secretory granules, probably by interacting with the disulfide bonds of prolactin. The altered peptide is inactive in bioassay, and is not bound by the highly diluted antiserum in the RIA, though it is detected by ICC after aldehyde fixation. The presence of cysteamine-altered prolactin in secretory granules does not seem to trigger degradation of granules by the lysosomal system.

NEURONS OF THE CAUDAL NEUROSECRETORY COMPLEX RECONSTRUCTED ULTRA-27.9 STRUCTURALLY. R.M. Kriebel; S.M. Gerttula\* and R.L. Parsons. Dept. of Anatomy & Neurobiology, Univ. of Vermont Col. of Medicine, Burlington, VT 05405.

It has been shown that the activity of neurosecretory cells is influenced by synaptic input, however, the integrative mechanisms furthered by synaptic influence are yet to be understood. The caudal neurosecretory complex (CNC) of fishes, specifically <u>P. latipinna</u> (green molly), is well suited for studies to this end. We have started a multidisciplinary program which is aimed at studying the synaptic control of neurosecretory cells using the CNC model. One phase of these studies is concerned with the distribution of synaptic terminals on these neuroendocrine cells. The size and linear orientation of the CNC makes this neuronal nucleus convenient ear orientation of the CNC makes this neuronal nucleus convenient for examining three-dimensional characteristics of the synaptic input to individual nerve cells. The CNC, located within the ter-minal five vertebrae, was fixed in vivo with 2.0% paraformaldehyde and 2.5% glutaraldehyde in phosphate buffer and processed routine-ly for plastic embedding. One micron sections were used to locate an area of CNC suitable for serial sectioning, i.e. numerous soma and adjacent neuropil. The block face was trimmed to remove ex-cess tissue and plastic, however, the size of this structure per-mitted thin sectioning of the entire spinal cord cross-sectional area. Serial thin sections were mounted on single slot formwar Serial thin sections were mounted on single slot formvar coated grids; three sections were placed on each grid. Meticulous records were kept during the process including section interfer-ence coloration as well as loss of sections. Multiple section loss resulted in the initiation of a new series of serially collected sections. The sections were stained with uranyl acetate and lead citrate. Randomly selected neurons were serially photographed to include their somal area, processes, and the synaptic contacts on these cells. The three-dimensional reconstructions were completed with computer assistance. Ultrastructurally the neurons of the molly caudal system appear a homogeneous cell type, but reconstructions showed that some cells had smooth cellular profiles while others had a more varied cellular contour. microenvironment of the smooth cells consists almost exclusively of other apposing neurosecretory cells or glial processes. The synaptic profiles on the smooth neurons were found at the axonal pole of the cell. The other neuroendocrine cells were more isolated and surrounded by neuropil. These cells received more synaptic terminals than the smooth neurons and the terminals were distribut-ed randomly over the somal membrane. These studies suggest that some of the caudal system neurosecretory neurons receive more direct synaptic influence than others. Supported by BNS - 8206452.

ULTRASTRUCTURAL AND IMMUNOCYTOCHEMICAL STUDIES OF CRYO-PREPARED (CP) NEURAL TISSUES. J.G. Linner<sup>\*</sup> and J.M. Krolak<sup>\*</sup> (SPON: J.C. Waymire). Dept. Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77225. Immunocytochemical (ICC) localization of soluble chemical moieties in the cytosol has been difficult with previous tissue preparation techniques. This study describes a cryo-preparation (CP) approach which renders these moieties present and visible via ICC staining (post-embedding avidin-biotin complex technique). Small bionses of fresh supraontic nucleus median eminence and

via ICC staining (post-embedding avidin-biotin complex technique). Small biopses of fresh supraoptic nucleus, median eminence and neural lobe were 'quick-frozen' with a bounce-free mechanical device! and subsequently freeze-dried in an apparatus developed in this laboratory. The tissues were either treated with osmium tetroxide vapors or left unosmicated. In either case, the tissues were infiltrated directly with pure resin under vacuum. Ultrathin (silver-gold) sections were collected on Delrin staining blocks coated with a Butvar-88 support film. These sections were incubated for 2 h at room temperature in solutions containing antibodies to either vasopression (from Dr. G. Nilaver), calmodulin (from Dr. J. Dedman) or tyrosine hydroxylase (from Dr. J. Haycock) at dilutions of 1:500,000-1:1,000,000.

Ultrastructural morphology was well preserved when compared to Ultrastructural morphology was well preserved when compared to tissues fixed with low % glutaraldehyde or commercially available freeze-drying apparatuses. Cytosolic antigens were readily present and stainable, in contrast to aldehyde fixation, and the apparent antibody avidity and spatial stain resolution were enhanced with the present CP technique. Osmication was found to have little or no effect upon the avidity of these antibodies. Extracellular compartments contained localizable material, and cisternae of intracellular membranous organelles were readily stained with no overriding concern relative to the diffusion artifact ubiquitous with pre-embedding ICC techniques. The procedural artifacts necessarily introduced by preparative methodologies are always constraints to the interpretation of ICC data. As alternative procedures become viable, these artifactual

data. As alternative procedures become viable, these artifactual constraints are altered. The present CP technique overcomes cytoplasmic reticulation (and concomitant loss of ultrastructure) during freeze-drying--previously a major disadvantage. Thus CP tissues prepared by this method can be intepreted with less tissues prepared by this method can be intepreted with less artifactual constraint which should allow heretofore unobtainable information to be gathered. For example, the present CP technique will allow us to investigate labile, soluble cell constituents (such as sugars, metallic ions and membrane lipids) with powerful techniques including cytochemistry, X-ray STEM analysis, autoradiography and serial reconstructions of analysis, autoradiography and cryo-prepared tissues. <sup>1</sup>J. Neurosci. Meth. 1, 353 (1979)

### AGING AND BEHAVIOR I

EFFECT OF AGE ON ESTRADIOL CYTOPLASMIC RECEPTOR ( ${\rm E_2R_C})$  LEVELS IN MICRODISSECTED BRAIN NUCLEI: CORRELATIONS WITH CHANGES IN STEROID-INDUCED SEXUAL BEHAVIOR. P.M. Wise, B. Parsons, T.C. Rainbow and B.S. McEwen. Dept. of Physiology, U. of Maryland, Baltimore, MD 21201 and the Rockefeller University, NY, NY 10021. We have reported that the maximal number of E2 nuclear receptors

We have reported that the maximal number of E<sub>2</sub> nuclear receptors (E<sub>2</sub>R<sub>n</sub>) is lower in the preoptic area of middle-aged compared to young cycling rats while no change was detectable in the medial basal hypothalamus (MBH) (Camp, P. and Wise, P.M., Endocrine Soc. Abs #478, 1981). The purpose of this study was to answer the following questions. (1) Are changes in  $E_2$ R<sub>0</sub> due to changes in maximal E<sub>2</sub>R<sub>0</sub> levels? (2) At what age are changes in E<sub>2</sub>R<sub>0</sub> first observed? (3) Are changes in E<sub>2</sub>R<sub>0</sub> due to changes in E<sub>2</sub>R<sub>0</sub> due to change in E<sub>2</sub>R<sub>0</sub> levels? (2) At what age are changes in L<sub>2</sub>R<sub>0</sub> first observed? (3) Are changes in E<sub>2</sub>R<sub>0</sub> due to change in E<sub></sub> levels accompanied by changes in  $E_2\text{-mediated}$  functions? To assess the effect of age on maximal  $E_2R_{\rm C}$  levels, we used 3-4, 7-8 and 10-11 mo old virgin female Sprague-Dawley rats ovariectomized 1 wk prior to use. The following nuclei were microdissected: bed nucleus of the stria terminalis (BNST), suprachiasmatic preoptic area (SCPOA), medial preoptic nucleus (MPN), periventricular preoptic nucleus (PVPN), periventricular anterior hypothalamic area (PVAHA), paraventricular nucleus (PVN), dorsomedial nucleus (DMN), ventro-medial nucleus (VMN), arcuate-median eminence (ANME), medial and cortical amygdala and pituitary gland. Cytosolic fractions were prepared and  $E_{\rm 2R_C}$  quantitated according to the method of Rainbow et al (J Neurosci 2:1439, 1983). There was no difference in maximal  $E_{\rm 2}R_{\rm c}$  in any brain area in 7-8 compared to 3-4 mo old rats. By 10-11 mo of age there was a decrease in the number of  $E_{\rm 2}R_{\rm c}$  in the SCPOA and MPN with a similar trend in the BNST and PVPN, areas included in the grossly dissected preoptic area used in our previous study. We observed a decrease in the VMN, but no change in the PVAHA, PVN, We observed a decrease in the value, but no change in the relative trans, rad, DNN or ANNE, areas included in the grossly dissected MBH. Since the VMN is involved in reproductive behavior, we examined if the de-crease in  $E_{2R_{\rm c}}$  in this area is correlated with behavioral changes. Young (3-4 mo) and middle-aged (10-11 mo) rats were ovariectomized and 2 wk later, they received Silastic capsules which produced physiological levels of plasma E2. Two days later, 4h before test-ing, rats received sc injections of progesterone. Proceptive beha-viors, lordosis quotient and lordosis quality score were assessed. Middle-aged rats showed deficits in all aspects of mating behavior. The data demonstrate that by 10-11 mo, rats exhibit decreased  ${\rm E_{2R}}_{\rm c}$ The data demonstrate that by 10-11 m0, rats exhibit detected E2<sub>AC</sub> levels in components of the preoptic area which parallel previously observed changes in E<sub>2</sub>R<sub>n</sub>. The use of microdissection methods allowed us to uncover changes in a particular nucleus of the MBH, the VMN. This change was correlated with deficits in E<sub>2</sub>-induced behavior. The data suggest that changes in estradiol receptors may af-For the ability of aging rats to respond to  $E_2$  and may contribute to the age-related transition to acyclicity and infertility.

INCREASED PHYSICAL ACTIVITY IS NOT ASSOCIATED WITH IMPROVED COLD 28.2 STRESS RESPONSE IN SENESCENT MICE RECEIVING HYPOTHALAMIC SELF-STIMULATION. <u>M. Talan</u>\*, J. <u>Whitaker</u>\*, D. <u>K. Ingram</u>\*, B. <u>T. Engel</u>\* (SPON: E. Bresnahan). Gerontology Research Center, National

Institute on Aging, Baltimore, MD 21224. Previous research in our laboratory (Talan, M., <u>Neurosci</u>., <u>Abs.</u> 8, 1982) indicated that electrical self-stimulation of the hypothalamus can retard an age-related loss in thermoregulatory ability to withstand cold stress in senescent male C57BL/6J mice. The objective of the present study was to determine whether this effect was due to increased physical activity which this paradigm also induced. In one experiment senescent mice (29 mo) were surgically implanted with hypothalamic electrodes and then were administered a cold stress test (3 hr exposure to 10° C with physical restraint). After matching for cold tolerance, an experimental group obtained hypothalamic stimulation of 0.5 sec train of 80-100 imp/sec square waves 0.5 msec each at a current of 10-40 µa for each bar press during 30 min daily sessions, while a yoked-control group received the same degree of electri-cal stimulation without bar pressing. Three weeks later there was no significant difference in response to cold stress Neither group showed a decline in cold tolerance commonly seen in age-matched, control animals tested at 3-week intervals. second experiment examined whether increasing the level of general activity produced effects in thermoregulation similar to those observed with self-stimulation. One group of 26-mo old mice was housed singly in standard cages; another group also was housed singly in standard cages but received forced treadmill exercise (doily for min accounts to be before a selection of the selection). (daily 60 min sessions at 5 m/min); and a third group was housed singly in activity-wheel cages and voluntarily exercised at a daily rate of 1.5 m/min. After being matched initially on their cold-stress responses, the groups were retested 3 weeks later. No significant differences in responses were found in spite of the difference correlege means the formula in spite of the different exercise regimens. Thus, the retardation of cold-stress response observed in senescent mice receiving hypothalamic self-stimulation is not due to increased physical activity but rather results from the effect of hypothalamic stimulation.

28.3 HYPOTHALAMIC MONOAMINES IN C57BL/6J FEMALE MICE: EFFECTS OF AGE AND ESTRADIOL N. Telford\*, C.V.Mobbs\*, H.H.OSterburg\*, and C.E.Finch (Spon: R.E.MCCaman). Andrus Gerontology Ctr. and Dept. of Biological Sciences, Univ. of Southern California, Los and Los Angeles, CA 90089-0191.

This study evaluates the effects of age and estradiol ( $E_2$ ) on hypothalamic monoamines. Three groups of C57BL/6J female mice (young, Y, 6 mo; middle-aged, M, 12mo; and old, 0, 17 mo) were ovariectomized (OVXed) for 7 d, then implanted subcutaneously ovariectomized (OVXed) for 7 d, then implanted subcutaneously with either an empty silastic capsule (sham), or a 6mm (lx, = ca. 6 pg E\_/ml plasma) or 18mm (3x, = ca. 10 pg E\_/ml plasma) E\_2-containing silatic capsule, or an E\_2-containing glass capsule (Sx, = ca. 15-20 pg E\_/ml plasma). Three weeks after implantation, mice were sacrificed at 1400h (12:12 L:D; lights on 0600h). Monoamines and their catabolites were measured in the whole hypothalamus using an HPLC equipped with an electrochemical detector. Levels of all compounds are expressed as ng/mg protein.

detector. Levels of all compounds are expressed as ng/mg protein. All levels and ratios are given as mean+S.E.M. Serotonin (5-HT) levels declined about 10% with age (all  $E_2$ groups combined): Y=30,7+0.7 (n=24); M=28.5+0.8 (n=26); 0=27.4+1.0 (n=22) (p<0.05, ANOVA). The ratio of 5-hydroxyindole acetic acid (5-HIAA) to 5-HT, an indication of the relative rates of 5-HT degradation and synthesis, increased with age: Y=0.308+0.011 (n=24), M=0.313+0.007 (n=26), 0=0.343+0.014 (n=22)

28.4 PENTOXIFYLLINE IMPROVES AGE RELATED DEFICITS IN MEMORY. L. de Toledo-Morrell, \* F. Morrell, S. Fleming\* and M.M. Cohen, Departments of Neurological Sciences and Psychology, Rush Medical College, Chicago, Ill. 60612.

We recently demonstrated a striking relationship between age related deficits in spatial memory and in hippocampal plasticity measured in the same subjects. We now report that pentoxifylline, a phosphodiesterase inhibitor which has been shown to increase intracellular ATP and to augment oxygen consumption in tissue slices, produces a remarkable reversal of the memory deficit in aged rats.

The behavioral task we used was the 8-arm spatial maze. In this task, every arm of the maze is baited with food. Since, once consumed, food is not replaced, the optimal strategy for an experimental animal is not to go back to an arm which has already been visited.

Different groups of young (3 mo. old) and aged (26 mo. old) Fischer 344 strain male rats were treated daily, 30-40 min. prior to testing in the 8-arm maze, with IP injections of a) saline, b) 20 mg./kg. of pentoxifylline, c) 20 mg./kg. of pentoxifylline plus 100 mg./kg. of choline chloride and d) 100 mg./kg. of choline chloride. The pentoxifylline plus choline group tested whether any effect shown by pentoxifylline might be mediated through facilitated use of neurotransmitter substrate.

A comparison of the performance of 'young-saline' and 'oldsaline' groups indicated that choice accuracy was markedly impaired (as shown by repeated entries into already chosen arms) in aged animals after about the third or fourth response. Pentoxifylline treatment, however, markedly improved choice accuracy among the aged animals. This effect was not due to improved substrate utilization since the performance of the 'pentoxifylline plus choline' group did not differ significantly from that of pentoxifylline alone group. Although choline did not improve performance in old animals, young rats treated with choline reached the criterion of three consecutive trials with no errors significantly faster than young saline control rats.

EPINEPHRINE FACILITATION OF MEMORY PERFORMANCE IN AGED MICE. D. B. Sternberg, P. E. Gold, J. L. Martinez, Jr., and J. L. <u>McGaugh</u>. Department of Psychobiology, University of Cal-ifornia, Irvine, CA 92717 and Department of Psychology, Uni-

itornia, Irvine, CA 92/1/ and Department of Psychology, Uni-versity of Virginia, Charlottesville, VA 22901. Considerable evidence indicates that with aging there are learning and retention deficits in both mice and rats. While there is evidence that changes in cholinergic systems in the central nervous system may underlie some deficits in memory, recent evidence suggests that changes in catechola-mines may also be important.

It is known that, in comparison with young animals, old animals show a diminished release of epinephrine with acute stress, such as a training-related footshock. If this diminished release is important to age-related memory deficits, then replacement therapy should be possible. When adminis-tered shortly after training, epinephrine (and other stress-related hormones) can enhance or impair retention performance

related hormones) can enhance or impair retention performance in young animals. The present study investigated the memory modulatory role of epinephrine in aged mice. Male CFW mice (4 mo and 24 mo old) were trained in a one-trial inhibitory (passive) avoidance task using a 600  $\mu$ A, 2 sec footshock. Immediately posttraining, the animals receiv-ed subcutaneous injections of saline or epinephrine (0.01, 0.1 or 1.0 mg/kg). Twenty-four hrs later the animals were tested for retention. All doses of epinephrine use caused significant facilitation in both young and old mice. The age-related differences were attenuated with the epinephrine injection. injection. Thus, it appears that the epinephrine injections may replace normal function.

Comparable findings were obtained in a study using ARS Sprague-Dawley rats, tested one week following training. Once again, facilitation was seen. The old animals administered epinephrine had retention scores which were comparable to those of young animals.

These findings support the view that adrenergic mechanisms play an important role in memory modulation in aged as well as young animals.

THE EFFECT OF AGE ON DIAZEPAM PHARMACOKINETICS AND DIAZEPAM-INDUCED HYPNOSIS. P. Hicks, C. Rolsten\*, C. Harrington\*, C. Davis\*, T. Samorajski, and J. Schoolar. Texas Research institute of Mental Sciences, 1300 Moursund, Houston, Texas 77030. We have previously reported that marked tolerance develops to the hypnotic effect of diazepam in mice (Hicks, <u>et al.</u>, <u>Soc.</u> <u>Neurosci</u>. Abstr. 8:443, 1982). The rate of tolerance development is much slower in old mice than in younger mice, and the older mice respond with a shorter latency. The mechanism of the age-associated difference in response latency and tolerance develop-ment is unknown. We have measured plasma concentrations of diaze-pam and its two biologically active metabolites, desmethyldiazepam and oxazepam, to assess the role of pharmacokinetic differences in the age-associated behavioral changes. Male 12-, 18- and 28-month old C57BL/6J mice were used that had been purchased as retired breeders from Jackson Laboratories (Bar THE EFFECT OF AGE ON DIAZEPAM PHARMACOKINETICS AND DIAZEPAM-

been purchased as retired breeders from Jackson Laboratories (Bar Harbour) and aged in our animal facilities. Diazepam was adminis-There in traperiton and the second mathematical second mathematic desmethyldiazepam and oxazepam were measured in plasma by high performance thin-layer chromatography with flurazepam as an

desmethyldhazepam and oxazepam were measured in plasma by high performance thin-layer chromatography with flurazepam as an internal standard. At the time of sacrifice the average body weight of the oldest mouse group was approximately 10% lower than either younger group ( $\overline{X}$  = 33.0 g,  $\overline{X}$  = 33.2 g,  $\overline{X}$  = 30.7 g for the 12-, 18- and 28-month old mice, respectively). Liver weight in the oldest mice was greater than for either younger group ( $\overline{X}$  = 1.46 g,  $\overline{X}$  = 1.57 g,  $\overline{X}$  = 1.89 g for the 12-, 18- and 28-month old mice, respectively). A significant proportion of the whole body weight loss in the oldest mice could be accounted for by a marked decrease in abdominal fat ( $\overline{X}$  = 1.47 g,  $\overline{X}$  = 1.46 g,  $\overline{X}$ =0.52 g for the 12-, 18- and 28-month old mice, re-spectively). Consistent with the shorter response latency, the older mice had a markedly higher and faster plasma accumulation of diazepam and both of its biologically active metabolites. The benzodiazepines are very lipid soluble drugs. Their dis-tribution in plasma is markedly influenced by the amount of body fat present. In post-mature mice there is loss of fat stores. This loss of adipose tissue seems to be a major factor in the higher accumulation of diazepam and its metabolites in plasma in older mice. The higher plasma levels clearly are responsible for the shorter response latency seen in older mice do determine the role these pharmacokinetic differences have in the age-associated decreased tolewares to the hynotic dofference for diazepam

the role these pharmacokinetic differences have in the age-associated decreased tolerance to the hypnotic effect of diazepam.

28.7

ANOMIA IN ALZHEIMER'S DISEASE: ASSOCIATED COGNITIVE DEFICITS F. Jacob Huff\*, Suzanne Corkin, and John H. Growdon\* (SPON: W.H. Sweet). Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139 A study of the cognitive deficits underlying the anomia of Alzheimer's disease will be reported. Patients with this clinical diagnosis were grouped by severity of anomia on the basis of ability to name pictures on the Boston Naming Test (BNT). Additional tests were administered in order to assess visual form perception, verbal fluency (listing members of natural categories, such as vegetables), recognition of the names of objects, and recognition of the category membership of objects and of the words that name the objects. Results were obtained for 12 patients with Alzheimer's disease and 11 healthy, age-matched control subjects. Patients with Alzheimer's disease were divided into 3 groups on the basis of their scores on the BNT. Non-anomic patients (N=3) were defined as those who obtained scores of 68 or higher, mildly to moderately anomic patients (N=4) as those with scores less than 32. In addition, ratings of the overall severity of dementia were made on the basis of the patient's independence and competence in activities of daily living. All 3 non-anomic patients were mildly demented. Among the mildly to moderatel anomic patients, dementia was mild in 3 and moderate in 2 patients. In the severely anomic group, dementia was mild in 1, moderate in 2, and severe in 1 patient. On a test of verbal fluency, deficits were observed in 2 of the 3 non-anomic patients and in all of the sames the scores severely anomic. Poor performance was characterized by a tendency to accept incorrect names belonging to the same category as the correct name, for example, accepting the word "hat" as the name for a picture of a coat. Recognition of the category membership of words and pictured objects was relatively preserved in all groups. A test of visual form perception revealed no deficit in non-anomic and mildly

The results suggest that two cognitive deficits may interact to Ine results suggest that two cognitive deficits may interact to produce anomia: a word retrieval deficit resulting in impaired verbal fluency, and a semantic deficit resulting in impaired name recognition. The word retrieval deficit may be present in patients who are unimpaired in naming pictures on the BNT. The semantic deficit occurs independently of a deficit in visual form perception, which is present only in some severe cases. Experience with additional patients will be incorporated into these results for presentation and discussion. Supported by grants MH32724 and RR00088.

AGE-RELATED INCREASED SUSCEPTIBILITY TO ANISOMYCIN-INDUCED 28.8 AMESIA IN MICE: EFFECTS OF PROLONCED TREATMENT WITH DIETARY CHOLINE CHLORIDE, S. J. Y. Mizumori, T. A. Patterson, M. R. Rosenzweig and E. L. Bennett. Dept. of Psychology and Melvin Calvin Lab., Univ. of Calif, Berkeley, CA 94720. Aged mice (14-15 mo) are susceptible to anisomycin (ANI)-

induced amnesia for longer periods of time after avoidance training than young controls (2-3 mo) (Davis et al., <u>Exp. Aging</u> <u>Res.</u>, 7:33, 1981). The purposes of this experiment were: 1) to investigate in more detail the characteristics of the extended retrograde amnesia (RA) gradient and 2) to assess whether the extended RA gradient could be ameliorated by dietary choline chloride.

Chloride. Male CD-1 mice were trained in a step-through passive avoid-ance task. ANI (120 mg/kg) was injected either 10, 15, 20, 30 or 45 min after training, Following a 7-day retention interval, it was found that while 2-3 mo old mice were susceptible to the effects of ANI administered up to 10 min post training, memory of 14-16 mo old mice was susceptible to disruption out to 20 min post training. Retention of 17-20 mo old mice was significantly impaired when ANI was injected as late as 30 min post training. Saline injected animals of all ages showed good retention. These data support the hypothesis that with advanced age, protein syn-thesis necessary for long-term memory formation progressively slows down. Based on evidence of a possible interaction between the cholinergic system and protein synthesis and findings of a decline in function of the cholinergic system with increased age, naive mice were placed on a choline enriched diet for 5.5 mo. Choline chloride (1.5 mg/ml) was added to the drinking water; standard lab chow was provided ad libitum. At 14.5 mo of age, ANI (120 mg/kg) was injected either 15 or 20 min after passive avoidance training, ANI induced amnesia in choline treated mice only when injected 15 min post training, <u>not</u> when injected 20 min post training. In contrast, control mice maintained on a standard diet were amnesic when ANI was injected either 15 or 20 min post training, These results suggest that dietary choline treatment can render new long-term memories less susceptible to disruption after training. In addition to assessment of overall retention, one may measure age-related changes in memory function more sen-

sitively by examining specific characteristics of RA gradients. To assess the extent to which this dietary manipulation specifically affected the cholinergic system, the brains were re-moved for regional weight measures, ChAT assay and cell counts. Brain weights did not differentiate choline treated mice from age-matched controls. However, cerebral hemispheres of both groups of aged mice weighed significantly less than that of young mice. Results of ChAT assay and cell counts will be presented.

28.9 AN IMPORTANT STRAIN DIFFERENCE BETWEEN THE BEHAVIORS OF CLOSELY-RELATED AGING C5781 MICE. <u>Kimberly A. Caris\*, Susan B. Beall\*,</u> <u>Donald R. Meyer, and Ronald F. Mervis#</u>. Departments of Psycholo-sy and Pathology#, The Ohio State University, Columbus, Ohio gy and 43210.

The use of C57B1/6NNIA mice obtained from the National Institutes of Aging (NIA) in various studies is attractive because such subjects can be purchased at older ages than a closelyrelated strain from the Jackson Laboratories (C57B1/6J). part of a continuing series of investigations evaluating the ef-fects of different dietary factors on behavior (and other parameters) in aging mice, we have found in studies using the Bartus passive-avoidance paradigm, that NIA mice are better performers than JAX mice. The male NIA and JAX mice were 13 months-old when tested, having been obtained when 8 months-old and assigned to various dietary groups for 5 months. The dietary treatments included variations in amounts of choline, hosphatidylcholine, and commercial lecithin (Central Soya Centrolex). Of 114 JAX mice, 33 (or 29%) passed the test (avoided for 300 sec.) and 81 failed it. Of 101 NIA mice, 63 (or 62%) passed the test and 36 failed it. There were no striking interactions between the 36 failed it. There were no striking interactions between the strain difference and dietary treatments.

PARKINSON-LIKE MOVEMENT DISTURBANCES OF THE AGED RODENT: RELATIONSHIP TO NEOSTRIATAL HIGH-AFFINITY  $^3\text{H}\text{-}\text{ODPAMINE}$  UPTAKE.

<u>J.F. Marshall and C.A. Altar</u>. Dept. of Psychobiology, University of California, Irvine, CA 92717. Aged rodents show movement disturbances that resemble some of the impairments of Parkinson's disease. These movement disorders,

the impairments of Parkinson's disease. These movement disorders, such as impaired swimming, are temporarily reversed by administra-tion of the dopamine (DA) agonist, apomorphine or the DA precursor, 1-dopa. Several known abnormalities in central DA transmission may contribute to the decline of dopamine-dependent sensorimotor skills in advanced age: (1) a loss of dopaminergic nerve terminals in the neostriatum, (2) a decreased number of postsynaptic dopamine receptors (D-1 and/or D-2), and (3) a reduced rate of DA synthesis or an enhanced rate of its enzymatic degradation in this structure. The present study examines a fourth possible contributor, alterations in the inactivation of dopamine via its contributor, alterations in the inactivation of dopamine via its reuptake into nerve terminals. We determined the concentrations of neostriatal catecholamines as well as the uptake of <sup>3</sup>H-DA into neostriatal synaptosomes

as well as the uptake of <sup>3</sup>H-DA into neostriatal synaptosomes prepared from young adult (3 mo) or aged (26-28 mo) Fischer 344 rats. The Na<sup>+</sup>-dependent uptake was examined using a range (5 nM to 1 µM) of concentrations of exogenous DA. Relative to young adults, the aged rodents showed significant decreases in the DA concentration of the neostriatum (5.9 + 0.4 ys 4.7 + 0.3 ng/mg tissue) and olfactory tubercle (3.8 ± 0.3 vs 2.9 ± 0.3 ng/mg tissue) without changes in the norepinephrine content of these structures. In contrast, the kinetics of dopamine uptake into neostriatal synaptosomes showed no age change (Km for young adult, 0.12 µM; for aged, 0.11 µM; and V<sub>max</sub> for young adult, 98 pmol/mg tissue/ 8 min; for aged, 96 pmol/mg tissue/8 min). The uptake of 0.5 µM DA into the olfactory tubercle also did not vary with age. These data indicate that, in aged rats, the ratio of available

These data indicate that, in aged rats, the ratio of available dopamine uptake sites to dopamine content is elevated in both neostriatum and olfactory tubercle. This increased ratio in aged animals could favor the inactivation of released DA by reuptake, particularly when extracellular DA concentrations are high. If so, then administration of DA uptake blockers should facilitate DA transmission and lead to improvements of motor function. The

DA reuptake blocker bupropion HCl (Burroughs-Wellcome) facilitate the vigor and success of aged rats' swimming at 25-50 mg/kg i.p. These experiments draw attention to the importance of consider-ing age-dependent changes in the inactivation of neostriatal dopamine by reuptake and indicate the possible behavioral consequences of these alterations.

28.11 THE NIGROSTRIATAL SYSTEM AND AGING. <u>T.H. McNeill, L.L. Koek\*and</u> <u>J.W. Haycock</u>. Department of Neurology, University of Rochester, Rochester, New York 14642 and Department of Neurobiology and Anatomy, University of Texas, Houston, Texas 77025.

Alterations in neurotransmitter systems of the basal ganglia have been postulated to contribute to the disruption of motor function and balance associated with aging. This study examined nigrostriatal (A9) and mesolimbic (A10) dopamien neurons for qualitative age-correlated changes using fluorescence histochemistry for catecholamines and immunocytochemical techniques for the catecholamine synthesizing enzyme tyrosine hydroxylase.

istry for catecholamines and immunocytochemical techniques for the catecholamine synthesizing enzyme tyrosine hydroxylase. A total of 30 C57BL/6NNia mice 3, 6, 10, 20, 25, and 30 months-of-age (5/group) were used for these studies. Mice were anesthetized with sodium pentobarbital, exsanguinated with saline, and perfused with 4% paraformaldehyde for peroxidaseanti-peroxidase immunocytochemistry or with 4% paraformaldehyde-.5% gluteraldehyde for histofluorescence of catecholamines. Coronal sections were cut at 25 um in thickness on an 0xford vibratome and tissue sections for immunocytochemistry were floated freely in a staining dish following the technique of Grzanna et al. (1978).

Results from this study suggest that age-correlated morphological changes in A9 but not all A10 neurons in the midbrain are present in the mature adult (10 mo.) C57BL/6NNia mouse and show progressive increase in severity until at least 30 months-of-age. These changes are characterized by progressive accumulation of lipofuscin in dopamine-containing perikarya, markedly reduced dopamine content per cell as determined visually by histofluorescence, and an increase in the number of large, fluorescent axonal dilations in dopamine-containing fibers of the mesolimbic nigrostriatal pathways. These data suggest that heterogeneous morphological aging patterns exist within dopamine-containing neurons of the midbrain and that based upon their terminal projection sites various regions of the striatum and cortex may be differentially affected in the aged brain. In addition, these findings support the belief that age-related changes in neural structure are not generalized to an entire brain nucleus or cell type but are selective for individual cells within an affected area. This work was supported by PHS Grant AG 03254. 28.12 ACCELERATION OF AGE-RELATED FUNCTIONAL DECLINE IN MICE FOLLOWING PRIOR CHRONIC ETHANOL CONSUMPTION. S.F. ZORNETZER, DEPT. PHARMACOLOGY, U.C. IRVINE, IRVINE, CA 92717

The degree to which chronic alcoholism and aging independently produce a shared set of deleterious biological changes is unknown. This study investigated some neurobiological domains sensitive to the potential interactions of prior chronic alcohol consumption and aging. The experiments were designed to determine whether chronic alcohol consumption during a defined period of life-span is capable of altering the normal consequences of aging upon both behavior and brain morphology.

normal consequences of aging upon both behavior and brain morphology. The experiments included behavioral and quantitative neuroanatomical studies performed on male C57BL/6J mice. Three major age groups (starting age: 2, 12 or 24 mo.) were tested. Each was subdivided into three subgroups (minimum number per subgroups = 12). One subgroup received the alcohol-containing liquid diet as the only source of fluid and calories for a 4-month period (Group A). A second group of age-matched mice was a liquid diet nutritional control and received the sucrosecontaining liquid diet (Group S). Mice in Group S were pair-fed with mice in Group A, on a cage-by-cage basis. The third basic group of mice received lab chow and water ad libitum. Alchohol was administered to one third of the mice via an ethanol-containing liquid diet in which ethanol provided 35%-42% (8.1% - 10.3% ethanol v/v) of the total caloric content. Blood ethanol concentrations (BEC) were sampled from mice thosen randomly from each cage receiving alcohol containing liquid diet.

chosen randomly from each cage receiving alcohol containing liquid diets. Behavioral tests began either at the end of the 30 day "dry out" period for half the mice in Group A (or the equivalent period for mice in Groups S or Lab Chow) or at 28 months of age (typically, life-span for these mice is 32 months of age) for the remaining mice. The behavioral tests for the mouse were selected as relatively robust probes for functional damage in either the hippocampal formation (spontaneous alternation) or the cerebellum (swimming and balancing behavior).

The neuroanatomical experiments evaluated quantitatively a number of morphological changes in the mouse brain produced by (1) normal aging and (2) the possible interaction of aging and chronic alcoholism. Cell count studies, using the correction procedures described by Abercombie (1946), were caried out. The results indicate that prior chronic ethanol consumption produces

The results indicate that prior chronic ethanol consumption produces significantly greater behavioral and morphological deterioration in mice at all ages tested. These data support the hypothesis that the deleterious effects of chronic ethanol consumption are compounded with the ongoing processes of age-related behavioral and CNS deterioration.

28.13 PLATELET MAO AND RESPONSE TO MAO INHIBITION IN ELDERLY DEPRESSIVES. R. C. Young, G. S. Alexopoulos\*, K. Lieberman\*, E. Kent\*, C. A. Shamoian. Dept. of Psychiatry, Cornell Univ. Med. College and N. Y. Hosp.-Cornell Med. Ctr., Westchester Div., White Plains, N.Y. 10605.

Major depressive illnesses are common in the elderly. The pathophysiology of these disorders has been hypothesized to involve amine neurotransmitter dysfunction. The activity of monoamine oxidase (MAO), an enzyme that degrades amine neurotransmitters, increases in brain and in platelets with aging; it is further increased in patients with degenerative dementia. Platelet MAO activity has been used as a possible index of brain MAO activity and as a marker of adequacy of MAO inhibitor therapy in young adults. While it has been speculated that MAO inhibitor the especially useful in depressed patients with high MAO activity, little data is available concerning such therapy in the elderly. Inpatients >55 years of age with major depression by RDC were evaluated after one week of psychotropic washout.

Inpatients > 55 years of age with major depression by RDC were evaluated after one week of psychotropic washout. Baseline platelet MAO activity was measured using benzylamine as substrate. Clinical history and symptoms were documented using the Schedule for Affective Disorders and Schizophrenia. Symptom severity was assessed using the Hamilton Depression Rating Scale (HDRS). Cognitive function was monitored using the Minimental State Scale (MMS). Resting pulse and sitting and standing blood pressure were monitored and serial electrocardiograms were obtained. Subjective side effects were rated using the Asberg Scale. Symptom ratings and platelet MAO activity were recorded weekly for at least four weeks of treatment with phenelzine at a fixed final dose of 30-60 mg/day (median 60 mg/day).

60 mg/day). Of the first thirteen patients studied, twelve (mean age 69.4) have completed the four week period. Their HDRS scores (median 26.5; range 17-35) decreased during treatment (median 13.0; range 0-29; p < .001). Changes in MMS scores and side effects scores were not statistically significant. Platelet MAO activity was inhibited during treatment (mean 80.9%; S.D. 16.6%; p < .001) and inhibition was apparent within the first week. Decreases (p < .01) in sitting and standing systolic and diastolic blood pressure occurred during treatment. Neither heart rate nor electrocardiographic conduction times changed during treatment.

Phenelzine can be therapeutically effective in elderly depressives. It is tolerated adequately. Hypotensive effects may limit its use in some patients.

Supported by Dept. of Psychiatry, C.U.M.C.

29.1 PLATELET MAO ACTIVITY IN GERIATRIC DEPRESSION. G.S. Alexopoulos,\* <u>K.W. Lieberman,\* R.C. Young, C.A. Shamoian. Dept. of Psychiatry.</u> New York Hospital-Cornell Medical Ctr., White Plains, N.Y. 10605

Monoamine oxidase (MAO) is an enzyme responsible for the oxidative deamination of biogenic amines and participates in the intraneuronal regulation of brain monoamine neurotransmitters. Platelet MAO activity has been studied in various psychiatric disorders. There have been contradictory findings concerning platelet MAO activity in unipolar depression. Platelet MAO activity is partly determined by heredity but also increases with age. Studies of elderly depressives may reveal a differential effect of aging on the MAO system in some clinical subgroups.

Platelet MAO activity was assayed in 38 geriatric hospitalized women with primary major depressive disorder and in 16 elderly women with no personal or family history of psychiatric disorders None of the subjects was on psychotropic medication or other drugs known to influence platelet MAO activity. Diagnosis was made according to Research Diagnostic Criteria. Symptomatology was rated with quantitative scales and family history was systematically obtained and classified according to Family History-Research Diagnostic Criteria. Platelet MAO activity was assayed using benzylamine as substrate and was expressed in nmol/mg protein/hour. Data were analyzed with one way ANOYA and Scheffe's post hoc comparison of means. Significance levels are two-tailed.

The platelet MAO activity of elderly depressed women as a group (N=38, MAO mean: 51.7, SD:21.0) was comparable to that of elderly normal controls (N=16, MAO mean: 66.0, SD=18.5). However, elderly depressed women with early age ( $\leq$  50 years) of illness onset (N=19, MAO mean: 61.9, SD: 20.2) and elderly normal controls. (F<sub>(2,51)</sub>=8.91, P $\leq$ .005). Differences in the clinical picture and family history of the two groups of elderly depressives did not appear to account for the lower platelet MAO activity of early age of onset depressives. The data suggests that aging reveals biological heterogeneity

The data suggests that aging reveals biological heterogeneity amongst unipolar depressed women.

(Supported by award from Department of Psychiatry, New York Hospital-Cornell Medical Center) 29.2 AROMATIC L-AMINO ACID DECARBOXYLASE ACTIVITY IN MICROVESSELS AND PARENCHYMA FROM BRAIN REGIONS OF AGING RATS. Isaac F. Roubein, Larry J. Embree and David W. Jackson\*. VA Med. Ctr., and Dept. of Neurology, LSUMC-Shreveport, LA 71130. The presence of aromatic L-amino acid decarboxylase (AAD) in

The presence of aromatic L-amino acid decarboxylase (AAD) in the cerebral microvessels (CMV) constitutes an enzymatic barrier to biogenic amine precursors at the microvascular level. Therefore, alterations in AAD activity with aging may adversely affect normal brain function.

We have determined the activity of AAD in CMV and parenchyma utilizing the carbidopa model. When carbidopa is given at a dose of 100mg/kg it inhibits AAD activity in CMV leaving the enzyme in brain parenchyma (P) essentially unaffected.

Groups of aging male rats (24-27 months) and young adults (3-4 months) were pretreated with reserpine (10 mg/kg i.p.) and 4 hr later with pargyline (75 mg/kg i.p.), followed after 30 minutes by carbidopa (100 mg/kg i.p.). The animals were sacrificed by decapitation 1 hr after the last injection. A second group of animals of identical ages received the same drug treatment except for carbidopa. The following regions were dissected: striatum (S), hypothalamus (HT), midbrain (MB), and cerebral cortex (CX), and the activity of AAD was determined in the brain regions of both groups of animals. The amount of dopamine synthesized was determined by the Lowry method.

Age (Months) (		(n)	A: Total (CMV+P) Activity*	B: Parenchymal Activity*	A-B=CMV Activity*

\*AAD activity is expressed as the amount of dopamine synthesized ( $\mu g$  formed/mg protein/30min).

Synthesized (µg formed/mg profein/Jumin). We conclude that aging has no effect on AAD activity in the brain regions examined. Therefore, the action of cerebrovascular AAD as an enzymatic barrier regulating the entrance of monoamine precursors into the brain parenchyma is essentially unaffected with aging. Research supported by Veterans Administration Medical Center and Louisiana State University Medical Center, Shreveport, LA.

29.3 SPECIFIC BEHAVIORAL IMPAIRMENTS IN ASSOCIATIONAL TASKS IN MICE WITH AN AUTOIMMUNE DISORDER. D.G. Spencer, Jr. and H. Lal. Dept. of Pharmacology, Texas Coll. of Osteopathic Med., Fort Worth, TX 76107.

Antibodies are selective for neuronal antigens (brain-reactive antibodies - BRA) increase in blood serum concentrations as C57BL/6 mice age (Nandy, K., in <u>The Aging Brain and Senile Dementia</u>, K. Nandy and I. Sherwin (Eds.). Plenum: New York, 1977). NZB mice have elevated titers of autoantibodies, including BRA, at all ages. In addition, NZB mice acquire the active avoidance task at a slow rate, relative to C57BL/6 mice (Nandy, K., Lal, H., Bennett, D., and Bennett, M., unpublished data). Since BRAs in humans have been hypothesized to produce the neuromorphological abnormalities observed following pre-senile and senile dementia (Ingram, C.R., Phegan, K.J., and Blumenthal, H.J., J. Gerontol., 29: 20, 1974), we undertook to characterize the NZB mouse behaviorally in order to determine whether their apparent cognitive deficits are specific or due to a more general sensorimotor impairment. NZB and CFW mice, ranging in age from 7 to 9 months, were studied in performance on a number of procedures designed to evaluate sensorimotor and stimulus-response associational learning and memory tasks. NZB subjects were no different from CFW mice in basic reflexes or startle thresholds, but the magnitude of the NZB shock startle response was less. NZB mice were also quicker to fall off a rotating rod than CFWs. Conversely, NZBs flicked their tail away from a radiant heat source faster than CFWs did. Although NZBs displayed the same locomotor activity as CFWs after four minutes in the open field, NZBs displayed large deficits in active and passive avoidance relative to CFWs, no strain difference was observed on the taste aversion task. From this pattern of information, we conclude that there is good evidence for a specific deficit in the formation or retention of stimulus-response associations in NZB mice. Further corroborative neurochemical and neuropathological studies should provide additional information on the appropriateness of the NZB autoimmune disorder as a model for the neuronal and behavioral change 29.4 AGE AND NEUROCHEMICAL CORRELATES OF BEHAVIORAL RIGIDITY IN RATS. A. M. Lowy\* and D. S. Olton, Dept. Psychology, The Johns Hopkins University, Baltimore MD 21218, D. K. Ingram\*, S. B. Waller, and M. S. Reynolds. Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, MD 21224. E. D. London. Addiction Research Center, National Institute of Drug Abuse, Baltimore MD 21224. (Spon: H. B. Popolow)

Previous experiments have demonstrated that rats have agerelated impairments in the performance of complex mazes, and have attributed these impairments to perseverative errors, indicating the presence of increased behavioral rigidity. The present study investigated further the effects of aging on learning and memory, specifically with regard to the phenomenon of behavioral rigidity. Two experiments, similar in procedure, were performed. Two groups of ACI rats, aged 9 and 22 months, respectively, were food deprived and tested five days a week. The design used two different T-mazes, each of which had two different components. The first component was a position discrimination on the stem of the T-maze. The other component was a discrete trial rewarded alternation discrimination on the arms of the same T-maze. Performance in each of the components was first tested simultaneously on one maze. Then the position discrimination in the stem was reversed using the second maze. Consequently, the procedure assessed rigidity using two different procedures simultaneously. Following training, the brains were removed and dissections were made to remove the hippocampus and the following areas of the cortex: cingulate, sensory-motor, occipital, frontal, auditory, and pyriform-perirhinal. The activities of L-glutamic acid decarboxylase and choline acetyltransferase were assayed in these regions, as was muscarinic binding with (<sup>3</sup>H)Quinclidinyl benzilate as the ligand. Although both groups of rats were able to learn the task, the rate of learning was more rapid in the younger group. Furthermore, the older rats were impaired in both components of the task. Additional experimentation suggested that the impaired performance of the aged rats was not due to visual defects because there was no age difference in a simple visual discrimination task. The results of the experiments support the hypothesis that behavioral rigidity increases with age in rats. 29.5 SERUM DOPAMINE-β-HYDROXYLASE ACTIVITY IN ALZHEIMER TYPE DEMENTIA. M.A. Oleshansky,\* B. Reisberg\* and S.H. Ferris\* (SPON: L.N. Neckers). Millhauser Labs, Dept. of Psychiatry, New York University Medical Center, New York, N.Y. 10016. Current research in Alzheimer Type Dementia (ATD) is focused on the theory of the terminal sectors of terminal sectors of terminal sectors of the terminal sectors of terminal sector

Current research in Alzheimer Type Dementia (ATD) is focused on the relationship between CNS pathology and cognitive deterioration. The degree of dementia appears to correlate with both the extent of senile plaques and the reduction of cortical choline acetyltransferase activity in post mortem brain tissue. Similarily, a reduction of noradrenergic cell bodies in nucleus locus coeruleus has been associated with significantly higher dementia scores and younger age at death. As these neuropathological studies require invasive procedures or post mortem examination, they are of limited value in the evaluation of a patient with dementia. We have assayed serum dopamine-B-hydroxylase (DBH) in patients with a clinical diagnosis of ATD in an attempt to develop a laboratory marker for this disorder. Serum DBH has been proposed to be an index of peripheral SNS activity should reflect in some way the CNS pathology that has been reported in ATD.

Blood was obtained from twenty four cases of ATD age 60 - 79 years (mean age 71), twenty four age-matched control subjects age 60 - 79 years (mean age 70) and fitteen young controls age 20 - 40 years (mean age 30). The older subjects were all ambulatory and were attending an outpatient clinic as patients or spouses. A diagnosis of ATD was made by two investigators (B.R. and S.F.) and patients with any other medical illness particularily cardiovascular disease were excluded. A battery of cognitive tests was given to the older subjects and a Global Deterioration Score (GDS) was assigned (Reisberg et al. Am. J. Psychiatry, 139:1136, 1982). DBH activity was measured by photometric assay in 20  $\mu$ l of serum (Nagatsu and Udenfriend <u>Clinical Chemistry</u>, 139:80, 1972). Mean serum DBH activity in the group of older subjects as a whole was nearly identical to that for the younger controls. Patients with moderate

Mean serum DBH activity in the group of older subjects as a whole was nearly identical to that for the younger controls. Patients with moderate to severe ATD (GDS 4-6) had serum DBH activity that was not different from their age matched controls (GDS 0-2). ATD subjects and the age matched controls were divided into two groups on the basis of median age (below 70 and above 70). There was a significant reduction (P < 0.05) in DBH activity in the younger ATD cases as compared to the older subjects with ATD. No significant correlation between DBH activity and severity of dementia within the range GDS 4-6 was found for either age group. Among the younger ATD cases, women appeared to have the lowest serum DBH activities.

Our data confirm and extend to an older population the finding that serum DBH activity does not change significantly as a function of age in a healthy adult population (Freedman et al. <u>Nature</u>, 236:310, 1972). It further demonstrates that serum DBH activity appears to be altered in ATD in an age-dependent manner. Serum DBH activity may be useful in the prospective evaluation of patients with ATD.

29.7 CORTICAL CHOLINERGIC AND BEHAVIORAL IMPAIRMENT FOLLOWING KAINIC ACID LESIONS OF RAT BASAL FOREBRAIN. B.Lerer, J.Warner\*, M.Zolcinski\*, E.Gamzu and E.Friedman\*. Depts. of Psychiatry and Pharmacology, New York University Medical Center, New York, NY 10016 and Pharmacology I, Hoffman-LaRoche Inc., Nutley, NJ 07110.

The magnocellular nuclei of the basal forebrain (MNBF) provide extensive cholinergic innervation to fronto-parietal cortex and are analogous to the nucleus basalis, implicated in the cognitive dysfunction in Alzheimer's disease. Bilateral MNBF neurotoxic lerions depleted cortical choline acetyltransferase (CAT) in frontal and parietal cortex but not in striatum or hippocampus.

parietal cortex but not in striatum or hippocampus. Behavioral testing began 3 wk post-operative, after MNBFlesioned rats recovered from the aphagia, adipsia and locomotor abnormalities resulting from the lesion. Rats were tested only if they weighed 20 g more than pre-operative baseline weight. The MNBF rats were compared to unoperated controls, sham-operated controls and control rats injected with kainic acid in the cortical area directly above the MNBF. Cortically-lesioned controls displayed the hyperactivity characteristic of MNBF rats for 7-10 hr after surgery, but were not aphagic, adipsic or behaviorally impaired.

MNBF-lesioned rats were impaired in 24 hr retention of a passive avoidance task with escapable footshock; however, their acquisition performance during the initial training trail was not different from that of the three control groups. There were no differences between the four groups in mean number of daily avoidances on a bar-press active avoidance task; however, the data suggested a slower rate of avoidance learning in the MNBF rats. Mean rates of motor activity were not different between groups and, therefore, do not account for the results obtained in these two tasks. Finally, all rats were tested in a task involving an exploratory response to one of two recessed feeding devices (see Gamzu et al. this meeting). The procedure required serial reversals of this spatial discrimination. MNBF-lesioned rats showed evidence of acquiring the task, as indicated by a decrease in the mean number of daily errors; however, their performance was significantly poorer than that of the three control groups. A cortical cholinergic deficit may underlie the memory impair-

A cortical cholinergic deficit may underlie the memory impairment and reduced cognitive functioning of Alzheimer's disease. We believe our rodent model is useful for studying the role of the cholinergic system in memory dysfunction and for developing treatment strategies to alleviate the deficits of Alzheimer's disease.

29.6 HIPPOCAMPAL NEUROPEPTIDES AND NEUROFIBRILLARY TANGLES IN AGING AND ALZHEIMER'S DISEASE. H. K. Kulmala and M. J. Ball\*. Department of Pathology, University of Western Ontario, London, Canada, N6A SC1.

Hippocampal neurons are afflicted by neurofibrillary tangles in normal aging and in Alzheimer's Disease (AD). Since a number of neuropeptides are putative hippocampal neurotransmitters, it is possible that peptidergic perikarya contain neurofibrillary tangles (NFT). We report the development of a dual staining procedure used to determine whether NFT are contained in peptidergic neurons.

dergic neurons. A block containing hippocampus was obtained from 10 persons dying with AD and 6 control subjects; ages 30 - 95 yrs. (postmortem delay 3 - 16 hrs.). Tissues fixed by immersion in 4% para-formaldehyde for 48 - 72 hrs. were stored 24 hrs. in 5% sucrose in phosphate buffer, then sectioned on a CO, freezing microtome at 40  $\mu$ m. Sections were stained using the PAP procedure with antisera against somatostatin (SOM), cholecystokinin (CCK), vaso-active intestinal peptide (VIP) (Immuno Nuclear) and Leu-enkephalin (ENK) (Dr. R. J. Miller, Univ. of Chicago), along with appropriate controls. Mounted sections were stained with Congo red-gallocyanin.

Postmortem delay (PMD) was found to affect the immunohistochemical localization of these peptides. Best results were obtained after the shortest PMD, while perikarya were not stained after 8 - 10 hrs. ENK neurons were seen in several subregions, similar to their distribution in rat hippocampus. Many VIP neurons, but few SOM or CCK neurons, were stained. However, less than 10% of VIP and ENK neurons in the subiculum and  $H_1$  of aged or AD brains contained NFT. Such immunoreactive cells thus appear relatively unaffected in aging or AD. Several of the tangle-bearing peptidergic neurons displayed large tangles, indicating that neurotransmitter synthesis may not have ceased in such cells. Most tangle-bearing neurons did not stain for any of the peptides; some of these may contain one of the neuropeptides at concentrations below the sensitivity of the present method.

29.8 COUNTS OF THE MAGNOCELLULAR CHOLINESTERASE-POSITIVE NEURONS IN THE BASAL FOREBRAIN OF YOUNG AND AGED MICE. J.C. Hornberger\* and S.J. Buell\* (SPON: R.J. Joynt). Dept. Neurology, Univ. Rochester Sch. Med. & Dent., Rochester, NY 14642.

Severe depletion of cholinergic markers and relative sparing of markers for other transmitter systems have been reliable findings of studies of dementia of the Alzheimer type (DAT). Evidence for loss of up to 80% of cells of the nucleus basalis of Meynert, the presumed cells of origin of cholinergic input to cortex has also been reported in DAT. Depletion of cortical cholinergic markers has also been reported in normal human and rodent aging. We determined quantitatively the number of magnocellular acctylcholinesterase-staining (AChE) neurons in the basal forebrain of the C57B1/6NNia mouse. Four 15-month and five 53month-old mice were injected with diisopropylphosphorofluoridate (2.0 mg/kg). Four hours later they were perfused transcardially with 2% paraformaldehyde, 2% glutaraldehyde fixative. The brains were then removed, placed in the fixative overnight, and Vibratome-sectioned in the coronal plane at 20um thickness. Every third section was stained for AChE. This method, in conjunction with <u>in vivo</u> treatment with DFP, is selective for soma of cholniergic neurons, staining them with substantially greater intensity than acetylcholinoceptive neurons and leaving unstained nonspecific esterases. We collected data from the level of the rostral pole of the globus pallidus to the level of the posterior commissure in the region shown by AChE staining. Neurons of the nucleus basalis magnocellularis, globus pallidus, nucleus interstitialis ansa lenticularis, and the ventral aspect of the jaraventricular nucleus, the supraoptic nucleus, and the posterior hypothalamic nucleus were not included. There was less than a % difference in total AChE-positive neuron number between age groups. There were no significant differences in cell numbers in any of the above specified anatomical loci. Additional cell count and size studies of the medial septum, tractus of the diagonal band of Broca, and the lateral preoptic nucleus will be presented. These findings of maintenance in aged animals of the number 29.9 NORADRENERGIC CHANGES IN SENESCENT MEMORY LOSS. F.M. Leslie, S.E. Loughlin, J.L. McGaugh, D.B. Sternberg and S.F. Zornetzer. Departments of Pharmacology and Psychobiology, University of California, Irvine, CA 92717. A decline in memory is commonly observed in aged animals.

A decline in memory is commonly observed in aged animals. Although it has been proposed that cholinergic dysfunction may underlie this process, recent behavioral and biochemical data suggest that other neurotransmitter systems may be involved. We have utilized morphological and biochemical techniques to examine the role of central noradrenergic systems in age-related memory decline. Male mice (CFW) were trained in a step-through inhibitory avoidance task, and tested 24 hours later for retention of the response. Animals were then sacrificed and their brains removed. One group of brains were formalin-fixed, embedded in paraffin and sectioned serially through the nucleus locus coeruleus (LC). The sections were missl-stained and analyzed to determine the number of nucleoli within the boundaries of LC. Brains from a separate experimental group were dissected into three areas - cortex, forebrain and cerebellum/brainstem - and analyzed by radioligand binding assay for changes in  $\alpha_2$ -receptor number. Regional receptor density was determined by Scatchard analysis of the binding of  $[^{3}H]$  rauwolscine, a selective  $\alpha_2$ -antagonist, to well-washed brain

Generative was betermined by Scatterind analysis of the bindle washed brain membranes. Tissue from 4-5 animals was pooled for each analysis. In general, aged mice (24-27 months) showed significantly lower retention of the shock avoidance response than did young controls. There was, however, considerable variability in the performance of individual aged animals. Analysis of the data suggested the presence of two sub-groups within the aged population – memory-impaired and nonimpaired. No significant differences were observed in the density of  $\alpha_2$ receptors in the brains of aged and young mice. It may be, however, that our method of analysis obscured individual differences in memoryimpaired animals. We are, therefore, currently using autoradiographic techniques to examine this question in further detail. In the morphological study, a significant decrease in LC cell count was observed in the aged population. Furthermore, there was a highly significant correlation between cell number and the degree of memory impairment. These data suggest that age-related degeneration of the noradrenergic locus coeruleus may have an important role in senescent memory loss.

29.10 LESIONS OF THE NUCLEUS BASALIS OF MEYNERT IMPAIR MEMORY IN SPRAGUE-DAWLEY RATS. <u>R. F. Berman, R. D. Crosland, D. J. Jenden, and H. J. Altman. Department of Psychology, Wayne State University, Detroit, MI 48202, Department of Pharmacology, UCLA Los Angeles, CA 90024, and Lafayette Clinic, Detroit, MI 48207. Converging lines of evidence indicate an important role for the based for basic of Delations.</u>

Los Angeles, CA 90024, and Lafayette Clinic, Detroit, MI 48207. Converging lines of evidence indicate an important role for the basal forebrain cholinergic system in memory processes. The principal origin for this cholinergic projection appears to be the magnocellular neurons in the region of the nucleus basalls of Meynert (NbM) (Fibiger, H.C., Brain Res. Rev., Vol. 4, 327-388, 1982). In Alzheimer's disease there appears to be a loss of basal forebrain cholinergic neurons (Whitehouse, et.al. Science, 215: 1237-1239, 1982). This suggests that the loss may underlie cognitive deficits associated with Alzheimer's disease, and that destruction of this region in experimental animals may impair meory. To date, there have been few experiments we examined the effects of neurotoxin lesions (i.e., Ibotenic acid) of the NbM in rats on retention of shock avoidance training. Sixty male, Sprague-Dawley rats 3 months of age were used. Twenty rats were stereotaxically injected, bilaterally, with  $0.5\mu$ l of Ibotenic acid (15  $\mu$ g/ $\mu$ l) into the region of the NbM and 20 rats were injected with vehicle only. Animals were allowed a 2 week postoperative recovery. The remaining 20 rats served as non-injected chamber, and then given a 1.0 mamp, 3 sec inescapable footshock. Retention of footshock training was then tested 30 minutes or 24 hours later by measuring the animals latency to again enter the darkened chamber. Animals were decapitated after retention stynificant correlation between the lagine and 24 hours after training. Lesioned animals showed a significant decrease (-28%+ 14.4 and -29%  $\pm$  14.2, respectively) in cortical CAT and AChE activities compared to non-operated controls. There was also a significant correlation between the impairment in retention performance and changes in cortical CAT and AChE activities, as well as a large and significant correlation between the changes in CAT and AChE activities. The results demonstrate the usefulness of NbM lesions as a model for studying the role of the basal forebrain

29.11 PERFORMANCE OF YOUNG AND AGED MICE IN AN EIGHT ARM RADIAL MAZE AND NEUROCHEMICAL CORRELATES. D. E. Bernstein and D. S. Olton. Deot. Psychology, The Johns Hopkins University, Baltimore MD 21218. D. K. Ingram, S. B. Waller, and M. S. Reynolds. Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, MD 21224. E. D. London. Addiction Research Center, National Institute of Drug Abuse, Baltimore, MD 21224. (Spon: B. Gordon).

Past studies have demonstrated that the performance of aged rats is impaired relative to that of young rats in complex learning tasks. The present experiment examined whether the age related decrement of rats previously observed in radial maze performance extended to another species, the C57BL/6J mouse. This study consisted of two experiments similar in procedure. Old and young mice, aged 28 and 8 months, respectively, were water deprived for five days each week, and their performance was assessed on a radial arm maze with isotonic saline as the reward. At the beginning of each test session, some isotonic saline was placed at the end of each arm so that the mice were rewarded for their first visit to each arm. Therefore, the optimal strategy was to visit each arm once during a trial. The number of choices made and the number of drinks taken in the first eight choices were recorded. Following training, the the rats were sacrificed and the brains were removed. The hippocampus and six cortical regions (cingulate, sensorimotor, occipital, frontal, auditory, and pyriform-perirhinal) were dissected. The activities of L-glutamic acid decarboxylase and choline acetyltransferase were aşayed in each of these regions, as was muscarinic binding with ('H)Quinuclidinyl benzilate as the ligand. Behavioral results indicated that the mice clearly learned to choose accurately on the maze. Both young and old mice began the task at chance levels and showed considerable improvement during the testing period. However, no significant age-related differences in performance were found. Neurochemical correlates of this performance are also presented. 29.12 EFFECTS OF DIETARY RESTRICTION ON NEUROTRANSMITTER SYNTHETIC ENZYMES AND MUSCARINIC BINDING IN ACINC RAT BRAIN. E.D. London, D.K. Ingram\* and S.B. Waller. Gerontol. Res. Ctr., Natl. Inst. Aging; Addict. Res. Ctr. Natl. Inst. Drug Abuse, Balto., MD 21224. Dietary restriction increases the lifespan of rats, and retards age-related decrements in striatal dopamine receptor concentrations (Levin et al., Science 214:561, Goodrick et al., <u>Gerontol.</u> 28:233). The present investigation was intended to assess effects of dietary restriction on other neurochemical markers in the striatum and three other brain regions.

Male Wistar rats were given a diet of 24% protein ad <u>lib</u> (AL) or every other day (EOD) from shortly after weaning. Rats were killed at 6 or 24 mo. The striatum (24 mo only), cerebral cortex, hippocampus and cerebellum were assayed. Muscarinic binding site densities (Bmax) and affinities for [H-3]quinuclidinyl benzilate were determined. Specific activities of choline acetyltransferase (CAT), L-glutamic acid decarboxylase (GAD) and tyrosine hydroxylase (TH) were determined radiometrically. All differences indicated below were significant ( $p \le 0.05$ ). Muscarinic binding studies revealed few differences between

Muscarinic binding studies revealed few differences between AL and EOD rats. At 24 mo, Bmax was 92% higher in the EOD striatum. At 6 mo,  $K_D$  differences were seen in the hippocampus and cerebellum where the values were 53% lower and 83% higher, respectively, in EOD than in AL rats. The hippocampus showed age-related declines in Bmax and  $K_D$  in both groups. In the cerebellum, no age differences in Bmax were noted; however,  $K_D$  increased between 6 and 24 mo in both groups. CAT was lower at 24 mo than at 6 mo in the cortex and cerebellum of FOD rats. Although EOD feeding did not affect

CAT was lower at 24 mo than at 6 mo in the cortex and cerebellum of EOD rats. Although EOD feeding did not affect cortical CAT, activities in EOD rats were higher than in AL rats in the striatum at 24 mo, the hippocampus at 6 and 24 mo, and the cerebellum at 24 mo.

The only age difference in GAD was in the cerebral cortex of EOD rats, where values at 24 mo were lower than at 6 mo. The only diet effect was in the cortex at 6 mo, where EOD rats had greater activity than AL rats. Cortical TH was higher at 24 mo than at 6 mo in both groups.

Cortical TH was higher at 24 mo than at 6 mo in both groups. Hippocampal TH was lower at 24 mo than at 6 mo in AL rats. In contrast, EOD rats showed no age differences in hippocampal TH between 6 and 24 mo. The only dietary effect on TH at any age was a lower cortical activity in EOD rats at 6 mo. Subjecting AL rats to the EOD regimen for 2 weeks at 24 mo did not influence the neurochemical activity

Subjecting AL rats to the EOD regimen for 2 weeks at 24 models not influence the neurochemical parameters discussed above. These findings demonstrate that EOD feeding from weaning selectively affects neurotransmitter systems in different brain regions. Effects on cholinergic parameters are greater than those on adrenergic or GABAergic markers, and represent chronic rather than acute effects. 29.13 SPATIAL VISION IN ALZHEIMER'S DISEASE. Mary Jo Nissen\*

SPATIAL VISION IN ALZHEIMER'S DISEASE. <u>Mary Jo Nissen\*</u> <u>Suzanne Corkin and John H. Growdon</u> (Spon: Edith V. Sullivan) Department of Psychology, Massachusetts Institute of Tech-nology, Cambridge, MA 02139. Alzheimer's disease is a degenerative brain disease that produces marked impairments in domains of performance that are mildly affected in normal aging. Although memory impairment is the most common and often the earliest symptom of Alzheimer's disease, deficits in language function and, occasionally, visual perception can be prominent even in the early stages. Human aging causes changes in spatial contrast sensitivity; Alzheimer's disease may produce an exaggeration of these effects. In addition, patients with Alzheimer's disease who present with visual complaints may have disorders of spatial vision that could be characterized more specifically by the patients' contrast sensitivity functions.

be characterized more specifically by the patients' contrast sensitivity functions. In order to investigate these possibilities, spatial contrast sensitivity was measured in 17 patients with Alzheimer's disease, one of whom had severe perceptual deficits, and 8 healthy, age-matched control subjects. The stimuli were stationary 700-msec vertical sinusoidal gratings of 0.5, 1, 2, 4, and 8 cpd. The mean luminance of the gratings, which were generated on an oscilloscope, was 5 cd/m<sup>2</sup>. The results from 16 of the patients indicated threshold elevation, relative to control subjects, of about 0.37 log unit at all frequencies tested. Although the possibility that the results

Ine results trom 16 of the patients indicated threshold elevation, relative to control subjects, of about 0.37 log unit at all frequencies tested. Although the possibility that the results reflect a criterion difference between groups cannot be ruled out, the similarity of their false alarm rates makes this interpretation unlikely. Rather, the neural degeneration of Alzheimer's disease appears to produce a true sensitivity loss. The remaining patient was unique. This 63-year-old woman had an impairment in object and face recognition so severe that she could not recognize her husband visually, despite good visual acuity. She had a right inferior homonymous quadrantanopia but an otherwise normal ocular examination. A CT scan showed enlargement of the cortical sulci over the lateral convexities posteriorly. An occasional sulcus in the posterior parietal region was capacious, especially on the left. This patient's contrast sensitivity to low and intermediate spatial frequencies was dramatically reduced relative to other Alzheimer patients. Her sensitivity loss was 0.84 and 0.68 log unit at 0.5 and 1 cpd, respectively, whereas her sensitivity as cepual to that of the other patients. This dramatic sensitivity loss to low spatial frequencies in a patient with a severe impairment in object and face recognition supports the view that low spatial frequency information is essential for those functions.

BEHAVIORAL AND FINE STRUCTURAL ASSESSMENT OF 13 MONTH OLD C57BL/6j MICE ON DIFFERENTIAL CHOLINE DIETS. <u>K. A. Doyle\*</u>, <u>L. D. Trombetta\* and H. P. Davis.</u> Dept. Psychol. and Dept. Pharmaceutical Sciences, St. John's Univ., Jamaica, NV. 11120. 29.15 NY 11439.

Retired breeder C57BL/6j male mice at 8-9 months of age were placed on either a choline enriched diet (250 mg choline/ gm diet), choline control diet (s-12 mg choline/gm diet), or choline deficient diet (<1 mg choline/gm diet), or gasive avoidance training. The median step-through-latencies at test for enriched, control, and deficient animals were 364 sec, 101.5 sec, and 15 sec, respectively (N=19-22 per group), and application of the Mann-Whitney U-test indicated that mice on the deficient diet had significantly power retention than control or enriched animals (p<0.05). Enriched and control mice were not significantly different (p>0.20).

and control mice were not significantly different (pP0.20). Light microscopy and electron microscopic ultrastructural analysis of the hippocampus revealed early degenerative changes in the astrocytes of the animals on the choline deficient diet. These effects included cytoplasmic clearing, with loss of cytoplasmic integrity, increases in smooth surfaced vesicles, and mitochondrial enlargement. Observations of neurons showed no significant changes in synaptic regions or in the appearance of neurofibrillary structures. or in the appearance of neurofibrillary structures. Occasionally large abnormally shaped mitochondria were seen in the axoplasm. No degenerative changes were observed in the control or enriched choline groups.

29.14

BIOCHEMICAL AND IMMUNOHISTOCHEMICAL EVALUATION OF CHOLINE ACETYLTRANSFERASE IN AGING AND SENILE DEMENTIA. <u>P. L. McGeer</u>, <u>E. G. McGeer</u>, J. <u>H. Peng\*</u> and J. Suzuki\*. Kinsmen Laboratory of Neurological Research, Dept. of Psychiatry, University of British Columbia, Vancouver, B. C., Canada, V6T 1M5. The primary cholinergic innervation of the neocortex is believed to be the substantia innominata area of the basal fore-brain. We have prepared a detailed map of cholinergic neurons in the human medial and basal forebrain by immunohistochemistry using a monoclonal antibody to human neostriatal choline acetyltransferase (ChAT) developed in a mouse hybridoma. By cutting thin sections of paraformaldehyde-glutaraldehyde fixed tissue and staining first for ChAT and then for cresyl violet, it has been possible to establish that all giant neurons greater than 30 microns in diameter in these areas are cholinergic. The numbers of cholinergic cells in the substantia innominata in normal and senile dementia cases have been determined as a normal and senile dementia cases have been determined as a function of age. We have also correlated such changes with ChAT function of age. We have also correlated such changes with that levels measured biochemically in various cortical areas on fresh post-mortem tissue. Both cholinergic cell counts in the medial basal forebrain and ChAT levels in the frontal cortex decline substantially with age. Senile dementia cases have medial basal forebrain cell counts and biochemical levels of cortical ChAT reduced to less than half those of controls of similar age. These data support the cholinergic hypothesis of memory and Inese data support the cholinergic hypothesis of memory and suggest that cholinergic deficiency dementia may be an appropriate clinical description for dementia cases that may or may not show extensive development of neurofibrillary tangles. 29.16 BIOCHEMICAL STUDIES IN RATS AFTER PROLONGED PHYSICAL

BIOCHEMICAL STUDIES IN RATS AFTER PROLONGED PHYSICAL CONDITIONING. Lewis L. Truex, Norman R. Mason and Michael J. Schmidt, The LiTJy Research Laboratories, Eli LiTJy and Company, Indianapolis, IN 46285. Physical conditioning decreases fat stores, increases cardiac capacity and increases oxidative metabolism in muscle. Physical conditioning is also purported to affect brain function and has been used in therapy programs for affective disorders. The present studies were undertaken to determine if physical condi-tioning resulted in measureable neurochemical changes in rodents, and to determine if there was a difference in the over-all adaptive physical capabilities of young (6-mo) and old (24-mo) rats. mo) rats.

mo) rats. Animals were exercised by treadmill running on a graduated in-tensity scale that continued for 13 weeks. An initial endurance test was used to establish baselines for the young and old animals. Following 8 weeks of conditioning, endurance was test-ed again, and biochemical determinations were made at the end of the 13-week conditioning period. The most striking observation was the effect chronic exercise had on the endurance capacity of was the effect chronic exercise had on the endurance capacity of young and old rats. Young animals were initially able to run a distance of  $1072 \pm 60$  meters, while old animals could only run  $420 \pm 27$  meters. After conditioning, both groups demonstrated improvement: young, 74 percent increase and old rats, 113 per-cent increase. Other changes noted were a 37 percent decrease in the epididymal fat pads of young rats and a 13 percent body weight reduction. Exercise did not reduce the fat pads of aged rats although a 7 percent reduction in body weight was observ-ed. Changes in baset weight were not observed in either ane ed. Changes in heart weight were not observed in either age group.

ed. Changes in heart weight were not observed in Fride age group. Although evidence of conditioning was apparent in the young and the old rats, no biochemical changes in muscle or brain were detected: brain and gastrocnemius muscle mitochondrial cyto-chrome oxidase activity; mitochondrial P/O ratios and respira-tory rates; the concentration of mitochondrial protein; or the binding of 3H-serotonin or 3H-diazepam to cortical mem-branes. There also were no age-related differences in these parameters. The post-decapitation induced accumulation of cyclic AMP was less in the cerebellum of old rats compared to young rats; but conditioning did not change these values. In summary, prolonged physical training, which was adequate enough to produce marked physical improvements in both young and old rats was not sufficient to result in detectable biochemical differences in the muscle or brains of animals after a 13-week training period. However, the experiments do demonstrate that aged rats have the capability of enhancing their endurance thresholds through a physical training regimen.

29.17 INFLUENCES OF AGEING AND PHOTOPERIODS ON ANALGESIA IN MICE. M. <u>Hirst\* and M. Kavaliers\*</u> (SPON: A. Hudson). Depts. of Pharmacology-Toxicology and Zoology, University of Western Ontario, London, Ontario, Canada, N6A 5C1.

Old mammals display altered behavioral responses to narcotic analgesics. Recent studies by us have shown that there are major age-related differences in the daily rhythms of aversive thresholds and analgesia induced by morphine. To pursue these findings we investigated the effects of various light-dark conditions on analgesia in mice of different age classes. Times of reactions to a hot-plate  $(55+/-0.5^{\circ})$  were assessed in young (1-3 month), mature (8-12 month) and senescent (24-30 month) male mice exposed to particular light-dark cycles (L:D 12:12; 16:8, 8:16; 12:12) after administrations of morphine sulphate (10 mg/ml/kg of bodyweight), or saline. The dark phase tests were conducted under low intensity (photosafe light - 0.005 uW/cm<sup>2</sup>) lighting conditions (which is necessary to observe diel changes in this period as normal laboratory lighting has a disruptive influence on dark phase responses). Composites were prepared of aversive threshold and analgesia measures so that 24-hour patterns accumulated from independent tests, with 2-hour intervals. Individual animals were not used for at least 4 days between two testing sessions. Significant day-night rhythms of responsiveness were observed in the treated mice. The diel rhythms were characterised by increases in aversive thresholds during the course of the light phase, with a significant dark phase enhancement and a precipitate fall in threshold with the dark-light transition. The timing of the nocturnal increase in analgesia, as well as the extent of the elevation, was dependent on the duration of the dark period. Other features of the response also varied with the L:D conditions. In all cases, however, there was a significant age-dependency in response in the dark phase; the old animals demonstrated a markedly lower level of analgesia at this time, but no consistent differences were evident in the light phases. The observed effects suggest that photoperiods and age interact to influence endogenous opiate systems. It re 29.18 AGING-RELATED CHANGES IN THE CORRELATIONS BETWEEN SNIFFING AND HIPPOCAMPAL RHYTHMIC SLOW-WAVE ACTIVITY IN THE RAT. Wm. B. Forbes and F. Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545. During odor discrimination training, sniffing exhibits a pre-

During odor discrimination training, sniffing exhibits a preferred latency relationship with rhythmic slow-wave activity (RSA) in the hippocampal formation; this relationship is strongest when animals are evaluating the behavioral relevance of odors (Macrides, Eichenbaum, and Forbes, J. Neurosci., 2:1705-1717, 1982). The present study analyzed sniffing (monitored with a nasal thermocouple) and hippocampal RSA (bipolar recording in dorsal field CAI) during open field behaviors in Fisher-344 rats aged 3, 18, 30, and 36 months. Analytic procedures were based on the fast-Fourier transform. There was a monotonic decrease with age in the incidence of higher frequency (7-10 Hz) sniffing and hippocampal RSA during free behavior. However, high frequency (8 Hz) hippocampal RSA could be elicited in animals of all ages by inducing them to struggle, suggesting that the reduced incidence of high frequency hippocampal RSA (in the older animals might be due to a decrease in the vigor of spontaneous movements in the open field. In the youngest animals, (1) the dominant frequency of sniffing matched that of hippocampal RSA (frequency entrainment) more often than would be predicted on the basis of chance; (2) preferred phase differences between sniffing and hippocampal RSA were reliably observed in the 5-9 Hz range; and (3) these preferred phase differences varied linearly as a function of frequency, implying an underlying latency relationship. These phennomena changed progressively with age as follows: (1) the incidence of frequency entrainments decreased; (2) the frequency range within which preferred phase differences were observed became increasingly narrow; and (3) the incidence of preferred phase differences decreased. In the oldest animals, preferred thespeci differences decreased. In the preferred phase difference at that fre-

29.19 FROLONGED NEUROLEPTIC EXPOSURE AND DOPAMINERGIC SUPERSENSITIZATION IN AGING MICE, P.K. Randall\*, J.S. Randall\* and J.A. Severson (Spon. F.N. Pitts, Jr.). Depts. of Physiology & Biophysics and Psychiatry, USC Sch. of Med. and Andrus Gerontology Ctr., L.A., CA 90089

Gerontology Cfr., L.A., CA 9009 Reports on supersensitization of striatal dopamine (DA) receptors in the aging rodent have been inconsistent. We previously reported that aging C57BL/6J mice show diminished supersensitization to moderate chronic haloperidol regimes by both neurochemical (3H-spiperone binding) and behavioral (apomorphine-induced stereotypic behavior) criteria. In order to determine whether this phenomenon is dependent upon severity of chronic drug treatment, we examined 6 1/2, 13, and 27-30 month-old C57BL/6J mice after 0, 30, 60, or 90 days of treatment with 2.5 mg/kg haloperidol administered in the drinking water. After a 7-day withdrawal period mice were tested for apomorphine-induced stereotypic behavior (1.0 mg/kg, IP.) On the following day mice were sacrificed and striata dissected for analysis of 3H-spiperone binding.

analysis of 3H-spiperone binding. Results were similar for binding and behavioral tests. Although receptor number (Bmax) and behavioral response to apomorphine varied significantly with age and duration of haloperidol treatment duration, the Age X Duration interaction did not approach significance, indicating a similar supersensitization in all ages. Haloperidol treatment produced a highly linear increase in both binding and behavioral response to apomorphine over the 90 days of treatment. Bmax for 3N-spiperone binding decreased significantly with age, while stereotypic behavior increased between 6 1/2 and 13 months and then declined slightly in the oldest group. Analysis of the time-course of stereotypic behavior following apomorphine injection revealed that the elevation of total stereotype scores in the older groups was the result of extended duration of the response rather than increases in peak response. No alterations in Kd for spiperone binding were observed.

In addition, a highly regular linear relationship was obtained between group means of 3H-spiperone Bmax and stereotypic behavior scores (r=.97). Correlations of binding and behavior between individual animals within groups, however, were poor.

These data suggest that diminished neuroleptic-induced DA-supersensitization in aging mice is probably confined to relatively short treatment durations.

29.20 LESION-INDUCED DA SUPERSENSITIVITY IN AGING MICE. J.S. Randall\* and P.K. Randall\* (SPON: J.K. Engelhardt ) Dept. of Physiology & Biophysics, USC Sch. of Med., Andrus Gerontology Ctr., L.A., CA 90089.

Regulatory adjustments of receptor number may be critical in the appearance of therapeutic or motoric side-effects of neuroleptic drugs. We have found that old mice are less likely than young to develop DA receptor-supersensitivity when given a moderate chronic regime (21-day, 1.2 mg/kg injected or 2.0 mg/kg in drinking water). Joseph et al. (Life Sciences, 1982), however, using a unilateral nigro-striatal lesion model in Wistar rats did not detect a difference in supersensitivity with age. Other results have as well been contradictory. In order to examine whether these differences resulted from species variation or from the technique employed for inducing supersensitivity, we investigated the contralateral rotational behavior to dopamine agonists in different ages of mice following unilateral 6-OHDA lesions of the nigro-striatal pathway.

Four, 10-, or 24-month-old C57BL/6J mice received unilateral striatal (0.5 mm anterior, 2.4 mm lateral, and 3.1 mm ventral from bregma) injections of 4 ul of 4 ug/ul 6-OHDA hydrobromide. Five, 10, and 20 days following this injection mice were tested for contralateral rotation to 2.0 mg/kg apomorphine. All mice, regardless of age, showed a regular increase in net contralateral rotations over this time period. There was no significant age effect either in percent of mice showing reliable contralateral rotation or in net contralateral turns of those which exhibited the behavior. In addition, the spontaneous contralateral asymmetry apparent following the lesion disappeared in a regular fashion- highly correlated with the appearance of contralateral rotation to apomorphine in all age groups.

These data suggest that the age related deficits in DA supersensitization which we have observed to chronic neuroleptic treatment are probably specific to that less severe stimulus. 30.1 WHAT IS THE RELATIONSHIP BETWEEN EMBRYONIC AND ADULT GROWTH PATTERNS IN THE TELEOST VISUAL SYSTEM. <u>L.C. SHELTON</u><sup>®</sup> and <u>R.D. FERNALD</u>, Inst. of Neuroscience, University of Oregon, Eugene, Or. 97403.

In the African cichlid <u>Haplochromis</u> <u>burtoni</u>, as in many teleosts, growth continues throughout its lifetime. As the body grows, so do both the retina and tectum maintaining a congruent visual map as they do so.

Visual map as they do so. It has been shown in adult <u>H.</u> <u>burtoni</u>, using <sup>3</sup>H-thymidine to locate newly generated neurons, that the retina enlarges symmetrically, partially ( $\approx 60\%$ ) by stretching the existing tissue and partially ( $\approx 40\%$ ) by the addition of new neurons at the margin of the eye. The tectum, in contrast, grows asymmetrically, adding new tissue only over about half its extent, primarily at the caudal pole and more medially than laterally.

Since a congruent visual map of the retina on the tectum exists throughout adult life, the distinctly different growth patterns of these two structures suggests the need for rearrangement of the fiber projections during growth. To account for this difference, it has been hypothesized that the sites of retinal ganglion cell termination are continuously re-located during adult growth. We have examined embryonic development in this species to understand whether this hypothesis is consistant with the growth pattern during embryogenesis. For example, compensatory differential growth in the embryo may hold the key to understanding the adult growth

By examining <sup>3</sup>H-thymidine labelled cells in embryos and young fry, following a variety of survival times, we can show that the retina of the embryo is growing quite asymmetrically. The tectum, on the other hand, is growing in a pattern very similiar to that of the adult. Whether or not this differential growth pattern between retina and tectum in the embryo is sufficient to compensate for the observed adult growth patterns is currently under investigation.

Supported by the Whitehall Foundation.

30.2 TRANSPLANTATION OF EMBRYONIC NEURAL TISSUE INTO THE HEMISECTED SPINAL CORD. B. H. Hallas. Department of Anatomy, New York College of Osteopathic Medicine, Old Westbury, NY 11568.

Previous investigations have demonstrated that embryonic spinal cord or neocortical tissue could be successfully transplanted into the mamalian spinal cord. Such transplants survived, grew, and established connections with the host brain. The nature of these connections, however, was unknown. The present research provides evidence that it is possible to reestablish afferent and efferent connections of the severed spinal cord by the placement of embryonic transplants into the lesioned area.

Hemisections were made in adult rat spinal cord between vertebrae C5 and C6. Immediately following the hemisections either 14-day embryonic spinal cord or 15-day embryonic neocortex was transplanted into the lesioned area. The host animals were then allowed to survive for 90 days at which time either HRP was injected directly into the transplants to determine the afferents to the transplants or electrolytic lesions were made in the transplants for the determination of the efferents. Additional electrolytic lesions were made in areas of the host brain that normally provide afferents to the intact cervical spinal cord.

The afferents to the transplants were provided by neural structures that normally have axons that course through the cervical spinal cord. Labeled neurons were located in the motor cortex, deep cerebellar nuclei, cervical and thoracic spinal cord. The efferents of the transplants terminated in areas of the spinal cord that were immediately surrounding the transplant. Large areas of terminal field degeneration were observed in the cervical spinal cord (Cl-C3), in the upper thoracic spinal cord, and in the lower brain stem.

Therefore, the results of these experiments indicate that an embryonic neural transplant is not only capable of completely filling the lesioned area of an adult spinal cord but receives afferents from the host's central nervous system that normally has axons coursing through the hemisected area and also provides efferents to the intact spinal cord. In addition, the transplants prevented a neural glial scar from forming along the entire interface between transplant and host spinal cord. The transplants then become incorporated into the spinal cord and function as a "bridge" between the severed ends of the spinal cord.

30.3 A METHOD FOR LOW MAGNIFICATION HIGH RESOLUTION PHOTOGRAPHY IN THE FLUORESCENCE MICROSCOPE <u>R. Martensson</u>, Medical Photographer, Department of Histology, University of Lund, Lund, Sweden.

In order to observe high-resolution histofluorescence one must use a 10x or higher objective depending on the construction of the dark field condenser, otherwise the illumination is not sufficient to photograph evenly throughout the preparation and in sufficient detail. When using these higher powers of magnification, montages are often constructed to represent the entire field of interest. Several technical problems arise in using this procedure: a) variability in background tone between photos within a montage; b) after exposing a tissue to fluorescent light for the time necessary to obtain the montage, the fluorescence can have faded to the point where it is no longer useful; c) cost of making a large montage can be prohibitive; d) the time necessary to photograph, copy, print and assemble the montage can be very long. With these problems in mind a method was developed to use a low power magnification which allows for a large field to be photographed in a single frame, and yet retain brightness, sensitivity and high resolution of detail within the photographed image. A Zeiss fluorescence microscope using transmitted light, standard dark field condenser and a 2.5x objective is used in this work. With this method one is able to: 1) increase the consistency of tone of photographs from experiments requiring large field representations, 2) save preparations from fading due to overexposure 3) save time, and 4) save money. Specifically a montage consisting of 30 separate photos, which exposes the specimen to 30 minutes of constant fluorescent illumination, and which takes 50 hours to develop and copy can now be represented more clearly on one single negative which is exposed to 3 minutes of fluorescent illumination. Examples are presented using catecholamine histofluorescence and serotonin immunohistochemistry. This procedure is also applicable for other tissue stains which require transmitted light using low power magnification.

**30.4** INTRACEREBRAL AND INTRASPINAL IMPLANTS OF LOCUS COERULEUS CELL SUSPENSIONS: DELETERIOUS EFFECT OF TRYPSIN IN THE SUSPENSION MEDIUM, <u>A. Bjorklund</u>,

H. Nornes, S. B. Dunnett, F. H. Gage and U. Stenevi\*. Department of Histology, University of Lund, Sweden, Department of Anatomy, Colorado State University, Fort Collins, Co. and Department of Experimental Psychology, University of Cambridge UK.

Dissociation of embryonic CNS tissue was devised as a technique for implantation of developing neurones into the depth of the brain in adult rats (Bjorklund et al. <u>Cell Tiss. Res.</u> 212:39, 1980; Schmidt et al. <u>Brain Res.</u> 218:347, 1981). This procedure, which involves incubation of the tissue in trypsin followed by mechanical dissociation, has been successfully applied to grafting of a variety of neuronal cell types, such as dopaminergic, serotonergic and cholinergic neurones. Initial attempts to graft suspended noradrenergic (NA) neurones taken from the developing locus coeruleus (LC) region were however unsuccessful. This prompted us to investigate which factors might hamper the survival of LC neurones in the dissociationimplantation procedure.

In the first series of experiments, the age of the donor foctuses was varied between 12 and 17 days of gestation (CRL of 7, 9, 11, 13, 15 and 20 mm were tested). The tissue was collected in room-tempered sterile glucose-saline, incubated in 0.1% orude trypsin (Sigma, Type II), washed and ruptured with a fire-polished Pasteur pipette, according to our standard procedures. 3-5µl aliguots of the resulting cell suspension were injected stereotaxically into the dorsal hippocampal formation denervated by 6-0HDA. After survival times of 4-8 weeks, the rats were processed for monoamine histofluorescence by the ALFA method. Although surviving grafts of good size, rich in non-monoaminergic neurones, were found in most animals, the grafted tissue from all donor ages contained at most only some single, scattered NA-containing neurones, and there was very little NA fibre outgrowth from the grafts.

In the next series of experiments, the LC region taken from 11 mm foetuses was dissociated as above, but the trypsin incubation step was omitted. 3µl aliquots were injected into the dorsal hippocampus and the thoraco-lumbar spinal cord in 6-0HDA denervated rats. All these grafts contained abundant NA-containing neurones. They had formed an extensive plexus of NA-containing fibres throughout the host hippocampus and the gray matter of the spinal cord, similar to what has previously been described with solid LC grafts (Bjorklund et al. <u>Brain Res.</u> 170:409, 1979; Nornes et al. <u>Cell Tiss. Res.</u> in press). These results suggest that some neuronal types may be relatively sensitive to trypsin in the dissociation procedure.

REINNERVATION OF DENERVATED HIPPOCAMPAL FORMATION BY 30.5 EMBRYONIC RAPHE CELL IMPLANTS. AN IMMUNOHISTOCHEMICAL STUDY IN THE RAT. H.W.M. Steinbusch, F.H. Gage, A. Björklund' and U. Stenevi\*. Dept. Pharmacology, Free University, Amsterdam, The Netherlands and \*Dept. Histology, University of Lund, Lund, Sweden.

Previous studies from one of our laboratories have clearly demonstrated that intracerebral implants of embryonic dopamine, noradrenaline, and acetylcholine neuronal cell structures exhibit the capacity to reinnervate specific brain areas in the adult host recipients. In addition, preliminary results on the survival and outgrowth of transplanted embryonic serotonin containing raphe nuclei using fluorescence histochemistry has been presented. In the present communication we present more complete evidence of cell survival and fiber outgrowth using an immunofluorescent method, in conjunction with the cell suspension implantation methodology.

Embryonic raphe cells were dissected from the region of the pontine mesencephalic flexure from embryonic rats with crown-rump length of 15 mm. 2 µl volumes of dissociated cell suspensions were injected into the dorsal anterior and posterior hippocampal formation unilaterally. The rats were pretreated with 5,7-DHT and DMI to induce a complete bilateral serotoninergic denervation. After a survival time of 3 months the rats were perfused and processed for immunofluorescence, using a specific and well characterized antibody to serotonin.

The results demonstrate that long term survival of raphe cells in suspension is effective and moreover, a limited number of 5-HT cells in suspension can induce an extensive density of reinnervation of the host hippocampus. The serotoninergic neurons in the suspensions implanted in the denervated rats give rise to a restored innervation of hippocampus on the side of the transplants. The contralateral side lacks any serotonin immunoreactivity. The ingrowth of newly formed fibers was not restricted to the dorsal and ventral parts of the hippocampus. The pattern of reinnervation of the host hippocampus by the transplanted raphe cells was found to be quite specific and resembles the distribution seen in the control brains. A dense plexus of serotoninergic varicose fibers was found in addition in the area of the medial forebrain bundle mostly in its caudal extent, however only on its ipsilateral side. Studies are currently in progress to investigate not only the ingrowth of serotoninergic fibers into the hippocampus but also the ingrowth of serotonin-containing raphe cell suspensions into the spinal cord after spinalectomy. Functional correlates of these denervating and reinnervating procedures are being tested.

EFFECTS OF REPETITIVE INDUCTION OF LONG-TERM POTENTIATION IN THE DENTATE GYRUS OF THE RAT. M.C. de <u>Jonge\* and R.J. Racine</u>. Dept. of Psychology, McMaster University, Hamilton, Ontario, 30.7 Canada L8S 4K1.

Canada L8S 4K1. High frequency trains of pulses applied to the perforant path can produce a long-term potentiation (LTP) of the perforant path to dentate granule cell synaptic response. Most LTP studies have utilized multiple trains to produce LTP and in some cases several sessions of trains have been applied to maximize the LTP effect. Even in these cases, however, LTP is far from permanent. The experiment reported here was designed to test the effect of inter-session interval on levels and duration of LTP and to datarning if residual chapters in responsitivity of the system determine if residual changes in responsitivity of the system could be detected after the response amplitude had decayed back to baseline. For example, although no residual potentiation is evident in terms of response amplitude after decay to baseline, subsequent LTP effects may be larger, last longer or occur at lower threshold.

Three groups of animals each received 5 sessions of 70 trains. The train intensity was increased in 10 steps during each train session in order to determine threshold and peak LTP effects. In group one, the 5 train sessions were 24 hours apart, followed In group one, the 3 train sessions were 24 hours apart, followed by a nine day decay period during which evoked responses were measured each day. In group two, the amplitude of the population spike was allowed to decay to halfway between the peak potentiated response and baseline, before the application of the next series of trains. After the 5th session, decay was followed for a nine day period. The third group was allowed to decay back to baseline amplitudes before each subsequent train session. A final nine day decay curve was determined for this group as well.

The animals administered a train session once every 24 hours showed daily increments in LTP of both population spike and population EPSP. The animals receiving train sessions after partial (50%) decay showed increases in LTP of the population partial (50%) decay showed increases in LP of the population EPSP but not population spike. The animals allowed to decay to baseline between train sessions showed no increase in peak LTP after the first session. None of the groups showed any changes, over sessions, in LTP threshold or decay rates. There does not then, appear to be any residual changes in responsitivity in the system once the response amplitude has returned to baseline. returned to baseline.

30.8 LONG-TERM POTENTIATION OF THE PERFORANT PATH-GRANILE CELL SYNAPSE IN THE CHRONIC RAT PREPARATION: EFFECTS OF CATECHOLAMINE

SYMAPSE IN THE CHRONIC RAT PREPARATION: EFFECTS OF CATECHOLAMINE DEPLETION. G.B. Robinson\* and R.J. Racine. (SPON: N.W. Milgram). Dept. of Psychology, McMaster University, Hamilton, Ontario, Canada L8S 4K1. Previous investigators (Bliss, T.V.P., Goddard, G.W. & Riives, M., J. Physiol., 334: 475, 1983) have shown that catecholamine depletion, in the anesthetized rat, reduces the level of long-term potentiation (LTP) of the perforant path-granule cell (PP-GC) europtic acconcere but not of the ponulation spike. It is possisynaptic response but not of the population spike. It is possible, however, that catecholamine depletion may result in a more depolarized GC population. Any further increase in excitatory It is possiinput might then be expected to probability of cell discharge. In the EPSP while increasing the probability of cell discharge. In have investigated this hypothesis in the chronic animal. This We allowed us to test the effect of catecholamine depletion both on baseline responses and on that component for LTP which lasts for days or weeks.

Rats were implanted with stimulating and recording electrodes in the PP and hilus of the fascia dentata, respectively, then al-lowed at least two weeks recovery. The effects of reserpine (same regimen as Bliss et al., 1983) on baseline PP-GC field responses was determined by comparison of I/O curves obtained im-mediately before and 24 hrs after injection. During potentiation trials, test responses were sampled once every 20 sec for 15 min, to establish baseline amplitude, and for 15 min after each of 8 trains presented in an ascending intensity series. Non-depleted controls received identical treatment. When the LTP had decayed to baseline the animals were tested under the opposite treatment condition.

Condition. Thus, each animal served as its own control. Catecholamine depletion itself resulted in a significant in-crease in the PP-GC population spike amplitude without affecting threshold. This was accompanied by a significant decrease in the EPSP amplitude. These effects on baseline responses are consistent with the proposed disinhibition hypothesis.

During potentiation trials depleted animals consistently ex-hibited greater levels of LTP (proportional to the current basehibited greater levels of LP (proportional to the current base-line) of the EPSP and population spike than was observed in the control condition. The potentiated EPSP, however, was still smal-ler in amplitude than before drug treatment. The level of EPSP and spike LTP in the depleted condition remained above that ob-served in the control condition for several days. Subtraction of drug effects, however, indicated that catecholamine depletion had no effect on that component of LTP which can persist for days or weeks.

INTRACELLULAR TESTS OF POSSIBLE LTP MECHANISMS. J. S. Taube 30.9 and P. A. Schwartzkroin (SPON: H.D. Patton). Dept. of Neurologand r. A. Schwartzkröin (Sröw n.D. Fatton). Dept. of weininge ical Surgery, University of Washington, Seattle, WA 98195. A description of the mechanisms underlying long term potentia-tion in hippocampus has been long in coming. Several investiga-tions suggest that changes may be localized to the synapses, whereas other experimental evidence implicate alterations in the dendritic tree or even in interneuron-mediated inhibition. Since most LTP experiments have utilized the technique of extracellular recording of field potentials, it has not been possible to determine what changes might be occurring at the level of the postsyn-aptic membrane of a single cell. We have monitored the intracellularly-recorded response to glutamate in order to test the hypothesis that glutamate sensitivity is altered, and have re-corded from interneurons to examine their role in LTP.

corded from interneurons to examine their role in LIP. 400  $\mu$ m thick guinea pig hippocampal slices were cut and main-tained <u>in vitro</u> at 35°C. Intracellular recordings were made from the soma of CAI pyramidal cells and extracellular field potent-ials were monitored simultaneously with another electrode locat-ed in nearby stratum pyramidale. Orthodromic input was elicited with stimulation in stratum radiatum. Glutamate (1 mM) was micro-pressure-injected from pipettes introduced in the CAI apical den-drites (30 epi 2, um tin dimetar 10 mass nucles). The drug drites (30 psi, 2 µm tip diameter, 10 msec pulse). The drug electrode was positioned to achieve a short latency, fast-rising depolarization, and the pulse duration adjusted so the response was subtreshold for action potential initiation. Afferent fib-ers were then tetanized (20 Hz for 5 sec, or 50 Hz for 1 sec) and the response to glutamate monitored for 30 min afterwards. Following tetanization the pyramidal cell was often hyper-

polarized (5-10 mV). Consequently, for subsequent testing, we adjusted the membrane potential to the pretentiated level by in-jecting depolarizing current into the cell. It was difficult to potentiate the intracellularly recorded EPSP, even though our extracellular field potential showed potentiation. The response to glutamate following tetanization was inconsistent, but usually showed either no change or a decreased amplitude. The amplitude of the glutamate response was extremely sensitive to the position of the electrode; when care was taken to control for this factor, no change could be found in the response to glutamate. It seemed unlikely that LTP was due to a decrease in inhibition since: 1) the EPSP/IPSP sequence (produced by Schaffer collateral stimula-tion) sometimes included a potentiated IPSP; this occurred independently of whether or not the EPSP was potentiated; 2) record-ings from interneurons located in stratum pyramidale indicated that interneuron activity was not decreased following tetaniza-tion; 3) intracellularly-recorded EPSPs in the interneurons were not decreased.

30.11 VOLTAGE-CLAMP ANALYSIS OF LONG-TERM SYNAPTIC POTENTIATION. German Barrionuevo, Stephen Kelso and Thomas H. Brown. Divis of Neurosciences, City of Hope Research Institute, Duarte, CA Division 91010.

Long-term synaptic potentiation (LTP) is an extremely per-sistent enhanced synaptic efficacy that can be induced by repeti-tive synaptic stimulation for periods of a few seconds or less Extracellular recordings performed in vivo on the hippocampal for-mation, suggest that LTP may last for hours, days, or weeks. LTP has been proposed to play a role in information storage in the nervous system.

nervous system. As part of an effort to understand more about the mechanisms underlying LTP, we have recently developed the capability of applying the technique of voltage-clamp analysis to synapses in the hippocampal slice (Brown and Johnston, <u>J. Neurophysiol</u>. in press; Johnston and Brown, In: <u>Brain Slices</u>, 1983). Here we report preliminary observations on our voltage-clamp studies of LTP. Intracellular recordings were made, using a timeshare single microelectrode current- and voltage-clamp device, from pyramidal neurons of the CA1 and CA3 regions. The slices were bathed in 10 µM picrotoxin to block the recurrent or feedforward inhibition that normally accompanies the monosynaptic excitatory synaptic

<sup>µ</sup>M picrotoxin to block the recurrent or feedforward inhibition that normally accompanies the monosynaptic excitatory synaptic inputs to these cells. LTP was induced by stimulating the afferents at 100 Hz for 1 second. This tetanic stimulation was presented 2-4 times at 5 second intervals. The input resistance, synaptic potential amplitude and synaptic current amplitude were measured before and 15 minutes to 1 hour after the tetanus. LTP was observed, under current- and voltage-clamp conditions, in six pyramidal neurons. As might be expected (Carnevale and Johnston, J. Neurophysiol. 47, 606, 1982), the synaptic currents increased more than the corresponding synaptic potentials. There was no increase in the input resistance after LTP. Mean (+ SE) values for the synaptic current amplitude, the synaptic potential amplitude and the input resistance, before and after the induc-tion of LTP, are given in the table below.

Control	After LTP	Percent of Control
9.8 + 2.4	15.3 + 4.4	156
- 0.5 + 0.1	 1.2 + 0.4	240
53 <u>+</u> 12	52 <u>+</u> 11	98
	$\frac{\text{Control}}{9.8 + 2.4}$ $0.5 + 0.1$ $53 + 12$	Control         After LTP $9.8 \pm 2.4$ $15.3 \pm 4.4$ $0.5 \pm 0.1$ $1.2 \pm 0.4$ $53 \pm 12$ $52 \pm 11$

We are presently attempting to determine whether the increased synaptic currents result from an increase in the synaptic conduc-tance and/or a change in the reversal potential. (NIH Grants NS 18861, NS18295 and a McKnight Foundation Scholar's Award).

30.13

QUANTAL ANALYSIS OF LONG-TERM SYNAPTIC POTENTIATION. <u>Douglas</u> <u>Baxter and Thomas H. Brown</u>. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010. Long-term synaptic potentiation (LTP) is an extremely per-sistent form of neuronal plasticity that can be induced by brief repetitive synaptic stimulation. Although LTP was originally thought to be unique to the hippocampal formation, it now appears to be a rather general feature of many central and peripheral synapses (Brown and McAfee, <u>Science 211</u>,1411, 1982; Swanson, et al., <u>Neurosci. Res. Prog. Bull. 20</u>; 1982). We were interested in knowing whether the mechanism responsible for LTP is pre- or postsynaptic. In principle, LTP could arise either from an increase in the average number of quanta released (termed the mean quantal content, m), and/or from an increase in the average amplitude of the postsynaptic response associated with the release of each quantum (termed the mean quantal size,  $\tilde{q}$ ). An increase in m implies a presynaptic mechanism while an increase in

the release of each quantum (termed the mean quantal size,  $\bar{q}$ ). An increase in m implies a presynaptic mechanism while an increase in  $\bar{q}$  could arise from either pre- or postsynaptic factors. Three methods of quantal analysis were used to determine whether LTP is due to an increase in m or  $\bar{q}$ . For the first quantal analysis of LTP, we selected the crayfish opener neuromuscular junction because of its numerous advantages for such studies. Conventional intracellular recordings were made from small muscle fibers in young crayfish. Several hundred evoked excitatory junctional potentials (EJPs) were collected before and 15 minutes to 2 hours after brief repetitive stimulation of the excitatory axon that innervates these fibers. that innervates these fibers. LTP was observed in 7 fibers. The EJP amplitudes increased on

L1P was observed in / fibers. The LJP amplitudes increased on the average to 179% of the pretetanic control values. The in-crease in LJP amplitude could be entirely accounted for by a corresponding increase in m. In no cases was there a significant change in  $\bar{q}$ . The table below summarizes the range of average measurements or calculated parameters, before and after LTP, as well as the average percent change. The parameter estimates (m and  $\bar{q}$ ) made by the three methods of quantal analysis were in evcellent accement excellent agreement.

Measurement or Calculated Parameters	Range During Control Period	Range After LTP	Mean % Change
EJP amplitude(uV)	63 - 260	93 - 430	79
m estimate	0.2 - 2.5	0.3 - 4.2	83
q̄estimate (μV)	107 - 320	109 - 328	-2

These findings suggest that LTP results from presynaptic changes that increase the mean number of quanta released. The generality of this conclusion is currently being tested by performing similar quantal studies of LTP in the hippocampus. (NS18861, NS 07190 and a McKnight Foundation Scholar's Award).

30.12 ASSOCIATIVE LONG-TERM SYNAPTIC POTENTIATION IN HIPPOCAMPAL SLICES.

ASSOCIATIVE LONG-TERM SYNAPTIC POTENTIATION IN HIPPOCAMPAL SLICES. <u>Thomas H. Brown and German Barrionuevo</u>. Division of Neuro-sciences, City of Hope Research Institute, Duarte, CA 91010. Associative long-term synaptic potentiation (LTP) has been suggested as a candidate mechanism for aspects of learning and memory in the vertebrate central nervous system. The essential phenomenon was first well-characterized in a series of <u>in vivo</u> studies performed on the interactions between two separate sets of synaptic inputs to the dentate gyrus (Levy and Steward, <u>Brain Res.</u> 175. 233. 1979: Levy. et al., Neurosci, in press; Levy and Synaptic Injust to the dentate gyrus (tevy and steward, <u>brain kes.</u> Steward, <u>Neurosci.</u> in press). One input was arranged to generate a weak and the other a strong extracellularly recorded synaptic response. Concurrent tetanic stimulation of both inputs produced a subsequent long-term enhanced synaptic efficacy in the preof either pathway alone failed to have this effect.

of either pathway alone failed to have this effect. One major breakthrough, in the effort to understand such use-dependent forms of cortical synaptic plasticity, was the develop-ment of the <u>in vitro</u> hippocampal slice preparation. The advantage of the hippocampal slice preparation is that the circuitry is well-defined and relatively simple and it is possible to apply to the slice powerful neurophysiological techniques that are imprac-ticable <u>in vitro</u> (Brown and Johnston, <u>J. Neurophysiol.</u>, in press; Johnston and Brown, In: Brain Slices, <u>1983</u>; Barrionuevo, et al., <u>Neurosci. Abst.</u> 1983). We were therefore interested in knowing whether associative LTP could be studied in the hippocampal slice. Intracellular recordings were made from 16 pyramidale neurons

whether associative LIP could be studied in the hippocampal slice. Intracellular recordings were made from 16 pyramidale neurons of the CAI region of the slice. One synaptic input to these cells was made to generate a weak (2-5 mV) excitatory postsynaptic potential (EPSP) and the other input was made to produce a strong EPSP that was 2-5 times larger. Seventy five percent of the cells showed associative LTP; that is, simultaneous tetanic stimulation of both input pathways resulted in a subsequent long-term enhanced events in the weak input was input in the tetanic tetanic tetanic. synaptic efficacy in the weak input under conditions in which the same tetanic stimulation of either input alone failed to have this effect. The average increase in EPSP amplitudes was 81%. Asso-ciative LTP was shown in some cases to last hours without decre-ment. The plastic changes were localized within the CA1 region

ment. The plastic changes were localized within the CAI region and appear to reside in the pre- or postsynaptic elements of the monosynaptic excitatory input to the pyramidal neurons. The increased synaptic efficacy could not be accounted for by any of several measured postsynaptic passive membrane properties. These results demonstrate that associative LTP occurs in vitro and is not unique to the dentate gyrus. The technical advantages of the hippocampal slice should facilitate more detailed analysis of the mechanism underlying this interesting form of long-term synaptic plasticity. (Supported by NIH grant NS18861 and a McKnight Foundation Scholar's Award).

INTRACELLULAR INJECTIONS OF EGTA BLOCK HIPPOCAMPAL LONG-TERM INITAGLELULAR INDECTIONS OF EGIA BLOCK HIPPOLAMPAL LONG-TEMP POTENTIATION, J. R. Larson\*, G. Barrionuevo, S. R. Kelso, F. Schottler\*, and G. Lynch. Department of Psychobiology, University of California, Irvine, CA 92717. It has been suggested that the long-term potentiation (LTP) of synaptic potentials seen in hippocampus after high frequency

stimulation of afferents is due to a calcium-dependent change in the post-synaptic neuron. To test this, we have injected the calcium chelator EGTA into hippocampal CAl pyramidal cells and measured synaptic potentials before and after high frequency stimulation of the Schaffer-commissural pathway.

stimulation of the Schaffer-commissural pathway. Hippocampal slices were prepared from rats and maintained in vitro. An extracellular recording electrode was positioned in field CA1 (s. radiatum or s. pyramidale) and a bipolar electrode placed in s. radiatum to activate the Schaffer-commissural fibers. Only slices in which high frequency stimu-lation of these fibers (5 trains of 10 or 30 pulses at 300 or 100 Hz) produced stable LTP of the dendritic field potential (at least 10% increase in slope and amplitude for 15 min) were used. We obtained intracellular recordings from 33 cells im-paled with control electrodes (filled with 4 M potassium aceacetate + 1.2-.5 M EGTA). All cells had resting membrane poten-tials greater than 55 mV, action potential amplitudes greater

than 60 mV, and input impedances greater than 15 megaohms. Single pulse stimulation of Schaffer-commissural fibers evoked stable EPSP's in all cells reported here. EGTA injec-tion (200 ms long .5 nA hyperpolarizing current pulses passed through the electrode at 2 Hz via a bridge circuit for 5 minthrough the electrode at 2 Hz via a bridge circuit for 5 min-utes) had no detectable effect on membrane potential, input impedance, and paired-pulse facilitation of EPSP amplitude. Twenty-eight of 33 cells recorded with control electrodes showed LTP of the evoked EPSP (at least 10% increase in EPSP amplitude lasting a minimum of 10 minutes after high frequency stimulation; overall mean of 30 + 4%), however only 6 of 26 cells injected with EGTA exhibited LTP (by the same criterion; overall mean of 1  $\pm$  3\%). The amount of LTP induced in the field potentials of the two groups did not differ. These results indicate that selective manipulation of the

These results indicate that selective manipulation of the target neuron can prevent the occurrence of LTP. Given the discrete effects of EGTA found here and reported by others for CAl pyramidal cells, it is reasonable to conclude that the drug's effects on LTP were mediated by calcium buffering.

INPUT FROM ERGORECEPTORS AND OTHER SENSORY MODALITIES ONTO LUMBAR 31.1

INPUT FROM ERGORECEFTORS AND OTHER SENSORY MODALITIES ONTO LUMBAR SPINORETICULAR NEURONS. Roger Thies. Dept. of Physiology & Bio-physics, Univ. of Okla. Hith. Sci. Ctr., Okla. City, OK 73190. The increase of blood pressure during exercise is due partly to signals from contracting muscles; the ascending pathways for this response are unclear. Other investigators have shown that type III afferent fibers respond to muscle contractions, to squeezing of tendons, and to injections of bradykinin (BK) and capsaicin (CAP); the terminals for these fibers are called ergoreceptors. Others have found that bilateral lesions of lateral reticular nuclei (LSN) in the medulus block this somatonessor response nuclei (LRN) in the medulla block this somatopressor response.

We have recorded with carbon fiber microelectrodes the activity of neurons located in laminae IV to VII on the left side of  $L_7$  & S<sub>1</sub> segments in 16 anesthetized cats. Antidromic stimuli were applied ipsi- and contralaterally to both nucleus reticularis gi-gantocellularis (NGc) and LRN. The 28 spinoreticular (SR) plied ipsi- and contralaterally to both nucleus reticularis gi-gantocellularis (NGc) and LRN. The 28 spinoreticular (SR) neurons projected predominantly contralaterally (20) and then bi-laterally (7), with similar numbers to NGc and LRN. Their con-duction velocity was  $42.6\pm2.3$  ( $\overline{x}\pm5.E.$ ) m/sec. Amplitudes with optimal localization were often only 0.1-0.5 mV, which precluded study of inputs to them in some cases. Of 11 SR neurons tested for somatic input, 5 were excited by squeezing the left gastrocnemius muscle or pinching the skin and one was inhibited; one was inhibited from the right gastroc.; 2 were inhibited by squeezing two or three limbs; and 2 were un-responsive. Eighteen of 25 SR neurons tested were fired by elec-

were inhibited by squeezing two or three limbs; and 2 were un-responsive. Eighteen of 25 SR neurons tested were fired by elec-trical stimulation of limb nerves; activity from medial gastro-nemius, lateral gastrocnemius, and sural nerves had minimum af-ferent conduction velocities of 7-30 m/sec, indicative of type III afferent fibers. About 15% of nerves also gave faster con-duction velocities of type I or II afferents. Four SR neurons were also fired by stimulation of the left sympathetic chain with minimum afferent conduction velocities of about 2 m/sec.

Six neurons were tested for responses to close arterial injec-tion of BK and/or CAP into the left gastroc. muscle. Injection of 10 µg/kg increased firing from 1=10/sec to 10-30/sec in two cells by BK, in two cells by CAP, and in one cell by both. One neuron that was inhibited by both chemicals was also inhibited by somatic stimulation of three limbs. This may represent a small population of SR neurons that are inhibited by ergoreceptors and other stimuli.

Lumbar SR neurons that respond to muscle ergoreceptors also respond to input from sympathetics, skin (sural nerve), and wide somatic fields. Consequently, information about muscle contrac-tion is integrated with other sensory inputs before transmission to the medulla. (Supported by American Heart Assoc. and Tulsa Chapter of Oklahoma Affiliate).

BASIENTION SENSITIVITY AND MOTOR CONNECTIONS OF VENOUS AFFERENTS: BASIS FOR A NEW ORTHOSTATIC MUSCLE TONUS - VENOPRESSOR MECHANISM. F. J. Thompson, B. J. Yates and J. P. Mickle. Dept. of Neuro-science, Univ. of Fla. Coll. of Med. and Vet. Med., Gainesville, FL 32610. 31.2 DISTENTION SENSITIVITY AND MOTOR CONNECTIONS OF VENOUS AFFERENTS:

FL 32610. Recently, details of a peripheral venous afferent input to the spinal cord (Thompson and BArnes, 1979), to the cerebral cortex (Thompson, Lerner, Fields and Blackwelder, 1980) and to somatic motoneurons (Thompson, Barnes, Wald, 1982) were reported. The connections revealed in these studies were proposed to provide the neural substrate for venous afferent elicited influences on skele-tal muscle tone. This model proposed that afferents from recep-tors in the long limb veins contribute to reflex control of the capacitance of the skeletal muscle venous reservoir through modu-lation of skeletal muscle tone (i.e., muscle tonus-venopressor lation of skeletal muscle tone (i.e., muscle tonus-venopressor mechanism).

lation of skeletal muscle tone (i.e., muscle tonus-venopressor mechanism). In the present series of experiments central neural responses to distention of segments of the femoral-saphenous veins were examined to determine the presence and properties of distention sensitive receptors in the walls of these veins. Stretch of the vein wall produced by increasing the intravenous pressure of isolated segments of the femoral-saphenous vein elicited evoked potentials in the sixth lumbar spinal cord segment. Threshold response appeared with distention pressures of 2-3 mmHg. Maximal responses were elicited with perfusion pressures of 18-20 mmHg; and half maximal responses were observed with pressures of 6-10 mmHg. In a second series of experiments, mechanical stretches of the vein wall with a mechanical transducer produced spinal evoked potentials with threshold stretches of 5 microms/mm. Single fiber recordings have revealed that the venous afferent fibers which entered the sixth lumbar cord segment included fibers which con-duct action potentials at 57 meters per second. These recordings were made with glass pipette microelectrodes with impedances of 50-60 mg ohms, inserted intracellularly into the fibers in the region where they entered the dorsal horn. Distention of a segment of the vein wall either by perfusion or by mechanical stretch elicited negative ventral root potentials.

by mechanical stretch elicited negative ventral root potentials. These potentials are known to be produced in the ventral root fibers as a result of excitatory postsynaptic potentials which are conducted electrotonically down the axons of motoneurons which course as ventral root fibers and provide a sensitive population

assay of facilitation to motoneurons. The properties of the venous afferent fibers observed in these experiments taken together with influence of venous afferents to to provide the functional basis for a VENOUS AFFERENT ELICITED MUSCLE TONUS - VENOPRESSOR MECHANISM. Supported by NIH grant RO1 HL 25619.

RESPONSES OF UPPER THORACIC SPINOTHALAMIC NEURONS TO GALL 31.3 RESPONSES OF OPPER THORACIC SFINOTHALAMIC NEURONS TO GALL BLADDER DISTENTION IN THE MONKEY. <u>Robert D. Foreman, W. Steve</u> <u>Ammons</u>, and <u>Robert W. Blair</u>. University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190. Chest pain has a number of causes, and is a particularly important indicator of ischemic heart disease. However, chest

Important indicator of ischemic heart disease. However, chest pain may also be the result of abdominal disease. A likely ex-planation for chest pain of abdominal origin is convergence of abdominal afferents onto spinothalamic neurons in the upper thoracic spinal cord whose somatic receptive fields are in the chest region. In support of this hypothesis is our recent finding that electrical stimulation of the greater splanchnic nerve activates  $T_2$  to  $T_5$  spinothalamic neurons of the monkey (Federation Proc. 42:582, 1983). The goal of the present study was to determine if these neurons respond to a more natural stimulus, distension of the gall bladder. Experiments were performed on 10 monkeys (Macaca fascicularis) which were anesthe-tized with  $\alpha$ -chloralose. The gray matter of the T<sub>1</sub> to T<sub>5</sub> seg-ments of the spinal cord was searched for cells which were anti-dromically activated by stimulation of the contralateral ventral posterior lateral nucleus of the thalamus. Thus, each neuron in posterior lateral nucleus of the thalamus. Thus, each neuron in this study was determined to be a spinothalamic tract neuron. The somatic field of each neuron was mapped. Most somatic fields were on the left chest and forearm. Thirty-two neurons were tested for responses to distention of the gall bladder with saline for 30 seconds at pressures ranging from 10 to 100 mm Hg. Twelve neurons (38%) responded to gall bladder distention with an increase in cell activity. Both tonic and phasic responses were observed. Pressure threshold for cell response varied from 20 to 80 mm Hg. In 7 cases there was a relationship between the magnitude of the cell response and the gall bladder distention magnitude of the cell response and the gall bladder distending magnitude of the cell response and the gall bladder distending pressure. Maximal responses were usually obtained at 80 mm Hg. The most effective distending pressure resulted in an increase in cell activity from 13  $\pm$  4 to 24  $\pm$  3 impulses per second. The liklehood of cell response was not related to laminar location or to the type of somatic input. The results demonstrate that increased gall bladder pressure activates upper thoracic spinothalamic neurons. This finding may explain the number of clinical observations of chest pain resulting from gall bladder disease. Supported by National Heart, Lung, and Blood Institute Grants HL22732. LEFT VENTRICULAR SYMPATHETIC AFFERENT FIBER DISCHARGE AND RECEP-31.4 TIVE FIELD DIMENSION CHANGES ASSOCIATED WITH CARDIAC STIMULATION BY BRADYKININ, CORONARY ARTERY OCCLUSION, AND ARRHYTHMIAS. H. Rodney Holmes, J. Andrew Armour, C. Dale Chapman<sup>#</sup>, Robert D. Foreman, Univ. of Okla. Hlth. Sci. Ctr., Okla. City, OK 73190. Receptors in the heart respond to mechanical and chemical stim-

uli. Comparison of afferent activity with measurements of the cardiac receptive fields demonstrates a relationship of the af-ferent discharge to the location and tensions of the receptors. To examine the relationship of the afferent discharge to recep-To examine the relationship of the afferent discharge to recep-tive field dimensions during noxious chemical stimulation by bradykinin (BK), coronary occlusions (CAO), and abnormal beats associated with premature ventricular contractions (PVC), we recorded single afferent fiber activity from the thoracic sym-pathetic rami communicantes of 34 alpha-chloralose (80 mg/kg) anesthetized dogs of either sex. After mapping the receptive field by probing, we placed sonomicrometer crystals around the field on its vertical, horizontal, and wall thickness axes. We measured conduction velocity and continuously recorded afferent measured conduction velocity and continuously recorded afferent activity, EKG, left ventricular (LVP) and aortic blood pressures, and the length dimensions of the receptive field. Waiting 20 min between each manipulation, we electrically induced PVCs, placed a BK soaked pledget on the receptive field, administered BK (1  $_{\mu}g/kg)$  into the heart, and reversibly occluded the left anterior descending and circumflex coronary arteries. We determined no  $\mu g/(g)$  into the heart, and reversibly occluded the left anterior descending and circumflex coronary arteries. We determined no functional differences between A6 and C fibers. Bradykinin always stimulated afferent activity. Intracardiac BK always resulted in length changes and pressure decreases, but the BK resulted in length changes and pressure decreases, but the by pledget on the epicardium only once resulted in length and LVP changes. With only one exception CAO stimulated activity of left ventricular receptors. CAO never stimulated activity of the two right ventricular receptors. Following CAO, the ventricle some-times changed its dimensional characteristics during contraction. This resulted in new receptive field length changes and afferent discharge characteristics. The PVCs always caused length changes discharge characteristics. The PVCs always caused length changes during the compensatory pause and the next heart beat. Asso-ciated with these length changes were increases in afferent acti-vity. However, LVP was near baseline during the pause, and the next beat was variably higher, lower, or the same as control pressure. These data further elaborate the relationship of af-ferent activity to receptive field dimensions during and follow-ing abnormal cardiac events such as PVC and CAO. The role of the BK stimulation of receptors is unclear. The magnitudes of the discharge rates were much higher than following the other mane-Ing anormal cardiac events such as PVC and CAO. The role of the BK stimulation of receptors is unclear. The magnitudes of the discharge rates were much higher than following the other mane-uvers. Furthermore, when LVP decreases and receptive field dimension changes comparable to these induced by BK were acheived by the other maneuvers, afferent activity decreased. 31.5 RESPIRATORY-RELATED VARIATIONS IN HEART RATE DURING SLEEP AND WAKING STATES IN AGED CATS, R. M. Harper. M. H. Chase. E. Lucas\*. D. Taube\* and R. B. Trelease\*. Depts. of Anatomy and Physiology, and the Brain Research Institute, UCLA, Los Angeles CA 90024; and Dept. of Anatomy, University of Arkansas, Little Rock AK 72201.

The principal source of heart rate variability during quiet sleep in cats is a respiratory-related sinus arrhythmia that is manifested as an increase in rate during inspiration and a decrease during expiration. The amplitude of sinus arrhythmia appears to be indicative of vagal tone, and extreme loss of amplitude during quiet sleep may indicate a cardiorespiratory disorder in the infant or a number of pathologies, including vagal neuropathy, in the adult. Sinus arrhythmia exhibits a distinct developmental course over the first 6 months of life in humans. However, only incomplete data are available for the development of such heart rate variability in later life. We examined the extent of sinus arrhythmia in 5 cats aged 9 -19 vears and 5 young adult cats during sleep and waking states.

We examined the extent of sinus arrhythmia in 5 cats aged 9 -19 years and 5 young adult cats during sleep and waking states. The cats were implanted with diaphragmatic EMG electrodes (which also provided a source of EKG signals), and with electrodes to monitor the EEC, eye movement and nuchal musculature in order to assess the animal's behavioral state. After at least 10 days of recovery, the cats were placed in an isolated temperature-controlled, sound-attenuated chamber for a 5 day period. Food and water were automatically provided. Data were digitized in real time on a large computer disk and magnetic tape.

Cardiac R-R interbeat intervals were calculated with an accuracy of 1 msec and plotted on an incremental plotter. Analysis included 1) an assessment of maximum and minimum R-R intervals at peak cardiac acceleration and deceleration values with each breath, and 2) spectral estimates of the amplitude of sinus arrhythmia calculated from an interpolated rate curve of the R-R intervals which were estimated at the respiratory frequency. The amplitude of respiratory-related sinus arrhythmia swas greatly exaggerated in aged cats, with the amplitude in some aged cats exceeding that of young adult cats by a factor of 3. These data indicate that vagal tone is enhanced in aged cats.

<sup>-</sup> These data indicate that vagal tone is enhanced in aged cats. The mechanism of this enhancement is not known; it may result from increased sensitivity of the baroreflex with age, or from altered patterns of forebrain or brain stem control of vagal efferent mechanisms. We conclude that respiratory-related heart rate variability increases in aged cats and that it provides an easily quantifiable assessment of vasomotor activity that appears to be age dependent. 31.7 RENAL NERVE-DEPENDENT DOPAMINERGIC ACTIVITY IN THE HYPOTHALAMUS IN THE RAT. <u>K. P. Patel and R. L. Kline</u> (SPON: T. Vilis). Dept. of Physiol., Univ. of Western Ontario, London, Ontario, CANADA N6A SC1.

Electrophysiological studies have demonstrated that renal afferent nerves project to hypothalamic sites involved in the regulation of arterial pressure and fluid balance. In addition, renal denervation has been shown to alter the concentration of catecholamines in the hypothalamus. In the present study we measured the turnover of dopamine (DA) and norepinephrine (NE) in the anterior hypothalamus and posterior hypothalamus in conscious Wistar rats by measuring the decline of [DA] and [NE] 90 min after administration of  $\alpha$ -methyl tyrosine. [DA] and [NE] at 90 min were expressed as a percent of the initial values for each tissue and the difference between renal denervated and intact groups was assessed using a t-test.

Mean arterial pressure (measured by indwelling catheter in the femoral artery of the unrestrained rat) and heart rate were not significantly different between intact and renal denervated groups. There was a significant decrease in DA concentration of the posterior hypothalamus of the renal denervated group compared to animals with intact renal nerves. [NE] was not significantly different between the intact and renal denervated groups. There was a significantly lower DA turnover in the anterior and posterior hypothalamus of the renal denervated group compared to similar hypothalamic sections of animals with intact renal nerves. However, there was no significant difference in the turnover of NE in the hypothalamic sections between intact and renal denervated groups. These results suggest that dopaminergic activity but not noradrenergic activity in the hypothalamus is dependent on intact renal nerves. It is conceivable that renal afferents influence dopaminergic activity involved in physiological responses related to kidney function and cardiovascular adjustments such as modulation of vasopressin release. (Supported by Ontario Heart Foundation). 31.6 TEMPORAL PATTERNING OF THE BAROREFLEX IN RESPONSE TO INDUCED TRANSIENT HYPERTENSION. J.D. Marks\*, R.C. Frysinger, <u>R.B. Trelease\* and R.M. Harper</u> (SPON: R. Saneto). Dept. of Anatomy and Brain Research Institute, UCLA, Los Angeles, CA 90024

Transient hypertension elicits a baroreflex which tends to reduce elevated arterial pressure. The temporal development of the baroreflex is important in analyzing its underlying neural control mechanisms. We analyzed beat-to-beat changes in the relationship between arterial pressure and intervals between systolic pulses in order to characterize this pattern.

Adult cats were instrumented with electrodes for monitoring sleep-waking states and with concentric bipolar stimulation electrodes in the central amygdala. Venous and arterial catheters were introduced via femoral vessels. Transient hypertension was induced in the awake animal using three different methods: 1) phenylephrine infusion, 2) aortic occlusion with a Swan-Ganz catheter, 3) stimulation of the central amygdala. Mean arterial pressure calculated on a beat-to-beat basis was paired with the interbeat interval. X-Y plots were made with arterial pressure on the abscissa and interbeat interval on the ordinate. The points were plotted with a vector conjecting sequential points. This plot allows differentiation of baroreflex phases through 1) the trend of the computable verdered points.

This plot allows differentiation of baroreflex phases through 1) the trend of the sequentially ordered points, and 2) the temporal "distance" into the plot where slope changes occur. The slope is analogous to the "gain" of the baroreflex, which constitutes the change in interbeat interval per unit change in arterial pressure.

The pressure-interval plot of a transient hypertensive episode is ellipsoidal in shape, consisting of 1) an ascending limb corresponding to the rise in arterial pressure, 2) an inflection point, and 3) a descending limb corresponding to the fall in arterial pressure. Central amygdala stimulation imparts an initial negative slope to the ascending limb followed by a sharp increase in interbeat interval, indicating that tachycardia accompanies the initial arterial pressure rise and is replaced by bradycardia. These findings suggest that central amygdala stimulation transiently inhibits the bradycardic component of the baroreflex. For a given trial, the descending limb is vertically shifted along the ordinate with respect to the ascending limb. Thus, during a transient hypertensive episode, the baroreflex exhibits hysteresis: a given arterial pressure maps onto a different interveat interval depending on whether the pressure is ascending or descending. .8 INTRACAROTID INFUSIONS OF α-ADRENERGIC DRUGS ALTER FIRING RATE OF SUPRAOPTIC (SON) NEURONS IN THE RAT. M.F. CALLAHAN, L.D. MITCHELL, S.I. BELLIN, & A.K. JOHNSON. Depts. of Psychology and The Cardiovascular Center, The University of Iowa, Iowa City, Iowa 52242. Controversy currently exists as to the role of central adrenergic neurons in the firing rate of SON neurons and the secretion of vasopressin. In this respect, Poulain and Waverley (Neuroscience, 7(4):773, 1982) reviewed evidence suggesting that βadrenergic receptor stimulation decreases, and α-adrenergic stimulation increases the firing of SON neurons. We have recently

initiated studies designed to assess the effects of  $\alpha$ -adrenergic

compounds on firing of SON neurons. Male albino rats (-350g) were anesthetized with urethane. Arterial blood pressure (and heart rate) were monitered by a catheter placed into the right external carotid artery and secured into place with the tip at the bifurcation of the internal and external carotid arteries. Single unit activity was recorded from antidromically identified neurons in the SON. At the conclusion of the experiments, animals were infused with 1.0 cc black ink to ensure patency and selectivity of drug delivery to the right hemisphere. All drug concentrations are expressed as the salt. Intracarotid infusions of the ag-adrenergic antagonists, Yohimbine and Rauwolscine (100-300 µg) resulted in an inhibition rester.

Intracarotid infusions of the  $\alpha_2$ -adrenergic antagonists, Yohimbine and Rauwolscine (100-300 µg) resulted in an inhibition or total block in the firing of spontaneously active cells which occured with a 5-10 sec. Latency. These infusions were usually associated with a small (10mm Hg) decrease in b.p. Infusions of low doses (50 µg) failed to affect SON neurons. Infusions of the  $\alpha_2$ -adrenergic agonist clonidine (5-7 µg) had no effect on firing of SON neurons except for an inhibition of activity which appears to accompany the initial increase in b.p. caused by clonidine. Infusions of the agonist at higher doses (10-20 µg) results in immediate excitation (latency = 5 sec.) followed by inhibition which is <u>usually</u> accompanied by a long period of excitation.

Infusions of the selective  $\alpha_1$ -adrenergic antagonist, Prazocin (25-75 µg), has little effect on SON neurons except for a period of excitation (beginning approximately 20 sec. post infusion) which accompanies a dramatic fall in blood pressure. The results of these preliminary experiments suggests that the

The results of these preliminary experiments suggests that the  $\alpha$ -adrenergic modulation of magnocellular neurons occurs via  $\alpha_2$ -adrenergic modulations, perhaps in the CNS. Further studies are being conducted to extend these dose-response relationships, and to examine the possible interactions of these adrenergic mechanisms in the regulation of magnocellular neurons during osmotic and angiotensin challenges.

MAGNOCELLULAR RESPONSES TO BOTH HYPERTONIC SOLUTIONS AND ANGIOTEN-31.9 SIN II. L.D. Mitchell, S.I. Bellin, M.F. Callahan and A.K. Johnson Dept. of Psychology and The Cardiovascular Center, Univ. of Iowa, Iowa City, Iowa 52242.

The activity of magnocellular neurons of the supraoptic nucleus (SON) in male Sprague-Dawley rats was used to determine the appropriate parameters for exciting neurosecretory cells by vascular administration of hypertonic saline or angiotensin (AII). Single units were identified by constant latency following stimulation of units were identified by constant latency following stimulation of the neurohypophyseal tract, the ability of antidromically-induced action potentials to follow stimuli of 70-100 Hz, and electronic discrimination to distinguish between induced and spontaneously occurring action potentials. Central blood pressure was monitored through the femoral artery and experimental solutions were infused through small bore tubing (PE 50) implanted into either the bi-furcation of the carotid artery or the femoral vein. Following

furcation of the carotid artery or the femoral vein. Following experimentation, placements of microelectrodes were confirmed by histological examination, and the patency of the carotid system was proved by the injection of ink staining the right hemisphere. When hypertonic saline solutions (lcc, 1-4M NaCl) were infused into the femoral vein of three rats, no alterations in the ac-tivity of magnocellular neurons were observed. Infusion of solu-tions (0.1cc, 167 mM - 1.5M NaCl) into the carotid artery of 15 rats (27 neurons) increased neuronal activity in a dose-dependent fashion. The most effective dose proved to be 100 uL of 0.7M NaCl for 10 sec., which was repeatedly applied without desensitization. Accompanying the enhanced excitation of the neuron was a brief Accompanying the enhanced excitation of the neuron was a brief rise in blood pressure (10-20 mm Hg) which appeared to terminate magnocellular activity. Comparable application of Locke's, Krebs or normal saline solutions did not affect either neuronal activity or blood pressure.

Infusions of AII (lng-300ug) in 100 uL bolus (10 sec), were also administered through the carotid artery. The magnocellular response was variable. AII increased firing in a dose-dependent response was variable. All increased firing in a dose-dependent manner, with a peak at 30ng. Above this dose, there was a re-duction in the response, with a concommitant rise in blood pressure. At a very high dose (15 ug), AII was observed to excite all magnocellular neurons in the face of a 50 mm Hg rise in blood pressure. These data suggest that the magnocellular neurons may be excited by both hypertonic saline and AII, although the response to the latter is more variable.

( USPHS grants HLP 14558 and NIMH MH00064)

31.10 REM SLEEP ATTENUATES THE PRESSOR RESPONSE TO AMYGDALA

REM SLEEP ATTENUATES THE PRESSOR RESPONSE TO AMYGDALA STIMULATION IN THE CAT. R. C. Frysinger. J. D. Marks\*. R. M. Harper and R. B. Trelease\*. Dept. of Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA 90024. The central nucleus of the amygdala (ACE) projects heavily to cardiorespiratory areas, including the hypothalamus, parabrachial pons and the nucleus of the solitary tract, while receiving input from a variety of limbic and cortical structures. The ACE is thus strategically located to modulate forebrain influences on lower brainstem cardiovascular areas forebrain influences on lower brainstem cardiovascular areas.

Stimulation of a region of the central amygdala that includes the central nucleus and the dorsomedial basolateral nucleus produces a rapid rise in arterial pressure in the awake cat. Quiet sleep reduces the magnitude of this pressor response (Trelease et al., <u>Neurosci</u>, <u>Abstr</u>, 8:723, 1982). The question remains whether REM sleep also influences this response. Four adult cats were surgically prepared with concentric

Four adult cats were surgically prepared with concentric bipolar stimulation electrodes in the central amygdala and with chronic implants for monitoring arterial pressure, EOG, neck and crural diaphragmatic EMG, and EEG from motor cortex, hippocampus, and lateral geniculate. Following recovery from surgery, the animals were given 0.5 sec, 100 Hz trains of 0.5 msec pulses at a current level sufficient to produce a profound rise in arterial pressure in the alert animal. Identical msec pulses at a Current level surficient to produce a profound rise in arterial pressure in the alert animal. Identical stimulus trains delivered during quiet sleep produced pressor responses 50% - 80% of the amplitude of the waking response. During REM sleep, the effect of the stimuli was almost completely abolished, only rarely attaining 20% of the values associated with the alert state. There was no consistent difference in the degree of attenuation between active PEM associated with the degree of attenuation between active REM periods (i.e., during eye movement episodes) and tonic REM periods (i.e., without eye movement). These results suggest a reduction in the effect of forebrain activity on the visceromotor system during REM sleep. Supported by HL-22418-05 and AHA-LA 678-1G2

LESIONS OF DORSOMEDIAL THALAMUS, BUT NOT INSULAR CORTEX. 31.11 ATTENUATE STIMULATION-ELICITED CARDIOVASCULAR CHANGES FROM ANTERIOR MEDIAL CORTEX. <u>Shirley L. Buchanan</u>, and D. A. Powell, Neuroscience Lab., VA Hospital and University of South Carolina, Columbia. S.C.

We have previously reported that electrical stimulation in We have previously reported that electrical stimulation in anterior medial cortex elicits heart rate (HR) decelerations and blood pressure (BP) depressor responses, along with increased <sup>3</sup>H-2-deoxyglucose (2DG) uptake (i.e., increased functional neural activity) in dorsomedial (DM) nucleus of the thalamus. Anterior insular cortex also appeared to have slightly increased <sup>3</sup>H-2DG uptake; additionally, this area is cardioactive to electrical stimulation. Stimulation of DM elicits large HR decelerations, but accompanied by BP pressor responses. In an effort to further trace this nathway rabbits were

decelerations, but accompanied by BP pressor responses. In an effort to further trace this pathway, rabbits were implanted bilaterally with bipolar stimulating electrodes in anterior medial cortex and lesion electrodes in either DM nucleus or insular cortex. Animals received 1-2 second trains ( $100 \text{ Hz}, \sim 100-400 \text{ µA}$ ) of electrical stimulation. Animals with positive electrodes (i.e., those eliciting HR changes of 10% or greater from prestimulus baseline) were cannulated for blood processor monocuments obstraneous patient (CMC) pressure measurement; electromyographic activity (EMG) respiration were also measured. Animals received four stimula-tion trials and two trials during which no stimulation was delivered ("zero" trials). Lesions were then made in either insular cortex, or DM nucleus of the thalamus. The animal was allowed to recover overnight, and the stimulation regimen was repeated.

Lesions of insular cortex had no effect on the autonomic changes elicited by stimulation of anterior medial cortex. DM lesions, however, appeared to attenuate the HR decelerations and BP depressor response elicited by stimulation of anterior medial cortex. These findings suggest that the stimulation-elicited changes from anterior medial cortex are routed through the dorsomedial nucleus of the thalamus. Animals with DM lesions were also more reactive to anterior medial cortical lesions were also more reactive to anterior medial cortical stimulation, as evidenced by the occurence of consistently larger EMG responses after the DM lesions. This finding may indicate that a generalized increased sensitivity to midline cortial stimulation occurs as a result of UM lesions leading to movement-biased HR increases. Although insular cortex is cardioactive to electrical stimulation, this pathway appears to be distinct from that arising in anterior medial cortex.

INSULAR CORTEX PARTICIPATES IN CARDIOVASCULAR INHIBITION, BUT IS 31.12 NOT NECESSARY FOR PAVLOVIAN CONDITIONED BRADYCARDIA IN RABBITS. D. A. Powell, Linda L. Hernandez, and Shirley L. Buchanan, Neuroscience Lab., VA Hospital and University of South Carolina, Columbia, S.C.

Columbia, S.C. A series of ongoing experiments using 2-deoxyglucose auto-radiography revealed that electrical stimulation of anterior midline cortex, which elicits cardiovascular inhibition, re-sulted in increased metabolic activity in two areas of the forebrain. One of these was the dorsomedial nucleus of the thalamus; the other was the anterior insular cortex. In the encode cories of our primetry of cutoid the efforts of plotter present series of experiments we studied the effects of electri-cal stimulation and lesions of insular cortex on cardiovascular mechanisms. New Zealand albino rabbits of both sexes were cal stimulation and lesions of insular cortex on cardiovascular mechanisms. New Zealand albino rabbits of both sexes were implanted with bilateral stimulation electrodes in the anterior or posterior insular cortex. After a 1 week recovery period heart rate (HR) and blood pressure (BP) as well as other sel-ected variables were assessed subsequent to 1 to 5 sec trains of biphasic electrical stimulation at 100 pulses per sec. Electri-cal stimulation of insular cortex produced bradycardia accom-panter ion, midling cortical stimulation. However the thresholds anterior midline cortical stimulation. However the thresholds were much lower and the bradycardia and depressor changes elicited were considerably greater than those produced by anterior midline cortical stimulation. In separate groups of rabbits radio frequency lesions were

made in anterior and posterior insular cortex and the animals compared with a group of sham operated animals during differential Pavlovian conditioning. Unlike lesions of the anterior midline cortex, lesions of the insular cortex did not attenuate or abolish the bradycardia associated with classical conditioning contingencies. In fact, the magnitude of the response appeared to be somewhat enhanced in lesioned animals. These

appeared to be somewhat enhanced in lesioned animals. These findings are thus comparable to those in which septal lesions have also been found to enhance the magnitude of the Pavlovian conditioned bradycardiac response even though electrical stimu-lation of the septum elicits BP and HR decreases. These findings support the contention that the insular region is a cortical area involved in autonomic activities. However, it does not appear to be necessary for the integration of the bradycardia associated with classical conditioning. Instead the present findings suggest that insular cortex may participate in cardiac changes by normally holding inhibitory cardiovascular mechanisms in balance. mechanisms in balance.

EFFECTS OF NALOXONE AND TRH ON PLASMA CATECHOLAMINES 31.13 AND ARTERIAL PRESSURE IN NORMAL AND ENDOTOXEMIC RATS. J.B. Long, C.R. Lake', A. Reid\*', B.A. Ruvio\*, and J.W. Holaday. Neuropharm. Br., Dept. of Medical Neurosciences, Div. of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, D.C. 20307, and Depts. of Psychiatry and Pharmacology, Uniformed Services Univ. of the Health Sciences, Bethesda, MD 20014.

Recent work in this and other laboratories has revealed the importance of sympatho-medullary function in the therapeutic cardiovascular effects of naloxone (NX) and thyrotropin releasing hormone (TRH) in treatment of endotoxic shock. In order to further investigate sympatho-medullary involvement in the therapeutic actions of these compounds, plasma norepinephrine (NE), epinephrine (E), and dopamine (DA) were evaluated during iv NX and TRH treatment of endotoxemia.

Male S.D. rats (400-600g) were implanted with external jugular vein and tail artery catheters. 24 hours following surgery, mean arterial pressure (MAP) was monitored and a pre-treatment venous blood sample was withdrawn (1.5 ml over 1 min). Immediately following withdrawal of this and subsequent equal-sized venous blood samples, rats were reinfused this and subsequent equal-sized venous blood samples, rats were reinfused with an equal volume of blood taken from a common donor pool to alleviate hypovolemia otherwise accompanying repeated sampling. The unrestrained, unanesthetized rats were injected with <u>E. coli</u> endotoxin (30 mg/kg, iv) or saline. When MAP declined by 20 mm Hg (or 15 min post-saline), a venous blood sample was withdrawn and followed immediately by iv injection of NX (3 mg/kg), TRH (4 mg/kg), or saline (1 ml/kg) and reinfusion of donor blood. Venous blood samples were additionally withdrawn 15 and 45 min following drug treatment. This schedule of blood sampling allowed measurement of plasma catecholamines (CA) during different stages of the MAP response to endotoxemia. In the absence of endotoxemia, analoxone altered neither MAP nor

during different stages of the MAP response to endotoxemia. In the absence of endotoxemia, naloxone altered neither MAP nor CA. In contrast, 15 min following TRH administration, a significant (p0.05) increase in MAP was associated with selective increases in plasma NE and E, but not DA. As previously demonstrated, endotoxin elicited an initial hypotension followed by a partial recovery at 15-30 min and a secondary hypotension at 45 min.; NX and TRH produced significant improvements in MAP of endotoxemic rats. In all cases, endotoxin evoked a large CA increase which progressively increased through 45 minutes irrespective of therapeutic treatment. Neither NX nor TRH significantly altered plasma CA levels from those measured in endotoxic rats treated with saline. These results indicate that therapeutic pressor effects of NX and TRH do not simply arise from enhanced sympatho-medullary outflowing of CA. Furthermore, these results reveal a dissociation between the changes induced by endotoxin in MAP and CA levels.

LESIONS OF PERIVENTRICULAR TISSUE OF THE PREOPTIC RECESS ATTENUATE PLASMA VOLUME RESTITUTION FOLLOWING HEMORRHAGE. S. L. 31.15 Bealer. Dept of Physiology, Univ. Tenn. Ctr. Hlth. Sci., Memphis, TN 38163

Electrolytic ablation of the periventricular tissue surrounding the anteroventral third ventricle (the AV3V region) results in profound alterations in fluid and electrolyte metabolism and cardiovascular regulation. Animals with lesions in this brain area have an attenuated capacity to increase sodium excretion to a number of experimental treatments, and fail to develop some forms of experimental hypertension. In addition, following recovery from the acute effects of AV3V lesions, rats have chronically decreased blood volume and plasma volume, while total extracellular fluid volume is increased compared to control animals. In order to further characterize the role of this brain region in cardiovascular regulation and maintenance of Drain region in cardiovascular regulation and maintenance of plasma volume, these experiments were designed to determine the effect of AV3V ablation on plasma volume restoration following hemorrhage. Animals were allowed at least two weeks to recover from the acute effects of either AV3V ablation or control sur-gery. Rats were then implanted with catheters in the femoral in order to monitor mean arterial blood pressure, inject the radioisotope, take blood samples, and perform the hemor-rhage. The following day, the conscious, unrestrained rats were injected intraarterially with 125-I labelled serum albumin, and plasma volume was subsequently calculated by radioisotope volume was removed from the animal via the femoral artery catheter. Two hours following the hemorrhage, plasma volume was scalar determined, and the percent of shed plasma which was re-stored during this period was calculated for both groups. There was no significant difference in mean arterial pressure between groups either prior to, or at any time following hemorrhage. However, control operated rats restored a significantly greater proportion of shed plasma volume  $(75\pm83)$  than animals with AV3V locies ((0.195)) lesions (49±8%), during this time. These data indicate that the periventricular tissue surrounding the AV3V region is important for the acute restoration of plasma volume which follows hemorrhage. (Supported in part by USPHS Grant HL-25877)

31.14 THE FEFECT OF BARODENERVATION ON THE RESPONSE TO HEMORRHAGE AND SUBSEQUENT OPIATE RECEPTOR BLOCKADE IN CONSCIOUS RABBITS

SUBSEQUENT OFFATE RELEFICE BLUCKADE IN CONSCIOUS RABBITS. J. C. Schadt, R. R. Gaddis\*, M. D. McKown\*, and D. Franklin\*, Dalton Research Center, U. Missouri, Columbia, MO 65211 We have previously shown that opiate receptor blockade with naloxone reverses the hypotension and tachycardia associated with hemorrhage. The pressor effect is due primarily to a sympathetically-mediated vasoconstriction and is accompanied by an increase in plasma norepinephrine (NE). In these same studies, we observed that the transition to hypotension during hemorrhage is abrupt and is accompanied by a decrease in heart rate (HR). The simultaneous drop in mean arterial blood pressure ( $\overline{BP}$ ) and HR suggests the loss of normal paroretiex function. If the transition to hypotension is mediated by a loss of baroreflex function, then naloxone could produce this pressor effect by increasing baroreflex mediated sympathetic vasoconstriction. Petty and Reid (Hypertension 3:I-142-I-147, 1981) have recently shown that naloxone increases baroreflex sensitivity in the conscious rabbit. Therefore, our hypothesis was: Naloxone requires an intact baroreceptor reflex to increase BP and sympathetic release of NE. In order to test this hypothesis we examined the cardiovascular (n=6) and plasma catecholamine (n=3) effects of hemorrhage and subsequent naloxone treatment in conscious rabbits before (Intact) and after chronic sinoaortic barodenervation (SABD). The experimental protocol involved hemorrhage until BP fell below 40mmHg. 60 sec after BP reached this level, naloxone (3 mg/kg) was injected IV. BP, HR, plasma epinephrine (E) and NE were measured at three points: 1) Control, before hemorrhage; 2) Hypotensive, after BP fell below 40mmHg; and 3) Recovered, 2 min postnaloxone. The results are shown below:  $\overline{BP} HR E NE$ of normal baroreflex function. If the transition to hypotension is mediated by a loss of baroreflex function, then naloxone could

Shown berow.	BP	HR	E	NE

In summary a	functional	haroref	lev annears	to be requi

ired for In summary, a functional baroreflex appears to be required for the increase in HR with hemorrhage, the postnaloxone bradycardia, and the large increase in adrenal medullary output during the hy-potensive stage. However, SABD potentiates the postnaloxone in-creases in BP and plasma NE. Indeed, the baroreceptors appear to buffer these effects. Therefore, the sympathetically-mediated pressor effect of naloxone does not require an intact baroreflex.

ROLE OF THE VENTROLATERAL MEDULLA IN THE CONTROL OF THE CEREBRAL 31.16 ISCHEMIC RESPONSE IN RABBITS, William G. LeBlanc.\* Philip M McCabe, James R. Haselton,\* Carole L. Haselton,\* Howard H. Ellenberger,\* and Neil Schneiderman. Program in Behavioral Medicine, Dept. Psych., Univ. of Miami, Coral Gables, FL 33124 The Cerebral Ischemic Response (CIR), produced by occlusion of the vertebral and carotid arteries, consists of elevated arterial blood pressure, bradycardia, and apnea. Previous research has demonstrated that the CIR is integrated in the medulla, but discrete electrical stimulation failed to elicit all three components of the CIR from a single location. However, in our laboratory we have found a site centered at the retrofacial nucleus (RFN) and the rostral extremity of the nucleus ambiguus (NA) which when stimulated (100 pps, .5 msec duration, 75  $\mu A$ , 10 second trains) produced a pressor response, bradycardia, and

10 second trains) produced a pressor response, bradycardia, and apnea for the duration of the stimulation. Stimulation sites producing cardiovascular and respiratory responses were mapped throughout the ventrolateral medulla (VLM) of the rabbit. Pressor responses (30-60 mmHg) could be obtained from most regions of the VLM. Stimulation near or in NA elicited a profound primary bradycardia (40-100 bpm), whereas more rostral sites (RFN) were associated with bradycardia that was reflexive to the pressor response. Respiratory responses exhibited a medial-lateral organization, such that stimulation of regions lateral to RFN/NA elicited increases in respiratory frequency and amplitude. Sites medial to RFN/NA produced brief apnea followed by increasing respiratory amplitude for the remainder of the stimulation interval. Stimulation near or in RFN/NA produced inspiratory apnea for the duration of the stimulation. Venti Ventilated animals exhibited attenuated bradycardia during stimulation sug gesting that apnea enhanced the bradycardia response. This effect was observed for reflexive bradycardia, but the apnea did not affect the primary bradycardia response to stimulation. We have also attempted to abolish the CIR by lesioning large

regions of the VLM. Lesions near the ventrolateral surface reduced the pressor component of the CIR but did not affect the bradycardia. Lesions that did not include RFN did not greatly affect spontaneous breathing. However, lesions that destroyed the full rostral-caudal extent of RFN resulted in respiratory failure. We have been unable to abolish all three components of the CIR with selective lesions in the VLM. Supported by NSF (BNS 8108539) and NINCDS (NS 18479) research grants.

EFFECT OF PCO2 ON THE GLUCOSE UTILIZATION OF CEREBRAL ARTERIES OF THE CAT USING  $^{14}\text{C-2-DEOXYGLUCOSE.}$ 31.17 D.R. Kostreva and E.J. Zuperku, Depts. Anesthes, & Physiol.

Med. Col. of Wis. and Wood VA Med. Ctr., Milwaukee, WI 53193 CO<sub>2</sub> is known to be a potent vasodilator of cerebral blood vessels. In addition, glucose is thought to be a major substrate for vascular smooth muscle metabolism. Since vasoconstriction probably requires more energy than vasodilatation, the effect of  $CO_2$  on the glucose utilization of vascular smooth muscle in cerebral blood vessels was studied in anesthetized cats. Six adult cats 2-3 kg were anesthetized with pentothal administered with an infusion pump at the rate of 20 mg/hr. The animals were intubated and placed on positive pressure ventilation with 100%  $O_2$  using a solenoid controlled ventilator that maintained tidal  $O_2$  using a solenoid controlled ventilator that maintained tidal volume, inspiratory time, and expiratory time constant. In 3 animals the arterial blood gases were maintained at an arterial  $PO_2$  of 350-500 Torr,  $PCO_2$  20-25 Torr, and pH 7.3-7.4. In the other group of three animals 9% CO<sub>2</sub> was added to the inspiratory gas mixture yielding arterial blood gas measurements of  $PO_2$  of 350-500 Torr,  $PCO_2$  of 55-60 Torr, and pH of 7.0-7.4 Once the blood gas measurements were stable, a single bolus of  $^{14}$ C-2-deoxyglucose, 100 uCi/kg (Pathfinders Labs), was injected i.v. Arterial samples were taken at regular intervals during the 45 min experiment for measurements of glucose, scintduring the 45 min experiment for measurements of glucose, scintilation counting and blood gas measurement. The animals were then sacrificed and the brains were frozen and sectioned at 20 um and prepared for autoradiography. After 12 days exposure, the autoradiographs were developed and some tissue sections were stained with cresyl violet or H & E for identification of cell stained with Cresyl volet of n & E for identification of cerr bodies or vascular structures respectively. Once cerebral ves-sels were identified from histological sections, the autoradio-graphs were scanned using a computerized densitometer with aper-ature settings of 10 or 25 um. These densitometer readings were then converted to glucose utilization values using Sokoloff's equation and the lumped constant for the cat brain. The cerebral arteries of the animals with low arterial  $PCO_2$  had glucose utilization measurements that were between 30% and 400% greater Utilization measurements that were between 30% and 400% greater than those measurements in similar cerebral arteries of the animals subjected to high  $PCO_2$ . This data suggests that the  $^{14}C^{-2}$ -deoxyglucose technique may possibly be useful for detecting vasoconstriction and vasodilatation of cerebral blood vessels, thereby indicating changes in cerebral blood flow of major cerebral arteries in the same animals that are used for brain mapping studies using this technique. - REGIONAL CEREBRAL VASOCONSTRICTION ELICITED BY ELECTRICAL STIMULATION OF THE MEDIAL PARABRACHIAL NUCLEUS IN RAT. S. Mraovitch, C. Iadecola, D.A. Ruggiero and D.J. Reis, Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

10021 The parabrachial nucleus of the pons (PBN) plays an important role in the regulation of the systemic circulation and autonomic nervous system (Mraovitch et al., Brain Res. 232:57, 1982). Stimulation of the PBN in cat or rat will elicit a marked elevation of arterial pressure resulting from differentiated excitation of preganglionic sympathetic neurons. In the present study, we sought to examine in rat, whether electrical stimulation of the PBN would also modify regional cerebral blocd flow (FCPE) or differentiate the charger or medicated theorem blood flow (rCBF), and if so, whether the changes are mediated through neural pathways intrinsic to brain. Rats were anethetized (chloralose), paralyzed (tubocurarine) and

artificially ventilated. In all animals, the adrenal glands were removed. Arterial pressure (AP), heart rate and body temperature were continuously monitored and blood gases were measured and controlled. PBN was electrically stimulated with intermittant trains (1 sec on/1 sec off) at 70 Hz and with an intensity (50-100 uA) corresponding to 3x the threshold current required for a 10 mmHg AP elevation. At all times, AP was maintained within the autoregulated range for rat rCBF. rCBF was measured in right and left samples of 9 brain regions by the 14C-

was measured in right and left samples of 9 brain regions by the 14C-iodoantipyrine technique with regional dissection (Nakai et al., Am. J. Physiol. 243:H226, 1982). In all animals, histological localizations of stimulated sites were carefully reconstructed. In unstimulated rats (n=5), rCBF ranged from 58  $\pm$  6 (ml/100 g x min) in corpus callosum to 103  $\pm$  8 in hypothalamus and parietal cortex. During stimulation of the medial PBN (PBNm) (n=5) rCBF decreased bilaterally in several brain regions ranging from -33% in control in occipital cortex to -26% in hippocampus (p<0.05). rCBF was also significantly reduced in frontal (-29%), parietal (-28%) cortex and caudate n. (-28%). In contrast, rCBF was unchanged in medulla, hypothalamus, thalamus and corpus callosum. The cerebral vasoconstriction persisted after unilateral transection of the cervical sympathetic trunk without differences in rCBF between innervated and sympathetic trunk without differences in rCBF between innervated and denervated sides. In 6 rats, stimulation of sites adjacent to the PBNm, including the caudal part of the nucleus and central grey matter, failed to modify rCBF.

We conclude that: (a) electrical stimulation of PBNm reduces rCBF; (b) the response is anatomically specific and restricted primarily to cerebral cortex and basal ganglia; (c) the vasoconstriction is not mediated by the sympathetic fibers to cerebral vessels nor by adrenal hormones. Excitation of projections originating in or fibers passing through the PBNm elicits a powerful cerebrovascular vasoconstriction which appears to be mediated by intrinsic neural pathways. ## PERIPHERAL AUTONOMIC NERVOUS SYSTEM I

THE MORPHOLOGY OF GRANULE-CONTAINING CELLS AND THEIR ASSOCIATION 32.1 WITH NEURONS IN THE GUINEA PIG (GP) CELIAC GANGLION (CG). J.A. Mascorro\* (SPON: R. Sankar). Department of Anatomy, Tulane University School of Medicine, New Orleans, LA 70112.

University School of Medicine, New Orleans, LA 70112. Small granule-containing cells (SGC) reside within sympathetic ganglia singly or in highly vascular groups. The single cells are interneurons (SIF cells) which receive preganglionic signals and inhibit the principal neurons. The clustered SGC are sparsely innervated and apparently do not make synaptic contacts upon neuronal elements. Instead, they may serve as endocrine systems for releasing neurotransmitters/neuromodulators into the ganglion environment. However, the exact nature of contacts from the SGC onto the ganglion neurons and their role in ganglion functions onto the ganglion neurons and their role in ganglion functions are not fully understood. This study will illustrate the morpho-logical association between SGC and neurons in hopes of offering structural correlates for at least some of the postsynaptic potentials which emanate from the GP CG.

Four adult guinea pigs were anesthetized and perfused with 3% glutaraldehyde in 0.1M phosphate buffer. The celiac ganglia were removed and processed for light and ultrastructural study follow-ing secondary fixation in osmium tetroxide.

Histologically, the CG was a composite of large often binucle-ate neurons, myelinated and unmyelinated nerve fibers, many blood vessels, connective tissue, satellite and Schwann cells as well as conspicuous SGC occurring singly or clustered. Two SGC clus-ters were noteworthy with respect to size, displaying 40 and 62 nuclear profiles. Ultrastructurally, certain SGC (Type A) showed a large complement of dense core granules 150-170 nm in diameter; a second SGC (Type B) was neuronal-like and contained granules measuring only 70-90 nm. This cell was positioned directly against neurons and only a thin rim of satellite cell cytoplasm intervened between the two. The clusters predominantly contained Type A cells, nevertheless B types also were a component. Nerve terminals with numerous small, clear core vesicles (and a few larger dense vesicles) synapsed upon the soma of Type A cells. A cells also gave rise to noticeable granule-rich processes which traveled through the ganglion and closely approached the principal neurons, but synapses were not seen.

Based upon morphology, the following conclusions are offered: 1) small, neuronal-like cells (Type B) containing many granules are closely associated with the principal ganglion neurons; 2) distinct synapses from either type of SGC upon neurons were not seen but certainly could exist; 3) B cells as well as A cell processes, because both are close to and minimally separated from neurons, may act as modulators by releasing their granule content(s) onto the neuronal surface.

RESPONSES IN CUTANEOUS VESSEL TONE AND RESPIRATION TO TRANSIENT 32.2 HYPONEMA IN MAN. M. Kollai\* (SPON: C. McC. Brooks). Dept. of Physiol., Semmelweis Med. Univ., budapest, Hungary 1082. The cutaneous vascular bed has been shown to be the target of a

number of reflexes, but is role in cardiovascular adaptation to hypoxia is still a matter of controversy. In response to chemo-receptor activation or arterial hypoxia, skin vasoconstriction, as well as vasodilation has been reported in different species. aim of the present study was to determine the changes in skin The vessel tone and skin sympathetic activity in response to transient systemic hypoxemia in man and also to study the relation of cutan-cous vasomotion to concomitant changes in respiration.

The studies were performed on young, healthy volunteers. Arterial oxygen tension was measured transcutaneously (TcPo2). photoplethysmography was employed to monitor changes in cutaneous protopieting single prior was employed to monitor changes in citianous vessel tone, and respiratory tidal volumes were measured by a Fleisch pneumotachograph. End tidal  $Co_2$  concentration, ECG, heart rate, finger skin resistance, and finger skin temperature were monitored continuously as well. Multiunit skin sympathetic activity was recorded in the median nerve at wrist level by using Tungsten microelectrodes. Informed consent was obtained from each participant.

Breathing 8%  $0_2$  in  $N_2$  for 90 sec reduced TcPo<sub>2</sub> from the control value of 95,4 ± 1.8 mm Hg to 51.7 ± 2.8 mm Hg. Respiratory tidal volume increased with hypoxia from the resting value of 582 ± 22ml to 746 ± 38 ml, while photoplethysmographic pulse amplitude de-creased to 60% of control, together with a 0.22 ± 0.03°C drop in skin temperature. The above values are means ± SE (n = 18). Schi temperature. The above values are means 15c (h = 16). Occasionally skin resistance was reduced as well. Skin sym-pathetic activity increased during hypoxia and each major burst was followed by a reduction in pulse amplitude. The respiratory and piethysmographic responses exhibited similar time courses, with corresponding peaks. Voluntary hyperventilation for 90 sec with room air also produced an initial reduction in pulse ampli-tude, however, it recovered within 60 sec.

It is concluded that in conscious human subjects transient systemic hypoxia leads to constriction of cutaneous vessels in the hand, and that the vasoconstriction is the result of increased traffic in sympathetic efferent fibers. Skin vasoconstriction can develop independently of respiratory changes; usually the con-comitant hyperventilation facilitates the cutaneous response.

THE EFFECT OF PROPRANOLOL, ATENOLOL AND MINOXIDIL ON PLASMA NOR-32.3 EPINEPHRINE AND EPINEPHRINE CONCENTRATION IN THE SPONTANEOUSLY HYPERTENSIVE RAT (SHR). James S. Hall\*, Ana M. Biediger\* and T. Kent Keeton\* (SPON: R. Allan Buchholz). Dept. of Pharmacology, The Univ. of Texas Health Science Center, San Antonio, Tx. 78284. To test the hypothesis that beta-adrenergic receptor antago-

nists (B-blockers) exert their antihypertensive effect by decreasing sympathetic nervous system (SNS) activity, the plasma concentration of norepinephrine (NE) and epinephrine (EPI) was measured In SHR after the administration of the  $\beta$ -blockers propranolol or atenolol (10 mg/kg, s.c.) or drug vehicle (control animals). The plasma concentration of NE and EPI also was measured in SHR treat-ed with the vasodilator minoxidil (0.5 mg/kg, i.p.) to determine the effect of a decrease in blood pressure per se on plasma catethe effect of a decrease in blood pressure per see on plasma cate-cholamines. Mean arterial pressure (MAP) and heart rate (HR) were measured in conscious, unrestrained rats via a chronically indwel-ling aortic catheter. Blood samples (0.8 ml) for the measurement of plasma catecholamines were drawn through the aortic catheter immediately before and at 0.5, 2, 4 and 8 hours after drug administration. Both atenolol and minoxidil produced a significant decrease in MAP by 0.5 hour post-injection, and MAP continued to fall until a maximal response of 15% occurred at 4 hours post-injection with atenolol and at 6 hours with minoxidil. In contrast, propranolol produced an initial increase (p < .01) in MAP of 10% at 1 hour post-injection followed by a depressor re-sponse which reached a peak of 15% at 4 hours. Plasma NE, but not EPI, concentration was increased significantly in the minoxidil-treated rats, when compared to the control rats, at 2 and 4 hours after administration when MAP was reduced. In contrast, neither propranolol nor atenolol produced an increase in plasma NE concentration at 4 hours post-injection, the time of the peak antihypertraining at shorts post-injection, the time of the peak antisppe tensive response to the drugs. Propranolol produced a 6-fold increase in plasma EPI (p < .001) and a smaller increase in NE (p < .001) concentration at 0.5 hr post-injection, corresponding with the early rise in MAP caused by propranolol, whereas atenolol had no effect on plasma catecholamines at this time. These results suggest that either SNS activity or NE release from sympathetic neurons is inappropriately low relative to the fall in MAP produced by the  $\beta$ -blockers as compared to minoxidil. Further-more, the early rise in MAP produced by propranolol may be related to its ability to increase plasma EPI concentration. (Supported by NIH grant HL 25681.)

32.5 DOPAMINE MAY BE A NEUROHORMONE IN THE RAT ADRENAL CORTEX. R. McCarty, R. F. Kirby and R. M. Carey\*. Departments of Psychology and Internal Medicine, University of Virginia, Charlottesville, VA. 22901

In the periphery, dopamine (DA) is a precursor for norepinephrine (NE) and epinephrine (EPI) biosynthesis and is itself a neurotransmitter in sympathetic ganglia. In addition, DA may function as a neurohormone in providing maximum tonic inhibition of aldosterone secretion from the adrenal cortex (J. Clin. Invest.  $\frac{66}{\text{DA}}$ : 10, 1980). For this study, we have quantified the amounts of  $\overline{\text{DA}}$ , NE and EPI localized in the adrenal cortex and have examined factors that regulate concentrations of DA. Adult male Sprague-Dawley rats (199-266g) were assigned to one of four groups: adrenal demedullated (ADM), (2) adrenal denervated (ADN),
 adrenal demedullated-denervated (DMN) and (4) sham-operated controls (SHAM). Following surgery, rats were housed in groups of 4/cage with food and water <u>ad lib</u> for 10 days. Rats were then sacrificed by decapitation and the adrenals were removed, weighed and homogenized in 0.1N HClO<sub>2</sub>. Catecholamine concentrations in adrenal homogenates were quantified by a radioenzymatic-thin layer chromatographic assay (see Table)

Catecholamine concentrations (µg/pair) in rat adrenals:

	SHAM	ADM	ADN	DMN
DA	3.03 ± 0.13	1.26 ± .05	2.50 + 0.09	1.31 ± .10
NE	10.38 ± 0.47	0.46 <u>+</u> .08	7.74 <u>+</u> 0.64	0.75 <u>+</u> .12
EPI	33.11 <u>+</u> 1.19	0.47 <u>+</u> .10	26.12 <u>+</u> 1.36	1.93 ± .28

Compared to SHAM, ADM and DMN reduced NE and EPI levels by 92-99% but DA levels by only 57-58%. ADN reduced levels of each catecholamine by 18-26%. These findings indicate that the adrenal cortex contains approximately 40% of the total gland content of DA and less than 8% of the gland content of either NE or EPI. Further, DA in the adrenal cortex does not appear to require an intact nerve supply to the adrenal. In a second experiment, we examined herve supply to the adrenal. In a second experiment, we examined the effects of inhibition of catecholamine biosynthesis with alphar methyl-p-tyrosine (AMPT, 250 mg/kg X 2) on DA content in SHAM and ADM rats. In saline-injected controls, ADM reduced NF and EPI levels by 96-98% but DA levels by only 75%. In SHAM rats, AMPT reduced adrenal DA by 44% and heart NE by 37%. In contrast, treat-most of ADM rates with AMPT increased adrenal DA levels bu (0% but reduced adrenal DA by 44% and heart NE by 3/%. In contrast, treat ment of ADM rats with AMPT increased adrenal DA levels by 49% but decreased heart NE by 36%. Thus, DA in the adrenal cortex does not appear to require <u>de novo</u> catecholamine biosynthesis. We suggest that adrenal cortical cells acquire DA from extracortical sites. Cells of the adrenal zona glomerulosa may utilize this substance as an inhibitor of aldosterone secretion.

ADRENAL TYROSINE HYDROXYLASE ACTIVITY: EFFECTS OF 6-HDA. 32.4

ADREMAL ITRUSING HIDROALLASE ACTIVITY. EFFECTS of 5 mon, UNILATERAL ADRENALECTOMY AND STRESS. Steven J. Fluharty\*, Gretchen L. Snyder\*, Edward M. Stricker and Michael J. Zigmond. Dept. of Biological Sciences, Univ. of Pittsburgh, Pittsburgh, PA 15260. Stress increases adrenal tyrosine hydroxylase (TH) activity, presumably in order to couple catecholamine (CA) synthesis with accelerated secretion. Damage to the sympathetic nerves similarly increases the demand for adrenal CA biosynthesis and elevates TH activity. In the present experiments we examined the effect of partial damage to the sympathoadrenal system on adrenal TH activity during stress.

Male, Sprague Dawley rats (250-300 g) were anesthetized with Equithesin and received either 6-hydroxydopamine (6-HDA; 100 mg/kg, iv), unilateral adrenalectomy (UAdx), or both. Some animais from each group were then treated acutely with insulin (20 U/kg, sc, 1 hr prior to sacrifice) or chronically exposed to cold ( $5^{9}$ C for 4 days). Animals were anesthetized and adrenal gland and heart were removed for determinations of TH activity and tissue CA content.

Four days after 6-HDA treatment, CA content of heart was re-duced by 90%. At this time adrenal TH activity was increased by duced by 90%. At this time adrenal TH activity was increased by 54% with no change in adrenal CA content. By 8 days TH activity had returned to normal despite the fact that cardiac CA levels remained low. Insulin and cold exposure resulted in still further increases in TH activity (by 105% and 168%, respectively). UAdx also increased TH activity in the remaining adrenal, by

UAdx also increased TH activity in the remaining adrenal, by 60%, within 4 days without a change in adrenal CA content. How-ever, by 8 days TH activity was still elevated and CA levels had increased by 70%. Both insulin and cold exposure further increased TH activity, by 173% and 150%, respectively. The combination of 6-HDA and UAdx produced an additive increase in TH activity in the remaining adrenal, at both 4 days (126%) and 8 days (55%). Moreover, insulin and cold stress each produced further increases in enzyme activity. These findings demonstrate that there is a substantial range of plasticity of CA biosynthesis within the adrenal medulla which permits enhanced synthesis and secretion during stress deenite nartial damage to the symmathesecretion during stress despite partial damage to the sympatho-adrenal system. (Supported by MH-29670 and MH-08758.)

SYMPATHECTOMY INHIBITS COMPENSATORY ADRENAL CORTICAL GROWTH. N. Kleitman and M. A. Holzwarth, Neural and Behavioral Biology Program and Department of Anatomical Sciences, University of Illinois, Urbana, IL 61801.

Illinois, Urbana, IL 61801. Compensatory adrenal growth, a proliferative response of the contralateral adrenal cortex after unilateral adrenalectomy, is known to be neurally mediated, but the neural substrate for the response is unknown. In the present experiment we have found that neonatal sympathectomy blocks compensatory adrenal growth in adult rats, suggesting an important role for the sympathetic nervous system in the mediation of this response.

Newborn rats were sympathectomized with repeated subcutaneous injections of 6-hydroxydopamine (6-OHDA, 50 mg/kg every 48 hrs for the first 15 days of life; n=18), or guanethidine (20 mg/kg, same schedule; n=22). Controls were vehicle-injected littermates (n=19). Anatomical evidence for successful sympathectomy included a reduction in catecholamine histofluorescence (de la Torre method) in the adrenal cortex, and decreased size and cell number in the superior cervical ganglion of rats injected with 6-OHDA or guanethidine. Rats underwent either left-adrenalectomy or sham operation at 40 days of age and were sacrificed 72 hrs later. Adrenals were cleaned, weighed, and assayed for DNA (Burton method) and RNA (Orcinol method).

In agreement with previous reports, the mean weight of the right adrenals of left-adrenalectomized vehicle-injected animals was  $32\pm9\%$  greater than that of sham operated animals (p=.001). This weight increase was accompanied by a  $14\pm5\%$  increase in DNA content (p=.02), suggesting that this was a cell proliferative response. After sympathectomy, the weight increase in right adrenals of left-adrenalectomized animals was attenuated in com-parison to the vehicle control group, and not statistically difparison to the ventre control group, and not statistically dif-ferent from sham operated sympathectomized animals (15±5% for 6-OHDA; 19±3% for guanethidine; p's>.05). There was no difference between the DNA content of right adrenals of left-adrenalec-tomized vs. sham operated animals (102±7  $\mu$ g vs. 103±8  $\mu$ g/gland for 6-OHDA; 102±9  $\mu$ g vs. 104±8  $\mu$ g/gland for guanethidine) thus the observed growth was not the result of cell proliferation. The weight increase in both sympathectomized and control group glands was accompanied by elevated RNA content which may have been the

result of increased secretory activity and cell hypertrophy. Thus, in sympathectomized rats, we observed no evidence of the proliferative compensatory adrenal growth response. Based on this observation and histofluorescence evidence, we conclude that the adrenal cortex is innervated by sympathetic catecholaminergic nerves, and that this innervation is involved in the mediation of compensatory growth in response to unilateral adrenalectomy. (Supported by NSF Grant PCM-8109756 and NIH PHS-5T32GM07.)

ORGANIZATION AND DISTRIBUTION OF THE RAT SUBDIAPHRAGMATIC VAGUS AND ASSOCIATED PARAGANGLIA J. C. Prechtl and T. L. Powley. Lab. Regulatory Psychobiology, Purdue Univ., W. Lafayette, IN 47907 Although an extensive literature exists on surgical and elec-trophysiological manipulations of the vagus of the rat, no detailed surgical anatomies of the nerve are available for the 32.7 species. Thus, specific conclusions pertaining to the vagus often involve problematic assumptions about the vagal distribution, connectivity, and composition. To provide a more detailed, microscopic anatomical description of the rat vagus, we prepared tissue blocks of the upper abdominal viscera taken from male (200-250g) Sprague Dawley rats. After the tissue was stained according to the pyridine silver method of Ranson and Davenport (1931), it was double embedded with celloidin and paraffin, and sectioned transversely at  $7\mu$ . Beginning at the diaphragm and proceeding to the cardiac sphincter, every 4th  $70\mu$  length was examined at 120X and 300X magnification. A section from each length was projected (140X) and traced onto a polar coordinate grid. All size and position information on the tracings was digitized and plotted with a computer program that normalized distances as percentages. The resulting plots summarized the sizes and locations of all fascicles and paraganglia having cross sectional areas greater than 700u

Of the 23 specimens studied, 17% had double anterior vagal trunks at the level of the diaphragm, 26% double posterior trunks and 4% both double posterior and anterior trunks. The hepatic branch comprised the first bifurcation below the diaphragm in 67% of the cases, and occurred on average at 18% of the distance from the diaphragm to the cardia. At 32% of the distance to the cardia, the accessory coeliac branched from the anterior trunk; it moved first laterally and then continued to spiral over  $180^\circ$ , traversing the posterior trunk before arriving to a peripheral part of the posterior fat mass of the lesser curvature. In 35% of the cases, the accessory was part of a common anterior-hepatic trifurcation. At 77% of the distance to the cardia, the posterior vagus arborized into numerous (19±1) bundles, the majority of which exited The infer durated of the analytic of which extreme onto the left gastric artery immediately following the departure of the fascicles of the accessory coeliac. All paraganglia noted on the esophagus  $(\overline{X}=8\pm1)$  were associated with the vagus, partic-ularly at or after a branch point. Approximately 33% of all para-ganglia occurred at the coeliac branching and 15% at the hepatic gangita occurred at the contract of an entry and 13% at the hepatin-branch point. Gastric and accessory coeliac branches also contain-ed paraganglia although in lower densities. Coeliac branch points contained the largest paraganglia  $(\overline{X}=2803\pm487\mu^{-})$  as compared to the overall average (1755±10 $\mu^{-}$ ); and it was these large para-ganglia that most commonly contained neurons (from 1 to 6) having soma diameters ranging from 14 to  $22\mu$ . Support for this research was provided by NIH grant AM27627.

VAGAL REGENERATION MAY MEDIATE THE SPARING OF VMH OBESITY OBSERVED 32.9 WITH PRIOR VAGOTOMY. <u>E. A. Fox\* and T. L. Powley</u> (SPON: F. R. Brush). Lab. of Regulatory Psychobiology, Purdue University, West Lafayette, IN 47907.

Although subdiaphragmatic vagotomy (VAGX) performed after ventromedial hypothalamic (VMH) lesions eliminates much of the Ventromedial hypothalamic (VHH) lesions eliminates much of the obesity typically produced by such damage (e.g. Powley and Opsah, 1974), VAGX performed prior to the lesions spares more of the obesity (e.g. King et al., 1978). To quantify the extent of such sparing and to characterize more completely the role of the vagus in the VMH syndrome, we gave 50-day-old female Sprague-Dawley rats VACV of the supervalues (N = 42). WAGX with pyloroplasty (N = 42), sham VAGX with pyloroplasty (N = 20), or sham VAGX with sham pyloroplasty (N = 20). The VAGX consisted of resecting each of the branches leaving the subdiaphragsisted of resecting each of the branches leaving the subdiaphrag-matic trunks and then resecting both the anterior and posterior vagus between the diaphragm and the cardia. After a 100-day re-covery period during which the animals were fed a wet mash diet, two-thirds of each group were given VMH lesions (lma, 18sec) and the remaining third, sham operations. Following the lesion, all groups were fed in succession a wet mash diet (6 wks), a high fat diet (10 wks), and a supermarket diet (4 wks) before they were cardified. Vacue function was encoured at the end of the encourt sacrificed. Vagus function was assessed at the end of the experi-ment by (1) cell loss in the dorsal motor nucleus of the vagus (DMN), (2) microscopic analysis of the vagus stained with pyri-(DMN), (2) microscopic analysis of the vagus stained with pyri-dine silver, and (3) basal and stimulated insulin secretion. Based on these analyses, complete VAGX was defined by cell loss in excess of 23.6% and an absence of normally formed vagal trunks. Forty-two animals satisfied these criteria; they averaged 52.7%cell loss in the DMN (range 23.9% to 77.1%). Lesioned animals with prior VAGX displayed 80% of the obesity observed in lesioned animals without VAGX. This expression of VMH obesity by the ani-cold of the prior VAGY management of the observed pluging mals with prior VAGX was associated with anatomical and physiological evidence suggesting that the vagus may have regenerated (see also Evans and Murray, 1954). All forty-two VAGX animals exhibited a consistent anatomical pattern: each proximal vagal trunk formed a neuroma below the diaphragm and immediately above a scar of the periesophageal tissues. The distal stumps of the hepatic, gastric and coeliac vagal branches had survived and contained axons. Axons issued from the neuroma and could also be found connecting the distal portion of the scar to surviving hepa-tic, gastric and coeliac stumps. Finally, insulin secretion occurred in response to electrical stimulation of the cervical vagus in 10 of 31 vagotomized rats that were tested. Additional re-search will need to determine the time course of vagal regenera-tion and to assess whether prior VACX prevents VMH obesity when regeneration is blocked. This research was supported by NIH grant AM 27627.

TONIC VAGAL INHIBITION AND ENHANCEMENT OF PORTAL PLASMA INSULIN 32.8 IONIC VAGAL INHIBITION AND ENHANCEMENT OF PORTAL PLASMA INSULIN CONCENTRATION. <u>King C. Lee\* and Ralph E. Miller</u>. Departments of Pharmacology and Medicine, Univ. of Ky., Lexington, KY 40536. The aim was to: 1) Determine if cutting a mainly afferent neural pathway between liver and brain, the hepatic vagus nerve,

neural patnway between liver and brain, the hepatic vagus nerve, would alter portal venous plasma immunoreactive insulin (IRI) con-centrations, and 2) find what role the celiac vagus nerve might have in IRI changes induced by hepatic vagotomy. (The celiac vag-us is a major efferent nerve trunk supplying the pancreas). In unanesthetized, spinalized (C7), adrenalectomized, male Sprague-Dawley rats (300 gms) the hepatic vagus was cut or sham cut prior to cutting or sham cutting the celiac vagus. The four groups, in the table below, were examined. GROUP HEPATIC VAGUS CELLAC VAGUS # ANIMALS

GROU

JP	HEPATIC VAGUS	CELIAC VAGUS	# ANIMALS
	sham cut	sham cut	9
	sham cut	cut	9
	cut	sham cut	7
	cut	cut	8

Portal plasma glucose concentrations were not different among the Portal plasma glucose concentrations were not different among the groups. Basal glucose (33 rats) was  $125\pm22 \text{ mg/dl}$  (mean  $\pm$  sem). Basal IRI concentrations for group 1 through group 4 were:  $3.5\pm1.1$ ,  $2.5\pm.7$ ,  $2.6\pm.9$ ,  $1.8\pm.5$  ng/ml (mean  $\pm$  sem). The changes in % are tabulated below. (Hepatic vagus cut/sham cut, 0 min, celiac vagus cut/sham cut, 21 min).

		TIN	1E (min)				
GROUP	-6	0	11	21	26	30	
1.	100	90± 7	6 <u>3±</u> 11	44±10	2 <u>6</u> ± 9	3 <u>2±</u>	7
2.	100	78± 6	91±33	75±14	105±19	110±	16
3.	100	124±30	145±31	186±58	240±97	459±2	24

un 1.	IRI 1	fell thr	ough mos	t of the	experim	ent (r	к. I

4. 100 94± 5 129±10 207353 771-00 10 Group 1: IRI fell through most of the experiment (p<.01). Group 2: IRI rose after celiac vagotomy at 21 min (p<.01). Group 3: IRI rose after hepatic vagotomy (p<.01). Group 4: IRI was not different from that of group 3 before, but was lower 10 min after, celiac vagotomy (p<.01). In summary: 1) Hepatic vagotomy (group 3,4) caused a rise in IRI which was reversed by celiac vagotomy (group 4). 2) Celiac vagotomy caused a rise in IRI in hepatic vagot animals (group 4). 3) The changes were independent of the portal plasma glucose concentra-tions.

The results are consistent with the hypothesis that signals from the liver affect portal venous plasma insulin concentrations via a tonically active vago-vagal pathway. The celiac vagus may be responsible for inhibitory as well as stimulatory influences on portal insulin concentrations. (Supported by BRSG Grant S07-RR-05374 NIH).

ANDROGEN-ESTROGEN SYNERGY IN RAT LEVATOR ANI MUSCLE: 32.10 HORMONAL REGULATION OF GLUCOSE 6-PHOSPHATE DEHYDROGENASE. S. R. Max, Dept. of Neurology, Univ. of Maryland Sch. Med., Baltimore, MD 21201.

The effects of castration (GDX) and hormone administration on the activity of glucose 6-phosphate dehydrogenase (G6PD) in the rat levator ani muscle of adult male rats were studied. GDX caused a decrease in G6PD activity. Chronic administration of testosterone propionate (TP) Increased G6PD activity in the levator ani muscle of castrated rats; the magnitude of the increase was related to the length of time the animals were castrated and to the length of time of exposure to hormone after GDX. The longer length of time of exposure to hormone after GDX. The longer the period of GDX before exposure to hormone, the greater the effect. For example, 7 days after GDX, treatment with TP (GDX) caused G6PD to increase by 50%; 30 days after GDX, TP caused G6PD to Increase by 100% with respect to uncastrated controls. Dihydrotestosterone (DHT) was less effective than TP in enhancing G6PD in the levator ani muscle from castrated rats; estradiol (E2) was ineffective. Combined treatment with E2 and DHT, however, was as effective as TP alone (Table). was as effective as TP alone (Table).

	Treatmen	it*	G6P1	0 (%)	Cont	rol)	
None					]	100	
GDX						50	
GDX + S	ΓP				2	200	
GDX + 1	DHT				1	100	
GDX + 1	E2					50	
GDX + 1	E2 + DHT				2	200	
*GDX -	30 days,	followed	by 14	days	of	hormone	treatmen

Apparently E2 is necessary for the maximal effect of androgen on G6PD activity, although in itself it is ineffective. TP may be maximally active because it can act Interfective, if may be maximally active because it can act as an androgen and can also be aromatized to E2 by muscle. DHT may be less effective because although it is a potent androgen, it cannot be aromatized to estrogen. Thus androgens and estrogens may exert synergistic effects on muscle. [Supported by grants from NIH (NS 15760) and NASA (NIC 2 100)] muscle. [Sup (NAG 2-100)].

INFLUENCE OF THE SACRAL SYMPATHETIC CHAIN ON URETHRAL FUNCTION 32.11 IN THE CAT. J.4. Downie, D. Pillay\*, D.M. Nance and J.A. Champion\*, Departments of Pharmacology and Anatomy, Dalhousie University, Halifax, N.S., Canada, B3H 4H7. The sympathetic nervous input to the urethra which is involved in lower urinary tract function is usually assumed to be carried in the hypogastric nerves (HGN). Nerve tracing experiments investigating the distribution of nerves to specific regions of the urinary tract revealed a substantial projection to the urethra from sacral sympathetic chain (SC) These observations were then followed by ganglia. electrophysiological and functional studies. In male cats 2% solutions of fast blue, nuclear yellow or bisbenzimide were injected into the lateral aspect of the bladder (B) above the ureteric orificies or into the preprostatic urethra (U) at least 1 cm below the bladder neck under aseptic conditions. to 68 h later the cats were deeply anesthetized and perfused with buffered formaldehyde/glutaraldehyde. The inferior mesenteric ganglion (ING) and SC ganglia were cut in 48  $\mu$  m sections on a cryostat and viewed in a fluorescence microscope. The SC ganglia provided 55% of the nerves reaching U but only 21% of nerves reaching B. Most of the remaining contribution arose from the IMG. Electrophysiological tracing of action potentials evoked by stimulation of the sympathetic chain was carried out in chloralose-anesthetized cats. Potentials evoked by stimulation of SC were slowly conducted to all major branches of the pelvic plexus. In contrast, potentials evoked from the HGN could not easily be found on the major plexus nerves. The synaptic junction in the SC pathway was in the lower lumbar SC ganglia or more distal. In a separate series of experiments lumen perfusion pressure was monitored as an index of functional urethral responses. SC stimulation at  $L_4$  to  $L_5$  induced urethral constriction which was of smaller magnitude than HGN stimulation. Urethral dilatations were also observed in some experiments. The constriction response was sensitive to prazosin (0.1  $\rm mg/kg)$  and to hexamethonium (2 mg/min). In conclusion, an extensive projection of neurons from the lower SC to the urethra can be demonstrated by both retrograde tracing and electrophysio-logical techniques. These neurones could represent a second sympathetic pathway (in addition to the HGN) involved in controlling urethral activity. Supported by the Medical Research Council of Canada.

32.12 SUBSTANCE P IN THE FEMALE REPRODUCTIVE SYSTEM AND THE EFFECTS OF CAPSAICIN. <u>H. Traurig\*, J. Cotton\*, R. Papka, A. Saria\* and F. Lembeck\*</u>. Department of Anatomy, University of Kentucky, School

Lembeck\*. Department of Anatomy, University of Kentucky, School of Medicine, Lexington, Ky 40536 and Institute Pharmacol., University of Graz, Austria. The female reproductive system possesses an abundant and functionally significant innervation by adrenergic, cholinergic and sensory fibers. Recently, peptidergic nerves, including substance P(SP)-immunoreactive fibers, have been demonstrated in various parts of this system. There is strong evidence substance P(SP)-immunoreactive Tibers, have been demonstrated in various parts of this system. There is strong evidence available that SP is the transmitter of certain primary sensory neurons conveying nociceptive information centrally as well mediating vasodilation and plasma extravasation peripherally. Immunohistochemical and radioimmunoassay methods were used to determine the distribution and concentration of SP in female determine the distribution and concentration of SP in female reproductive organs of Sprague-Dawley rats. Capsaicin is known to deplete certain peptidergic fibers in adults and induce degeneration of certain primary sensory neurons in neonates. Some rats were injected (s.c.) with capsaicin to determine if the SP in the reproductive tract is attributable to primary sensory neurons and if SP depletion resulted in diminished reproductive function. Immunohistochemical whole-mount prenartions and an indirect immuno-fluorescence technique sensory neurons and if SP depletion resulted in diminished reproductive function. Immunohistochemical whole-mount preparations and an indirect immuno-fluorescence technique revealed SP-like immunoreactive nerves throughout the reproductive system. Regional differences in the number of SP fibers were: vagina) cervix  $\cong$  uterine horns  $\cong$  oviducts) ovary. RIA of SP correlated well with histochemical observations revealing the highest concentration in the vagina (8.9 pmoles/g wet wt.) followed by cervix, uterine horns and ovaries. There was no significant change in SP concentration during the estrous cycle. significant change in SP concentration during the estrous cycle. Pretreatment of rats as neonates with capsaicin caused a permanent depletion of assayable SP in all organs studied. Additionally, in capsaicin pretreated rats the time of vaginal opening was delayed by 3-4 days ( $36.9\mp$  0.27 VS 41.0  $\mp$  0.57) and while pretreated rats cycled normally they were less efficient in mating (sperm-positive vaginal lavage) and maintaining pregnancy compared to age matched, vehicle injected controls. Assay of tissues of pregnant rats revealed a decline in SP concentration but no change in total organ SP content during pregnancy. These results suggest that SP-containing nerves may play a role in female reproductive function. e.g., bw modulating play a role in female reproductive function, e.g., by modulating neurogenic organ hemodynamics; neonatal capsalcin treatment may result in a disturbance of some aspects of reproduction; and the afferent side of certain reproductive reflex mechanisms may be SP-dependent. # **REGULATION OF AUTONOMIC FUNCTION I**

CATECHOLAMINE LEVELS IN ADRENAL VENOUS AND PERIPHERAL PLASMA CALEGIDEATING LEVELS IN ADJACATED VEROS AND TEATINGKAL TEAMIC FOLLOWING STIMULATION OF BEHAVIORALLY IDENTIFIED HYPOTHALAMIC SITES IN THE CAT. S.L. Stoddard-Apter, V. Bergdall\* and B.E. Levin. Indiana Univ Sch. of Med., Fort Wayne, IN 46805 and New Jersey Med. Sch., Newark, NJ 07103 This study was designed to determine the sympatho-adrenal CALL STATES AND ADDALES AND ADDALES AND ADDALES AND TEATING AND THE STATES AND ADDALES AND ADDALES AND ADDALES AND THE STATES AND ADDALES AND ADDALES AND ADDALES AND THE STATES AND ADDALES A

(SA) concomitants of hypothalamically elicited aggressive behavior in the cat. Electrodes were lowered into the brain of awake cats to elicit aggressive behavior: escape, defense, or attack. Experimental measurements were made in the acute preparation. Cardiovascular (CV) parameters of mean arterial blood pressure (MAP) and heart rate (HR) were monitored continuously through an indwelling arterial cannula. For each behaviorally identified site, concurrent, continuous blood samples were taken from either the adrenal vein ipsilateral to the side of stimulation, or both adrenal veins, and from the atrium during four 1 min periods -- two prior to stimulation and two following stimulus onset. Each site was stimulated (biphasic, square-wave pulses; 60 Hz; 30 sec) at intensities which evoked behavior in the awake animal (0.2-0.5 mA). levels of norepinephrine (NE) and epinephrine (E) were Plasma determined by radioenzymatic assay. Effects of hypothalamic stimulation on adrenal catecholamine (CA) secretion (ng/ml/kg/ min) were determined by comparing ratios of the change in E from the baseline average of E to the change in NE from its baseline average. In all instances, stimulation resulted in an increase in adrenal E that was greater than the increase in adrenal NE. However, the magnitude of this differential increase varied with the individual behavior, with the greatest differential increase  $(\Delta E/\Delta NE = 10.74 \pm 2.94)$  observed following stimulation of a site in the ventromedial nucleus which elicited attack behavior. Stimulation of defense sites resulted in an increase in E about 3 times greater than the increase in NE, while escape behavior was accompanied by approximately equal increases in both CAs. The greatest activation of the peripheral sympathetic nervous component of the SA system appeared to be associated with attack, since stimulation of this site resulted in an average 10-fold increase in peripheral NE levels. Although both MAP and HR generally increased, the changes did not parallel those for adrenal CAs. Stimulation of an escape site elicited the greatest increase in HR (35.0  $\pm$  7.1), while stimulation of an attack site elicited the smallest CV responses. These data suggest that different hypothalamically elicited aggressive behaviors are accompanied by characteristic profiles of SA activation. SYMPATHO-ADRENAL ACTIVATION MAY BE MODULATED BY POSTSYNAPTIC

SYMPATHO-ADRENAL ACTIVATION MAY BE MODULATED BY POSISYMAPTIC (D<sub>2</sub>) DOPAMINE RECEPTORS IN THE HINDBRAIN. <u>Stephen P. Arnerić\*</u> and John P. Long\*, (SPON: W.J. Steele), Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA 52242. Dopamine (DA) analogs can stimulate the release of epineph-rine from the adrenal medulla through central mechanisms to produce hyperglycemia (Arnerić et al., 1982, Soc. for Neurosci. ABST. 8: 421). The central site of action and the DA receptor subtypes involved in this response have not been previously datarmined. Everytments reported here were performed using male determined. Experiments reported here were performed using male Sprague-Dawley rats.

To eliminate descending neural pathways from the hypothala-mus a midbrain transection (MBT) was performed. MBT did not attenuate apomorphine-induced hyperglycemia. Nerve transec-tions, together with central injections of pimozide (a relative-Is selective antagonist of  $D_2$  receptors) suggest that DA analogs activate DA receptors in the hindbrain to stimulate epinephrine release.

The ranked ordered potencies of a number of experimental and clinically active DA receptor agonists were calculated for the compounds to increase serum glucose († SG), inhibit the accumulation of DOPA using in vivo Y-butyrolactone procedure (+ DOPA) and inhibit food intake (+ FI). Positive correlation were found and infibit rood intake ( $\langle FI \rangle$ ). Positive correlation were found for the following: + FI versus + DOPA, re0.96; + SG versus +DOPA, r=0.98; + SG versus + FI, r=98. Despite the positive correlation for the ranked ordered potencies to + SG and + DOPA, the dose-response relationships to + SG and produce other dopa-minergic actions suggest it is unlikely that presynaptic DA receptors mediate the hyperglycemic effect. Consistent with this idea the putative DA autoreceptor agonist TL-99 [2-dimethylamino-6,7-dihydroxytetralin] does not produce hyperglydenoting and the system of the sympatho-adrenal system. Experiments using DA agonists devoid of  $D_1$ -agonist properties still produce hyperglycemia which is dependent on sympatho-adrenal activation. The actual potency (dose-response curves) of DA analogs to activate the sympatho-adrenal system correlates more closely with postsynaptic mediated actions [i.e. hyperacti-vity and rotational behavior] than with presynaptic mediated actions [inhibition of DOPA accumulation].

Together these data suggest that postsynaptic DA receptors of the D<sub>2</sub> subtype located in the hindbrain may modulate the activity of the sympatho-adrenal system. (Supported by NIH grant GM-22365, a grant from Eli Lilly and NIMH grant #MH-08857.)

33.3 Testosterone & Estrogen Effects on Thermosensitive Neurons

Testosterone & Estrogen Effects on Thermosensitive Neurons in Hypothalamic Tissue Slices. N.L.Silva and J.A.Boulant. Dept. of Physiology, Ohio State Univ., Columbus, Ohio 43210. The preoptic area and anterior hypothalamus, PO/AH, plays an important role in the regulation of both body temperature and reproductive activity. In vivo and in vitro electrophysiological studies have demonstrated that approximately 40% of the PO/AH neurons may be classified as temperature-sensitive. Other studies show that many PO/AH neurons possess binding sites for estrogen and testosterone. Futhermore, these two steroids have been shown to alter the activity of certain PO/AH neurons. The purpose of the present study was to examine the specificity of in\_vitro PO/AH neurons for their responses to temperature, testosterone and estrogen.

responses to temperature, testosterone and estrogen. Male Sprague-Dawley rats were decapitated, their Male Sprague-Dawley rats were decapitated, their brains were removed and their hypothalamus blocked. PO/AH tissue slices (300-400 µm thick) were maintained in a humidified chamber which was constantly perfused with an oxygenated nutrient medium (7.4 pH, 300 mOsm/kg, 10 mM glucose). The medium perfusing the slices was maintained at 37°C, but could be rapidly changed between 32°-42°C. During perfusion with a normal nutient medium, each PO/AH single unit was characterized according to its spontaneous firing rate and thermosensitivity. Following this single unit was characterized according to its spontaneous firing rate and thermosensitivity. Following this determination, the tissue perfusion was switched to a nutrient medium containing either 0.1 nM testosterone or 0.1 nM estradiol. The spontaneous firing rate and thermosensitivity were again examined during these steroid perfusions to determine the type of cell affected and the interactions between neuronal thermosensitivity and testosterone/setrogensetivity.

In the present study, the same proportions of thermo-sensitive and insensitive neurons were found as were found in previous studies. Testosterone and estradiol affected the firing rates of 30-40% of both the temperaturethe firing rates of 30-40% of both the temperature-sensitive neurons and the temperature-insensitive neurons. Of the neurons that were affected by these two steroids, the predominent effect was excitation; however, testosterone and estradiol tended not to excite the same neurons. Therefore, while there appear to be separate populations of testosterone-sensitive and estrogen-sensitive neurons, there does not appear to be a major distinction between the steroid-sensitive neurons and the neurons that are either temperature-sensitive or temperature-insensitive. temperature-insensitive.

EFFECTS OF BARORECEPTOR DEAFFERENTATIONS ON 33.4 CIRCULATORY AND THERMAL RESPONSES TO BILATERAL COMMON CAROTID ARTERY OCCLUSION IN THE COLD-EXPOSED HINDLIMB OF ANESTHETIZED CATS. <u>Carl A. Ohata</u>. US Army Research Institute of Environmental Medicine, Natick, MA 01760 Previous experiments in this laboratory demonstrated that cold-

induced vasodilation is commonly associated with a concomitant pressor response. Due to individual variations in the pattern of cold-induced vasodilation, bilateral common carotid occlusion (BCCO) was used as an alternate technique to induce a large and reproducible pressor and vasodilatory response. Responses in mean arterial blood pressure, heart rate, mean femoral arterial blood flow, footpad temperature and heat loss, and calculated femoral arterial vascular resistance and footpad thermal insulation during a 5 minute BCCO were determined when the hindlimb was exposed to room air, after hindlimb immersion in a 0°C bath, after each baroreceptor deafferentation with the hindlimb still exposed to cold, and after re-exposure to room air in 16 cats anesthetized with chloralose. In order to determine which baroreceptors anesthetized with chloralose. In order to determine which baroreceptors were mediating the responses during BCCO, the following baroreceptor deafferentations were performed in sequence: sympathetic deafferenta-tions were performed by bilateral stellate to  $T_{4}$  ganglionectomies, aortic deafferentation was performed by applying phenol to the aortic arch and bilateral denervations of the vagus nerves, and carotid deafferentations were performed by applying phenol to both carotid sinuses and sectioning the carotid sinus nerves. A large pressor response during BCCO was observed in the phases prior to carotid denervation, and was attenuated thereafter. A tachycardia during BCCO occurred in the neurally intact bases but was attenuated by sympathectomy, enhanced by vagotomy, then attenuated after carotid denervation, and was attenuated phases, but was attenuated by sympathectomy, enhanced by vagotomy, then attenuated after carotid denervation. An initial femoral arterial vasoconstriction during BCCO occurred in the first 1-3 minutes and was followed by a decline in vascular resistance. A secondary vasodilation was observed in the neurally intact cold phase, after sympathectomy, and after vagotomy. A large hyperemia during BCCO occurred in the phases prior to carotid denervation, and was attenuated thereafter. large reduction in footpad thermal insulation during BCCO occurred only in the neurally intact cold condition, after sympathectomy, and after in the neurally intact cold condition, after sympathectomy, and after vagotomy; thermal insulation decreased slightly after carotid denerva-tion, but was unchanged during BCCO in both room air exposures. Consequently, a warming and increased heat loss of the footpad during BCCO occurred only in the neurally intact cold condition, after sympathectomy, and after vagotomy. These responses were attenuated by carotid denervation and were not observed during BCCO with the hindlimb in room air. In conclusion, BCCO elicits responses similar to that observed during cold-induced vasodilation. The pressor response, peripheral vasodilation, hyperemia, and footpad warming during BCCO was mediated oricinally by the carotid sinus nerves and required was mediated principally by the carotid sinus nerves and required exposure of the hindlimb to cold.

THERMOREGULATORY ALTERATIONS IN CATS WITH LESIONS IN THE PONTINE TEGMENTUM. L. <u>Amini-Sereshki<sup>\*</sup></u> and <u>A.R. Morrison</u>. (SPON: A. Rosenquist). Dept. of Animal Biology, Univ. of Penn., Sch. of 33.5 Vet. Med., Phila. Pa 19104.

Bilateral pontine tegmental lesions abolish the atonia of paradoxical sleep (PS). Cats in PS without atonia do not shiver, pilocreat or curl their bodies protectively when placed in the cold (Hendricks,'82), which supports the idea that during PS cold (hendricks, 62), which supports the idea that during ro there is a state-related change in thermoregulatory control (Parmeggiani, 77). The present experiments were done to study the alterations in thermoregulatory responses of pontine-lesioned cats in wakefulness. Thresholds for shivering and panting, and the body posture at different environmental temperatures, were noted in 4 cats before and after placement of pontine lesions. Intact cats started to shiver, showed slight piloerection and Intact cats started to shiver, showed slight piloerection and curling of the body at ambient temperatures  $(T_a)$  of  $8-10^\circ$  C. When placed in a cage at  $T_a=35^\circ$  C they did not pant, extend their bodies, exhibit vasodilation in the pinnae, or show obvious signs of thermal discomfort. On the contrary, following pontine lesions that induced PS without atonia, cats were more sensitive to thermal changes. They shivered, piloerected and curled their bodies at  $T_a=15-17^\circ$  C. When placed in a cage at  $T_a=35^\circ$  C, they panted within a few minutes (respiratory rate =120-150/min.), extended their bodies and exhibited vasodilation in the pinnae. A normal cat did not begin panting until 2.5 hours after being normal cat did not begin panting until 2.5 hours after being placed in  $T_{a=}36.5^{\circ}$  C. These preliminary results suggest an alteration of the thermoregulatory control in wakefulness of pontine-lesioned cats that exhibit PS without atonia. This alteration is most likely due to the disruption of the central mechanisms involved in thermoregulation because of the discreteness of the lesions. The heightened sensitivity of cats with pontine lesions to thermal load during wakefulness makes the apparent insensitivity to cold of cats in PS without atonia all the more striking. (Supported by NS 13110.)

AUTORADIÓGRAPHIC LOCALIZATION OF MONOAMINE RECEPTOR SITES IN RIE DORSAL VACAL COMPLEX OF THE DOC. H.A. Robertson, R.A. LESLIE, and K.M. Murphy\*. Depts. of Pharmacology and Anatomy, Dalhousie University, Halifax, N. S. Canada B3H 4H7 Nuclei in the lower brainstem play a central role in the regulation of autonomic function. For example, the nucleus tractus solitarius (NTS), which has a dense noradrenergic innervation, appears to be involved in the regulation of blood pressure. The antihypertensive agent clonidine may exert its pressure. The automyperturbate again constraint  $\mu$  of the automyperturbation of  $\alpha_2$ -adrenoreceptors in this area. Another nucleus in this area, the area postrema (AP), is a chemoreceptor trigger zone for the emetic response to dopaminergic agents such as apomorphine. Because of the obvious importance of monoaminergic mechanisms

in the autonomic functions in this brain area, we have examined In the autonomic functions in this brain area, we have examined the distribution of  $\alpha_1$  and  $\alpha_2$ -adrenoreceptors and dopamine receptors in the dog medulla oblongata using light microscopic antoradiographic techniques. The dog was chosen because, unlike some species (rat, for example), the dog shows an emetic unlike some species (rat, for example), the dog shows an emetic response. Four adult male dogs were anaestetized with sodium pentobarbital and perfused with 4 L. of 0.1% formalin in 0.1 M sodium phosphate buffer (pH 7.3). Frozen sections ( $16 \ \mu m$ ) were thaw-mounted on slides and incubated with 3H-prazosin, 3H-p-aminoclonidine, or 3H-spiroperidol. Specific binding for  $\alpha_1$  and  $\alpha_2$ -adrenoreceptor and D<sub>2</sub> dopamine receptors was determined using 100  $\mu$ M phentolamine and 10  $\mu$ M domperidone. respectively. The slides were opposed to LKB ultrofilm in x-ray cassettes and exposed for at least 3 months. The most dramatic finding was the very heavy labelling of the

dorsomedial NTS with the  $\alpha_2$ -adrenoreceptor ligand  ${}^{3}$ H-p-aminoclonidine.  $\alpha_2$ -Adrenoreceptors were concentrated in the dorsomedial NTS, and were found throughout the rostrocaudal the dorsomedial NTS, and were found throughout the rostrocaudal extent of the nucleus and including commissural, gelatinous, dorsomedial, dorsolateral and medial subnuclei. There was little or no labelling in the solitary tract itself. The AP was also labelled but the receptor density was less than one half that in the NTS. Only very light labelling was seen with the  $\alpha_1$ -adrenoreceptor ligand <sup>3</sup>H-prizosin and the D2-dopamine receptor ligand <sup>3</sup>H-spiroperidol.

The remarkably high density of  $\alpha_2$ -adrenoreceptors in this region of the brain reinforces the idea that this could be the locus of the antihypertensive actions of clonidine. (Supported by the N.S. Heart Foundation and the Department of National Defence.)

COMPARISON OF THE TOPOGRAPHIC DISTRIBUTION OF INSULAR 33.7 COMPARISON OF THE TOPOGRAPHIC DISTRIBUTION OF INSULAR CORTICAL AND CENTRAL AMYGDALOID INPUTS TO THE NUCLEUS TRACTUS SOLITARIUS AND DORSAL MOTOR NUCLEUS IN THE RABBIT. J.S. Schwaber, B.S. Kapp<sup>1</sup>, G.A. Higgins\* and <u>P.A. Driscoll-Mendes\*<sup>1</sup></u>. E.I. du Pont de Nemours & Co., Glenolden, PA 19036, and <sup>1</sup>Dept. Of Psychology, The Univ. of Vermont, Burlington, VT 05405. In this study we have compared the pattern of dis-tribution of descending inputs from the insular cortex to the nucleus tractus solitarius (NTS) and dorsal motor nucleus (DVN) to those arising from the central nucleus of the amygdela (CR).

nucleus of the anygdala (CE). Tritiated proline/leucine (50-100 nl) injections were placed into the insular cortex at various anterior were placed into the insular cortex at various anterio posterior levels. In a representive case, a 100 nl posteriorly located injection site covered the ventral portion of the dorsal and the ventral agranular cor-tices and excluded the dorsally located granular in-sula.Anterogradely transported label was followed in autoradiograms into the medulla bilaterally and pro-duced the heaviest terminal field in the NTS and DVN, extending throughout the next conduct of both duced the heaviest terminal field in the NTS and DVN, extending throughout the rostro-caudal extent of both nuclei. The label is distributed in a topographic pat-tern in both structures bilaterally, but is much heav-ier on the contralateral side. At rostral levels fib-ers appear to reach the NTS/DVN from two descending bundles, including a component traveling in the pyram-idal tract ipsilateral to the injection site. At in-termediate levels of the DMN label is present laterally and additionally completely encapsulates the nucleus. In the NTS, particularly heavy label is present in the dorsomedial, lateral and ventrolateral subdivisions. The CE projection to the medulla appears to be entirely ipsilateral and more heavily innervates the reticular formation ventrolateral to the NTS/DVN. Within the NTS, as compared to the insular input, heavy terminal labeling is present within the parvocellular and inter-mediate subnuclei and is relatively light within the lateral and ventrolateral subnuclei. It is particular-ly interesting that the posterior agranular cortical input, in common with the input from CE, is pronounced within the dorsomedial NTS, a region receiving baro-receptor inputs in the rabbit. These findings further indicate that rabbit insular cortex is involved in the central system integrating emotional, as well as extending throughout the rostro-caudal extent of both nuclei. The label is distributed in a topographic patcentral system integrating emotional, as well as cardiovascular and other autonomic events.

33.9 DIRECT PROJECTION FROM RAT MEDIAL PREFRONTAL CORTEX TO THE SOLITARY NUCLEUS. R.R. Terreberry\* and E.J. Neafsey (SPON: A.J. Castro). Dept. of Anatomy, Loyola Univ. Med. Ctr., Maywood, IL 60153.

A recent study has reported a substantial projection from the lateral prefrontal cortex to the solitary nucleus (NTS) in the rat (van der Kooy et al, Neurosci. Lett. 33:123-127, 1982). A small projection from the medial prefrontal area to the NTS was also mentioned. The present study investigated the cortical projec-tions from the medial prefrontal cortex to the NTS complex in the rat by utilizing both retrograde and anterograde transport of horseradish peroxidase conjugated with wheat germ agglutinin (HRP-WGA). The rats were anesthetized with Ketamine HCl (100mg/kg,IP) and placed in a stereotaxic frame. The cisterna magna was opened to prevent cortical swelling and a small piece of bone (2x5mm) was The prevent correct swelling and a small piece of bone (2X)mm) was removed just rostral to bregma on one side. In one series of ex-periments (n=4), stereotaxic injections of .03-.04  $\mu$ l of a 1% solution of HRP-WGA (Sigma) in physiological saline were made into the medial prefrontal cortex (3.5mm norstral, .75mm lateral to bregma, depth of 3.5mm) using a 1  $\mu$ l Hamilton syringe fitted with a 50  $\mu$ m tip. In the second series of experiments (n=3), stereo-taxic injections of .03-.04  $\mu$ l of 1% HRP=WGA were made into the NTS complex (.5mm rostral, .5mm lateral to obex). After survival periods of 2 days, the animals were reanesthetized, transcardially perfused with 1.25% glutaraldehyde and 1% paraformaldehyde, and the tissue was processed for HRP histochemistry according to the TMB procedure of Mesulam (J. Histochem. Cytochem. 26:106-117, 1978)

Following brainstem injections retrogradely labeled neurons were found in the paraventricular nucleus of the hypothalamus. central nucleus of the amygdala, insular cortex and in the infra-limbic, prelimbic and anterior cingulate regions of the medial prefrontal cortex. The infralimbic labelling consisted of a dense band of labeled neurons and was bilateral. Cells in the prelimbic and anterior cingulate regions were less densely packed. Injec-tions of the prelimbic-infralimbic region of prefrontal cortex resulted in anterograde labelling within the NTS. Label was found throughout the rostral-caudal extent of the NTS and was bilateral but howing controlement to the interim of the TS was bilateral but heavier contralateral to the injection site. The projection from the medial prefrontal cortex to the NTS suggests that this area of cortex may function primarily as a "visceral motor" corti-cal region that may play a role in regulating autonomic activities. Preliminary data from our lab indicate that electrical stimulation in this cortical region alters the activity of respiratory neurons in the NTS complex. Supported by NIH grant NS16146 and BRSG grant RR05368 from Loyola University.

THE ORGANIZATION OF INSULAR CORTEX PROJECTIONS TO THE AMYGDALOID 33.8 CENTRAL NUCLEUS AND AUTONOMIC REGULATORY NUCLEI OF THE DORSAL MEDULLA. B.S.Kapp, J.S.Schwaber<sup>1</sup>, & P.A.Driscoll-Mendes\*. Dept. of Psychology, Univ. of Vermont, Burlington, VT 05405, & <sup>1</sup>Dupont

Central Research Neurobiology Group, Glenolden, FA 19036. We have presented evidence in the rabbit suggesting that (a) the amygdaloid central nucleus (ACE) may contribute to cardiovas-cular regulation (Kapp <u>et al.</u>, 1983), (b) projections from the ACE to medullary cardiovascular regulatory nuclei exist which may mediate this contribution (Schwaber  $\underline{et}$  al., 1982), and (c) the ACE may be an important component within a larger interconnected system, including the insular cortex, involved in cardiovascular/ autonomic regulation (Kapp <u>et al.</u>, 1982). The present experiment was performed to further examine the anatomical organization of this system. Since the insular cortex has been demonstrated to project to the ACE and to the nucleus of the solitary tract (NTS) (Saper, 1982; Kapp <u>et al</u>, 1982), the present study was designed to determine if insular cortex neurons which project to the ACE also project via collaterals to the NTS.

Nincteen New Zealand rabbits received injections of True Blue (5%, 40-600 nl) aimed at the ACE. Three to four weeks later, injections of Bisbenzimide (10%, 400 nl) were made along the anterior-posterior extent of the NTS and the vagal dorsal motor nucleus. From two to three days thereafter the animals were sacrificed, and the insular cortex was sectioned (30 um) and examin-ed using fluorescent microscopy for the presence of single and double labeled neurons.

The majority of labeled insular cortex neurons were found to be single labeled, and less than five percent contained both Bb and TB. Furthermore, Bb and TB labeled neurons demonstrated different topographical distributions which varied along the anterior-posterior extent of the insular cortex. At anterior levels Bb labeled neurons were found in the innermost region of layer V, and extended in an uninterrupted continuum from the dorsal portion of the dorsal agranular insula dorsally through the granular insula and into the lateral pre-central cortex. True Blue labeled neurons at this anterior level were located within layer V of the agranular insular cortex but primarily lateral to Bb labeled neurons. At more posterior levels, both Bb and TB labeled neurons demonstrated similar, overlapping distributions and were located within layer V of the agranular and granular insula.

These results suggest that primarily separate populations of neurons within the insular cortex project to the ACE and the dorsal medulla autonomic regulatory nuclei, and that these pop ulations demonstrate partially different topographical distributions.

33.10 NEURAL CONTROL OF INSULIN AND GASTRIC ACID SECRETION: FUNCTIONAL ORGANIZATION OF VAGAL PREGANGLIONIC NEURONS. W.B. Laughton,\*H.R. Berthoud and T.L. Powley, Lab. of Regulatory Psychobiol., Purdue University, W. Lafayette IN 47907 Recent HRP studies have substantiated that the vagal efferent

Recent HRP studies have substantiated that the vagal efferen-preganglionic perikarya are distributed in the dorsal motor nuc-leus of the vagus (DMV) and the nucleus ambiguus. Although the issue of organ and response specificity has been addressed in several of these studies by selectively injecting HRP into vagal target organs or peripheral vagal branches (e.g. Laughton and Powley, Neurosci. Abs. 5:46,1979; Luiten et al, Neurosci Lett. 33(10):S310,1982; Kalia and Mesulam, J. Comp. Neurol. 193:467, 1980), the results do not unequivocally support the existence of a viscerotopic organization within the motor nuclei. a viscerotopic organization within the motor nuclei. Since there are different vagal motor functions in many organs, and since there is no simple relationship between the vagal branches and motor functions, the present study addressed the specificity issue using a more functional approach.

motor functions, the present study addressed the specificity issue using a more functional approach.
Male Sprague-Dawley rats bearing preimplanted gastric fistulae were overnight food deprived, anesthetized, and equipped with arterial and venous catheters. Incidental activation of sympathetic adrenergic mechanisms was suppressed with a and β blockers. After surgical exposure of the dorsal medulla, semi-microelectrodes (<50µ) were introduced into the brainstem region of the DW with a sampling procedure chosen to yield a systematic map. Plasma insulin and glucose concentration, gastric acid secretion, heart rate and blood pressure were continuously monitored before, during, and after a period of electrical stimulation (50µA, 50µz, 1 msec. for 10 min.). Gastric acid was measured using a saline pressure-perfusion system and a Radiometer Copenhagen on-line titrator. Blood sampled was continuously replaced with an identical volume from similarly deprived donor rats.</li>
45 percent of the stimulation sites yielded significant insulin responses (37% increased, 8% decreased); 49% of the sites yielded changes in gastric acid output (34% increased, 8% decreased, 4% biphasic response). There was no correlation between vagal activation of the two subdiaphragmatic responses, gastric acid and insulin (r=0.05). Generally, the responses studied tended not to covary, however there were low but significant (0.2 to 0.3) correlations between insulin and glycemia, heart rate and blood pressure, and gastric acid and blood pressure, while stimulation of the cervical vagus yielded strong correlations (>0.9). These results indicate that individual electrode placements within the DMV are capable of selectively activating one or more vagally mediated responses and support the idea that the responses examined are independently organized in the DMV. amined are independently organized in the DMV. COMPARISON OF GASTRODUODENAL AND CARDIOVASCULAR RESPONSES 33.11 PRODUCED BY ELECTRICAL STIMULATION OF THE DORSAL MOTOR NUCLEUS OF THE VAGUS AND NUCLEUS AMBIGUUS IN THE CAT. Pagani\*, W.P. Norman, D.K. Kasbekar\*. and R.A. Gillis\*. Depts. of Pharmaci, Physiol., and Anat., Georgetown Schs. of Med. and Dent., Washington, D.C. 20007 F.D. Georgetown Univ.

Schs. of Med. and Dent., Washington, D.C. 20007 Studies were performed to compare the role of the dorsal motor nucleus of the vagus (DMV) and nucleus ambiguus (NA) in gastroduodenal and cardiovascular control in cats. Animals, fasted for 24 hrs., were anesthetized with alpha-chloralose, and artificially ventilated. A midline abdominal incision was made and extraluminal force transducers were sutured to the antrum, pylorus, and proximal duodenum oriented to record circular smooth muscle activity. Gastroduodenal motility was analyzed by calculation of the minute motility index (MMI). Arterial pressure (AP) and heart rate(HR) were also monitored. A stimulating electrode (David Kopf SNE 100) was placed in either the DNV or NA, and verification of placement was made at the termination of the experiment by reacting Na ferrocya-nide with iron deposited by the electrode tip. Stimulation parameters were 100-133 uA, 50 Hz, and 0.2 msec pulse duration, unless otherwise stated.

parameters were 100-133 uA, 50 Hz, and 0.2 msec pulse duration, unless otherwise stated. Stimulation of the DMV(n=15) produced significant increases (p<0.01) in the MMI of the antrum, pylorus, and proximal duo-denum of 1743, 28+3, and 17+5, respectively. These changes occurred with bradycardia of -11.3+3.4 beats/min and with no significant change in AP. Altering the frequency of stimula-tion from 50 to 100 Hz did not diminish the cardiovascular or motility responses. Stimulation of the NA (n=13) produced comparable effects on antral, pyloric, and duodenal motility. Associated with these responses was a large decrease in HR of 81.9+12.5 beats/min and a decrease in AP of 19.8+5.2 mmHg. Altering the frequency from 50 to 100 Hz greatly attenuated the motility response evoked by stimulation of the NA. In-creasing the frequency had no effect on HR or AP. These data indicate that stimulation of the DMV and NA produce comparable effects on gastroduodenal motility. How-ever, motility response. This is in agreement with anatomical findings which do not find the NA as an origin for pregang-lionic parasympathetic vagal fibers innervating the stomach. In addition, activation of the DMV pathway appears to pro-duce selective effects on the gastrointestinal tract, while activation of the NA pathway poduces both motility and car-diovascular effects. (Supported by AM NS 29975).

33.13 EFFECT OF TRH AND GABA ON VAGAL EFFERENT ACTIVITIES IN THE RAT WITH RESPECT TO GASTRIC ACLD STIMULATION. <u>Y.GOTO\*, Y.Tache</u>, <u>H.Debas\*, and D.Novin</u>, Center for Ulcer Research and Education, VA Wadsworth, Los Angeles, CA and Psychology Department, UCLA, Los Angeles, CA.

TRH and GABA have been shown to act within the brain to stimulate acid secretion in the rat through vagal dependent path-ways, because vagotomy completely abolished acid output induced

by TRH or GABA. This study was performed to obtain direct evidence for vagal stimulation by neural-acting substances. Experiments were performed in urethane-anesthetized male rats. TRH (0.1-lµg, stimulation by neural-acting substances. Experiments were performed in urethane-anesthetized male rats. TRH (0.1-lµg, intracisternally) or  $\beta$ -(p-chlorophenyl)-GABA (PCPGABA, 1-8mg/kgs.c.), a lipophilic GABA derivative, dose-dependently stimulated acid output in gastric fistula rats. The maximal acid responses to TRH and PCPGABA were 25+4 and 38+3.5c H<sup>2</sup>(10m monosticula) and econosticular such bicker acid responses to TRH and PC PGABA were 25-4 and  $38\pm3\mu Eq. H^+/10min$ , respectively and comparatively much higher than those to pentagastrin ( $32\mu g kg^{-1}h^{-1}i.v.$ ) or histamine (10mg/kg, s.c.). The effect of TRH and PC PGABA on vagal efferent discharges were studied. A pair of Pt-wire electrodes were placed upon a fine vagal bundle dissected from the proximal por-tion of the divided vagus. Basal vagal discharges averaged about 10 spikes per second. Intracisternal TRH (0.1-1 $\mu g$ ) increased vagal efferent discharges immediately after its appli-cation and this response persisted for 30 min. PCPGABA poten-tiated vagal efferent firings within 15 min of s.c. injection and showed plateau levels 30 min later. The time-course and and showed plateau levels 30 min later. The time-course and dose-dependency of the effects of TRH and PCPGABA were coincident to those of acid responses. It was also found that TRH action appears to be different from GABA effect, because substance P  $(10-50\mu g/kg i.v.)$  inhibited only the vagal impulses

stimulated by PCPGABA. These results indicate that the hypersecretion of acid by TRH and PCPGABA can be explained by centrally-induced changes in parasympathetic nerve activity. This experimental method for monitoring vagal efferent impulses will be useful for studying the modulation of the autonomic nervous system.

33.12 ADRENERGIC VAGAL EFFERENT NEURONS PROJECT TO THE STOMACH. T.C. Ritchie, D.G. Gwyn, M.C. Sullivan\*, P.J. McKinney\*, R.B. Leonard and J.D. Coulter. Marine Biomedical Institute. Univ. Tex. Med. and J.D. Coulter. Branch, Galveston, Texas and the Dept. of Anatomy, Dalhousie Univ. Med. School, Halifax, Nova Scotia, Canada. We have previously reported the existence of catecholamine

(CA)-containing vagal efferent cells in the dorsal motor nucleus (DMN) of the rat (Ritchie et al., <u>Neurosci</u>., 1982, 7: 1471-1482). These cells were identified by double labeling for dopamine-B-hydroxylase (DBB) and for HRP retrogradely transported from the cervical vagus nerve. The cells exhibiting DBH-immunoreactivity probably contain either norepinephrine or epinephrine. We now report that at least a portion of the CA vagal efferent cells project to the stomach.

HRP (Miles; 15% solution) was injected into the anterior and posterior stomach walls at multiple sites ( $10 \mu$ /site) and a 2 or 3 day survival period was used. Transverse frozen sections ( $25 \mu$ m) were taken through the medulla and stained first for HRP  $\mu m)$  were taken through the medulla and stained first for HRP (NINH\_SO\_C-CoCl\_)-DAB) and then for DBH (immunocytochemistry, PAP method). Cells stained with both labels contain black HRP reaction granules on a homogenously brown stained cytoplasm. HRP-positive cells were distributed bilaterally throughout the rostrocaudal extent of the DMN and both within and ventral to the

rostrolaudal extent of the DMN and both within and ventral to the rostral nucleus ambiguus (NA) in agreement with earlier studies (Leslie et al., <u>Br. Res. Bull</u>. 1982, 8: 37-43). Neurons doubly stained from HRP and DBH were bilaterally distributed in the rostral one third of the DNN. The distribution of CA-containing vagal efferent cells which project to the stomach coincides with the distribution of HRP-DBH cells identified previously as projecting through the cervical vagus. In addition, a few HRP-DBH cells were located near, but not within, the NA. This finding confirms our earlier suggestion that a second population of CA-containing vagal efferent cells is associated with the Al cell group. Since the DMN may have collateralized projections, it is proup. Since the DMW may have collateralized projections, it is possible that the DBH-positive vagal efferent cells project to thoracic and subdiaphragmatic structures in addition to the stomach. Supported by grants from the Medical Research Council, Canada, and the NIH NS12481, NS11255 and NS07185.

33.14 AMYGDALOID LESIONS AND INTRACISTERNAL BOMBESIN: EFFECTS ON CASTRIC SECRETION. Carlos V. Grijalva, Yvette Taché, Mark W. Gunion and John H. Walsh\*. Dept. of Psychology, Brain Research Institute and Center for Ulcer Research and Education, UCLA, Los Angeles, CA 90024

In a recent study we reported that intracisternal bombesin attenuated the increase in gastric acid scretion induced by lateral hypothalamic (LH) lesions (Taché et al. Life Sci. 31: 2485-2491, 1982). The present experiment examined the effects of amygdaloid lesions alone or in combination with intracisternal (IC) bombesin on gastric secretion and blood gastrin. Two groups of male rats were given large anodal electrolytic lesions of the amygdala (encompassing the central and medial nuclei but also encroaching upon the lateral and cortical regions) and two other groups were give control operations. After at least 2 months postoperative recovery all rats were food but not water deprived for 24 h, anesthetized with methohexital, and then one amygdala group (AmB, N=6) and one control (CB, N=9) group were injected (IC) with bombesin (500 ng). The remaining amygdala (AmS, N=7) and control (CS, N=7) groups were injected with an equal volume of saline (10 µl). Immediately following the injections the pylorus was ligated. The rats, all conscious, were decapitated 2 h later and gastric contents and trunk blood collected.

Bombesin significantly reduced gastric acid output and concentration and increased pH in CB rats and induced a small but nonsignificant reduction in gastric volume in both the AmB and CB groups. Interestingly, rats in Group AmS exhibited significantly higher gastric pH levels and lower gastric acid output and concentration levels than rats in Group CS and did output and concentration levels than rats in Group CS and did not differ from Group AmB on these parameters. The lack of a bombesin effect in Group AmB may have been due to the fact that amygdaloid lesions alone induced changes similar to those seen following bombesin injections in nonlesioned control animals [means: pH; CS = 1.8, CB = 6.8, AmS = 4.3, AmB = 4.4, Acid con-centration (mEq/1); CS = 67.0, CB = 5.7, AmS = 18.3, AmB = 14.9, Acid output ( $\mu$ Eq/2h); CS = 99.9, CB = 1.3, AmS = 22.9, AmB = 6.7]. Although there was a trend for bombesin to increase gastrin levels in control animals and to reduce these levels in amygdaloid rats these results were quite variable and nonamygdaloid rats these results were quite variable and nonsignificant.

The present findings of increased pH and decreased gastric acid following amygdaloid lesions are consistent with recent studies showing that the severity of gastric ulceration in rats Rev. 6:381-390, 1982) or by LH lesions (Geiselman, P.J. & Grijalva, C.V. 5th Eur. Neurosci. Meeting, Liege, 1981) can be attenuated by prior lesions of the centromedial amygdala. Support: AM 30110 (YT), AM 17328 (CURE), UCLA URG 09528 (CVG).

ANALYSIS OF HEART RATE VARIABILITY IN DIABETIC PEOPLE. 33.15 Walter N. Tapp\*, Mark Wiesen\*, Gerald A. Curtis\* and Benjamin H. Natelson. Depts. of Neurosciences and Medicine, VAMC and New Jersey Medical School, East Orange NJ 07018.

Heart rate varies considerably in normal people but becomes much more regular in diabetics with severe disease. This is usually attributed to loss of respiratory sinus arrhythmia due to usually attributed to loss of respiratory sinus arrhythmia due to peripheral autonomic neuropathy in diabetics. Typically, heart rate variability has been assessed by gross measures of varia-bility, such as the standard error. In this study, we used spectrum analysis to evaluate the sources of variability in heart rate data in greater detail. The spectrum decomposes variability into its constituent frequencies, and recent evidence suggests that particular frequencies. We recorded heart rate from 14 diabetics and 12 normals. Subjects were asked to lie quietly for 15 min, then their ECG was recorded for 10 min and the digitized record of heart rate was stored on a computer. Snectrum esti-15 min, then their ECG was recorded for 10 min and the digitized record of heart rate was stored on a computer. Spectrum esti-mates were computed by fast fourier transform. As predicted by the clinical literature, diabetics exhibited significantly less heart rate variability at the respiratory frequency (0.3 Hz) than normals (p < 0.01). This is consistent with other evidence of parasympathetic dysfunction in the control of diabetic heart rate. Surpisingly however, diabetics exhibited significantly more heart rate variability in the low frequency band (< 0.06 Hz) than normals (p < 0.01). This means that diabetics actually exhibited larger slow changes in heart rate than normals. Heart than normals (p < 0.01). This means that diabetics actually exhibited larger slow changes in heart rate than normals. Heart rate variability along this slow time course can reflect parasym-pathetic and sympathetic influences. However, because of their frequent parasympathetic deficits, it may be reasonable to regard the low frequency band of most diabetics as predominantly sympathetic. This interpretation is supported by the finding that diabetics with signs of frank sympathetic dysfunction, such as orthostatic hypotension, had markedly reduced low frequency power. These patients exhibit flat spectra with low power (i.e., variability) across all frequencies that would be consistent with loss of both parasympathetic and sympathetic inputs to the heart. In contrast, patients with increased low frequency variability may have early renal disease which is manifested by subtle changes in the renin-angiotensin system. In pharmacological experiments, inhibition of angiotensin converting enzyme in-creased amplitude in the low frequency band. If this hypothesis can be supported, it will mean that spectrum analysis of heart rate may be a useful non-invasive tool in the detection of early renal dysfunction in the diabetic patient. Regardless of this, however, these data indicate that changes in heart rate vari-ability in diabetics are far more complex than was previously appreciated. (Supp. by VA med. res. funds, HL 26760, HL 24498)

ENDOCRINE AND AUTONOMIC REGULATION: NEURAL CONTROL OF IMMUNE SYSTEM

34.1 DECREASED NATURAL KILLER CELL ACTIVITY IN ALZHEIMER'S DISEASE.

DECREASED NATURAL KILLER CELL ACTIVITY IN ALZHEIMER'S DISEASE. L.J. Kraus\* (SPON: M. O. Berman), Department of Neurology, Boston University School of Medicine, Boston, MA 02118 Growing evidence suggests that altered immune function occurs in Alzheimer's disease and senile dementia of the Alzheimer's type (AD/SDAT). In this study we report substantial changes in one mea-sure of cellular immunity, natural killer cell activity (NKCA), in late stage patients with AD/SDAT. NKCA is a particularly appropriate measure to study immune function in AD/SDAT. NK cells are regulated by interferon (IF), a serum factor produced in response to viral infection. Viral infec-tion has been suggested in AD/SDAT. AD/SDAT is associated with Down's syndrome (trisomy-21). The gene for the species specific interferon response, IF-Rec, occurs on chromosome 21. NKCA is un-der genetic control and is influenced by HLA type. A strong gene-tic component, including HLA associations, exists in AD/SDAT. Fin-ally, NKCA is influenced by a variety of neuroendocrine hormones and peptides which may be altered due to cholinergic loss in AD/ SDAT. SDAT

NKCA was measured in a standard 4 hr <sup>51</sup>Cr release assay against NKCA was measured in a standard 4 hr "Cr release assay against K562 targets. Lymphocyte effectors were tested at multiple effec-tor/target ratios from 1.5:1 to 60:1. We first studied 7 carefully diagnosed, medication free, late disease stage SDAT patients and 7 matched controls. NKCA was depressed and the shape of the lytic curve was altered in all SDAT patients tested. These 7 subjects plus 12 additional late stage AD/SDAT patients were tested with matched normal controls and controls with other neurologic dis-orders in subsequent experiment. Acain WKCA was depresed in AD/ orders in subsequent experiments. Again NKCA was depressed in AD/ SDAT patients. However, in 10 AD/SDAT patients tested in the early stages of disease NKCA was elevated compared to controls. Subjects with other disorders including Huntington's disease and multi-in-farct dementia did not differ from normal controls. Monoclonal an-tibodies were used to determine the percent of various cell sub-To be the set of the end of the set of the

with purified or **X** IF 1000 units VSV/ml/&x10<sup>5</sup> cells, then tested for NKCA. 3 late stage AD/SDAT patients showed no increase in NKCA with off. 1 patient showed no change with **X** IF while 2 patients had decreased NKCA. NKCA was augmented with both of **X X** IF in controls. Depressed NKCA & hyporesponsiveness to IF in AD/SDAT may re-flect immune exhaustion resulting from chronic viral infection, or may be a secondary effect of cholinergic loss, or may be due to an unidentified suppressive factor. Furthur studies of this phenome-non may result in the development of new diagnostic tools and ul-timately in strategies for the management and prevention of di-sease sease.

34.2 VARIATION IN SERUM PROLACTIN LEVELS DURING THE PRIMARY IMMUNE VARIATION IN SERVE PROLAGINAL LEVELS DURING THE PRIMARY TEMDER RESPONSE: <u>B.L. Spangelo</u>, N.R.S. Hall, J.P. McGillis' and A.L. <u>Goldstein</u>. Dept. of Biochemistry, The George Washington Univer-sity Medical Center, Washington, D.C. 20037. Evidence exists that suggests an involvement for prolactin (PRL) in modulating the immune response. Hypophysectomized rats have been shown to have significantly reduced antibody titers to SPEC (Berger J. et al. Lite Endocrinol. -08, 506 1081) unless

SRBC (Berczi, I., <u>et al.</u>, <u>Acta Endocrinol.</u>, <u>98</u>: 506, 1981) unless PRL was administered at a concentration of 200 ug/day for 10 days. This treatment restored the immune response to control levels. Furthermore, immunodeficient athymic mice have been found to have abnormally low serum PRL levels compared to normal littermates (Pierpaoli, W., et al., Clin. Exp. Immunol., 24: 501, 1976). was restored to normal levels by thymic implantation at birth PR L The present studies were performed to establish the relationship of PRL to the primary immune response. Male Swiss Webster mice housed individually were injected i.p.

with SRBC (0.2 ml of 10% packed cells). This T-cell dependent antigen elicited an immune response which was quantified by measuring hemagglutination titers in individual animals. Seru Serum levels of PRL were determined by radioimmunoassay. Peripheral PRL levels were found to decrease significantly during the course of the immune response as analyzed by one-way analysis of variance ( $p \neq 0.025$ ). Twenty-four hours after SRBC injection (day 1), PRL decreased approximately 30% as compared to uninjected controls. PRL remained depressed throughout the logarithmic phase of the immune response and as antibody titers fell from peak levels on days 5 through 7, the concentration of PRL gradually returned to control values. The possibility of a direct influence on lymphocytes was examined by incubating various concentrations of PRL  $(10^{-1} to 10^{-1} M)$  in mitogen-stimulated splenic cell cul-tures. PRL was found to enhance significantly the mitogenic potentials of Con-A and PHA (T-cell mitogens). However, there was no observed effect using the B-cell mitogen LPS. The enhancement of T-cell mitogensis coupled with the signi-

ficant depression of serum antibodies to uring the immune response to a T-cell dependent antigen suggests a potential role for PRL in modulating the immune response. Whether this modula-tory influence is exerted upon subpopulations of lymphocytes will require further experimentation.

34.3 EFFECT OF SUPERFUSED THYMOSIN FRACTION 5 AND THYMOSIN α<sub>1</sub> ON IN <u>VITRO PITUITARY</u> ACTH RELEASE. J.P. McGillis, N.R. Hall and <u>A.L. Goldstein</u>. Dept of Biochemistry, The George Washington University, Washington, DC 20037

Results from various studies have suggested that peptides produced by components of the immune system constitute part of an immune-neuroendocrine circuit. In particular, studies have shown that intracerebroventricular injection of Thymosin Fraction 5 (TSN-5), a partially purified thymic extract, and Thymosin  $\alpha_1$ (TSN  $\alpha_1$ ), a 28 amino acid constituent of TSN-5, cause a specific increase in serum corticosterone in mice. Intra-peritoneal injection of TSN-5 also caused an increase, but at much higher doses, while i.p. injection of TSN- $\alpha_1$  at doses up to 100 ug/ animal had no significant effect on serum corticosterone. Since these materials are active in the brain at 100 fold lower doses, and since they have been shown to have no effect on corticosterone production by adrenal fasciculata cells in vitro, it was hypothesized that their effect is at the level of the hypothalamic-pituitary axis. An in vitro superfusion system was used to test this hypothesis.

In these studies, pituitary glands were dissected from male Wistar rats. Four animals were sacrificed between 0800 and 0900. The pituitaries were quartered and placed in the superfusion apparatus. The pituitaries were superfused with Medium 199 at a rate of 0.5 ml/min. They were then pulsed for 1 min with the peptides to be tested. Two ml fractions were collected and analyzed for ACTH by RIA. In these experiments there was no change in ACTH production when superfused with TSN-5 (1 pg-Img), or TSN  $\alpha_1$  (10<sup>-10</sup> to 10<sup>-6</sup>M). CRF was used as a positive control and was found to be effective from 10<sup>-9</sup> to 10<sup>-6</sup> M. Based on these results, we believe that the site of action of these materials is either at the hypothalamus or at some site influencing the hypothalamus. 34.4 PLASMA B-ENDORPHIN CONCENTRATIONS IN PATIENTS WITH HEREDITARY ANGIONEUROTIC EDEMA (HANE). <u>R.Perricone<sup>+</sup></u>, <u>C.Moretti<sup>+°°</sup></u>, <u>C.De Ca-</u> rolis<sup>+°</sup>, <u>L.Fontana<sup>+°</sup></u>, <u>G.De Sanctis<sup>+°</sup></u>, <u>L.Gnessi<sup>+°°</sup></u>, <u>A.E.Panerai and</u> <u>F.Fraioli<sup>+°°</sup></u>. Dept. Pharmacology, School of Medicine, University of Milano, <sup>+</sup>VI Clinica Medica, University of Rome and <sup>°°</sup>V Clinica Medica, University of Rome, Italy.

Angioneurotic edema is manifested by attacks of swelling of the extremities, face, trunk, airways or abdominal viscera occurring after psychological and physical stress or secondary to trauma. Cutaneous attacks are characterized by being non pitting and pruritic, differently from what observed in other edematous conditions such as urticaria, moreover HANE differentiates from similar conditions also for the complete absence of pain. The etiopathology of HANE is referred to Cl inhibitor (ClINH) deficiency due to a decreased production of ClIN or by the production of functionally inactive ClINH. Two orders of considerations led us to investigate a possible role of circulating B-endorphin in the pathophysiology of the disease. First, the existence of close links between the immune-system and endogenous opiates such as the presence of speficic binding sites for B-endorphin on the terminal complex of human complement; second, the clinical observation of the absence of pain in these patients during attacks. We measured B-endorphin and B-lipotropin plasma concentrations using an HPLC-RIA coupled method in patients before, dueing and after the HANE attack. Moreover, we evaluated plasma B-endorphin and B-lipotropin in patients during remission or in relatives of HANE patients. Plasma B-endorphin increase dramatically during a HANE attack without a concomitant increase in B-lipotropin, thus indicating that the increase we observed was not dependent on the presence of stress. During remission B-endorphin concentrations decreased although in some patients they remained high, but again in presence of low B-lipotropin concentrations and HANE. In vitro studies in order to better characterize this relationship are in progress.

- 34.5 INNERVATION OF A LACRIMAL GLAND. B. Walcott,<sup>1</sup> Kent T. Keyser,\*<sup>2</sup> and John Mclean.\*<sup>3</sup> lDept. of Anatomical Sciences, <sup>2</sup>Dept. of Psychiatry, SUNY, Stony Brook, New York and <sup>3</sup>Department of Zoology, University of Melbourne, Parkville, Australia.
  The Harderian gland of the bird is the major lacrimal gland and the tears produced by it are complex, containing lysozyme, IgA, and other bacteriosides in a serous fluid. The serous fluid and other components are produced by a tubular secretory epithelium while the IgA is produced by a very large population of plasma cells. Tear production is modulated by the autonomic nervous system and the gland is richly innervated. We have examined the innervation pattern to the two cell populations using histochemical techniques. We have confirmed a dense acetylcholineesterase network using a modified Coupland-Holmes technique. This network extended throughout the gland and appeared to be associated with both cell populations. Using the Falck-Hillarp technique we found varicose fibers around superficial blood vessels and among the plasma cells. There was very little positive staining associated with the secretory epithelium. There was no suggestion of the presence of serotonin by this method or by immunocytochemistry. The glyoxalic acid method also showed an extensive noradrenergic innervation primarily among the plasma cells. Ultrastructurally, the chromate/dichromate method showed dense chromaffin reaction product in vesicles in nerve varicosities in the region of the plasma cells but such endings were never seen associated with the secretory epithelium. Immunocytochemical methods revealed the presence of Substance-P-like, L-Enkephalin-like, and Vaso-Intestinal-Peptide-like immunoration frears, including the IgA, may be neurally modulated and that there are many putative transmitters present. Supported by GM 28804 and NS 19350.
- 34.6 SYNPATHETIC INNERVATION OF THE SPLEEN. S.Y. Felten, R.K. <u>Malone\*, D.J. Madyra\* and D.L. Felten.</u> Dept. of Anatomy, Univ. of Rochester, Sch. of Med., Rochester, NY 14642 and Dept. of Anatomy, Indiana Univ. Sch. of Med., Indianapolis, IN 46223. Recent anatomical, physiological, immunological and behavioral studies have supported the hypothesis that the nervous system can modulate responses of the immune system. While humoral agents, such as corticosteroids, can influence the immune response, the possibility that neurotransmitters can also play a modulatory role has been investigated. This study was undertaken to further explore the noradrenergic sympathetic innervation of the spleen in the rabbit and the rat. Postganglionic sympathetic fibers and varicosities were demonstrated using the SPG (glyoxylic acid) method of de la Torre. Acetylcholinesterase was localized by the procedure of Karnovsky and Roots. In addition, norepinephrine levels were measured using HPLC with electrochemical detection (LCEC). The following conclusions were drawn: 1.) Both the rabbit spleen and the rat spleen are extensively innervated by noradrenergic fibers. These fibers enter the spleen through vascular plexuses which follow the central arteries, through a diffuse subcapsular plexus, and through the trabeculae. 2.) Noradrenergic varicosities are present primarily around arteries in the white pulp. Numerous fibers exit from these plexuese and enter the parenchyma of the white pulp, where they end in proximity to lymphocytes. 3.) The vascular and parenchymal varicosities are often associated with yellow fluorescent cells. 4.) Acetylcholinesterase is present in the rabit spleen. In the rabbit, AChE seems to be independent of neural elements, and is generally associated with the germinal zones of the white pulp. In an additional study on the noradrenergic innervation of the spleen in the streptozotocin diabetic rat, norepinephrine levels and density of varicosities were found to be increased in almost all groups of rats with dia
  - all groups of rats with diabetes. The higher content of norepinephrine suggests that the lymphocytes in the spleen of the diabetic rat may be subjected to higher levels of the transmitter. We hypothesize that this relationship may in part explain the altered immune responses in the diabetic state, exacerbated by an enhanced presence of a substance thought to be inhibitory.

(Work on the diabetic rats was supported in part by a Juvenile Diabetes Foundation grant.)

EFFECTS OF 6-HYDROXYDOPAMINE AND RESERPINE ON THE GROWTH OF 34.7 LPC-1 PLASMACYTOMA. C. G. Frondoza\*, R. Grzanna and R. L. Humphrey\*. Oncology Center and Department of Cell Biology and Anatomy, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. There is increasing evidence for a functional relationship between the nervous system and tumor development and growth. I Τn particular, the sympathetic nervous system has been implicated in the neural regulation of tumor growth. We have studied the effects of chemical sympathetcomy with 6-hydroxydopamine (6-OHDA) and of long-lasting depletion of peripheral catecholamine stores

with reservine on the growth of LPC-1 plasmacytoma. BALB/c mice were treated with 6-OHDA postnatally (100 mg/kg s.c. every other day for 2 weeks). The effectiveness of the drug treatment was verified by assays of dopamine- $\beta$ -hydroxylase, the biosynthetic enzyme of norepinephrine, in samples of heart and spleen tissue. Reserpine (100  $\mu$ g/kg) was injected i.p. into adult mice. One to two million LPC-1 cells were injected into the calf. Tumor growth was monitored by caliper measurements of the calf diameter and the median survival time for each group of mice was determined. Seven to 10 mice were used in each set of experiments. A significantly slower tumor growth rate was observed in mice treated with 6-OHDA along with an increase in the median survival time from 23 to 28 days. Injections of a single dose of reserpine on the day of tumor transfer did not alter the tumor growth curve or median survival time. Repeated injections of reserpine on day 10, 15 and 20 were toxic. A striking de-crease in the rate of tumor growth and a profound increase in the median survival time from 22 to 33 days were observed when reserpine was given 12 days after tumor transfer, a time at which the tumor mass is established. Reserpine showed no direct cytotoxic effects on LPC-1 tumor cells in tissue culture.

Analysis of the tumor growth curves revealed that the time of appearance of the tumor mass (day 12) was not altered by either drug treatment but that the slope of the growth curves in treated mice was less steep than that measured in control mice, suggesting that the log-phase of tumor growth rather than the latency period is primarily affected. Since both 6-OHDA and reserpine treatment deplete peripheral norepinephrine stores, the data may be taken as evidence for an involvement of the sympathetic nervous system in the modulation of LPC-1 tumor growth. (Supported by USPHS grants CA-31499 and NS-15199)

34.8

EFFECTS OF STRESS AND MORPHINE ON GROWTH OF A MAMMARY ASCITES TUMOR (13762B) IN RATS. J.W. Lewis, Y. Shavit, G.W. Terman, R.P. Gale\* & J.C. Liebeskind, Depts. of Psychology and Medicine, University of California, Los Angeles, CA 90024. Stress has been shown variously to accelerate and retard tumor development in laboratory animals. The type of tumor studied, amount or type of stress experienced, and timing of stress exposure relative to tumor induction or implantation appear to be important factors in determining which outcome is obtained. We have reported that daily exposure to 10 min of inescapable footshock for 4 days prior to tumor injection enhances growth of a mammary ascites tumor (MAT 13762B) in rats. This effect is blocked by naltrexone suggesting mediation by opioid peptides. In the present experiment we: A) compared the effects of footshock stress given before or after injection of this tumor; B) assessed the effects on tumor development of morphine administration and of stress in animals made tolerant to morphine; and C) determined whether tolerance develops to the effect of stress with chronic (14 days) exposure. Groups of 45 day old female Fischer 344 rats (n=15 to 20) were studied. Footshock stress was 10 min of intermittently applied ion laboratory and the provention of the stress was 10 min of intermittently applied

studied. Footshock stress was 10 min of intermittently applied (on 1 sec every 5 sec)  $_2$ .0 mA, 60 Hz sine waves. All rats were injected i.p. with 10 MAT 13762B cells, and survival was recorded for 30 days.

recorded for 30 days. Compared to nonstressed controls, the percent of animals surviving and the median survival time was decreased equally in groups exposed to footshock daily for 4 or 14 days before tumor injection. Daily footshock for 4 or 14 days after tumor injection also enhanced tumor development although these effects were less marked. Morphine treatment (daily s.c. injections of 30 mg/kg for 2 days, then 50 mg/kg for 12 days) before tumor administration did not affect survival. This same morphine regimen also did not prevent the tumor enhancing effect of stress in animals receiving 4 days of footshock before tumor injection. This regimen given after tumor injection, however, did significantly decrease survival time and percent survival. Thus, exposure to stress either before or after tumor injection enhances the development of MAT 13762B. Although our previous work indicates involvement of opioid petides, stress

injection enhances the development of MAT 137628. Although our previous work indicates involvement of opioid peptides, stress was still capable of enhancing tumor development in animals made tolerant to morphine and no evidence was seen for development of tolerance to this effect after 14 footshock sessions. These results are paralleled by our findings on the effects of these stress procedures and morphine on an index of immune function, cytotoxic activity of natural killer cells (Shavit et al., this volume). (Supported by NIH grant NS07628 and a gift from the Brotman Foundation) volume). (Supporte Brotman Foundation)

THE EFFECTS OF STRESS AND MORPHINE ON IMMUNE FUNCTION IN RATS. 34.9 Y. Shavit, J.W. Lewis, G.W. Terman, R.P. Gale\* and J.C. Liebeskind. Departments of Psychology and Medicine, UCLA, Los Angeles, CA 90024.

Los Ange's, CA 90024. Stress can adversely affect both cellular and humoral aspects of immune function. Natural killer (NK) cells appear to act in immune surveillance against viral disease and neoplastic growth. NK activity is reduced after such stresses as food deprivation and surgery. We have suggested that the effect of stress on NK activity in rats is mediated by opioid peptides. Intermittent footshock stress causes opioid-mediated analgesia, whereas an equal amount of continuous footshock causes analgesia independent of opioid systems. We found that NK activity was suppressed in rats exposed to the "opioid" footshock paradigm, and this effect was blocked by naltrexone. NK activity in rats given the "nonopioid" stress did not differ from control values. To investigate further the involvement of opioids in this phenomenon we sought to determine if the effect of the opioid stress would develop tolerance with repeated exposure and cross-tolerance in morphine tolerant rats. In the first experiment, rats were subjected daily to the

exposure and cross-tolerance in morphine tolerant rats. In the first experiment, rats were subjected daily to the opioid form of footshock (2.0 mA; on 1 see every 5 sec for 10 min) for either 4 or 14 days. A third group served as non-stressed controls. Three hours after the last stress session, rats were anesthetized and their spleens removed and dissociated into a single cell suspension. Lymphocytes were co-cultured with YAC-1 target cells labelled with chromium-51, and NK activity was measured in a 4 hr chromium release assay. In the second experiment, one group of rats was treated with morphine for 14 days (30 mg/kg for 3 days, then 50 mg/kg); a second group received no drug. Ten days after the beginning of morphine treatment half of each group was subjected to the opioid form of stress for 4 days. Activity of NK cells was measured as described above.

opioid form of stress for 4 days. Activity of NK cells was measured as described above. The percent of specific NK cytotoxicity was equally reduced after 4 or 14 days exposure to the opioid form of stress (P<.05 compared to nonstressed controls). Morphine treatment alone (14 days) had no effect on the activity of NK cells, nor did it attenuate the suppressant effect of the opioid form of stress. That is, the activity of NK cells was equally suppressed after 4 days of stress in both morphine treated and no drug groups. These findings of naltrexone antagonism but lack of tolerance and cross-tolerance are paralleled by our findings on the effects of this same footshock stress on tumor growth in rats (Lewis et.al., this volume). INNERVATION OF THYMUS TRANSPLANTS IN NUDE MICE: AN ULTRASTRUCTURAL STUDY. <u>M.R. Cullen\* and K. Bulloch</u>, Department of Neurology, SUNY Stony Brook, Stony Brook, New York 11794. The developing thymus, prior to the onset of its functional and structural organization, is innervated by the autonomic nervous system. (ANS) In a recent light and fluorescent histochemical study a similar temporal and distributive pattern was seen in the establishment of functional thymus transplants under the kidney capsule of nude mice (Bulloch et al, 1983). The present study extends these earlier findings by analysing at the ultrastructural level, the size, type and distribution of ANS nerves within the established thymic transplant. Thymuses were removed from E-18 embryos of B10 mice and placed under the kidney capsule of syngenetic nucles. Mice and placed under the kidney classified post-operative week and the transplanted thymus was fixed and embedded in epon-araldite. Ultrathin sections were stained with uranyl acctate and lead citrate. Ultrastructural analysis demonstrated that myelinated and non-myelinated fiber bundles penetrate the thymic capsule and the interface between the kidney and the thymus. The myelinated fibers measured 2 um microns or less in diameter while the non-myelinated fibers were found to be lum in size. Myelination did not accompany the nerve fibers in the parenchyna of the gland. However, nonmigratory thymic cells were found to engulf these nerves in a fashion similar to that seen in support cells of the nervous system. Surface nerves formed a complex network among the thymocytes directly under the capsule while inter-thymic nerves enter the parenchyma in bundles along the vasculature and interlobular septa. Some larger nerve fibers terminate in encapsulated receptor-like structures at the cortico-medullary boundaries and in the interlobular septa. Smaller fibers formed enpassant boutons near parenchymal cells. Mature lymphocytes were common in the vicinity of these nerve bundles. Ultrastructural analysis verifies that the types and distribution of nerve fibers innervating functional thymic transplants is comparable to those nerves found innervating normal mouse thymus. These data further support a role for the ANS innervation in the development of thymic competency. Supported by NIH grant NS 18401

35.1 INTRAVENTRICULAR ARGININE VASOPRESSIN INCREASES CEREBROSPINAL FLUID ABSORPTION IN THE ANESTHETIZED RABBIT P. MCL. Black, A. TSOURAS,\* L. Foley.\* Neurosurgical Service, Massachusetts General Hospital and Harvard Medical School, Boston, Mass. 02114. Ventriculo-cisternal perfusions in rabbits anesthetized with pentobarbital were used to evaluate the effect of arginine vasopressin (AVP) on cerebrospinal fluid (CSF) formation and absorption. The baseline CSF formation rate Vf was calculated during 3 hours of perfusion by the relationship  $\hat{Y}f=\hat{V}i$  ((Ci/Co)-1) where  $\hat{V}i$  was the infusion rate, Ci the inflow concentration of the indicator dextran blue and Co the outflow concentration of dextran blue as measured spectophotometrically. The absorption rate  $\hat{V}a$  was calculated by the equation  $Va=\hat{V}f+\hat{V}i-\hat{V}o$  where  $\hat{V}o$  is the outflow rate. Synthetic arginine vasopressin was then infused at a rate of 250 uU/minute for 3 hours and CSF formation and absorption rates were recalculated under these conditions.

absorption rates were recalculated under these conditions. The CSF formation rate did not change with arginine vasopressin infusion: the control value was  $10.25 \pm 5.1$  ul/min. (mean  $\pm$  S.D.); the value during AVP infusion was  $12.2 \pm 6.7$  ul/min. The pressure was kept constant during these infusions at the cisternal opening pressure of the animal. The CSF absorption rates increased significantly with arginine vasopressin infusion into the ventricles. For nine animals the mean absorption rate was  $5.7 \pm$ 3.7 ul/min. before arginine vasopressin administration: during the administration it rose to  $19.1 \pm 12.2$  ul/min. This increase was significant at  $p \le 0.02$  by the 2 tailed t test. A similar increase was not seen with infusion of oxytocin or lysine vasopressin at the same concentration and rate. These data show that intraventricular arginine vasopressin increases the CSF absorption rate in rabbits. This is a novel finding and one whose mechanism requires further study. 35.2 REVERSAL OF EXPERIMENTAL DIABETES MELLITUS BY INTRACRANIAL ALLOCRAFT OF FETAL PANCREAS. <u>Alan Fine</u>. Department of Neurobiology, The Weizmann Institute of Science, Rehovot 76100, Israel.

Embryonic neural tissue can be transplanted into the brain of unrelated rats, where it may survive indefinitely, differentiate anatomically and biochemically, and influence the behavior of the host. Juvenile adrenal medullary grafts can also survive in, and influence, the brain (Freed, W.J. et al., <u>Nature 292</u>:351, 1981). Such findings suggest that other endocrine allografts might survive within the immunologically "privileged" confines of the CNS. If their hormones continued to be produced and released appropriately, and could pass out of the brain with the bulk flow of CSF, such grafts might be useful for the treatment of certain endocrine diseases.

I have tested this hypothesis in an animal model of insulindependent diabetes. Normal young adult male PVG/Hooded rats (blood glucose less than 150 mg/dL) were made diabetic by single i.v. or i.p. injections of streptozotocin (60 mg/kg). From 5 to 10 fetal pancreases, of 15-16 day gestation WF (major histocompatability barrier) or SPD (histocompatability undefined) embryos, were injected into the cisterna magnum of diabetic rats (blood glucose at least 300 mg/dL). Control diabetic rats received equivalent intracisternal injections of vehicle alone; a second group of control animals received equivalent fetal pancreas grafted into the kidney capsule. Urine volume and glucose, water intake, blood glucose, and weight were monitored before and throughout the experiment. Within the first week after grafting, fetal pancreas recipients, but not vehicle-recipient controls, returned to normal levels in all measured parameters. At the time of abstract submission, intracisternally-grafted animals have remained non-diabetic beyond 1 month. This result indicates that, despite the blood-brain barrier, hormones from intracranial endocrine grafts can pass from the CSF to the periphery in physiologically and therapeutically significant amounts, and that such grafts can survive for a prolonged period without rejection. (Supported by a Bantrell Fellowship, with assistance from Ames Division, Miles Laboratories.)

35.3 CHOROID PLEXUS EPITHELIAL CELLS IN CULTURE: BIOCHEMICAL AND PHARMACOLOGICAL CHARACTERISTICS. D. H. Gabuzda\*, E. J. Hunnicutt, C. J. Owen\* and J. A. Nathanson. Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02144. The epithelial cells of the choroid plexus are involved in the optimelial cells of the choroid plexus are involved in

The epithelial cells of the choroid plexus are involved in the secretion of cerebrospinal fluid (CSF). Recent physiological evidence indicates that the production of CSF from these cells may be influenced by catecholamines, either blood-born or released from adrenergic nerve terminals present in the choroid. Previous biochemical studies from this laboratory (Nathanson, <u>Mol. Pharmacol. 18</u>, 199-209) have identified in presence, in choroid secretory cells, of a very active adrenergic-stimulated adenylate cyclase with beta\_receptor characteristics. Unfortunately, physiological investigations of the possible function of this enzyme have been hampered because of the inaccessability of the choroid plexus in situ.

We now report studies investigating the biochemical and pharmacological characteristics of epithelial cells separated and purified from intact bovine lateral and fourth ventricle choroid plexus. These cells are isolated in artificial CSF by selective, graded enzymatic digestion with trypsin combined with special mechanical agitation, followed by sieve filtration and washing under gentle conditions. For calf choroid obtained from the slaughterhouse, additional precautions must be taken to avoid fungal and bacterial contamination. Acutely isolated cells demonstrate 70-955 viability and, when placed in artificial CSF, are able to accumulate cyclic AMP from endogenously synthesized ATP. Such cyclic AMP accumulation is markedly stimulated in the presence of isoproterenol.

stimulated in the presence of isoproterenol. We have also been able to maintain these cells in viable condition in culture for periods up to four days. After day three, precautions must be taken to prevent significant fibroblast contamination. Cell survival in modified MEM is enhanced using collagen-coated substrates, high cell density, and fetal calf serum. Cells also survive in suspension culture. After several days in culture, such cells are still able to synthesize cyclic AMP from ATP and display receptor sensitivity to adrenergic agonists. 35.4 TRACER PROTEIN ENTERS THE BRAIN AROUND PENETRATING BLOOD VESSELS; EVIDENCE FOR AN ACTIVE MOVEMENT OF HORSERADISH PEROXIDASE (HRP) THROUGH THE PERIVASCULAR SPACES AND MICROVASCULAR BASAL LAMINAE M.L. Rennels, T.F. Gregory\*, O.R. Blaumanis\*, K. Fujimoto\* and <u>P.A. Grady</u>, Departments of Neurology and Anatomy, University of Maryland School of Medicine, Baltimore, MD 21201

Maryland School of Medicine, Baltimore, MD 21201 After administration into the cerebrospinal fluid (CSF), HRP enters the perivascular spaces surrounding penetrating arterioles and moves rapidly into the brain substance through the basal laminae around capillaries arising from these vessels. Solutions of HRP (4.0%) were infused into the lateral ventricles of anesthetized cats and dogs and allowed to circulate in the CSF spaces for 4 min. to 2 hrs. The animals were then fixed by intravascular perfusion of aldehydes. Intracerebral tracer distribution was studied in Vibratome sections of the brain after incubation in tetramethylbenzidine. After HRP circulation for 4 min., penetrating arterioles and capillaries were surrounded by tracer reaction product but venules were not. After 6 or 10 min. HRP circulation, however, the intraparenchymal microvasculature was outlined, <u>in toto</u>, throughout the brain. The tracer thus appears to <u>move along</u> penetrating arterioles to capillaries and thence to venules and veins. After incubation of adjoining sections from the same animals in diaminobenzidine, electron microscopy showed dense reaction product in the perivascular spaces, filling the basal laminae around capillaries and dispersed throughout the extracellular spaces of the surrounding parenchyma. In further experiments this rapid HRP influx along the intraparenchymal microvasculature was abolished if the heart was topped prior to tracer infusion. After 10 min. HRP circulation, reaction product was found only along the ventricular and pial borders and in open perivascular spaces around the largest penetrating vessels. Similarly, perivascular tracer penetration did not occur if the intracranial arterial pulse was damped by partial ligation of the dog brachicephalic artery prior to HRP infusion and circulation for 6 min. The exchange of solutes between the CSF and cerebral extracellular spaces is generally attributed to diffusion. However, HRP movement through the perivascular spaces and within the basal laminae aroun

COMPARISON OF ELECTRICAL RESISTANCE, BUBBLE WITHDRAWAL AND COORDINATE METHOD FOR CANNULATION OF VENTRICLES. <u>B.H. Herman</u>, <u>S. Berger<sup>\*</sup> and S.G. Holtzman</u>.<sup>\*</sup> Department of Pharmacology, Emory University School of Medicine, Atlanta, GA 30322. A comparison was made of three methods of lateral intra-35.5 ventricular (LV) cannulation in the rat brain. Rats in a control group (n = 8) were cannulated using traditional stereotaxic coordinates. In a second group (n = 8), electrical resistance was used to localize the ventricle and differ-entiate it from surrounding brain areas. In a third group (n = 8), a bubble withdrawal technique was employed where as the cannula was lowered in brain.

Differences in electrical resistance in rat brain was an accurate method for locating the LV. The LV showed significantly lower resistance than areas immediately above it (corpus callosum) and the fiber tracts immediately below it. Although histological analyses indicated that all three wethods produced accurate LV canulation (all 24 rats had LV placements), the electrical resistance technique was associated with optimal placement within the LV. Using the resistance procedure, greater access was obtained to posterior portions of the ventricular system. Electrical resistance in rat brain was about 25% greater than in physiological saline, presumably due to the presence of additional ions in CSF.

Also described is a novel stereotaxic cannula holder that may be used in the bubble withdrawal procedure or in obtaining acute samples of cerebrospinal fluid.

Supported in part by USPHS Grant DA00541 and by Research Scientist Development Award DA00008.

### BEHAVIORAL PHARMACOLOGY: DOPAMINE

SERINE POTENTIATES NEUROLEPTIC ACTIVITY IN THE RAT. 36.1 F. Petty, B. Proctor\* and A.D. Sherman\*. Vet. Admin. Ned. Cent. and Dept. Psychiat., Univ. Ia. Col. Med., Iowa City, IA 52242. Three animal behavioral paradigms -- catalepsy, antagonism of amphetamine induced stereotopy, and inhibition of the conditioned-avoidance response (CAR) -- demonstrate a high (.75 - .95) rank-order correlation with antipsychotic drug potency in humans. Pharmaceutical firms have used these on a routine Since elevated levels of serine have recently been reported in psychotic humans (Waziri et al., Brit. J. Psychiat., in press), we examined interactions of L-serine, D-serine and D and L-methionine with trifluoperizine in these three behavioral paradigms. Pilot experiments with the CAR had demonstrated a potentiation of neuroleptic effect, so we chose a dose of trifluoperazine (0.53 mg/kg catalepsy, 0.25 mg/kg stereotopy and CAR) intended to optimize finding potential potentiation of neuroleptic effect. L-serine was administered with trifluoperazine at a dose of 200, 300, and 400 mg/kg IP. A dose related potentiation of neuroleptic activity was seen in all three behaviors, whereas no significant effects were noted with 800 mg/kg of L-serine administered alone. D-serine had no significant effect on catalepsy or stereotopy but did potentiate inhibition of the CAR, although significantly less than L-serine. D and L-methionine were without effect in any of the three behaviors.

These data are difficult to interpret in light of numerous These data are difficult to interpret in light of numerous reports that methionine exacerbates psychosis in about 1/3 of psychotic patients (Cohen et al., Biol. Psychiat., 8:209, 1974) and that serine induces psychotic symptomatology in patients with episodic psychosis in remission (Pepplinkhuizen et al., Lancet, May 1, 454, 1980) and would seem to be at odds with the "abnormal methylation" hypothesis of schizophrenia. Clinical trials with acute and chronic serine administration in psychotic patients are in progress and will also be dis-cussed.

cussed.

EFFECTS OF IMIPRAMINE, BUPROPION, CHLORPROMAZINE, CLOZAPINE, DI-PHENHYDRAMINE, AND PREFEEDING ON RATS RESPONDING UNDER A DIFFER-PHENHIDRAMINE, AND PREFEDING ON RAIS RESPONDING UNDER A DIFER-ENTIAL-REINFORCEMENT-OF-LOW-RATE 72-SEC SCHEDULE (DRL 72). G.T. <u>Pollard and J.L. Howard</u>, Department of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709 Under a DRL schedule, a response is reinforced only if a specified period has elapsed since the previous response. A DRL

schedule requiring a relatively long pause, 72 sec, was proposed as a screening method for antidepressant drugs: tricyclics (e.g., imipramine), monoamine oxidase inhibitors (e.g., phenelzine), and some atypical antidepressants (iprindole, mianserin, trazadone, fluoxetine, one dose of bupropion) were shown to decrease responses and increase reinforcements, whereas non-antidepressants (alcohol, chlordiazepoxide, morphine, pentobarbital, chlorpromazine, diphenhydramine) did not produce this pattern of change; the antidepressants nomifensine and bupropion (at higher doses), which increase locomotor activity in rodents, produced doses), which increase locomotor activity in rolents, produced false negatives by increasing responses and decreasing rein-forcements (0'Donnell, J.M. and Seiden, L.S., <u>Psychopharmacology</u>, 78:214, 1982; O'Donnell, J.M. and Seiden, L.S., <u>Pischopharmacology</u>, 1983; Seiden, L.S., <u>Fed. Proc.</u>, 1983; in press). These results were obtained in albino rats responding for water. In the were obtained in albino rats responding for water. In the present study, in which hooded rats responded for food on a DRL 72, imipramine (5.0, 10, 20 mg/kg i.p.) produced a true positive; chlorpromazine (0.5, 1.0, 2.0 mg/kg i.p.), clozapine (10, 20 mg/kg i.p.) and prefeeding produced false positives (decreased responses, increased reinforcements); bupropion (10, 20 mg/kg (i.p.) produced a false negative (increased responses, decreased reinforcements); and the behaviorally active dose of diphenhydramine was found to be very close to the convulsant dose Preliminary results from a DRL 36, which yielded baseline reinforcement rates about the same as those of O'Donnell and Seiden, suggested also a pattern of false positives for nonantidepressants which reduce operant responding and false negatives for antidepressants which increase operant responding. Strain of rat, type of reinforcer, and the adequacy of testing of response-decreasing non-antidepressants are discussed as possible explanations for the disagreement with previous results.

Systemic injections of apomorphine in newly-hatched chicks induced prolonged pecking at conspicuous spots located on the cage walls. This response was mediated by mature and stereospecific dopamine receptors since it was blocked by pretreatment with various dopamine antagonists, including (+)-butaclamol, but not by other classes of antagonist drugs or by (-)-butaclamol. The specificity of the chick dopamine receptor was further investigated using a series of antagonists having different relative affinities for the D-1 (adenylate cyclase-linked) and D-2 types of mammalian dopamine receptors. Drug efficacy in blocking the pecking response was unrelated to the affinity for the adenylate cyclase-linked receptor, but was highly correlated with the affinity for the D-2 receptor site. An even higher correlation was found between anti-pecking activity in the chick and clinical efficacy of the above drugs as antipsychotics. Therefore, the receptor mediating the pecking behavior is similar to the mammalian D-2 site and may be useful as a model for investigating antipsychotic

36.5 SELF-INJECTION OF NEUROTENSIN INTO THE VENTRAL TEGMENTAL AREA (VTA). Paul W. Glimcher\*, Adrienne A. Giovino\* and Bartley G. Hoebel. Department of Psychology, Princeton University, Princeton, NJ 08544.

08544. Earlier work by our group has demonstrated that neurotensin (NT) is a potent reinforcer when administered into the VTA in the conditioned place preference paradigm (Glimcher et al., NY Acad Sci., 400:422, 1982). In order to cross-validate this finding we utilized the intracranial self-injection technique to further demonstrate the reinforcing properties of NT in the VTA. Ten animals were unilaterally implanted with 22 gauge stainless steel guide cannulas which intercepted the VTA (A 2.2, L 0.6, V 7.5). Animals were then placed in an operant chamber which contained two levers. One delivered NT, while the other delivered nothing and served as a control for nonspecific activity. Animals were tested in 4-hour sessions every third day. After an initial training period they reliably self-administered NT at regular, repeatable rates. Animals typically received 2.5 ug of NT in 50 nl of saline during 0.5 sec per bar-press. They consistently preferred the active bar to the inactive one, pressing on the average 5 to 20 times per hour for NT and typically less than once per hour on the blank lever.

In order to demonstrate that NT was in fact responsible for the self-administration behavior, 3 animals which had demonstrated consistent operant performance over an extended period were tested for response extinction by substituting saline for NT. These animals demonstrated a decrease in rate to less than half of their NT levels after 3 to 5 sessions of saline substitution.

We conclude from these data and our earlier work that NT is a potent reinforcer in the VTA in both operant and nonoperant paradigms. Supported by PHS grant MH35740. 36.4 THE EFFECTS OF NALTREXONE AND AMPHETAMINE ON SQUIRREL MONKEY BEHAVIOR IN GROUPS. James T. Winslow\*, Arnold Kozak\* and Klaus <u>A. Miczek</u>. Dept. of Psychology, Tufts Univ., Medford, MA 02155.

Amphetamine has been shown to produce a profound disruption of social behavior in primates. Opiate antagonists have been reported to increase affiliative behavior. Catecholamines and en dogenous opioids may exert opposing functions on social behavior. In the following studies we examined the effects of several doses of naltrexone on social and non-social behaviors exhibited by treated individuals in established groups of adult male, female and juvenile squirrel monkeys (<u>Saimiri scureus</u>). The colonies formed stable social relationships and are reproductively active. Temperature, humidity and lighting mimic the natural habitat.

Temperature, humidity and lighting mimic the natural habitat. A catalogue of social and aggressive behaviors and postures, olfactory and sexual behaviors, and non-social behaviors such as walking and feeding was used, and a continuous behavioral record was collected. Using the focal animal technique, the frequency and duration of behaviors were summarized over a two hour observation period. The method of data collection permitted the identification of the focal monkey as the recipient or initiator of social interactions.

Naltrexome (0.1, 1.0, 10.0 mg/kg, IM) produced dose-related increases in the frequency and duration of social encounters initiated by untreated monkeys toward treated monkeys. Treated monkeys were touched, investigated, huddled with, threatened and grasped more often by untreated monkeys following administration of naltrexone. Selected doses also increased walking and marking behavior. The frequency of social initiatives by treated monkeys decreased as dose of naltrexone increased. Feeding was reduced at the highest dose, which also produced nausea. The increase in affiliative behavior following naltrexone

The increase in affiliative behavior following naltrexone treatment appears to be an indirect effect on the social behavior of untreated members of the group directed toward the treated monkey. Similar indirect drug effects on social behavior have previously been reported for amphetamine and alcohol, and may be related to changes in the treated monkey's behavior, appearance or odor.

We have shown earlier that amphetamine leads to social withdrawal of treated monkeys in established groups. Naltrexone (0.1 mg/kg IM) enhanced amphetamine (0.3 mg/kg IM) induced increase in locomotion and grooming. Naltrexone reduced the frequency of limb flicks and head jerks induced by amphetamine, and increased feeding behavior suppressed by amphetamine. Naltrexone did not antagonize the suppressive effects of amphetamine on social behavior in the monkeys studied.

vior in the monkeys studied. The findings confirm the disruptive effects of catecholamine activation, but indicate a complex relationship with opioids.

36.6 PHENCYCLIDINE (PCP) GENERATES CONDITIONED REINFORCEMENT IN THE NUCLEUS ACCUMBENS (ACC) BUT NOT IN THE VENTRAL TEOMENTAL AREA (VTA), Adrienne A. Glovino\*, Paulu W. Glimcher\*, Cruz A. Mattei\* and Bartley G. Hoebel (SPON: C.R. Gallistel). Department of Psychology, Princeton University, Princeton, NJ 08544.

Several groups have suggested that PCP may exert some of its effects on dopaminergic brain substrates. Involvement of some dopaminergic neurons in brain reward processes led us to investigate the possibility that the mesencephalic dopamine (DA) system might be a central substrate for reinforcing effects of PCP. This hypothesis suggested that PCP might generate reinforcement in the VTA or in the ACC, two important poles of the mesolimbic DA system. Twenty-eight animals were stereotaxically implanted with 22g s.s. guide cannulas in the VTA (A 2.2, L 0.6, V 7.5) and 17 with cannulas in the ACC (A 9.8, L 0.8, V 5.8). The conditioned place preference paradigm of Rossi and Reid (Physiol. Psychol., 4:269, 1976) was used. The experimental chamber was a rectangular tilt cage, one end of which was covered, the other left open to bright illumination. Animals were placed in the cage for 900 sec on the first 4 days of testing and allowed to demonstrate their place of preference, measured as time spent in each environment. On the next 4 days animals were confined to the bright environment after receiving injections of drug or vehicle. On the final day animals were allowed to express their preference after a saline injection, thus acting on their memory of the drug's effects. An increase in time spent on the bright side, when compared to baseline data generated on the bright eliminates confounding performance effects associated with some drugs by performing the test in an nondrugged condition.

VTA animals were divided into 3 groups receiving PCP (10 ug or 20 ug) or saline. Neither of these two doses produced a significant shift in preference for the bright side, suggesting that the VTA is not a site at which PCP generates its rewarding effects. The ACC animals were divided into 2 groups which received either PCP (20 ug) or saline. Animals which received PCP demostrated a statistically significant increase in preference for the bright environment with which injections had been paired (pc0.005). We conclude from this that the ACC is a brain site sufficient for generating PCP reward in the place preference paradigm.

36.7 REWARDING REFECTS OF AMPHETAMINE AND COCAINE IN THE NUCLEUS ACCUMBENS AND BLOCK BY FLUPENTHIXOL. Edward F. Aulisi\* and Bartley G. Hoebel. Department of Psychology, Princetor University, Princeton, N.J. 08544. The nucleus accumbens (ACC) is an area rich in dopaminergic

terminals; rats will self-inject amphetamine directly into this region (Hoebel, B.G., Monaco, A.P., Hernandez, L., Aulisi, E.F., Stanley, B.G., and Lenard, L., <u>Psychopharmacology</u>, in press). This suggests that stimulants can act in the ACC to generate reinforcing effects by way of dopamine (DA) receptors. To test this hypothesis, amphetamine (AMPH) and cocaine (COC) were tested for reward effects in the ACC using a different reinforcement paradigm along with isomers of a DA receptor blocker, cis-flupenthixol (c-FLU) and trans-flupenthixol (t-FLU).

Seventy rats were implanted with 26 gauge canulas in the ACC (A 9.8, L 0.8, V 5.8). They were tested in a tilt cage with one half covered and the other half exposed to bright light. were tested for 900 sec/day for 4 days and found to prefer the dark side. The next four days, they received ACC injections of either AMPH, AMPH & c-FLU, AMPH & t-FLU, COC, COC & c-FLU, or COC & t-FLU and were confined to the bright side of the cage. On day nine, they received saline injections only and were free to

choose their place of preference. AMPH and COC caused a conditioned shift in preference toward the bright side. Thus, rats preferred to spend additional time in an environment associated with ACC injections of these DA This place preference was significantly attenuated when the DA receptor blocker, c-FLU, was added to either AMPH or COC. There was no significant decrease in place preference when the inactive isomer, t-FLU, was used. In conclusion, AMPH and COC injections in the ACC caused a

conditioned place preference in rats. These effects were blocked by an antipsychotic drug delivered centrally. Given the relative specificity of flupenthixol for DA receptors, these results suggest that the rewarding effects of amphetamine and cocaine in the nucleus accumbens involve a dopaminergic system.

36.8 A COMPARISON OF ALCOHOL AND d-AMPHETAMINE EFFECTS ON AGGRESSION A COMPARISON OF ALCOHOL AND <u>d</u>-AMPHELATINE EFFORT A. <u>Miczek</u> OF FEMALE MICE IN DIFFERENT HORMONAL STATES. <u>Klaus A.</u> <u>Miczek</u> and Joseph F. DeBold. Dept. of Psychology, Tufts ford, MA 02155.

Aggression in females has not been extensively investigated, Aggression in females has not been extensively investigated, and little is known about the endocrine and neural processes which may mediate it. It was our objective to challenge female mice pharmacologically in situations that engender aggressive behavior toward other females or toward males. We studied fe-males which were either (1) ovariectomized, (2) ovariectomized and maintained on testosterone, or (3) lactating. The rationale for these drug-hormone interactions derives from their demonstrated effects on male aggression and their potentially common sites of action in the brain.

After the hormonal state of the female CFW mice was experimentally prepared, each female, housed together with a male, con-fronted either a female or a male intruder mouse that was placed into her home cage. Videorecords of each 5-min confrontation were analyzed with the aid of computer. The frequency, duration and pattern of attack bites, threats, pursuits, tail rattles, as well as non-aggressive behavior such as grooming, rearing, and walking, were determined. <u>d</u>-Amphetamine sulfate (0.63-5 mg/kg) and or its saline vehicle were injected IP 30 min before the test, and alcohol (0.1-5.6 g/kg) or its water vehicle were administered orally 15 min before the test. Female mice attacked, threatened and pursued female intruder

mice, after ovariectomy, during prolonged testosterone (7.5 mm capsule, SC) treatment, or during lactation; male opponents were attacked less. Amphetamine disrupts the pattern of female aggressive behavior toward female intruders only at higher doses (2.5, 5.0 mg/kg) regardless of their hormonal state. The low level of aggressive behavior toward males remained unaltered by (2.5. ampletamine. By contrast, a biphasic action of alcohol on ag-gressive behavior was seen after alcohol administration to ovargressive behavior was seen after alcohol administration to over-iectomized mice, i.e. a 0.1 g/kg dose increased attacks and threats toward female intruders, whereas 1.7 and 3.0 g/kg alcohol doses decreased these responses. Testosterone prevented the en-hancing effect of 0.1 g/kg alcohol. Lactating females only showed a suppression of aggression in response to alcohol.

These results demonstrate that the hormonal state can alter the behavioral response to alcohol and to a lesser extent to  $\underline{d}\text{-amphetamine}$  . The sex of the opponent also altered the drug effects on aggression. Finally, the pattern of alcohol response seen in females is different from that seen earlier in male mice, but the amphetamine response in females paralleled that of males.

DISCRIMINATIVE STIMULUS PROPERTIES OF A LOW DOSE OF APOMORPHINE IN THE RAT. Andrew H. Tang\* and Allegra A. Cangelosi\*, (SPON: J. M. Braughler). The Upjohn Company, Kalamazoo, MI 49001. 36.9

The direct dopamine (DA) receptor agonist, apomorphine, is thought to have a dose-dependent dual effect on central DA systems. At low doses, apomorphine reduces DA neuronal activities through selective stimulation of DA autoreceptors. At higher doses, post-synaptic DA receptors are also stimulated, enhancing DA neuronal activities. Male Sprague-Dawley rats were trained to discriminate a low dose (0.1 mg/kg s.c.) of apomorphine from a control treatment (s.c. saline injections) in a 2-lever, food reinforcement procedure. The does of apoinorphine was chosen to activate DA autoreceptors predominantly. Other direct-acting DA agonists tested for stimulus generalization shared the discriminative DA agonists tested for stimulus generalization shared the discriminative stimulus properties of apomorphine. The doses which produced maximum apomorphine lever choice are as follows: n-propyl norapoinorphine (0.03 mg/kg); pergolide mesylate (0.03 mg/kg); apomorphine (0.1 mg/kg); legotrile mesylate (0.3 mg/kg); apomorphine (0.1 mg/kg); and broinocriptine (10 mg/kg). The greater potency of the (-) over the (+) isoiner of 3-PPP supports the premise that DA autoreceptors mediated the discriminative stimulus effects of apomorphine in these experiments. Neither d-ambetamine until heperide the procession.

mediated the discriminative stimulus effects of apomorphine in these experiments. Neither d-amphetamine, methylphenidate nor cocaine generated more than 20% apomorphine-appropriate lever choice. The selective lever choice produced by the training dose of apomor-phine was partially antagonized by haloperidol or sulpiride. On the other hand, some of the antipsychotic drugs produced significant proportion of apomorphine-appropriate lever choice: haloperidol (50%); chlorpro:nazine (50%); clozepine (80%).

ANTAGONISM OF APOMORPHINE ENHANCED STARTLE BY  $\alpha_1$  -ADRENERGIC 36.10 ANTAGONISM OF APOMORPHINE ENHANCED STARLE BY a<sub>1</sub>-ADREMENDIC ANTAGONISTS. <u>M. Davis, J.H. Kehne</u>, and <u>R.L. commissaris</u> Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508 Considerable data indicate that catecholamines modulate sensorimotor reactivity as measured by changes in the startle

reflex. Activation of dopamine (DA) receptors via the direct reflex. Activation of dopamine (DA) receptors via the direct DA agonist apomorphine increases acoustic and tactile startle (Davis and Aghajanian, 1976; Geyer et al., 1977; Kehne and Sorenson, 1978). The excitatory effects of apomorphine can be blocked by the DA antagonists haloperidol (Davis and Aghajanian, 1976) or pimozide (Kehne and Sorenson, 1978). Surprisingly, the  $\alpha_1$ -adrenergic antagonist phenoxybenzamine also blocked apomorphine excitation of acoustic startle (Kehne and Sorenson, 1978). However, because of the possible nonselective effects of phenoxybenzamine the present study was designed to determine whether other  $\alpha_1$ -adrenergic antagonists

designed to determine whether other  $\alpha_1$ -adrenergic antagonists would also block apomorphine enhanced startle.

Would also block apponorphine enhanced startle. Groups of 5 rats each were pretested for acoustic startle and then 1 day later pretreated with a given drug or its vehicle and 15-30 min later injected with appmorphine or water. Startle response amplitude was monitored for 30 min beginning immediately after the second injection. Two days later these procedures were repeated except that rats provide in injected with appmorphine now were injected with previously injected with apomorphine now were injected with water and vice versa.

The  $\alpha_1$ -adrenergic antagonists WB-4101 or prazosin potently The  $\alpha_1$ -adrenergic antagonists WB-4101 or prazosin potently attenuated the normal excitatory effect of 3.0 mg/kg apomorphine, i.p. on startle. The ED50 dose of prazosin was 30  $\mu$ g/kg, i.p. In contrast, much higher doses of prazosin (250 or 1000  $\mu$ g/kg) only slightly decreased the excitatory effects of 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) on startle. The  $\beta$ -adrenergic antagonist propranolol and the mixed  $\alpha_1$ ,  $\alpha_2$ -adrenergic antagonist phentolamine failed to block apomorphine. The  $\alpha_2$ -adrenergic antagonists yohimbine and pinerovane markedly potentiated the excitatory effects of piperoxane markedly potentiated the excitatory effects of apomorphine.

Taken together the data suggest that DA and norepinephrine may act in concert to enhance accustic startle. Curiously, however, drugs that decrease central noradrenergic transmission however, drugs that decrease central horadrenergic transmission by other mechanisms (clonidine, 6-OHDA) failed to affect apomorphine excitation. Moreover, WB-4101 and prazosin do not the block excitatory effects of d-amphetamine on startle. Changes in the disposition of apomorphine after  $\alpha_1$ -adrenergic drugs and/or the participation of peripheral adrenergic catecholamines in modulating the excitatory effects of apomorphine are currently being investigated.

ANALYSIS OF STEREOTYPED BEHAVIOR USING A COMPUTER SUPPORTED OBSERVATIONAL METHOD. Donna L. McCorkle, Mark H. Lewis, Alan A. Baumeister, Laura Staples\*, and Richard B. Mailman. Biological Sciences Research Center, Neurobiology Curriculum and Depts. of Psychiatry and Pharmacology, University of North Carolina School of Medicine, Chapel Hill, NC 27514 36.11

Stereotyped behavior, while repetitive and invariant, actually involves a variety of differentiated response topographies. It has been customary in the pharmacology topographies. It has been customary in the pharmacology literature to assess stereotyped movements along the dimension of intensity, using rating scales, and more recently, with various automated devices. As these methods have a number of disadvantages, we have developed an observational method that employs an electronic data collecting device (Datamyte®, ElectroGeneral Corp., Minneapolis, MN) with TRS-80 Model II microcomputer hardware and software support. This permits us to output of facts of darge arm this permits us to microcomputer naroware and software support. Inis permits us t quantify effects of drugs on multiple response topographies. T method allows for the generation of interval scale data and, hence, the application of powerful parametric statistics. Comparisons between the effects of thioridazine (an "atypical" antipsychotic drug) and mesoridazine (a major thioridazine metabolite) in attenuating apomorphine-induced stereotypy were used to illustrate the utility of the method. Whereas mesoridazine showed some attenuation of apomorphine-induced mesorida2ine showed some attenuation of apomorphine-induced gnawing, thioridazine surprisingly potentiated this response when apomorphine was administered by the intraperitoneal route. In contrast, no difference was noted between the two compounds in their ability to antagonize stereotyped gnawing when apomorphine was administered subcutaneously. Other topographies analyzed for drug vs. metabolite differences included licking, sniffing, and locomotion. Effects of thioridazine and mesoridazine on the time course of apomorphine-induced behavior were also examined. The present method appears to be sensitive to effects of dose, time, as well as route of administration, and is easily adapted to a wide variety of behavioral models. As these data demonstrate, this represents an improvement over intensity rating scales.

(Supported in part by HD/MH16834, ES01104, MH14277 and HD03110.)

36.12 SELF-STIMULATION IN REGIONS OF CATECHOLAMINE HYPER OR HYPO INNERVATION PRODUCED BY NEONATAL 6-HYDROXYDOPAMINE. S. Kurumiya, T. Takeichi, M. Umemoto, T. Itakura, and M. E. Olds.\* Psychol. Div., Osaka City Univ.; Dept. of Neurosurg., Wakayama Med. College; Calif. Inst. of Tech., October 2010, Pasadena, CA 91125.

Damage was inflicted to the catecholamine (CA) systems on days 3 and 5 after birth and self-stimulation (SS) tests were days 3 and 5 after birth and self-stimulation (SS) tests were given when the rats were 4-5 months old. Each rat pup received bilateral intraventricular injections of pargyline (P, 50 mg/kg, i.p.) followed by 6-hydroxydopamine (6-0HDA, total dose, 400 µg); or desmethylimipramine (DMI, 25 mg/kg, i.p.) followed by 6-0HDA. Control pups were given P plus CSF which contained ascorbic acid. In the first experiment, the animals aged 150 days or older were implanted with monopolar electrodes (62 or 100 µm) aimed at the locus coeruleus. Each subject was given first a session of 10-12 h, and then five daily consecutive sessions of 2 h each in nergant in which depression of a lever led to the apoli-

operant chambers in which depression of a lever led to the appli-cation of a brain stimulus of 60 Hz sine waves, 0.25 sec duration and current intensity selected to produce optimal responding. The test animals learned to SS almost immediately, at very high rates. The controls required several sessions, never reaching the rates of the test animals. Fluorescence visualization of CA in the dorsal pons at the site of SS showed massive loss of A6, A5, the dorsal pons at the site of S5 showed massive loss of A6, A5, and A4 cell bodies, but not A1-A5 perikarya, and the presence of a dense network of CA fibers and terminals in test animals but not in controls. Levels of CA were reduced in tissue samples of frontal cortex, caudate n., hypothalamus, but levels of norepinephrine in the dorsal pons samples were elevated. In Experiment 2, animals which had received DM1+6-DHDA or DM1/Vehicle, wore implement with electrodes in the outpatenties

In Experiment 2, animals while had received white-involution DHi+Vehicle were implanted with electrodes in the substantia nigra, or the ventral tegmentum, or the medial prefrontal cortex (MFC), or the n. accumbens. There was no difference in the percentage of SS sites obtained in the substantia nigra and ventral tegmentum of test and control animals, but the rates of SS were lower in the test animals. Fluorescence visualization of the CA in these two regions, at the tip of the probes, showed a near CA in these two regions, at the tip of the probes, showed a near total loss of A9 cell bodies and a reduction of A10 cell bodies. Visualization of CA at the tip of the probes in the MFC showed a loss of CA input to the deep layers but not the shallow layers. The rates of SS in the MFC and the n. accumbens did not differ between test and control animals. In the test animals, the levels of dopamine (DA) in the cortex were 10% of control levels but the levels of NC did not differ from those in control animals.

These results demonstrate the presence of normal or enhanced SS behavior in regions where NE or DA perikarya were greatly reduced, or where the DA input was greatly reduced.

36.13 MICROWAVE RADIATION-INDUCED ALTERATIONS IN OPERANT BEHAVIOR OF RATS: A COMPARISON WITH d-AMPHETAMINE AND BARBITURATE. R.M. Lebovitz and J. Orr\*. Dept. Physiology, University of Texas Health Science Center, Dallas, Texas 75235.

This laboratory has shown that microwave radiation (MWR) at macroscopically non-thermogenic dose rates produced a differential effect on ongoing schedule controlled and extinction components of a repeated multiple schedule in rats. It would be

components of a repeated multiple schedule in rats. It would be useful to have a behaviorally similar pharmacologic model with which to compare the results of acute exposure to MWR. Male, hooded (Long-Evans) rats weighing from 250-350 g were trained and maintained on a multiple-schedule of fixed-ratio (FR) 25 for 15 minutes alternated with ten minute time-out (TO) periods. The two components were distinguished by the 25 for 15 minutes alternated with ten minute time-out (TO) periods. The two components were distinguished by the presence or absence of non-contingent food cup illumination. This basic 25 minute multiple schedule was repeated five times producing a continuous operant session duration of 120 minutes. The animals were irradiated (actual or sham) coincident with their operant performance. Each animal received a 6-8 g daily food supplement and was run once per day, five days per week, in its active (dark) phase. Operant trials were carried out in cylindrical irradiation cells under computerized behavioral control, with groups of 32 (16 sham, 16 irradiated) animals run simultaneously. Otherwise, animals were individually housed with water available ad lib. ad lib.

Otherwise, animals were individually housed with water available ad lib. Exposure to pulse modulated (PM) or to continuous wave (CW) MWR at 3.5 mW/g yielded essentially no change in performance during the successive FR components of the repeated multiple schedule. TO response rates were reduced and the rate of extinction increased. Separate experiments had verified that at this dose rate PM or CW MWR did not significantly elevate whole body temperature during a three hour exposure. IP injection of d-amphetamine sulphate (in saline, with saline controls) yielded a marked decrease in FR response rates with dose rates above 0.5 mg/kg, coupled with a dispersion of the inter-response time histograms. TO response rates were essentially unaffected by d-amphetamine at doses of from 0.25 to 2.0 mg/kg. In contrast, IP injection of Na-pentobarbital (at 0.5 and 1.0 mg/kg, in saline with saline controls) yielded a marked reduction in TO response rates. FR responding was either not affected or slightly elevated, similar to the result with MWR at dose rates near behavioral threshold. Thus, while d-amphetamine reduced high, FR operant response rates, it had little effect on the low rates of TO responding. The result of low doses of pentobarbital was to produce a differential effect on FR and TO response rates that approximated that of non-thermogenic MWR. that approximated that of non-thermogenic MWR. Supported by NIH Research Grant RO1-ES-02750 (RML).

STRIATAL PHARMACOLOGY OF AN ANIMAL MODEL RESEMBLING HUNTINGTON'S 36.14 DISEASE (HD). B.I. Diamond, C. Shah\*, A. Hitri and R.L. Borison. Psychiatry Dept., Medical College of Georgia, Augusta, GA 30912. We have previously demonstrated that the one week daily i.p. administration of  $\beta,\beta$ -iminodipropionitrile (IDPN) to animals re-

sults in irreversible spontaneous and unprovoked choreatic head and truncal movements that resemble HD. Furthermore, we demonstrated that this model shows neuroanatomical changes consistent with stri atal degeneration, and biochemical changes including increased striatal dopamine release and the reduction of high and low affinity striatal <sup>3</sup>H-spiroperidol binding sites; these changes parallel those found clinically in HD. We now discuss our further experi-ments, including the striatal pharmacology of the IDPN animal model. All subjects were white male Sprague-Dawley rats (200-250g). We first attempted to replicate our animal model via the direct daily injection of IDPN stereotactically into the caudate-putamen nucleus. This treatment failed to affect behavior, implicating a peripherally formed metabolite of IDPN as being responsible for central neurotoxicity. In pharmacological studies, spontaneous stereotyped behavior and locomotor activity were quantified before and after acute drug administration. The cholinesterase inhibitor physostigmine at low doses (0.25mg/kg) failed to affect behavior, but at higher doses (0.5mg/kg) decreased stereotypy without affecting locomotion. The anticholinergic agents benztropine (0.5 mg/kg)or trihexyphenidyl (0.5 mg/kg) significantly increased all behavior-al activities. At low doses (0.05 mg/kg) the dopamine agonist apo-morphine reduced stereotypy, however at higher doses (0.7 mg/kg)there was an increase in behavioral activity. Likewise, the in-direct dopamine agonist, d-amphetamine, in a dose per se subthresh-old for producing stereotypy, potentiated both stereotypy and loco-motion. In contrast, typical dopamine receptor blocking neurolep-tics, haloperidol (0.5mg/kg) or trifluoperazine (1.2mg/kg) reduced tics, haloperidol (0.9mg/kg) or trifluoperazine (1.2mg/kg) reduced all behaviors. Atypical dopamine blockers (viz., those with few extrapyramidal actions.) but with intrinsic anticholinergic activi-ty, thioridazine, clozapine, fluperlapine, actually potentiated behavior in 30%, 66% and 66% of animals respectively. An atypical neuroleptic with very low anticholinergic activity, molindone (1.2mg/kg) failed to affect behavior. These studies therefore demonstrate that the IDPN animal model mimics the clinical phar-rescioner of UD macology of HD.

36.15 SOME EFFECTS OF NEUROLEPTICS ON OPERANT AND REFLEXIVE LICKING

IN RATS. <u>S.E. Gramling\* and S.C. Fowler</u>. Dept. of Psych., Univ. of Miss., University, MS 38677 The rate reducing effects of neuroleptics on operant behavior have been variously attributed to motoric, dissociative and anhedonic (reward-reducing) processes. Heretofore, it has proved impossible to separate clearly the degree of involvement of a given process in a given experimental effect. The present research proposes the rats' licking behavior as a model system for separating neuroleptics' motor effects from these other putative effects. In this procedure the motor requirements of the response are equated by requiring a lick response in either an operant or reflexive lick condition; thus it should be and then use this result to estimate how much of the neuroleptics'

effect on operant licking is the result of motor effects per se. Rats in the operant lick condition (N=9) were trained to lick a dry horizontal disk (FR 15) for water reinforcement delivered elsewhere in the chamber. Rats in the reflexive condition (N=7) licked water from a reservoir. The surface of the disk and the reservoir water level were both 10mm below the aperture in the chamber through which rats extended their tongues to lick. chamber through which rats extended their tongues to lick. Three neuroleptics, Chlorpromazine (CPZ:0.5, 1.0, 2.0 mg/kg, ip.) Clozapine (CLOZ: 2.5, 5.0, 7.5 mg/kg, ip.) and Haloperidol (HAL: 0.6, .12, .24 mg/kg, ip.) were administered in an acute dosing regime. Lick rate and lick duration data were collected via a

laboratory computer system. Rats in both lick conditions exhibited dose dependent reduckats in both lick conditions exhibited use dependent events tions in average rate for all three neuroleptics. Moreover, operant licking showed greater rate reductions than reflexive licking for each of these drugs. On the measure of lick dura-tion, these three neuroleptics produced dose dependent increases in lick duration in the reflexive lick condition. Neuroleptics' effects on operant lick duration were mixed with some animals showing increases and some decreases on this measure.

The larger decrease in rate exhibited by the operant lickers compared to the reflexive lickers cannot be attributed to a motoric effect since the kinetic requirements for the response were the same for both groups. Thus, the explicit operant con-tingency, or the "conditionedness as opposed to motoricity" of the response seems to be an important determinant of neuroleptics the response seems to be an important determinant of neuroleptic effects on behavior. Since any response requirement necessi-tates a motor process for its expression the interpretation that a neuroleptic is acting by attenuating some motor process can never be completely dismissed. Nevertheless, the lick model may which motoric effects may be separated from dissociative and anhedonic effects of neuroleptics.

ALTERATIONS OF APOMORPHINE INDUCED STEREOTYPED REARING BY HYPER-36.17 BARIC AIR, J. P. Johnston and R. B. Philp? The Department of Pharmacology and Toxicology, The University of Western Ontario, London, Canada.

The effect of high partial pressures of nitrogen on neurochem-ical mechanisms is largely unknown. In order to study the effect of hyperbaric air on the function of dopaminergic systems, apomorphine induced rearing in mice, combined with HPLC analysis of its distribution was used. Male Swiss mice, acclimatized to the experimental conditions were injected subcutaneously with either apomorphine or saline. The mice were then subjected to either I ata, 4 ata, or 7 ata of air or an 80/20 Helium/Oxygen mixture. The behaviour of each animal was evaluated using a rating scale devised by Fray et al (1980). In a similiar experiment, mice were sacrificed at various time intervals and brain and plasma samples were analyzed by HPLC for apomorphine levels. Pressure had no significant effect on the onset of rearing. At the lowest dose (5.0 mg/kg), neither the onset nor the peak frequency of rearing was affected by pressure. There was, however, a signifi-cant increase in the duration of rearing activity at 4 ata air. On the other hand, high doses of apomorphine (50.0 mg/kg) showed no changes in the onset or duration of the rearing response, although the peak frequency at 7 ata was significantly less than at other pressures. No changes in the rearing response were observed with the He-O<sub>2</sub> gas mixture at all pressures tested. Analysis of brain and  $\beta$  lasma samples showed that no change in the distribution of apomorphine occurs under pressure. At 60 minutes following injection of the high dose, apomorphine levels in plasma and brain were 210.99 ± 30.8 ng/ml and 2.20 ± 0.235 ug/g plasma and brain were  $210.99 \pm 30.8$  ng/ml and  $2.20 \pm 0.235$  ug/g respectively. In animals receiving the same dose but subjected to 7 ata air, brain and plasma levels were  $201.47 \pm 36.27$  and  $2.08 \pm 0.356$  ug/g respectively. These results suggest that the observed changes in appmorphine induced stereotyped rearing under hyperbalance in the control of the control of the stereotyped rearing under hyperbaric air are due to a central mechanism rather than to changes in central apomorphine distribution. 36.16 EFFECTS OF PIMOZIDE ON APPETITIVE BEHAVIOR AND LOCOMOTOR ACTIVITY: A COMPLEX REWARD AND PERFORMANCE INTERACTION. <u>Spivak,K<sup>3</sup>, Bleir,K<sup>3</sup></u>, & <u>Amit, Z.</u> (Spon: P. Braun ). Center for Studies in Behavioral Neurobiology, Concordia University, 1455 de Maisonneuve Blvd, Rm. H1013, Montreal, Que., Canada, H3G1M7.

Behavioral effects of pimozide, a dopamine receptor Behavioral effects of pimozide, a dopamine receptor blocker were examined in a runway paradigm using food reward and in an open-field. Male rats were injected with one of 3 doses of pimozide (0.25 (PI), 0.5 (P2), 1.0mg/kg (P3)), vehicle (V1 or V2) or Ringer's (R) 4hr prior to testing in the runway (pretreatment). Two groups received pimozide (1.0mg/kg (PP)) or vehicle (PV) In after the test trial in the home cage (postreatment). A no reward group (NR) received no (postreatment). A no reward group (NR) received no food reward on test days. There was one test trial per day for 12 consecutive days. The running behavior of each animal was examined as a function of the individual measures comprising total running time performance (latency to leave start box, run time down the alley and latency to enter goalbox). There were no significant differences between groups P3 and NR in no significant differences between groups P3 and NR in total running time performance and in run time down the alley nor between P3 and its respective control group. Groups P2 and P3 however, showed larger latencies to leave the start box in comparison to the NR and control groups. The behavioral effect was reversed at the entry to the goalbox. The NR group showed the largest latency to enter the goalbox across test days in comparison to P1, P2, P3, PP and control groups. The posttreated pimozide group (PP) showed reductions in saccharin-flavored food consumption over days indicative of a conditioned taste aversion (CTA). Adapts indicative of a conditioned taste aversion (CTA). Group P1 demonstrated a similar pattern of decline in food consumption. The day following the runway testing phase, all animals were given their appropriate treatment condition and placed in open Field chambers where activity levels were measured. Groups P1, P2, and P3 exhibited significantly lower activity counts than the NR and control groups. Th The results from this study using these paradigms indicate that the behavioral effects observed in pimozide treated rats are not equivalent to the behavioral effects demonstrated by rats receiving no reward.

36.18 DETERMINATION OF JERKER-MICE SPONTANEOUS ROTATION AND MEASUREMENT

DETERMINATION OF JERKER-MICE SPONTANEOUS ROTATION AND MEASUREMENT OF BEHAVIORAL EFFECTS OF NEUROLEPTICS. <u>C. Hofer\*</u>, <u>H. Utena\* and</u> <u>Sakuma\*</u>. Dept. of Psychiatry, Wayne State University, 951 <u>E. Lafayette</u>, Detroit, MI 48207 (Spon: Robert Vertes, Ph.D.) This study investigated rotation of jerker mice, a behavior controlled by a single gene (X11) and characterized by a strong compulsive circling locomotion of quite long duration. The spe-cific stability of jerker-rotation makes this behavior amenable to instrumental measuring of variations. Spontaneous rotation appeared with greater frequency than the other sterrotyped beappeared with greater frequency than the other stereotyped be-haviors such as head tossing and was found to peak at midnight during a diurnal cycle (Experiment 1). The time-course change of jerker rotation indicated an increase of distance, duration and total amount of movement under conditions of amphetamine, chlorpromazine and perphenazine, whereas velocity decreased over time in the diazepam condition only, with the decreasing velocity peaking at 30 minutes following injection of diazepam. The log-effects of those drugs reveal the different clinical profiles of The stimulant (amphetamine) and the anti-psychotics each drug. (chlorpromazine, perphenazine) appear to produce jerker rotation, while diazepam appears to be disruptive (Experiment 2). To account for the data on amphetamine and diazepam it has been suggested that the dopinergic system may be involved in the spontaneous rotation, but contrariwise results of major tranquilizers suggest a specificity of jerker rotation as a phenotype. Sin it is doubtful that the jerker mouse has a genotypic auditory Since disturbance, the discrepancy of the results may indicate that the sensory motor system is involved in some way in the interaction between serotonergic and dopinergic systems.

ASCORBIC ACID POTENTIATES THE BEHAVIORAL RESPONSE TO HALOPERIDOL 36.19 BUT NOT TO CLOZAPINE. <u>George V. Rebec, Laura K. White\* and Kevin</u> D. Alloway. Dept. Psychol., Indiana Univ., Bloomington, IN 47405

We have previously shown that ascorbic acid (AA) crosses the blood-brain barrier and accelerates neuronal activity in the neostriatum of the rat (Ewing, A.G. et al., <u>Brain Res.</u>, <u>261</u>:101, 1983). Haloperidol, a dopamine (DA) receptor antagonist, produces comparable effects (Rebec, G.V. et al., <u>Neuropharmacology</u>, 19:281, 1980). In fact, an accumulating body of evidence suggests that AA may modulate DA transmission by interacting with the DA receptor (Heikkila, R.E. et al., <u>Res. Comm. Chem. Pathol</u>. <u>Pharmacol.</u>, 34:409, 1981). If this is the case, then pretreat-ment with AA may potentiate the behavioral response to halo-peridol and possibly other DA antagonists. To test this hypothe-sis, we examined the ability of AA to alter haloperidol-induced catalepsy, a presumed index of DA receptor blockade.

catalepsy, a presumed index of DA receptor blockade. Adult, male rats received ip injections of either saline or 1000 mg/kg AA (PH adjusted to 7.0); 10 min later the animals received sc injections of either saline or 0.5 mg/kg haloperidol. Catalepsy was measured at 15 and 60 min after the last injection. Although AA alone produced no evidence of catalepsy, this compound significantly enhanced the cataleptic behavior produced by haloperidol at both the 15- and 60-min test times. It is conceivable, therefore, that AA interacts with the DA receptor to potentiate the action of haloperidol. This effect may not be generalizable to all DA antagonists, however, since AM failed to enhance the behavioral response to clozapine (10.0 mg/kg), a relatively weak cataleptogenic agent. Supported, in part, by USPHS Grant DA-02451 (GVR).

36.20 AMPHETAMINE-INDUCED REGRESSION TO AKINESIA: CHANGES IN POSTURE & LOCOMOTION OPPOSITE TO THOSE IN RECOVERY FROM LATERAL HYPOTHALAMIC DAMAGE. S. Servidio, D. Alander, T. Schallert, and P. Teitelbaum. Det. Psychology, Ohio State Univ., Columbus, OH; Univ. Ill. Med. School, Rockford, IL; Dept. Psychology, Univ. Texas, Austin, TX;

and Dept. Psychology, Univ. Il., Urbana-Champaign, L. During recovery from lateral hypothalamic akinesia, movement first recovers in the lateral plane, followed by longitudinal movements. Verticle head scans and rearing are the last to recov-er. Recovery of locomotion following hypothalamic damage entails the gradual recruitment of more caudal body segments, as well as an increase in the amplitude of movements within a given movement dimension (lateral, verticle, eg.).

Rats injected with d-amphetamine sulfate (20 mg/kg, ip) regress through a sequence of motor behaviors opposite to what is seen during recovery from hypothalamic akinesia. This regression is characterized by a sequential reduction of movement along geomet-ric dimensions, as well as by an overall decrease in the amplitude of movements within a given dimension. Thus, movements in the verticle plane (verticle head scans, rearing) are first seen, but are gradually replaced by longitudinal trajectories, consisting of forward locomotion with the head held in line with the body. Later, there is a decrease in movements in the longitudinal plane, as large <u>lateral</u> head scans emerge, often culminating in rotation and/or pivoting (pivoting involves lateral movement with no forward locomotion, while rotation entails both lateral and forward movement). Finally, as the amplitude of lateral movements decreases, the snout becomes fixed to the floor and the animal becomes virtually akinetic. Particular aspects of the environment (walls, corners) can redirect movements in any geometric plane.

In addition, rats given amphetamine drown when placed in a tank of water. This drowning can readily be attributed to the regres-sion to akinesia. Indeed, the identical sequence of events observed in the open field is also observed in water; verticle movements, including raising the head and snout from the water, are replaced by longitudinal and finally by lateral movements (circling in water with the entire body held below the water level).

Amphetamine-induced motor behaviors have classically been des-cribed as "random", "non-directed", and "haphazard" stereotypics. The present analysis, however, indicates that changes in posture and movement induced by amphetamine reflect the systematic breakdown of movements in geometric planes, until finally, a state of akinesia is attained.

36.21 DOPAMINE RECEPTOR AGONIST PROPERTIES OF BROMOCRIPTINE. O.F.Jenkins\* and D.M.Jackson. Dept. of Pharmacology, Univ. of Sydney, NSW 2006, Australia. Bromocriptine (BRC) dose-dependently (5-20 mg/kg,

Bromocriptine (BRC) dose-dependently (5-20 mg/kg, IP) produced long lasting (up to 8 hr) locomotor stimulation in mice and stereotyped behaviour in rats. In mice, the locomotor stimulation was preceded by a period of depression lasting 60 min after injection. Low doses of apomorphine (<0.5 mg/kg, IP) selective for dopamine (DA) autoreceptors were able to enhance the BRC-induced depression of activity. The BRC-induced depression of activity. The BRC-induced depression since, in mice pretreated with reserpine and alpha-methyl-p-tyrosine (AMPT), BRC had no effect on the locomotor stimulation induced by postsynaptic DA receptor active doses of apomorphine has no effect on the locomotor stimulation induced by postsynaptic DA receptor active doses of apomorphine (>0.5 mg/kg, IP) at a time when the depressant effect of BRC was maximal (15-75 min post-BRC). Pretreatment with AMPT alone was without effect on the BRC-induced depression. The stimulant effect of BRC on locomotor with AMPT alone was without effect on the BRC-induced depression. The stimulant effect of BRC on locomotor activity in mice and stereotyped behaviour in rats was abolished by prior treatment with reserpine and AMPT. This is direct evidence that BRC does not exert its behavioural effects by direct stimulation of postsynaptic DA receptors. However, BRC was able to dose-dependently enhance the stimulant effect of apomorphine in both mice and rats after reserpine and AMPT treatment, at a time when the stimulant effect of BRC was maximal in naive animals (3-5h). (BRC also enhanced the effect of apomorphine in non-pretreated rats). Thus, while BRC appears to have some intrinsic activity on the postsynaptic DA receptors, concomitant stimulation by another agonist may be required for production of behavioural effects. Blockade of DA synthesis by pretreatment with AMPT alone also completely blocked BRC-induced locomotor stimulation in mice. This could be reinstated by administration of a low (behaviourally inactive) dose of L-DOPA (50 mg/kg, IP) which has been shown to restore normal intraneuronal DA stores (Ahlenius, S., Anden, N.-E., Engel, J., <u>Brain Res.</u>, 62:189, 1973). This suggests that BRC may act by a combination of pre- and postsynaptic mechanisms which have yet to be fully elucidated. In any case, BRC cannot be considered a DA receptor agonist in the generally accepted sense of an apomorphine-like compound. receptor agonist in the generally accepted sense of an apomorphine-like compound.

- MECHANISMS INVOLVED IN THE SEX DIFFERENCE OBSERVED IN THE 37.1 SEROTONIN BEHAVIORAL SYNDROME. C.T. Fischette, K. Renner\* an B.S. McEwen. The Rockefeller University, New York, NY 10021. and <u>The hormonal</u> environment determines the response of male and female rats to a standard dose of pargyline (50mg/kg) and trypto-phan (50mg/kg) which produces the "serotonin behavioral syndrome" (Fischette et al., <u>Soc. of Neurosci</u>. 1982). The sex difference observed in the frequency of animals exhibiting this syndrome could be due to differences in: (a) serotonin receptors (number or affinity within a particular region); (b) the ability of each sex to synthesize a particular tegran, (c) uptake of precursor or release, reuptake or catabolism of serotonin; or (d) drug metabolism. We have begun a series of experiments to differentiate between these possibilities. One approach is to examine the response of male and female rats to a direct serotonin receptor agonist (5 methoxy and temate rats to a direct scrotonin receptor agoinst () methody N,N dimethyltryptamine), thus bypassing the synthetic and meta-bolic pathways that are necessary steps in producing the syndrome using pargyline and tryptophan. We report that a sex difference in the frequency of animals exhibiting this syndrome occurs at the threshold dose (1 mg/kg). However, at all doses tested (0.5mg/kg - 5.0mg/kg), females displayed a greater intensity of each symptom than males. This suggests that there is a sex difference at the receptor level, although differences in drug availability and metabolism remain a possibility. Another ap-proach is to examine the elevation in brain and spinal cord amine levels in males and females using pargyline and tryptophan. In spinal lumbar regions, for example, serotonin levels are similarly elevated in both sexes after drug treatment; norepine-phrine and dopamine levels are also somewhat elevated. Thus, the role of other amines besides serotonin in the behavioral syndrome must also be investigated, even though a sex difference in sensitivity to serotonin appears to remain a central factor.

TOLERANCE AND REVERSE TOLERANCE TO LYSERGIC ACID DIETHYLAMIDE. 37.3 P.B. Silverman. Neuropsychopharmacology Section, Texas Research Institute of Mental Sciences, Houston, Texas 77030. Rats lesioned unilaterally along the nigrostriatal pathway ex-hibit rotational (circling) behavior in response to administra-tion of dopamine agonists. In this paradigm, lysergic acid di-ethylamide (LSD) acts like a direct dopamine receptor agonist, ethylamide (LSD) acts like a direct dopamine receptor agonist, inducing rotation contralateral to the lesioned side (Pieri et al, Nature 252, 586, 1974). While tolerance to LSD has been reported in a wide variety of behavioral tests, and tolerance to the LSD hallucinatory experience is rapid and widely reported, rotational behavior in response to LSD administration was reportedly unchanged by daily administration. We previously reported that a single small dose of apomorphice or LSD induced a perma-nent, environment specific, behavioral effect in 6-hydroxydopa-mine lesioned rats (Silverman and Ho, Nature 294, 475, 1981). Perhaps, then, unchanged response to daily LSD treatment was a result of two phenomena, the usual rapid tolerance to LSD and a contradictory long-term sensitization resulting from prior LSD This possibility was tested by varying the inadministration.

terval between successive drug administrations. Rats were anesthetized with pentobarbital and lesioned along the nigrostriatal pathway by stereotaxic microinjection of 6hydroxydopamine HBr. At least two weeks passed prior to behavio-ral testing. Rotational behavior was tested in clear plastic hemispherical bowls and was counted by an observer. When observed in the bowls after daily administration of LSD,

rotation was found to be highly variable with no clear tolerance development. When tested in the bowls before and after two LSD treatments in the home cage, significant tolerance was found. Rats tested with LSD at two week intervals exhibited a remarkable increase in response to successive treatments. Rotations doubled on the second treatment compared with the first. When given a third treatment, explosively rapid rotation, hyperthermia, and death resulted. Controls showed that the increased response to

LSD was not a result of the passage of time from lesion to test. The results show that response to repeated LSD in a "dopami-nergic" behavioral paradigm is a function of context and timing.

37.2

A COMPARISON OF MIANSERIN AND METHYSERGIDE AS ANTAGONISTS OF THE EFFECT OF LYSERGIC ACID DIETHYLAMIDE ON FIXED RATIO BEHAVIOR IN RATS. L. P. Dwoskin\* and S. B. Sparber\*. (SPON: J. H. O'Brien). Department of Pharmacology, Medical School, University of Minnesota, Minneapolis, MN 55455. In a previous study low doses of mianserin (0.1-1.0 mg/kg, ip), which did not alter fixed ratio (FR) behavior in rats, were found to completely block the behavioral effect of a low dose of lysergic acid diethylamide (LSD; 50  $\mu$ g/kg, ip), a serotonin (5-HT) agonist (JPET 225, 77, 1983). The behavioral effect of higher doses of LSD (100 or 200  $\mu$ g/kg) was antagonized, but not completely blocked by the behaviorally inactive doses of mianserin tested. The next higher dose (10 inactive doses of mianserin tested. The next higher dose (10 mg/kg) of mianserin was behaviorally active and produced a lesser antagonism of the behavioral effect of LSD. In the present study, the capacity of mianserin (1.0-5.0 mg/kg) to more effectively block both response suppression

mg/kg) to more effectively block both response suppression and/or disruption produced by  $100 \ \mu g$  of LSD/kg was examined, and compared to the antagonism produced by methysergide (0.1-35 mg/kg), a so-called classical 5-HT antagonist. Behaviorally inactive doses of mianserin (1.0-2.5 mg/kg) completely antagonized the behavioral effect of 100  $\mu g$  of LSD/kg, such that responding was indistinguishable from control. The results support the hypothesis that mianserin, at doses which are behaviorally inactive, acts as a pharmacologic antagonist at 5-HT receptors stimulated by LSD. Low doses of methysergide (1.0-2.5 mg/kg) alone were found to be behavorally active; the A higher dose of methysergide (35 mg/kg) produced a suppression A higher dose of methysergide (35 mg/kg) produced a suppression of responding and a decrease in the number of reinforcers earned. Behaviorally inactive and active doses of methysergide were able to only partially antagonize the behavioral effect of LSD. The dose of methysergide (35 mg/kg), which alone produced a significant behavioral suppression, antagonize the LSD-induced disruption of responding without antagonizing the LSD-induced suppression of responding. Therefore, the results indicate that mianserin is a much more effective antagonist of the behavioral effect produced by LSD than is methysergide, since mianserin was able to completely antagonize both effects of this dose of LSD on operant behavior. Additionally, the data suggest that there may be at least 2 separate mechanisms whereby LSD affects schedule-controlled responding. Methysergide, in some selective manner, may block the the Methysergide, in some selective manner, may block the disruptive effect of LSD while producing a minimal or physiological antagonism of the LSD-induced rate-suppression. Supported in part by U.S.P.H.S. grants DA 00532 and GM 07397.

BLOCKADE OF 5-HTP INDUCED ANIMAL MODEL OF DEPRESSION WITH A 37.4 BLOCKADE OF 5-HTP INDUCED ANIMAL MODEL OF DEPRESSION WITH A POTENT AND SELECTIVE 5-HT2 RECEPTOR ANTAGONIST (LY3857). J.N. Hingtgen\*, Ray W. Fuller<sup>1</sup> and M.H. Aprison, Inst. of Psychiat. Research and Depts. of Psychiat. and Biochem., Indiana Univ. Sch. of Med., Indianapolis, IN 46223 and Lilly Research Laboratories,<sup>1</sup> Eli Lilly and Company, Indianapolis, IN 46285. Some types of human depression may be related to an increased relates of free servicing (S-HT) acting at hupersensitive postrelease of free serotonin (5-HT) acting at hypersensitive postrelease of free serotonin (5-HT) acting at hypersensitive post-synaptic receptors (Aprison et al., In: <u>Neuropharmacology and</u> <u>Behavior</u>, Plenum, 1978; Aprison et al., In: <u>New Vistas in De-</u> <u>pression</u>, Pergamon, 1982; Hingtgen and Aprison, <u>Behav Brain Sci</u> 5:108, 1982). Support for this hypothesis comes from our pre-vious data indicating that acute pretreatment with clinical doses of the antidepressants, mianserin, amitriptyline, imipramine and iprindole resulted in varying degrees of blockade of D,L-5-hydroxytryptophan (5-HTP; 50 mg/kg I.P.) induced depression in rats working on an operant schedule for milk reindepression in rats working on an operant schedule for milk rein forcement. Additional studies with acute and chronic adminis-tration of amitriptyline, mianserin and trazodone have shown similar blockade of 5-HTP induced depression. To distinguish between presynaptic and postsynaptic events, these drug effects were compared to those of fluoxetine, a known specific uptake blocker of serotonin (5-HT), which potentiates a lower dose of 5-HTP and to methysergide a postsynaptic blocker of 5-HT 5-HTP and to methysergide, a postsynaptic blocker of 5-HT, which almost completely abolished the depressive effect of 5-HTP. Using the same animal model of depression, we studied the effects of a potent and selective 5-HT2 receptor antagonist, LY53857 [4-isopropy]-7-methyl-9(2-hydroxy-1-methyl-propoxycarbonyl)4,6,6A,7,8,9,10,10A-oct-ahydroindolo(4,3-FG)quino Itine maleate; Fuller and Snoddy, <u>Endoctrin</u>, 105:923, 1979]. In doses as high as 5.0 mg/kg, LY53857 had no effect on the base-line performance of rats working on a VI 1 schedule. When LY53857 was given 60 min prior to 50 mg/kg D,L-5-HTP it blocked (90%) 5-HTP depression in doses as low as 0.1 mg/kg (I.P.). At a dose of 0.025 mg/kg, pretreatment with LY53857 resulted in less than a 50% blockade of 5-HTP induced depression. These results suggest that the 5-HTP depression is mediated by sero-tonergic mechanisms involving 5-HT2 receptors, since LY53857 is a selective antagonist of these receptors. These data also support the suggestion that some antidepressants are acting on  $5-HT_2$  receptors in our model of depression. Recent data from two other research groups (Takahashi et al. and Segawa et al. In: New Vistas in Depression, Pergamon, 1982) strengthen this hypothesis. These latter studies as well as our data support our hypersensitive postsynaptic serotonergic receptor theory of depression and suggest that LY53857 could be of interest as a possible antidepressant agent of the general type proposed by Aprison and Hingtgen (In: <u>Serotonin</u>, Plenum, 1981).

DIFFERENTIAL ACTIONS OF SEROTONIN RECEPTOR ANTAGONISTS ON THE 37.5 HEAD SHAKE RESPONSE AND THE SEROTONIN SYNDROME IN RATS. I. Lucki, M. Nobler\* and A. Frazer. Depts. of Psychiatry and Pharmacology, University of Pennsylvania, & Veterans Administration Hospital, Phila. PA 19104.

Ligand binding studies have identified certain serotonin (5HT) receptor antagonists with selective affinity for 5HT-2 receptors, such as ketanserin or pipamperone, and other 5HT receptors, gonists with affinity for both 5HT-1 and 5HT-2 receptor anta-gonists with affinity for both 5HT-1 and 5HT-2 receptor sites, such as metergoline or methysergide (Leysen et al., <u>Life Sci.</u>, 1981, <u>28</u>:1015). This study compared the actions of these four 5HT receptor antagonists on two different behavioral responses in rats that are produced by 5HT receptor activation: 1) the head shake response; and 2) the serotonin syndrome.

Tats that are produced by Shi receptor activation: 1) the head shake response; and 2) the serotonin syndrome.
The head shake response was produced by the administration of carbidopa (102 uMoles/kg, i.p.) followed 30 min later by 5-hydroxy-L-tryptophan (5HTP; 681 uMoles/kg, s.c.). Rats were observed for a 5 min period starting 90 min after the 5HTP injection. Pretreatment with all four 5HT receptor antagonists administered intraperitoneally 60 min prior to observation blocked the head shake response. The ID50s calculated for each antagonist were: metergoline (.10 uMoles/kg), ketanserin (.77), pipamperone (1.14), and methysergide (1.81). All four 5HT receptor antagonists, quipazine (12 uMoles/kg, i.p.).
All of the symptoms of the serotonin syndrome were produced by 5-methoxy-N,N-dimethyltryptamine (13.7 uMoles/kg, i.p.). Pretreatment with metergoline (2.5 uMoles/kg) and methysergide (18.9 uMoles/kg) blocked the appearance of the syndrome. In contrast, pretreatment with ketanserin and pipamperone (51.4 and 53.3 uMoles/kg, respectively) failed to block any of the symptoms of the serotonin syndrome.

the serotonin syndrome.

The differential actions of 5HT receptor antagonists on the The differential actions of 5HT receptor antagonists on the head shake response and the serotonin syndrome suggest that dif-ferent 5HT receptors are involved in these two behavioral re-sponses. The order of potency for the 5HT antagonists to block the head shake response agrees with the order of their potency to displace 3H-spiroperidol binding in rat frontal cortex, a measure of affinity for the 5HT-2 receptor (Leysen et al., 1981). In contrast, the ability of 5HT receptor antagonists that potently displace 3H-serotonin binding to block the serotonin syndrome, combined with the inability of selective 5HT-2 receptor antagon-ists to block the syndrome, suggests that the serotonin syndrome This research was supported by USPHS grants MH-36262, MH-29094, and funds from the Veterans Administration.

THE EFFECT OF METERGOLINE ON HABENULAR SELF-STIMULATION. 37.6 Shinshu Nakajima. Dept. of Psychology, Dalhousie Univ., Halifax, Nova Scotia, Canada, B3H 4J1.

The habenular nuclei along with the stria medullaris and fasci-culus retroflexus constitute an epithalamic pathway connecting the limbic forebrain with the limbic midbrain. This pathway is similar in many respects to the hypothalamic pathway, the medial forebrain bundle. As in the hypothalamus, electrical stimulation of the structures in the epithalamus gives rise to a rewarding effect. Since lessions in the median raphe suppresses habenular self-stimulation, a question was asked whether the rewarding effect of habenular stimulation depends on serotonergic transmission.

Rats were implanted with bipolar electrodes into the habenular complex or the lateral hypothalamic area, or both, and then trained to respond by making a contact with an empty drinking spout. Habenular self-stimulation was completely suppressed by metergoline (5 mg/kg, i.p.) for a period of 10-30 min in all animals, but hypothalamic self-stimulation was only a little influenced by the same dosage of the drug. The differential effect was particularly clear in those animals that had both habenular and hypothalamic electrodes: the same animals making the same response demonstrated different degrees of suppression depending on which electrode was connected to a stimulator. The difference was statistically significant. Chlorpromazine (2 mg/ kg, i.p.) suppressed habenular and hypothalamic self-stimulation in an equal fashion; physiological saline had no effect. The suppression of habenular self-stimulation by metergoline cannot be attributed to perceptual or motoric disturbance, or to a change in arousal level.

The results suggest that habenular stimulation becomes no longer rewarding when serotonin receptors are blocked by metergoline. One possibility is that habenular stimulation produces a rewarding effect by exciting the serotonergic neurons originating from the raphe and projecting to the hypothalamus where catecholamines make important contributions. Another possibility is that there is a separate system of structures outside the medial forebrain bundle that is capable of generating a rewarding effect and that serotonin plays a more important role in that system than catecholamines.

(Supported by NSERC of Canada, Grant No. A0233. Metergoline was a gift from Prof. L. Valzelli and Farmitalia, Milano)

37.7 ESTRADIOL AND PROGESTERONE INFLUENCE L-5HYDROXYTRYPTOPHAN-INDUCED MYOCLOUS IN GUINEA PIGS: SEX DIFFERENCES IN SEROTONIA-STEROID INTERACTIONS. L.H. O'Connor\*and H.H. Feder\*(SPON: I. Zucker). Institute of Animal Behavior, Rutgers Univ., Newark, NJ 07102. L-5-Hydroxytryptophan (L-SHTP) induces a myoclonic behavior syndrome in guinea pigs characterized by rhythmic jerks of the head and body. This behavior is caused by intense central ser-otonergic activity. We evaluated effects of estradiol and pro-gesterone on L-5HTP-induced myoclonus in male and female guinea Myoclonic behavior was assessed by measures of total pigs. number of myoclonic jumps over all observations and maximum num-

ber of myoclonic jumps per min. Effects of estradiol and pro-gesterone on L-5HTP-induced myoclonus were examined using the same relatively how doses of the steroids used for activation of species-typical female sexual behavior. All animals were gonad-ectomized. In the absence of steroids, myoclonus was higher in males than females. Estradiol alone and sequential treatment with estradiol and progesterone altered myoclonus in both sexes.

With estradiol and progesterone altered myoclonus in both sexes. <u>Estradiol.</u> When 3.5ug estradiol benzoate was injected 46 hours prior to L-SHTP (100mg/kg), myoclonus was enhanced in females but not in males. However, a higher dose of estradiol (10ug) inject-ed 46 hours prior to a lower dose of L-SHTP (80mg/kg) enhanced myoclonus in males. Therefore, estradiol has similar effects on myoclonus in males and females although there are sex differences in sensitivity to L-SHTP and perhaps also to estradiol. <u>Progesterone.</u> We found sex differences in effects of progest-erone on myoclonus. In females, effects of progesterone depended

rives set of the round set uniferences in effects of progesterone depended on time since progesterone injection and pretreatment with estra-diol. When progesterone (0.5mg) was given 6 hours before I-5HTP (100 or 125 mg/kg) in females, the facilitative effects of estra-diol (3.5ug) were reversed. Progesterone given 6 hours before L-SHTP did not alter myoclonus unless females were primed with estradiol. The inhibitory effects of progesterone on myoclonus  $% \left( {{{\mathbf{x}}_{i}} \right)$ in estradiol-primed females followed the same time course as the facilitative effects of progesterone on sexual receptivity. Whe L-SHTP was given just prior to or after the period of sexual re-When ceptivity induced by progesterone in estradiol-primed females, there was no inhibitory effect of progesterone on myoclonus. when L-5HTP was given during the period of sexual receptivity, But then myoclonus was suppressed compared to females treated with estradiol alone. This temporal correlation suggests the progestin receptor mechanisms proposed to mediate progesterone's effects on sexual behavior are also involved in the inhibitory effects of progesterone on myoclonus in females. In contrast to females, progesterone (0.5mg) given 6 hours before L-SHTP (80mg/kg) enhanced myoclonus in estradiol-primed males. Therefore, progesterone has opposite effects on myoclonus in estradiol-primed males and females.

INSULIN INTENSIFIES THE DISCRIMINATIVE STIMULUS EFFECTS OF LSD 378 (SPON: J. R. Coleman). Behav. Pharmacol. Lab., Dept. of Ps Psychol.,

Univ. of South Carolina, Columbia, SC 29208. In rats trained to discriminate LSD (0.08 mg/kg i.p., 15 min In rats trained to discriminate LSD (0.08 mg/kg i.p., 15 min before session) from saline in a two-lever operant chamber, insu-lin (5.0-6.0 U/kg i.p., 15-25 min before session) more than dou-bled the percentage of LSD-appropriate responding in tests with low doses of LSD (0.02 mg/kg), mescaline (8.0 mg/kg), and psilozy-bin (0.25 mg/kg). In addition, insulin induced smaller increases in drug-appropriate responding following low doses of the nonhal-lucinogenic LSD congener lisuride and two tetrahydro- $\beta$ -carbolines (TUPCL) is hidder here the sefection of the nonhal-(THBC's); it did not, however, alter the effects of either psilo-cin or 5-methoxy-N,N-dimethyltryptamine, both of which are known to be highly lipid soluble (P. K. Gessner et al., <u>Life Sci.</u>, <u>7</u>: 267-277, 1968). Insulin can increase brain levels of certain large neutral

amino acids, primarily by lowering plasma levels of other large neutral amino acids that share and compete for the leucine-prefer-ring brain transport system (J. D. Fernstrom and R. J. Wurtman, ring brain transport system (J. D. Fernstrom and R. J. Wurtman, <u>Science</u>, 174:1023-1025, 1971; D. C. Markowitz and J. D. Fernstrom, <u>Science</u>, <u>197</u>:1014-1015, 1977). In the present study, valine (100.0 mg/kg i.p., 30 min before session) prevented the insulin-induced potentiation of 0.02 mg/kg LSD. In rats trained to dis-criminate <u>d</u>-amphetamine (1.0 mg/kg i.p., 15 min before session) from saline, insulin (5.0 U/kg i.p., 15 min before session) in-creased amphetamine-appropriate responding following lisuride but did not increase the effects of d erebeto incel did not increase the effects of <u>d</u>-amphetamine itself, which enters the brain through an active transport system that is not competitively inhibited by large neutral amino acids (W. M. Pardridge and J. D. Connor, <u>Experientia</u>, 29:302-304, 1973). It was tentatively concluded that the potentiating effects of insulin were due to its indirect effect on the leucine-preferring brain transport system, and that LSD and several related substances to some extent depend upon this system for passage across the blood-brain barrier.

Although insulin-induced augmentation of the effects of THBC's was relatively small, this interaction may be of clinical significance, since THBC's occur endogenously in mammals in both brain and periphery (adrenal gland) (S. A. Barker et al., <u>Biochem.</u> Pharmacol., 30:9-17, 1981). Moreover, these compounds have poten-tially important behavioral effects in rats when injected intratially important behavioral effects in rars when injected intra-cerebroventricularly in nanogram quantities, e.g., they increase voluntary ethanol consumption (R. D. Myers and C. L. Melchior, <u>Pharmacol. Biochem. Behav.</u>, <u>7</u>:381-392, 1977; R. D. Myers and M. M. Oblinger, <u>Drug Alc. Depend.</u>, <u>2</u>:469-481, 1977; L. Tuomisto et al., <u>Pharmacol. Biochem. Behav.</u>, <u>17</u>:831-836, 1982). J. B. Appel. Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, S. C. 29208.

Recent (unpublished) research has indicated that the serotonin (5-HT) precursor 1-5-hydroxytryptophan (5-HTP), when given in combination with a decarboxylase inhibitor (Ro 4-4602), substitutes partially (50%) for the hallucinogen lysergic acid diethylamide (LSD) in rats trained to discriminate LSD (0.08 mg/kg) from saline. In an effort to more fully characterize both the LSD and 5-HT cues, experimentally-naive male albino rats (N=6) were trained to discriminate 5-HTP (50 mg/kg) from saline in a two-lever, water-reinforced drug discrimination procedure; Ro 4-4602 (50 mg/kg) was always administered 1 hr prior to 5-HTP to block the direct, peripherally-mediated disruptive effects of 5-HTP. LSD (0.04-0.16 mg/kg) produced a dose-dependent substitution for 5-HTP; maximum drug-lever responding was 83% after 0.08 mg/kg of LSD. The 5-HT2 receptor antagonist ketanserin (1.0 mg/kg) Dro Lues may be related to common interactions with central 5-HT2 receptors, although further research utilizing various monoaminergic agonists and antagonists is required before definitive conclusions can be drawn.

### BEHAVIORAL PHARMACOLOGY I

38.1 DRUG-INDUCED REVERSIBLE HEMIPLEGIA: A RAT MODEL. S. Brailowsky, R.T. Knight\* and K. Blood\*. Dept. of Neurology, Univ. of Calif., Davis; V.A. Med. Ctr., Martinez, CA. 94553 In an attempt to develop a reversible animal model of sensorimotor deficits we administered epicortical GABA by means of osmotic minipumps, to the sensorimotor region of pate to the sensori-

In an attempt to develop a reversible animal model of sensorimotor deficits we administered epicortical GABA by means of osmotic minipumps, to the sensorimotor region of rats trained previously to run on a narrow beam. The chronic delivery of the drug (5, 50 and 500 ug/ul/hr. for 7 days) produced a motor deficit in a dose-dependent manner: the animals progressed from a complete inability to walk on the beam to different degrees of contralateral hemiparesis. The high dose group was totally unable to perform the test while in the low and medium dose groups slips and misplacing of the rear paw were seen in the first 3 days. These changes disappear in most animals by the 10th day, with a gradient in the seriousness of the deficits from the starting point to recovery. In the rats in which saline was the delivered solution or in those in which the minipump did not empty its content, the recovery was present by the third day post-surgery. The histology showed lesions at the canula implantation site variable in size from 8 to 15 mm<sup>2</sup>. There was no difference in size between the lesions of the control and low and medium dose animals. However, high dose rats had larger lesions. This data suggests that locally applied GABA can reliably produce a reversible sensorimotor deficit in rats.

38.2 INDUCTION OF SELF-INJURIOUS BEHAVIOR IN RATS BY MICROINJECTION OF MUSCIMOL INTO THE SUBSTANTIA NIGRA. A. Baumeister\* & G. Frye, Biol. Sci. Res. Ctr., Sch. of Med., Univ. N. Carolina, Chapel Hill, 27514.

Severe self-injurious behavior (SIB) is frequently exhibited by persons belonging to several clinical populations. Studies with humans and animals suggest that such behavior is related to perturbations in dopaminergic systems in the basal ganglia. While studying seizure susceptibility in rats following ethanol withdrawal we found that animals given microinjections of the GABA agonist muscimol into the substantia nigra frequently bit themselves. A review of the literature revealed other anecdotal reports of muscimol-induced SIB (e.g., Taha et al., Psychpharm., 1982, 77, 272). This finding was of particular interest because other dopamine-related behaviors (i.e., stereotypies) are also other dopamine-related behaviors (i.e., stereotypies) are also mediated through the striatalnigral GABAergic pathway. In the persent study we investigated further the role of GABA in the production of SIB. Muscimol (10, 30, 100 or 300ng) in 0.5ul sa-line was injected bilaterally (0.5ul/min) into the caudal sub-stantia nigra (zona reticulata) of ether anesthetized male Sprague Dawley rats. Immediately afterwards, rats were placed in clear plastic reaces with birs crid floors. Behavior was obin clear plastic cages with wire grid floors. Behavior was ob-served during one minute periods every ten minutes for three hours. Muscimol (30, 100 & 300ng) produced self-biting and tissue damage in 26, 46, and 10% of the rats, respectively. Among the animals that exhibited SIB, 67% bit their tail, 16% bit their paws, and 50% had multiple lesion sites. The animals showed no evidence that self-biting was painful, but bites by other animals did evoke squealing. Muscimol also produced ste-reotyped sniffing, head nodding, and gnawing on the wire floor. No SIB was observed after microinjection of saline. When the opportunity to gnaw was limited by testing the animals in cages with a smooth plastic floor the frequency of SIB increased and the dose-response curve was shifted to the left. SIB occurred most frequently at 30ng, the dose that produced the most intense stereotyped gnawing on the wire floor. The percentage of an-imals that exhibited SIB when gnawing was prevented was 42%, 69%, and 36%, in the 10, 30, and 100ng groups, respectively. tency to onset of SIB was longest on the plastic floor but in-creased with dose on both floor types. Another GABA agonist, THIP, at 100 and 300ng produced SIB in 25% and 12% of the animals respectively. However, simultaneously administered bicuculline methiodide (300ng) did not block muscimol-induced SIB. (Supported by PHS grants AA-05713, HD03110, HD07201).

LIBRIUM PREVENTS THE ANALGESIA AND SHUTTLEBOX ESCAPE DEFICIT 38.3 LIBRIUM PREVENTS THE ANALGESTA AND SHOTLEBOAL DOWNED ELECT TYPICALLY OBSERVED FOLLOWING INESCAPABLE SHOCK, Robert C. Drugan; Susan M. Rvan. Thomas R. Minor and Steven F. Maier\*, Department Susan M. Ryan, Thomas R. Minor and Steven F. Maier\* of Psychology, Box 345, University of Colorado, Boulder, CO 80309 SPON: M. Laudenslager.

It has been shown that GABA is an important neurotransmitter involved in the production of the learned helplessness effect. Gavish and Snyder (1980) demonstrated that GABA receptors have benzodiazepine recognition sites. From this data, they proposed that these two receptor systems are functionally interrelated. Due to the potential interactions between GABA and benzodiazepines it seemed reasonable to investigate the impact of a benzodiazepine on the learned helplessness effect using both behavioral epine on the learned helplessness effect using both behavioral and analgesic indices. Rats received 10 mg/kg i.p. chlordiaze-poxide (CDP) daily for four days in order to tolerate out any sedative effects. On Day 5, animals received 5 mg/kg CDP or equivolume vehicle 30 minutes prior to 80 five-second, 1-mA ines-capable tail shocks. On Day 6, subjects were also injected with either CDP or vehicle 30 minutes prior to test. In Experiment 1 testing, animals then received 5 five-second 1-mA footshocks in subjects were also injects with an analytic second test. a shuttlebox. Tail-flick analgesia was measured both prior to and following the shocks. In Experiment 2 testing, animals re-ceived 5 FR-1 and 25 FR-2 signalled 1-mA escape trials for which latency to escape was measured. CDP administered prior to the inescapable shock session completely abolished both the analgesia and the shuttlebox escape deficit typically observed 24 hours following inescapable shock. Control groups determined that neither blocking analgesia nor abolishing the escape deficit was a state dependent effect. Finally, subjects given CDP immediate-ly preceding shuttlebox tests showed facilitated learning. However, this was demonstrated not to be a general learning facili-tation since nonshock controls given CDP prior to test showed equivalent performance to nonshock vehicle controls; instead, facilitation by CDP suggests that shuttlebox impairment may result partially from fear and anxiety. Overall, these data suggest that fear, anxiety, and the benzodiazepine receptor complex may participate in the production of several behavioral indices of learned helplessness.

CNS AND BEHAVIORAL CONSEQUENCES OF EXPOSURE TO PHENOBARBITAL. 38.4 and J. Diaz, Dept. of Psych., Univ. of Wash., Seattle, WA,98195. The brain growth spurt marks a time of enhanced vulnerability to insults. We have demonstrated that exposure to phenobarbital during the entire brain growth spurt results in a 10% brain growth deficit. This study describes the effects of phenobarbital exposure early in the brain growth spurt.

Four day old female Long-Evans rats were matched by weight and assigned to one of 7 groups. Drug group animals were given daily subcutaneous injections of 60mg/kg of phenobarbital from days 5subcutaneous injections of 60mg/kg of phenobarbital from days 5-8, while vehicle group animals were given daily subcutaneous injections of the vehicle from days 5-8. The groups were as follows: 1) artificially reared (AR) animals, given phenobarbital and sacrificed on day 9 (n=12); 2) AR animals, given the vehicle and sacrificed on day 9 (n=10); 3) normally reared (NR) siblings of groups 1 and 2 sacrificed on day 9 (n=18); 4) AR animals, given phenobarbital, returned to their without on day on determined on the 19 (n=70). (5) AD pairs of the same set of the same se (a 10), 4) at all mars, given phenobartar, fetu her to their mothers on day 9 and sacrificed on day 18, (n=7); 5) AR animals, given vehicle, returned to their mothers on day 9 and sacrificed on day 18, (n=7); 6) animals that were given phenobarbital and artificially reared from days 4-18, (n=8); 7) animals that were normally reared from days 4-18 in litters of 10, (n=10).

A battery of reflex tests, including negative geotaxis, free fall righting and cliff avoidance were conducted each day on animals from groups 4-7. The occurrence of eye opening and inci-

sor eruption was noted. At the time of sacrifice, each animal's brain, liver, kidney and spleen were removed and weighed. Chi Square tests revealed that incisor eruption and eye opening occurred earlier in AR animals than in NR animals (p(.05). The phenobarbital animals reached the criteria for free fall righting and cliff avoidance later than the vehicle animals (p < .05). This table summarizes mean weights (grams):

						,	
	BARB-9	VEH-9	NR-9	BARB-NR	VEH-NR	BARB-AR	NR
BODY WT	16.7	15.6	16.9	28.3	28.2	30.7	32
BRAIN WT	.693	.739	.841*	1.22	1.22	1.14	1.35*
LIVER WT	.747	.574	.454*	1.01	.961	1.33	.996*

The 7% brain weight deficit after 4 days of phenobarbital The 7% brain weight deficit after 4 days of phenobarbital suggests that the early part of the brain growth spurt may be especially vulnerable to disruption. Behavioral deficits from the phenobarbital were observed days after the administration of the drug. The recovery of brain weight in animals normally reared after the drug exposure, which was not seen in animals that remained artificially reared, further suggests that environmental factors following a drug insult may be crucial in recovery. The course of recovery from the behavioral deficits remains to be determined. (\*  $p_{c}O_{5}$ ) remains to be determined. ( \* p<.05)

38.5 ANXIOCENIC PROPERTIES OF CONVULSIVE AGENTS. L. Prado de Carvalho, P. Venault \*, J. Rossier and G. Chapouthier \* (SPON : M.L. Simon), Depts I and II, Laboratoire de Physiologie Nerveuse, CNRS, 91190 Gif-sur-Yvette, France.

In a previous paper, we have demonstrated that Methyl 8-Carboline-3-Carboxylate (B-CCM), a convulsant benzodiazepine (BZ)-anta-This is consolved to be a set of the set of of interest because both these drugs have been variously implicated with the BZ-GABA-Cl  $\bar{}$  ionophore complex. In the conflict model used, mice previously trained to press a lever for food were trained on 15 min conflict/non-conflict sessions divided as follows : two 5 min periods during which each lever press resul-ted in a food pellet ; one 5 min period (conflict) where each lever press was similarly rewarded but also concomitantly punished with a 50-100  $\mu$ A electric foot-shock. Pressing rates were always reduced during conflict periods as compared to non-conflict periods. At higher shock intensities, conflict lever pressing levels were low and anxiolytic drugs had a lever pressing enhancing effect. Conversely, at lower shock intensities, high pressing levels were obtained during conflict and anxiogenic effects could thus be studied. The duration of lever presses were always shorter during conflict than during non-conflict periods, and comparable during conflict than during non-conflict periods, and comparable under all shock intensities. Mice were trained until stable day-to-day performances were obtained. Base line pressing rates were established for each 5 min period. The effect of a drug was eva-luated by comparing performances (5 min periods) of each mouse under the effect of the drug to previous day performances. Anxiety was assessed by a decrease in the number of lever presses during the period of conflict. In control experiments mice were trained in comparable 15 min food reverded escience but per submitted to in comparable 15 min food rewarded sessions but not submitted to conflict training. Drugs were administered subcutaneously, in subconvulsive doses, at appropriate times before the beginning of the test : 5 min for PTZ (25 mg/kg) and 30 min for Picrotoxin (0.75 mg /kg). Our results show that under PTZ or Picrotoxin, the number of lever presses during conflict were significantly reduced as compa-red to previous day levels. In control mice, no reductions were seen following PTZ or Picrotoxin, thus the observed effect seems to be conflict related. The reduction of lever presses during conflict was interpreted as a demonstration of the anxiogenic effects of PTZ and Picrotoxin.

EFFECTS OF PROPRANOLOL AND MIDAZOLAM ON PENTYLENETETRAZOL DIS-CRIMINATION AND LEVER PRESSING BEHAVIOR. <u>Douglas M. Wilkison\*</u>. (SPON: Liang-Fu Tseng). Dept. of Pharmacology, Med. Col. of Wisconsin, Milwaukee, WI 53226. The two-lever pentylenetetrazol (PTZ)-discrimination paradigm

has been proposed as a model for the interoceptive cues of anxiety based on the ability of antianxiety agents, esp. benzo-diazepines, to block the PTZ-cue and the anxiogenic properties of PTZ in humans. Propranolol, on the other hand, has been proposed

Propranolol, on the other hand, has been proposed as a clinically useful antianxiety agent, which exhibits little anticonflict action in the Geller-Seifter conflict test. To further characterize the antianxiety effects of propranolol and the utility of the PTZ-discrimination model for anxiety the effects of propranolol (2-10 mg/kg) were determined on PTZ-discrimination and lever pressing in trained rats. Likewise the effects of midazolam (0.03-0.6 mg/kg), a benzodiazepine, and combined treatment were determined

effects of midazolam (0.03-0.6 mg/kg), a benzodiazepine, and combined treatment were determined. Rats were shaped to lever-press for food reinforcement (60% sweetened condensed milk) to an FR10, then trained to discrimi-nate 20 mg/kg PTZ from saline. Midazolam administered ip 15 minutes before PTZ blocked the PTZ-discrimination (ED50 = 0.11 mg/kg, n=7). Propranolol (2-10 mg/kg) was without effect on PTZ-discrimination. However, 10 mg/kg propranolol shifted the dose-response curve for midazolam to the right. ED50 = 0.39 mg/kg, n=7 for midazolam with 10 mg/kg propranolol. Operant behavior was measured by the number of reinforcements earned in 15 minutes and the latency to the first reinforcement. PTZ depressed reinforcements 50% and increased latency 113% compared to saline pretreatment of PTZ treated rats produced a dose-dependent increase in reinforcement sand decrease in latency. Behavior approached that during saline discrimination at 0.3125 mg/kg midzolam. Propranolol pretreatment (10 mg/kg) signifi-cantly depressed reinforcement rate and increased latency but did not significantly change the normalizing action of midazolam on these parameters. As with diazepam, midazolam is a potent antagonist of the interoceptive cue of PTZ. However, proprano-lol up to doses which depress operant behavior does not antago-nize PTZ discrimination. Evidence suggests that propranolol either augments PTZ or antagonizes midazolam. This work is supported, in part, by Pharmaceutical Manufacturers Association Foundation.
STIMULUS PROPERTIES OF OXAZEPAM: A 1,4-BENZODIAZEPINE. W. J. Millard, P. Riley\*and J. Szostak\* Laboratory of Behavioral Medicine and Pharmacology, Mount Holyoke College, South Hadley, MA 01075-1462 USA. 38.7

The stimulus properties of oxazepam were evaluated in a drug discrimination procedure in which the administration of the drug (5.0 mg/kg, i.p.) and vehicle were correlated with fixed-ratio schedules of food reinforcement. Acquisition of the discrimination by the rat subjects was followed by generalization tests in which the dose of oxazepam was varied (1.0-24.0 mg/kg), and substitution tests in which varying doses of benzodiazepine anxiolytics other than oxazepam where administered (e.g., chlor-diazepoxide). Stimulus generalization to the oxazepam stimulus was found, and varied in a dose-dependent manner. Further tests were completed with compounds having a high affinity for the benzodiazepine recognition site (e.g., Ro 15-1788, CL 218,872), and compounds possesing anxiolytic properties but not benzodiaze-pine ligands (e.g., ethanol, pentobarbital, buspirone, clonidine). The degree of drug generalization was highly correlated with anxiolytic potency. The stimulus properties of oxazepam were evaluated in a drug

ANXIOGENIC-LIKE PROPERTIES OF BENZODIAZEPINE ANTAGONISTS. 38.9 D.K.

ANXIOGENIC-LIKE PROPERTIES OF BENZODIAZEPINE ANTAGONISTS. D.K. Hoffman\* and D.R. Britton. Department of Physiology, University of New Mexico School of Medicine, Albuquerque, N.M. 87131. Benzodiazepine (BDZ) antagonists have been identified on the basis of their ability to block the effects of anxiolytic and anticonvulsant BDZs such as diazepam (DZP). Two of these compounds, the convulsant Ro 5-3663 and the so-called pure antagonist Ro 15-1788, were studied for their ability to block the behavioral effects of DZP. These effects were assessed by testing animals in an onen field neradigm (Britton and Britton testing animals in an open field paradigm (Britton and Britton, 1981) and by challenging the ability of DZP to stimulate food consumption in a familiar environment.

Male, Sprague-Dawley albino rats were treated with an i.p. injection 30 min. prior to testing with either DZP, Ro 15-1788, Ro 5-3663 or a combination of DZP and an antagonist. Control animals received an injection of the drug carrier. Both antagonists reversed the hyperphagic actions of DZP when animals ware tested in a familiar appriarement. In the open field were tested in a familiar environment. In the open field paradigm, animals were fasted for twenty-four hours then introduced into a well illuminated open field where they had increasing the amount of food eaten and the mean amount eaten  $D_{\rm eat}$  and  $D_{\rm eat}$  and increasing the amount of food eaten and the mean amount eaten per approach. DZP also decreases grooming and rearing. Both of the antagonists effectively reversed these effects of DZP. Ro 15-1788 at a dose of 0.5 mg/Kg completely reversed the effects of 2.0 mg/Kg DZP. In addition, RO 15-1788 given alone at higher doses (up to 8.0 mg/Kg) accentuated the animals' responsiveness to novelty. Although Ro 15-1788 has been shown not to have significant convulsant or pro-convulsant activity, these data show that it is not pharmacologically inert. Rather, it appears to interact with a population of BDZ receptors in a manner which potentiates the animals response to "anxiogenic" stimuli. 38.8

PROCONVULSANT EFFECTS OF THE BENZODIAZEPINE AGONIST, CL 218,872. C.L. Melchior,<sup>1</sup> K. Garrett<sup>1\*</sup> and B. Tabakoff.<sup>1+2</sup> <sup>1</sup>Alcohol and Drug Abuse Research and Training Program, Department of Physiology and Biophysics, University of Illinois at Chicago, Health Sciences Center, Chicago, IL 60612. Both the triazolopyridazine, CL 218,872, and methyl beta-carbo-line carboxylate (MBCC) interact with the Type 1 benzodiazepine receptor. CL 218,872 is regarded as a specific agonist, display-ing anxiolytic, sedative and anticonvulsant properties. MBCC has been classified as an antagonist or inverse agonist and has been shown to cause convulsions. In this study, we examined the inter-actions of these two compounds in C57Bl mice. As measured on a Stoelting Activity Monitor, motor activity was decreased by an intraperitoneal injection of 10.0 mg/kg CL 218,-872. Both 0.25-1.0 mg/kg I.P. of MBCC and 0.5-2.0 mg/k g of an-other benzodiazepine receptor antagonist, R0 15-1788 were equally effective in blocking CL 218,872 depression of motor activity. Given alone, the above-stated doses of R0 15-1788 had no effect on motor activity, while MBCC, in doses of 1.0 mg/kg or higher, decreased motor activity. In comparison, R0 15-1788 was more effective than MBCC in blocking the depression in motor activity caused by 2.0 mg/kg di-azepam. MBCC blocked diazepam induced depression only at doses which, by themselves, produce convulsions. A dose of 5.0 mg/Kg of MBCC

blocking the depression in motor activity caused by 2.0 mg/kg di-azepam. MBCC blocked diazepam induced depression only at doses which, by themselves, produce convulsions. A dose of 5.0 mg/kg of MBCC caused convulsions in 100% of the treated animals. The MBCC-induced convulsions could be blocked by prior injection of 2.0 mg/kg of diazepam, 1.0 mg/kg of R0 15-1788, or 20.0 mg/kg of CL 218,872. Doses of MBCC of 1.0 or 2.0 mg/kg produce little or no convulsant activity by themselves. Interes-tingly, convulsant activity was significantly <u>increased</u> when these doses of MBCC were given together with low <u>doses</u> of CL 218,872 (0.5-10.0 mg/kg). In contrast, low doses of diazepam, given with 1.0 or 2.0 mg/kg of MBCC, did not result in convulsions. When 3.0 mg/kg of bicuculline was used in place of MBCC to produce convul-sions, 0.5 mg/kg of CL 218,872 again increased the severity of the convulsions. CL 218,872 alone did not cause any convulsions. These results indicate that high doses of CL 218,872 are seda-tive and anticonvulsant, but low doses are proconvulsant. Procon-vulsant activity gives CL 218,872 a unique profile among compounds classified as anxiolytic benzodiazepine agonists. **38.10** DIAMINE INHIBITION OF GLYCINE AND GABA UPTAKE. <u>George M. Strain</u> and <u>Wayne Flory</u>. Vet. Physiol., Pharmacol., and Toxicol., Louisiana St. Univ. Sch. Vet. Med., Baton Rouge, LA 70803. Several diamines have been reported to block the uptake of amino acid transmitters: diaminopropionic acid (glutamate, GABA),  $\beta$ -N-oxalyl-L- $\alpha$ ,  $\beta$ -diaminopropionic acid (glutamate), and ethylenediamine (GABA). When simple aliphatic diamines are administered in the brain vertricles they produce effects ranging from purely depressant (ethylenediamine) to purely excitatory (1,3-diaminopropane) to a mixture of both effects (1,6-diaminohexane) [Soc. Neurosci. Abstr. 6:149, 1980]. We therefore examined the effects of the simple aliphatic diamines on synaptosomal uptake of the amino acids glutamate, aspartate, GABA and glycine as an explanation for the <u>in vivo</u> neurotoxic effects. Crude synaptosomes were prepared by a modification of the method of Gray and Whittaker [J. Anat. 96:79, 1962]. Whole brain was used for glycine transport; otherwise the forebrain was dissected free. Amino acid Concentration was 10 µM, as a mixture of tritiated and cold. Synaptosomes (P2 pellet) were

dissected free. Amino acid concentration was 10  $\mu$ M, as a mixture of tritiated and cold. Synaptosomes (P2 pellet) were preincubated for 5 min at 25°C. Transmitter was added and transport was terminated after 10 min by a rinse of cold buffer and vacuum filtration. Controls were transported in sodium-free buffer. Diamines studied for inhibitory effects were the homologous series of ethylenediamine to 1,7-diaminoheptane. DL-2,4-diaminobutyric acid (DABA) was also included for comparative purposes. Results (average of three experiments performed in triplicate) were expressed as a percentage of control. control.

control. The diamines were most inhibitory to the uptake of glycine and GABA. Weaker effects were seen on glutamate, while aspartate was unaffected. The pattern of inhibition for glycine and GABA was similar, and effects were dose-dependent. 1,2-diaminopropane was most inhibitory, followed by ethylenediamine and 1,7-diaminoheptane. The reported inhibitory effect of DABA on GABA and glutamate uptake was confirmed. Comparable effects were seen on glycine and aspartate uptake, but GABA effects were by far the most potent. Diamine inhibitory effects were approximately 100x less potent than DABA. The observed effects provide an explanation for the in vivo

The observed effects provide an explanation for the <u>in vivo</u> depressant effects of the diamines, but not the excitatory effects. The relatively weak inhibitory effects preclude the use of diamines as efficient pharmacologic agents, but the structure-activity results will provide information for the development of more effective agents.

38.11 THE INTERACTION OF CNS DEPRESSANTS AND CABAERGIC DRUGS IN MICE SELECTIVELY-BRED FOR THE NARCOTIC EFFECTS OF ETHANOL. <u>T.D.</u> <u>MCIntyre, H.P. Alpern. Department of Psychology, University</u> of Colorado, Boulder, CO 80309.

Recent evidence strongly suggests a common mechanism linking the effects of ethanol (ETOH), barbiturates, and benzodiazepines (J.N. Nestoros, <u>Prog. Neuro-Psychopharmacol.</u> 5:591, 1981). This premise was investigated in two lines of mice (short sleep, SS and long sleep, LS) which have been genetically selected for differential narcotic sensitivity to ETOH. Earlier reports indicated either no differential sleep-time response to barbiturates (Erwin et al. <u>Pharmacol.</u>, <u>Biochem. and Behav</u>. 4:679, 1976) or a greater sensitivity to sodium pentobarbital in the SS line (O'Connor et al. <u>Pharmacol., Biochem. and Behav</u>. 17:245, 1982). This report demonstrates that if the dose-response relationship is examined thoroughly the mice more sensitive to the narcotic effects of ETOH (LS) are also significantly more sensitive to the narcotic effects of pentobarbital and barbital as well as the benzodiazepine, chlordiazepoxide (CDX). Additionally, two doses (10 & 20 mg/kg) of the  $\gamma$ -aminobutyric acid (GABA) agonist amino-oxyacetic acid (AOAA) were employed in conjunction with these central depressants in order to demonstrate a common substrate of action in these mice. Therefore, we conclude that these results support the notion that the differential narcotic response of SS and LS mice to intraperitoneal in jections of ETOH, barbital and CDX is mediated, at least in part, by the GABA system. 38.12 DISCRIMINATIVE STIMULUS PROPERTIES OF L-PHENYLISOPROPYLADENOSINE. Ronald C. Browne, Pfizer Inc., Central Research, Groton, CT 06340.

The recent discovery of metabolically stable analogs of adenosine has contributed to the elucidation of adenosine receptors in brain. The present investigation examined the ability of adenosine analogs to bind to adenosine Al receptors, and their ability to mimic the behavioral effects of L-PIA in a drug discrimination paradigm. Adenosine receptor binding was performed using the method of Bruns et. al. (PNAS 77: 5547-51, 1980) and the displacement by various compounds of 1 nM [3H-CHA] binding to adenosine deaminase treated rat membranes was determined. Non-specific binding was defined by 10  $\mu$ M L-PIA, and IC50's were calculated by linear regression analysis. Male Sprague-Dawley rats were trained to discriminate 0.1 mg/kg of L-PIA from vehicle in a two-lever operant paradigm. Discrimination accuracy was established following about 40 training sessions as evidenced by most animals emitting their first FR-10 responses on the appropriate lever in 9 out of 10 consecutive sessions. The discriminative stimulus properties of L-PIA could be completely blocked with the methylxanthines IBMX, caffeine, theophylline and partially antagonized by 8-parasulfophenyltheophylline. Generalization testing indicated that a number of adenosine analogs were capable of mimicking the discriminative effects of L-PIA; the D-isomer of PIA was found to be about 30 times weaker than the training drug. By contrast, the A2 agonist NECA and adenosine 5'-cyclopropyl carboxamide (5'-CPC) were more potent than L-PIA in eliciting the L-PIA cue. In general, there was a good correlation between the potency whereby Al agonists displaced [3H-CHA] and iduced generalization in the discrimination test. However, the A2 agonists NECA and 5'-CPC were more potent in cueing than would be predicted by their ability to bind to Al sites. Furthermore, we found that both clonidine (0.1 mg/kg) and diazepam (3.2 mg/kg) substituted completely in the discriminative stimulus assay, but were relatively weak in binding to Al sites. These results indicate the rats trai

38.13 CENTRAL EFFECTS OF ADENOSINE AND ITS ANALOGS ON SPONTANEOUS LOCOMOTOR ACTIVITY, V.L. Coffin,\* J. W. Phillis, H.J. Altman, and R.A. Barraco. Wayne State University, School of Medicine, Detroit, Mich. 48201.

Adenosine and its analogs depress neuronal firing at many levels of the neural axis. The case for adenosine being a synaptic modulator in the CNS is supported by demostrations of its release from a variety of <u>in vivo</u> and <u>in vitro</u> preparations, by its effects on adenylate cyclase activity, and by its inhibitory effects on the presynaptic release of several different types of neurotransmitters (Phillis, J.W. and P.H. Wu, <u>Prog. in Neurobiol.</u>, 16: 187, 1981). Adenosine and its analogs are also known to have marked behavioral effects, including sedative and anticonvulsant activity. L-N<sup>0</sup>-phenylisopropyl-adenosine (L-PIA), a metabolically stable analog of adenosine, has been shown to produce decreases in spontaneous locomotor activity (Snyder, et al., <u>Proc. Natl. Acad Sci.</u>, 78: 3260, 1981) and schedule-controlled operant responding (Coffin, V.L. and J.M. Carney, In: <u>Physiology and Pharmacology of Adenosine</u>

78: 3260, 1981) and schedule-controlled operant responding (contin, VL. and J.M. Carney, In: Physiology and Pharmacology of Adenosine Derivatives, 1983) following parenteral injections. Mice were implanted with chronic indwelling cannulas and injected in the lateral cerebral ventricle (ICVT) with adenosine, adenosine analogs, and an adenosine uptake inhibitor. The effects on spontaneous locomotor activity were assessed. Adenosine, as well as its analogs, produced dose-related decreases in locomotor activity. The relative order of potency for locomotor depression was: 5'ethylcarboxamide adenosine (NECA) >> L-PIA > 2-chloroadeno-sine >> PIA > adenosine. Caffeine blocked adenosine's effects, as well as the effects of an analog (NECA) on spontaneous locomotor activity. Certain dose combinations of adenosine and caffeine produced stimulation, whereas this effect was not observed with NECA. Papverine, a specific adenosine uptake inhibitor, was also studied in this paradigm. The dose-effect curve of papaverine had the same effect on papaverine as with adenosine. Combinations of adenosine and papaverine had additive effects in depressing spontaneous locomotory activity. In summary, the data show that adenosine and its analogs can potently depress spontaneous locomotor activity in mice and these depressant effects are mediated by central mechanisms. Furthermore, caffeine can antagonize these central depressant effects, 38.14 DEVELOPMENT OF TOLERANCE TO THE HYPOTHERMIC ACTIONS OF CAFFEINE IN THE RAT. <u>A.J. Schlosberg</u>. Neurosciences Program, Univ. of Alabama in Birmingham, Birmingham, AL 35294. Groups of adult, male rats received caffeine (100 mg/kg, i.p.)

Groups of adult, male rats received caffeine (100 mg/kg, i.p.) or vehicle for 1, 2, 4 or 7 days. Rectal temperatures wer recorded immediately prior to and 2 hr after drug administration. Caffeine-induced hypothermia (-2.0 to  $-2.5^{\circ}$ C) was only observed after the first injection of the drug. Within 24 hr, an apparent tolerance to caffeine was displayed by all rats which received additional injections of the drug: The hypothermic response was significantly attenuated or absent in rats given 2 or 4 and 7 daily drug treatments, respectively. In order to assess possible changes in brain amine levels and endocrine responsivity following repeated exposure to this xanthine, rats in each test group were killed 2 hr after their last caffeine injection. Caffeine significantly increased the brain content of tryptophan, serotonin and 5-hydroxyindoleacetic acid, and these effects were relatively constant over days. Acute and chronic caffeine failed to systematically alter the brain levels of norepinephrine and dopamine. Caffeine significantly elevated the serum levels of nonesterified fatty acids (NETA) irrespective of the number of injections; the rise in serum NEFA was, however, greater with subsequent administrations of the drug (days 4 and 7), but a drug x days interaction was not found. In contrast to the above effects, caffeine-induced changes in the serum levels of glucose and insulin followed the same time-course described for the emergence of tolerance to the hypothermic actions of the drug. Increases in serum glucose (+55%) and insulin (+93%) levels were only observed in rats given a single injection of caffeine. After the second through seventh injection, glucose and insulin levels did not vary significantly refrom control levels in vehicle-treated rats. That chronically caffeinated rats were capable of exhibiting glucose and insulin responses to other agents was confirmed in rats given daily injections of caffeine over a 7 day period. On the eighth day, rats previously exposed to 100 mg/

- BEHAVIOURAL STIMULANT EFFECT OF A SMALL DOSE OF B-PHENYLETHYL-38.15 AMINE FOLLOWING SPECIFIC INHIBITION OF TYPE B MONOAMINE OXIDASE. C.T. Dourish, Psychiatric Research Division, CMR Building, University of Saskatchewan, Saskatoon, Saskatchewan S7N ONO. The endogenous amine *B*-phenylethylamine (PEA) is structurally similar to the psychomotor stimulant amphetamine (AMPH) and has been proposed to mediate the actions of the latter compound. The behavioural effects of AMPH in rodents are well documented. Doses of 0.5 to 2.0 mg/kg of AMPH increase co-ordinated locomotion and exploration whereas doses of 5 mg/kg and above induce progressively more severe forms of stereotyped sniffing, rearing, gnawing and body movements. A major weakness in the argu-ment that PEA may be an endogenous AMPH is the inability of PEA ment that PEA may be an endogenous AMPH is the inability of PEA to elicit a behavioural stimulant effect comparable to that induced by low doses of AMPH. Recent studies in this laboratory have demonstrated that the administration of increasing doses of PEA to rodents induces "AMPH-like" stereotypy but not locomotor stimulation. PEA is a specific substrate for type B monoamine oxidase (MAO) and, therefore, is metabolized extremely rapidly in tissue. The present study examined the behavioural effects of low doses of PEA following pretreatment with deprenyl, a specific inhibitor of type B MAO. Male Wistar rats were injected with PEA at doses of 0, 1, 2, 4, 8 or 16 mg/kg 4h after an injection of 4 mg/kg 1-deprenyl or saline. Testing was conducted in individual plexiglass cages positioned in automatic activity recording devices (Opto Varimex Minor) controlled by a microprocessor/microcomputer system. The system generated scores for horizontal and vertical activity and ambulation. Behavioural observation supplemented the automatic recording during a 60 min test. PEA or deprenyl alone had no significant effect on behaviour. However, ANOVA revealed a significant interaction of the two drug treatments. In deprenyl-pretreated rats PEA (4 mg/kg) elicited an "AMPH-like" increase in co-ordinrats PEA (4 mg/kg) elicited an "AMPH-like" increase in co-ordin-ated locomotor activity and exploration which was devoid of stereotypy. This behavioural pattern was never observed in rats treated with PEA alone. Higher doses of PEA (8 or 16 mg/kg) in deprenyl-pretreated rats induced hyperactivity and stereotyped sniffing accompanied by head and body movements, such as have been previously described after large doses of PEA alone. These data suggest that pretreatment with the specific type B MAO inhibitor deprenyl can unmask the behavioural stimulant effect of PEA. The present results do not support the hypothesis that MAO inhibition simply produces a shift in the PEA dose response curve. Supported by Dent. Health. Province of Saskatchewan. curve. Supported by Dept. Health, Province of Saskatchewan.
- 38.17 DOPAMINERGIC FACILITATION OF ACOUSTIC STARTLE IS DUE TO ENHANCED SENSORY RATHER THAN MOTOR EFFECTS. <u>R.L. Commissaris</u>\*, <u>S. Yang\*, L. Dember\* and M. Davis.</u> Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508 (SPON: M. Bowers). Previous work has suggested that the primary acoustic statle object in the primary normal unput of log log.

Previous work has suggested that the primary acoustic startle circuit in the rat is: auditory nerve, ventral cochlear nucleus (VCN), nuclei of the lateral lemniscus, nucleus retioularis pontis caudalis (RPC), spinal interneuron, lower motor neuron, muscles (Davis et al., 1983). Using electrical stimulation at various nuclei along the acoustic startle circuit, it has been possible to identify the locus within the startle circuit for the expression of a number of modulatory influences on this behavior, including the potentiated startle response (Berg and Davis, 1983) and response habituation and sensitization (Davis et al., 1982). This technique has also been used to localize the site of ultimate action of some systemically administered drugs (Commissaris and Davis, 1982). In these studies, 'startle' is elicited progressively along the pathway from the VCN to the RPC. The site farthest along the circuit where a treatment still affects electrically-elicited 'startle' is considered to be the point where that modulatory influence is inserted into the startle pathway. The present study employed this electrically-elicited 'startle' response to examine the neural loci for the facilitation

The present study employed this electrically-elicited 'startle' response to examine the neural loci for the facilitation of startle by 1) decreased glycinergic transmission produced by strychnine and 2) increased dopaminergic transmission produced d-amphetamine and apomorphine. Male rats (350-400g) received bilateral, single-pulse stimulations of RPC or VCN alternating with acoustic noise bursts. Both acoustic and electricallyelicited 'startle' responses were elicited for a 14-minbaseline period before i.p. injection of various doses of strychnine (0.25-1 mg/kg), d-amphetamine (2-8 mg/kg), apomorphine (1.0,3.0 mg/kg) or vehicle. Acoustic and electrically-elicited 'startle' responses were then measured for 20 min post-injection.

for 20 min post-injection. As expected, all three agents markedly increased acoustic startle amplitude. Strychnine increased the 'startle' elicited electrically from either the VCN or the RPC; these data are consistent with its facilitatory effects on acoustic startle when administered spinally. In contrast, both d-amphetamine and apomorphine failed to enhance 'startle' responses elicited from either the VCN or RPC, suggesting that dopaminergic modulation of acoustic startle is expressed at or before the VCN (i.e., VIII nerve or cochlea). Taken together, the data suggest that glycinergic modulation of the reflex arc, while the dopaminergic modulation of startle occurs on the sensory side.

38.16 THE EFFECTS OF AMPHETAMINE AND APOMORPHINE ON FRONTAL CORTEX SELF-STIMULATION. <u>Nancy J. Leith</u>, Dept. Pharmacol., Vanderbilt Med. Sch., Nashville, TN 37232.

Although investigators (Mora, Life Sci. 22, 1978; Mora and Myers, Science 197, 1977) have concluded that dopamine (DA) is the important neurochemical substrate for frontal cortex (FC) self-stimulation (SS) behavior, pharmacological manipulations of DA function have yielded data inconsistent with such a straightforward relationship. Most notably, d-amphetamine (d-AMPH) did not significantly facilitate FC SS (Goodall and Carey, JCPP, 89, 1975) and apomorphine (APO) decreased responding over a wide range of doses (Mora, Life Sci. 22, 1978). The latter effect was interpreted as indicative that the direct activation of DA receptors by APO disrupts the contingency relationship between the rat's behavior and the functioning of the DA system. However, recent work (Leith, <u>Brain Res.</u>, 1983, in press) has demonstrated that the effects of APO on medial forebrain bundle (MFB) SS are a complex function of drug dose and current intensity and previous work (Leith and Barrett, <u>Psychopharmacologia 46</u>, 1976) indicated that AMPH facilitation of MFB SS is also a function of current intensity. The present study was undertaken to pharmacologically characterize FC SS using a procedure that generates a response ratecurrent intensity function for each animal which allows assess-

ment of drug effects at both supra and subthreshold intensities. Twenty-four rats were implanted with bipolar electrodes in the medial FC and trained to bar press to receive 0.5 sec trains of 60 Hz ac current. Daily sessions consisted of repeated sampling of the rat's responding at 14 current intensities. The reinforcement threshold was defined as the current intensity at which responding decreased to 50% of the maximum rate. The average baseline threshold value for these animals was 15 µA.

Ine threshold value for the maximum face. The average baseline threshold value for these animals was 15  $\mu$ A. Using this procedure, d-AMPH (.3 mg/kg) significantly lowered the threshold, with no effect on response rates that were above threshold. The 1 isomer was equipotent and produced identical changes. Apomorphine (.1-.2 mg/kg) lowered responding at suptrathreshold intensities and increased responding at subthreshold values, identical to that obtained with MFB electrodes. However, low doses of APO (.02 mg/kg) had no effect on SS responding whereas such doses elevate the threshold for MFB SS. This effect on MFB SS is thought to be related to a selective interaction of low doses of APO with presynaptic autoreceptors and the lack of effect on FC SS is consistent with the absence of autoreceptors on FC dopamine neurons (Bannon <u>et al., Molec. Pharmacol. 19</u>, 1981). Thus, the present work demonstrates that the effects of DA agonists on FC SS are nearly identical to the effects of those same

Thus, the present work demonstrates that the effects of DA agonists on FC SS are nearly identical to the effects of those same drugs on MFB SS. Previously reported differences are most likely the result of sampling the responding only at suprathreshold values. (Supported by MH29217).

38.18 CHRONIC ADMINISTRATION OF ATYPICAL NEUROLEPTICS DIFFERENTIALLY ALTERS BEHAVIORAL SUPERSENSITIVITY MEDIATED BY TWO DISTINCT BRAIN REGIONS. R. Halperin, V. Haroutunian\*, P. Szynkowicz\*, J. J. <u>Guerin, Jr.\* and K. L. Davis\*.</u> Psychiatry Service, V.A. Medical Center, Bronx, NY 10468, and Mt. Sinai Medical School, N.Y.NY 10029

Center, Bronx, NY 10468, and Mt. Sinai Medical School, N.Y.NY 10029 In the rat, direct injection of dopamine (DA) into the caudate putamen (CP) or nucleus accumbens (AC) elicits stereotypy and locomotor responses, respectively. The magnitude of these behavioral responses is believed to index DA receptor sensitivity at the injection site. We have shown that chronic pre-treatment with the atypical neuroleptic fluotracen can selectively enhance the locomotor response to intra-accumbens injection of DA, leaving the stereotypy response to striatal DA injection unaltered (Halperin, R., Guerin, J.J. & Davis, K.L. <u>Life Sci</u>. In press, 1983). We now report the effects of pre-treatment with the atypical neuroleptics metoclopramide (Wet), sulpride (Sul), and clozapine (Cloz) as compared to haloperidol (Hal) or vehicle (Veh) in terms of their ability to enhance the stereotypy and locomotor responses to intracerebral DA injection.

Each rat was chronically implanted with drug-injection cannulas aimed bilaterally at either the CP or AC. In Experiment 1, 46 rats were given sweetened drinking water containing either Met (100 - 400 mg/l), Hal (10 - 40 mg/l) or sucrose alone. Drug concentrations increased progressively over a period of 21 consecutive days. In Experiment 2, 61 rats were injected once dailv (i.p.) with either Cloz(30mg/kg), Sul (50 - 100 mg/kg), Hal(0.5 mg/kg) or saline for 21 consecutive days. In both experiments each rat was centrally injected with 10 µg of DA bilaterally five days after the termination of drug treatment. Stereotypy in CPcannulated rats, or locomotion in AC-cannulated rats was measured immediately after the central DA injection. Pre-treatment with Met, as compared to sucrose alone, enhanced

Pre-treatment with Met, as compared to sucrose alone, enhanced' the stereotypy response to DA injection to the CP, but did not alter the locomotor response to DA injection to the AC. Pretreatment with both Cloz and Sul, as compared to Veh, enhanced the locomotor response to DA injection to the AC, but did not alter the stereotypy response to DA injection to the CP. Pre-treatment with Hal enhanced both behavioral responses to central DA injection.

Understanding the mechanisms through which these systemically administered drugs exert their selective effects on behaviors mediated by different brain regions has important implications for dissociating the antipsychotic and dyskinetic effects of chronic neuroleptic treatment.

ATTENUATION OF APOMORPHINE INDUCED STEREOTYPY BY CAPTOPRIL PRETREATMENT. A. Sudilovsky, B. A. Turnbull,\* L. H. Miller,\* and L. J. Traficante.\* Frinceton, N. J. and Department of Biobehavioral Sciences, Boston University Medical Center, Boston, Mass. Captopril, an antihypertensive agent that inhibits the angiotensin converting enzyme (ACE) has also been found to significantly increase serum prolactin levels in hypertensive patients (Aberg, H.E. et al, <u>IRCS Medical Science</u>, <u>B</u>: 217, 1980). This increase suggests a possible captopril-dopamine system interaction and led us to examine the effect of captopril on apomorphine induced behavioral stereotypy. In the first series of trials 10 adult Sprague-Dawley male rats were injected intraperitoneally with apomorphine (2 mg/kg) or with apomorphine (2 mg/kg) plus captopril (5, 10, 20, or 50

or with apomorphine (2 mg/kg) plus captopril (5, 10, 20, or 50 mg/kg) following a fully crossed design. Treatment groups were randomly assigned and, at least, seven days passed between treatment administrations. Stereotyped behavior was rated using a 0-3 point scoring method (Tarsy, D. and Baldessarini, R.J., <u>Neuropharmacol.</u>, <u>13</u>: 927, 1974) for segments of 10 seconds every 15 minutes over a period of 80 minutes starting immediately after injection. Although a trend toward attenuation of the stereo-typed behavior induced by apomorphine was observed during the 60 and 75 minute scoring segments. ANOVA indicated that the 60 and 75 minute scoring segments, ANOVA indicated that the concurrent administration of captopril did not significantly

Concurrent administration of captopril and not significantly alter stereotypy. In the second series of trials, rats (N=10) received captopril (20 mg/kg, i.p.) at 60, 90, or 120 minutes prior to the administration of apomorphine (2 mg/kg, i.p.). Scoring and all other procedures were as noted above. The data obtained deconcerned a consistence to conversion of morphic induced demonstrated a significant attenuation of apomorphine induced stereotypy, (p = 0.0026). Post-hoc analyses utilizing the

stereotypy, (p = 0.0026). Post-hoc analyses utilizing the Newman-Keuls method determined that whereas no significant differences existed between animals pretreated with captopril, all three pretreated groups were significantly different from that receiving apomorphine alone (p <0.05). Radio-receptor assay measuring labelled spiroperidol dis-placement (Creese, I. and Snyder, S.H., <u>Nature</u>, <u>270</u>: 180, 1977) demonstrated that captopril does not competitively bind to the dopamine receptor at concentrations ranging from 0.01 to 10 µg/ml. Thus the attenuation of the apomorphine induced stereotypy in rats pretreated with captopril does not appear to be due to a displacement of anomorphine from the dopamine receptor site by captopril. Alternatively, the observed results may be explained by captopril-induced alterations in endogenous modulators or antagonists of the dopamine receptor.

DISCRIMINATIVE STIMULUS PROPERTIES OF TWO ERGOTS, ERGONOVINE 38.21 AND LERGOTRILE. K. A. Cunningham, P. M. Callahan\* and J. B. Appel. Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, S. C., 29208.

Ergot derivatives exhibit diverse central and peripheral phar-macological properties, possibly because of structural similari-ties between the ergoline ring and monoaminergic neurotransmitters. Clinically, these compounds are useful in the treatment of disorders ranging from migraine headache and post-partum The mortage to Parkinsonian and senile dementia; several ergots may also be hallucinogenic. Since drug discrimination (DD) has been useful in reliably differentiating between the effects of LSD and lisuride in vivo and in delineating their underlying neuronal mechanisms (White and Appel, <u>JPET</u>, 221: 421, 1982), we have been using this method recently to investigate several other ergots.

Thus, male albino rats were trained to discriminate ergonovine (2.0 mg/kg, i.p.) (N=7) or lergotrile (N=7) from saline in a two-lever, water-reinforced task. Within 20-30 sessions, both groups had reached a criterion of >85% correct. During groups had reached a criterion of >85% correct. During extinction test sessions, dose-response tests indicated that both the ergonovine and lergotrile cues were dose-dependent. LSD (0.04-0.24 mg/kg) and lisuride (0.02-0.08 mg/kg) were shown to substitute completely for the training drug cues in both groups. Administration of the direct dopamine (DA) agonist apomorphine (0.01-0.25 mg/kg) was followed by drug-appropriate responding in the lergotrile-trained group but saline-appropriate responding in the acromyting groups. At the doces appropriate responding in the ergonovine group; at the doses tested (1.0-2.0 mg/kg), the direct serotonin (5-HT) agonist quipazine did not mimic either cue. Attempts to antagonize the discriminable effects of ergots suggest that the DA antagonist haloperidol (0.0625 mg/kg) attenuates the lergotrile cue (partially), but has little or no effect on the ergonovine cue.

While these preliminary results might support our earlier hypothesis (Holohean et al., Eur. J. Pharmacol., <u>81</u>: 595, 1982) that DA plays a prominent role in mediating the effects of lergotrile, the mechanism(s) underlying the ergonovine cue remain obscure. More extensive research, in which several DA, 5-HT and noradrenergic agonists and antagonists are being administered alone or in combination with the training drug, is in progress.

38.20 DISCRIMINATIVE STIMULUS PROPERTIES OF INTRACRANIAL SELF-STIMULA-DISCRIMINATIVE STIMULUS PROPERTIES OF INTRACRANIAL SELF-STIMULA-TION: EFFECTS OF <u>D</u>-AMPHETAMINE, MORPHINE, NICOTINE AND PHENCYCLI-DINE. <u>Gerald J. Schaefer and Richard P. Michael</u>. Depts. of Psy-chiatry and Pharmacology, School of Medicine, Emory University and The Georgia Mental Health Institute, Atlanta, GA 30306.

Rats were implanted with single stimulating electrodes in the medial forebrain bundle-lateral hypothalamus (MFB-LH) and trained to discriminate the presence or absence of intracranial selfstimulation (ICSS) in a two-choice discrete trial task. For e trial, the animal was required first to press an "initiating" For each trial, the animal was required first to press an initiating lever which gave either suprathreshold ICSS or no ICSS. If the animal received ICSS, it was required to go to the right "choice" lever for further ICSS. If it received no ICSS on the initiating lever, the animal was required to go to the left choice lever for ICSS. A wrong choice terminated the trial without reward. Half of the animals were required to press the right choice lever when the initiating lever produced a suprathreshold stimulus and the The initiating lever produced a suprathreshold stimulus and the left choice lever when the initiating lever produced no stimulus to obtain the reinforcing stimulus. The opposite conditions were in effect for the other half of the animals. After establishing the discrimination, test sessions with vehicle and drug solutions were interposed between training sessions. During test sessions, the initiating lever produced current intensities that were either 0-10-20-40-60-80-100% of that produced by the choice lever. In addition, during test sessions, in contrast to training sessions, addition, during test sessions, in contrast to training sessions, aresponse on either choice lever produced the reinforcing stimulus and terminated the trial. The dependent measure was the number of trials completed on the ICSS-appropriate choice lever as a func-tion of the current intensity of the initiating lever. Animals were tested with d-amphetamine (0.1 - 1.0 mg/kg), morphine (0.1 - 1.0 mg/kg), nicotine (0.1 - 0.56 mg/kg), and phencyclidine (0.3 - 3.0 mg/kg). For each dose of drug a function relating the selec-tion of choice lever to the current intensity on the initiating lever was determined and this was compared to the function pro-duced by the vehicle usine the Litchfield and Wilcoxon (1949) duced by the vehicle using the Litchfield and Wilcoxon (1949) procedure. None of the doses of these drugs altered the discrimi-native stimulus properties of ICSS as evidenced by an absence of changes in the detection of the discriminative stimulus. While ICSS produces reliable discriminative stimulus properties in the MFB-LH of rats, the effects are not altered by drugs that have been demonstrated in other tasks to produce discriminative stimu-lus effects and to alter the reinforcement threshold for ICSS. These data suggest that the effects of drugs on the ICSS rein-forcement threshold can be dissociated from the effects on the detection threshold. 38.22 LONG-LASTING ANTICONVULSANT EFFECTS OF DIAZEPAM ARE STRAIN DEPENDENT. Sandra E. File, Department of Pharmacology, The School of Pharmacy, University of London, Brunswick Square, London WC1N DEPENDENT. 1AX, England.

Paul et al (Nature 281:688,1979) reported a high correlation between receptor occupancy by diazepam and protection against pentylenetetrazole-induced seizures. A full anticonvulsant effect was achieved as long as 15 h after diazepam injection, at a time when brain concentrations of the parent compound and its metabolite would be very low. Such long-lasting protective effects of diazepam have both theoretical and clinical importance; we therefore tried to replicate the results, using several mouse strains and more than one convulsant agent.

We tested two inbred strains (C3H/HE from Olac, and NIH from Hacking & Churchill) and two outbred strains (Tuck No. 1 strain, and CFLP from Hacking & Churchill). Male mice (n=8/group) were injected with 4 mg/kg diazepam and 1.5, 3, 6, 12, 18 or 24 h later they were challenged with a convulsant dose of pentylenetetrazole (80 mg/kg) or of picrotoxin (8 mg/kg). The latencies to show (80 mg/kg) or of picrotoxin (8 mg/kg). Ine latencies to snow myoclonic jerks and full tonic-clonic convulsions were scored. Six hours after diazepam injection, 90% of the C3H/HE mice were protected against pentylenetetrazole seizures, but only 60% of the CFLP mice, 25% of the NIH and 12.5% of the Tuck mice. By 12 h even the C3H/HE mice showed 0% protection. The protective effects of

This we have been unable to show a full anticonvulsant effect any longer than 6 h after diazepam injection, and for this length of time only in one strain. The clear strain differences in the duration of diazepam's effects are likely to be pharmacokinetic in nature (Schweri, WGBR Jan. 1983). It seems that the long-lasting protection reported by Paul et al may apply only to the strain of mice used in that study. We used the same doses of diazepam and pentylenetetrazole and our longest-lasting protection was found in a strain closely related to that used in the original study. 38.23 CONDITIONED EMOTIONAL RESPONDING: EFFECTS OF SAFETY SIGNALS ARE BLOCKED BY A BENZODIAZEPINE ANTAGONIST. K. L. Hadskis and

ARE BLOCKED BY A BENZODIAZEPINE ANTACONIST. K. L. Hadskis and H. A. Robertson. Depts. of Psychology and Pharmacology, Dalhousie University, Halifax, N.S., Canada, B3H 4H7 Since the discovery of a specific receptor for benzodiaze-pines in 1977, it has been postulated than an endogenous benzo-diazepine-like compound might exist. However, there has as yet been no conclusive proof for the existance of such a ligand. In order to provide proof for the existance of such a compound, we have studied the effects of a benzodiazepine agonist and antagonist on conditioned emotional responding in rats. A benzodiazepine aconist with anxialvtic but no anticonvulsant benzodiazepine agonist with anxiolytic but no anticonvulsant properties (PK 9084), and a benzodiazepine receptor antagonist (CGS 8216) which appears to lack any of the partial agonist (or both of the appears to fact any of the partial agoinst effects seen with Rol5-1788 (Robertson & Rilves, Brain Res., in press) were studied. The phenol quinoline PK 9084 effectively displaces  ${}^{3}$ H-benzodiazepines from receptor sites in vitro and in our experiments significantly increased responding in rats experiencing chronic fear. It was without effect on animals given a safety signal (and consequently not experiencing chronic fear). CGS 8216 significantly decreased responding in the animals receiving the safety signal but had no effect on the chronic fear group. It also antagonized the anxiolytic effects of PK 9084.

errects of rK 9084. These results support the hypothesis that safety signals produce their effects by causing a release of an endogenous benzodiazepine-like compound. The reversal of the effects of PK 9084 by CCS 8216 provides evidence that this anxiolytic agent produces its effects through a benzodiazepine receptor, perhaps a receptor which mediates anxiolytic effects uniquely. (Supported by the MRC). (Supported by the MRC).

38.24 INTERACTION OF BENZODIAZEPINE ANTAGONISTS AND NEUROTRANSMITTER ANTAGONISTS WITH CHLORDIAZEPOXIDE UNDER A DIFFERENTIAL ANTAGONISTS WITH CHLORDIAZEPONIDE UNDER A DIFFERENTIAL REINFORCEMENT OF LOW RATE (DRL) SCHEDULE. John M. Carney\* and <u>Mitsutaka Nakamura</u>\* (SPON: R. Blair). Dept. of Pharmacology, Univ. Okla. Hlth. Sci. Ctr., Oklahoma City, OK 73190. Male Sprague Dawley (SD) rats were food deprived to 80% of <u>ad</u> <u>11bitum</u> feeding weight and trained to respond under a differential reinforcement of low rate (DRL) 15 sec schedule of food reinforcement. Under control conditions approximately 60% of the total DRL responses resulted in food reinforcement. Relatively low does of chlordiazepoxide produced a dose related increase in the non-reinforced DRL responses and a decrease in the percentage of food reinforced responses. A dose of 32 mg/kg chlordiazepoxide produced decreases in total DRL responses and resulted in a roughly equal number of reinforced and non-reinforced responses. Both CGS8216 and R015-1788 blocked the effects 10 mg/kg chlordiazepoxide, which produced substantial increases in non-reinforced responding. Pretreatment with 10 mg/kg methysergide had no direct effect on DRL behavior and failed to alter the effects of 10 mg/kg chlordiazepoxide Bisecultine (3 mg/kg) and Picrotoxin (3 mg/kg) also failed to modify the effects of 10 mg/kg chlordiazepoxide. In contrast to the interaction of these compounds with the relatively low chlordiazepoxide dose, antagonism of the behavioral suppressant dose of chlordiazepoxide (32 mg/kg) was obtained with R015-1788, CGS8216 and bicuculine. A bicuculine dose of 3 mg/kg reversed the disruption produced by 32 mg/kg chlordiazepoxide and returned the DRL responding to its normal IRT pattern. The data to date are consistent with a benzodiazepine/GABA receptor mediated mechanism for suppression behavior, but do not support a simple GABA mediated mechanism for the response rate increasing and possibly the anxiolytic effects.

NORADRENERGIC INVOLVEMENT IN THE YOHIMBINE-INDUCED EXCITATION 38.25 NORADENERGIC INVOLVEMENT IN THE FORINGING-INDOLED EXCITATION OF ACOUSTIC STARTLE: EFFECTS OF 6-OHDA AND DSP4. John H. Kehne<sup>#</sup> and Michael Davis. Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508 (SPONSOR: J. Tallman). The acoustic startle reflex in rats has been shown to be In acoustic startle reflex in rats has been shown to be augmented by IP administration of the  $\alpha_2$ -adrenergic antagonist yohimbine (Davis & Astrachan, Psychopharmacol., 75: 219-225, 1981). The purpose of the present study was to determine whether peripheral and/or central noradrenergic neurons are necessary for the expression of the excitatory effect of unbirding or constitution that the start of the excitatory effect of yohimbine on acoustic startle. The neurotoxins 6-hy

6-hydroxydopamine (6-OHDA) The neurotoxins 6-hydroxydopamine (6-OHDA) or N-(2-chloroethyl)- N- ethyl-2-bromobenzylamine (DSP4) were used to produce depletions of norepinephrine (NE). The ability of yohimbine (1.25 mg/kg, IP) to increase startle was tested in neurotoxin-pretreated rats or their appropriate controls. controls.

Depletion of both central and peripheral NE with DSP4 (50 mg/kg, IP; 1-2 days prior to testing) completely blocked the excitatory effect of yohimbine on acoustic startle. The excitatory effect of yohimbine on acoustic startle. The yohimbine-induced excitation was still observed in adrenalectomized rats, indicating that release of adrenal catecholamines is not involved. Furthermore, pretreatment with intravenous 6-OHDA (20 mg/kg, 1-3 days prior to testing) failed to block the yohimbine excitatory effect, indicating that peripheral noradrenergic neurons are not involved. In contrast, when central noradrenergic denervation was produced by direct infusion of 6-OHDA into the lateral ventricle, a significant attenuation of the yohimbine-induced excitation was seen. Since there is evidence that activation of spinal significant attenuation of the yohimbine-induced excitation was seen. Since there is evidence that activation of spinal noradrenergic neurons facilitates the startle reflex (Astrachan & Davis, Brain Res. 206: 223-228, 1981), the effect of yohimbine was assessed in rats specifically depleted of spinal NE. Intrathecal administration of 6-OHDA into the lumbar spinal cord, which causes a potent and selective reduction in spinal NE content, blocked the excitatory effect of yohimbine on startle.

these data indicate that central. and In summary, particular, spinal NE-containing neurons are necessary for the expression of yohimbine-induced excitation of acoustic startle.

We would like to thank Dr. G. Jonsson, Dr. S. Ross, and Astra-Lakemedel AB for generously supplying the DSP4. Supported by NSF Grant BNS-8120476 and the State of CT.

39.1 AN ANIMAL MODEL FOR EVALUATING THE BEHAVIORAL EFFECTS OF THE INTERACTION OF EXERCISE AND CNS DRUGS. S.B. McMaster\* and J.M. <u>Carney\*</u> (SPON: H.D. Christensen). Dept. of Psychiatry and Behavioral Sciences and Dept. of Pharmacology, College of Medicine, Univ. of Okla. Hlth. Sci. Ctr., Oklahoma City, OK 73190.

Previous work has shown that exercise in the form of treadmill running results in enhanced sensitivity to the behavioral effects of a variety of compounds (Carney, J.M.; Nakamura, M. and Christensen, H.D. <u>Pharmacologist</u> 24:130, 1982). Rats tested on an operant task exhibit greater performance disruption in response to drugs administered following an exercise session than to either drug or exercise alone. This effect has been demonstrated with muscarinic antagonists and psychomotor stimulants following fixed speed and duration running.

The present study was undertaken to examine various parameters of the exercise treatment. Male Sprague-Dawley rats (275-300g) were food deprived to 80% of their <u>ad lib</u> feeding weight and trained to respond under a multi-component fixed ratio (FR) 30 time out (TO) 10 min. schedule. Each daily session consisted of four alternating FR and TO components. Under this schedule, relatively little responding occurred during the TO components; response rates during the FR components were between one and two responses per sec with little intra-subject variability. Exercise conditions tested included four treadmill speeds and four session durations.

These conditions resulted in a graded disruption of operant behavior. The degree of impairment was directly related to the level of exercise. Exercise-induced changes in body temperature were not predictive of behavioral disruption. For example, running at a speed of 1 mph for 30 and 60 min resulted in equivalent temperature increases. In contrast, 30 min of treadmill exercise resulted in no significant disruption of performance while 60 min of exercise produced significant decreases in operant behavior. The impact of exercise speed and duration on the behavioral potency of muscarinic antagonists and the suitability of this paradigm as a model of the CNS effects of exercise will be discussed. (Supported in part by USAMRDC DAMD 17-81-C-1246.) 39.2 MORPHINE PLACE-PREFERENCE: EXAMINATION OF THE PARADIGM AND ITS ASSOCIATIVE PROPERTIES. <u>A. Rackham, A.</u> <u>Blanderw, & Z. Amit.</u> Center for Studies in Behavioral Neurobiology, Concordia University, 1455 de Maisonneuve Blvd. W., H1013, Montreal, Quebec, Canada, H3G IMZ.

Previous morphine place-preference (P.P) studies have shown that rats will spend from 29-66% of the time in an environment where they experienced the effects of morphine. To examine the possibility that the low magnitude of morphine F.P. is a function of weak associations formed between the drug and the environment, the following studies sought to determine whether there is any difference in the magnitude of P.P. for a previously established non preferred side between rats that experienced the effects of morphine (10mg/kg., jp.) and rats that experienced the effects of morphine in the home cage. Expt.1 included 4 habituation days followed by 3 repeated trials (( 4 Drug-Treatment (D.T.) days and 1 non-drug Test day)). Following habituation days, rats were divided into 8 equal groups (n=6) which determined the place (non preferred side or home cage) and sequence of D.T. (established by a latin square design) over the 12 D.T. days. Results showed no significant (sig.) difference in time spent on the non preferred side of the box as a change from habituation days, spent the same amount of time on that side over Test days as rats that were conditioned with morphine in that side over D.T. days. To determine whether the time spent on the non preferred side was in fact opiate receptor mediated, all rats in expt.2 were pretreated with naloxone (7mg/kg.ip.) prior to morphine injections. The procedure was identical to that used in expt.1. Results showed no sig. difference between groups. Within groups analysis showed that the shift in time spent on the non preferred side of the box was blocked by naloxone when D.T. took place in the morphered side of the box, however, not when D.T. took place in the home cage. These results suggest that the low magnitude of preference observed in morphine F.P. studies may be attributed to the inability of rats to form strong associations between the effects of morphine and the environmental cues in the box.

39.3 RELIABILITY AND VALIDITY OF THE CUMULATIVE DOSING PROCEDURE FOR BEHAVIORAL PHARMACOLOGY, M.F. Jarvisš E.A. W alkerš E.L. Ramerizš G.C. Wagner. Dept. Psychology, Rutgers Univ. New Brunswick, NJ. The cumulative dosing procedure has recently been applied to schedule-controled and drug discrimination paradigms. The main advantage of the procedure is that an entire dose-response curve may be determined in one day. To date, however, there has been no systematic attempt to establish its reliability or validity.

11 male Long Evans rats were trained to respond for water delivery on an FI 90 sec schedule. When responding had stabilized, rats were advanced to the cumulative dosing schedule of five 10 min sessions separated by 5 min time out periods. Amphetamine (AMPH) was administered i.p. in doses of 0.5, 0.5, 1.0, 2.0, & 4.0 mg/kg starting 5 min before the first session and then repeated at the start of each time out period. This procedure was repeated following 2 baseline days. Thereafter, single daily sessions of 30 min were conducted. When responding had restabilized, AMPH (.5, 1.0, 2.0, 4.0, 8.0) was administered every third day 15 min before the session (traditional dose response curve).

before the session (traditional dose response curve). Under baseline (saline) conditions, the response rates for the 5 daily (cumulative) sessions were 12.1, 12.4, 13.1, 13.3, 13.6 (x=12.9) resp/min and for the single (traditional) session was 11.6 resp/min. There baseline response rates were not significantly different. Across rats the correlation for the mean cumulative and traditional response rates was .62 (p $\zeta$ .05). Also under baseline conditions, the quater life values were .67, .67, .69, .67, .69 (x=.68) for the cumulative and .72 for the traditional procedures. These baseline quater life values were significantly different but correlated across all rats (r=.81;p $\zeta$ .01).

.69 (x=.68) for the cumulative and .72 for the traditional procedures. These baseline quater life values were significantly different but correlated across all rats (r=.81;p $\lt$ .01). Amph disrupted responding in a dose-dependent manner (albeit differentially) in the cumulative (ED50=4.7mg/kg) and traditional (ED50=3.4mg/kg) procedures. Although significantly different, these ED50 values were highly correlated (r=.73;p $\lt$ .01). The ED50 obtained in the first and second cumulative determinations were 5.7 and 3.3mg/kg. These values were significantly different but correlated across rats (r=.95;p $\lt$ .01). Finally,A.4PH exerted rate dependent effects, thereby, producing a decrease in quater life values. For the five doses of AMPH the quater life values were .63, .55, .44, .27, .11. (cumulative) and .67, .58, .32, .35, & .08 (traditional). Except at the lowest AMPH dose, these quater life values did not correlate. These results indicate that the rate but not pattern of re-

These results indicate that the rate but not pattern of responding in multiple sessions is similar to that obtained in a single session and that the cumulative dosing procedure is reliable and valid. However, differences in the pattern of responding may interact with the rate dependent effects of a drug. 9.4 ANALGESIA IN DEFEATED MICE: EVIDENCE FOR MEDIATION VIA CENTRAL RATHER THAN PITUITARY OR ADRENAL ENDOGENOUS OPIOIDS. <u>Michael I.</u>. <u>Thompson\* and Klaus A.</u> <u>Miczek</u> (SPON: L. Shuster). Dept. of Psychology, Bicchemistry and Pharmacology, Tufts Univ., Medford and Boston, MA 02155.

It has been suggested that endogenous opioids released from the pituitary and/or adrenal glands are critical for the analgesia produced by stress. Recently, we have demonstrated that mice subjected to defeat in a confrontation with another mouse exhibit pronounced analgesia which is mediated by endogenous opioids, as evidenced by naloxone reversibility and morphine cross-tolerance. The present experiments pursued two different approaches in order to determine the relative contributions of endogenous opioid sources in the brain vs. those from the pituitary and adrenal glands.

In order to investigate the contribution of the adrenals, separate groups of B6AF mice were (1) adrenalectomized one week prior to defeat, (2) pretreated with reserpine (2 mg/kg IP) for two days prior to defeat, or (3) injected with corticosterone (1 mg/kg) 30 min prior to defeat. Neither elimination nor facilitation of adrenal activity affected the analgesic response observed following defeat. These data suggest that adrenal activation during defeat is not crucial for this type of analgesic response. Since we have previously demonstrated that reduction of  $\frac{beta-endorphin}{beta-endorphin}$  from the pituitary by dexamethasone or hypertonic saline pretreatment did not alter the analgesic response, we conclude that endogenous opioids from the CNS and not from peripheral sources mediate this analgesic response.

al sources mediate this analgesic response. In further experiments we determined possible sites in the brain at which endogenous opioids may mediate the analgesic response in defeated mice. B6AF mice were implanted with a guide cannula;  $2.5-10~\mu g$  naloxone or morphine were infused in  $2.5-5~\mu l$ through a 33-ga. injector cannula into the periaqueductal gray or the arcuate nucleus. After the sites were determined to produce morphine analgesia, naloxone was infused immediately prior to the defeat test. When infused into periaqueductal gray or arcuate n., but not into surrounding regions, naloxone abolished the analgesic response. These results indicate that analgesia from defeat is produced by action of endogenous opioids originating from CNS sources on classic pain pathways. 39.5 THE SALINE EFFECT: BEHAVIORAL RECOVERY FROM BRAIN DAMAGE FOLLOW-INC INTRACRANIAL INJECIONS OF AN ISOTONIC SUBSTANCE. <u>R. Labbe\*</u>, <u>D. G. Stein and B. A. Sabel</u> (SPON: D. Chad). Brain Res. Lab., Dept. Psychology, Clark Univ., Worcester, MA 01610.

We have recently shown (Sabel and Stein, <u>Physiol</u>. <u>Behav</u>., <u>28</u>:1017, 1982) that isotonic saline, a widely used control substance, prevented behavioral deficits, neuronal death and reactive gliosis when injected intracerebrally following caudate nucleus (CN) damage. With the present experiment we attempted to replicate our previous findings and to determine whether sparing or recovery had taken place.

Thirty male, Long-Evans rats (170 days old, 360-470 g) were randomly assigned to the five surgical groups (n=6): group C received sham operations, whereas all other groups received bilateral intracerebral injections of 5 ul of isotonic saline immediately following surgery 1.5 mm posterior to the lesion site. The animals survived either 7 days (groups 75 and 7L) or 31 days (31L and 31S) after surgery. In the 31-day survival group, secondary lesions were made in the CN on day 25 to prepare the brains for subsequent Fink-Heimer analysis. The animals' behavior was tested from postoperative day 2-6 (7L and 7S) or days 10-25 and 27-31 (31L and 31S) on a 2-choice footshock learning maze without undergoing spatial reversals.

days 10-25 and 27-31 (31L and 315) on a 2-choice footshock learning maze without undergoing spatial reversals. Confirming our earlier results, saline-treated animals (31S) showed (1) less refusals to run, (2) shorter latencies to reach the goal box and (3) more avoidances on significantly more days than rats of group 31L. No differences were found between groups 7S and 7L. It is interesting to note that various behavioral and lesion measures correlated significantly in group 31S but not in group 31L. These findings may be taken to suggest that recovery of function rather than sparing had taken place. Presently, using the Fink-Heimer technique, we are studying whether saline may have prevented degeneration secondary to brain trauma. It should be emphasized again that the assumption that saline is a "neutral" substance with no effects on morphology and behavior may have to be reconsidered.

We thank Michael Saffran for his dedicated help; supported by United States Army Research and Development Command Contract #DAMD-82-C-2205. 39.6 TOLERANCE TO AND WITHDRAWAL FROM THE EFFECTS OF CHRONIC DEFEAT. L. Shuster, M.L. Thompson\*, K. A. Miczek and J.T. Winslow\*, (SPON:Herbert Barry, III). Depts. of Biochemistry, Pharmacology, and Psychology, Tufts Univ., Boston and Medford, MA 02111. Mice subjected to repeated attack by another mouse display an

Mice subjected to repeated attack by another mouse display an analgesic response that is fully blocked by naltrexone or naloxone, and shows complete cross tolerance with morphine. The aim of the present series of experiments was (1) to characterize the tolerance phenomenon in greater detail and (2) to determine whether or not physical dependence develops to the endogenously released opioids.

B6AF mice were exposed to daily defeat for 5 to 6 days. The development of tolerance to the effects of defeat was assessed by the tail flick method. Immediately following defeat on the 6th day, mice were observed closely for 2 hours for standard signs of spontaneous withdrawal. On the following day, the same mice were defeated and then observed for withdrawal signs for 20 mins. following the injection of 10 mg/kg naloxone, IP. Results for these mice were compared to a group of mice subjected to a single defeat test immediately before the withdrawal test. Tail flick latency following defeat was significantly reduced

Tail flick latency following defeat was significantly reduced by the third day, and continued to decline until by the 6th day the response was similar to baseline. Mice showed very few signs of spontaneous withdrawal. However, chronically defeated mice displayed significant amounts of withdrawal jumping following naloxone injection on the 7th day. These results suggest that a dependence-like phenomenon develops to physiologically released endogenous opioids following chronic defeat.

dependence-like phenomenon develops to physiologically released endogenous opioids following chronic defeat. Defeat tolerant mice showed cross tolerance to morphine and also to the putative <u>kappa</u> receptor agonist ketocyclazocine. Defeat tolerant mice showed reduced sleep time to barbiturates, but not to alcohol.

In additional experiments, acute defeat experience disrupted operant fixed-ratio performance. Within 3-14 days of chronic defeat, baseline operant performance was recovered. However, the dose effect function for morphine on fixed-ratio performance was the same before and after defeat. The results suggest that the effects of chronic defeat are not limited to pain perception but extend to other behavioral processes.

- 39.7 BEHAVIORAL EFFECTS OF SARIN IN RATS. M.R. Landauer\*, J.A. Romano, R.M. Alvarez\*, and J.H. McDonough (SPON: M.J. Kallman). US Army Chemical Systems Laboratory and US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010. The effects of the organophosphate sarin (isopropyl methyl phosphonofluoridate) on the establishment of a conditioned taste aversion (CTA), rotorod performance (RTR) and spontaneous motor activity (SMA), as well as the LD50 were evaluated in 171 adult male rats. In Exp 1, rats were acclimated to a daily 30 min period of water availability. When consumption had stabilized, they were given a 30 min access period to 0.2% saccharin (SAC) solution which was immediately followed by a sc injection of 61, 71, 84, 98 µg/kg sarin or the saline vehicle. Three days later, the animals (N=6-7/group) were given a two-bottle choice test (SAC vs water) and the percent SAC consumed was calculated. The ED50 was determined by graphical interpolation from the dose effect curve and was calculated to be 71 µg/kg sarin. In Exp 2, motor coordination was evaluated by placing rats on an accelerating rotorod (0-45 rpm in 90 sec). Time spent on the rotorod in sec was recorded as the dependent variable. Rats received four training trials and 30 min prior to the 90 sec test trial they received a sc injection of 61, 71, 84, 98 or 115 µg/kg sarin or saline (N=7-8/group). Doses of 98 and 115 µg/kg noduced performance decrements that differed significantly from sal ine control values. The ED50 was 95 µg/kg sarin. In Exp 3, locomotor activity was measured by placing an animal into an open-field (41 X 43 cm) and determining the number of photobeam interruptions in a 30 min test. Al1 animals received three 30 min acclimation trials and were administered 61, 71, 84, 98, 115 µg/kg sarin or saline vehicle 30 min prior to the fourth (test) trial (N=6/group). Motor activity was significantly decreased from control values for the two highest doses and the ED50 was calculated using seven d
- 39.8 HYPERTHERMIC RESPONSES TO THYROTROPIN RELEASING HORMONE (TRH) AND CHOLERA ENTEROTOXIN (CE) ARE MEDIATED BY DIFFERENT MECHANISMS. M. Cohn, D. Taube\*, D. J. Wooten\*, and M. L. Cohn. Dept of Anesthesiology Research, C.R. Drew Med Sch, Los Angeles, CA 90059

Anesthesiology Research, C.R. Drew Med Sch, Los Angeles, CA 90059 Anti-inflammatory steroids (AIS) and nonsteroidal anti-inflammatory drugs (NSAID) have been shown to inhibit prostaglandin (PR) synthesis. While a strong correlation has been established between anti-inflammatory properties of both groups of drugs and their potencies as inhibitors of PR synthesis, AIS have been found to inhibit phospholipase activity and NSAID to directly inhibit PR synthetase complex. Data indicating that thermic response to TRH is blocked by NSAID (Cohn et al, 1980) combined with reports that antipyretic properties of NSAID are also associated with PR inhibition suggested that TRH produces hyperthermia by stimulating PR synthesis and release. More recent observations that AIS fail to suppress thermic response to TRH (Cohn et al, 1983) suggest that antipyretic activities of AIS and NSAID are regulated by different mechanisms. To test further this hypothesis, we compared here the antipyretic effects of AIS and NSAID on thermic responses to TRH and CE. Male Sprague-Dawley rats (250g) were implanted with cannulae secured 2 mm above proptic anterior hypothalamic (PO/AH) nuclei. After 10-day recovery period, rats were treated with either lysine acetylsalicylate (.32  $\mu$ M), tolmetin (.40  $\mu$ M), acetaminophen (.10  $\mu$ M), hydrocortisone sodium succinate (HSS -.03 - .7  $\mu$ M) or the vehicle phosphate buffer injected into PO/AH 5 min prior to injection of either TRH (.003 - .14  $\mu$ M) or CE (.2 ug) into same locus. Test substances were freshly prepared, Millipore filtered and injected over 60 sec period in constant volume of .5 ul into PO/AH through injection needles 2 mm longer than guide cannulae. Equipment was sterilized prior to use. Temperature (T<sup>0</sup>) was recorded every 30 min for 3 h prior to treatment and every 15 min thereafter with thermistor probe inserted 6 cm into colon. Groups consisted of at least 6 rats for each drug and dose. Each rat was used once; sites of injections were histologically confirmed upon completion of ABSI INENCE SYNDROME FOLLOWING CONTINUOUS INFUSION OF CLONIDINE. R.J. Exley\*, D.H. Malin, A.G. Hempel\* and T.H. Schauweker\*. Univ. of Houston-Clear Lake, Houston, Tx. 77058. The alpha-2 adrenergic agonist, clonidine, has a number of op-iate-like actions. These include sedative, anxiolytic, analgesic and respiratory-depressing effects. In addition, like the op-iates, clonidine can potently reverse many symptoms produced by optiate abstinence and continuous naloxone infusion. In view do these similarities, it was hypothesized that continuous clonidine infusion might produce a state of dependence similar to opiate dependence.

Four male rats were implanted s.c. under either anesthesia with Alzet model 2001 osmotic minipumps filled with 4 mg/ml clonidine in normal saline. These rats received .033 mg/kg/hr.cloni-dine on a continuous basis. Four other rats were implanted with osmotic minipumps filled with saline alone. After 120 hrs. of dine on a continuous basis. Four other rats were implanted with osmotic minipumps filled with saline alone. After 120 hrs. of infusion, all pumps were removed. Twenty four hours after removal, all animals were observed for 15 min. for standard behavioral signs seen in opiate withdrawal. The clonidine abstinent group displayed 23.0  $\pm$  2.3 symptoms (mean  $\pm$  SEM), while the control group displayed 1.2  $\pm$  .9 symptoms. This difference was significant, p <.001. The clonidine abstinent group had highly elevated numbers of wet-dog shakes, head shakes, abdominal writhes.

elevated numbers of wet-dog shakes, head shakes, abdominal writhes, scratches and teeth chattering. At 25 hours post pump removal, all animals received a low sub-cutaneous dose of morphine sulphate (4 mg/kg). Fifteen minutes later, all rats were observed again. As in opiate abstinence syn-drome, morphine virtually reversed the symptoms. The clonidine-abstinent group and the control group had 2.5  $\pm$  1.8 and 0  $\pm$  0 symptoms, respectively. By the 39 hours post pump removal, the clonidine abstinent group again had significantly more overall symptoms than the control group: 18.8  $\pm$  3.9 vs 3.8  $\pm$  2.4, respec-tively. At 40 hrs. post pump removal, all rats were injected with .033 mg/kg clonidine s.c. Fifteen minutes post injection. with .033 mg/kg clonidine s.c. Fifteen minutes post injected with .033 mg/kg clonidine s.c. Fifteen minutes post injection, all rats were observed again. Once more, the symptoms were vir-tually reversed. The clonidine abstinent group and the control group had 0.5  $\pm$  0.3 and 0  $\pm$  0 overall symptoms, respectively. The present findings may be consistent with several reports

in the clinical literature of patient distress following abrupt termination of clonidine treatment. The present findings may also have implications regarding mechanisms of opiate dependence. One of the many effects of opiates is suppression of brain adren-ergic systems. The data presented here suggest that prolonged suppression of advances customs along may be sufficient to prosuppression of adrenergic systems alone may be sufficient to pro-duce a state of dependence, and account for certain behavioral symptoms of opiate abstinence syndrome.

39.11 INTRACEREBRAL INFUSIONS OF CARBACHOL AFFECT MALE SEX BEHAVIOR. E. M. Hull, D. Bitran\*, E. A. Pehek\*, and L. G. Clemens. Dept. of Psychology, State Univ. of New York at Buffalo, Amherst, NY 14226; and Dept. of Zoology, Michigan State Univ., East Lansing, MI 48824, Feminine sexual behavior is facilitated by intracerebral infu-sions of cholinergic agonists in male and female rats. This facilitation is blocked by peripheral injections of the muscarinic an-tagonist atropine. Peripheral cholinergic manipulations in male

rats have yielded contradictory results, suggesting variously that cholinergic mechanisms facilitate, impair, or fail to affect mas-culine sex behavior. The effects of central cholinergic manipulations on masculine sex behavior have not been explored previously. The medial preoptic area (MPOA) is an important regulatory area

The medial preoptic area (MPOA) is an important regulatory area for the expression of masculine sex behavior. Preoptic lesions disrupt copulation, while electrical stimulation of the area facil-itates it. Furthermore, testosterone implanted in the MPOA re-stores copulation in castrated males. The present study investi-gated the effects on masculine sex behavior of the cholinergic agonist carbachol, infused into the MPOA and the lateral ventri-cles (IV) cles (LV).

Cannulae were implanted bilaterally in the MPOA or the LV of when compared to vehicle, infusion of carbachol into the Volume into the Volume interval and the vehicle was shown into the vehicle was shown into the vehicle was shown into the vehicle vehicle with a receptive female began immediately and lasted until 30 min after the first intromission. When compared to vehicle, infusion of carbachol into the LV

significantly delayed the onset of masculine sex behavior. Infusions of carbachol into the MPOA also increased the latency to begin copulation, but then decreased the number of intromissions required for an ejaculation. Other measures of sex behavior, including the time interval between intromissions, were not significantly altered by carbachol infusions.

These data may suggest a cholinergic inhibition of sexual arousal in male rats, and a more localized cholinergic enhancement, within the MPOA, of a copulatory mechanism. (This research was supported in part by USPHS Grant HD-06760 to

LGC and by BRSG Grant 2S07RR0706617 to EMH.)

39.10 NORADRENERGIC MEDIATION OF ETHANOL INDUCED DEPRESSION OF LOCOMOTOR ACTIVITY, <u>M. Abitbol\*, C.M.G. Aragon\*</u>, Z.W. Brown,and Z. Amit. Center for Studies in 2. A. Diowi, and 2. Anto. Center for Stores in Behavioural Neurobiology, Concordia University, 1455 DeMaissoneuve Blvd., Montreal, Que. Canada, H3C1M7. The effect of FLA-57 on ethanol induced excitation

and depression of locomotor activity was tested in the open field. Male Long Evans rats were pretreated with open field. Male Long Evans rats were pretreated wit the dopamine-beta-hydroxylase inhibitor,FLA-57 (30mg/kg), or saline for five days.On day six rats were intraperitoneally injected with either one of three doses of ethanol (0.5,0.8 or 2.0gm/kg), or saline and were then immediately placed in the open field. Locomotor activity was measured at 5 minute intervals for a 30 minute period. Immediately after the 30-minute period animals were sacrificed by docamitation. Twok blood was collected and even decapitation. Trunk blood was collected and gas chromatographic analysis was used to determine blood ethanol levels.

The brains were rapidly extracted and then assayed by High Pressure Liquid Chromatography (HPLC) with electrochemical detection. No variation in the levels of ethanol were found in animals pretreated with FLA-57 or saline. HPLC norepinephrine determinations revealed that whole brain NE levels were reduced by 25% in comparison to controls.

The results show that treatment in all three doses of ethanol produces a dose dependent depression of or exhance produces a dose dependent depression of locomotor activity and this depression seems to be attenuated with animals pretreated with FLA-57. In addition, it is interesting to note that significant positive correlations were found between activity and NE levels in saline-saline animals. Data also indicate a significant negative correlation between activity and ethanol levels in saline-ethanol animals with all three doses. No significant correlations between activity and NE levels or activity and ethanol levels were found with groups receiving FLA-57 pretreatment. The results are discussed in terms of the possible role of the central noradrenergic system in the effects of ethanol on locomotor activity.

39.12 EFFECTS OF PYRIDOSTIGMINE AND SOMAN ON OPERANT BEHAVIOR IN THE RAT H.E. Modrow\* and J.H. McDonough. (SPON: B. Hackley). U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010.

Anticholinesterase compounds typically depress behavioral out-puts in a variety of behavioral test situations. This depression of behavior affords a distinct end-point in the study of the toxicology of these compounds. Recovery of normal behavior provides another objective measure of the impact of toxic compounds on behavioral function. The purpose of the present study was to com-pare the effects of two anticholinesterase compounds, the peripherally acting reversible carbamate, pyridostigmine, and the centrally active irreversible organophosphate, soman, on steady-state variable interval (VI) operant performance in rats.

variable interval (VI) operant performance in rats. Twenty-three rats were trained to lever press for sweetened milk reinforcement on a VI-60 schedule. Session length was 60 min with responses printed out in five min blocks. A performance sta-bility criterion of  $\leq \pm 10\%$  variation from the mean of three con-secutive days performance was imposed on each animal for each drug test. Pyridostigmine Br (vehicle, 0.01, .032, .10, .32, 1.0 mg/kg) was administered i.m. according to a Latin square design. Testing began immediately following injection, thus allowing ob-servation of both the onset and decline of drug effect. Following completion of the pyridostigmine dose effect curve, the rats were tested with one of five doses of soman, 45.6, 50.0, 54.8, 60.1, or  $65.9 \ \mu g/kg$ . Although the test was conducted identically to the pyridostigmine tests, each animal was tested at only one dose of soman due to its permanent bond with the cholinesterase molecule.

Low doses of pyridostigmine did not appear to have a effect on performance. Only 1.0 mg/kg pyridostigmine produced a significant reduction in responding, a decline to approximately 67% of base-line levels. Soman-induced effects were markedly dissimilar. Total cessation of operant responding was seen in nearly all ani-The time to cessation of responding was found to be dose mals. dependent.

Operant response rates returned to baseline levels within two Operant response rates returned to baseline levels within two days after every dose of pyridostigmine. This was not the case with soman. Toxicity was seen after the three highest doses. The surviving animals at the dose of 54.8 µg/kg soman rapidly reattained baseline levels of performance. However, surviving animals tested at 60.1 and 65.9 µg/kg soman required in excess of nine days to return to baseline levels. This effect may be due to tolerance, as cholinesterase levels were still very low, or simply to recovery from the acute debilitating effects of soman exposure.

39.13 BEHAVIORAL EVIDENCE THAT NICOTINE ADMINISTRATION HAS ANXIOLYTIC ACTIONS IN RATS. C.A. Sorenson and L.O. Wilkinson\*. Neuroscience Program, Amherst College, Amherst, MA 01002. A series of experiments was designed to examine possible

A series of experiments was designed to examine possible anxiolytic actions of nicotine using the acoustic startle response (ASR), a skeletal reflex elicited by the presentation of a loud tone, and the potentiated startle effect (PSE), an increase in the magnitude of the reflex which occurs if the tone is presented during a light stimulus previously paired with footshock. Since all known anxiolytic drugs depress or block the PSE, it appears to be a valid model of anxiety.

The first experiment tested the effect of nicotine administration on the PSE. Rats were trained over a two day period to associate a dim light with footshock. On the following day, they were presented with 80 115 db tones, of which half were accompanied by the light. Half of these animals were pre-injected with .4 mg/kg nicotine, s.c., and the others received the saline vehicle. Nicotine treated rats showed a significant attenuation of the PSE with no change in startle baseline. Thus, nicotine appears to have anxiolytic properties by this test.

.4 mg/kg nicotine, s.c., and the others received the saline vehicle. Nicotine treated rats showed a significant attenuation of the PSE with no change in startle baseline. Thus, nicotine appears to have anxiolytic properties by this test. The second experiment tested the effect of nicotine withdrawal on baseline ASR. It was predicted that if nicotine has anxiolytic effects, animals withdrawn from chronic treatment should show a rebound anxiogenic effect. Two groups of rats were administered a low (approximately 3 mg/kg) and a high (approximately 15 mg/kg) dose of nicotine in their drinking water. Rats withdrawn after 10 days from the high dose and tested daily for 4 days with 40 tones showed a significant increase in ASR on day 3 of withdrawn after 15 days from the low dose showed no change in ASR amplitude compared to controls on each of the 4 daily tests following withdrawal.

drawal. The third experiment examined the possible locus of action of nicotine by comparing the effects of nicotine and diazepam administration on the increase in ASR produced by treatment with 5.0 mg/kg of the anxiogenic drug, yohimbine, which is known to increase locus coeruleus unit activity. Yohimbine-enhanced startle appeared to be partially depressed by the administration of 1.25 mg/kg diazepam, i.p., whereas the administration of .4 mg/kg nicotine, s.c., had no effect on yohimbine-enhanced startle. These results suggest that the anxiolytic effects of diazepam and nicotine are mediated at least in part by different neural mechanisms. 39.14 DOES NICOTINE STIMULATE LOCOMOTOR ACTIVITY BY ACTING CENTRALLY? P.B.S. Clarke\* and R. Kumar\* (SPON: R. J. Dooling) Dept. of Psychiatry, Institute of Psychiatry, London SE5 8AF, U.K. We have previously reported that in non-tolerant rats,

We have previously reported that in non-tolerant rats, (-)-nicotine depressed and then increased locomotor activity. With repeated drug testing, the initial depressant action was replaced by a marked stimulation which was prevented by systemic injection of the secondary amine mecamylamine, but not by systemic injection of the quaternary ganglion blocker hexamethonium. Since neither nicotinic antagonist altered locomotor activity when given alone, we suggested that nicotine may increase locomotor activity by stimulating central receptors (<u>Br. J.</u> <u>Pharmac. 78</u>, 329-37). However, hexamethonium has surprisingly low peripheral potency in rats (Romano C. <u>J. Pharm. Exp. Ther.</u> <u>217</u>, 828-33, 1981), and so we have reexamined this conclusion using another quaternary nicotinic antagonist, chlorisondamine. As previously described, rats were tested for gross locomotor activity in photocell cages, for 80 minutes starting immediately after sc injection of (-)-nicotine bitartrate (neutralized, dose as base) or saline (control). The first experiment investigated whether the development of

The first experiment investigated whether the development of tolerance depended on repeated exposure to the photocell cages. Male rats were randomly allocated to 4 groups, each of 8 subjects. Groups 1 and 2 were tested daily for 5 consecutive days with saline and nicotine (0.4 mg/kg), respectively. The remaining two groups received equivalent injections of saline or nicotine in their home cages and were not tested. On days 6 and 7, all 32 subjects were tested once with nicotine (0.4 mg/kg) and once with saline, counterbalanced within each group. Tolerance to the locomotor depressant action occurred only in rats pretreated with finitorial functions familiarity.

Subsequent experiments employed nicotine-tolerant rats. Locomotor activity was increased in a stereospecific way; (-)-nicotine (0.1-0.4 mg/kg) was about ten times more potent than (+)-nicotine (0.4-1.6 mg/kg). Mecamylamine (1.0 mg/kg), given sc either 20 minutes before or 20 minutes after nicotine (0.4 mg/kg), blocked the drug's stimulant action. Pretreatment with chlorisondamine (0.01, 0.1 mg/kg sc) had little or no such effect, whereas 2  $\mu$ g (base) given intraventricularly completely prevented the nicotine-induced locomotor stimulation for at least three weeks. Neither antagonist altered locomotor activity in saline test sessions.

Thus a few injections of nicotine, rather than apparatus familarity, unmasked a marked locomotor stimulant action which may reflect a tonic stimulation of brain nicotine receptors. Intraventricular injection of chlorisondamine produced an extremely long-lasting blockade of this central action.

# PEPTIDES: BIOCHEMICAL CHARACTERIZATION

40.1 THE DISTRIBUTION, CHROMATOGRAPHIC CHARACTERIZATION, AND RECEPTOR INTERACTION OF A PHI-LIKE PEPTIDE IN RAT AND PORCINE BRAIN. <u>M. C. Beinfeld\*, D. M. Korchak\*, B. L. Roth\* and T. L. O'Donohue</u> (SPON: C. L. McLaughlin). Dept. Pharm., St. Louis Univ. Med. Sch. 1402 S. Grand Blvd., St. Louis, MO 63104 and NINCDS, Bethesda, MD 20205.

PHI (acronym for a peptide with a C-terminal histidine and a N-terminal isoleucine amide) is a recently discovered porcine intestinal peptide with strong sequence homology with VIP, secretin, glucagon, GIP (gastric inhibitory peptide), and hGRF (human growth hormone releasing factor). PHI shares many biological actions of VIP, though is frequently less potent than VIP.

Preliminary studies by Christofides <u>et al</u>. indicate that brain contains a PHI-like peptide with a distribution identical to VIP. This observation was confirmed by the isolation of PHI from porcine brain by Tatemoto <u>et al</u>. A PHI-specific antiserum with weak cross-reactivity with

A PHI-specific antiserum with weak cross-reactivity with secretin (0.65%) and glucagon (0.46%), but none with VIP, GIP, hGRF, or motilin was developed and used to characterize and measure PHI peptides in rat and porcine brain.

In agreement with Christofides <u>et al</u>, the distribution of PHI in the rat brain closely follows that of VIP. In most of the areas the PHI and VIP concentrations were the same within experimental error. Highest PHI/VIP levels were in cerebral cortex, amygdala, hippocampus, anterior hypothalamus, and striatum. The cerebellum and pineal were very low in both VIP and PHI. In porcine brain the VIP content is much lower than rat brain and the PHI levels are correspondingly lower. This high correlation between the distribution of VIP and PHI agrees with the suggestion of Christofides <u>et al</u>. that PHI and VIP may arise from the same precursor.

C18 HPLC analysis of porcine brain extracts reveals a single peak of PHI-like immunoreactivity which co-clutes with synthetic PHI but which separates from secretin, motilin, and VIP. Rat brain extracts, run on either C18 HPLC or phenyl HPLC chromatographic systems, contain a single PHI-like peptide which separates from porcine PHI, eluting earlier by several minutes. This rat PHI peptide also separates from secretin, VIP, and motilin. This data suggests that rat brain contains a PHI-like peptide with similar but not identical amino acid composition to porcine PHI, which is slightly less hydrophobic. We also determined that PHI had high affinity for inhibition of ( $^{125}$ I)-VIP binding in rat brain. In general, PHI had an IC<sub>50</sub> of 20-30 M M in rat forebrain and approximately 300 nM in rat cerebellum. These data indicated that PHI could serve as an endogenous modulator of VIP binding in rat brain.

Supported in part by NIH NS-18335 and a grant from the American Parkinson Disease Association.

40.2 PHE-MET-ARG-PHE-NH-2-LIKE IMMUNOREACTIVITY IN RAT SPINAL CORD: DISTRIBUTION, CHARACTERIZATION AND BIOLOGICAL ACTIVITY. H.-Y. T. Yang, J. Tang\* and E. Costa, Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032 Previously, we have determined that Try-Cly-Gly-Phe-Met-Arg-Phe (VCCEMPE) is unsured with the distributed in set reincleared During the source

Previously, we have determined that Iry-Gly-Gly-Phe-Met-Arg-Phe (YGGFMRF) is unevenly distributed in rat spinal cords. During the course of this study, Phe-Met-Arg-Phe-NH<sub>2</sub> (FMRF-NH<sub>2</sub>)-like immunoreactivity in rat central nervous system including spinal cord was described by immunohistochemical technique (Weber et al., Science <u>214</u>;1248, 1981). Because of the structural similarity between these two neuropeptides, we have decided also to study, in rat spinal cord, the distribution, biochemical characterization and biological activity of FMRF-NH<sub>2</sub>-like peptide. Antiserum to FMRF-NH<sub>2</sub> was prepared by immunizing rabbits with FMRF-NH<sub>2</sub>-hemocyanic conjugate. The antiserum shows no significant affinity for CCK 8, CCK 4, substance P, met-enkephalin but cross-reacts with YGGFMRF very slightly (0.1%). Rostro-caudally, FMRF-NH-like immunoreactivity is evenly distributed ranging from 0.21 ± 0.01 to 0.29 ± 0.02 for cervical to sacral region. With respect to dorso-ventral distribution, FMRF-NH<sub>2</sub>-like immunoreactivity and list ± 0.01). The values are calculated as pmol FMRF-NH<sub>2</sub> equivalent per mg protein. Biochemical analysis of the immunoreactive material by gel filtration and reverse phase chromotography revealed that the main endogenous FMRF-NH<sub>2</sub> like material, similarly to authentic FMRF-NH<sub>2</sub>, is reduced by CNBr, almost totally abolished by trypsin, but not affected by carboxypeptidase A treatment. The results indicate that the endogenous FMRF-NH<sub>2</sub>-like material is similar to but not identical to authentic FMRF-NH<sub>2</sub> limmunoreactive material was partially purified by antibody-sepharose affinity column chromatography from bovine medulla oblongata and its analgesic activity tesduced the analgesia elicited by YGGFMRF.

40.3 HETEROGENEITY OF LUTEINIZING HORMONE RELEASING HORMONE-IMMUNOREACTIVITY STUDIED USING A MONOCLONAL ANTIBODY. <u>Richard J. Knapp\*</u> and <u>Ludwig A. Sternberger\*</u> (SPON: Shailesh P. Banerjee). Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, N.Y. 14642.

Sch. of Med., Rochester, N.Y. 14642. Different studies have presented evidence for the presence of extended forms of luteinizing hormone releasing hormone (LHRH) in the hypothalamus and elsewhere. These studies have depended on low resolution gel filtration chromatography and antisera-based RIA for the characterization of these immunoreactive substances. Using a high affinity (Kd = 2.2 x  $10^{-10}$ M) monoclonal antibody against LHRH, we were able to determine the anatomical distribution and concentration of hypothalamic immunoreactivity and, in addition, isolate high molecular weight material by combined dialysis and immunoaffinity chromatography.

In the isolation procedure, hypothalami dissected from male Sprague-Dawley rats were extracted with 2N acetic acid and the insoluble material removed by centrifugation. LHRH was removed from the extract by dialysis against 2N acetic acid using dialysis tubing having a molecular weight cutoff of 2,000. The acetic acid was replaced by 1mM H<sub>3</sub>PO<sub>4</sub> in a second dialysis step. Insoluble material was removed after four washes in buffer by centrifugation and neutralized with NaOH. Monoclonal antibody immobilized on CH Sepharose 4B was then added to the combined soluble material. Following incubation, the gel was packed into a syringe column, washed with high ionic strength buffer, rinsed with saline and eluted with 10mM  $H_3PO_4$ .

With the theorem is a second state of the second state of the second state of the state of the

40.4 DELTA-SLEEPING-INDUCING PEPTIDE (DSIP): OCCURRENCE IN DIFFERENT FORMS. <u>Markus Graf\* and Abba J. Kastin</u>. VA Medical Center and Tulane University School of Medicine, New Orleans, LA. 70146. DSIP has been isolated from the blood of sleeping rabbits and, in 1977, characterized as a nonapeptide. Measurement by RIA show-

ed this peptide to occur in brain and plasma mainly in a large molecular form. We have now assayed DSIP levels in peripheral organs of the rat by RIA after extraction of the tissue with water, a procedure yielding a 10x higher level of immunoreactive than after acid extraction. The measurable amount of DSIP-DSIP than after acid extraction. The measurable amount of DSIP-like material decreased in frozen organs to about 50% over 5 months of storage. Although no marked differences due to the tem-perature ( $-20^{\circ}$ C or  $-80^{\circ}$ C) of storage were found, stability seemed to be better at  $-80^{\circ}$ C, at least for the first month. DSIP-like material was found in all rat organs tested. The levels (per mg wet weight tissue + SEM) were: stomach 849 + 41 pg, kidney 799 + 59 pg, jejunum 730 + 36 pg, duodenum 627 + 63 pg, pancreas 539 + 83 pg, spleen 521 + 18 pg, thymus 484 + 23 pg, ileum 455 + 40 pg, colon 331 + 26 pg, adrenal 270 + 22 pg, liver 268 + 32 pg, and muscle 86 + 7 pg. The low value in muscle is still 10x higher than the amount of immunoreactive DSIP in blood. The rank order of the organs according to their content of DSIP-material was similar whether levels were based on mg wet weight or mg protein. Based on organs according to their content of DSIr-material was similar whether levels were based on mg wet weight or mg protein. Based on protein, the parts of the intestine showed increased levels com-pared to the other organs; e.g. in jejunum and duodenum these levels were significantly (pc0.01) higher than in stomach. Gel-chromatography on Sephadex G-15 and G-25 of organ extracts (spleen, liver and jejunum) revealed DSIP-like material mostly larger in size than DSIP. The amount of small DSIP-like material was determined by preadsorption to charcoal-dextran. At tissue concentrations of 2mg/ml, charcoal-dextran did not remove much DSIP-like immunoreactivity. At higher concentrations of the tissues (>2mg/ ml), even more DSIP-like structures were found after treatment with charcoal. Addition of synthetic DSIP resulted in a recovery of around 80% in stomach, jejunum, spleen, and thymus apparently independent from the concentrations of the homogenates. At a liver concentration of 4mg per ml, however, no increase of DSIP was found after addition of synthetic peptide to the homogenate. Yet with decreasing concentrations of the homogenate to less than lmg ml, the recovery of the added peptide increased to reach about 80%. These results suggest a binding process with masking properties at higher concentrations. We find  $\alpha$ -globulin to be responsible for at least part of this binding effect. Albumin and iron ions (1 mM) also appear to be able to bind or aggregate DSIP. We conclude that in the periphery, DSIP is present in a bound form with only minor amounts freely available at more physiological conditions.

40.5 PICROTOXININ AND PMA STIMULATE THE SECRETION OF MULTIPLE FORMS OF SOMATOSTATIN FROM CULTURED RAT BRAIN CELLS. <u>R. A. Peterfreund</u> and <u>W. Wale</u>. Peptide Biology Laboratory, The Salk Institute, La Jolla, California 92037. Picrotoxinin (PTX) and Phorbol 12-myristate, 13-acetate (PMA)

are two effective stimulators for secretion of somatostatin like immunoactivity (SSLI) from dispersed cells of fetal rat brain maintained in long term primary culture. Previous work in vivo using electrical stimulation and our own investigations in vitro with potassium depolarization have suggested that secreted SSLI is composed of at least two molecular forms, authentic somatostatin 14 (SS14) and a 28-residue, amino terminally extended form of somatostatin,SS28. The present experiments were intended to identify the molecular forms of SSLI secreted by cultured hypothalamus cells following stimulation by PMA or PTX. Hypothalamus tissue from fetal day-18 Sprague Dawley rats was enzymatically dispersed with collagenase and plated in a serum supplemented medium on poly-D-lysine coated dishes. On day 10 in culture, cells were washed with Krebs Ringer solution, allowed to equilibrate and then treated with either PMA (100 nM), PTX (5  $\mu$ M) or high potassium Krebs Ringer solution (59 mM, isotonic). Medium was collected into an equal volume of 2N acetic acid containing protease inhibitors, heated, cooled and applied to Bond Elut C18 reverse phase cartridges for concentration, desalting and deproteinizing. SSLI was eluted with a solution of  $CH_3CN/TEAF$ , collected into glass tubes and lyophilized. The dried material was resuspended in TEAF and applied to a Waters µBond Pak Cl8 reverse phase HPLC column eluted with a gradient of CH<sub>3</sub>CN. Three main peaks were recovered from stimulation buffer of cells treated with PMA, PTX or 59 mM K+ as determined by RIA with antiserum S201, which detects the central portions of SS14. Peak l comigrated with synthetic SS28 and represented 10-15% of total recovered SSLI. Peak 2 coeluted with synthetic SS14 and repre-sented 70-80% of total recovered SSLI. Peak 3, representing 10% of SSLI eluted after SS14 (more hydrophobic). Only Peak 2 was detected by antiserum S39 which is directed towards the amino terminus of SS14. All three peaks were also detected in acetic acid extracts of cultured hypothalamus cells. Together the data suggest that PTX and PMA, as well as 59 mM K+, stimulate the release of at least two forms of somatostatin from brain cells in vitro. The major form appears to be SS14. However, significant quantities of an SS28-like form of somatostatin are recovered. Since PMA and PTX may exert their action through receptors or receptor linked ionophores, the present findings are consistent with a possible receptor mediated release of SS28 in the brain.

40.6 THE EFFECTS OF MORPHINE ON GLUCOSE METABOLISM ( $C^{14}$ -2-DEOXY-GLUCOSE) IN RAT BRAIN AS MEASURED BY QUANTITATIVE AUTO-RADIOGRAPHY. E.M. Hiesiger\*, R.M. Voorhies\*, L. Lipschutz\*, G. Basler\*, W.R. Shapiro and G.W. Pasternak. Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, Departments of Neurology, Neurosurgery and Pharmacology, Cornell University Medical College, New York, N.Y. 10021 USA. The effect of opiates on cerebral ischaemia has become a timely issue in clinical and laboratory investigations. The two major parameters affecting ischaemia are tissue metabolism and blood flow. Using  $C^{14}$ -2-deoxyglucose (2DG) and quantitative autoradiographic technique (QAR), we measured the effect of acute morphine administration on local cerebral glucose utilization (LCGU) in awake adult rats. Five mg/kg of morphine was given intravenously as a bolus, ten minutes prior to LCGU determinations, lowering mean systolic pressure 7 mm Hg,  $P_a^{0}Q_2$  7.37 torr and pH .08. Mean  $P_aCO_2$  increased 10.13 torr and mean bicarbonate ion concetration rose by 1.7 mg %. During the course of the experiment, hemoglobin fell by 1.9 gms. Temperature was maintained at a physiologic level. During the expansion. Eleven gray and three white matter structures were examined. LGGU was depressed in a number of gray matter structures: caudate (-28%), priform cortex (-19%), medial geniculate (-30%), habenula (-32%), inferior colliculus (-25%), periventricular gray (-19%), amygdala (-16%), and hippocampus (-11%) showed no significant decrease in LGGU when compared to controls. However, statistical significance was achieved only in medial thalamus (po0.05) and habenula (po0.03), areas very rich in opiate receptors. Reductions in LCGU were also seen in some white matter regions: corpus callosum (-30%) and internal capsul (-46%), and anterior commissure (-4%). Although difficult to dissect from the effects of hypercapnia, morphine administered acutely to the rat at 5 mg/kg i.v., does decrease LGO. Further work is needed to

40.7 MOTILIN-LIKE PEPTIDES IN RAT AND PORCINE BRAIN: FURTHER CHROMATO-GRAPHIC, IMMUNOLOGIC, AND DEVELOPMENTAL STUDIES. <u>D.M. Korchak\*</u>, <u>G. Nilaver, T.L. O'Donohue and M.C. Beinfeld\*</u> (SPON: P.A. Young). Dept. of Pharmacol., St. Louis Univ. Med. Sch., 1402 S. Grand Blvd., St. Louis, MO 63104, Dept. of Neurology, Columbia Univ. College of Physicians & Surgeons, New York, NY 10032 and NINCDS, Bethesda, MD 20205.

We have previously reported the presence of motilin-like peptides detected by radioimmunoassay (RIA) and immunocytochemistry in rat and human brain. These early studies demonstrated that this motilin-like substance differs both immunologically and chromatographically from porcine intestinal motilin (PIM). To eliminate the possibility that these differences are due to rat <u>vs.</u> pig species differences, we have examined motilin-like peptides in porcine brain extracts.

Our preliminary results indicate that porcine brain, like rat brain, contains motilin-like peptides which also differ immunologically and chromatographically from PIM. Our conclusion from these results is that both porcine and rat brain contain motilinlike peptides which differ substantially from PIM and may represent a class of novel neuropeptides which share some immunologic determinants with PIM.

We have examined the development of this motilin-like immunoreactivity from 4 days prior to birth to greater than 180 days after in the forebrain, hindbrain, cerebellum, and pituitary of rats in comparison with VIP and CCK. In all regions examined, the motilin concentration was highest 4 days before birth and decreased after that time, with different time courses in different tissues. The motilin content in forebrain and hindbrain was about 50% of the maximum content 4 days before birth, was maximal at about 10-30 days, and decreased after that. In the cerebelum, the motilin content was about 10% of the maximum 4 days before birth, was maximal from about 5 to 40 days after birth and declined sharply afterward. In the pituitary, the motilin content was about 15% of the maximum 4 days before birth and rose gradually between 20 and 180 days. In contrast, the development of CCK and VIP was entirely postnatal. In both the forebrain and hindbrain both VIP and CCK rose slowly from day 1 and peaked between day 28 and 60. In forebrain and hindbrain the concentration of motilin, CCK and VIP was clearly decreased in the older animals.

The presence of substantial motilin immunoreactivity in the brain before birth is suggestive of a possible role for motilin in the regulation of development.

- 40.8 THE CEREBELLINS: ISOLATION OF TWO RELATED CEREBELLUM-SPECIFIC PEPTIDES. J. R. Slemmon\* J. Hempstead\* and J. Morgan\* (SPON: R. Chizzonite). Dept. of Physiol. Chem. and Pharmacol., Roche Institute of Molecular Biology, Nutley, N.J. 07110 Peptides could provide a useful tool for identifying specific cell types and metabolic specialities present in anatomically defined areas. In order to detect such peptides, tissue from various brain regions were analyzed on high performance liquid chromatography(HPLC). The work described here
  - specific teps and metabolic specialties present in anatomically defined areas. In order to detect such peptides, tissue from various brain regions were analyzed on high performance liquid chromatography(HPLC). The work described here centers on two such region-specific peptides, isolated from rat cerebellum, that share almost identical primary structure. The cerebelli were dissected from young rats (6-8 weeks) and immersed in liquid nitrogen. This material was held in a liquid nitrogen freezer until use. Frozen cerebelli (24 gms) were homogenized in 6M guanidine HCl using a Brinkman polytron, after which an equal volume of 1M pyridine acetate, pH 4, was added. The homogenate was centrifuged at 20,000g for 1 hr, and the supernate was passed through reversed phase preparative cartridges(Waters Assoc., Sep Pak Cl8, 20ml per cartridge). The two cerebellum-specific peptides were eluted from the cartridges in 0.1% TFA, 30% acetonitrile and taken to drymess. HPLC purification included two chromatographic systems. Initially the dried fractions were resuspended in 0.1% TFA amd separated by reversed-phase chromatography (Altex Ultrasphere ODS column, 1 x 25 cm) using a linear acetonitrile qradient. The peptides were eluted at 18% acetonitrile. The peptide-containing fractions were pooled, dried and resuspended in 0.1% TFA containing SmM SDS. This material was chromatographed in an ion-pairing system (Altex IP column, 0.46 x 25cm) employing 5mM SDS as the pairing reagent in all buffers. The peptides were eluted at 36% acetonitrile and showed baseline resolution. Amino acid analysis indicated the peptides differed by only one extra serine residue. Gas phase sequencing demonstrated one of the peptides contained an extra serine residue on the amino terminus. The carboxyl terminus proved resistant to exopeptidase treatment and preliminary evidence suggests it to be a modified glutamyl or glutaminyl residue.

The developmental time-course for these peptides indicated they appear about six days after birth and reach a maximum by approximately day twenty, and in general parallel the formation of the internal granular cell layer of the albino rat cerebellum.

40.9 DISTRIBUTION AND CHARACTERIZATION OF FMRFamide-LIKE PEPTIDES IN RAT BRAIN AND DICESTIVE SYSTEM. J.F. Bishop\* (SPON: R.P. White), W.W. Watson, J. Groome<sup>5</sup> and T.L. O'Donohue. Experimental Therapeutics Branch, NINCDS, Bethesda, MD 20205, and Dept. of Zoology, Univ. of New Hampshire, Durham, NH 03824. The molluscan cardioexcitatory peptide Phe-Met-Arg-Phe-NH<sub>2</sub> (FMRFamide) has recently been found in rat brain and may therefore serve a neuromodulatory or neurotransmitter role in mammals. Studies conducted in this lab have utilized a FMRFamide specific radioimmunoeascivity in the rat CNS and digestive system, and 2) the high pressure liquid chromatographic (HPLC) elution profile of immunoreactive FMRFamide in extracts of rat brain, pancreas, and duodenum. Preliminary experiments indicated that one of three FMRFamide-directed antisera generated in this lab was highly specific for the C terminal of FMRFamide, and the RIA consistently registered linear increases in FMRFamide equivalent immunoreactivity was assessed for 14 rat brain FMRFamide immunoreactivity was assessed for 14 rat brain

FMRFamide immunoreactivity was assessed for 14 rat brain regions, as well as for rat pancreas and duodenum. Highest concentrations were found in pancreas and duodenum, and within the brain, highest concentrations were found in septum, hypothalamus, and midbrain. Lowest concentrations were found in striatum and cerebellum.

In addition to tissue distribution, HPLC elution characteristics of the FMRFamide-like substance were examined. Results of reverse phase HPLC of brain, pancreas, and duodenum indicated that three separate immunoreactive peaks were present in each tissue. All three peaks eluted significantly later than standard FMRFamide-like material, the presence of FMRFamide bioactivity in this region was examined using the <u>Busycon</u> radula protractor muscle bioassay. Significant levels of FMRFamide bioactivity were detected in extracts of this tissue.

Although the precise structure of the FMRFamide-like peptides remains to be determined, their widespread distribution indicates possible central and peripheral roles. 40.10 CHARACTERIZATION OF PANCREATIC POLYPEPTIDE IMMUNOREACTIVITY IN RAT BRAIN USING A C-TERMINAL HEXAPEPTIDE (CTH) ANTISERUM. D.A. DiMaggio\*, J.A. Olschowka, D.M. Jacobowitz, K.Buchanam<sup>\*</sup> and T.L. O'Donohue (SPON: B. Turner). Experimental Therapeutics Branch, National Institute of Neurological and Communicative Disorders and Stroke, and Laboratory of Clinical Science, National Institute of Mental Health, National Institutes of Health, Bethesda, MD 20205 and The Queen's University of Belfast, Belfast Ireland.

In previous immunocytochemical studies (Olschowka et al. <u>Peptide</u> 2:309-331, 1981) an extensive system of bovine pancreatic polypeptide-like immunoreactive neurons was identified in rat brain. However, when using the antibody employed in these studies for radioimmunoassay of brain tissue, essentially no immunoreactive material could be measured. As there is interspecies variation in the structure of pancreatic polypeptide (PP), it was hypothesized that the radioimmunoassay for bovine PP may not recognize rat PP. Since the C-terminal hexapeptide (CTH) of PP is relatively conserved between species, an antibody was generated in rabbits against CTH-amide conjugated to succinylated thyroglobulin. Using the C-terminally directed antisera, PP-like immunoassay. Antibody specificity was assessed with various structurally related peptides. No cross reactivity of CTH free acid was found in the RTA at doses up to 1 uM, but some cross reactivity was evident with neuropeptide Y (NPY, 0.02\$).

When used immunocytochemically, the CTH-directed antiserum stained the same neuronal system in rat brain as did the BPP antiserum. Preabsorption of each antisera with the respective hapten (1 uM) eliminated staining. In addition, a decrease in staining was apparent following preabsorption of both antisera with NPY (1 uM).

Gel filtration chromatography and radioimmunoassay of pancreas tissue produced a single peak of immunoreactivity eluting considerably later than BPP and NPY, suggesting the peptide has a lower molecular weight than these peptides.

Fractionation of brain and pancreas tissue by reverse phase high performance liquid chromatography resulted in a major CTHimmunoreactive peak at 28% acetonitrile as well as an occasional peak eluting earlier. The CTH-immunoreactive material eluted prior to both NPY and BPP.

Consistent with the HPLC and gel filtration data suggesting that rat brain and pancreas immunoreactive peptide is distinct from NPY or BPP is data obtained from a preliminary amino acid analysis of HPLC purified immunoreactive peptide from pancreas. Further studies are now in progress to identify the structure of brain and pancreas CTH-immunoreactive material. 41.1 SPECIFIC, CALCIUM-DEPENDENT ACTIVATION OF CYCLIC AMP ACCUMULATION BY VASOACTIVE INTESTINAL PEPTIDE (VIP) IN RAT HIPPOCAMPAL SLICES. <u>Anne M. Etgen and Edward T. Browning</u>. Dept. Biol. Sci., Rutgers Univ., New Brunswick, NJ 08903 and Dept. Pharmacol., Rutgers Med. School, Piscataway, NJ 08854. The intraneuronal localization of VIP and its release from synaptosomes and brain slices by depolarizing agents suggest that this pantide may same as a nourotherprinter on purported later

The intraneuronal localization of VIP and its release from synaptosomes and brain slices by depolarizing agents suggest that this peptide may serve as a neurotransmitter or neuromodulator. Because the greatest endogenous levels of VIP are found in higher brain centers (e.g., cerebral cortex and limbic system, including the hippocampus) and VIP is a stimulator of adenylate cyclase, we examined its effects on cAMP accumulation in rat hippocampal slices. Transverse slices (350 µm) from ovariectomized adult female rats were equilibrated for 1 hr, incubated with VIP under various conditions, and cAMP extracted and quantified using a competitive protein binding assay. VIP (10 µM) produced rapid (16-fold in 1 min) and striking elevations of hippocampal slice cAMP content (approximately 140-fold in 30 min). In contrast, other peptides (e.g., glucagon, somatostatin, enkephalins, LHRH, ACTH analog, arginine-vasopressin) produced little or no change in cellular cAMP levels. Two-fold elevations in CAMP were seen with VIP concentrations as low as 20 nM; the cAMP response was half maximal a 1 µM VIP and maximal between 10 and 20 µM. At maximally effective concentrations, VIP was 86% as effective in increasing cAMP as maximal concentrations of forskolin, a compound which activates adenylate cyclase in most cell types. Further experiments demonstrated that removal of calicum from the bathing medium severely attenuated the ability of VIP to stimulate cAMP accumulation in hippocampal slices; the addition of EGTA to the bath decreased the cAMP response further. Moreover, VIP-induced cAMP elevations in cellular cottex also responded to VIP with 30-50-fold elevations in cellular cottex) also responded to VIP with 30-50-fold elevations in cellular cottex also presponded to VIP with 30-50-fold elevations in cellular cottex also presponded to VIP with 30-50-fold elevations in cellular cottex also responded to VIP with 30-50-fold elevations in cellular cottex also responded to VIP with 30-50-fold elevations in cellular cottex also resp

Supported by USPHS Grants MH 36041 and BRSG RR 07058 and NSF Grant BNS 81-10564. 41.2 DEVELOPMENT OF VIP-STIMULATED ADENYLATE CYCLASE IN THE RABBIT RETINA. Jonathan A. Pachter\* and Dominic <u>Man-Kit</u> Lam (GPON: peter Kellavay). Program in Neuroscience and Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030. In the adult rabbit retina, vasoactive intestinal polypeptide (VIP) immunoreactivity has been detected and localized in sublaminas 1 and 5 of the inner plexiform layer (Tornqvist et al., Histochem. 76:137). Although the function of VIP in the retina is unknown, it has been shown to be a very potent stimulator of adenylate cyclase activity in the adult rabbit retina (Schorderet et al., Eur. J. Pharmacol. 71:131). In order to study the development of putative postsynaptic VIP receptor systems, we have investigated the maturation of VIP-stimulated adenylate cyclase activity in the developing rabbit retina. Several correlations were found between the time courses of development of VIP-stimulated adenylate cyclase activity and the previously described development of dopamine-stimulated CAMP formation in the rabbit retina (CAMP form

of VIP-stimulated adenylate cyclase activity and the previously described development of dopamine-stimulated cAMP formation in the rabbit retina (Pachter and Lam, ARVO '83). VIP-stimulated activity is evident at birth and rises sharply at approximately postnatal day 6 (D6). This rise in the stimulatory potency of VIP is concurrent with a similar sharp increase in dopamine-stimulated adenylate cyclase activity. VIP-stimulated activity reaches adult levels approximately two weeks after birth, which is shortly after the rabbits first open their eyes. The maturation of VIP-stimulated adenylate cyclase activity to adult levels also correlates well with the timing of maturation of the dopamine-stimulated system. These results suggest that common factors may influence the development of VIP-stimulation and dopaminergic stimulation of one system may influence that of the other.

41.3 ACTIVATION OF LOCUS COERULEUS NEURONS BY CORTICOTROPIN-RELEASING FACTOR (CRF). R.J. Valentino, S.L. Foote, G. Aston-Jones, and <u>F.E. Bloom. Behavioral Neurobiology Laboratory, The Salk</u> Institute, La Jolla 92037.

Institute, La Jolla 92037. The recently characterized hypothalamic peptide, CRF, is thought to be important in the mediation of physiological and behavioral responses to stressful stimuli (Vale, W., Science 231:1494, 1981). We investigated the effects of CRF on spontaneous activity of noradrenergic neurons of the locus coeruleus (NE-LC) since CRF-immunoreactive fibers have been localized in this area (Blocm, F.E., Reg. Peptides, 4:43, 1982; Olschowka, J.A., Neuroendocrinology, 35:305, 1982; Swanson, L.W., Neuroendocrinology, 36:165, 1983) and because these neurons have been implicated in the mediation of stress responses. Spontaneous single unit activity of NE-LC neurons in halothane-anesthetized rats was recorded before and after intraventricular (i.v.t.) injections of CRF or its acidic derivative, CRF-OH. CRF (3 µg, i.v.t.) increased the spontaneous discharge rate of all 12 NE-LC neurons tested by an average of 65  $\pm$  17% (S.E.M.), with the largest increases occurring 7 min after Injection. In contrast, CRF-OH, the less active derivative, did not alter the spontaneous activity of NE-LC neurons when administered in the same dose (maximu increase = 18 + 11%; n = 5 cells). Likewise, lower doses of CRF (1 µg, i.v.t.) were ineffective. While iontophoretic application of CRF to NE-LC cells did not consistently alter spontaneous discharge rate, the pressure application (4-40 psi) of CRF directly to these cells through a multibarrel micropipette resulted in increases in discharge rate in 9 of 14 neurons. Pressure application of CRF to cerebellar purkinje cells or to neurons of the mesencephalic nucleus of the trigeminus had no effect on the spontaneous activity of these cells. Preliminary studies in 3 unanethetized, sling-restrained rats support these findings. Intraventricular injection of CRF (1 µg) increased the spontaneous single unit and multiple unit activity of NE-LC cells in all 3 rats, and 0.3 µg was effective in 1 of 2 rats tested. The onset of the increase in activity vari 41.4 CALCITONIN RECEPTORS IN THE PERIAQUEDUCTAL GRAY MATTER MEDIATE ITS ANALGESIC ACTIONS. <u>A. Fabbri\*, C.B. Pert, and A. Pert</u>. Clinical Neuroscience Branch and Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

Calcitonin (CT) evokes a potent and long lasting analgesic effect that is not opiate-mediated following intraventricular or intrathecal administration in rodents and man (Fraioli et al., <u>Eur.</u> <u>J. Pharmacol.</u> 78:381, 1982). Little, however, is known regarding the specific sites of action of this peptide in eliciting analgesia. In this study, we have visualized the calcitonin receptor distribution in the rat midbrain and hindbrain with autoradiographic procedures and then evaluated the analgesic effects of both human (hCT) and salmon (SCT) calcitonin following direct injections into the periaqueductal gray matter (PAG), a region of uniquely high CT binding.

binding. For receptor visualization, serial 25-um sections were taken through the caudal half of the rat brain. These sections were exposed to <sup>125</sup>I-sCT and then processed for autoradiography using tritium-sensitive film. The autoradiography revealed exceptionally heavy binding of sCT in the ventral and ventrolateral segments of the PAG extending along the entire rostral-caudal axis. The mesencephalic reticular formation and the nucleus tractus spinalis nervi trigemini were also relatively high in sCT binding at this level of the brain. In order to assess the analgesic effects of calcitonin and

In order to assess the analgesic effects of calcitonin and relate these effects to the receptor distribution, rats were implanted with chronically indwelling canulae guides aimed for the PAG. Following recovery, the animals were injected intracerebrally with 0.3, 1, 3, and 10 nmoles of sCT, 10 nmoles hCT, or saline. Additional groups of rats were pretreated with either 5 mg/kg of naloxone or saline prior to intracerebral sCT. All animals were tested in the tail-flick and hot plate tests at 5, 15, 30, 60, 90, 120, and 150 min after intracerebral injections. sCT was found to induce a dose-dependent increase in hot-plate latencies but appeared to have little effect in the tail-flick test. At all doses tested, the effect was significant between 15 and 30 min, reaching a peak at 60 min and lasting throughout the duration of testing. hCT was much less effective than sCT in eliciting an analgesic effect and was also less potent in displacing <sup>125</sup>I-SCT bound to slide-mounted sections of rat PAG. Autoradiographic and histological analyses revealed that in rats in which CT elicited a significant analgesic effect, the injection had been made into the area of the PAG containing high CT binding. Injections which were less effective or ineffective had been made outside of this region. These findings suggest that the ventral aspect of the PAG may be an important site of action of CT or a CT-like peptide in eliciting analgesia. 41.5 EFFECTS OF CALCITONIN ON SEROTONERGIC NEURONS IN RAT CNS: LACK OF CORRELATION TO PEPTIDE'S ANALGESIA. <u>M.Parenti, F.Tirone<sup>°</sup>, A.Grop-</u> <u>petti<sup>°</sup>, V.Sibilia<sup>°</sup>, A.Pecile<sup>°</sup> and V.R.Olgiati.</u> Department of Pharmacology, University of Milan, Italy. Several evidences suggest that calcitonin (CT) may act as a neuro

Several evidences suggest that calcitonin (CT) may act as a neuro transmitter in CNS. Immunoreactive CT-like substance has been detected in the nervous system of different animal species including man. Binding sites for the peptide have been demonstrated in rat and human brain. Analgesia, changes in prolactin release, and inhibition of feeding have also been reported after CT administration.

However, most of the information concerning the anatomical organization of CT neurons, their connections with other neuronal systems, and in general, their physiological role in CNS, are still lacking. Only very recently, evidence has been given suggesting functional interactions between CT and dopaminergic or gabaergic neurons.

In this context, using autoradiographic techniques, we have found that CT-binding sites are clustered in bulbar areas densely populated of serotonergic neurons. We have therefore investigated whether CT and serotonergic neurons are functionally connected in CNS.

Since serotonin (5-HT) has been often involved in noxious inhibitory control we have also evaluated whether these connections are relevant to the CT's antinociceptive activity. Here we report that intraventricular administration of CT at

Here we report that intraventricular administration of CT at doses ranging from 0.1 to 5.0 ug/rat, enhances 5-hydroxyindoleacetic acid (5-HIAA) concentrations in several CNS areas including striatum, hypothalamus, mesencephalon, pons, medulla oblungata, cerebellum and spinal cord.

However, no correlations have been found between the alteration of 5-HT metabolism and the analgesic effect of the peptide. The increase in 5-HIIA levels 1) is longer-lasting, 2) is

The increase in 5-HIIA levels 1) is longer-lasting, 2) is elicited by doses of CT by far lower than those necessary to induce analgesia and 3) is not restricted to the brain areas involved in pain control.

Moreover, neither inhibition of tryptophan hydroxylase by pchloro-phenylalanine nor block of 5-HT receptors by metergoline reduces the analgesic effect of CT, suggesting that the integrity of serotonergic system is not relevant to the CT's antinociceptive activity.

It is concluded that 5-HT neuronal activity may be modulated by CT. This effect however does not seem to be related to the peptideinduced analgesia.  41.6 ELECTROPHYSIOLOGICAL ACTIONS OF NEUROTENSIN(1-13), NEUROTEN-SIN(1-8), AND NEUROTENSIN(8-13) ON SINGLE NEURONS IN HYPOTHALAMIC EXPLANTS. <u>F. Baldino, Jr., L. G. Davis and B. Wolfson</u>, E.I. du Pont de Nemours & Co., Glenolden Laboratory, Glenolden, PA 19036

Neurotensin, a tridecapeptide, (NT) is differentially distributed throughout the CNS in a pattern which parallels the distribution of specific high-affinity binding sites for this peptide. This observation, coupled with the known pharmacological actions of NT, suggests a neurotransmitter-like role for this peptide in the CNS. The medial preoptic hypothalamus (MPO) contains dense concentrations of NT and NT binding sites. Furthermore, microinjection of NT into this nucleus produces a profound decrease in body temperature. Because the physiological actions of NT on individual neurons is unknown, we chose to study the effects of NT on single neurons in explants of the MPO in vitro. Standard in vitro electrophysiological techniques were employed. Cultures were prepared from newborn rats and maintained in roller tubes 3-4 weeks. NT was administered either through the superfusion fluid or via micropressure ejection (0.5-10 psi). On line perievent histograms were used to quantitate neuronal responsiveness to NT.

Ejection of NT (lmM-50pM) produced a consistent, dose-related, excitatory effect on the majority of cells studied. This effect also varied linearly as a function of the pressure used to eject the peptide (0.7-10 psi). The remaining cells studied were either unresponsive to NT or inhibited by NT. The N & C terminal fragments of NT (NT<sub>(1-8)</sub>; NT(8-13))did not influence the spontaneous rate of these neurons, suggesting that the active (excitatory)portion of NT may be contained in a mid-region of NT. Additionally, NT was tested for its ability to interact with other putative neurotransmitter systems that have been co-localized with NT in MPO. NT was ineffective in modifying the reductions in spontaneous rate produced by iontophoretically applied GABA (10 nA) and dopamine (100 nA). However, the excitatory effects of iontophoretically applied at concentrations that did not alter spontaneous rate. NT(8-13) and NT<sub>(1-8)</sub> were without effect on the excitatory actions of glutamate.

These data indicate that NT, but not the NT<sub>(1-8)</sub> or NT<sub>(8-13)</sub> fragments, exerts a predominantly excitatory effect on single neurons in the MPO in <u>vitro</u> and at subthreshold (below excitatory) concentrations enhances the actions of excitatory amino acids.

41.7 NEUROTENSIN: A POSSIBLE FACTOR IN HIBERNATION IN THE WHITE-FOOTED MOUSE (<u>PEROMYSCUS LEUCOPUS</u>). <u>J.E. Coughlin\*, and W.H.</u> <u>Watson, III</u> (SPON: E. Hagstrom, Dept. of Psychology). Dept. of Zoology, UNH, Durham, NH 03824. A study is being conducted to investigate the role of the (MR)

A study is being conducted to investigate the role of the brain and gastrointestinal peptide, neurotensin (NT), in hibernation. The hypothesis that NT is involved in hibernation is based on four observations: (1) Injection of NT into the brains of a variety of species of mammals including the whitefooted mouse (<u>Peromyscus leucopus</u>) causes hypothermia; (2) The area of the brain associated with temperature regulation (the preoptic-anterior hypothalamus, POAH) contains the greatest concentration of sites sensitive to NT's hypothermic effect; (3) The POAH contains the highest concentrations of NT as well as NT specific binding sites (for review see Uhl, <u>Annals of N.Y. Acad. Sci.</u>, 400:132, 1982); (4) NT hypothermia, like hibernation, occurs via decreased metabolic rate rather than increased heat loss thru the skin (for review see Bissette, et. al., <u>Annals of N.Y. Acad. Sci.</u>, 400:268, 1982). To prove NT is involved in mammalian hibernation, it must be demonstrated that blockine the activity of NT alters

To prove NT is involved in mammalian hibernation, it must be demonstrated that blocking the activity of NT alters hibernation. This is being accomplished by injecting NT specific antibodies into the brains of hibernating white-footed mice (antibodies generously supplied by Dr. Marvin Brown, Salk Inst., La Jolla, CA and Dr. Robert E. Carraway, Univ. of MA, Worcester, MA). Following ten weeks of short day photoperiod exposure (6L:18D) and an ambient temperature of  $4^{\circ}$ C, whitefooted mice exhibited daily bouts of hibernation of 4-12 hours in length, during which body temperature dropped from  $36^{\circ}$ C to  $^{\circ}22^{\circ}$ C. This system allows for the testing of inhibitors on bouts of hypothermia on a daily basis. This is not possible with other hibernators, such as the woodchuck (<u>Marmota monax</u>), which exhibits hypothermic bouts of 10-20 days in length, in the winter only.

Preliminary results have shown that intraventricular injections of NT antibodies (2 ul; 1 ul will bind with 1 p mole of NT) 12 hours before the onset of torpor caused a delay in the occurrence of hibernation, but did not alter the duration of the bout or the degree of temperature change from the control serum injections. A more elegant system using osmotic pumps to continuously infuse the inhibitor or the control vehicle is currently being employed. This will allow for the injection of the drugs during an entire bout of hypothermia, and avoid any artifacts due to handling of the animals. 41.8 PRIOR COLD EXPOSURE ANTAGONIZES NEUROTENSIN-INDUCED HYPOTHERMIA IN MICE. W.D. Merritt\*, G. Bissette, D. Luttinger, A.J. Prange, Jr. and C.B. Nemeroff, Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514. Neurotensin (NT), an endogenous tridecapeptide, produces hypo-

Neurotensin (NT), an endogenous tridecapeptide, produces hypothermia after injection into the cerebroventricular system of many mammals and has been postulated to play a role in mammalian thermoregulation. Previous studies have shown that central or peripheral administration of thyrotropin-releasing hormone antagonizes the hypothermia induced by intracisternal (IC) NT and this antagonism is dependent upon the synthesis of prostaglandins (PG) within the CNS (Regulatory Peptides 4:285-292, 1982). This study was designed to investigate the effect of prior cold exposure on NTinduced hypothermia in mice. Once defined, we determined whether the effect of prior cold exposure was dependent upon prostaglandin synthesis within the central nervous system. Adult male Swiss-Webster mice were exposed to a 6°C environment

Adult male Swiss-Webster mice were exposed to a 6°C environment in individual metal cages for 3 hours per day on 4 consecutive days. Controls were placed in identical cages at 26°C. On the fifth day, all animals received IC NT or saline vehicle alone. Colonic temperatures were measured using a digital display thermocouple probe 0, 30, 60, 120, and 180 minutes post-injection. After exposure of the mice to a 6°C environment for 4 days, the hypothermia produced by IC NT (1, 3, and 10  $\mu$ g) was significantly attenuated. Interestingly, cold exposure and subsequent IC NT in a 26°C ambient temperature did not produce any alteration in the hypothermic response to IC NT (1, 10  $\mu$ g). However, when mice were briefly exposed (30 min) to a 6°C environment immediately prior to IC injection and then placed in a 26°C environment, antagonism of NT (1  $\mu$ g) induced hypothermia did occur. In contrast to the effects of 4 days of cold exposure, mice placed in a cold (6°C) environment for 3 hours per day for only one or two days prior to injection did not exhibit any antagonism of the hypothermic effects of NT (1  $\mu$ g) when studied in a cold (6°C) environment. Four days of cold exposure also antagonized the hypothermia produced by bombesin (0.3, 1  $\mu$ g), a neuropeptide which is thought to produce hypothermia by a different mechanism than NT (Regulatory Peptides 1:53-60, 1980). Pretreatment with indomethaccin (15 mg/kg, SC), but not acetylsalicylic acid (100 mg/kg, SC), 30 min prior to IC NT completely prevented the antagonism of NTinduced hypothermia in the cold-exposed animals. Indomethacin inhibits PG synthesis in both the CNS and in the periphery whereas acetylsalicylic acid inhibits PG synthesis only in the periphery (but not in the CNS). These results suggest that blockade of PG synthesis in the CNS can prevent the antagonism of NT-induced hypothermia induced by previous cold exposure. (Supported by NHM MH-33216, MH-33127, MH-34121, MH-2236 and NICHBH D-03110).

TOPOGRAPHIC ORGANIZATION OF THE MESOLIMBIC DOPAMINE SYSTEM AS 41.9 DEMONSTRATED FUNCTIONALLY BY MICROINJECTION OF NEUROTENSIN INTO SUBNUCLEI OF THE VENTRAL TEGMENTAL AREA. <u>P. W. Kalivas\*</u> and <u>J. S. Miller\*</u> (SPON: W. Macklin). Dept. Fharmacol., LSU Med. Ctr., New Orleans, 70112. Microinjection of neurotensin (NT) into the ventral tegmental area (VTA) of the rat has been shown to produce both an increase

in locomotor activity and a decrease in colonic temperature. In this study, male S. D. rats were implanted with injection can-nulae into the VTA, and NT ( $2.5 \ \mu g$ ) or saline infused in a volume of 0.25 µl/side. Careful histological analysis of can-nulae placement revealed that hypothermia was most often produced following injection of NT into the caudal, midline VTA; corresponding to the nucleus linearis centralis. In contrast, increased motor activity occured after injection of NT into the lateral VTA (nucleus paranigralis) and the nucleus fascicularis. Both hypothermia and hyperactivity were seen simultaneously in

Both hypothermia and hyperactivity were seen simultaneously in rats injected into the nucleus linearis rostralis. It is possible that both the hypothermia and hyperactivity produced by intra-VTA NT result from activiation of ascending dopamine (DA) neurons. To test this, a neuroleptic, fluphenaz-ine (2.5  $\mu$ g/side) was microinjected into various forebrain loci simultaneously with NT infusion into the VTA. Fluphenazine in-jection into the diagonal band of Broca (DBB) blocked NT hypothermia, while intra-nucleus accumbens injection blocked the hyperactivity. Thus, NT may activate DA neurons in the medial VTA which project to the DBB to produce hypothermia and neurons VTA which project to the DBB to produce hypothermia and neurons in the lateral VTA projecting to the nucleus accumbens to pro-duce hyperactivity. This postulate was further substantiated by HPLC measurement of DA metabolites in various forebrain regions after NT injection into the VTA. Injection of NT into the nucleus linearis centralis produced a marked increase in DA metabolites in the DBB, while injection into the nucleus para-nigralis produced a perferential rise in DA metabolites in the pucleus accumbene. Further supporting a VTA-diagonal hand projection system was the observation that HRP injection into the DBB resulted in retrogradely labeled cells predominately in the midline VTA, of which 35% were immunohistochemically double labeled for tyrosine hydroxylase.

Thus, the mesolimbic DA system is topographically organized with respect to NT action in the VTA. NT acts in the nucleus linearis to activate a VTA-DBB DA system causing hypothermia and in the nucleus paranigralis to activate a VTA-accumbens DA pathway producing hyperactivity.

EFFECT OF ENKEPHALINS AND SUBSTANCE P ON THE CONTRACTION OF VAS 41.11 DEFERENS OF AGING RAT. J.T. Huang\* and W.C. Ko\* (Sponsor: D. Sutton). Virginia Mason Res. Ctr., Seattle, WA 98101. The question of whether the vas deferens from an aging rat has

a different response to enkephalin and substance P than that from a young rat was investigated in this communication. Vas deferens from Fisher 344 strain rats were isolated after the rats were from Fisher 344 strain rats were isolated after the rats were decapitated. The vas deferens was then mounted in a 10 ml organ bath containing Krebs solution maintained at  $37^{\circ}C$  and bubbled with 95% 0<sub>2</sub> and 5% CO<sub>2</sub>. The electrical field stimulation was applied to the vas deferens at 60 v with 0.5 m sec. duration in every 10 seconds. After a stable twitching contraction was es-tablished, the effect of enkephalin and substance P was studied by adding these substances to the organ bath. The concentration of D'Ala -D-Leu -enkephalin (DADLE), which inhibited 50% of the twitching contraction of the vas deferens.

inhibited 50% of the twitching contraction of the vas deferens, which was 8 x 10 M for young rats (4 to 6 months) and 2.4 x  $10^{-1}$  M for old rats (24 to 26 months). The concentration of D-Ala<sup>-</sup>Methionine-enkephalinamide (DAME) which inhibited 50% of the contracnine-enkephalinamide (DAME) which inhibited 50% of the contrac-tion was 10 times higher than that of DADLE. These results indicate that the vas deferens of the old rats were less sensitive to the enkephalin than that of the young rats. The difference between young and old vas deferens was also exhibited after the vas deferens were treated with trypsin for 30 min. The sensi-tivity of the young vas deferens to DADLE or DAME was signivas deferens were treated with trypsin for 30 min. The sensi-tivity of the young vas deferens to DADLE or DAME was signi-ficantly decreased after it was treated with trypsin but there was no significant change of the sensitivity in the old vas defer-ens. 2.5 x 10 <sup>M</sup> of substance P potentiated the contraction of the young vas deferens about 30% and the old vas deferens about 130%. After the vas deferens was treated with trypsin, the poten-tiation effect of substance P was increased to 70% and 240% in the young and old vas deferens was more sensitive to substance P. Since enkephalin may primarily affect the neural elements of the vas deferens of the vas deferens (Blackwell, et al., 1978), the ef-fect of aging on the nerve and muscle of the vas deferens is different. (Supported by NIH RR05588)

STRUCTURE-ACTIVITY RELATIONSHIPS OF THE INHIBITORY ACTIONS OF 41.10 SUBSTANCE P ON NICOTINIC CHOLINERGIC RECEPTORS. N.D. Boyd, M.P.

SUBSTANCE P ON NICOTINIC CHOLINERGIC RECEPTORS. M.D. BOYGY M.P Anthony X S.E. Leeman, Department of Physiology, University of Massachusetts Medical Center, Worcester, MA 01605 Substance P (SP) inhibits the cholinergic stimulated release of dopamine from PC12 cells, a sympathetic neuronal cell line. The concentration dependency and reversibility of this inhibi-The concentration dependency and reversibility of this inhibi-tion is similar to that previously reported for adrenal chro-maffin cells. In order to characterize the site on  $PC_{12}$  cells through which SP exerts this action, we have examined the effect of SP, SP fragments and related peptides on the influx of  $^{22}Na^+$  that is stimulated by nicotinic agonists. A concen-tration dependent inhibiton of carbamylcholine-induced  $^{22}Na^+$ uptake use obscrudet, the Up-1s of the various portides uptake was observed; the ID50's of the various peptides examined are: % Relative

These results indicate that both the N-terminal and the Cterminal sequences of SP are necessary for maximal inhibition. The low potency of eledoisin and physalemin which share a similar C-terminal sequence with SP but different N-terminal amino acids, reinforce the importance of the N-terminal sequence of the SP molecule in its inhibitory action. These results are consistent with the existence of a SF

receptor site on  ${\rm PC}_{12}$  cells that modulate nicotinic cholinergic function and thus catecholamine release. The structureactivity relationships observed here suggest that these sites possess different structural requirements for activity when compared with those on guinea pig ileum smooth muscle, frog spinal motoneurons and rat salivary glands, where the biological activity has been viewed for the most part as residing only in the C-terminal portion of the SP molecule. (NIH Grant # AM29876)

NOVEL HEXAPEPTIDE ANALOGS OF SUBSTANCE P (SP) AS PUTA-41.12 NUVEL NEARPHILE ARALOGS OF SUBSTANCE P (SP) AS PUTA-TIVE SP ANTAGONISTS. E.R.Baizman\*, D.A.Kiefer\*, D.M.Lo-Presti\*, N.J.Meo\*, M.H.Perrone\*, R.F.Diehl\*, A.K.Pierson\*, P.E.Hansen\*, T.D.Gordon\*, and B.A.Morgan\*.(SPON: H. Ted-eschi). Sterling-Winthrop Research Institute, Rensselaer P.E.n... eschi). Ster. 12144.

eschi). Sterling-Winthrop Research Institute, Rensselaer N.Y. 12144. The proposed physiological role of SP as a nocicep-tive sensory transmitter has prompted us and others to investigate SP antagonist analogs as a new class of po-tential analgesics (Baizman, et al., Soc. Neurosci. 8:986 1982; Sandberg and Iversen, J.Med.Chem.25:1009,1982). Two hexapeptides, Win 51149 (A) and Win 49337 (B) were synthesized and compared with two undecapeptides previously described as being SP antagonists: D-Pro<sup>2</sup>, D-Trp<sup>7</sup>.9SP (C) and D-Pro<sup>2</sup>, D-Pre<sup>7</sup>, D-Trp9SP (D) (Folkers, et al., Acta Physiol. Scand. 111:505,1981). In our experiments, all 4 analogs showed parallel displacement curves for 3H-SP binding in brain,with Ki values ranging from 0.7-12.9UM. In the atropinized gui-nea pig ileum, pA<sub>2</sub> values for 3 of the 4 analogs were approximately equal (pA<sub>2</sub>: A = 6.4; B = 5.6; C=5.7; D= 4.6) and reflect competitive antagonism of SP. Both hexarep-tides showed little or no agonist effect in this tissue At concentrations of 1-300M, each analog also produced reversal of SP-induced (100M) increases in the electri-cally stimulated twitch height of the rat vas deferens, but none reversed contractions augmented by acetylchol-ine (ACh), bradykinin or histamine. Salivation induced in the rat by i.v. bolus injection of SP (0.7-2.2nmoles kg) was significantly inhibited by 10-min. infusion of 0.7umole/kg of (C) and by 3.4umoles/kg of (A). Intra-thecal (i.t.) pretreatment inhibited ACh-induced writh-ing behavior in the mouse in a dose-related manner(AD<sub>50</sub> in nmoles/mouse: A= 4.7; B= 1.8; C= 3; D= 2.4). In ag-rement with others (Fiercey. et al., Science 21/2:1361, 1981) who have reported hindlimb flaccidity after in-traspinal injections of SP antagonists, we find that analog (C) showed an AD<sub>50</sub> for antagonists, we find that analog (C) showed an AD<sub>50</sub> for antagonists, we find that analog (C) showed an AD<sub>50</sub> for antagonists of writhing (3nnoles i.t.). In contrast, i.t. injections of the hexapettide (A) showed a 14-fold separation N.Y. 12144. The proposed physiological role of SP as a nocicep.

EXCESSIVE GROOMING INDUCED BY SUBSTANCE F, BOMBESIN, AND RELATED PEPTDES IN MICE. <u>W. H. Simmons\* and</u> <u>G. Neisenberg</u>. Dept. of Biochemistry and Biophysics, Loyola University Medical School, Maywod, IL, 60153. After intracerebroventricular injection in mice, substance F (20 µg), physalaemin (1 µg), and eledoisin (40 ng, 200 ng, and 1 µg) induced excessive grooming behavior, but no sustained scratching. In contrast, bombesin (50 ng, 250 ng, and 1.25 µg) induced both grooming and scratching behavior. The effect of substance F (20 µg) completely disappeared after 17 minutes. The duration of action of eledoisin (1 µg) was somewhat longer while bombesin (100 pg) was gtill strongly active after 53 minutes. [pGlu, MePhe], Sar<sup>9</sup> (substance P, induced enhanced locomotion and grooming at doses of 1 and 5 µg with a duration of EXCESSIVE GROOMING INDUCED BY SUBSTANCE P, BOMBESIN, 41.13 of substance P, induced enhanced locomotion and grooming at doses of 1 and 5 µg with a duration of action of about 30 minutes (1 µg). Treatment with twice daily injections of 10 µg [pGlu<sup>5</sup>, Mełhe<sup>8</sup>, Sar<sup>9</sup>] (substance P 5-11) or 1 µg bombesin did not induce significant tolerance to the effects of substance F, eledoisin, or bombesin. The observations described here suggest that the grooming/scratching behavior induced by beptagin is characterically different from induced by bombesin is phenotypically different from that induced by substance F, physalaemin, and eledoi-sin. The very short duration of action of substance P suggests that this peptide is rapidly inactivated. The virtual lack of tolerance formation is compatible

with the view that substance F and bombesin may be involved in the mediation of nociceptive stimuli.

41.14 Effects of Hypoxia and Denervations on Carotid Body Peptides. G.R. Hanson, L. Jones and S. Fidone, Depts. Biochem. Pharmacol. & Toxicol. and Physiol., Univ. of Utah, Salt Lake City, UT. 84112. The carotid body is the chief peripheral organ of arterial chemoreception in mammals and plays an important role in the regulation of respiratory and cardiovascular systems. Regulatory neuropeptides, such as substance P and metenkephalin, have been localized in the carotid body and are thought to affect the chemosensory activity of this organ; however their precise func-tion is unknown. We have conducted studies to determine if these peptide systems might assist in mediating the response of the carotid body to natural stimuli, such as hypoxia. Thus, using RIA techniques (Hanson, et al., J. Neurochem., 35 [1980] 1370-1374) concentrations of both substance P- and metenkephalin-like immuno-reactivity were determined in the carotid bodies of rabbits placed

techniques (naison, et al., <u>or neurocimen</u>., <u>probability</u> (production) (and the probability of the probab sympathectomy only prevented the hypoxia-related changes metenkephalin levels. in

Although additional studies are required to elucidate the significance of the above findings, these data suggest that substance P and metenkephalin play a significant regulatory role in the physiological responses of the carotid body. (Supported by USPHS Research Grants NS-12636, NS-07938 and MH-37762).

SUBSTANCE P-INDUCED FACILITATION OF A SPINAL NOCICEPTIVE REFLEX: COMPARISON WITH ELEDOISIN AND PHYSALAEMIN. <u>R. Cridland\*, K.</u> Yashpal\* and J.L. Henry. Department of Physiology, McGill University, Montréal, Québec, H3G 1Y6. We have reported that intrathecal administration of substance 41 15

We have reported that intrathecal administration of substance P to the rat induces a transient dose dependent decrease in re-action time to flick of the tail from a noxious radiant heat stimulus (Pain <u>14</u>: 155-167, 1982). This transient effect, which lasts less than 5 min, is resistant to the opiate antagonist naloxone, but is followed by a rebound overshoot which is blocked by intrathecal administration of naloxone (Can. J. Physiol. Pharmacol. <u>61</u>: 303-307, 1983). In view of the suggestion that different types of substance P receptors exist in peripheral tissues, because differential sensitivities exist to the substance P homologues eledoisin and physalaemin, we tested these homologues in our experimental paradigm to detertested these homologues in our experimental paradigm to deter-mine whether they might have differential effects when given centrally. Thus, eledoisin and physalaemin were each adminis-tered intrathecally to determine whether they alter reaction time in the tail flick test.

time in the tail flick test. Male Sprague-Dawley rats were implanted chronically with intrathecal catheters to the lumbar spinal cord. After one week of recovery, tail flick latency was measured in trials of ten tests, one test each five min: three tests to establish control latency (usually set at 15-20 sec) and seven tests to plot the time course of effects on reaction time. Substance P, eledoisin and physalaemin were each given as 10 µg in 10 µl of ortificiel combrenies lived flice of the to value of eledoisin and physalaemin were each given as 10 µg in 10 µl of artificial cerebrospinal fluid followed by a further 10 µl of the vehicle to flush the catheter. The molar dose of each peptide, then, was: substance P, 7.4 nmole; eledoisin, 8.4 nmole; physalaemin 7.9 nmole). Substance P reduced the response time to flick of the tail, to 28.9 ± 12.7 (S.D.) percent of con-trol (n = 10). Eledoisin and physalaemin reduced this time to  $25.7 \pm 7.4$  (n = 7) and  $23.5 \pm 12.2$  (n = 6), respectively. The time course of the responses was similar to that reported earlier for substance P including the rehound overshoot. Administration for substance P, including the rebound overshoot. Administration of vehicle had no effect on reaction time.

These results support the suggestion that substance  $\ensuremath{\mathsf{P}}$  facilitates transmission through spinal nociceptive pathways and demonstrates that the homologues eledoisin and physalaemin have similar effects as substance P. (Supported by the Canadian Medical Research Council).

41.16 PROINFLAMMATORY POTENTIAL OF SUBSTANCE P - GENERATION OF PHLOGOGENIC MACROPHAGE PRODUCTS. H.P.Hartung, and K.V.Toyka" (SPON: H.G.Ross). Dept. of Neurology, Univ. of Duesseldorf Medical School, W. Germany. Besides its role as a neurotransmitter Substance P (SP) has been implicated in vasodilation and neurogenic plasma extravasation thereby promoting humoral inflammatory responses. It has recently been shown to augment endocytosis by macrophages (MØ), the major cellular com ponent of the inflammatory process. We studied whether SP evokes heightened metabolic activities in MØ as reflected by enhanced oxidative and arachidonic acid metabolism. Adherent peritoneal MØ elicited with albumin or C.parvum were incubated in serumfree medium in the presence of SP (1 nM-1 µM). After 60 min or 12 h, respectively, release of superoxide anin (O\_1) and H.O., and prostaglandin E (PGE) and thromboxane B\_ (TXB) Was determined photometrically (oxygen radicals) or by radio-immunoassay (Hartung,H.P. et al. J.Immunol., 130:1345, 1983). SP induced significant release of oxygen radical being maximally effective at 0.6 µM. Kinetigs gave a pla to a do se-dependently excited liberation of PGE and TXB, the latter in higher amounts (7 ng/12 h). This effect was abolished in the presence of indomethacin. Kinetics showed a steep increase within 6 h and levelling off thereafter. Exposure of MØ for 5 min sufficed to initia te 50% of maximal release. MØ could be specifically desensitized to SP. Pulse time studies and specific deactivation suggest a receptroligand interaction. Evidence for binding of SP to MØ will be demonstrated by immunocytochemistry. O\_ and H\_O\_ are known to be cytotoxic to tumor cells and "microbes," mediate endothelial injury and partake in inflammation. FGE and TXB are established mediators of immunoinflammatory responses contributing to vasodilation and the formation of edema, as well as triggering platelet release reaction. PGE moreover modulates MØ - T cell interaction.

modulates  $M\emptyset$  - T cell interaction. We have provided evidence for novel effects of SP. SP causes  $M\emptyset$  to set free important phlogistic compounds. We suggest that this action of SP may be relevant in the context of neuroinflammatory diease. SP liberated from damaged nerve endings would lead not only to vasodila-tion, as has been known before, but also via its action on MØ to further destruction of nervous tissue and aug-mentation of phlogistic responses due to the effects of toxic oxygen derivatives and arachidonate cyclooxygena-tion products.

41.17 DIRECT QUANTITATION AND CHARACTERIZATION OF THE RELEASE OF SUB-STANCE P FROM THR MYENTERIC PLEXUS. Sheri A. Baron\*, Bernard M. Jaffe\* and Alan R. Gintzler\* (Spon: A. Wakade). Downstate Medical Center, Brooklyn, NY 11203.

It has been suggested that substance P (SP) may be an excitatory neurotransmitter in the enteric nervous system and may play a role in the local modulation of intestinal motility. There is however, only indirect evidence that SP is released from intramural neurons in the gut wall and as a consequence its role as an enteric neurotransmitter remains speculative. We report here the first direct quantitation of the release of SP from the myenteric plexus. A dynamic system has been developed in which the in vitro release of SP from 2 longitudinal muscle myenteric plexus (LM-MP) strips is obtained during continuous superfusion and measured directly by using a highly sensitive radioimmunoassay specific for SP. Electrical stimulation produced a marked increase in the rate of release of SP. The frequency-dependence profile (0.5-40 Hz) of release was multitonic rather than linear. Stimulation of 0.5 Hz increased the rate of release bove basal values by approximately 133% (9 pg/min above mean basal release). Stimulation at 1 and 5 Hz also increased the rate of release but there were no significant differences among the mean increases in the rate of release of SP elicited by the above frequencies. Stimulation at 7.5 Hz produced an abrupt additional elevation in the rate of release (38.0 pg/min above mean basal release) possibly indicating recruitment of additional SP containing neurons. Increasing the frequency to 40 Hz, but not 10 or 20 Hz, produced a further increase in the rate of release elicited by 20 Hz stimulation. was reduced by 95% by omitting Ca<sup>++</sup> from the superfusion buffer or by cooling the preparation to 3° C. Pretreatment with tetrodotxin (TTx; 1 ug/ml for 20 min) substantially reduced the magnitude of the increase in the rate of release of SP but did not abolish it. Despite TTx pretreatment a significant portion (53%) of the electrically induced increase in SP release remained. Since, TTx resistant-Ca<sup>++</sup> dependent action potentials are characteristic of only Type 2 (AH) cells, a portion of SP

The ability of electrical stimulation to release SP from the myenteric plexus in amounts sufficient to produce a physiological response in a Ca<sup>+</sup> and temperature dependent fashion in combination with data provided by indirect pharmacological experiments strongly suggests that SP functions as a neurotransmitter in the enteric nervous system. Supported by Grants DA02893, HD06488.

41.19 BOMBESIN AND SUBSTANCE P AS EXCITATORY NEUROTRANSMITTERS IN THE MUSCULARIS MUCOSA OF CANINE COLON. <u>F. Angel\*, V.L.W. Go\* and J.H. Szurszewski</u>. Dept. Physiology and Gastroenterology Unit, Mayo Medical School, Rochester, MM S5905. In the muscularis mucosa of canine colon, transmural

In the muscularis mucosa of canine colon, transmural electrical nerve stimulation induces an excitatory response which is not mediated by cholinergic, adrenergic, purinergic or serotonergic nerves. Two peptides found in the isolated muscle, bombesin and substance P, contract the muscle when added exogenously. Substance P has a direct effect on the smooth muscle whereas bombesin acts through a nervous pathway. The aims of the study were to determine: 1) if these two peptides are the excitatory transmitters in the colonic muscularis mucosa; and 2) the relationship, if any, between bombesin- and substance P-containing neurons. Strips of muscularis mucosa were placed in a superfusion apparatus to record contractile activity. The superfusate (0.1 ml/sec) which passed over each strip was collected before and during transmural electrical stimulation (10 Hz, 200 µs, 10 V) and analyzed for bombesin- and substance P-like immunoreactivity. In control conditions, the concentration (mean  $\pm$  SEM) of bombesin and substance P mas, respectively, 6.0  $\pm$  0.98 pg/ml; 5.60  $\pm$  0.96 pg/ml. During transmural nerve stimulation the concentration of bombesin and substance P increased significantly (p < 0.01) to 9.41  $\pm$  0.98 pg/ml, and 7.16  $\pm$  0.98 pg/ml, respectively. In the presence of tetrodotoxin (10<sup>-6</sup> M) and in a calcium-free solution, these increases of bombesin and substance P during nerve stimulation were blocked. Furthermore, bombesin (10<sup>-7</sup> M), when added exogenously to the superfusion, released substance P induced by nerve stimulation. The effect of exogenously added bombesin and the release of substance P induced by mores in and the release of substance P, induced by nerve stimulation and exogenously bombesin in control experiments that transmural stimulation releases bombesin from intramural nerves and that bombesin acts on substance P-containing nerves to release substance P, thereby causing contraction. Supported by NH Grant AM 17238.

41.18 EVIDENCE FOR A NONCHOLINERGIC AFFERENT PATHWAY FROM COLON TO PRE-VERTEBRAL GANGLIA: POSSIBLE MEDIATION BY SUBSTANCE P. S. Peters\* and D. L. Kreulen (SPON: J. J. Galligan). Dept. of Pharmacology, Univ. of Arizona, Coll. of Medicine, Tucson, AZ 85724. In prevertebral sympathetic ganglia, both cholinergic and non-

In prevertebral sympathetic ganglia, both cholinergic and noncholinergic transmission is observed following nerve stimulation in vitro. Cholinergic (fast) excitatory postsynaptic potentials (e.p.s.p.s) are nicotinic and noncholinergic (slow) e.p.s.p.s are believed mediated by Substance P (SP). Cholinergic input also is observed, arising from a colonic afferent pathway. The degree of cholinergic activity increases when the colon is distended or induced to contract. Our objective was to determine whether a noncholinergic afferent pathway between the colon and ganglia exists which can be activated physiologically. The inferior mesenteric ganglion (IMG) and a segment of distal colon (3.5-4 cm) connected by the lumbar colonic nerves were excised from guinea pigs and pinned separately in a 2-chamber bath. Both chambers were perfused with oxygenated Krebs buffer, but drugs were administered only into the ganglion compartment. The caudal end of the colon segment was ligated and the oral end fastened to a fluid injector and pressure transducer assembly. Responses to colon distension or hypogastric nerve stimulation were recorded intracellularly from principal ganglion cells using glass microelectrodes of 49-100 M  $\Omega$  resistance. Distension (5-10 cm pressure) caused a pressure-dependent increase in frequency and amplitude of cholinergic blockade with hexamethonium (10<sup>-4</sup>-10<sup>-5</sup><sup>N</sup>), 9 of 27 cells (33%) depolarized an average of 3.3 ± .4 mV (S.E.M.) upon distensions of 10-15 cm H<sub>2</sub>O pressure. Depolarizations, In most neurons the slow depolarizations returned to baseline within 3 min after cessation of distension. Redistension resulted in depolarizations in 3 of 4 cells. Stimulus-evoked slow e.p.s.p. amplitude did not decrease after prolonged (15-min) distension, suggesting a lack of membrane desensitization by the noncholinergic transmitter. Hyperpolarizing the membrane from -47 to -89 mV by current injection failed to enhance the amplitude of depolarization (n=1). Putative SP antagonist D-prof, D-try, 9,

ENDOGENOUS LABELING OF POLYPEPTIDES BLOCKED BY CYCLOHEXIMIDE IN 42.1 THE GOLDFISH MAUTHNER AXON. <u>E. Koenig</u>. Div. of Neurobiology, Dept. of Physiology, SUNY, Buffalo, NY 14214. Studies in this laboratory have focussed on endogenous

protein synthesizing activity in mature and growing vertebrate axons. Recently, we showed that naked goldfish retinal ganglion cell (RGC) axons regenerating in vitro incorporate gangiion ceidi (ncc) axons regenerating in vito incorporate amino acids into axonal protein after decentralization from the explant and that the incorporation is blocked by cycloheximide or emetine (Koenig & Adams, <u>J. Neurochem</u>, <u>39</u>:386, 1982). Major polypeptides showing cycloheximide-sensitive labeling in RGC axons and in lumbar spinal roots of the rat include " and A tublis, actin and neurofilament polypeptides (Koenig, <u>Soc</u>, <u>Neurosci</u>, <u>Abstr.</u> 8, p.788, 1982). I now report preliminary findings regarding polypeptides exhibiting cycloheximide-sensitive labeling in the large myelinated axon (M-axon) of the goldfish Mauthner neuron. Microscopic samples of M-axon, goldfish Mauthner neuron. Microscopic samples of M-axon, isolated from the myelin sheath, were analyzed by a special gel microslab system after in vitro incubation of goldfish spinal cord with <sup>35</sup>S-methionine in the presence or absence of cycloheximide. Autoradiograms of gels showed that several polypeptides were labeled in the absence but not in the presence of cycloheximide. While a polypeptide of about 72K showed the heaviest labeling, tubulin and actin were also labeled but to a lesser extent. There were other unidentified polypeptides also labeled. Goldfish axons do not have major 200K and 70K polypentides that are homologous to mammalian polypeptides also labeled. Goldfish axons do not have major 200K and 70K polypeptides that are homologous to mammalian neurofilament polypeptides (Koenig, unpublished). They do have, however, a major 145K polypeptide that may be homologous, but there are also major 135K, 125K and 121K polypeptides that may constitute neurofilament subunits, as judged by their apparent equivalence to the 145K polypeptide. The findings that the M-axon exhibits cycloheximide-sensitive labeling of axoplasmic polypeptides is consistent with the demonstration Axoplasmic polypeptides is consistent with the demonstration that this axon contains RNA whose composition includes 26S, 18S, 5S and 4S species, as well as polydisperse RNA (Koenig, <u>Brain Res., 174</u>:95, 1979). These findings add further support to the hypothesis that local synthesis of certain cytoskeletal components of transport groups IV (SCb) and V (SCa) may be necessary to compensate for the biological decay they may undergo during transport.

POSTTRANSLATIONAL PROTEIN MODIFICATION BY AMINO ACID ADDITION IN 42.2

POSTTRANSLATIONAL PROTEIN MODIFICATION BY AMINO ACID ADDITION IN AXOPLASM ISOLATED FROM SQUID GIANT AXONS. N.A. Ingoglia, M.F. Zanakis, G. Chakraborty\* and A. Giuditta\*. Dept. of Physiology, NJ Medical School, Newark, NJ O7103 and Int. Institute of Gen-etics and Biophysics, Naples, Italy. Axoplasm of the squid giant axon contains a variety of species of transfer RNA as well as their cognate aminoacyl tRNA synthetases. These axons, like all axons, are essentially devoid of ribosomes as well as significant amounts of ribosomal RNA, and have not been shown to be capable of supporting protein synthesis. The purpose of the present experiment was to determine if trans-fer RNA in giant axons is capable of transferring amino acids to acceptor proteins as a participant in the posttranslational modi-fication of endogenous axonal proteins. In the first series of experiments <sup>3</sup>H-amino acids or <sup>3</sup>H-amino-acylated tRNAs were incubated with 5 µl of axoplasm and a reaction mixture. The reaction was stopped by the addition of

reaction mixture. The reaction was stopped by the addition of cold 5% TCA and radioactivity in amino acid, nucleic acid and protein fractions was determined by extraction in cold and hot TCA. Under these conditions no radioactivity was found in the protein fraction. This was also the finding following injection of 3H-amino acids and 3H-aminoacylated tRNA directly into the of 3H-amino acids and 3H-aminoacylated tNNA directly into the axon. Thus, under the conditions described above there is no evi-dence of transfer of amino acids from tRNA to proteins. In other experiments, axoplasm was pooled to a volume of 50-100 ul, homo-genized gently and centrifuged at 150,000xg for 1 hour. Some of the high speed supernatant was incubated with labeled amino acids and an appropriate reaction mixture and the remainder was passed through an S200 Sephacryl column before incubation with the same reaction mixture. There was no incorporation of amino acids into through an S200 Sephacryl column before incubation with the same reaction mixture. There was no incorporation of amino acids into protein in the high speed supernatant fraction. However, in the S200 purified fraction, a fraction devoid of molecules of less than 25,000 MW,  $^{3}$ H arg, lys, tyr, leu and asp were all incorporated into proteins in amounts of 44, 30, 7, 5 and 3.5 xs heat inactivated controls. The sulfonic amino acid taurine was not incorporated into protein suggesting that the binding of the carboxylic amino acids to protein is not the result of non-specific binding. The radioactivity present in the protein fraction was shown by amino acid analysis to still be present as the parent amino acid, and could be released by incubation in proteinase K. was shown by amino acid analysis to still be present as the parent amino acid, and could be released by incubation in proteinase K. This addition of amino acids to protein is not protein synthesis since the reactions occurred in a partially purified fraction of the 150,000 g supernatant, a fraction devoid of ribosomes and free amino acids. Thus, we conclude that the reactions we are observing represent the posttranslational addition of a range of amino acids to proteins in axoplasm, and that these reactions are usually inhibited by an unknown factor(s) of less than 25,000 MW.

42.3 AXONAL TRANSPORT IN RAT SCIATIC NERVES OF A HIGH MOLECULAR WEIGHT COMPLEX CONTAINING ELEMENTS CAPABLE OF TRANSFER RNA DEPENDENT POSTTRANSLATIONAL PROTEIN MODIFICATION. M.F. Zanakis, G. Chakra-borty\* and N.A. Ingoglia. Dept. of Physiology, NJ Medical School Novark, NJ 07102 Postivand N.A. Ingoglia. Dept. of Physiology, NJ Medical School Newark, NJ 07103. Experiments were performed to determine whether a non-riboso-

mal tRNA dependent post-translational protein modification reaction is present in the rat sciatic nerve, and whether the ele-ments necessary for such a reaction are transported axonally. Ligatures were placed on the sciatic nerve (one and two cm. from the sciatic notch). Six days later, when axonally transport-ed material would have accumulated proximal to the first ligature but not the second, segments proximal to the first ligature but not the second, segments proximal to each were removed homoge-nized, and centrifuged at 150,000g for 60 min. The high-speed supernatant was analyzed for the incorporation of <sup>3</sup>H-amino acids into a hot TCA insoluble product using a suitable reaction mix-ture. No incorporation of amino acids into proteins occurred when

into a hot TCA insoluble product using a suitable reaction mix-ture. No incorporation of amino acids into proteins occurred when compared to heat-inactivated controls in the supernatant fraction. However, when the supernatant was passed through a Sephacryl S-200 column, significant incorporation into protein of <sup>3</sup>H arg, lys, leu, asp, tyr (but not tau) was found in a fraction containing molecules of greater than 125,000 daltons (F1). Furthermore, the incorporation in the proximal segment was always greater than in the distal segment, indicating axonal transport of the elements necessary for the reaction. Radioactivity in the reaction product could not be solubilized by successive washes in cold TCA or in chloroform:methanol, but was released from the pellet following incubation in protease, indicating that the <sup>3</sup>H-amino acids were covalently bound to endogenous proteins. We next tested the reaction in regenerating nerves. Sciatic nerves were crushed bilaterally and allowed to regenerate for 7 days prior to ligation as described above. When analyses were performed as in normal nerves results showed the incorporation of all of the above amino acids into protein in F1, but in amounts varying from 2 to 20 times normals. This indicates a large in-crease in the activity of the elements necessary for this reaction in regenerating axons compared to normals. Other experiments were performed to determine if the reaction was tRNA dependent. SDS PAGE analysis of F1 demonstrated the presence of 45 RNA. When tRNA is removed from the reaction by DEAE cellulose chromato-graphy, the amino acid incorporation decreased by 90%, but was restored by the addition of either endogenous or exogenous tRNA, indicating that the reaction is dependent, ribosomal RNA inde-pendent postranslational protein modification reaction within axons of the rat sciatic nerve. The activity of this reaction is increased significantly during regeneration.

42.4 POSTTRANSLATIONAL PROTEIN MODIFICATION BY tRNA DEPENDENT AMINO ACID ADDITION IN REGENERATING OPTICATION BY CRWA DEPENDENT AMINO ACID ADDITION IN REGENERATING OPTIC NERVES OF GOLDFISH. <u>G. Chak-</u> raborty\*, M.F. Zanakis, N.A. Ingoglia. (Spon: F.P.J. Diecke) Dept. of Physiology, NJ Medical School, Newark, NJ 07103. The experiments described below were performed to determine if tRNA found in regenerating optic axons of goldfish is parti-cipating in post-translational protein modification by addition of amino acid to endogenous axonal protein

cipating in post-translational protein modification by addition of amino acid to endogenous axonal proteins. The first series of experiments were performed to see if 4S RNA is transported axonally in regenerating optic axons prior to innervation of the goldfish optic tectum. Both optic nerves of goldfish were cut and regenerating nerve stumps were analysed for the presence of 4S RNA at 2,4,6 and 10 days of regeneration. In each case, <sup>3</sup>H-uridine (3-5 µci) was injected into both eyes two days prior to sacrifice. RNA was extracted by phenol extraction and 4S RNA was determined by SDS-PAGE. <sup>3</sup>H-4S RNA in regenerating optic nerves was compared with normals (intact optic nerve) and regenerating controls (both optic nerve and regenerating controls (both optic nerve and retina) artery were cut). No significant difference in the amount of  $^{3}H-4S$  RNA in the nerve was detected at 2 or 4 days of regeneration but the proportion of  $^{3}H-4S$  RNA doubled at 6 and 10 days of regeneration. This data suggests that 4S RNA (probably tRNA), is transported axonally in regenerating optic nerves of goldfish prior to reconnection.

nection. In other experiments, both optic nerves were cut and 6-8 days later optic nerves were homogenized, centrifuged at 150,000xg and the supernatant was passed through a Sephacryl S-200 column. The supernatant and the S-200 void volume (F1, mol. wt. > 120,000 dalton) were incubated separately with <sup>3</sup>H-lys and assayed for their ability to incorporate <sup>3</sup>H-lys into protein. Supernatants exhibited no ability for such incorporation, but F1 incorporated <sup>3</sup>H-lys into protein in amounts approximately 15 times heat in-activated controls. These values ( $\sim$  96 DPM/µg protein). Experi-ments using other amino acids (leu, pro, arg, asp) have shown similar results in the void volume obtained from a Sephadex G25-40 column. In all experiments the greatest incorporation, less with neutral amino acids and still less with the acidic amino with neutral amino acids and still less with the acidic amino acid.

These experiments indicate that: (1) tRNA is axonally trans-These experiments indicate that: (1) tRNA is axonally transported in the optic nerves of goldfish prior to reconnection of optic axons, (2) posttranslational modification of axonal protein occurs in regenerating optic nerves of goldfish (3) such modification is higher in regenerating optic nerves, compared to that of normal nerves (4) it is likely that the elements required for posttranslational protein modification are transported axonally in these regenerating optic nerves.

RETROGRADE AXONAL TRANSPORT OF FREE GLYCINE IN THE 42.5 BRANCHIAL NERVE OF APLYSIA. K.E.Carlson\* and C.H.Price, Dept. of Biology, Boston Univ., Boston, MA 02215. The axonal transport(AT) of small molecules such as amino acids is a controversial subject and has received little attention compared with the AT of macromolecules. Furthermore the existence and functional significance of the retrograde AT of small molecules has been poorly documented. In this study, the retrograde AT of free glycine in the identified axons of neurons R3-14, which apparently use glycine as a chemical messenger, characterized by biochemical and autoradiographic means. The soma of R3-14 are located in the parietovisceral ganglion(PVG) and of No-14 are located in the parietovisceral ganglion(rvo) and their axions project down the branchial nerve(BN) to end in a large field in the pericardial region(PR). Using a double-chambered apparatus, the PR was incubated in media with 3H-amino acids for 4-48h while the BN-PVG tissue was isolated and perfused with plain or chemically altered media. The BN and PVG were then either rapidly frozen(for scintillation counting) or fixed for autoradiography(AR). When 3H-glycine was used, radioactivity entered the BN rapidly (the front moved at about 2 mm/h), reached the PVG by 3h, and was largely(85% or more) in the free amino acid form (TCA soluble). When anisomycin was used on the PR in parallel form (TCA soluble). When anisomycin was used on the PR in parallel experiments, the amount of 3H-macromolecules in the BN and PVG was reduced by 97% compared with controls. In AR sections of the BN from a 24h incubation, more than 30% of the silver grains over the nerve were contained in R3-14 axons although these structures occupy less than 10% of the nerve area. Radioactivity accumulated in the PVG(4X greater in the right than left hemigranglion due to the presence of the R3-14 soma). The majority of this label remained in the free form but a significant amount of newly synthesized 3H-protein was always present in the nerve and ganglion. Retrograde AT of free glycine was inhibited by(in decreasing order of effectiveness) mercuric ions, vinblastine, Nocodazole, and 2,4-DNP. When other amino acids(leu, ser, glu, or ala) were used, 3-23X less label appeared in the BN (12h runs) and the R3-14 axons were not preterentially labeled in AR. Incubating the PR in 3H-GABA, in contrast, resulted in 2X more transport into the nerve than when gly was used. Most of the 3H-GABA was localized over small axons and glia while the R3-14 axons were poorly labeled. This work demonstrates the selective and active retrograde AT of a small molecule from terminal regions back to soma, a process which probably involves the compartmentalization of the soluble amino acid in a transportable organelle. The special handling of glycine by R3-14 provides further evidence for a non-metabolic role for glycine in these neurons, probably as a neursh messenger. Supported by NIH #16399.

## AXOPLASMIC TRANSPORT II

43.1 DIFFERENT INCORPORATION AND TRANSPORT PATTERNS OF <sup>3</sup>H-PROLINE IN THE DORSAL COLUMN NUCLEI OF NEONATAL AND ADULT CATS. N. <u>Contos</u>, <u>L. Barber\* and K.J. Berkley</u>. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

Univ., lalianassee, FL 32300. The results of previous studies in our laboratory suggested that macroglia participate in the transfer of  ${}^{3}$ H-pro-labeled molecules from the dorsal column nuclei (DCN) to their targets in the brainstem. Developmental studies by others have demonstrated that, in general, macroglia are not fully developed in neonatal cats. Thus, if the above hypothesis is correct, incorporation and transport of  ${}^{3}$ H-pro-labeled molecules from DCN to their targets should differ in neonates and adults. Two studies were directed at this prediction. First, the DCN of 6 day old and adult cats were examined at the electron microscopic (EM) level to characterize differences in their macroglia and neurons. Second, the DCN of kittens ages 1,6, and 9 days as well as adult cats were injected with  ${}^{3}$ H-pro, allowed to survive 24 hours, and their brains processed for light microscopic (LM) autoradiography. The labeling patterns in the neonate and adult DCN and their targets in the inferior olive and thalamus were then compared.

Drains processed for fight microscopic (EM) autoratiography. The labeling patterns in the neonate and adult DCN and their targets in the inferior olive and thalamus were then compared, The EM study demonstrated striking differences both in macroglia and neurons in the neonate and adult. In the neonate, astrocytic processes were less densely filled with filaments and occupied more of the neuropil. Astrocytes were less regularly organized in their relationship to neuronal soma and myelination was rarely observed. Neurons were much smaller. In the LM autoradiographic study, the labeling patterns in developing brains of kittens aged 1-9 days did not vary much from each other but were distinct from those in the adult. At the DCN injection site, glial cells were densely labeled in both the neonate and adult, but, in the neonate, many more neurons appeared to be labeled, especially near the center of the injection sites. Corresponding differences occurred at DCN's terminal targets in the inferior olive and thalamus. Both targets were markedly more intensely labeled in the neonate. More over, in the neonate, terminal labeling appeared over portions of the intralaminar complex of the thalamus, (a region that has never been reported to receive DCN terminations in the adult even after extensive injections or lesions that invade regions surrounding DCN).

DCN). These results support the hypothesis that in the adult cat macroglia are involved in the transport of <sup>3</sup>H-pro-labeled molecules from DCN to their terminal targets. The results further suggest that the lack of incorporation of <sup>3</sup>H-pro by neurons in adult DCN and the corresponding attenuated terminal labeling may be related to the larger size and possible slower metabolic rate of adult neurons and/or to the more systematic associations between the neurons and their enveloping macroglial processes. Supported by NSF grant BNS 79-03423. 43.2 REDISTRIBUTION OF NEURONAL DIPEPTIDYLAMINOPEPTIDASE II FOLLOWING COLCHICINE TREATMENT. M.C. Bundman, P.J. Lew\* and C. Gorenstein. Department of Pharmacology, University of California, College of Medicine, Irvine, CA 92717. Using histochemical techniques, we have previously shown that dipeptidylaminopeptidase II (DAP II) is highly localized to a small number

Using histochemical techniques, we have previously shown that dipeptidylaminopeptidase II (DAP II) is highly localized to a small number of neuronal cell populations in rodent brains. (Gorenstein, Tran and Snyder, J. Neurosci., 10, 1096, 1981). The discrete distribution of DAP II suggests that it may play a role in the metabolism of a unique brain peptide.

In an attempt to enhance the histochemical visualization of enzyme activity in brain areas which stained marginally for DAP II we reasoned that intracerebroventricular (ICV) injections of colchicine would lead to an accumulation of enzyme in cell bodies. However, rather than an accumulation in neuronal perikarya, colchicine produced an unexpected redistribution of DAP II. Cell bodies which normally contained DAP II were depleted of staining and DAP II had, instead, accumulated in the dendrites of these cells.

Although the effect was not uniform throughout the brain, all DAP II containing neurons except those of the mesencephalic nucleus of the trigeminal nerve displayed some degree of change. The effect was dose dependent, time dependent and reversible. Progressive effects were seen with 25, 50, 100 and 400  $\mu$ g of colchicine 24 hours post-injection. The effects of 100  $\mu$ g colchicine were seen earliest at three hours, were maximal at 18-24 hours and had reversed by 5 days post-injection. Cresyl violet stained sections showed normal morphology in all the affected areas.

This paradoxical redistribution produced by colchicine raises some fundamental questions concerning the role of DAP II and that of other peptidases in neuronal function.

43.3 PARADOXICAL REDISTRIBUTION OF DAP IL CONTAINING ORGANELLES FOLLOWING COLCHICINE TREATMENT. C

ORGANELLES FOLLOWING COLCHICINE TREATMENT. C. Gorenstein, M.C. Bundman and C.E. Ribak. Departments of Pharmacology and Anatomy, University of California, College of Medicine, Irvine, California 92717 Dipeptidylaminopeptidase II (DAP II), a brain peptidase, is highly concentrated in a small number of neuronal populations. In the present study DAP II has been localized in the rat olfactory bulb at the electron microscopic level. Examination of the somata of mitral cells shows that the reaction product specific for DAP II is contained in lysosomes, lypofuscin granules, short eisternae close to the endoplasmic reticulum, and dense granules. The most intense staining appears within lysosomes and lypofuscin granules. The short cisternae appear to coil and spiral and are seen occasionally as C-shaped lamellae and ringlets. More

and are seen occasionally as C-shaped lamellae and ringlets. More commonly these structures are seen as spiraling lamellae that appear to have an unlabeled core. Dense granules are also commonly seen containing a dense core surrounded by an unlabeled membrane. No labeled organelles were observed in mitral cell dendrites. DAP II activity was also studied in rats treated with colchicine. Colchicine (100µg) dissolved in distilled water was injected into the lateral ventricle of rats. Twenty-four hours later rats were perfused with 40/o paraformaldehyde and 10/o glutaraldehyde. Brains were dissected and 50 µm sections were obtained with a vibratome prior to staining for DAP II activity. Light microscopic studies have indicated a redistribution of DAP II label in these preparations. At the electron microscopic level, organelles containing DAP II appear concentrated in the somata at the base of dendrites rather than diffusely localized throughout the perikaryal cytoplasm as observed in untreated animals. In addition, DAP II containing lysosomes penetrate into dendrites where In addition, DAP II containing lysosomes penetrate into dendrites where they appear to be more elongated and often dumbbell shaped. Some DAP II containing organelles resemble the cisternae of smooth endoplasmic reticulum that are often found in the peripheral cytoplasm of the dendrites. The distribution of other organelles such as mitochondria, rough endoplasmic reticulum and the Golgi complex appeared unaffected

rough endoplasmic reticulum and the Golgi complex appeared unaffected by the colchicine treatment. The changes in the types of DAP II containing organelles and their redistribution in colchicine preparations suggests that colchicine has an effect on the GERL system. This effect appears opposite to that described in previous studies on protein transport within dendrites and axons where colchicine blocks the active movement of proteins and organelles so that they accumulate in the soma. The findings of the present study suggest that colchicine disrupts the intracellular matrix that sequesters lysosomes in somata. Supported in part by grants from NIDA 03131 (CG) and NS-15669

3,4-DIMETHYL-2,5-HEXANEDIONE IMPAIRS AXONAL TRANSPORT OF NEUROFILAMENT PROTEINS. J. W. Griffin<sup>1</sup>, D. C. Anthony<sup>\*+</sup>, K. Fahnestock<sup>\*†</sup>, P. N. Hoffman<sup>1</sup> and D. G. Graham<sup>\*+</sup>. <sup>1</sup>Dept. of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. and <sup>+</sup>Dept. of Pathology, Duke Univ. Sch. of Med. Durham, N.C. 3,4-dimethyl 2,5-hexanedione (DMHD) is a recently developed, more potent analogue of the neurotoxic hexacarbon, 2,5-hex-anedione (HD) (Anthony, et. al., Tox. Appl. Pharm., in press). Administration of DMHD results in intraaxonal accumulation of neurofilaments (Anthony, et. al., J. Neuropath. Exp. Neurol., in press). DMHD is known to interact with e-amino groups of pro-teins to form pyrrole rings, and Anthony, et. al. have postulated that the neurotoxicity of DMHD results from oxidation of the pyrrole rings, leading to covalent crosslinking of neurofila-ments. In this study we examined the effect of DMHD on axonal transport of cytoskeletal proteins in rat lumbar motor neurons and compared the changes seen to those produced by 8, B<sup>1</sup>-iminodi-projeonitrile (IDPN), an agent known to selectively impair neuro-

and compared the changes seen to those produced by  $\beta_{+}\beta^{+}$ -iminodi-propionitrile (1DPN), an agent known to selectively impair neuro-filament protein transport (Griffin, et. al., Science, 202:633). Rats received .6mM/kg DMHD i.p. for 5 days. <sup>35</sup>S-methionine was injected into the lumbar ventral horns of both DMHD-treated and control rats (5 weeks of age). The sciatic nerves were removed 2, 4, 12, and 21 days after labeling, and divided into 3 mm segments. The proteins in each segment were separated by SDS-PAGE and visualized by fluorography. In addition, the bands corresponding to the neurofilament proteins, tubulin, actin, and an SCb marker protein (Mr = 113 kd) were cut out, solubilized, and counted. For each of these proteins, we calculated the half velocity (HV) as the distance in mm reached by the 50th percen-tile of total radioactivity in that protein divided by days after

The of total radioactivity in that protein divided by days after injection. DMHD impaired transport of all slow component consti-tuents, most profoundly retarding the neurofilament proteins (12 day half velocity = <.25 mm/day, compared to 2.07 in controls). Transport of tubulin, actin, and the SCb marker protein was only moderately reduced (70-90% of control velocities). The changes produced by DMHD were essentially identical to those produced by DMHD were essentially identical to those produced by IDPN. IDPN reduced the HV of neurofilament protein 4-10-fold, while reducing the HV of tubulin, actin and SCb marker protein transport to 50 to 80% of normal. The similarities between DMHD and IDPN in pathologic changes and in effects on axonal transport are consistent with recent studies (Griffin, et. al., Ann. Neurol., in press) showing that HD shares with IDPN the ability to produce segregation of neurofilaments from microtubules within the axon. The similarities in effects on cytoskeletal organization and axonal transport of neurofilament proteins suggest that these agents may share biochemical actions. share biochemical actions.

43.5

ALTERATIONS IN FAST TRANSPORTED PROTEINS FOLLOWING INJURY TO HYPOGLOSSAL AXONS. J. D. Redshaw<sup>K</sup> and M. A. Bisby<sup>\*</sup> (SPON: G. E. Lucier). Department of Medical Physiology, University of Calgary, Calgary, Alberta Canada T2N 4NI. Previously we reported that a number of alterations in the composition of fast axonally transported proteins (FTP) occurred following sciatic nerve injury. The most significant of these changes involved the ratio of labelling of two polypeptide bands S<sub>1</sub> (MW 28,000) and S<sub>2</sub> (MW 23,000) which could be readily identi-fied and compared on fluorographs of SDS-PAGE gels containing transported proteins. The S<sub>2</sub>/S<sub>1</sub> ratio increased after axotomy, reached a peak by 14 days and returned toward normal values by 42 days. Motor axons prevented from regeneration and reinnervation failed to demonstrate this return toward normal values. Axotomy of retinal ganglion cell axons failed to induce any alteration in the S<sub>2</sub>/S<sub>1</sub> ratio. We postulate that this change in the S<sub>2</sub>/S<sub>1</sub> ratio is correlated with the ability of a neuron to regenerate its injured axon. However, Skene and Willard (J. Cell. Biol., 89:96, 1981) reported no change in GAP 23, a polypeptide probably identical to S<sub>2</sub>, following axotomy of rabbit hypoglossal moto-neurons. Therefore the purpose of the present study was to re-evaluate the S<sub>2</sub>/S<sub>1</sub> ratio in normal and regenerating hypoglossal axons. The right hypoglossal nerve of anaesthetized male rats was axons.

axons. The right hypoglossal nerve of anaesthetized male rats was crushed with forceps proximal to its muscular ramifications where it crosses the digastric muscle. The rats were allowed to recover for varying periods from 1 to 28 days prior to the stereotaxic administration of 100  $\mu$ Ci of  $^{35}$ [S]-methionine into the hypoglossal nuclei. Radio-labelled FTP were recovered within the hypoglossal nerves 10 mm proximal to a collection ligature four hours after isotope injection. Labelling of FTP within normal and regenerating sciatic nerves were performed as pre-viously described (Bisby, M.A. J. Neurobiol. 11:435. 1980).

normal and regenerating sciatic nerves were performed as pre-viously described (Bisby, M.A., J. Neurobiol. 11:435, 1980). Hypoglossal and sciatic nerve segments were processed for either one or two dimensional gel electrophoresis and fluorography. Analysis of the fluorographs revealed significant alteration in the  $S_2/S_1$  ratio, with an increase in  $S_2$  labelling following axotomy of either hypoglossal or sciatic nerves. This increase returned toward normal values three weeks following hypoglossal nerve injury. We conclude, that in the rat, peripheral moto-neurons of the hypoglossal nuclei and lumbar spinal cord respond similarly to axon injury and that the observed changes in the composition of FTP are correlated with the regenerative capacity of the axon.

of the axon. Supported by MRC of Canada and Alberta Heritage Foundation for Medical Research.

SELECTIVE INHIBITION OF RETROGRADE AXONAL TRANSPORT BY ERYTHRO-43.6

SELECTIVE INHIBITION OF RETROGRADE AXONAL TRANSPORT BY <u>ERYTHRO-</u> 9-[3-(2-HYDROXYNONYL)]ADENINE (EHNA). D.S. Forman, <u>K.J. Brown\*</u> and <u>M. E. Promersberger\*.</u> Dept of Anatomy, Uniformed Services <u>University</u> of the Health Sciences, Bethesda, MD 20814. Little is known about the factors that control the direction of fast axonal transport. We have found that <u>erythro-9-[3-(2-</u> hydroxynonyl)]adenine (EHNA) reduces the mean <u>velocity</u> of microscopically visible organelles that are transported in the retrograde direction, but has little or no effect on the transport of organelles in the anterograde direction. Acutely isolated giant motor axons from the walking legs of lobsters were mounted in lobster medium in a perfusion chamber. Organ-elle movements at 23-25°C were visualized with Nomarski optics and video microscopy, and recorded using a video tape recorder. Velocities were measured with a Colorado Video 610E Video and video microscopy, and recorded using a video tape recorder. Velocities were measured with a Colorado Video floE Video Pointer. The following table shows the mean velocity in  $\mu$ m/sec  $\pm$  SEM (N) of retrogradely and anterogradely moving particles before and during the perfusion of ImM EHNA, and after washing with the TUNA. out the EHNA:

	Retrograde
Control (before EHNA)	$1.74\pm.07$ (51)
1mM EHNA	0.89±.04 (56)

leciogra	ue	Anterograde	
74±.07	(51)	0.63±0.08 (26)	
89±.04	(56)	0.69±0.05 (34)	
72+ 09	1431	0.57+0.03 (29)	

After removal of EHNA  $1.72\pm.09$  (43)  $0.57\pm0.03$  (29) It can be seen that in the presence of 1mM EHNA, the mean velo-anterograde movements of microscopically visible particles were not obviously affected. Retrograde movements of elongated mitochondria were also inhibited reversibly, while anterograde movements of mitochondria were not affected. A higher concen-tration of EHNA, 4mM, produced more inhibition of retrograde particle velocity (71%), and a slight (16%) decrease in the anterograde velocity. However, 4mM EHNA produced irreversible damage to the axons after 10-15 minutes. Permeabilized axons (D S Eoman et al. ) Neurosci in press) were also used to damage to the axons after 10-15 minutes. Permeabilized axons (D.S. Forman et al., J. Neurosci., in press) were also used to demonstrate the effect of EHNA. The mean velocity of retrograde movements reactivated with 0.2mM ATP was reduced by 72% in the presence of 2 mM EHNA; the mean anterograde velocity in the same axons showed a smaller (29%) but significant (t-test;p<.05) reduction. The effects of EHNA on retrograde transport may be related to the actions of EHNA as an inhibitor of dynein and o protein carboxymethylation (P. Bouchard et al., Proc. Nat. Acad. Sci. USA, 78: 1033, 1981). EHNA is the first agent reported to affect retrograde and anterograde transport differentially. It may prove to be a useful tool for analyzing the factors that control the direction of fast axonal transport. (Supported by NIH grant GM30450.) 43.7 THE CELLULAR ORIGIN AND BIOSYNTHESIS OF RAT OPTIC NERVE PROTEINS. E.R. Lewis, J.M. Gilbert, L.I. Benowitz and P. Strocchi. Mailman Res. Ctr., McLean Hospital, Belmont, MA 02178 and Harvard Medical School, Boston, MA 02115. High resolution 206E (two-dimensional gel electrophoresis) was

High resolution 2DGE (two-dimensional gel electrophoresis) was used to characterize neuronal and glial proteins of the rat optic nerve, to examine the phases of intraaxonal transport with which the neuronal proteins are associated, and to identify the ribosomal populations on which these proteins are synthesized. Neuronal proteins synthesized in the tagtinal ganglion cells were identified by injecting the eye with  $[^{-5}S]$ -L-methionine, followed by 2DGE analysis of fast and slow axonally transported proteins in particulate and soluble fractions. Proteins synthesized by the glial cells were labeled by incubating isolated optic nerves in the presence of  $[^{-5}S]$ -L-methionine and then analyzed by 2DGE. A number of differences were seen between filamentous proteins of neurons and glia. Most strikingly, the multiple subunits of  $\alpha$ - and  $\beta$ -tubulin in glia had a distinctly different 2D configuration than the tubulin subunits found among axonal proteins. There were two neurofilament proteins of the glial cimpartment. The fast axonally transported proteins of the glial compartment. The fast axonally transported (on 2DGE) with proteins synthesized by rat CNS rough microsomes; this finding suggests that rough endoplasmic reticulum may be a major site of synthesis for fast transport, including tubulin subunits, actin and neurofilament proteins. Supported by N I H grants AGO2126, ROINS16943, 5KO270713 and the Marion Benton Trust.

43.8 CENTRAL AND PERIPHERAL AXOTOMY OF DORSAL ROOT GANGLION (DRC) CELLS DIFFERENTIALLY AFFECTS SLOW AXONAL TRANSPORT. M.M. Oblinger and R.J. Lasek, Dept. of Devel. Genetics and Anatomy, Case Western Reserve Univ., Cleveland, OH 44106. Many early reports that chromatolysis of DRG cells occurs only after peripheral branch axotomy suggested that the DRG cell

Many early reports that chromatolysis of DRG cells occurs only after peripheral branch axotomy suggested that the DRG cell selectively recognizes, and responds differently, to a signal created by axotomy of its central vs. its peripheral axon. We have examined changes in the synthesis and metabolism of cytoskeletal and associated proteins occurring in the DRG cell body after axotomy of either the peripheral or central branch. The cytoskeletal proteins were studied by labelling DRG cells and analyzing these labelled proteins after they were transported into the axons by slow axonal transport.

Slow transport profiles were compared in control animals, and animals that sustained either an axotomy of the fifth lumbar (L5) dorsal root near its entry into the spinal cord or an axotomy of the sciatic nerve 60 mm from the L5 DRG two weeks earlier. To label axonally transported polypeptides associated with the two major slow rate components, SCa and SCb, DRG cells of adult male albino rats were pulse-labelled by microinjection of <sup>35</sup>S-methionine. At post-injection times ranging from 3-28 days, animals were sacrificed and the entire L5 system removed. Consecutive 2 mm segments of nerve were cut and samples were subjected to SDS polyacrylamide slab gel electrophoresis and fluorography. Resulting changes were quantitated by excising individual protein bands from gels and determining the radioactivity by liquid scintillation counting. A number of changes in slow axonal transport resulted from a

A number of changes in slow axonal transport resulted from a peripheral branch axotomy; however, central branch axotomy produced no apparent alterations in the rate or composition of SCa or SCb in either dorsal root or peripheral branch axons. After peripheral axotomy several quantitative changes, including a dramatic reduction in the ratio of labelled neurofilament proteins to tubulin in peripheral branch axons, and a less robust reduction in central branch axons, occurred. Our observations indicate that while axotomy of the peripheral branch of the DRG cell influences some aspect of synthesis and/or assembly of cytoskeletal proteins, central branch axotomy does not. The differential response of the DRG cell to axotomy of its central vs. its peripheral branch may be related to differences in the information that reaches the DRG cell body by retrograde transport.

43.9 SELECTIVE ROUTING OF FAST TRANSPORTED PROTEINS IN BRANCHES OF SENSORY AXONS. <u>R. Dino Rulli\* and David L. Wilson</u> (SPON: Ronald G. Clark.) Dept. of Physiology and Biophysics, University of Miami Sch. of Med., Miami FL 33101 Each nerve cell in the 8th and 9th dorsal root ganglia (DRG)

Each nerve cell in the 8th and 9th dorsal root ganglia (DRG) has a single axon emerging from the cell body which bifurcates into two processes: one is directed centrally in the dorsal root (DR), and the other peripherally in the sciatic nerve (SN). We have attempted to determine the degree to which the proteins being transported in each branch can differ. Following a  $^{35}$ S-methionine labeling of the DRG, the fast transported proteins are collected at ligatures on DR and SN.

Following a  $^{52}$ S-methionine labeling of the DRG, the fast transported proteins are collected at ligatures on DR and SN. The collected proteins are then separated by two-dimensional polyacrylamide gel electrophoresis (2-D PAGE) and fluorographed. An earlier qualitative analysis of the fluorographic patterns showed no discernable differences in species of proteins shipped down the DR and the SN (Stone & Wilson, 1979).

We have performed a quantitative analysis, in which a given spot in the DR gel is punched out and counted, and its counts are compared to the counts in the spot treated in the same way from the SN gel. The null hypothesis states that each protein spot will exhibit the same ratio of cpm SN/cpm DR. The present results show that not all proteins have the same ratio. This suggests that there is some differential shipping of the proteins in fast axonal transport, and that the cell body and/or axon has some influence on the specificity of proteins being transported in the two axon branches. We gratefully acknowledge support from NSF grant BNS 81-17817 and NIH training grant NS 07044. 43.10 AXONAL TRANSPORT AND METABOLISM OF CYTOSKELETAL PROTEINS IN THE PREGANGLIDNIC FIBERS OF CHICKEN CILIARY GANGLION. <u>P. Paggi\* and</u> <u>R.J. Lasek</u>, Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ., Cleveland, 0. 44106.

<u>R.J. Lasek</u>, Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ., Cleveland, O. 44106. The axon and its presynaptic terminal are structurally and functionally very different. However, the cytoskeletal proteins of the axon terminal are supplied through the axon by axonal transport. Therefore, all of the proteins that are in the axon terminal must also be present in the axon. The differentiation of axoplasm into synaptoplasm must involve major changes in the composition of the axonal proteins when they enter the presynaptic terminal. In order to study the mechanisms which convert the axonal cytoskeleton of the axon into that of the presynaptic terminal, we have examined axonally transported proteins in the fibers innervating the ciliary ganglion. Three week old chickens received injections of <sup>35</sup>S-

Three week old chickens received injections of  $^{35}$ smethionine in the cerebral aqueduct and were sacrificed at different intervals of time after injection, ranging from 18 to 42 days. Labelled proteins were analyzed in segments of the oculomotor nerve, which contain both the oculomotor nerve fibers and the preganglionic fibers, and in the ciliary ganglion , which contains the terminals of the preganglionic terminals. The radiolabelled proteins were subjected to one and two-dimensional SDS-PAGE and fluorography. Axonal transport was similar to that observed in other neurons. Slow component <u>a</u> (SCa) was defined by the neurofilament proteins (NFP) and tubulin, and slow component <u>b</u> (SCb) was defined by actin and a variety of other typical SCb proteins. The cytoskeletal proteins showed different behaviours when they reached the ganglion. Actin and tubulin, which begin to appear the ganglion at day 2 remain heavily labelled in the ganglion at day 32. By contrast, NFP starts to appear in the ganglion at day 9 and slowly increases during the later times. Both actin and tubulin apparently have a longer residence time in the ganglion. The long term presence observed for both actin and tubulin in the do the NF proteins. Quantitative analyses are underway to determine the differential rates of turnover of the cytoskeletal proteins when they reach the ganglion. The long term presence observed for both actin and tubulin in the ganglion is consistent with the structural features of the cytoskeleton in the presynaptic terminal. Microfilaments and microtubules are generally more abundant than neurofilaments in the synaptic terminal region. These observations are consistant with the hypothesis that differential metabolism of axonally transported cytoskeletal proteins play an important role in the conversion of the axonal cytoskeleton into that of the presynaptic terminal. 43.11 RETENTION OF AXONALLY TRANSPORTED NEUROFILAMENT PROTEINS ALONG MOUSE RETINAL GANGLION CELL AXONS. R.A. Nixon, K.A. Bishop\* and W.H. Fisher\*. Harvard Medical School; McLean Hospital, Belmont. MA 02178

Hypotheses have been advanced that neurofilaments are trans ported along axons as either a pre-assembled cytoskeletal lattice or as precursors to a stationary axonal lattice. To examine whether neurofilament proteins (NFP) may contribute to stationary axonal structures, we have quantitatively examined the fate of NFP in retinal ganglion cell (RGC) axons from 1 to 168 days (d) after synthesis. The short length (9-10 mm) of the mouse optic pathway (optic nerve and tract) permitted a detailed study of proteins retained in axons long after the main waves of transported proteins that entered synapses. Groups of 80-100 mice injected intravit-really with [<sup>3</sup>H]proline were analyzed to determine changes in the absolute radioactivity (dpm) of NFP subunits (200K, 140K, 70K) and in the relative distribution of this radioactivity along RGC axons at 11 post-injection intervals from 1 to 168 d. After SDS-PAGE, changes in NFP dpm from entire optic pathways minus axon terminal regions (OP), reflecting NFP entry into and exit from axons, were quantitated in each of 8-10 mice per time point. The regional distribution of labeled NFP was also determined in 8 consecutive 1.1 mm segments of OP from 6 mice at each time point. NFP were detected in segment 8 by 17d, although the main wavefront reached this point by 25d, indicating a transport rate of 0.2-0.3 mm/d. Each major NFP subunit behaved similarly in all studies. Loss Loss of NFP dpm between 17 and 168d was biphasic; each of the two rates was linear. Dpm declined 60% between 17 and 45d, but between 45 and 120 d only 45% of the remaining label disappeared. At 168d, 6-9% of the initially transported NFP was still present in axons. Retention of NFP was not accounted for by continual contributions from RGC perikarya. From 1 to 30d, the NFP wavefront progressed through consecutive OP segments. By 30d, segments 7 and 8 were most intensely labeled although the trailing end of the wave spanned the entire OP and contained more than half of the labeled NFP. From 6 to 15d, NFP dpm in segments 1 and 2 declined, giving the impression of a moving, trailing edge. In contrast to this NFP. early redistribution of labeled NFP, however, no change in axonal distribution occurred after 45 d even though >40% of the NFP dpm was still present along the optic pathway (>30% of its segments 1-4). Therefore, beyond 45d post-injection, the rate at which NFP dpm declined appeared to be similar in each segment, suggesting that the radioactivity retained in the axon was not part of a mov-ing wave. These data indicate that a substantial stationary pool of NFP exists along RGC axons which may reflect the presence of a stationary cytoskeletal structure. **43.12** ACCUMULATION OF FAST-TRANSPORTED ACHE AND ADENYLATE CYCLASE *i*.1 A NERVE LIGATURE IS UMAFFECTED BY CONDITIONS THAT INHIBIT ACCUMULATION OF <sup>3</sup>H-PROTEIN. *R. Hammerschlag, F.A. Bolen\* and R.C. Carlsen* Div. Neurosciences, City of Hope Res. Inst., Duarte, CA 91010 and Dept. Human Physiology, Univ. Calif. Sch. Med., Davis, CA 95616 The intrasomal passage of pulse-labeled proteins to the fast transport system of the axon can be inhibited by either  $Co^{2+}$  or monesin (Stone & Hammerschlag, Cell Mol Neurobiol 1:3,1981; Hammerschlag et al, <u>J Cell Biol</u> 93:568,1982). This decreased export, resulting from perturbing Golgi or peri-Golgi events, was detected for all individual fast-transported AchE activity at a crush on the accrumulation of fast-transported AchE activity at a crush on the corresponding dorsal or ventral root (Larivière & Lavoie, <u>J Neurochem</u> 39:882,1982). We have explored further this apparent anomaly, using an in vitro preparation of bullfrog dorsal root ganglia (DRG) and spinal nerve. Effects of 0.18mM Co<sup>2+</sup> or 0.1µM monensin on fast transport of AChE were examined in two types of studies. <u>First</u>, "in transit" AChE was allowed to clear out of the fibers prior to nerve ligation, and fast transport of <sup>3</sup>H-leulabeled protein was monitored concomitantly. Under these condition of AchE activity, while <sup>3</sup>H-protein decreased 95±2%. In the presence of monensin (n=6), AChE decreased 19±4%; <sup>3</sup>H-protein decreased 7±2%. In the presence of co<sup>2+</sup> and monensin on newly-synthesized enzyme. (This level of DFP did not inhibit transport of <sup>3</sup>H-protein.) After washing to remove unbound DFP, exposure of DRG to Co<sup>2+</sup> (n=6) increased AChE 1±16%, while <sup>3</sup>H-protein decreased 83±10%. Exposure to monensin (n=6) He activity and the accumulation of adenylate cyclase (AC) was studied as in the first protocol above to examine whether the AChE results might be observed for other fast-transported particulate enzyme. Exposure of DRG to either Co<sup>2+</sup> (d=2) was studied as in the first protocol above to examine wheth Studied as in the first protocol above to examine whether the Ante results might be observed for other fast-transported particulate enzymes. Exposure of DRG to either  $Co^{2+}$  ( $0\pm 2\%$  decrease, n=3) or monensin ( $8\pm 3\%$  decrease, n=3) had little or no effect on the build-up of AC activity at the ligature, similar to the findings in the AChE studies. Interpretation of these results depends on whether AChE or AC are among the fast-transported species that have been separated and quantitated on two-dimensional gels. If have been separated and quantitated on two-dimensional gels. If they are not, the present findings suggest that newly-synthesized fast-transport proteins reach the axon by two distinct intrasomal routes, one of which is insensitive to  $Co^{2+}$  and monensin. Supported by NSF:8112129 and MS:RG1296-A1 (RH); NIH:NS15065 (RCC).

- DIFFERENTIAL 43.13 DELIVERY OF SULFATED PROTEINS BY FAST AXONAL TRANSPORT. <u>GC Stone, R Hammerschlag, and JA Bobinski.</u>\* Div. of Neurosciences, City of Hope Res. Inst., Duarte, CA 91010. Among the most abundant 150 individual proteins fast-Among the most abundant 150 individual proteins fast-transported in vitro in bullfrog dorsal root ganglia (DRG)/spinal nerve preparations is a subset of species that are unique in that they contain sulfate moieties while lacking any carbohydrate (Stone et al., <u>Trans.Amer.Soc.Neurochem.,14</u>,143). The present study has sought to <u>confirm this observation</u>, further characterize these proteins, and determine if their unusual property correlates with their intracellular destination. The presence of non-plucocutated could fate containing fact transported proteins (FIRE) The story of the second and the sec nerve was cut in segments, each of which was homogenized and exposed to mild acid hydrolysis as above. This treatment demonstrated a gradient of acid-labile  $^{35}\mathrm{SO}_4$ -cpm from background levels in segments immediately distal to the ligature to maximum cpm values in the "front" of FTPs. Together these findings suggest that a unique sub-population of FTPs preferentially destined for neuronal terminals can be characterized as containing sulfated tyrosine residues. Supported by NSF 8112129 and MS-R61296-A1.

COMPARISON OF CALCIUM AND STRONTIUM SEQUESTRATION IN NERVE AXONS IN RELATION TO AXOPLASMIC TRANSPORT, <u>S. Ochs, R.A. Jersild</u>, <u>Jr.\*, T. Breen\* and R. Peterson\*</u>. Departments of Physiology and Anatomy, Indiana University School of Medicine, 635 Barnhill Drive, Indianapolis, IN 46223. The requirement for Ca to maintain axoplasmic transport has previously been shown using <u>in yitro</u> downflow of <sup>3</sup>H-labeled proteins in sciatic nerve following injection of the L7 dorsal root ganglion of cats by our usual methods. Deletion of Ca from the medium blocks transport after several hr. Additionally, high levels of Ca also block transport. Transport may continue for a while in the face of high Ca, presumably as a result of while in the face of high Ca, presumably as a result of mechanisms of Ca regulation present in nerve fibers to keep free Ca at low levels. These were indicated in studies of nerves exposed to high Ca and finding organelles considered important in Ca regulation, the mitochondria and ER, as well as Ca-binding The regulation, the mitocholdrid and Ex, as well as Carbinding protein sites in the axoplasm, to contain increases in electron-dense particles when using a pyroantimonate method. To identify Ca in these particles X-ray microanalysis was used. Because the energy spectrum of Sb in the pyroantimonate overlaps with Ca, a special computer subtraction technique was required to show the preserve of Ca. To further show the relation of Ca to show the presence of Ca. To further show the relation of Ca to these sites, Sr was employed as a tracer of Ca insofar as Sr has a chemical similarity and has similar physiological actions. nerves exposed to high Sr (20-85 mM), an increased number of particles was seen with the pyroantimonate technique. As wi In As with particles was seen with the pyroantimonate technique. As with Ca, they were distributed in the mitochondria, ER, axoplasm and along the axolemma. Sr has its X-ray energy peak far removed from Sb allowing its clear identification to be made with X-ray microanalysis. The particles showed both Sr and Ca present in them in most cases. In some particles Sr and in others Ca alone was seen. At high levels of Sr a block of transport was seen. This could be due to a displacement of Ca from the Ca sequestering sites or to an action of Sr on the calmodulin Ca-Mg ATPase considered to underly the transport mechanism. The Arrase considered to underly the transport mechanism. The presence of Ca in axons was also shown without the use of pyroantimonate. Pieces of desheathed nerves were exposed to varying concentrations of Ca from 20-75 mM and then frozen with Freen-12 cooled down to  $-160^{\circ}$  C with liquid N<sub>2</sub> before being dried under vacuum at low dehydration temperatures. The nerves were cut into small sections and infiltrated under vacuum with Source either directly or after comication them under vacuum Spurr either directly or after osmicating them under vacuum. Sections cut for EM and X-ray microanalysis showed high Ca in Sections out for  $\Sigma^{n}$  and  $X^{-1}$ ay introducing is showed high K. A low amount of Na and high levels of Cl and P were also seen. Na and Cl were present in high amounts outside the nerve fibers. Supported by NIH #NSO 8706-14 and NSF #BNS 79-14029.

43.15 INCREASED DURATION OF AXOPLASMIC TRANSPORT IN <u>VITRO</u> WITH ADDED GLUCOSE OR  $\beta$  -HYDROXYBUTYRATE, L.C.J. Gaziri\* and S. Ochs. Department of Physiology and Medical Biophysics Program, Indiana University School of Medicine, 635 Barnhill Drive, Indianapolis, IN 46223.

IN 46223. Fast axoplasmic transport was earlier shown in this laboratory to be closely dependent on oxidative metabolism supplying ATP to the transport mechanism. It is rapidly blocked by anoxia or by agents interfering with the production of ATP. Previously we found that transport was maintained without addition of glucose or other metabolites to an in yiro medium. We have now initiated a study of transport in cat sciatic nerve, measured as customary in our laboratory by the downflow of labeled protein after injection of the L7 dorsal root ganglia with "H-leucine, to determine the length of time for which endogenous metabolites are able to maintain axoplasmic transport in vitro and the possibility of maintenance of transport continues for close to for determination of ATP and creatine phosphate (CP) by adding metabolites to the incubating medium. Without the addition of exogenous metabolite, transport continues for close to 6 hr in yitro before a block occurs. Taking a small sample of nerve for determination of ATP and creatine phosphate (CP) by a luciferin-luciferase method, the content of high energy phosphate (~P), the combined level of ATP and CP, is seen to fall linearly in the nerves during this period of time. The block of transport occurs when the level of ~P falls to about half of its control value, from 1.3 to 0.6 umol/g. Glycogen falls in an exponential fashion, being reduced to half its control value in about 3 hours. Glucose is more quickly depleted from the nerve with a fall to near zero in less than 2 hrs. Most of this fast fall is due to its leakage to the medium in the first 15 minutes of incubation. The addition of 5 or 15 mM glucose to the medium maintains fast transport well beyond the 6 hr time; for at least 13 hrs. The longer lasting downflow was present not only in the desheathed peroneal branch but it occurred as well in the sheathed tibial branch. Glucose therefore can readily pass through the perineurium of the sheathed nerves to enter the endonenrial 43.16 EFFECTS OF TETRODOTOXIN UPON AXOPLASMIC TRANSPORT IN THE DEVELOP-ING VISUAL SYSTEM OF THE ALBINO RAT. <u>R.V. Riccio and M.A.</u> Matthews, Dept. of Anat., LSU Med. Ctr., New Orleans, La.

Matthews, Dept. of Anat., LSU Med. Ctr., New Orleans, La. The role of retinal neuronal activity in regulating the development of postsynaptic visual relay centers in the brain is presently a topic of considerable interest. As a prelude to a morphological analysis of these regions, we have assessed the effect of tetrodotoxin (TTX)-induced impulse blockade upon axoplasmic transport in the optic nerve. Timing of toxin application was designed to coincide with proposed critical periods of development of the lateral geniculate nucleus, superior colliculus and visual cortex. Intraocular injections of 0.5-0.7 ul. TTX (in citrate buffer) at concentrations of 10-4, 10-5, and 10-6M were administered over a two minute period in rats aged 5-21 days postnatal. Control animals received an identical volume of citrate buffer, (pH 7.30). Injections for both groups were repeated every two days to insure a continuous suppression of impulse activity throughout the period examined.

impulse activity throughout the period examined. In order to test the effect of intraocular TTX upon axonal transport in the optic nerve, 0.5ul. of 3H proline or 3H fucose was injected into the eye of similar groups of animals at ages 5,9,13,18, and 21 days postnatal. Following survival periods of 3,6,9, and 12 hrs. levels of radioactivity were measured within fresh samples of both the lateral geniculate nucleus and the superior colliculus employing liquid scintillation spectroscopy and autoradiography. Each dosage of TTX produced no significant difference in the rate of appearance of 3H proline labeled proteins at the optic tectum or lateral geniculate nucleus when compared to controls at each survival period tested. However, a substantial difference (approximately 35%) in 3H fucose levels is apparent on days 9-21 following three hours survival in animals treated with 10-4M TTX. These amounts decrease slightly to 26% of controls by 6 hours and maintain this approximate level throughout the survival period. A qualitative assessment of retinal ganglion cell populations suggest no difference between control and TTX-treated groups at 21 days postnatal. Our results indicate that the effect of TTX upon a developing

Our results indicate that the effect of TTX upon a developing system of functionally-related neurons may not be restricted to impulse blockade alone but could also affect axoplasmic transport of glycoproteins some of which are known to be incorporated into synaptic membranes upon reception of appropriate visual stimuli. Morphometric studies are in progress to assess parameters of synaptogenesis, dendritic development and other indicators of neuronal differentiation within the retina and visual relay centers.

Supported by NIH Grant NS 14699 and a Grant-in-Aid of Research from Sigma Xi.

43.17 RETROGRADE AXONAL TRANSPORT OF ANTIBODIES TO SYNAPTIC MEMERANE PROTEINS AND GLYCOPROTEINS. R. J. Wenthold, R. A. Reale<sup>\*</sup> and K. K. Skaggs<sup>\*</sup> Dept. of Neurophysiology and Waisman Ctr., Univ. Wisconsin, Madison, WI 53706.

Univ. Wisconsin, Madison, WI 53706. The axonal transport of horseradish peroxidase and lectins has been widely used to trace neural connections. Recent studies have suggested that the retrograde transport of lectins is dependent upon the selective binding of the lectin to glycoproteins or glycolipids on the surface of neuronal membranes. Thus glycoproteins and/or glycolipids are implied to be part of the class of endogenous molecules retrogradely transported in axons. In an effort to further characterize the nature of the endogenous molecules which are retrogradely transported, we have made antibodies against synaptic membrane proteins and studied the transport of these antibodies. One preparation of antibodies was made in rabbits against synaptic membranes from guinea pig brain. A second preparation of antibodies was made in guinea pigs against the con-A binding proteins of DOC solubilized synaptic membranes from rat.

proteins of DOC solubilized synaptic membranes from rat. Retrograde transport was studied in the rat hypoglossal nerve by injecting undiluted antiserum (1 to 40 ul) into the tongue. Survival times ranged from 4 hours to 4 weeks. Following fixation with 4% paraformaldehyde, antibodies were immunocytochemically localized using either the PAP technique or the indirect labeling method with HRP-conjugated antibodies. In general, results from both antisera were similar, but antibodies degainst synaptic glycoproteins labeled more intensely. Although cells in the hypoglossal nucleus were labeled after survival times as short as 4 hours, labeling was more intense with 6 and 12 hour survival times. Labeling is still intense with a survival time of 24 hours but visibly more diffuse than with shorter times. Progressively less intense and more diffuse labeling was associated with survival times of 48 hours and 1 weeks after the injection. Specific labeling was not observed when control antisera, including normal rabbit serum, normal guinea pig serum, rabbit anti-aspartate aminotransferase, and rabbit anti-rat albumin were used. A limited number of studies done in the guinea pig using antibodies against guinea pig synaptic membranes gave results similar to those in the rat. These results suggest that antibodies to synaptic membrane

These results suggest that antibodies to synaptic membrane proteins may serve as retrograde markers and be useful in neural tract tracing studies. Furthermore, by studying the transport of antibodies to individual synaptic membrane proteins, information may be obtained as to the nature of retrogradely transported proteins. (NS 18907, HD-03352, ENS 7912939) 43.18 LOCALIZATION OF AXONALLY TRANSPORTED WHEAT GERM AGGLUTININ CONJUGATED TO HORSERADISH PEROXIDASE WITHIN AXONS OF CHICK RETINAL GANGLION CELLS, J.H. LaVail and I.K. Sugino\*. Department of Anatomy and Neuroscience Program, University of California, San Francisco, CA 94143. Recently we found that affinity-purified <sup>125</sup>I-wheat germ agglutinin (WGA) was selectively taken up and transported from chick retinal ganglion cell bodies to axon terminals in the optic tectum. We have now compared the distribution of WGA conjugated to horseradish peroxidase (WGA-HRP) with that of affinity-purified <sup>125</sup>I-WGA within chick retinal ganglion cells after axonal transport. One- to two-day-old chicks were injected intravitreally with 15 μl of buffered saline containing 10 μg/μl WGA-HRP. After 23-25 hrs the chicks were reamesthetized and fixed by perfusion. The brains and injected eyes were sectioned and reacted for HRP. Unstained sections of

eyes were sectioned and reacted for HRP. Unstained sections of layer <u>d</u> of the contralateral optic tectum were examined by EM. Various profiles were categorized as axons, axon terminals, dendrites, glia or unknown. In contrast to the labeling with  $1^{25}$ J-WGA in which the density of silver grains was highest over axons, axon terminals showed the highest labeling density with WGA-HRP (0.61 labeled organelles/ $\mu$ m<sup>2</sup> of tectal area). Axons were less frequently labeled (0.21 organelles/ $\mu$ m<sup>2</sup>). The relative labeling of nonaxonal structures was also significantly different with WGA-HRP. Only 4% of the WGA-HRP labeled organelles were found in dendrites or glial and neuron cell bodies compared to 40% with  $^{125}$ J-WGA. The intraaxonal distribution of organelles labeled with  $^{425}$ J-WGA. The intraaxonal distribution of organelles labeled with  $^{425}$ J-WGA. The intraaxonal ormpared to that labeled with  $^{125}$ J-WGA. The intraaxonal distribution of organelles are paramembrane. In comparison, the conjugate also was nonuniformly distributed within axonal profiles. It occupied a band about 60 nm wide within the axoplasm; the greatest concentration was found about 70 nm in from the plasma membrane. A peak of label was found about 30 nm in from the plasma membrane. The HRP labeled located just inside the plasma membrane. The HRP labeled lectin occupied a band about 70 nm in from the plasma dendu about 70 nm in from the plasma membrane. Baek of label was found about 30 nm in from the plasma membrane. The HRP labeled lectin occupied a band about 74 nm wide with a peak concentration located about 90 nm in from the axon plasma membrane. Based on these distributions, we have hypothesized that  $^{125}$ I-WGA accumulates within hypolemmal cisterns of the smooth endoplasmic reticulum in the axon and terminal. The WGA-HRP labels a more extensive system of tubules and cisterns as well as lyosomes within the axon and terminal. Supported in part by grant ROl NS 13533 from the N.I.H. 43.19 ANTEROGRADE AXOPLASMIC TRANSPORT OF WHEAT GERM AGGLUTININ IN THE EMBRYONIC AND POSTHATCH CHICK VISUAL PATHWAY W.J. Crossland, C.J. Uchwatt and Taichang Jang<sup>4</sup> Dept. of Anatomy, Wayne State Univ. Schl. Med. Detroit, MI 48201. We have extended our observations on the axoplasmic transport

rates of the lectin wheat germ agglutinin (WGA) and have evidence of a more rapid rate of anterograde axoplasmic transport in the chick visual system than heretofore reported.

Tracer substance was injected into the anterior pole of the retina, which projects to the caudodorsal pole of the optic tectum, to take advantage of the large intraretinal and intratectal transport distance in the chick. The following substances were injected in different experiments: Wheat germ substances were injected in different experiments: Wheat germ agglutinin-horseradish peroxidase conjugate (WGAHRP); wheat germ agglutinin-fluorescein isothiocyanate conjugate (WGAFITC); tritiated wheat germ agglutinin (/H-WGA); and <sup>3</sup>H-L-proline. Post-hatch chicks were injected under open ether anesthesia. After appropriate survival times the animals were sacrificed and the best for a service of the service After appropriate survival times the animals were sacrificed and the brains fixed and cut either on a freezing microtome (WGAHRP, WGAFITC) or after being embedded in paraffin ( ${}^{3}\text{H}\text{-WGA}$  or  ${}^{3}\text{H}\text{-}$ proline). The length of the visual pathway was measured in each experiment. No allowance was made for incorporation time of the label or for shrinkage of the pathway during fixation. The embryonic (stage 38, 12 days of incubation) retinotectal pathway (21.5 mm) was labeled with either WGAHRP or  ${}^{3}\text{H}\text{-WGA}$  after a two hour post-injection survival period to yield a transport rate greater than 258 mm/day. WGAFITC, although a much less sensitive marker, labeled the pathway at three hours after injection (shorter survival times not attempted). vielding a

injection (shorter survival times not attempted), yielding a

injection (shorter survival times not attempted), yielding a rate of a least 170 mm/day. In the post-hatch chicks WGAHRP and  $^{3}$ H-proline were transported to the caudal tectum (32.5 mm) in 2 1/4 hours yielding a transport rate of at least 346 mm/day. These rates are greater than those previously measured in the chick using scintillation counting methods.

We conclude three things from these observations: First, WGA travels in the rapid phase of anterograde axoplasmic transport, at a rate approximately equal to that of proteins and glycoproteins which incorporate <sup>3</sup>H-proline. Second, the rapid phase of axoplasmic transport in the visual pathway of the chick is at least 50% faster than previously measured. Third, histological observation of the fate of transported substances is a more sensitive method of determining the presence of tritium label than scintillation counting. (Supported by grant EY-01796 from the National Eye Institute).

SLOW AXONAL TRANSPORT IN THE WOBBLER MOUSE (MURINE MOTOR NEURON DISEASE). <u>H. Mitsumoto and P. Gambetti</u>. Institute of Pathology (Neuropathology), Case Western Reserve Univ., Cleveland Ohio 44106 43 20 DISEASE). H. Mitsumoto and P. Gambetti. Institute of Pathology (Neuropathology), Case Western Reserve Univ., Cleveland Ohio 44106 The wobbler mouse develops hereditary motor neuron disease characterized by progressive atrophy, paralysis, and contracture, predominantly affecting forelimb muscles. Detailed morphological analyses showed that the neuronal degeneration begins in the peri-karyon (primary neuronopathy). In more advanced stages of the di-sease, proximal axonal pathology develops in the ventral roots and the brachial plexus (Mitsumoto and Bradley, Brain, 1982). We studied slow axonal transport in wobbler mice (n=9) at six weeks of age, since the disease was clearly manifested and rapidly pro-gressing at this age. C57BI/6J mice at same age were used as controls (n=10). Under Halothane anesthesia, C-7,8 and T-1 pos-terior right half laminectomy was performed. At 2 locations of each spinal level, 0.25 ul of 355-methionine adjusted to 200 uci/ul was stereotactically microinjected into the right ventral horn. At 5 and 15 days after the injection, the right brachial nerve, with corresponding ventral roots, was dissected out and cut into 2 mm segments. Each nerve segment was homogenized, an aliquot was sampled for scintillation counting, and the remainder was processed in 10% polyacrylamide-gel-electrophoresis (SDS-PAGE) and fluorography. Major SDS-PAGE polypeptide bands were indi-vidually cut and processed for scintillation counting. In the wobbler mice, the amount of radioactivity migrating with slow transport was reduced by more than 50% at 15 days (P<0.01); per-cent distribution of the transported radioactivity showed a sig-nificant accumulation at the ventral root level. Although all labeled polypeptides advancing with the slow component a (Sca) and slow component b (Scb) were diminished, neurofilament triplet proteins (145K and 68K) were most severely affected (P<0.001). No qualitative differences were found between fluorograms from wobbler and control. The present findings suggest that slow axon wobbler and control

Wobbler and control. The present findings suggest that slow axonal transport in the wobbler motoneuronopathy is impaired at the ventral root level. The abnormal slow axonal transport and morphological changes in the brachial nerve of the wobbler mouse will be correlated. (The study was supported by the ALS Society of America, Veterans Administration, and NSI4509.)

### MONDAY PM

SYMPOSIA

- SYMPOSIUM. CELL RECOGNITION IN DEVELOPMENT OF THE 44 SYMPOSIUM. CELL RECOGNITION IN DEVELOPMENT OF THE NERVOUS SYSTEM. U. Rutishauser, Case Western Reserve University School of Medicine (Chairman); J. Silver, Case Western Reserve University School of Medicine; D.R. Bentley, University of California, Berkeley; F: Bonhoeffert, Max-Planck-Institut für Virusfor-schung, Tübingen. This session will focus on recent advances in studies of nerve guidance and recog-nition. Dr. Silver will describe axonal growth during development and regeneration of the mammalian CNS, with emphasis on the role of neuron-glial cell inter-actions, fasciculation, and the influence of extra-cellular spaces or channels. Recent work will be dis-cussed on the growth of axons in the developing corpus cussed on the growth of axons in the developing corpus callosum and their guidance across the cerebral mid-line by a sling-like glial structure. Dr. Bentley's presentation will consider mechanisms for pathfinding by peripheral pioneer neurons in grasshoppers, in by peripheral proheer heatons in grasshopers, in particular the evidence that growth cones of early fibers navigate along a chain of cells whose placement consitutes the initial guidance mechanism underlying long-distance neural projections. Dr. Bonhoeffer will describe studies demonstrating that retinoganglion describe studies demonstrating that retinoganglion cell growth cones can distinguish between cell surface membranes of retina and tectum, and that the anterior-posterior axis of the tectum displays a graded attraction for growth cones from temporal retina. His presentation will include new techniques for analyzing growth cone recognition properties, and for mapping of long range neural pathways. The chemistry and bio-logy of a cell adhesion molecule from neural tissue, called N-CAM, will be discussed by U. Rutishauser. Topics will include the methods used to identify and purify cell adhesion molecules, a description of the structural and binding properties of N-CAM, and studies which indicate how cell adhesion involving N-CAM can contribute to the development of neural N-CAM can contribute to the development of neural tissues and pathways.
- SYMPOSIUM. MONOAMINERGIC INNERVATION OF CORTEX: NEW EVIDENCE OF SYMPOSIUM. MONOAMINERGIC INNERVATION OF CORTEX: NEW EVIDENC ANATOMICAL AND PHYSIOLOGICAL SPECIFICITY. S. L. FOOTE, Institute (chairman); J. H. Morrison, Salk Institute; M. Molliver, Johns Hopkins Univ. Sch. of Med.; B. Waterhouse, Univ. Texas, Dallas; R. A. Nicoll, Univ. Foote, Salk  $\frac{E}{D}$ of

California, San Francisco. Recently, there has been substantial progress characterizing the anatomy and physiology of the noradrenergic and serotonergic innervation of neocortex. It is the purpose of this symposium to summarize the most important of these developments and to synthesize them, along with previous knowledge, into working hypotheses concerning the physiological functions of these pathways. Data relevant to four basic characteristics of these locus coeruleus and raphe systems have

been selected for detailed review and interpretation: 1) light-microscopic data demonstrating that terminal arborization patterns of noradrenergic and serotonergic fibers The relation patterns of noradrenergic and serotonergic fibers arborization patterns of noradrenergic and serotonergic fibers are highly systematic in the rodent and are specialized for each functional cortical region in the primate. Both density and laminar distribution vary by region in the primate, suggesting that within each region specific neuronal populations serve as targets for this innervation, 2) ultrastructural data demonstrating that many of these monoaminergic terminals form specialized synaptic contacts onto neuronal elements, 3) data suggesting that norepinephrine and serotonin, either released from terminals or applied by microiontophoresis, have specific effects on well-defined functional activity of cortical target neurons in vivo, and 4) the demonstration, in vitro, of molecular and ionic mechanisms possibly subserving these postsynaptic electrophysiological effects. These four areas have been chosen because they are ones in which substantial progress has recently been made and because the results obtained have been in many cases unexpected and have caused the most dramatic shifts in how cases unexpected and have caused the most dramatic shifts in how the brainstem monoaminergic systems and their functioning are currently perceived. These four sets of data are mutually reinforcing (and somewhat overlapping) and suggest a specific interaction of these monoamine systems with neocortex to alter the latter's functioning via spatially localized and temporally discrete modification of neuronal information processing.

COLLATERAL PROJECTIONS TO STRIATE AND EXTRASTRIATE CORTICES FROM 46.1 THE DORSAL LATERAL GENICULATE, PULVINAR AND EXTRASTRIATE CORTEX IN THE MACAQUE MONKEY: A DOUBLE LABEL RETROGRADE TRACER STUDY. A. Lysakowski, G.P. Standage and L.A. Benevento. Dept. of Anatomy,

A. Lysakowski, G.P. standage and L.A. Benevento. Dept. of Anatomy, Univ. of Illinois Medical Center, Chicago, IL 60612. As part of our ongoing studies on the organization of thalamo-cortical pathways. we made multiple injections of retrograde tra-cers into visual cortical areas VI and V4, both of which are later-al geniculate (DLC) and pulvinar targets. Tracers used were HRP. Nuclear Yellow and Granular Blue in combination with Fast Blue.

Injection sites for each tracer were varied between experiments. Striate (V1) injections produced a vertical band of cells oriented in a dorsomedial-ventrolateral direction close to the lateral border of the rostral lateral pulvinar (PLB) and more diffuse clusborder of the Postral lateral pulyinar (PLB) and more diffuse cut tering in the inferior pulyinar (PL). In the region between the caudal lateral pulyinar (PLY) and PI, there seemed to be a bridge of cells moving medially from PLB- $\gamma$  to PI. The PLG was heavily labelled in all layers from this VI injection, as expected. V4 injections produced 2-3 vertically oriented bands in PLB- $\gamma$ 

V4 injections produced 2-3 vertically oriented bands in PLE-y starting medial to the V1 band laterally and extending medially to PL's border with medial pulvinar (PM) and P1. There were spaces between these bands which may be the locus for bands of cells pro-jecting to other cortical areas. In the DLC, there were V4-projec-ting cells mostly in the interlaminar zones, although some were found nearby within the laminae (JCN 203:455-474, 10<sup>8</sup>1) and some nearby in the white matter surrounding the DLC. In addition, V4 injections of retrograde tracers produced cells in the oral pulvinar, PM and dorsomedial nucleus. Thalamic double labelling was found only in PI (<2°). Other subcortical areas which were found found only in PI ( $\le 2^{-1}$ ). Other subcortical areas which were found to project to VI and V4 were medial and lateral hypothalamic areas and the claustrum. The caudal claustrum projected to both VI and V4 with a small percentage of cells ( $\le 1^{\circ}$ ) double labelled. Layers 5 and 6 of the occipitotemporal (OTS), posterior middle temporal (PMTS), medial bank of inferior occipital, lateral bank

and floor of intraparietal, and the lower bank of superior temporal (STS) sulci had one large, single labelled cell population which projected to V4 and overlapped another, smaller one which projected to V1. The area corresponding to the middle temporal region (MT) (the floor of STS, near the junction with the lateral sulcus) showed a much heavier labelling of cells projecting to VI than to V4. STS, OTS and PMTS showed some double labelling (<1%) in layers 5 and 6, in addition to V4-projecting cells in layers 2 and 3.

It seems that separate populations of DLC cells project to VI and V4 and that any retinal influences from the thalamus to V4would arise from PI and regions of PL which receive superior colli-culus inputs. Thus far, based on these results, collateralization appears to be a restricted characteristic of the monkey visual system. Supported by NEI EY2940.

46.3 CORTICAL AFFERENTS TO VISUAL AREA PO IN THE MACAQUE. C.L. Colby, CONTICAL AFFERENTS TO VISUAL AREA PO IN THE MACAQUE. <u>C.L. Colby</u> <u>R. Gattass<sup>4</sup>, C.R. Olson<sup>4</sup> and C.G. Gross</u>. Dept: of Psychology, Princeton University, Princeton, N.J. 08540 and Instituto de Biofísica, UFRJ, Rio de Janeiro, Brasil Area PO is a retinotopically organized area located on the

anterior bank of the parieto-occipital sulcus extending onto the medial surface. Its visual topography is unusual in that the representation of the periphery predominates (Covey, Gattass Gross, Neurosci. Abs. 1982). To determine the afferents to PO and the topography of those

afferents, distinguishable fluorescent retrograde tracers (nuclear yellow and bisbenzimide) were injected into representations of the and lower peripheral visual field under physiological upper guidance.

Substantial label was found in V1, V2 and the intraparietal sulcus (IFS) in all cases. Label in V1 was found exclusively in the depths of the calcarine fissure representing the periphery. In V2, label was confined to the ventromedial surface and to the depth of the most medial part of the lunate sulcus which also represent the periphery. Labeled regions in IPS included two distinct areas: a caudal zone, beginning at the anterolateral surface of the annectant gyrus and extending onto the lateral bank of the IPS, and a more rostral zone in the fundus of the IPS.

Moderate label was seen in the posterior superior temporal sulcus. Some label was found in area V3, both on the anterior bank of the lunate sulcus and on the ventral surface. Sparse label was seen in and around the arcuate sulcus. Little or no

label was seen in area V4 on the prelunate gyrus. There was no intermingling of the two kinds of label in areas V1, V2 or V3. The topographic location of the label in these W, V2 or V3. The topographic focation of the laber in tasks areas corresponded with the retinotopic location of the injection site in PO as determined by electrophysiological recording. The segregation of transported label from upper and lower visual field representations was maintained in the IPS areas which suggests that these areas may also be retinotopically organized. Within STS there were both regions of segregation and areas of overlap for the two tracers.

Several lines of evidence suggest that PO may be homologous to Area M in the owl monkey described by Allman and Kaas. Both areas are located on the medial surface, have large receptive fields and a complex retinotopic organization which over-represents the periphery relative to other visual areas. Connections of M appear to be very similar to those of PO, including the connection with V2.

The retinotopy and connections of PO suggest that it may be more involved in orientation and localization than in pattern recognition.

46.2 NEURONS IN THE MONKEY VISUAL SYSTEM WHICH PROJECT TO VI AND V2. H. Kennedy and J. Bullier, Laboratoire de Neuropsycho-Togie Expérimentale, INSERM-U 94, Bron, France.(SPON:M. de Ryck) In a recent study we found that a fair proportion of the neurons afferent to areas 17, 18 and 19 of the cat have branching axons which innervate more than one region. We were interested to see if a similar situation exists in the monkey. One of two retrograde fluorescent tracers (fast blue and diadimino yellow) was injected deep in the posterior bank of the lunate sulcus (V2) and the other at a shallow angle to the cortex on the operculum (V1). Injections were positioned in such a way as to include retinotopically corresponding regions.

positioned in such a way as to include retinotopically corresponding regions. Subcortically we found numerous double labelled cells in the lateral pulvinar, the intralaminar nuclei and claustrum and few double labelled cells in the inferior pulvinar. The dye injected in V2 was also found in some lateral geniculate neurons, principally in the interlaminar zones, with few of these cells being double labelled. It appears therefore, that, in the monkey as in the cat, V1 and V2 do share some subcortical affectors. that, in the monkey as in the cat, VI and V2 do share some subcortical afferents. In the cortex labelled neurons were found in the fundus

and anterior bank of the lunate sulcus, the prelunate gyrus, the posterior bank of the superior temporal sulcus, and in inferior temporal cortex. Labelled neurons were mostly in lamina 6 except in the fundus of the lunate sulcus where many filled cells were found in laminae 2 and 3. Double labelled neurons were found in 5 extrastriate sites where there was an overlap of neurons labelled by either marker. The feedback from prestriate areas to VI and V2 arises mostly from cells in lamina 6 and shows a sizable proportion of branching axons and, in this respect, resembles the situation in the cat.

PROJECTIONS OF AREA V2 IN THE MACAQUE. <u>I.C. Ungerleider</u>, Lab. Neuropsychology, NIMH, Bethesda, MD 20205, <u>R. Cattass</u>\*, <u>A.P.B.</u> <u>Sousa</u>\*, Dept. Neurobiologia, Instituto de Biofisica, UFPJ, Rio de Janeiro RJ, Brazil and <u>M. Mishkin</u>, Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Cortical and subcortical projection fields of area V2 in the macaque were examined by the use of autoradiographic and degeneration tracing techniques. In one series of rhesus monkeys (N=6), the full extent of the projection fields of V? was determined by making large sector lesions that collectively included all of V2. In a second series of monkeys (N=14), the topographic organization of the fields was determined by injecting tritiated amino acids into 16 selected V2 sites. These sites, which were identified electrophysiologically, included the representation of the center of gaze and positions ranging from about 2.5° to greater than 45° in both the upper and lower visual fields. The results showed that V2 projects to two areas located Cortical and subcortical projection fields of area V2 in the

The results showed that V2 projects to two areas located anterior to it, Zeki's areas V3 and V4. Together, V2, V3, and V4 are arranged in adjacent cortical belts throughout most of their extents. Like V2, V3 and V4 appear to be topographically organized, with the upper field located ventrally and the lower organized, with the upper liefd located ventrally and the lower field dorsally. The vertical meridian is represented at the V3/V4 border, while the horizontal meridian is represented at the V2/V3 border and again at the anterior horder of V4, at least out to 5°. As in V2, the horizontal meridian in V4appears to be split and doubly represented, since an injection on the horizontal meridian of V2 results in label in V4 both on the horizontal meridian representation in its upper viewal field the horizontal meridian representation in its upper visual field and on the horizontal meridian representation in its lower visual field. The fact that injections of V2 beyond 400 result in label in V3 but not in V4 suggests that the representation of the visual field within V4 may not extend to the for englishory

the far periphery. In addition to the projections to V3 and V4, V2 was found to In addition to the projections to V3 and V4, V2 was found to project topographically to area MT. Projections of V2 were also seen to area P0, but only after injections of the far periphery in V2. This finding is consistent with the large representation of the periphery in PO (Covey et al., '82). Finally, there is a projection from V2 back to striate cortex. In contrast to the forward cortical projections of V2 to areas V3, V4, MT, and PO, which terminate predominantly in layer IV and the deep part of layer III and often appear as columns, the backward projection of V2 to striate cortex terminates in layers I II and V

of V2 to striate cortex terminates in layers I, II, and V. Subcortical projections of V2 were found to the superior colliculus, the inferior and lateral pulvinar, and the reticular nucleus of the thalamus. All of these projections appear to be topographically organized.

46.5 THE CONNECTIONS OF THE VENTRAL POSTERIOR AREA (VP) IN THE MACAQUE MONKEY. <u>A. Burkhalter\* and D. C. Van Essen</u>. Biology Division, Caltech, Pasadena, CA 91125.

Previous studies from this laboratory have indicated that a distinct visual area, VP, adjoins the anterior margin of V2 in the ventral half of the occipital lobe of the macaque. VP contains a representation of only the upper part of the visual field, whereas V3, which adjoins the dorsal half of V2, contains a representation V3, which adjoins the dorsal half of V2, contains a representation of only the lower part of the visual field. We regard VP and V3 as separate areas because V3 receives a major input from V1 while VP does not, and because they differ in their myeloarchitecture and in their callosal inputs (Van Essen et al., Soc. Neurosci. Abstr. 5: 812, 1979; Newsome et al., Soc. Neurosci. Abstr. 6: 579, 1980). We have analyzed the inputs and outputs of VP by making injections of a mixture of horseradish peroxidase and H-proline into VP in three hemispheres. The corpus callosum was cut, and the resultant pattern of degenerating terminals served to delineate the borders of several topographically organized visual areas.

No detectable projections were found from V1 to VP or from VP to V1, thereby confirming that there is a major dorso-ventral asymmetry in the connections of V1. Reciprocal connections were found between VP and several topographically organized extrastriate areas, including V2, MT, and V3A. In all three cases, there were patchy projections to an as yet unnamed visual area anterior to VP, which others have shown to project to infero-temporal cortex. In addition, there were projections to v3A and in two cases dorsal to it. In one case, there were projections to cortex on the parahippocampal gyrus, in area IF or TH. Subcortical projections were solved to the inferior and lateral No detectable projections were found from V1 to VP or from VP there were reciprocal connections with the inferior and lateral subdivisions of the pulvinar.

Characteristic differences in the laminar organization of inputs and outputs were used to distinguish between ascending (forward) and descending (feedback) connections. V2 is the only contical area that provides ascending inputs to VP. All other cortical targets receive ascending inputs from VP and can therefore be regarded as at a higher hierarchical level of processing.

The pattern of connections of VP differs in several significant respects from that reported for V3 by Zeki (J. Physiol., <u>277</u>: 245, 1978). This strengthens the argument that information from upper and lower parts of the visual field is processed in distinctly different fashion in macaque extrastriate cortex.

46.7 COLOR SELECTIVITY OF V4 CELLS AND INDUCED SPECTRAL PROPERTIES. F.M. de Monasterio\* (SPON: M.J. Hoffert). Section on Visual Pro-cessing, Clinical Branch, National Eye Institute, NIH, Bethesda, Maryland 20205.

I report here results obtained from single cells in the foveal representation of the prelunate gyrus of macaque cortex, area V4 using a semichronic, paralyzed and anesthetized preparation. Cell responses were evoked with narrow-band stimuli of the appropriate responses were evoked with narrow-band stimuli of the appropriate size, shape and orientation. These lights were matched either for an equal-quanta spectrum (13 log quanta/s.cm<sup>2</sup> at the screen) or a 2°-CIE equal luminosity at the low photopic range (ca. 200 td). Broad-band lights provided diffuse background illumination. Due to the significant response variability of many V4 cells, respon-ses were summed over 10 trial blocks and, within each block, the wavelength presentation sequence could be randomized. Spectral responses due to the visition units from response curves were expressed as standard deviation units from the prestimulus activity at each wavelength.

Few V4 cells showed color-opponent responses. Classification of color non-opponent cells into 'color biased' and 'color unselective' groups depended on the arbitrary selection of a spectral cutoff criterion (Schein, Desimone & de Monasterio, ARVO Abstracts 1983). The majority of V4 cells responded well to white lights. 1985). The majority of V4 cells responded well to white lights. Steady-state chromatic adaptation with weak backgrounds showed that V4 cells receive input from 2 or 3 cone types. While these inputs were not antagonistic in color non-opponent cells, both the peak sensitivity and badwidth of responses mediated by signals from green- and red-sensitive cones indicated that antecedent spectral interactions affected cell inputs. When using weak chromatic backgrounds in non-equilibrium conditions (i.e. simultaneously flashing test and background lights), a transient but marked desensitization of some cone inputs could be evoked. In color non-opponent cells, this desensitization produced a transient coloropponent behavior similar to that found in retinal ganglion cells. The antecedent opponent mechanism underlying the transient desensitization also induced a transient suppression of the responses to the simultaneous presentation of end-spectral lights. The results are noteworthy in at least two respects. First,

The results are noteworthy in at least two respects. First, they demonstrate the existence of transient adaptational anomalies in cells of a central level of the primate visual system. Like the similar retinal anomalies, they are consistent with recent psycho-physical findings in humans. Second, the results are relevant to problems of neuronal taxonomy in area V4. Because of antecedent spectral interactions, stimuli delivered in close spatial or tem-poral presentation may induce transient color opponency in color non-opponent cells. On this basis it is possible not only to misclassify V4 cells, but even also to draw elaborate erroneous conclusions regarding 'higher level' properties of the neurons.

46.6 THE THE CONNECTIONS OF AREA V4 OF MACAQUE MONKEY EXTRASTRIATE CORTEX. D. J. Felleman and D. C. Van Essen, Division of Biology, Caltech, Pasadena, CA 91125.

V4 is a visual area in the macaque that was originally identified on the basis of its strong inputs from V2. Its full extent is not known, but it is generally considered to occupy most of the pre-lunate gyrus plus neighboring portions of the lunate sulcus and superior temporal sulcus (STS). Complexities in its internal organization have led to suggestions that V4 may contain distinct subdivisions.

To study the inputs, outputs, and intrinsic connections of V4, we made injections of <sup>3</sup>H-proline or a combination of <sup>3</sup>H-proline and HRP in three hemispheres, two in anterior V4 and one in posterior V4. For two hemispheres, two in ancerior is and one in pac-erior v4. For two hemispheres the corpus callosum was cut to allow the distribution of label to be related to the pattern of interhemispheric connections. On the basis of the laminar distribution of anterogradely labeled terminals and retrogradely labeled cells, each connection was designated as having an ascending

cells, each connection was designated as having an ascending (forward), descending (feedback), or intermediate pattern. In all three cases, ascending inputs to V4 arose primarily from V2 and to a lesser extent from V3 and V3A. Each of these areas received feedback from V4. We did not detect any input from V1, but is received to a work feedback are used. but in one case there was a weak feedback projection to layer II ٧1. σf

The major ascending output from V4 was to the temporal lobe, primarily in inferotemporal cortex (II or TE). The posterior V4 injection labeled a long, narrow strip across posterior II and extending into area TF in the occipito-temporal sulcus (OTS). The

extending into area IF in the occipito-temporal sulcus (OIS). The anterior V4 injections labeled one or two major foci in posterior II and one focus in IF. There was a feedback pathway from these regions to V4. In the one V4 injection that was near the hori-zontal meridian representation there was also label in a topo-graphically organized region posterior to II. From both of the anterior V4 injections there were ascending outputs to area MSI (an MI-recipient zone in the fundus of the SIS) and to area POa on the lateral bank of the intraparietal sulcus. Neither of these pathways was detected after the posterior V4 injection, however. Subcortical projections were also seen to the lateral and inferior pulvinar, claustrum, putamen, and the caudate and pregeniculate nuclei.

putamen, and the caudate and pregeniculate nuclei. The intrinsic connections in V4 are highly complex, with evidence for forward, feedback, and intermediate patterns in different patches. We found no systematic relationship between the pattern within a patch and its location with respect to the injection site. It is clear from these experiments that there are anatomically distinct subdivisions within V4, but unclear whether these warrant classification as distinct visual areas. Supported by NIH Grant EY 02091.

46.8 RECEPTIVE FIELD PROPERTIES OF NEURONS IN VISUAL AREA V4 OF THE MACAQUE. R. Desimone and S.J. Schein<sup>#</sup>. Laboratory of Neuropsychology, NIMH and <sup>#</sup>Section on Visual Processing, National Eye Institute, Bethesda, MD. 20205.

National Eye Institute, Bethesda, MD. 20205. V4 is a visuotopically organized prestriate area that receives major input from V2 and is a major source of visual input to inferior temporal cortex. The color properties of V4 cells have been described by us and others previously. In the present study we report the spatial properties of V4 cells. Single neurons were studied within the representation of the central  $5^{\circ}$  of V4 in 4 anesthestized (N<sub>2</sub>O), paralyzed macaques, with a semi-chronic preparation. We mapped the excitatory receptive field (RF) by hand and then measured the response to sine-wave gratings and bars. The cells could be divided into two groups based on their responses to gratings. divided into two groups based on their response to gratings. Both groups had similar RF widths, equal to  $0.9^{\circ} + 0.4$  x Eccentricity. The optimal spatial frequency for cells in the first group, however, had a period greater than the RF width, while that of cells in the second group had a period equal to or less than the RF width. Thus, the first group appeared to show summation within the RF, while the second group appeared to show summation within the RF, while the second group appeared to show spatial interactions within the RF. Some (but not all) of the properties of the two groups appear to be analogous to properties of striate simple and complex cells, respectively. Cells of the first group were tuned to low spatial frequencies (mean 0.4 cpd), were often single-phase sensitive to flashed gratings of optimal frequency, gave modulated responses to drifting gratings (35% mean modulation), and responded best to wide bars (mean 2.0 x RF width). By contrast, cells of the second group were tuned to higher spatial frequencies (mean 3.1 cpd), were rarely single-phase sensitive, gave unmodulated responses to drifting gratings (10% mean modulation), and responded best narrow bars (mean 0.4 x RF width). Cells of both groups normally had a large suppressive zone

Cells of both groups normally had a large suppressive zone located around the RF extending up to 10-20 degrees from the RF center. Although dark bars, light bars, annuli and gratings failed to elicit any response outside the RF, such stimuli often reduced the response to an RF stimulus by 80% or more.

Although the two groups of cells in V4 may represent a continuum rather than a dichotomy, the similarity to the simple/complex division in striate cortex suggests that the latter duality might be carried far into the visual pathway. In addition, the powerful interaction between the RF and the large silent suppressive surround suggests that V4 cells respond best to a difference in visual content between the RF and its surround.

EFFECTS OF VISUAL CORTICAL LESIONS ON VISUAL TRACKING IN CATS. 46.9 R.J. Tusa, J.L. Demer\* and S.J. Herdman, Wilmer Eye Institute, Johns Hopkins Hosp. and Univ. of Md., Baltimore, Md., 21205

Johns Hopkins Hosp: and Univ. of Md., Baltimore, Md., 21205. Left hemisphere cortical lesions were made by subpial aspira-tion in 6 adult cats under general anesthesia. Ablations included all visual cortex in 2 cats (VC); PMLS (Clare-Bishop) in the lat-eral suprasylvian sulcus in 2 cats (PMSL); areas 17 & 18 in one cat (17/18); and 17 & 18 + corpus callosum section in one cat (17/ 18 + CC). Slow phase eye velocity in response to a full field optokinetic nystagmus (OKN) drum, which was slowly accelerated (.27 deg/s<sup>2</sup>) or stepped from 4-120 deg/s, was measured using the magnetic search coil during both binocular and monocular viewing. Eye velocity was plotted against retinal slip velocity (target velocity minus eye velocity). Visual-vestibular interactions were determined by measuring vestibulo-ocular reflex (VOR) gain (eye vel/head vel) in the dark during sinusoidal head rotation (.05 and .25 Hz, 30 deg/s), compared to VOR gain in the light with an OKN drum moving in or out of phase with the head.

Measurements were made 5 days, 3 weeks and 7 weeks post-opera-tively and compared to pre-operative performance. The extent of

tively and compared to pre-operative performance. The extent of the lesions were confirmed histologically. In cats with VC lesions, peak eye velocity to the left (towards the lesion) for binocular OKN was 50% of pre-operative measure-ments and this peak eye velocity occurred at a lower retinal slip velocity. OKN in the other direction was unchanged and this di-rectional asymmetry persisted through the study. The cat with the 17/18 lesion had no deficit in OKN, whereas the cat with the 17/18+ CC lesion had a deficit similar to the cats with the VC lesions. Cats with PMLS lesions also had an OKN deficit similar to cats with VC lesions, but they completely recovered by 3 weeks. During monocular OKN viewing, there was a significant deficit in peak eye velocity to the left for nasal-temporal and temporal-nasal stimu-It; and to the right for nasal-temporal stimuli only. This occur-red in the cats with the VC lesion, 17/18 + CC lesion and tran-siently in cats with the PMLS lesion. Alterations in visual-vestibular interactions following cortical lesions were found to be predictable from the individual VOR and OKN responses.

Our preliminary results suggest that OKN deficits in cats are similar to those found in primates following large, unilateral cortical lesions. We hypothesize that the cortical contribution for OKN in via areas 17/18. This region appears to enhance slow phase eye velocity ipsilaterally through extrastriate cortex. Following a unilateral 17/18 lesion, the contralateral 17/18 areas can be used to enhance slow phase eye velocity toward the side of the lesion through the corpus callosum. Although PMLS also appears to be involved with OKN, other areas are able to compensate following its removal.

46.10 FUNCTIONAL NEUROANATOMY OF VISUALLY GUIDED REACHING IN THE MONKEY. R. J. W. Mansfield and D. N. Pandya. Department of Neurology, Boston University School of Medicine, Boston, MA 02118 and Rogers Memorial Veterans Administration Hospital, Bedford, MA 01730.

A central question in the study of primate vision is the relation between defined anatomical structures and specific behavior. To address this question we have developed a double isotope 2-deoxy-D-glucose (20G) method of labelled local cerebral glucose utilization and applied it to the analysis of visually wided restricted by the method. guided reaching in the Rhesus monkey. In the paradigm task a monkey fixated then grasped with its right hand small targets that appeared at random intervals displaced 10° to the right of ints midline. With only the target zone illuminated a bolus intravenous injection of  $[^{14}C]$ -2DG (100 µCi/kg) was given and rapid trials conducted for 45 minutes. Subsequently following a second intravenous bolus injection of  $[^{14}]$ -2DG (3 mCi/kg) the task was continued for 45 minutes but in the absence of illumination. The animal was deeply anesthetized, perfused with 3.3% buffered formalin, the brain blocked and rapidly frozen in Freon 22. Cryostat sections (20  $\mu$ m) cut serially at 200  $\mu$ m intervals were developed separately for tritium and carbon-14 autoradiogra-phy to yield a ten-fold isolation of both tritium and carbon 14 images. Using calibrated standards and a computer image proces-sing system the optical densities of the autoradiographs could be referenced back to levels of glucos metabolism. To differen-tiate in a given region between intrinsic task-specific metabolic activity and extrinsic input from other regions of enhanced meta-

bolism, adjacent sections were stained for cytochrome oxidase. The autoradiographs revealed regions of differential glucose metabolism both cortically and subcortically that were not coex-tensive with dense cytochrome oxidase labelling. In both the visually guided reaching task and in its dark control limbic and motor regions such as cingulate gyrus and basal ganglia had increased glucose metabolism but in the visually guided task increased glucose metabolism but in the visually guided task increased labelling was found in the majority of regions known to receive a more direct visual input. In V1 the region of in-creased glucose metabolism was confined to a portion of the opercular surface representing the central 5<sup>0</sup> with the densest label in layer IVC. In the more anterior portions of the visual system the region of increased metabolism was enlarged so that in the inferotemporal cortex most of area TE was engaged consistent with the larger foveal representation in that area. In general the results are consistent with a graded activation of cortical regions along the visuo-motor pathway in a focal visually guided task.(Supported by F.R.N.S. and NIH Grant EY 04854; and by Veter-ans Hospital, Bedford, MA, and NIH Grant NS 16841.) ans Hospital, Bedford, MA, and NIH Grant NS 16841.)

DEFICITS IN PURSUIT EYE MOVEMENTS AFTER CHEMICAL LESIONS OF MOTION-RELATED VISUAL AREAS IN THE SUPERIOR TEMPORAL SULCUS OF 46.11

MOTION-RELATED VISUAL AREAS IN THE SUPERIOR TEMPORAL SULCUS OF THE MACAQUE MONKEY. <u>W.T. Newsome</u>, <u>R.H. Wurtz</u>, <u>M.R. Dursteler</u>\*, <u>and A. Mikami</u>. Lab. Sensorimotor Res., National Eye Institute, NIH, Bethesda, MD 20205. Neurons in identified visual areas (including MT and MST) of the superior temporal sulcus (STS) are selective for the direction and speed of stimulus motion. We produced chemical lesions of these motion-related areas to determine whether cells in those areas arouside information whether cells in these areas provide information about stimulus motion for the generation of smooth pursuit eye movements.

We trained monkeys to fixate a spot of light and measured eye We trained monkeys to fixate a spot of fight and measured eye movements using the magnetic search coil technique. After a monkey had begun to fixate, the spot of light went out and another spot of light at a variable location on the horizontal meridian began to move towards or away from the fixation point at  $16^{\circ}$ /sec (a step-ramp paradigm). The monkeys were required to bidth interval. shift fixation and pursue the moving spot. A monkey's response could generally be divided into three phases: first, a brief interval (60-100 msec) of nonfoveal pursuit before making a saccade; second, a saccadic eye movement to bring the fovea onto the moving target; third, post-saccadic foveal pursuit of the moving target for the duration of the trial. Our analysis is concerned with the pre-saccadic pursuit and with the first 100 msec of post-saccadic pursuit--those intervals of pursuit which must depend upon visual motion information derived from a known must depend upon visual motion information derived from a known location on the peripheral retina. A microliter syringe was insulated so that recording of multiple unit activity could be obtained from the tip. Motion related visual areas were identified and injections were made near the representation of the horizontal meridian. For reversible lesions we injected one ul of muscimol (lug/ul) into the area. For irreversible lesions we injected 4 ul of ibotenic acid (15ug/ul). Following injection of muscimol, presaccadic initiation of pursuit to targets moving in affected regions of the visual field had a longer latency (by 50-120 msec) or did not occur at all. Latency of saccades to the target remained about the same, as did initiation of pursuit to targets in the ipsilateral

all. Latency of saccades to the target remained about the same, as did initiation of pursuit to targets in the ipsilateral visual field. On the day following the injection, pursuit initiation in the test hemifield returned to the preinjection levels. Following injection of ibotenic acid in one monkey the velocity of pursuit was severely reduced for about 200 msec after the saccade. This monkey did not initiate presaccadic pursuit before or after the injection. The monkey recovered from the deficit within a week. These results suggest that motion information from visual areas of the STS is important for the generation of pursuit eye movements in response to targets moving on the perioheral retina. moving on the peripheral retina.

FINE-RESOLUTION, QUANTITATIVE ACTIVITY-LABELING OF MACAQUE BRAIN WITH 2-DEOXYGLUCOSE. S.J. Schein & F.M. de Monasterio\*. Section on Visual Processing, Clinical Branch, National Eye Institute, Bethesda, MD 20205. Activity-labeling with 2-deoxyglucose (Sokoloff et al 1977) results in intracellular accumulation of water-soluble 2-deoxyglucose-6-phosphate (2-DC-6-P). Standard tissue processing (rapid freezing, cryomicrotomy, mount-ing and rapid heat-dehydration) produces autoradiograms (ARCs) with resolution of ~50µm (Goochee, Rasband & Sok-oloff 1980). An early attempt to obtain fine-resolution maps of galactose, another water-soluble molecule, used ing and rapid heat-dehydration) produces autoradiograms (ARCS) with resolution of ~50µm (Goochee, Rasband & Sok-oloff 1980). An early attempt to obtain fine-resolution maps of galactose, another water-soluble molecule, used freeze-drying of a small piece of intestine and plastic embedding (Stirling & Kinter 1967). A similar procedure, but using freeze-substitution or solvent immersion, was applied to a snail nerve ganglion (Sejnowski et al 1980). In addition to the unsuitability of these me-thods for a large brain, they provide only qualitative ARGs (Stirling & Kinter; Reingold et al 1981), whose interpretation may be complicated by the finding that some of the retained label is chemically bound to gly-cogen (Witkowski & Yang 1982). A previous report (Schein & de Monasterio 1981) pre-sented empirical studies of the process of freeze-sub-stitution. Here, we present the underlying physical principles of the process, principles necessary for the design of conditions (solvent, temperature and time) which minimize loss of 2-DG-6-P and allow complete replacement of water. We also present the chemistry of withdrawal of tissue label, which dictates some of the conditions for freeze-substitution, the choice of em-bedding material and the method for mounting of sections on slides. Autoradiography uses sheet film. Tissue processing which follows these principles pro-duces sharp ARGs with minimal loss or movement of 2-DC-6-P. The resolution of <sup>14</sup>C-ARGs is roughly equal to section thickness. Full-size sections of macaque brain can be obtained at a thickness of 7µm. ARG with <sup>3</sup>H gives still finer resolution but at a sacrifice: Only the surface of such 'thick' sections is imaged on film. Results with this new method for the ocular dominance system of macaque striate cortex will be presented. Conversion of film density into glucose utilization relies on use of the operational equation (Sokoloff et al) and calibration of film density as a function of tissue radioactivity. We present a new calibration method which can

46.13 THE PATTERN OF VISUAL CALLOSAL CONNECTIONS IN THE CAT AS REVEALED IN TANGENTIAL SECTIONS OF THE UNFOLDED CORPEX. J. Olavarria\* and R.C. Van Sluyters (SPON: E. Marg). Neurobiology Group and School of Optometry, University of California, Berkeley, CA 94720.

Note that be a series of the first of the series the series of the series of the series of the series the series of the series o

Labeled cells formed an elaborate pattern whose organization was similar in all cats studied. The location of this pattern correlates well with the representation of the vertical meridian in the various visual areas mapped by Tusa, Palmer and Rosenquist, and others. Thus, a densely labeled band extends along the entire lateral border of area 17. A second band, located more laterally, virtually surrounds a broad region of cortex containing areas 18, 19, 21b and 20a. Two densely labeled areas bridge the gap between these two bands and appear to correspond to patches of callosal projections previously reported within area 18. A large labeled region covers most of areas 21a, DLS and VLS. This region also covers the posterior portions of the PMLS and PLLS areas, while anteriorly, near the fundue of the lateral suprasylvian sulcus, it narrows and lies in the region of the border between these two areas and the AMLS and ALLS areas. The present approach has provided detailed information regarding the overall organization of visual callosal connections in the normal cat, thereby encouraging its application to studies of the development and modifiability of this pathway. DRUGS OF ABUSE: NONOPIATES I

47.1 THE EFFECTS OF DIAZEPAM WITHDRAWAL ON FLURAZEPAM, BICUCULLINE AND FICROTOXIN SELZURE THRESHOLD IN DIAZEPAM DEPENDENT RATS. <u>C.E. Reigel, J.r.\* and W.M. Bourn, Dept. of Pharmacology, Toxicology and Nuclear Pharmacy, School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209 Benzodiazepine (BZ) binding to the BZ receptor increases GABA receptor affinity for endogenous GABA, thus enhancing GABAergic for the full statement of the statement of th</u>

Benzodiazepine (BZ) binding to the BZ receptor increases GABA receptor affinity for endogenous GABA, thus enhancing GABAergic function. GABAergic function may also be manipulated at two other distinct sites: the GABA receptor itself and the GABAergic chloride ionophore. Bicuculline (BCC) and picrotoxin (PTX) produce convulsions through actions at the GABA receptor and the GABAergic chloride ionophore, respectively. Recently flurazepam (FZP) has been demonstrated to produce convulsions in rats, possibly through actions at a BZ receptor.

In the present study FZP, BCC and PTX seizure thresholds were determined in diazepam (DZ) dependent, withdrawn rats and vehicle withdrawn control rats in an attempt to implicate the possible site(s) responsible for DZ physical dependence and the hyperexcitability seen during withdrawal. Rats with chronically implanted cortical electrodes were assigned to two groups for each seizure threshold study. Each group received a series of 30 intraperitoneal injections, one every 12 hours. DZ dependent rats received 100 mg/kg DZ suspended in 1% Tween 80. Vehicle control rats received only the 1% Tween 80 vehicle. FZP, BCC and PTX seizure thresholds were determined by continuous tailvein infusion 36 hours after the last injection of DZ or vehicle, a period previously determined to be the peak of DZ withdrawal as assessed by weight loss and increased irritability. Only FZP and PTX seizure thresholds were decreased during DZ withdrawal (see below).

	Seizure Threshold:	mg/kg
	DZ Withdrawn	Vehicle Withdrawn
FZP	41.4 + 2.1 (11)	63.3 + 2.8 (11) +

Results were compared to FZP, BCC and PTX seizure thresholds in barbital dependent, withdrawn rats. Supported in part by a fellowship from the American Founda-

Supported in part by a fellowship from the American Foundation for Pharmaceutical Education (C.R.). 47.2 SYNAPTIC EFFECTS OF DELTA-9-TETRAHYDROCANNABINOL AND ITS 11-HYDROXY METABOLITE ON CAT SPINAL MOTONEURONS. S.A. <u>Turkanis and P. Karler\*</u>. Dept. of Pharmacology, Univ. of Utah, School of Medicine, Salt Lake City, Utah 84132.

Delta-9-tetrahydrocannabinol (delta-9-THC), the major psychoactive constituent of marihuana, elicits a variety of central depressant and excitatory effects, which range from sedation and ataxia to frank convulsions. The purpose of the present work was to identify possible synaptic mechanisms of action for these central effects of delta-9-THC. To this end, conventional electrophysiological techniques were used to uncover synaptic effects of delta-9-THC and its principal active metabolite, 11-hydroxy-delta-9-THC, (0.01-0.1 mg/kg i.v.) on the spinal cord of adult cats with their spinal cords severed and their brains destroyed ischemically. The results of the investigation demonstrated that both drugs enhanced the excitatory postsynaptic potential (EPSP) amplitude to suprathreshold values. Subsequent experiments showed that delta-9-THC and its metabolite under the same conditions increased the motoneuron membrane resistance, an effect which may account for the rise in EPSP amplitude. Moreover, the EPSP enhancement does not appear to be associated with an increase in the afferent input because neither drug affected the compound action potential recorded from the dorsal roots near the point where they enter the spinal cord. In contrast to the increase in the EPSP, delta-9-THC reduced the amplitude of the inhibitory postsynaptic potentials (IPSPs), but the metabolite exerted no effect. In addition to excitation, both cannabinoids elicited depression, as evidenced by an increase in the firing threshold for the motoneuron action potential. The data are compatible with well-established properties of delta-9-THC in conscious animals because the drugs evoke a complex mixture of central effects.

Delta-9-THC and the 11-hydroxy derivative exert, in general, similar effects on the spinal cord; likewise, the comparative results reported previously from other test systems also indicated a similarity in their pharmacological properties. The data demonstrate that the metabolite may contribute to the activity of the parent drug. The findings with EPSPs and IPSPs suggest possible sites and mechanisms of drug action, such as alterations in postsynaptic receptor sensitivity, transmitter equilibrium potentials and transmitter release; whereas the increases in membrane resistance and motoneuron firing threshold are probably related to drug-caused postsynaptic conductance changes. Regardless of the precise mechanisms, if the above effects are applicable to higher sites in the CNS, they may contribute to delta-9-THC's central excitatory and depressant properties. (Supported by NIDA research grant DA-00346).

DOSE-RELATED EFFECTS OF PHENCYCLIDINE ON SPONTANEOUS AGGRESSIVE 47.3 BEHAVIOR IN THE RAT. B.D. Greenberg\*, J.W. Russell\*, and D.S. Segal. Psychiatry Dept., Sch. of Med., Univ. of Calif., San Diego, La Jolla, CA 92093. Phencyclidine (PCP) abuse has been frequently associated with the second s

violent behavior in humans. There have been a number of studies investigating the effects of PCP on experimentally-induced aggressive behavior in animals, with findings which vary depending upon the methodology used. It is unclear from the available results whether PCP will alter species-specific aggressive inter actions under conditions in which animals exhibit a relatively low level of spontaneous aggression. In several previous studies the effects of PCP were examined in pairs or groups of drug-treated animals. This approach does not allow characterization of the response of the drug animal to the pattern of behavior of its untreated partner, and vice-versa. We therefore investigated the effects of PCP in pairs of rats in a paradigm in which spontaneous aggression was infrequent and when only one animal of a pair was drug-treated.

Male Wistar rats were habituated individually for 7 days to sound-attenuated chambers identical to the test chamber. On the sound-attenuated chambers identical to the test chamber. On the eighth day, pairs of rats, selected randomly, were placed into the test chamber for the first time 5 min after one animal re-ceived saline and the other animal was injected with saline or 0.25, 0.5, or 1.0 mg/kg PCP (s.c.). Testing took place in the dark phase of the illumination cycle. Animals were videotaped for 60 min after injection, and the following behaviors were subsequently rated: boxing (mutual upright posture), attack, submissive behavior, and allogrooming.

Phencyclidine induced dose-related alterations in the pattern of spontaneous aggressive behavior. At the lowest dose tested (0.25 mg/kg), PCP produced attacks by the drug-treated animal and a corresponding increase in submissive behavior by the untreated partner, as well as an increase in boxing behavior by untreated partner, as well as an increase in boxing behavior by both animals. In contrast, the highest dose of PCP tested (1.0 mg/kg) elicited attacks and allogrooming by the untreated animal. The lowest dose effect is interpreted as the result of PCP-induced distortion of perception of social cues, while the highest dose result appears to be due to a general disruption in social communication by ataxia in the PCP-treated animal. This work was supported in part by USPHS Grant DA-01994-05; B.D.G. is the recipient of a NSF predoctoral fellowship and D.S.S. is the recipient of NIMH Greer Scientist Award MH-70183-10.

DOSE AND TIME REQUIREMENTS FOR BENZODIAZEPINE PHYSICAL DEPENDENCE PRODUCTION. <u>H.C. Rosenberg, W.M. Gilliam\* and T.H. Chiu</u>. Dept. of Pharmacology, Medical College of Ohio, Toledo, OH 43699. Studies were performed to determine the dose and treatment duration required to produce physical dependence on benzodiaze-474

duration required to produce physical dependence on benzodiaze-pines in cats. Dependence was evaluated by rating 20 possible abstinence signs after giving the antagonist, Rol5-1788. Follow-ing chronic daily intragastric administration of flurazepam (FZP), Rol5-1788 produced tremor, increased muscle tone, panting, salivation, pupillary dilation, piloerection, and defecation (Eur. J. Pharmacol. 81: 153, 1982). Rol5-1788 alone or immedi-ately after an acute dose of benzodiazepine did not produce any abstinence cions. The incidence and severity of abstinence signs abstinence signs. The incidence and severity of abstinence signs was dependent on the antagonist dose, but was maximal at doses of 2 mg/kg and above.

To determine the dose requirement of dependence, animals were treated 5 weeks with 1, 5 or 20 mg/kg FZP. All animals had an abstinence syndrome upon antagonist administration. Abstinence

The set of the set of

weeks, Rol5-1788 precipitated an abstinence syndrome that was essentially the same as that seen in cats treated with FZP. Dependence resulting in spontaneous abstinence signs usually

Dependence resulting in spontaneous abstinence signs usually requires prolonged treatment with large doses of benzodiazepines. In contrast, dependence as measured by an antagonist precipi-tated abstinence syndrome is possible 24 hrs after a single dose, and is almost as intense after chronic treatment with a rather low dose (1 mg/kg FZP) as after much higher doses (20 mg/kg). Supported by DHHS grants DA02194 and NS16595. FZP, diazepam and Ro15-1788 were generously supplied by Hoffmann-LaRoche, Inc.

NEUROPHARMACOLOGICAL PROFILE AND TOLERANCE ASSESSMENT FOR ACUTE 475 ADD CHRONIC EFFECTS OF 2,5-DIMETHOSYL4-METHYLAWHETAMINE (DOM) IN THE RAT. <u>B. Hine<sup>+</sup> and M. Torrelio<sup>\*</sup></u>. Millhauser Labs, Dept. of Psychiatry, New York Univ. Med. Ctr., New York, NY 10016. Phenethylamine hallucinogens have been considered agents that produce, in animal studies, a unique neuropharmacological profile of amphetamine-like stimulant effects at low doses and responses characteristics of indolealkularine hallucinogene at high doces

characteristic of indolealkylamine hallucinogens at high doses. The present experiments used a variety of response measures to assess this generalization after intraperitoneal injections of racemic DOM hydrochloride (0.25-4.0 mg/kg) over a 15-day period in male Sprague-Dawley rats. Receptor blocking studies also were performed to further characterize the involvement of dopamine and serotonin in these responses.

Acute DOM produced a bidirectional effect on vertical activity (rearing), with maximal increases above saline controls at 0.25-0.5 mg/kg and significant decreases at 1.0 mg/kg and higher doses. Maximal production of head-twitch responses occurred at a DOM dose of 1.0 mg/kg. An increase in the number of head twitches and rear-ings occurred for several dose levels after 5 daily injections, followed by a decreasing number of responses over the next 10 days. Unidirectional increases in rectal temperatures occurred at 0.25 mg/kg and higher doses, with a similar pattern of increases and then decreases in the hyperthermic response over 15 days. At 2.0 mg/kg, only a progressive increase in hyperthermia occurred with daily injections. DOM produced a dose-related induction of palpe-bral ptosis to which tolerance did not develop over 15 days. Although no changes in water consumption occurred after acute DOM, a progressive increase occurred, with increasing doses, over the 15-day period. The involvement of dopamine in DOM-induced head twitches and rearing was demonstrated by the blockade or attenu-ation of these responses after pretreatment with haloperidol (0.25 and 0.5 mg/kg). However, although methysergide pretreatment at 10 mg/kg had no effect on DOM-induced rearing, head twitches and ptosis were significantly attenuated. Haloperidol increased DOM

induced prosis. These data indicate that DOM can induce both amphetamine- and These data indicate that DOM can induce both amphetamine- and indolealkylamine-like effects over a range of doses in rats, and repeated administration may produce changes in the expression of these responses that do not reflect a tachyphylaxis or unidirec-tional tolerance. In addition to extending existing data on the involvement of dopamine in DOM-induced responses, the results suggest the desirability of including a variety of measures when developing profiles for pharmacological actions of agents such exp DOM as DOM.

PHENCYCLIDINE-INDUCED LOCOMOTOR ACTIVITY IN THE RAT IS BLOCKED BY 47.6 A 6-HYDROXYDOPAMINE LESION OF THE NUCLEUS ACCUMBENS OR VENTRAL EGMENTAL AREA: COMPARISONS TO OTHER PSYCHOMOTOR STIMULANTS. Edward D. French and Guido Vantini\*, Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228.

A considerable volume of evidence now exists documenting the effects of phencyclidine (PCP) on central neurotransmitter systems, effects of phencyclidine (PCP) on central neurotransmitter systems, in particular dopamine (DA). Behaviorally and biochemically, PCP shares some of the actions produced by amphetamine (AMPH). Several groups have reported that forebrain DA systems mediate the AMPH hyperactivity since 6-0HDA lesions of either the mesolimbic DA con-taining nucl. accumbens (NAc) or Al0 neurons of the VTA projecting to forebrain can block this AMPH effect. Also there recently has been found an interaction between PCP and SKF10047 (a  $\sigma$  opiate receptor agonist) in receptor binding analyses and in operant dis-criminative stimulus paradigms. Interestingly, SKF also produces in the rat behavioral changes similar to those produced by PCP. The goal of the present study was to examine the role of the mesolimbic NAc system in mediating the locomotor stimulant actions of PCP and SKF.

Using photocell equipped cages and gross behavioral observa-tions the motor activating and behavioral effects of AMPH (1.5mg/ kg), SKF (25mg/kg), scopolamine (1mg/kg) and caffeine (10mg/kg) were measured and compared to PCP's (5mg/kg) actions. 5mg/kg was selected as the optimal dose of PCP based upon a dose-response deselected as the optimal dose of PCP based upon a dose-response de-termination of maximum locomotor activity with minimal interfer-ence from an accompanying ataxia. While all compounds produced a moderate to large degree of hyperactivity with varying time cours-es for the effects, gross behavioral observations indicated a greater similarity between PCP and SKF than between any of the other drugs. Following bilateral 6-OHDA lesions of the nucleus accumbens (4ug/ul-2ul vol.) the robust locomotor stimulating effect of PCP was blocked. Such lesions also successfully prevent-ed AMPH- and SKF-induced hyperactivity but not the behavioral acti-vation caused by scopolamine or caffeine. In another set of ex-periments rats received bilateral 6-OHDA (4ug/ul-lul vol.) or vehicle injections into the VTA and were subsequently administered AMPH, PCP, and SKF. As with NAC lesions such treatment signifi-AMPH, PCP, and SKF. As with NAc lesions such treatment signifi-cantly attenuated the locomotor stimulating effects of all three

cantly attenuated the locomotor stimulating effects of all three compounds. In both lesion experiments NAc DA content was measured and found to be reduced by 87-91%. These results strongly suggest that the locomotor hyperactivity produced by PCP, SKF, and AMPH is subserved by a common presynaptic mechanism present within the mesolimbic DA system.

47.7 COMPARATIVE EFFECTS OF SUB-CHRONIC BUSPIRONE OR NEUROLEPTICS ON COMPARATIVE EFFECTS OF SUB-CHRONIC BUSFIXORE OK REUROLEFICS ON RAT BRAIN DOPAMINE FUNCTION. Brian A. McMillen, Dept. Pharmacol., School of Medicine, East Carolina Univ., Greenville, NC 27834. Buspirone is an anti-anxiety drug without any other benzodi-azepine activity. Previous reports showed buspirone to be an

antagonist of rat dopamine (DA) presynaptic autoreceptors (1). In addition, buspirone reverses catalepsy due to either DA recep-tor blockade or DA depletion (2). Thus, it was hypothesized that long term buspirone treatment could alter brain DA receptors or metabolism. Buspirone was compared to known inhibitors of DA receptors, haloperidol or trifluoperazine. For sub-chronic receptors, matoperiods of thiludoperazine. For sub-chronic studies, buspirone (1.0 mg/kg/day) or haloperiod (0.3 mg/kg/day) were administered s.c. via 2 week osmotic minipumps (Alza). Without drug washout, rats were challenged with either 1.0 mg/kg buspirone or 0.1 mg/kg haloperiod). The table shows that halo-peridol, not buspirone, caused a marked sub-sensitivity to both challenge drugs.

	stria	s.e.m.	
2 weeks	no drug	1.0 bus	0.1 halo
incision only	$1.61 \pm 0.11$	4.67 ±0.16	4.09 ±0.16
1.0 buspirone	1.47 ±0.07	3.88 ±0.34*	3.62 ±0.24
0.3 haloperidol	2.40 ±0.18*	3.13 ±0.15 <sup>+</sup>	3.04 ±0.12+
*p<0.05, +p<0.01;	different fr	om respective	controls
(Dunnett's t test)	), 6 to 8 rat	s per group.	

Results from 3 months of daily administration p.o. of either 3.0 mg/kg buspirone or 1.0 mg/kg trifluoperazine were simiar to these data from the sub-chronic experiment. Buspirone, 3.0 mg/kg/day, mg/kg buspirone of 1.0 mg/kg tillubperazite were similar to these data from the sub-chronic experiment. Buspirone, 3.0 mg/kg/day, altered neither tyrosine hydroxylase nor pre-synaptic DA receptor sensitivity, tested <u>in vitro</u> after a 4 day drug washout. The Bmax and Kd for 3H-spiperone binding to striatal membranes was significantly less after buspirone than after 3 months of tri-fluoperazine (Bmax= 314 ±15 vs 404 ±18 fmoles/mg and Kd= 0.18  $\pm$ 0.01 vs 0.28  $\pm$ 0.01 nM, respectively). These data are in harmony with those of Hyslop et al. (this volume). Co-administration of buspirone for two weeks with trifluoperazine prior to the 4 day drug washout significantly reversed the effect of trifluoperazine on striatal 3H-spiperone binding. These data suggest that: (1) buspirone should be free of extra-pyramidal risk as neither sub-sensitivity to haloperidol challenge nor super-sensitivity of DZ receptors occured after chronic treatment; (2) buspirone did not alter DA autoreceptor function; and (3) trifluoperazine-induced alterations of DZ receptors may be reversed by co-administration of buspirone. This latter effect may be secondary to other ef-fects of buspirone on the extrapyramidal system (1,2). (Supported by a contract from Bristol-Myers Co.) 1. McMillen, et al., J. Neurosci. 3:733, 1983. ROLE OF CATECHOLAMINES IN PLACE PREFERENCE CONDITIONING WITH 47.9

ROLE OF CATECHOLAMINES IN PLACE PREFERENCE CONDITIONING WITH PSYCHOSTIMULANTS, M.T. Martin-Iverson, R. Ortmann\* and H.C. Fibiger, Div. Neurol. Sci., Dept. Psychiat., University of Bri-tish Columbia, Vancouver, B.C., Canada, V6T 1M5. It has been shown that whereas d-amphetamine-induced place preferences can be attenuated by dopamine (DA) receptor blockade, or by lesions of DA-containing terminals in the region of the nucleus accumbens (Spyraki, C. et al., <u>Brain Res.</u>, 253:185,1982), place preferences induced with cocaine are resistant to such treatments (Spyraki, C. et al., <u>Brain Res.</u>, 253:195, 1982). The present study extends these findings to two other psychostimu-lants, methylphenidate (MPD) and nomifensine (NFS). Place preference conditioning was conducted following the pro-cedure of Spyraki et al. (1982), using different doses of MPD (2.5, 5.0 and 10.0 mg/kg, i.p.) and NFS (5, 10 and 20 mg/kg, i.p.). All doses of MPD and NFS produced significant place preferences, but rats receiving vehicle injections exhibited no preferences. (1992) and min after receiving haloperidol (HAL: 0.25-0.5).

preferences. Other rats were conditioned with MPD (2.5 or 5.0 mg/kg, i.p.) 30 min after receiving haloperidol (HAL: 0.25-0.5 mg/kg, i.p.), or received HAL (0.2 mg/kg) prior to conditioning with NFS (5 mg/kg, i.p.). In all cases, HAL failed to attenuate

place preferences. Central CA depletions were induced in other rats by intraven-Central CA depletions were induced in other rats by intraventricular injections of 6-hydroxydopamine (6-0HDA, 250 ug, base, dissolved with 0.3 mg/ml ascorbate in 10 ul of 0.9% saline) after treatment with pargyline (50 mg/kg, i.p.). One week later, place preference conditioning tests were conducted. Although DA was reduced by 30% (n. accumbens) to 19% (striatum) of control values, and whole brain noradrenaline was reduced to 13% of control values, no attenuation of place preferences was observed. Both treatment with HAL (0.2 mg/kg, i.p.) and CA depletions induced with 6-0HDA were effective at attenuating the locomotor stimulant effects of MPD (5.0 mg/kg, i.p.). HAL (0.2 mg/kg, i.p.). The present study demonstrates that the reinforcing properties and motor stimulant effects of MPD and NFS are mediated by different neural substrates. Taken together with previous

different neural substrates. Taken together with previous experiments, it appears that the neural substrate(s) mediating the rewarding effects of MPD, NFS and cocaine are distinct from the system(s) mediating the reinforcing effects of d-amphetamine

47.8 EFFECTS OF DIFFERENT CLASSES OF PSYCHOPHARMACEUTICALS ON CERE-BRAL CAPILLARY PERMEABILITY AND BLOOD FLOW. J. Schwartzman\*, S. Preskorn, T. Kent\*, S. Goldberg\* and R. Glotzbach\*. Departments of Psychiatry and Pharmacology. University of Kansas Medical Center, Kansas City, Kansas 66103. Antidepressant drugs such as amitriptyline increase the effective permeability (PS) of cerebral capillaries to water without altering cerebral blood flow (CBF). This effect occurs is both opinter and radate to aligned by processor.

in both primates and rodents at clinically relevant concentra-tions and is enhanced by chronic treatment similar to their clinical use. This increase appears to be dependent on an Clinical use. This increase appears to be dependent on an intact central adrenergic system supporting the concept that one function of this system is regulation of the cerebral microcirculation. These observations do not tell us whether the effect is a general phenomenon observed following any psychopharmaceutical. In this set of studies, we examined the effects of a novel antidepressant, mianserin, in a dose-dependent fashion (1, 10, 100 and 1000 ug/kg i.v., and 1 ug/kg i.c.v.) as well as two other classes of drugs: antipsychotic and anti-anxiety agents. For the former, we did a dose-response (0.4, 1.0 and 10 mg/kg i.v.) study with haloperidol (H) and also examined effects of fluphenazine (F), thiothixene (IX) and thioridazine (IR) at a fixed dose (0.4 mg/kg i.v.). For the latter, we have to date examined only one dose of diazepam (D), 1 mg/kg i.v. We tested the effects of these treatments on PS and CBF as function of CO<sub>2</sub> administration in 225-250 gm, male Sprague-Dawley rats using a dual label radioisotope technique previously described (Brain Res. 249:23-30, 1982). Results:

Table:	Effect of	diff	erent c	lasses	s of dr	ugs or	CBF a	and PS
	at hypocapnia and hypercapnia.							
		C*	M* * *	H**	F	ΤX	TR	D
CBF at	$CO_{2} = 20$	163	179	57	45	52	19	49

doses; ***	1 ug/kg i	.c.v.	, resul	ts whi	ich wei	re the	most p	profound.
The results show that, unlike amitriptyline, neither antipsy- chotic nor anti-anxiety agents increase PS but do reduce CBF especially under hypocapnic conditions. Conversely, the novel antidepressant increased PS but did not alter CBF. These results indicate that PS and CBF can be separately affected and that these changes distinguish different classes of psycho- pharmaceuticals. To date, the effect on PS appears to be restricted to drugs with mood effects. Supported in part by MH-00272, NS-1752 and the PMAF.								

47.10 COCAINE WITHDRAWAL: EFFICACY OF TYROSINE. M. S. Gold<sup>1</sup>, A. L. C. Pottash<sup>1</sup>, W. J. Annitto<sup>\*1</sup>, K. Vereby<sup>\*2</sup>, D. R. Sweeneyl, Fair Oaks Hospital, Summit, N.J. 07901<sup>1</sup> and N.Y. State Drug Testing Laboratories, Brooklyn, N.Y. 11217<sup>2</sup>.

In a preliminary report we have described a cocaine withdrawal syndrome consisting of drug craving, irritability, anergia, de-pression, fearfulness, hypersomnia, shaking, nausea, which may be accompanied by an autonomic discharge.<sup>1</sup> In all cases where this withdrawal syndrome has been demonstrated the cocaine user had virtually unlimited access to cocaine on the basis of personal Virtually unlimited access to cocaine on the basis of personal or family walth, profession, or distributing the drug. The post-cocaine crash or cocaine withdrawal is frequently given by addicts as the reason they can not stop self administration of cocaine. In animal models of cocaine self administration co-caine is preferred to food and with unlimited access animals may self administer cocaine to the end points of seizures and death.

In an attempt to treat the cocaine withdrawal syndrome as we had previously accomplished with the narcotic withdrawal syndrome<sup>2</sup>, we hypothesized that severe cocaine withdrawal is related to depletion of catecholamines. Support for this hy pothesis has come from one demonstration of low 3-methoxy 4hydroxyphenylglycol and tyrosine in cocaine addicts. As a preliminary test of the catecholamine depletion hypothesis of (0.1 gm/kg) tyrosine to six cocaine addicts in an open, non-blind trial. Patients were rated on a twice daily basis for blind trial. Patients were rated on a twice dairy basis for withdrawal signs and symptoms. Tyrosine had consistent anti-withdrawal effects. In addition to allowing successful detox-ification, tyrosine may be a useful post-detoxification pharma-cotherapy. These clinical data support a functional catecholamine depletion hypothesis for cocaine withdrawal on the basis of tyrosine's ability to increase DA, NE, and E. Though other treatments may be found to be equally efficacious (eg. methylphenidate, amphetamine, MAO inhibitors) tyrosine as an amino acid catecholamine and thyroid hormone precursor has no apparent abuse potential and offer the hope of restoring hemostatic balance to the cocaine deranged catecholamine systems. Double-blind placebo controlled trial of tyrosine in cocaine withdrawal is in progress and will be discussed.

ESTROGEN MODULATES THE EFFECTS OF AMPHETAMINE ON LOCOMOTOR ACTIVITY IN MALE RATS. <u>Richard P. Michael and Charles H.K. West</u>. Department of Psychiatry, Emory University School of Medicine and 47.11 Georgia Mental Health Institute, Atlanta, GA 30306. Behavioral and neurochemical studies in rats have shown that

exogenously administered estrogen can alter the effects of dopa mine agonistic drugs, thereby suggesting that estrogen may modu-late dopamine neurotransmission under certain circumstances. Recent work has shown that the effects of estrogen depend upon the time between its administration and the behavioral test. The long time-course for these effects is consistent with a genomic mechan-ism of action, but short-term behavioral effects have not been This study investigates the change in the locomotor examined. activity increase induced by <u>d</u>-amphetamine (d-A) following treatment with estradiol benzoate (EB). Male rats were administered ment with estradiol benzoate (EB). Male rats were administered EB (50 µg/kg, s.c.) and were subsequently tested at various times from 45 min to 20 days for changes in locmotor activity (infrared beam interruptions, 10 min sessions) induced by acute (15 min pretreatment) administration of d-A (0.25 mg/kg, s.c.). Tests with d-A were separated by at least 2 days since control tests had demonstrated no change in response to d-A with this treatment regimen. The EB + d-A scores were compared with scores from control tests with seame oil vehicle + d-A. Throughout each 20 day test period following EB, the baseline activity scores after saline injections did not differ significantly from control scores. Therefore, the data for d-A are expressed as a percentage of saline scores collected within a few days of each d-A test. The EB effect on the sensitivity of the animals to d-A cold be divided into 3 phases: (1) an acute (45 min) increase in sensitivity and (3) a divided into 3 phases: (1) an acute (45 min) increase in sensitivity and (3) a slow time course (2 - 16 days) increase in sensitivity and (3) a slow time course (2 - 16 days) increase in sensitivity to  $\underline{d}$ -A. Control tests with  $\underline{d}$ -A yielded increases in activity scores (mean  $\pm$  SEM) ranging from 308  $\pm$  21% to 328  $\pm$  28% of saline baseline values. When activity was monitored 45 min after EB administration, the response to d-A was significantly increased to 435 ± 49% over saline baseline. In contrast, 1 day after EB treatment, the d-A response was significantly reduced to only 279 ± 20%. The d-A response was significantly reduced to only 279 120 and Tests 2 to 16 days after EB treatment all revealed significant increases over baseline in the response to d-A (2 days: 422 ± 48%, 4 days: 395 ± 39%, 8 days: 431 ± 63%, 12 days: 459 ± 48%, 16 days: 392 ± 30%). By 20 days, the response to d-A was slightly but not significantly above control values. These results show the PM that EE can alter the hyperactivity response to <u>d</u>-A, probably via more than one mechanism of action. Furthermore, a short latency behavioral effect of EB has been demonstrated, implying a nongenomic mechanism.

### CHARACTERIZATION OF CHOLINERGIC RECEPTORS

MONOCLONAL ANTIBODIES AGAINST THE  $\alpha-\text{BUNGAROTOXIN}$ 48.1 MONOCLONAL ANTIBODIES AGAINST THE α-BUNGAROTOXIN BINDING PROTEIN OF CHICK OPTIC LOBE. <u>H. Betz and F. Pfeiffer</u> \* Max-Planck-Institute for Psychiatry, Dept. of Neurochemistry, D-8033 Martinsried, FRG. α-Bungarotoxin (α-BTX) binds with high affinity and nicotinic-cholinergic specificity to a membrane pro-tein of the chick visual system. Several properties of this a-BTX receptor are consistent with the characteri-zation of this protein as a neuronal nicotinic acetyl-choline receptor. Also, the toxin binding site region of this protein has been localized on a polypeptide of M<sub>r</sub> = 57,000 (Betz <u>et al., J. Biol. Chem., 257</u>:11390, 1982).

In order to investigate the function and cholinergic ligand site(s) of the  $\alpha$ -BTX receptor, monoclonal antibodies (mAbs) have been produced against the detergent-solubilized protein after >1000 fold purification gene-solutized protein after rioto for purilication on  $\alpha$ -BTX-derivatized agarose and wheat germ agglutinin-sepharose. From one fusion of the spleen of a hyperimmunized mouse with the myeloma cell line x63-Ag8.653, fourteen independent stable hybridoma clones have been routcell independent stable hybridom clones have been established which secrete mAbs against the solubilized chick  $\alpha$ -BTX binding component. None of the mAbs crossreacts to a significant extent (<1-2%) with solubilized ACAR from chick muscle or Torpedo electric organ. Some, however, recognize the  $\alpha$ -BTX receptor of the rat phaeochromocytoma cell line PC12

About half of the mABs inhibit  $\alpha$ -BTX binding to membrane fractions or detergent extracts of chick optic lobe. The binding of a few, but not all of the latter class of mAbs is blocked by nicotinic-cholinergic antagonists. The mAbs are thus concluded to recognize at least three different epitopes on the chick  $\alpha$ -BTX binding protein. Several of the non-blocking mAbs produce a down-regulation of  $\alpha$ -BTX binding sites in produce a down-regulation of  $\alpha$ -BTA binding sites in chick retina cultures by increasing the degradation of the toxin receptor. Also, the mAbs are shown to be useful reagents for the immunoaffinity isolation/ precipitation of the  $\alpha$ -BTX receptor from chick and rat (PC12) cells.

MONOCLONAL ANTIBODY (mcab) 247G: EXAMPLE OF A FUNCTIONAL PROBE FOR THE ACETYLCHOLINE RECEPTOR (AcChR) MOLECULE. <u>M. Mihovilovic\* and D. Richman\*</u> (SPON. J. Crayton). Dept. of

M. Mihovilovic\* and D. Richman\* (SPON. J. Crayton). Dept. of Neurology, The University of Chicago, Chicago, Illinois 60637. Binding of mcab 2476 to purified, solubilized AcChR from <u>Torpedo californica</u> results in stable AcChR-mcab 2476 complexes in which I mcab molecule binds per every 2  $\alpha$ -bungarotoxin ( $\alpha$ Bgtx) binding sites. The immune complex binds only one  $\alpha$ Bgtx molecule: binding is characterized by a second order rate constant, k<sub>1</sub>, of 1.92 ± 0.30 x 10<sup>5</sup> M<sup>-1</sup> s<sup>-1</sup>, which compares to the kinetically resolved fast  $\alpha$ Bgtx binding component of native solubilized AcChR (k<sub>1</sub> = 1.62 ± 0.11 x 10<sup>5</sup> M<sup>-5</sup> s<sup>-1</sup>). The kineti-cally resolved slow  $\alpha$ Bgtx binding component of the solubilized AcChR (k<sub>2</sub> = 0.35 x 10<sup>5</sup> M<sup>-1</sup> s<sup>-1</sup>) is not expressed in the immune complex. complex.

complex. Inhibition of aBgtx binding to AcChR by benzoquinonium reveals that the ligand binds to two sites of the AcChR characterized by I<sub>6</sub> values of  $5.0 \pm 1.0 \times 10^{-7}$  M and  $3.5 \pm 1.5 \times 10^{-4}$  M, while AcChR-near 2476 complexes express only the low affinity benzoquinonium binding site. Thus our data indicate a correspondence between the low affinity benzoquinonium binding site and the kinetically resolved fast m8tx binding component of the and the kinetically resolved fast  $\alpha$ Bgtx binding component of the AcChR molecule. These results demonstrate the ability of anti-AcChR mcabs to functionally probe the AcChR molecule.

48.3 THE STRUCTURE AND TRANSMEMBRANE NATURE OF THE ACETYLCHOLINE RECEPTOR IN AMPHIBIAN SKELETAL MUSCLE AS REVEALED BY CROSS-REACTING MONOCLONAL ANTIBODIES. Bruce E. Hedges\*, Sargent, Larisa Tsavaler\*, Lydia Clemmons\*, and Jon M. Lindstrom (SPON: Carla J. Shatz). Dept. of Structural Biology, Stanford University School of Medicine, Stanford, CA 94305, and Receptor Biology Laboratory, The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

A collection of 126 monoclonal antibodies (mAbs) made against acetylcholine receptors (ACRRs) from the electric organs of Torpedo californica or Electrophorus electricus was tested for cross-reactivity with AChRs in cryostat sections of skeletal Cross-reactivity with AGRS in cryostal sections of sected muscle from Rana pipiens and Xenopus laevis by indirect immuno-fluorescence. Fifty mAbs (40%) cross-reacted with AChRs from Rana; 25 mAbs (20%) cross-reacted with AChRs from Xenopus. mAbs Kana; 25 mAbs (20%) cross-reacted with AChKs from Xenopus. mAbs specific for each of the four subunits of electric organ AChR ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ) cross-reacted with AChRs from each amphibian spe-cies. mAbs cross-reacting with Xenopus AChRs were, with one exception, a subset of the mAbs cross-reacting with Rana AChRs. The major difference detected between the two species was in binding by mAbs specific for the main immunogenic region (MIR) of the  $\alpha$ -subunit. Whereas 23 of 33 anti-MIR mAbs cross-reacted with <u>Rana</u> AChRs, only one of these mAbs cross-reacted with <u>Xenopus</u> AChRs. <u>Some</u> (32) of the cross-reacting mAbs were tested for binding

Some (32) of the cross-reacting mAbs were tested for binding to AChRs in intact muscle. Of these 21 mAbs bound to AChRs only when membranes were made permeable with saponin. Electron microscopy using immunoperoxidase or colloidal gold techniques revealed that these mAbs recognize cytoplasmic determinants and that mAbs which do <u>not</u> require saponin in order to bind AChRs in intact muscle recognize extracellular determinants.

These results suggest that AChRs in skeletal muscle of Rana and Xenopus are composed of subunits corresponding to the  $\alpha$ ,  $\beta$ , and <u>Xenopus</u> are composed of subunits corresponding to the  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  subunits of AChRs from fish electric organs. The sub-unit specificity of mAbs whose binding was examined by electron microscopy suggests that parts of each subunit ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ) are exposed on the cytoplasmic surface and that, as in AChRs from fish electric organs and mammalian muscle, the MIR on  $\alpha$  subunits of <u>Rana</u> AChRs is exposed on the extracellular surface. <u>Supported</u> by the National Science Foundation, the National

Institutes of Health and the Muscular Dystrophy Association.

48.4 PROTEOLYTICALLY DERIVED FRAGMENTS OF THE ALPHA SUBUNIT OF THE ACETYLCHOLINE RECEPTOR FROM TORPEDO CALIFORNICA THAT BIND 1251-ALPHA-BUNCAROTOXIN. <u>B. Oblas,\* N. D. Boyd\* and R. H. Sing</u> (SPON: J. Walsh) Depts, of Anatomy and Physiology, Univ. Massachusetts Med. Ctr., Worcester, Massachusetts 01605 Singer.\*

We have previously reported a nitrocellulose protein transfer technique which we have used to confirm that the alpha-bungaro-toxin binding site resides on the alpha subunit (40K) of the Torpedo californica acetylcholine receptor. (Oblas, B., et. al., <u>Anal. Biochem.</u>, 130:1, 1983). We are now extending the use of this technique to define further the location of this binding site on the 40K subunit by studying the ability of proteolytically derived fragments of this subunit to bind  $^{125}$ I-alphabungarotoxin.

The alpha subunit was solubilized and digested with various proteolytic enzymes including <u>Staphylococcus</u> aureus Vg protease, papain, chymotrypsin and trypsin. The resulting peptide fragments were separated on a 20% sodium dodecyl sulfate (SDS)-polyacrylamide gel and transferred in a renaturing environment to a nitrocellulose sheet which was then incubated with <sup>125</sup>I-alpha-bungarotoxin. Autoradiography (2-6 days) revealed different patterns of binding for each enzyme treatment. After proteolytic digestion with Vg protease, <sup>125</sup>I-alpha-bungarotoxin bound to a single peptide fragment of apparent molecular weight 17K, while proteolytic digestion with papain resulted in two fragments of 33 and 27K which bound the labeled toxin. None of the fragments of the alpha subunit obtained by chymotrypsin digestion was found to bind <sup>125</sup>I-alpha-bungarotoxin. Limited digestion by trypsin conbind ---1-alpha-bungarotoxin. Limited algestion by trypsin con-verted the 40K subunit into two fragments of apparent molecular weights of 37 and 33K which have affinity for the labeled toxin. More extensive digestion by this enzyme resulted in a decrease in fragments and a concomitant appearance of a 17K fragment that bound the labeled toxin. No labeling was observed for these fragments when a 100 fold excess of unlabeled toxin was added to the incutation the incubation mixture.

The entire amino acid sequence of the Torpedo californica alpha subunit has been reported (Noda, M., et. al., <u>Nature</u>, 299: 793, 1982) and shown to contain two pairs of basic residues, Arg-Lys and Lys-Arg which upon trypsin digestion would yield two fragments with molecular weights similar to the two larger molecular weight fragments reported here. The isolation of the smallest fragment will allow the determination of that region of the alpha subunit in which the alpha-bungarotoxin site resides.

48.5 PROTEIN-BLOTTING ANALYSIS OF  $\alpha$ -BUNGAROTOXIN BINDING TO THE ACETYL-CHOLINE RECEPTOR: SPECIES COMPARISON, PROTECUTIC FRACHENTS, AND MBTA SPECIFICITY. Thomas L. Lentz, Jonathan M. Gershoni\*, Paul Wilson\*, Donna Klimowicz\*, Linda M. Hall, and Edward Hawrot. Depts Cell Biology and Pharmacology, Yale Univ. Sch. Med., New Haven, CT and Dept. Genetics, Albert Einstein Coll. Med., Bronx, NY.

We demonstrated previously the direct binding of  $\alpha$ -bungarotoxin (BuTX) to the  $\alpha$ -subunit of the acetylcholine receptor (AChR) from Torpedo electric organ after immobilization onto protein blots (J. Cell Biol., 95:422a, 1982). Further studies have been carried out to determine whether BuTX binding to protein blots could be used to detect AChR from other sources. Membrane fractions were pre-pared from <u>Torpedo</u> and <u>Electrophorus</u> electric organ and <u>Drosophila</u> brain. Enriched extracts were prepared by cobratoxin column chro-matography of goldfish brain, embryonic chick muscle, a mouse mus-cle cell line (BC3H1), and denervated rat skeletal muscle. Samples were solubilized in LDS sample buffer and electrophoresed on 10%polyacrylamide gels. Protein blots were prepared by electropho-retically transferring the resolved AChR subunits from the gels onto Zetabind, positively charged nylon membrane filters. The filters were then quenched with  $1^{2}$  hemoglobin, incubated with  $1^{2}$  J-BuTX, washed and autoradiographed. In all cases, one polypeptide band (40-44kd depending on species) bound labeled toxin. These results suggest that species over a wide spectrum of taxonomic classes contain a receptor component analogous to the  $\alpha$ -subunit of <u>Torpedo</u>. To further characterize the BuTX binding site on <u>Torpedo</u> <u>Torpedo</u>. To further characterize the BuTX binding site on <u>Torpedo</u> AChR, proteolytic fragments of the  $\alpha$ -subunit were prepared and tested for BuTX binding. After excising the  $\alpha$ -subunit from gels treated with sodium acetate, specific proteolytic fragments were prepared by digesting with different proteases. The fragments were electrophoresed, transferred to filters, and incubated with  $^{125}I$ -BuTX. Distinct and reproduceable peptide maps were obtained for each protease. BuTX bound to 28 and 19kd fragments of  $\alpha$ -sub-unit produced by V-8 protease; to 29, 18, and 14kd fragments after papain digestion; and to 28, 20, and 17kd fragments after brome-lain digestion. To test whether the BuTX binding detected on pro-tein blots correlates with the physiologically-relevant acetylchotein blots correlates with the physiologically-relevant acetylcho-line binding site, the effect of 4-(N-maleimido)benzyltrimethyl-ammonium iodide (MBTA) on toxin binding was tested. Various conammonium iodide (MBTA) on toxin binding was tested. Various concentrations of MBTA (0.5-10µM) (gift of A. Karlin) were incubated with <u>Torpedo</u> membrane samples containing 0.3µM AChR. Aliquots from each sample were either solubilized in Triton X-100 and assayed for their ability to bind <sup>125</sup>I-BuTX or were solubilized, electrophoresed, transferred to filters, and incubated with <sup>125</sup>I-BuTX. Prior affinity alkylation with MBTA was found to inhibit to the same degree binding of BuTX to the Triton-solubilized intact AChR and to the isolated α-subunit immobilized on the filters. Supported by NSF (BNS8203825), NIH (GM32629), and MDA.

IDENTIFICATION OF AN Mr 43,000 PROTEIN KINASE IN ACETYLCHOLINE RECEPTOR-ENRICHED MEMBRANES. A.S. Gordon, D. Milfay\*, and I. Diamond. Dept. of Neurology, Univ. of Cal. Sch. of Med., San Francisco, CA 94143.

We have shown that acetylcholine receptor (AChR)-enriched We have shown that acetylcholine receptor (AChR)-enriched membranes from <u>Torpedo californica</u> have an endogenous protein kinase activity which phosphorylates the AChR in <u>situ</u>. We have now used 8 azido ATP, an ATP photoaffinity analog, to identify the kinase in these membranes. We first determined that 8 azido ATP reacts with the ATP binding site of the receptor kinase by studying its effect on receptor phosphorylation. AChR-enriched membranes were preincubated for 20 min with increasing concentrations of 8 azido ATP before assaying for protein kinase activity. Oprresponding decreases in receptor phosphorylation concentrations of 8 azido ATP before assaying for protein kinase activity. Corresponding decreases in receptor phosphorylation were observed, suggesting that 8 azido ATP binds to the receptor kinase. Incubation of AChR-enriched membranes with  $\lceil \alpha - 2^{-1} \rceil$  8 azido ATP and subsequent irradiation with UV light resulted in the covalent labeling of one major band of M\_43,000. Alkaline stripped membranes which show a selective reduction in the M\_ 43,000 polypeptide also show a corresponding reduction if necertariation of photoaffinity label. This was recovered in the neutralized alkaline extract which showed one band at M\_43,000 when labeled with the photoaffinity ligand. We also found that when labeled with the photoarrinity light. We also found that endogenous protein kinase activity decreased in the alkaline extracted membranes in proportion to the loss of  $M_{\rm p}$  also  $M_{\rm p}$  and  $M_{\rm p}$  are subtracted and  $M_{\rm p}$  and  $M_{\rm p}$ 

The binding of [ H]-terracaine ([ H]-terr) to hisotinic postsynaptic membranes from Toppedo electric tissue has been studied at 4°C by ultracentrifugation and ultrafiltration. Tetracaine had been identified as a ligand that displaces bound ['H]histrionicotoxin ([ <sup>3</sup>H]-HX) only weakly (IC<sub>50</sub>=100 µM) when cholinergic sites are occupied by carbamylcholine (carb), but potently (IC<sub>50</sub>=0.4 µM) in the absence of cholinergic ligands. The nonspecific interaction of ['H]-TET with the membranes is characterized by a partition coefficient, P=80 mol/g protein per mol/ml. In the absence of cholinergic ligands [<sup>3</sup>H]-TET binds with high affinity (Keq=350nM) to a number of sites equal to 0.4860.11 the number of [<sup>3</sup>H]-HX, is equal to 1 : 1.1±.3 : 1.3±.2. Cholinergic ligands alter the affinity wites. This binding is not the number of high affinity sites. With receptor sites fully occupied by α-bungarotoxin (α-BgTX) or tubocurarine (50 µM), Keq equals 0.4 and 0.9 µM respectively, while in the presence of carb (100µM), Keq-30 µM. Since [<sup>3</sup>H]-TET binds with the same affinity in the presence of absence of α-BgTX, we conclude that 1) the binding of α-BgTX produces no local change of receptor steric effect.

The kinetics of  $[{}^{3}\text{H}]$ -TET binding have been analyzed by ultrafiltration to define tetracaine's effect on receptor conformational equilibria. The kinetics of  $[{}^{3}\text{H}]$ -TET dissociation at equilibrium was measured as the rate of exchange for unlabelled tetracaine. In the absence of cholinergic ligands or in the presence of  $\alpha$ -BgTx, dissociation kinetics were characterized by a single rate constant ( $t_{\perp}$ =35 min) for greater than 80% of the exchange reaction. Inclusion of tubocurarine (50 µM) or carb (100 µM) changes the  $[{}^{3}\text{H}]$ -TET dissociation rate to  $t_{2}$ =15 min and (0.5 min, respectively. The association rate constant for  $[{}^{3}\text{H}]$ -TET binding measured in the absence of cholinergic ligands is 4.5 x 10 ${}^{4}\text{M}$ -min<sup>-1</sup>, or an order of magnitude slower than the rate of  $\alpha$ -BgTx binding. We conclude that tetracaine induces a conformational change in the nicotinic receptor which is distinct from the high-affinity or desensitized state induced by cholinergic agonists. (Supported by USPHS Grant NS-19522 and Predoctoral Training Grant GM-07805.)

48.9 NICOTINIC-INDUCED RELEASE OF ENDOGENOUS DOPAMINE FROM RAT STRIATAL SLICES FOLLOWING CHRONIC TREATMENT WITH NICOTINIC AGONISTS. T. C. Westfall and H. Perry<sup>\*</sup>. Dept. of Pharmacology, St. Louis Univ. School of Medicine, St. Louis, MO 63104.

Several investigators have reported that activation of nicotinic-cholinergic receptors within the striatum results in the release of labelled dopamine (DA) following incubation of tissue with radioactive amine (Neuropharmacol. 13:693, 1974; Anesthes. 48:118, 1978; Brain Res. 106:117, 1976). Although the use of labelled compounds to assess transmitter release has been a useful tool, there are nevertheless problems that make this technique less reliable than measuring the release of the endogenous transmitter itself. The purpose of the present study was to examine the release of endogenous DA from slices following acute activation of nicotinic-cholinergic receptors and in slices obtained from rats chronically treated with the nicotinic agonist dimethyl phenylpiperazinium (DMPP, 17 mg/kg/day for 7 or 14 days) or saline by means of Alzet osmotic pumps placed subcutaneously. Animals were decapitated and striata rapidly removed in the cold room. Striata were dissected with glass manipulators, sliced sagittally with a MacIlwain tissue chopper to a thickness of 0.5 mm. Following a preincubation period in Krebs-Ringer solution at 370 for 15 min, the slices were placed in wire baskets and mm. incubated for various times in 750 µl of buffer in the absence or presence of varying concentrations of DMPP or nicotine for 5 min. Dopamine released from the tissue into the incubation medium was measured by injection of 20 µl aliquots of the incubation media directly into the HPLC. Dopamine was quantified with an electro-designed absorber paintering ab 0.7402 (Media Locat aligner explose chemical detector maintained at 0.7402 (Model LC-4A glassy carbon electrode). The routine solvent was 12% methanol, 175 mM acetic acid, 1 mM EDTA and 2 mM heptane sulfonic acid and the pH adjusted to 3.8 with 10 M NaOH.

DMPP in concentrations of 100, 500, 750 and 1000  $\mu\rm M$  produced an increase of 1.06±.24, 4.73±5.3, 6.67±.53 and 6.84±.59 of DA/g/ min from control slices. The DMPP-induced release from slices obtained from animals chronically treated with the agonist for 7 days was 1.95±.43, 5.83±.48, 7.77±.58 and 7.16±.35, and were not different from control. The DMPP-induced release from slices obtained from animals chronically treated with DMPP for 14 days was significantly lower than from control slices or slices from animals treated with DMPP for 7 days. There was an increase of 1.36±.14, 2.45±.31, 4.66±.28 and 5.06±.67 for the 4 concentrations, respectively.

These results demonstrate that the chronic treatment of animals with a nicotinic agonist results in slices which are subsensitive to the DMP-induced release of endogenous DA. Studies are underway to define the mechanism of this response. Supported by USPHS Grants DA-02668 and HL-26319. 48.8 NICOTINIC AGONIST BINDING INCREASES IN RAT HIPPOCAMPUS FOLLOWING FIMBRIAL TRANSECTION. A.L. Morrow, R. Loy and I. Creese. Dept. of Neurosciences, Univ. of Calif., San Diego, Sch. of Med., La Jolla, CA 92093.

The regulation of cholinergic receptors in the hippocampal formation of the rat has been studied by removal of the septal and diagonal band afferents and by muscarnic receptor blockade. While chronic treatment with atropine or scopolamine increases H-QNB binding (a muscarnic ligand), removal of the cholinergic afferents does not. Nicotinic cholinergic binding sites labeled with T-I-d-bungarotoxin are likewise unaltered. As it is unclear if this ligand labels all nicotinic receptor labeling. Nicotinic H-ACh binding (Kd=15.2+1.9) was performed according to Schwartz et al. (Mol. Pharm. 22:56, 1982) using eserine to prevent hydrolysis. Eight days following knife transection of the fimbria/fornix there is a 49% increase in the specific binding is due to a 45% increase in the affinity of H-ACh for its binding site with no change in Bmax (p<.05, 1-tailed Students t-test). Using Munson and Rodbard's LIGAND computer program we have confirmed a change in affinity by simultaneous analysis of the saturation data for operated and y simultaneous analysis of the affinity of H-ACh to be identical for control and operate tissue significantly worsens the fit in each of four such comparisons.

48.10 SPONTANEOUS OPENINGS OF THE ACETYLCHOLINE RECEPTOR CHANNEL, <u>Meyer B. Jackson</u>. Dept. of Biology & Mental Retardation Research Center, Univ. of California, Los Angeles, CA 90024. Patch clamp recordings from embryonic skeletal mouse muscle in culture revealed infrequent channel currents of short duration in the absence of cholinergic agent. The amplitude of these channel currents was identical with the amplitude of channel currents elicited by the cholinergic agonist suberyldicholine. This equality was maintained over a range of voltage, using either sodium or cesium as the major cation of the patch electrode filling solution and the cell bathing solution. Treatment of cells with --bungarotoxin blocks these channel currents. The receptor binding site was chemically modified by treatment first with dithiothreitol and then with N-ethylmaleimide. This treatment blocked agonist elicited openings but not spontaneous openings. Thus, spontaneous openings are not prevented when the binding site of the receptor is interfered with. These experiments indicate that an acetylcholine receptor channel complex fluctuates briefly and infrequently into the open state

in the absence of cholinergic activation.

48.11 BARBITURATES ALLOSTERICALLY REGULATE HIGH AFFINITY ACETYLCHOLINE BINDING TO NICOTINIC RECEPTORS, <u>B.A. Dodson\* and K.W. Miller\*</u> (SPON: G.J. Crosby). Depts. of Anaesthesia and Pharmacology, Harvard Medical School, Massachusetts General Hospital, Boston, MA 02114 USA.

Barbiturates have been shown to modify acetylcholine (ACh) binding to the acetylcholine receptor (AChR)-rich membrane from <u>Torpedo</u>. Amobarbital decreased [<sup>3</sup>H]ACh binding by 70% with an apparent K<sub>d</sub> = 18 ± 3.5  $\mu$ M. Secobarbital, which itself has no effect on [<sup>3</sup>H]ACh binding, antagonized the effect of amobarbital in a competitive manner with an apparent K<sub>d</sub> = 84  $\mu$ M (Dodson and Miller, <u>Soc. Neurosci. Abstr.</u>, 8: 340, 1982). A pentobarbital binding site has been characterized, which appears to interact allosterically with the ACh binding site on the AChR-rich <u>Torpedo</u> membrane (Miller <u>et al.</u>, <u>BBRC</u> 105:659-666, 1982). Here we will show that it is through this barbiturate binding site that the barbiturates are able to allosterically regulate the binding.

AChR-rich membranes were prepared from the electroplaques of freshly killed <u>T.nobiliana</u> by differential and gradient centrifugation. The change in displaceable [ $^{14}$ C]amobarbital (6 µM) binding to AChR (4 µM) by amobarbital (0-1 mM), with and without 0.1 mM carbamylcholine and/or 10 µM  $\alpha$ bungarotoxin ( $\alpha$ BTX), or by secobarbital (0-2 mM) was determined by centrifugation assay at pH 7.0. All binding data were fitted to mass action curves by a non-linear least squares method.

Both amobarbital and secobarbital displaced [<sup>14</sup>C]amobarbital in a competitive manner with Kds of 26 ± 4.2 µM and 94 ± 9.1 µM, respectively. These Kds are comparable to the apparent Kds (above) obtained by [<sup>14</sup>]ACh binding studies.  $\alpha$ BTX alone had no effect on [<sup>14</sup>C]amobarbital binding, but carbamylcholine decreased [<sup>14</sup>C]amobarbital binding by 50%. This carbamylcholine sensitivity was, however, completely blocked by  $\alpha$ BTX. These data are consistent with the barbiturate binding site being on the AChR protein, but not on the ACh binding site itself. Furthermore, the concentration dependence of both the decrease in [<sup>14</sup>C]amobarbital binding by carbamylcholine and the decrease in is consistent with allosteric regulation. Thus we have presented data supporting the hypothesis that there exists a barbiturate binding site on the AChR protein, but not on the ACh binding site itself, which can allosterically regulate ACh binding.

48.12 CHARACTERIZATION AND PARTIAL PURIFICATION OF MUSCARINIC ACETYLCHOLINE RECEPTORS SOLUBILIZED BY ZWITTERIONIC DETERGENT. M. Gavish and M. Sokolovsky<sup>\*</sup>. Department of Pharmacology, Rappaport Family Research Institute, Faculty of Medicine, Technion, POB 9697, Haifa, and <sup>\*</sup>Department of Biochemistry, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel.

The muscarinic acetylcholine receptors were solubilized from rat brain cortex by Zwitterionic detergent 3-[(chloramidopropyl) dimethylammonio]-lpropanesulfonate (CHAPS). About 35% of the binding activity was solubilized and 40% retained in the pellet. Binding of the muscarinic antagonist  $|{}^{3}\text{H}|$ -N-methyl-4-piperidyl benzilate (4NNPB) was saturable. Scatchard analysis revealed a single population of binding sites with K<sub>D</sub> value of 0.7nM and Bmax value of 340 fmoles/mg protein. The affinity of the CHAPS soluble receptors to the agonists oxotremorine and carbamylcholine and for the antagonists QNB and atropine was found to be similar to that of the muscarinic receptors. The molecular weight of the CHAPS soluble muscarinic receptors as determined by chromator-graphy on Sepharose-6B was found to be 320,000 daltons. The soluble receptors were purified 10 fold by chromatography on DEAE-cellulose or hydroxylapatite.

#### **BLOOD-BRAIN BARRIER I**

49.1 COLLOIDAL CARBON AS A COMBINED OPHTHALMOSCOPIC AND MICROSCOPIC PROBE OF THE RETINAL-BLOOD BARRIER INTEGRITY. Manuel del Cerro, Donald A. Grover\* and Wesley M. Williams\*. Center for Brain Research, University of Rochester School of Medicine, Rochester, N.Y. 14642. The retinal vasculature is characterized by having a barrier restrictive of the free movements of molecules between blood and retinal tissue (BRB). Anatomically and physiologically, this barrier is the ocular counterpart of the blood-brain barrier (BBB). While studying the effects of an experimental immunopathy, we searched for a probe

The retinal vasculature is characterized by having a barrier restrictive of the free movements of molecules between blood and retinal tissue (BRB). Anatomically and physiologically, this barrier is the ocular counterpart of the blood-brain barrier (BBB). While studying the effects of an experimental immunopathy, we searched for a probe that would permit us to test the barrier in the same eye by ophthalmoscopy, light microscopy, and electron microscopy. Colloidal carbon, administered intravenously, permitted us to achieve these goals. The tracer can be seen in the choroidal and retinal circulation, and abnormal deposits of it can be visualized in vivo. The ophthalmoscopic findings can be corroborated and extended by stereomicroscopy and by light microscopy. Subsequently, the plastic embedded specimens can be used for a transmission electron microscopical study. This tracer, thus, permits a sequential clinical, histological, and even ultrastructural evaluation of the status of the BRB.

49.2 BRAIN CAPILLARY PERMEABILITY TO INORGANIC IONS. <u>Q.R. Smith, C.-Y. Tai\* and S.I. Rapoport</u> (SPON: R.M. Steinman). Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, NIH, Baltimore City Hospitals, Baltimore MD 21224 The cells of the blood-brain barrier are connected by rings

The cells of the blood-brain barrier are connected by rings of tight junctions, which restrict intercellular diffusion and limit exchange of inorganic ions between plasma and brain. Ions move from plasma to brain directly across cerebral capillaries into brain extracellular fluid (ECF), or indirectly across the choroid plexus or arachnoid membrane into cerebrospinal fluid (CSF), with subsequent diffusion into brain ECF. To determine the ion transport properties of the cerebrovascular endothelium, we measured\_initial ugake, following an i.v. bolus injection of  $2^{N}$ a,  $4^{C}$ Ca,  $2^{M}$ g or  $2^{C}$ Cl, into 12 brain regions and CSF of the rat. Initial uptake analysis, by minimizing the time for diffusion between CSF and brain ECF, made it possible to distinguish ion flux at the cerebral capillary from the contribution of CSF to brain radioactivity. Radiodisotopes (20-200 µCi/kg) were injected i.v. into pentobarbital-anesthetized rats, and timed arterial blood samples

Radioisotopes (20-200  $\mu$ Ci/kg) were injected i.v. into pentobarbital-anesthetized rats, and timed arterial blood samples were collected for 5-60 min, when the rats were killed. Samples from brain, cisternal CSF and plasma were collected and analyzed for radioactivity. Transfer constants (k) for unidirectional uptake were calculated from brain parenchymal and CSF radioactivities at the time of death divided by the plasma concentration integral of unbound tracer.

Integral of unbound tracer. Ion fluxes into CSF were 10-40 times greater than into brain tissue, so that a concentration gradient from CSF to brain was rapidly established for each tracer. Regional brain k's werg greatgr for regions closest to ventricular CSF. For <sup>2</sup>Na, <sup>2</sup>Ca and <sup>3</sup>Cl, brain k's ranged 3-6, fold, with minimu values in the frontal-parietal cortex. For <sup>4</sup>K and <sup>2</sup>Mg, k's ranged less than 3-fold. Acetazolamide-induced inhibitiog of <sup>Cl</sup> entry into CSF did not alter the cerebral cortex k for <sup>3</sup>Cl, but in periventricular regions k fell by up to 50%. When uptake time was limited to 30 min or less, frontal cortex k reflected movement primarily across the brain capillaries, with a minimal contribution from CSF. In the frontal cortex cerebrovascular permeability (cm/sec) was 60 x 10 <sup>6</sup> for g, 17 x 10 <sup>6</sup> for Mg, 8 x 10 <sup>6</sup> for Na, 5 x 10 for Cl and 2 x 10 <sup>6</sup> for Ca. The calculated electrical resistance of the brain capillary was 12,500  $\Omega \cdot cm$ . The permselectivity ( $P_{s} > P_{Ma}, P_{c}$ ) and large electrical resistance of brain capillaries suggest that ion movement across the capillaries is predominantly transcellular, across the vascular endothelium. Furthermore, 50% or more of the ion influx into rat brain may be from tracer that first enters CSF. 49.3 VESICLES WITHIN ENDOTHELIAL CELLS IN FROG SCIATIC NERVE DO NOT TRANSPORT HRP IN EITHER LUMENAL OR ANTILUMENTAL DIRECTIONS. <u>M.E. Michel\*, N.L. Shinowara and S.I. Rapoport. (SPON:J.Thompson)</u> Lab.Neurosciences, and Section Experimental Morphology, National Institute on Aging, Gerontology Research Center, Baltimore, MD 21224.

The endothelium of blood vessels within sciatic nerve of Rana pipiens is replete with vesicles at both their lumenal and ablumenal surfaces. With electron microscopy these vesicles appear as either round bottomed flasks attached by a narrow neck to the cell surface, or as free vesicles within the cytoplasm near the cell surfaces. Anastomosing vesicles are not uncommon, but transcellular channels formed by chains of fused vesicles have not been found. The contribution of these two vesicular populations to an endothelial blood-nerve barrier has not been described. To test the transport capabilities of the lumenal vesicles we injected horseradish peroxidase (HRP, 25 mg/ml; 0.1 ml) into the dorsal lymph sac of adult female (endoneurial) endothelial surface we slowly injected HRP (5 mg/ml; 1-3  $\mu$ l) into the endoneurim via a small slit in the surrounding perineurial sheath. These frogs were sacrificed 5-30 min after endoneurial injection. Fixed sciatic nerves were chopped into 80-100  $\mu$ m sections, reacted with 0.05% diaminobenzidine with 0.01%  $H_{20}$  for 1 hr at room temperature on a covered shaker, and processed routinely for electron microscopy.

Intravascular HRP was confined to the lumen of endoneurial blood vessels at all post-injection times. Vesicles at the lumenal surface were lined by the dense reaction product at both 5 and 60 min, and no progressive filling of cytoplasmic or ablumenal vesicles at the later times could be discerned. No tracer appeared at the endoneurial surface of the endothelial cells and no filled vesicles were seen attached to this cell surface. HRP injected into the endoneurial surface of the endothelial cells and end cell surface. Tracer filled the interendothelial celft within junctional regions but appeared halted by regions of membrane apposition near the lumen. No differences in the location of tracer-filled vesicles were seen in tissues taken at 10 and 30 min after injection of HRP. Tracer was not associated with the lumenal cell surface; tracer-filled vesicles were seen only in the vicinity of the ablumenal surface. We conclude from these studies that the endoneurial endothelial vesicles do not transport HRP in either a lumenal or antilumenal direction.  49.4 [14C]SUCROSE PERMEABILITY OF ENDONEURIAL CAPILLARIES IN THE FROG SCIATIC NERVE. <u>S.I. Rapoport and A. Weerasuriya\*</u>.
(Spon. R.E. Taylor) Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, NIH, Baltimore City Hospitals, Baltimore, Maryland 21224 USA The endoneurial space in a vertebrate peripheral nerve

The endoneurial space in a vertebrate peripheral nerve fascicle is separated from blood and extracellular tissue fluid by the endoneurial vasculature and the perineurium respectively. Functionally, these two barriers constitute the blood-nerve barrier. The perineurium of the frog sciatic nerve is relatively impermeant to small hydrophilic solutes ([14C]sucrose permeability - 5.6  $\times$  10<sup>-7</sup> cm/sec) and has a moderate electrical resistance (478  $_{\rm Q}$ cm<sup>-</sup>), indicating that it presents a significant hindrance to the transperineurial passage of substances. A characterization of the dynamics of fluid volume and solute concentrations within the endoneurial space also requires a description of the permeability of the other part of the blood-nerve barrier - the endoneurial capillaries. We estimated the permeability-surface area product (PA) of endoneurial capillaries of frog sciatic nerve to 14C]sucrose at room temperature with an <u>in vivo</u> perfusion arrangement. The perfusion medium (frog Ringer with 2% bovine serum albumin) containing 14C]sucrose and a tritiated blood space indicator, was infused into both legs of an urethame-anaesthetized frog via the descending aorta, at a pressure head of 16-23 mm Hg. An outlet was provided by cannulating the ventral adominal vein. Perfusion times ranged from 4 to 8 min. At the end of the perfusion period the nerves were removed from the frog and desheathed. After their dry weights had been determined, the perineuriums and desheathed nerves were dehydrated, solubilized and their radioactivities measured with conventional procedures. PA of the endoneurial capillaries to [14C]sucrose were setimated to be 5.0  $\pm$  0.79 (S.E.M., n=20)x10<sup>--</sup> sec<sup>--</sup>. In a one cm length of nerve with a diameter of 0.7 mm, the calculated PA fog [14C]sucrose of the endoneurial capillaries is 1.9 x 10<sup>--</sup> cm/sec. This supports the hypothesis that, under normal conditions, the endoneurial capillaries their normal conditions the endoneurial capillaries exercise their regulatory functions.

- 49.5 PERMEABILITY ROUTES OF HORSERADISH PEROXIDASE ACROSS THE FROG PER-IPHERAL NERVE SHEATH. N.L. Shinowara, M.E. Michel\* and S.I. Rapoport. Sec. Experiment. Morphol. & Lab. of Neurosciences, NIA-Gerontol. Res. Ctr., Balto. City Hospitals, Baltimore, MD. 21224 Normally, intravascular horseradish peroxidase (HRP, Sigma Type VI, 20 mg/kg body wt., 1 hr circulation time) is kept out of the endoneurium of the frog nerve by the perineurium and endoneurial blood vessels. We examined the possible routes of HRP movement across and within the nerve sheath (epineurium and perineurium) when it was applied directly to the epineurial surface of the nerve (in vitro, in physiological saline, or in vivo with gelfoam) or to the endoneurium by injection through a perineurial perforation. Nerves were fixed by immersion, in 2-3% glutaraldehyde in buffer or Ringer's, reacted with diaminobenzidine, postfixed and processed for electron microscopy. The tightest region of the perineurium to HRP was the inner 1-2 layers of perineurial cells; the arrangement of multiple layers of perinteurial certis, the arrangement of multiple layers of cells joined by tight junctions and interspersed with connective tissue markedly retard-ed the intercellular movement of tracer which was applied to the nerve exterior. When HRP had extension lateral access to sheath layers at the site of injection into the endoneurium, tracer moved readily between layers, indicating that the tight junctions, which joined adjacent layers, were incomplete and ineffective in retard-ing the lateral and circumferential diffusion of HRP within the perineurium. HRP, which leaves a trail by binding to cell membranes and connective tissue components, reached the endoneurium when applied to the nerve for 2 hr or more, probably damaging perineur-ial cells. Entry of injected HRP into the inner perineurial layers from the endoneurium also was associated with damaged cells, which often contained HRP. Numerous vesicles within perineurial cells did not appear to contribute to tracer movement. In rare cases occasional tracer-filled vesicular pits were found in regions free of HRP in the adjoining extracellular space. This suggests possible vesicular uptake of HRP, followed by vesicular movement from sites of uptake; however, there was no evidence of HRP discharge from the vesicle. In conclusion, the outer perineurial layers have incomplete barrier layers. Cellular integrity appeared compromised by HRP over time and cellular damage was associated with HRP move-ment across the inner layers. The presence of some isolated, HRPfilled vesicles was not clearly related to transcellular trans-port and discharge. Vesicles were not responsible for the majority of HRP movement across the perineurial cell layers.
- 49.6 FURTHER EVIDENCE FOR OPENING THE BLOOD-BRAIN BARRIER (BBB) BAY DMSO AND HYPEROSMOTIC STRESS. <u>R. Broadwell, B.</u> Balin, <u>M. Salcman, and R. Kaplan</u>, University of Maryland School of Medicine, Baltimore, Maryland 21201

We have reported that within 2 hr. of intravenous administration of HRP in the company of DMSO in mice, the BBB is opened transiently to the circulating HRP (Science 217:164, 1982). Such opening could be attributed to vesicular transport through the cerebral endothelial cells, the formation of patent transendothelial channels, and/or a widening of tight junctions between contiguous endothelial cells. In an effort to ascertain how the BBB is modified by DMSO, mice were injected intravenously with 10-20% DMSO/HRP and fixed 5 min or less after injection. Mice so injected exhibited numerous focal exudates of HRP surrounding blood vessels throughout the brain. Ultrastructural inspection of these "leaky" vessels revealed that the vessels were undamaged and contained numerous HRP-positive vesicles, tubules and dense bodies. The latter were demonstrated by acid phosphatase cytochemistry to be lysosomes. Tubules that could be mistaken for a transendothelial cells; however, a few tight junctions did appear open and filled with HRP that extended into the basement membrane and perivascular space. Labeled vesicles lying in proximity to the cytoplasmic side of the abluminal membrane may be indicative of pits in the abluminal surface exposed to the exutated HRP and, therefore, would not be vesicles engaged in active transport. To test this possibility, normal mice and mice hyperosmotically stressed by imbibing 2% NaCl for 5-7 days were injected with HRP/saline into the lateral cerebral vesticles. Serial thin sections revealed that many of the vesicles were indeed invaginations of the abluminal surface of endothelial cells from only salt-stressed mice was coated with HRP reaction product. Inspection of some of these cells disclosed that the tight junctions were open and flood with HRP. These observations suggest that: (1) DMSO acts on the BBB by opening the tight junctions; (2) the movement of HRP and associated cell surface membrane into the cerebral endothelian cells resored with HRP reaction product. Inspection of some of t

49.7 VASCULAR INFUSION WITH SITS RESULTS IN LABEL OF CIRCUMVENTRICULAR, LIMBIC, AND OTHER BRAIN STRUCTURES, L.C. Schmued\*and J.H. Fallon, UCI Dept. of Anatomy, University of California, Irvine, CA 92717

Although most cerebral blood vessels are considered impervious to exogenous tracers such as HRP. Evans Blue, Pontamine Sky Blue, Reduced Silver, and India Ink, it is apparent that certain restricted regions do possess permeable capillaries. These regions are often referred to as circumventricular organs and have been described by a number of authors including Reese and Karnovsky, (%7) and Broadwell and Brightman (76) These studies employed HRP to indicate capillary permeability and subsequent neuronal uptake.

In our study we used the fluorescent retrograde tracer SITS to study regional permeability differences in the blood brain barrier. This tracer has been previously employed to demonstrate axonal retrograde transport by covalent binding of the tracer to nerve terminals (Schmued and Swanson, '82). In this experiment, a 0.1% solution of SITS in 0.9% saline is injected into the rat heart. After 10 minutes, the rat is perfused with saline containing 0.1% SITS followed by 10% neutral buffered formalin. Frozen sections are cut and counterstained with Ethidium Bromide.

Prozen sections are cut and counterstained with Ethidium Bromide. Our results indicate selective labeling of several distinct classes of CNS structures. As expected, all vascular endothelial cells and the choroid plexus are heavily labeled. Also, consistent with the findings of Broadwell and Brightman, is the labeling of circumventricular organs and other structures including the arcuate, supraoptic, paraventricular, diagonal band, cranial motor, and cranial parasympathetic nuclei. We also found labeling, in distinct cytoarchitectonic subdivisions of a number of other nuclei, particularly those comprising limbic structures. Some of these limbic structures include the islands of Calleja, cingulate cortex, anterior thalamus, midline thalamus, perirhinal cortex, dorsolateral septum, amygdala, lateral habenula, subiculum, and hippocampus. Most hippocampal labeling was found in the inferior, deep granule cells of the dentate gyrus with some cells labeled in the hilus and isolated pyramidal cells throughout Ammon's horn.\* Other labeled structures which are not classically considered limbic include the locus coeruleus, pretectum, dorsal raphe, some cerebellar Purkinje cells and midbrain central grey. Regions which exhibit extensive vascular staining but virtually no neuron perikaryal label include sensory nuclei, neocortex, and extrapyramidal motor structures.

It is not clear why we see SITS uptake in structures not included in the classical circumventricular organ system. It may be the result of a more sensitive method, or it may be the result of the physical, chemical, and pharmacological properties of the tracer employed. We are currently investigating the possibility that limbic structures as well as hypothalamic structures are able to sample trophic factors from the peripheral environment. (Supported by NIH Grants NS 16017 and 15321).

49.8 INCREASED PERMEABILITY OF C-6 ASTROCYTOMA VASCULATURE MONITORED WITH AN ULTRASTRUCTURAL TRACER. C.L. Edmonds, R.R. Shivers and <u>R. Del Maestro</u>, Departments of Zoology and Clinical Neurological Sciences, University of Western Ontario, London, Ontario, Canada.

Ontario, Canada. Capillaries of brain gliomas have been shown to lack a blood-brain barrier (BBB). Also, peri-tumoral neuropil is frequently edematous which suggests that it too is hyperpermeable in the presence of tumors. In spite of these observations, little is known about the anatomical basis of tumor and peritumoral capillary hyperpermeability or the functional relations between them. To determine the ultrastructural basis for lack of a BBB in tumors and peritumoral neuropil, a protein tracer was injected into the brain vasculature of rats which had been innoculated with C-6 astrocytoma cells. At various times during tumor development, horseradish peroxidase was injected into the external jugular vein. At 10, 30 and 60 min. post-injection the brains were perfused and tumor, peritumoral and contralateral areas were examined with 60kv and 1000kv (high voltage) electron microscopy. Single and complex vesiculo-tubular channels filled with HRP reaction were observed in the endothelial cytoplasm of peri-tumoral and contralateral areas of tumor-bearing rats. Often, the vesiculo-tubular channels spanned the endothelium to form a continum from the luminal to abluminal surface. Tight junctions of both tumor-bearing and control tissue appeared intact and free of reaction product. Large, thin-walled sinusoidal blood vessels were seen in the tumors. HRP reaction product was present in pinocytotic vesicles and multivesicular bodies of the tumor cells. Results of this study support the notion that the HRP-filled vesiculo-tubular channels of peritumoral and contralateral tissue form an unrestricted route for transport of material across the endothelium. Supported by the N.S.E.R.C. of Canada.

- 49 9 AUGMENTED UPTAKE OF A NEUTRAL AMINO ACID BY THE PITUITARY NEURAL LOBE IN DEHYDRATED RATS. P.M. Gross, R.G. Blasberg\*, C.S. Patlak\* and J.D. Fenstermacher\*. (SPON:J.H. Hurst). National Cancer Insti-tute and National Institute of Mental Health, Bethesda, MD 20205 The pituitary neural lobe is a dense terminal field of projections from hypothalamic cell bodies that synthesize and elaborate the vasoactive hormone, vasopressin, during conditions such as dehydration. The mechanism of vasopressin secretion involves a vesicular exocytotic process at the interface of nerve terminals and capillary bed in the neural lobe. It is not known to what ex-tent vasopressin secretion influences the rate of solute transport traction by the neural lobe of a small neutral amino acid,  $\alpha$ -aminoisobutyric acid (AIB, MW=103) during normal and dehydrated (5 days of water deprivation) conditions in conscious albino rats. In order to determine the extraction fraction (E) for AIB by the In order to determine the extraction fraction (E) for AIB by the expression,  $E = K_4/F.V_C$  (where  $K_i =$  the tissue transfer rate constant for AIB corrected for vascular space, F = rate of blood flow and  $V_C =$  plasma fraction of arterial blood), the following four measurements were necessary in separate groups of normal and dehydrated animals: 1) plasma volume, V, was evaluated with  $^{125}I_{-}$  albumin given by iv injection in 2 minute experiments; 2) K<sub>4</sub> was estimated from 12 second studies using  $^{14}C_{-}$ AIB, which was given by iv pulse injection, and included rapid arterial blood sampling; 3) F was determined with  $^{14}C_{-}$  iodoantipyrine, administered by iv ramp infusion in 20 or 60 second experiments; and 4) arterial hematocrit was determined conventionally. Horizontal intact sections (20  $\mu$ m thick) of frozen whole pituitary glands were autoradiographed to film. Measurements in the neural lobe of V<sub>p</sub>, K<sub>1</sub> and F were quantified from computerized image analysis. In the neural lobes of normal animals, we found that  $V_p$ ,  $K_i$ , F and E were 34 µl/g, 0.67 ml/g/min, 5.0 ml/g/min and 23%, respectively. the Well of ping, 0.07 mJ g/min, J.0 mJ/g/min and 2.5%, respectively. Values for normal brain tissue (e.g., caudate nucleus) in conscious rats are 5  $\mu$ J/g, 0.0004 mJ/g/min 1.3 mJ/g/min and 0.1%, respectively. Our results in the neural lobe of control rats replect the special characteristics of this structure's circulatory bed, viz, high capillary density, fenestrated endothelia, and extremely rich perfusion under normal conditions. In dehydrated rats, each of the measurements was increased.  $K_1$  was elevated 4 to 5-fold, indicating a markedly augmented extraction of AIB by the neural lobe. These findings demonstrate that transport processes across neural lobe capillaries and/or pituicyte cellular membranes are greatly stimulated during conditions of high vasopressin secretion.
- **49.10** EFFECT OF 2450 MHz MICROWAVE ENERGY ON THE BLOOD-BRAIN BARRIER TO HYDROPHILIC MOLECULES. W. M. Williams\*. Center for Brain Research and Dept. of Radiation Biology and Biophysics, Univ. of Rochester School of Med. and Dent., Rochester, NY 14642. Microwave energy at 2450 MHz was found ineffective in increasing the permeability of the blood-brain barrier to the hydrophilic tracers HRP and  $[^{14}C]$  sucrose. Furthermore, a diminished permeability to HRP and sodium fluorescein was apparent after 180 minutes of exposure to microwaves at an incident power density of 20 mW/cm<sup>2</sup>. Colonic temperature, as well as temperature within the cerebral cortex, hypothalamus, cerebellum and medulla, was elevated by less than 1°C over those of sham-exposed rats. A significant (p< .05) decrease in the permeability to HRP and  $[^{14}C]$  sucrose occurred after exposure to an incident power density of 56 mW/cm<sup>2</sup> for 30 minutes. These exposures induced a moderate hyperthermia with brain and colonic temperatures increasing to ~40 to 41°C. Extending exposure time to 90 minutes also resulted in diminished permeability to HRP was similarly affected by exposure to ambient heat ( $42t^{22}C$ ) which produced brain and colonic temperatures that were comparable to those observed after 90 minute microwave exposures.

those observed after 90 minute microwave exposures. Reduction in permeability to HRP correlated with a suppressed incorporation of the tracer by pinocytosis in cerebral microvessels. Suppression of blood-brain barrier permeability to hydrophilic tracers was most pronounced at brain temperatures exceeding  $\sim 40^{\circ}C$  and is demonstrated to be temperature dependent. 49.11 TRAUMATICALLY INDUCED CHANGES IN EXTRACELLULAR SPACE IN THE RAT SPINAL CORD. N.R. Clendenon, W.A. Gordon\*, M.E. Nesham\*, and J.N. Allen, Jr.\*, Dept . of Neurology, Ohio State Univ., Col. of Med., Columbus, OH 43210.

Previous studies utilizing the rat model of experimental spinal cord trauma assessed the sequential development of edema formation, electrolytic alterations and infiltration of blood during the acute period subsequent to injury (Clendenon, N.R. et al., <u>Soc. Neurosci. Abst.</u> 7:87, 1981). Trauma was induced by the weight drop method (5g,18cm) onto the dura exposed cord. Control spinal cords were removed by the non-traumatic hydraulic pressure technique (DeSousa, B.N. and Horrocks, L.A., <u>Dev. Neurosci. 2</u>: 115, 1979). Laminectomy controls showed non-significant increases in tissue water, sodium, and chloride levels and a significant increase in blood infiltration. Increased tissue water was significant at 10 min after injury and continued to rise. Blood in-filtration into traumatized cord at 15 min was 5-fold greater than in laminectomized controls. Sodium and chloride levels were also increased at 15 min and potassium levels were decreased at 30 min.

Using the same model of spinal cord injury changes in extra-cellular fluid volume were examined by utilizing the inulin space method. Inulin, having a low molecular weight (approx 5,000), is an appropriate extracellular marker and its distri-bution in brain is well documented. The method of Ross and Mokotoff (J. Biol. Chem. 190:659, 1951) was used to assay inulin in blood and spinal cord samples from nephrectomized rats given in i.v. bolus of marker (400 mg/kg body wt) 3 to 5 hrs prior to sacrifice. Inulin space for control spinal cords was 13.3%±0.70 (S.E.M.). Laminectomy resulted in a non-significant decrease in extracellular space to 86% of control. By 15 min following injury, the extracellular space was significantly (p<0.001) reduced to 56% of the laminectomy control. A similar decrease was found at 30 min.

These results, together with the rapid loss of  $Na^+, K^+$ activated ATPase activity at the site of maximal injury (Clendenon, N.R. et al., <u>J. Neurosurg. 49</u>:563, 1978), suggest an intracellular uptake of fluid and metabolites from the extracellular compartment and a loss of membrane integrity affecting ionic pumps. (Supported by NIH grant NS-10165).

- 49.12
- BLOOD-BRAIN BARRIER DYSFUNCTION DURING SEIZURES AND NOREPINEPHRINE INFUSION IS ENHANCED BY LOCUS CERULEUS LESION. S. I. Harik and T. McGunigal, Jr.\* Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, Ohio 44106. The functions of the putative noradrenergic innervation of erebral microvessels from the locus ceruleus (LC) remain ambiguous. Although such innervation does not seem to control cerebral blood flow, there is increasing evidence that it may ambiguous. Although such innervation does not seem to control cerebral blood flow, there is increasing evidence that it may modulate transport and permeability functions of the blood-brain barrier (BBB). Here, we studied the effect of LC lesion on the leakage of albumin across the BBB under steady state conditions and during seizures and hypertension, both of which are known to be associated with increased leakage of macro-molecules across the BBB. Two weeks after unilateral chemical LC lesion, awake but restrained rats were given <sup>125</sup>J-radio-iodinated serum albumin (RISA), 100 µCi/Kg, intravenously and then infused with saline or 10 µg/kg/min of one of the following agents for 30 min: norepinephrine (NE), isoproterenol (ISO) or angiotensin (AT). In another group we studied the effect of 15 min of bicuculline-induced seizures in anesthetized, paralyzed and artificially ventilated rats. At the end of the experiment, the brain was immediately perfused <u>in situ</u>, to remove intravascular RISA. Bilateral samples from the frontal and pmeital cortex and hippocampus were measured for their RISA and NE content. Data was analyzed by comparing the results of NE-depleted structures, ipsilateral to LC lesion, with those from the contralateral side by the paired t test. The magnitude and the duration of hypertension induced by NE, AT and seizures, RISA content of NE-depleted rections was significantly higher than those of the contralateral side. Also, the leakage of RISA into the parietal cortex was higher than into the frontal cortex. Infusion of AT, ISO, or saline did not cause significant differences in RISA content be-tween the 2 sides. These results suggest that noradrenergic innervation of cerebral microvessels from the LC help preserve

tween the 2 sides. These results suggest that noradrenergic innervation of cerebral microvessels from the LC help preserve the integrity of the BBB during pathophysiological conditions associated with increased circulating catecholamines.

### SENSORY TRANSDUCTION I

PHOTOCURRENTS, N DURING LIGHT 50.1 KINETIC MEASUREMENT OF NUCLEOTIDE CHANGES AND PROTEIN PHOSPHORYLATION ACTIVATION DURING LIGHT ACTIVATION C. Biernbaum\*, R.H. Cote\*, E. Brewer, D Rownds. Lab. of Molecular OF FROG PHOTORECEPTORS. м. Schobert\*, H. Hamm, and D. Bownds. Zoology, Univ. Biology and Dept. of Wis., Madison, 53706.

Purified suspensions of frog rod outer segments still attached Purified suspensions of frog rod outer segments still attached to the mitochondria-rich inner segment portion of the receptor cell (o.s.-i.s.) can be prepared by gentle suction treatment of the isolated retina, followed by Percoll gradient centrifugation. These structures maintain normal dark currents and light re-sponses for several hours. The quantities of o.s.-i.s. material obtained (0.1 mg/retina) permit simultaneous chemical analysis. Nucleoside trioprophate and cuplic ONE pavele similar to those of obtained (0.1 mg/retina) permit simultaneous chemical analysis. Nucleoside triphosphate and cyclic GMP levels similar to those of the living retina are observed. A 20-60% decrease in cyclic GMP can be observed within 100-300 msec after onset of illumination using either rapid freezing or acid quenching techniques, pro-viding a conclusive demonstration that cyclic GMP levels can change on the time scale of excitation and adaptation processes. Uptake and light-induced extrusion of  $^{45}$ Ca is also observed. GTP Uptake and light-induced extrusion of  $^{45}\text{Ca}$  is also observed. GTP and ATP undergo a slower light-induced decrease, and their recovery after bright flash illumination lags the return of the dark current but correlates with the return of light sensitivity. Rhodopsin (38K) and one small protein (12.5K) are reversibly phosphorylated upon illumination, and four proteins (36K, 13K, 12.3K, and 12K) are dephosphorylated. The phosphorylation of rhodopsin continues during the return of conductance after bright illumination, after the dephosphorylation proteins have terminated. Current studies are comparing the protein phosphorylation changes with concurrent conductance and sensitivity changes.

OF TRYPSIN ACTIVATED ROD OUTER SEGMENTS DENT HYPERPOLARIZATION. PHOSPHODIESTERASE 50.2 INJECTION INTO SEGMENTS (ROS) CAUSES (PDF) J.B. Hurley\*, LIGHT-DEPENDENT and Y. Shimoda\* & W.H. Miller. Div. of Biology, California Inst. of Tech., Pasadena, CA 91125 and Dept. of Ophthal. & Visual Science, Yale Med. School,

New Haven, CT 06510. Previous biochemical and physiological studies have cyclic GMP and hyperpolarize the ROS PDE to hydrolyze was extracted from ROS memuranes, activated by trypsin, purified to homogeneity (with a specific activity of 1000 µmol cyclic GMP/min/mg) and injected activity of 1000 umol cyclic GMP/min/mg) and injected into ROS of the isolated retina of the toad, <u>Bufo</u> <u>marinus</u>. Brief injections of PDE caused a marked light-dependent hyperpolarization lasting for minutes. The middle light response on the record below is to a light flash given after a 200 msec injection of PDE indicated by the downward spike on the signal trace below the record. The initial hyperpolarizing phase of this receptor potential has the same amplitude and latency as the controls, but except for the voltage dependent depolarization just following the "nose", the recovery phase of the light response is inhibited for about 2 min while the membrane potential remains hyperpolarized by 10 to 20 mV. Injection using the same pipette that had been Injection using the same pipette that had been ted to denature the trypsin-activated PDE showed light-dependent effect. The injection of heated heated to denature the trypsin-activated PDE showed no light-dependent effect. The injection of activated PDE would be expected to increase the rate of cyclic GMP hydrolysis causing the ROS to slowly hyperpolarize. Light would be expected to accelerate the hyperpolarization by increasing the rate of cyclic GMP hydrolysis. The paucity of inhibitor relative to PDE following its injection may be an important factor in the marked prolongation of the light response. (Supported by USPHS Grants AI-19276 relative to the factor in the marked prolongation of the light response. (Supported by USPHS Grants AI-19296 (M. I. Simon, Cal. Tech.) and EY-03196 (W.H.M.) and fellowships from Fight for Sight, Inc., New York City (Y.S.) and the Alex. B. Cox Memorial Fund, Yale Medical School (Y.S.).)

50.3 INJECTION OF CYCLIC GMP-DEPENDENT PROTEIN KINASE INTO ROD OUTER SEGMENTS (ROS) CAUSES DEPOLARIZATION THAT IS INHIBITED BY ILLUMI-NATION. Y. Shimoda<sup>\*</sup>, W. H. Miller, R. M. Lewis, A. C. Nairn<sup>\*</sup> and <u>P. Greengard</u>. Depts. Ophthalmology and Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

Previous biochemical and physiological studies have suggested that cyclic GMP depolarizes ROS and that cyclic GMP hydrolysis, regulated by a light-dependent phosphodiesterase, causes hyperpolarization. We have investigated the role of cyclic GMP-dependent protein phosphorylation in this system. Cyclic GMP-dependent protein kinase purified to homogeneity from bovine lung (specific activity; 5 µmol/min/mg using histone h2b as a substrate) was injected from glass micropipettes into ROS of isolated <u>Bufo</u> marinus retina. Injection of the protein kinase causes (1) a depolarization and (2) a reduced amplitude of the light-induced hyperpolarizing response. Both the depolarization and the reduced amplitude of the light response were found to recover on a time scale of minutes. Injection of protein kinase that had been inactivated by heating to 60°C for 20 minutes caused a slight hyperpolarization during injection and no detectable change in the amplitude of response. The application of cyclic GMP-dependent protein kinase immediately prevented further depolarization.

the depolarization caused by injection of cyclic GMP-dependent protein kinase immediately prevented further depolarization. The above data indicate that the activity of the injected kinase depends on the high endogenous ROS level of cyclic GMP, which is significantly reduced by activation of the light-dependent phosphodiesterase. The data are consistent with the interpretation that endogenous ROS cyclic GMP normally depolarizes the ROS through the activation of an endogenous cyclic GMP-dependent protein kinase. (Supported by USPHS Grants EY-03196 (W.H.M.) and NS-08440 (P.G.) and fellowships from Fight for Sight, Inc., New York City (Y.S.) and Alexander B. Cox Memorial Fund, Yale Medical School (Y.S.).)

- 50.4 INTERNAL DIALYSIS OF SOLITARY SALAMANDER ROD PHOTORECEPTORS.
  - P. R. Robinson, P. R. Macleish and J. Lisman. Dept. of Biology, Brandeis University, Waltham, MA., and Dept. of Neurobiology, Harvard Medical School, Boston, MA.

The study of phototransduction in vertebrate rod photoreceptors would be greatly facilitated if the composition of the cytoplasm could be reliably manipulated. Recent work shows that the internal dialysis method(1) can be used to alter the cytoplasmic composition of <u>limulus</u> photoreceptors allowing several types of melecules, including proteins, to be introduced into the cell's cytoplasm (2). We have applied a similar method to solitary vertebrate rods prepared by enzymatic dissociation of the darkadapted tiger salamander (<u>Ambystoma tigrinum</u>) retina. Using electrodes with a hum tip diameter and resistances between 5 and 15 megaphm, seals of 1-50 gigaphm were obtained on either the inner or outer segment of solitary rods suspended in an amphibian salt solution with ImM Ca. After the patch membrane broke spontaneously or was disrupted with large voltage pulses, the cell was studied in the "whole cell" recording mode. Total membrane currentwas measured under voltage-clamp conditions using a current-tovoltage transducer with series resistance compensation. In order to find conditions which support transduction in dialyzed rods, several electrode solutions were tested. Since the internal composition of rods is not well defined, the design of the electrode solution was somewhat arbitrary. Satisfactory results were obtained with a dialysis solution containing 92mM K-aspartate, 5mM MgCl\_, 7mM NaCl, 1mM NaHCO\_, 10mM taurine, 1mM Na-ATP and 1mM Na-GTP (pH 7.4). When the cell was clamped at the resting potential (-20 to -400 W), the peak response to a sturating light was 30-40 pA. Such responses were stable for an hour or more. Current-voltage relations in the dark showed both inward and outward rectification and a slope resistance of approximately 1 gigaohm at rest. These properties are in reasonable agreement with those obtained using conventional intracellular recording techniques. It appears that this method will be useful for introducing melecules into functioning vertebrate rod photorece

50.5 BUFO ROD RESPONSES REVEAL A CONTRIBUTION OF THE SODIUM PUMP. <u>K.N. Leibovic</u>. Department of Biophysics, State University of New York at Buffalo, Buffalo, NY 14214. High intensity light flashes elicit a response from vertebrate

High intensity light flashes elicit a response from vertebrate photoreceptors, characterized by a hyperpolarizing spike which is followed by a plateau and relaxation to the resting potential.

We have found that perfusion of the isolated retina with ouabain reduces and abolishes the spike and --more slowly-- the remainder of the response. At the same time the resting potential remains almost constant. These data were obtained from intracellular recordings in the isolated retina of Bufo marinus.

Curlinar recordings in the isolated retina of buto marinus. Our interpretation of these data is as follows: Ouabain specifically inhibits the Na+-K+ ATPase. As the pump is inactivated by ouabain so the spike disappears. Therefore we propose that the spike arises from an electrogenic Na+-K+ pump. During the normal physiological response to a bright flash, as the outer segment conductance is shut off, so the pump relaxes and this explains the response relaxation from the spike to the plateau. The contribution of the pump to the membrane potential is therefore equal to the difference between the saturated (largest) spike and the plateau. During the normal light response the pump follows the outer segment conductance. On the other hand, during ouabain perfusion the experimental observations lead us to the conclusion that the pump also affects outer segment conductance. This would explain why the plateau amplitude decreases as the spike is reduced and why the resting potential remains steady.

In the light of our data we will also show why the spike cannot be due to any simple voltage sensitive conductance, which may be activated by a given membrane hyperpolarization. Supported in part by NIH grant R01-E¥03672-01A1. 50.6 REVERSAL OF THE REACTION WHICH INACTIVATES METARHODOPSIN CAN BE A SIGNIFICANT SOURCE OF SPONTANEOUS QUANTUM BURS IN <u>LIMULUS</u> MEDIAW PHOTORECEPTORS. John Lisman, Ellen Armstrong, and Laur Blumberg. Dept. Biol., Brandeis Univ., Waltham, MA 02254. Many photoreceptors produce observable responses to single photons. The similar events which occur spontaneously in the dark could potentially have three sources: 1. Spontaneous isomerization of rhodopsin; 2. On the assumption that a photon converts rhodopsin to an active pigment state (M<sup>\*</sup>) which is then converted to an inactive state (M), spontaneous events could be generated if M spontaneously reverts to M<sup>\*</sup>; 3. A reaction which is normally turned on by M<sup>\*</sup> might turn on spontaneously. To examine the role of these reactions, we have measured the rate of spontaneous quantum bumps in the UV receptors of Limulus median eye. These cells have a rhodopsin with peak absorbance near 360 nm and a metarhodopsin with a peak near 470 nm. Measurements using the early receptor potential indicate that there is little or no dark regeneration of metarhodopsin to rhodopsin over the time course of 8 hours. It was therefore possible, by chromatic adaptation, to produce stable variation in the ratio of rhodopsin to metarhodopsin (R/M). After such adaptations, cells were dark-adapted until the spontaneous quantum bump rate became stable. If reaction 1 were the sole source of spontaneous events, their rate should be highest when R/M is high. If reaction 3 were the source, the rate should be independent of R/M. We found, however, that the rate is highest when R/M is low, consistent with reaction 2 as a source. The results therefore suggest that the reaction which inactivates metanhodops in is reversible and that such reversions can be a significant source of spontaneous quantum bumps when the

metarhodopsin concentration is high.

50.7

CALCIUM MEDIATES THE LIGHT-DEPENDENT DECREASE OF THE MAINTAINED VOLTAGE-DEPENDENT K CURRENT IN <u>LIMULUS</u> VENTRAL PHOTORECEPTORS. K. Chinn\* and J. Lisman. (SPON: M. Woodruff). Dept. of Biol., Brandeis Univ., Waltham, MA 02154. In addition to its effect on the light-activated Na conductance, light reduces the maintained voltage-dependent K current (Ik) in <u>Limulus</u> ventral photoreceptors (Sci. 212:1273, 1981). We have investigated the mechanism underlying this light-dependent decrease in Ik. To test whether the light-induced rise of Ca; might be responsible, we buffered Ca; by pressure-injecting the Ca buffer EGTA (pCa 7.1) while monitoring the injection volume using dye absorbance. At intracellular concentrations of about 60 mM EGTA the effect of light on the maintained outward current (Ifn). This was necessary because in EGTA-injected cells we found a maintained in MN it oblock the voltage-dependent decrease in Ik. To further test this idea we performed a three microelectrode experiment. This was not due to an activation of Ca in the dark reversibly reduced the voltage-dependent decrease in Ik. To further test this idea we performed a three microelectrode current. This was not due to an activation of Ca in the dark reversibly reduced the voltage-dependent ductard current. This was not due to an activation of I<sub>in</sub> because Ca injection reduced Ik even under conditions where I<sub>in</sub> was blocked with Ni. We also investigated whether changes in H were important in the light dependent decrease in Ik, by pressure injecting PH buffer (MOPS, pH 7.2) into photoreceptors. MOPS (100-200 MM) did not affect the light-induced reduction of Ik, indicating that changes in Jk were superiments in activate as that the light-induced decrease. These experiments show that the light-induced decrease in Ik occurs via a Ca-dependent mechanism. occurs via a Ca-dependent mechanism.

CLUMPING OF AUDITORY STEREOCILIA DURING TEMPORARY THRESHOLD 50.8 SHIFT. M. J. Mulroy. Dept. of Anatomy, Sch. of Med., Medical College of Georgia, Augusta, GA 30912. The objective of this study was to determine if anatomical changes in the stereocilia of auditory hair cells occur during

the period of temporary threshold elevation (TTS) following exposure to loud noise. Alligator lizards with normal right and left ears were used. The functional state of the ears was assessed by measuring their averaged evoked response (N<sub>1</sub> of the cochlear potential) to acoustic clicks. The left ear was exposed to moderately intense broadband noise for a short duration and the recovery time of  $N_1$  to its preexposure level was measured to ensure that the TTS was of sufficient duration to permit fixation of the ear during TTS. The ear was exposed to the noise again, its response was measured, and the ear was fixed immediately by cochlear perfusion. The inner ear was removed, mounted in a depression slide and observed under a light microscope. It was then processed for observation with a scanning electron microscope. In unexposed ears the individual stereocilia in a tuft are separated from each other. In noise-exposed ears the stereocilia adhere to adjacent stereocilia within the tuft. The phenomenon is unambiguous and easily within the tott. The phenomenon is unantiguous and easily seen with the light and scanning electron microscope in the basal region of the basilar papilla where the stereocilia are freestanding (uncovered by a tectorial membrane) and very long. When examined with the transmission electron microscope the cell membranes of the stereocilia are intact, that is, the stereocilia are not fused. I interpret these results to indicate that during exposure to noise, which is intense enough to induce TTS, the hair cell actively protects itself by clumping its stereocilia together. This could modify the mechanical response of the stereocilia and thus could temporarily elevate the threshold of the hair cell. STRETCH ACTIVATED SINGLE ION CHANNEL CURRENTS RECORDED FROM 50.9 EMBRYONIC CHICK SKELETAL MUSCLE. F. Guharay\* and F. Sachs\* (SPON: R. McIsaac). Dept. of Biophysical Sci., SUNYAB, Buffalo, NY 14214. After forming a giga-seal, suction (-5 cm of Hg) applied to the interior of the patch pipette causes an increase in channel activity. The stretch activated channel is cation selective but discriminates poorly between sodium and potassium ions (rev. potential  $\alpha$ -30 mV). The open channel conductance is 70 pS with 150 mM KCl on both sides of the patch. A suction of 8.4 cm of Hg produces an e-fold change in the probability of the channel being open. Treatment of the cells with cytochalasins A,B and E makes the cells more sensitive to stretch,  $0.28~{\rm cm}^2$ of Hg producing a similar change in the probability of the channel being open. Kinetic analysis shows that the channel has one open and three closed states. By matching the open and closed time distributions to a four state sequencial model C(1)-C(2)-C(3)-O(4), the effect of applied stretch is reflected only in one rate constant (K<sub>12</sub>). The increase in the rate constant K12 with increasing stretch underlies the observed increase in channel activity with in-creasing stretch. Supported by NINCDS 13194 to F.S.

BEHAVIOR OF A SINGLE NEURON IN A RECURRENT EXCITATORY LOOP. 50.10 0. Diez-Martínez\*, and J.P. Segundo of Departamento de Fisiología, F Cultad de Medicina, Universidad Nacional Autónoma de México, Mé-xico, D. F. 04510. MEXICO; Department of Anatomy and Brain Rese-Fa arch Institute, University of California at Los Angeles, CA 90024. USA.

This communication examined the practical possibility and consequences of recurrent excitation, or positive feedback on the rate of impulse discharge of an isolated nerve cell. Inhibitory recurent circuits have been explored extensively. Excitatory ones, however, although occurring in the Central Nervous System, have been largely ignored. Since there are no excitatory fibers conv ing upon the neuron of the slowly adapting organ (SAO), a recu-rrent excitation loop was constructed by enabling each impulse fibers converg from the SAO of crayfish to trigger through an electronic circuit a brief stretch or "tug" of the receptor muscle. Each tug, when applied independently influenced the discharge as would an EPSP generated by the activation of a "recurrent collateral circuit". Introduction of recurrent excitation led to characteristic discharge timings; hence, even an isolated neuron can have intrinsic mechanisms that prevent positive feedback from freezing it in a extreme non-operational state. Such timings depended critically on the "phase" i.e., on the time elapsed between a SAO impulse and the tug.

When the control discharge was stationary because the SAO muscle length remained invariant, phases of a few ms, simply changed the pattern to one of doublets, and affected little the average rate. As the phase increased, bursts appeared and bursts and interburst intervals became more prolonged. With the largest phases examined (40 ms), the discharge consisted of a slow alternation of about 30 s high rate bursts separated by equally long intervals. When the discharge was modulated by .2 cps sinusoidal length varia ---tions, with recurrent excitation the peak-to-peak rate (i.e., the receptor's overall sensitivity) and the proportion of the cycle without afferent discharges increased, and the rate vs. length display was distorted even though remaining with a "loop-plus-extension" shape.

These changes were phase dependent: for example, loops could have A sharp high peak at one phase and be flat-topped at another. When a length jitter was superimposed upon either an invariant or a sinusoidal varying length, exaggerating interspike interval variability, recurrent excitation exerted fewer, weaker and some what different effects: e.g., it reduced the overall intensity of the invariant cases and shortened the proportion of the cycle with discharges in the modulated ones.

MEMBRANE POTENTIAL REGULATION OF cAMP: CONTROL MECHANISM 50.11 FOR SWIMMING BEHAVIOR IN THE CILIATE PARAMECIUM. M. C. Gustin\* N. M. Bonini<sup>\*</sup>, and D. L. Nelson<sup>\*</sup> (Spon: G. Felsten). Biochemistry and Neurosciences Training Program, Univ. of Dept. of Wisconsin, Madison, WI 53706. The membrane potential of the excitable cell Paramecium

tetraurelia controls the frequency and direction of the ciliary beat, thus determining its swimming behavior. Hyperpolarization results in increased forward swimming speed, whereas depolariza-tion, after transiently reversing the direction of the power stroke, slows forward swimming. The reversal in swimming <u>direc-</u> <u>tion</u> is known to be mediated by Ca<sup>+</sup>, which enters through vol-tage-sensitive channels of the ciliary membrane. We have found that swimming <u>speed</u> can be controlled by changing intracellular cAMP, and further that the membrane potential itself regulates cAMP levels. Membrane potential was manipulated by varying the external  $K^{//2}$  ratio and cyclic nucleotides were measured by ratio and cyclic nucleotides were measured by external K /Ca ratio and cyclic nucleotides were measured by radioimmunoassay. In a representative experiment, the resting level of cAMP, 95 pmoles/10 cells, increased to 126 pmoles upon hyperpolarization and decreased to 78 pmoles upon depolarization. These changes in cAMP were correlated with increased and decreased forward swimming speed, respectively. IBMX, a phosphodiesterase inhibitor, at 1 mM potentiated the changes in cAMP levels. C AMP in the extracellular medium was found to be low under all Cyclic conditions of hyperpolarization and depolarization; therefore changes in intracellular levels cannot be explained by altered membrane transport of cAMP. Extracellular cAMP alone had no effect on swimming speed; however, the membrane-permeant deriva-tive monobutyryl cAMP induced a 2-3-fold increase in swimming speed, and was reversible upon dilution of the drug. IBMX could also stimulate cells to swim forward at twice the control level. Although parametic contain substantial amounts of cCMP (100-200 pmoles/10 cells), the levels did not vary significantly used pmoles/10<sup>6</sup> cells), the levels did not vary significantly upon membrane potential manipulation, even with IBMX present. Permeant derivatives of cGMP were without effect on swimming speed.

Our results suggest that the membrane potential regulates intracellular cAMP in <u>Paramecium</u>. Alteration of cAMP may in part mediate the effect of membrane potential on swimming speed since cAMP itself is capable of increasing swimming speed. Our data also indicate that the regulation of cAMP levels by membrane potential must occur at the level of the adenylate cyclase or phosphodiesterase.

50.12 PSYCHOPHYSICAL ASSESSMENT OF SENSATION MAGNITUDE ELICITED BY IMPULSE TRAFFIC IN SINGLE RAPIDLY ADAPTING LOW THRESHOLD MECHANORECEPTOR SENSORY AXONS IN AWAKE HUMANS. W. J. Culp\*(1) mtLHANWLKEEFINK SENSORY AXONS IN AWAKE HUMANS. W. J. Culp\*(1), J. Ochoa (1), E. Torebjork\*(2), H. Woehlck (1) and J. Baird\*(3). (1) Dartmouth Medical School, Hanover, NH; (2) University Hospital, Uppsala, Sweden; (3) Dartmouth College, Hanover, NH. Work using intraneural microstimulation (INNS) has demonstrated that die a coodities to surface of the second se that it is possible to excite single identifiable myelinated sensory axons in awake humans. Afferent impulses in single sensory axons from glabrous skin give rise to specific sensations that are 'pure' in quality and projected by the brain to the cutaneous receptor field innervated by that axon (1,2). Natural cutaneous stimuli adequate for low threshold mechanoreceptors leads unavoidably to multi-unit activation. Here we report results of psychophysical studies assessing information transfer using INMS

to drive single axons of identified RA and Pacini units. Stimulation of single axons of RA type evokes a painless sen-Stimulation of single axons of KA type evokes a painless sen-sation of flutter-vibration. Magnitude estimation experiments in which the subject ranks the perceived frequency of 'vibration' associated with impulse trains of various frequencies demonstrate that RA units behave linearly, giving a Stevens' power function exponent near 1.0. These results confirm related findings from other INMS studies (3). Just noticeable difference (JND) experi-ments chou that the minimu detectable change in impulse frequency ments show that the minimum detectable change in impulse frequency is a constant proportion of the modulus frequency. Thus sensation magnitude in single sensory RA 'channels' appears to follow Weber's law. Available information indicates that estimates of sensation magnitude as a function of afferent impulse frequency in single RA sensory axons are as precise as similar frequency estimations using multi-unit afferent signals elicited by vibration stimuli applied to the skin. Thus impulse activity in a single RA sensory afferent provides sufficient information for accurate central decoding of magnitude.

In contrast, similar experiments using INMS to drive single axons of Pacini units demonstrate that impulse frequency in single axons is not a sufficient signal for subjective estimation of vibration frequency. This is so in spite of the fact that the sensation elicited by INMS of a single PC unit is perceived by the subject as being qualitatively identical to that evoked by a single RA. The exponent for the Stevens' power function derived from magnitude estimation in single PC units show values ranging from 0.4 to near zero. JND measurements show that human subjects are nearly unable to correlate sensation magnitude with the fre-

quency of impulse activity in single PC axons. (1) Torebjork, H. E. and Ochoa, J. L. (1980) Acta Physiol. Scand. <u>110</u>, 445-447. (2) Ochoa, J. L. and Torebjork, H. E. (1983) J. Physiol. (in press). (3) Torebjork, H. E., <u>et al</u>. (unpublished).

## INVERTEBRATE LEARNING AND BEHAVIOR I

MODIFICATION OF B-PHOTORECEPTOR ADAPTATION PREDICTS DIFFERENTIAL LIGHT RESPONDING FOLLOWING CONDITIONING IN <u>HERMISSENDA</u>. T. Crow, Dept. of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261. 51.1

Conditioning produces a number of cellular neurophysiolog-ical changes in the B-photoreceptors of <u>Hermissenda</u> (Crow and Alkon, 1980; Crow, 1982). However it is unclear how cellular changes in the B-photoreceptors are related to the actual change in phototactic behavior produced by conditioning since photore-sponses are enhanced by conditioning and normal positive photosponses are enhanced by conditioning and normal positive photo-tactic behavior is suppressed following conditioning. In order to further investigate this apparent paradox I have investigated the role of the B-photoreceptors in mediating differential re-sponding to different light intensities following conditioning. The amount of time during an observation period that Hermissenda remain in a test light is a graded function of light Intensity. This measure of phototactic behavior is positively correlated with the intensity of the test light used to recover

<u>Hermissenca</u> remain in a test light is a graded function of light intensity. This measure of phototactic behavior is positively correlated with the intensity of the test light used to measure phototactic behavior (n=25, r=.73, p<.01). Following pre-test measurements at three different light intensities animals received 150 pairings of light and rotation (n=20) or 150 random presentations of light and rotation (n=15). Twenty-four hours after conditioning both paired and random groups were again testeo at the same three light intensities. The paired group (n=20) remained in the 'dim' test light significantly longer than their baseline tests (p<.01) or the random controls (p<.01). However, the paired group remained in the 'bright' test light significantly less that the baseline measures (p<.01) or the random controls (p<.05). Random controls did not exhibit differential responding to the different light intensities after random presentation of light and rotation. Following conditioning and post-test measures of phototactic behavior recordings from light adapted B-photoreceptors revealed changes in the photoresponses to light that parallel the be-havior results. The conditioned group (n=12) exhibited a sig-nificant increase in spike activity in response to the 'dim' test light (p<.05) and a decrease in activity in response to the 'bright' test light (p<.05) as compared to the photo-responses at the same light intensities of the random controls (n=10). The finding that conditioning produces differential

(n=10).

(held). The finding that conditioning produces differential responding to different light intensities that is associated with similar changes in the B photoresponse suggests that the conditioned change in phototactic behavior may be explained by cellular changes intrinsic to the B-photoreceptors. Conditioned changes in photoreceptor adaptation (Crow, 1983) may underly differential phototactic suppression observed after conditioning.

CHANGES IN <u>HERMISSENDA</u> TYPE B PHOTORECEPTORS INVOLVING A VOLTAGE-DEPENDENT CA<sup>++</sup> CURRENT AND A CA<sup>++</sup>-DEPENDENT K<sup>+</sup> CURRENT DURING RETENTION OF ASSOCIATIVE LEARNING. J. Farley\*, Dept. Psychology, 51.2 Princeton U., Princeton, NJ 08544 and D.L. Alkon, Sect. on Neural Systems, Lab. of Biophysics, NINCDS-NIH, MBL, Woods Hole,MA 02543 (SPON: E.F. MacNichol, Jr.). A persistent, associative-training produced reduction of a

A persistent, associative-training produced reduction of a fast, voltage-dependent K<sup>+</sup> current (I<sub>A</sub>) has previously been reported in Hermissenda Type B photoreceptors as a biophysical correlate of the associative suppression of phototaxis (Alkon et al. Science, 215:693, 1982). Type B cells, in turn, have been shown to be causally related to this simple form of learning (Farley et al., Science, 1983, in press). To assess the possible contribution(s) of other long-lasting conductance changes accompanying associative learning, we minimized, by pharmacologic and electrophysiologic means, the contribution of I<sub>A</sub> to training-produced differences in Type B membrane properties. Peak and steady state light-evoked generator potentials of ligated B cells were significantly greater for associatively-

ligated B cells were significantly greater for associatively-trained (n=13) vs. random-control animals (n=7)  $[37.9 \pm 2.5 vs.$ trained (n-13) vs. random-control animals (n-7) [37.9  $\pm$  2.3 vs. 25.4  $\pm$  1.9 mV (peak), p<.01; 28.10  $\pm$  2.2 vs. 19.9  $\pm$  2.1 mV (steady state), p<.05], one and two days following training, when 15 mM 4-aminopyridine (4-AP) ion - which under voltage-clamp se-lectively blocks LA - was added to the bathing solution. Signi-ficantly greater input resistances were also observed for B cells in 4-AP from animals exposed to paired vs. random-control condition [61.4  $\pm$  5.7 vs. 25.22  $\pm$  6.2 MΩ; p<.05]. Training produced differences in the long-lasting depolarization (LLD) response of the Type B cell following light offset were abolished, however. Type B cells from paired animals were also significantly more Type b certs from partical animals were also significantly more likely to exhibit a transient, regenerative depolarization which depends on  $Ca^{++}$  influx (9/13 vs. 1/7 cells, p<.05) during its response to light, as well as in the dark in response to applied depolarizing current (p<.05). In addition, large depolarizing currents gave rise to a significantly larger after-hyperpolarization [-9.82 vs. -6.9 mV; pc.05] which other results indicate arises from activation of a Ca<sup>++</sup> dependent K<sup>+</sup> current ( $I_C$ ). Similar results in the absence of 4-AP have been observed when Similar results in the absence of 4-AP have been observed when  $I_A$ 's contribution to the generator potential was minimized by administering a 10 sec, 40 mV depolarizing current step prior to light. The results indicate that changes of other currents, probably involving  $I_{Ca}^{++}$  and  $I_{Ca}^{++}$ - $\chi^+$  (cf. Alkon et al., Soc. Neurosci. Abstr., 1983), in addition to  $I_A$ , account for learning-induced changes of the transient and steady-state Type B light response. These results also indicate that learning-induced response. These results also indicate that learning-induced changes of  $I_{\rm A}$  are largely responsible for the previously observed learning-induced changes of the LLD.

EFFECTS OF INTERSTIMULUS INTERVAL AND CONTINGENCY ON 51.3

EFFECTS OF INTERSTIMULUS INTERVAL AND CONTINGENCY ON CLASSICAL CONDITIONING IN <u>APLYSIA</u>. <u>R. D. Hawkins, T. J. Carew</u> and <u>E. R. Kandel</u>. Center for Neurobiology & Behavior, Columbia Univ., and N.Y. State Psychiatric Instit., N. Y., N. Y. 10032. The siphon withdrawal reflex of <u>Aplysia</u> undergoes differential classical conditioning with cutaneous stimulation of the siphon or mantle shelf as the conditioned stimulus (US) (Carew et al., 1983). This reflex has proven to be a useful system for analyzing the neural mechanisms of conditioning (Hawkins et al., 1983). To test the generality of this system, we have begun to compare the properties of conditioning in <u>Aplysia</u> with those of conditioning in vertebrates. We first examined the effect of the interstimulus interval (ISI) by varying the time between presentation of the US<sup>+</sup> and different groups of animals (N≥12 per group). Significant differential conditioning was obtained 15 minutes after five training trials when the onset of the CS<sup>+</sup> preceded onset of the US by 0.5 seconds (p<.01), and marginal conditioning was obtained when the ISI was 1.0 second (p<.05, one tail). By contrast, no significant US by 0.5 seconds (p < .01), and marginal conditioning was obtained when the ISI was 1.0 second (p < .05, one tail). By contrast, no significant learning occurred when the CS<sup>+</sup> preceded the US by 2, 5, or 10 seconds, when the onsets of the stimuli were simultaneous, or when US onset preceded the CS<sup>+</sup> by 0.5, 1.0, or 1.5 seconds (backward conditioning). Thus, conditioning in <u>Aplysia</u> resembles many instances of vertebrate conditioning (e.g., Gormezano, 1972) in having a steep ISI function, with optimal learning occurring when the CS precedes the US by approxi-mately 0.5 seconds mately 0.5 seconds.

Conditioning in vertebrates has been shown to depend not only on the temporal relation of the CS and US (contiguity) but also on the degree of temporal relation of the CS and OS (contiguity) but also on the degree of correlation or contingency between the stimuli (e.g., Rescorla, 1968). We tested the importance of contingency in <u>Aplysia</u> by giving one group (N=20) five trials of normal differential conditioning with a 5 minute intertrial interval (ITI), and a second group (N=20) the same training but with five additional USs inserted between the paired trials. Presentation with five additional USs inserted between the paired trials. Presentation of these additional USs reduced the degree to which the US was contingent on the CS, but did not change the number of pairings (the amount of contiguity). When tested 24 hours after training, animals receiving normal training showed significant learning (p < .05), whereas animals receiving additional USs did not. The lack of learning in the reduced contingency group was not simply due to the increased temporal density of USs, since another group (N=24) which received five trials of normal training with the same US density (2.5 minute ITI) also showed significant learning (p < .01). Thus, the occurrence of USs which are not signaled by the CS reduces conditioning. These results indicate that conditioning of the withdrawal reflex

These results indicate that conditioning of the withdrawal reflex shows effects of interstimulus interval and contingency similar to those seen in vertebrates. It therefore may be possible to analyze the neural mechanisms of these features of conditioning in <u>Aplysia</u>.

A TEST OF HEBB'S POSTULATE AT IDENTIFIED SYNAPSES WHICH MEDIATE CLASSICAL CONDITIONING IN <u>APLYSIA</u>. <u>T. J. Carew</u>, T. W. Abrams, R. D. Hawkins, and E. R. Kandel. Center for Neurobiology & Behavior, Depts. Physiol., Neurol., & Psychiat., P&S, Columbia Univ., and N. Y. State Psychiatric Instit., N. Y., N. Y., 10032. 51.4

Hebb postulated that classical conditioning is produced by alterations in the strength of synapses when use of those synapses contributes to the generation of action potentials in a postsynaptic neuron. Despite its major impact on theories of learning, Hebb's postulate has not yet been tested directly in a neural circuit known to mediate associative learning. Recently <u>Aplysia</u> has been shown to exhibit differential classical condi-tioning of a simple withdrawal reflex (Carew et al., 1983), and a specific associative change has been localized to an identified set of synapses between sensory and motor cells for the reflex (Hawkins et al., 1983). Thus, this system has provided an opportunity to test the Hebb postulate directly

We first asked whether postsynaptic activity is <u>sufficient</u> to produce associative changes. We used a differential training procedure in which associative changes. We used a differential training procedure in which action potentials in one sensory neuron (SN) are paired with an uncon-ditioned stimulus (US) and action potentials from another SN are specifically unpaired (Hawkins et al., 1983). The experiment had two phases: in Phase I we paired activity in one SN with action potentials in the postsynaptic motor neuron (produced by injected current), and produced unpaired activity in another SN (5 trials, 5 min. iti). This was followed by a test to assess EPSP amplitude from each SN. In Phase II, activity in the back SN. activity in both SNs was produced either paired or unpaired with tail nerve stimulation, followed by a second test. After pairing with postsynaptic spikes (Phase 1; N=10) EPSPs from both SNs showed synaptic postsynaptic spikes (Fnase 1, N=10) EPS's from both Sixs showed synaptic depression (x EPSP amplitude = 50% of pretraining control). By contrast, after pairing with tail-nerve stimulation (Phase II; N=8), there was clear differential facilitation (x paired EPSP = 151% control, unpaired = 47% control, p < .01). Thus, at the same synapses where postsynaptic activity was not effective as a US, tail-nerve stimulation was effective.

We next asked whether postsynaptic activity is <u>necessary</u> for associ-ative changes to occur. In 10 experiments the postsynaptic cell was held hyperpolarized during training so that it did not fire action potentials to the US (tail-nerve stimulation). Despite the lack of postsynaptic activity, differential facilitation still occurred (x paired EPSP = 175% Control, unpaired = 86% control, p <.005). Our results show that postsynaptic activity is neither sufficient nor

necessary to produce associative changes at synapses in <u>Aplysia</u>. How-ever, this does not imply that a Hebb-type mechanism might not contribute to other instances of learning. It will be of interest to assess the relative importance of presynaptic activity and postsynaptic factors in different forms of learning in the several vertebrate and invertebrate systems where a cellular analysis is now possible.

ASPECTS OF THE CELLULAR MECHANISM OF TEMPORAL SPECI-FICITY IN CONDITIONING IN <u>APLYSIA</u>: PRELIMINARY EVIDENCE FOR CA<sup>2+</sup> INFLUX AS A SIGNAL OF ACTIVITY. <u>T.W.Abrams</u>, 51.5

FOR CA<sup>-</sup> INFLUX AS A SIGNAL OF ACTIVITY. <u>1. W. Abrams</u>, <u>T. J. Carew</u>, R. D. Hawkins and E. R. Kandel. Center for Neurobiology and Behavior, Columbia Univ., College of Physicians & Surgeons, and New York State Psychiatric Institute, New York, N. Y. 10032. In conditioned stimulus (US), a tail shock, produces presynaptic facilitation of the synaptic connections from the siphon sensory neurons (SNs) in the conditioned stimulus (CS) pathway. The facilitation is amplified if a SN bas fired action potentials immediately prior to (arsy in the conditioned stimulus (CS) pathway. The facilitation is amplified if a SN has fired action potentials immediately prior to receiving facilitatory input from the US, as occurs during conditioning when the CS precedes the US. This activity-dependent amplification of presynaptic facilitation provides a mechanism for temporal specificity in conditioning of the reflex (Hawkins et al., 1983). To investigate this activity dependence we have the circuit

To investigate this activity dependence, we bypassed the circuit carrying the facilitatory input from the tail by substituting for the tail shock brief ( $\sim$ 1 sec) puffs of serotonin (5HT) onto somata of siphon SNs. We first tested whether preceding spike activity enhances the response of SNs to 5HT. We used an A-B-A protocol in which single cells alternately received either A) 5HT puffs without paired activity of B) paired 5HT puffs delivered immediately following a 0.5 sec train of intracellularly stimulated spikes at 10 Hz. Spike durations were tested before and after training, and spike broadening was used as an index of the 5HT response. In 10 experiments, SNs showed more spike broadening after paired 5HT puffs than after 5HT puffs in the absence of paired activity (x spike duration = 117% vs. 107% of pretraining control, p<.001).

p < .001). We next investigated the possibility that the brief elevation of intracellular Ca<sup>+</sup> produced by activity in SNs transiently increases their response to 5HT and thereby serves as a signal for temporal specificity. To jest this hypothesis we eliminated Ca<sup>+</sup> influx by reducing external Ca<sup>+</sup>, without directly altering the Na<sup>+</sup> or K<sup>+</sup> fluxes or the voltage changes that occur during the spike. In 5 experiments, we paired 5HT puffs with\_0.5 sec spike trains in 5Ns in both normal SW (10<sup>-2</sup> M Ca<sup>+</sup>) and in Ca<sup>++</sup>-free SW (10<sup>-7</sup> M Ca<sup>++</sup>), using a protocol similar to that described above. All pre- and post-tests were conducted in normal SW. After pairing in normal SW containing Ca<sup>+-</sup>, cells exhibited significantly more spike broadening than they did after pairing in Ca<sup>+-</sup>-free SW (x spike duration = 118% vs. 94% of pretraining control, p <.002). These preliminary results suggest that Ca<sup>+-</sup> influx in SNs of the C5 pathway may serve as a temporally discrete intracellular signal indicating that these cells have recently been active. We speculate that Ca<sup>+</sup> influx may provide temporal specificity by transiently modulating the cyclase system through which 5HT exerts its action.

LONG-TERM POTENTIATION, ACTIVITY-DEPENDENT NEUROMODULATION, AND ASSOCIATIVE INFORMATION STORAGE IN APLYSIA. E.T. Walters and J.H. Byrne. Dept. of Physiol. and Cell Biol., Univ. Texas Med. Sch., Houston, TX. 77025. Long-term potentiation (LTP) has attracted considerable at-

tention as a possible neural substrate for learning and memory, but neither its mechanisms nor functions have been analyzed con-clusively. Stimulation procedures commonly used to produce LTP may cause concurrent homosynaptic activation and heterosynaptic modulation of the test synapses. Therefore activity-dependent neuromodulation (amplification of heterosynaptic modulation by paired spike activity in modulated cells) may be a mechanism underlying LTP. This possibility is also interesting because activity-dependent neuromodulation can underlie associative con-ditioning (Walters and Byrne, 1983; Hawkins et al, 1983). To test this hypothesis we examined the interaction of homo-

To test this hypotnesis we examined the interaction of nono-and heterosynaptic facilitation using a training procedure in <u>Aplysia similar</u> to that used to produce LTP in vertebrate prep-arations. Brief, high frequency stimulation of individual peri-pheral nerves produced LTP of connections from the stimulated nerve but only transient facilitation of connections from adja-cent nerves. To separate the homo- and heterosynaptic effects we examined monosynaptic connections from tail sensory neurons to entor neurons and calceted a peripheral nerve that did not ac. We examined monosynaptic connections from tail sensory neurons to motor neurons and selected a peripheral nerve that did not ac-tivate the sensory neurons. Two or more sensory neurons were stimulated artificially to produce single test EPSPs every 10 min. After 2 baseline EPSPs the peripheral nerve was stimulated with ten 20 Hz trains delivered at 5 sec intervals for 45 sec with ten 20 Hz trains delivered at 5 sec intervals for 45 sec (100 pulses total). LTP was only produced when this heterosynap-tic stimulation was paired with artificial intracellular activa-tion of 100 spikes in the sensory neuron. These coactivated neurons (N=8) showed significantly more facilitation after 2 hours than sensory neurons exposed to nerve shock alone (N=12, p<.01), intracellular activation alone (N=6, p<.025), or test stimuli alone (N=11, p<.005). While neither nerve shock nor in-tracellular activation alone produced synaptic facilitation 2 hours after training (LTP), both nonassociative forms of training produced weak facilitation that lasted at least 30 min. The cellular neoperties of LTP in this preparation resemble

The cellular properties of LTP in this preparation resemble the associative changes produced by pairing sensory neuron acti-vation with tail shock. Both processes may involve the Ca<sup>++</sup> de-pendence of serotonin evoked CAMP synthesis (Walters and Byrne, 1983; Hawkins et al, 1983; Ocorr et al, this volume). The simple training procedure described here should facilitate further sub-cellular analysis of long-term neuronal modifiability. In adcellular analysis of long-term neuronal modifiability. In ad-dition, these results suggest that LTP may be a manifestation of a rather general form of associative information storage activity-dependent neuromodulation.

PRESYNAPTIC MECHANISM OF LONG TERM FACILITATION AT THE CRAYFISH 51.7 HURDHUSCULAR JUNCTION INVOLVES SODIUM IONS. J.M. Wojtowicz and H.L. Atwood, Department of Physiology, University of Toronto, Toronto, Ontario, Canada. M5S 1A8

Toronto, Ontario, Canada. M55 1A8 Repetitive stimulation of the excitatory axon innervating the opener muscle of the crayfish claw delivered at 10-20 Hz, for 15-30 minutes results in a gradual increase in amplitude of the excitatory potentials (EPSPs). This enhancement can persist for minutes and sometimes hours after the stimulation is discontinued. The mechanism of such long term facilitation (LTF) was studied by simultaneous presynaptic and postsynaptic intracellular recording. The presynaptic axon was penetrated near the terminal branches, so that the amplitude of the action potentials (AP), the membrane notential (Fu) and the input resistance in the terminal arborizapotential  $(E_M)$  and the input resistance in the terminal arborizapotential (EM) and the input resistance in the terminal arboriza-tion could be measured. During LTF, the amplitude of the AP was reduced by 5-10mV while its width was increased. EM became more negative by about 5 mV without a detectable change in the input resistance. The hyperpolarization was blocked by ouabain (0.5-1.0 mM) and is thought therefore to be caused by an electrogenic sodium pump. Ouabain also reduced the AP amplitude and enhanced the EPSP.

Together the reduction of the amplitude of the AP and the activation of the sodium pump suggest an accumulation of sodium ions in the terminal axonal branches during the LTF. The time course of the recovery of the AP was followed by the recovery of the LTF

A causal role for sodium in LTF was confirmed by intra-axonal injections of this ion via the recording micropipettes. Such injections resulted in reductions of the APs and a prolonged enhancement of the EPSPs.

Supported by an operating grant from the Medical Research Council of Canada.

PERSISTENT ACTIVATION OF ADENYLATE CYCLASE UNDERLIES THE TIME COURSE OF SHORT-TERM SENSITIZATION IN <u>APLYSIA</u>. <u>Vincent F. Castellucci</u>, <u>Lise Bernier\*</u>, <u>James H. Schwartz</u> and <u>Eric R. Kandel</u>. Center for Neurobiology and Behavior, Columbia University, College of Physicians & Surgeons, and New York State Psychiatric Institute, New York, N. Y. 10032.

Sensitization of the gill and siphon withdrawal reflex results from presynaptic facilitation at the excitatory synapses made by sensory neurons on gill and siphon neurons. The facilitation is accompanied by a depression of a difference which produces on depression of a  $K^+$  current in sensory neurons which produces an increased influx of Ca<sup>++</sup> and an increased release of transmitter. Serotonin simulates the natural presynaptic facilitation and produces depression of the K<sup>+</sup> current by means of a cAMP-dependent protein phosphorylation. By using a specific protein inhibitor of the cAMP-dependent protein kinase isolated from muscle, we had previously found that the time course of short-term sensitization does not reside in a persistent phosphorylation of the substrate protein(s), but requires a kinase kept active by the persistent elevation of cAMP. Furthermore, this elevation of cAMP in sensory neurons was found to be mostly free in the cytosol, not bound to protein and thereby unprotected from degradation by phosphodiesterases.

degradation by phosphodiesterases. We next inquired: What keeps the level of cAMP elevated? Is it the persistent activity of the adenylate cyclase? To explore this question, first we triggered the memory for short-term sensitization (broadening the action potential with serotonin, 10° or 10° M), and then we pres-sure-injected sensory neuron somata with GDP  $\beta S$  (10° M), an analog of GDP which is an inhibitor of the cyclase. We found that GDP $\beta S$  rapidly shortened the duration of the action potential (N=16), indicating that the memory analysis of the cyclase. memory requires a persistent activation of adenylate cyclase. The action potential could again be broadened by intracellular injection of cAMP. Forskolin applied at a concentration of  $10^{-6}$  M (N=5) partially reverses the inhibition by  $\text{GDP}_\beta\,\text{S}_{\bullet}$ 

These results and our earlier data indicate that there are two separate molecular steps for the readout and the time course of memory. The memory is read out (or refrieved) when the substrate protein is in the phosphorylated state. This readout is determined by an active kinase. By contrast, the duration of the memory is determined by a sustained elevation of intracellular cAMP which is caused by the persistent activity of an adenylate cyclase.

51.8 ASSOCIATIVE CONDITIONING ANALOG IN APLYSIA TAIL SENSORY NEURONS SELECTIVELY INCREASES CAMP CONTENT. K.A. Ocorr, E.T. Walters, and J.H. Byrne, Dept. of Physiol. and Cell Biol. Univ. of Texas Medical School, Houston, Texas 77025. Sensory neurons involved in the tail withdrawal reflex of Aplysia are located in symmetrical clusters in each pleural ganglion. These cells exhibit heterosynaptic facilitation in response to noxious tail stimulation which is mimicked by bath application of serotonin (5-HT) (Walters et al, 1983). Appli-cation of a classical conditioning paradigm to individual sen-sory neurons produces a temporally specific amplification of the heterosynaptic facilitation when tail stimulation (the US) is paired with intracellular depolarization (the CS) (Walters and Byrne, 1983 and this volume). The present study was designed to examine the role of cAMP in the associative conditioning of these neurons. neurons.

Neurons. We first examined whether brief (60 sec) exposure to 5-HT could increase levels of cAMP in surgically isolated clusters of sensory neuron somata, as well as in the remnants of the pleural ganglia and in the abdominal ganglia. In all cases exposure to 5-HT resulted in an elevation of the cAMP levels compared to con-

5-HT resulted in an elevation of the cAMP levels compared to con-trols (see also Cedar and Schwartz, 1972; Pollock et al, 1982). The cAMP levels (in the presence of  $10^{-4}M$  R0 20-1724) were deter-mined by radioimmunoassay and normalized to protein content. The differential conditioning paradigm of Walters & Byrne was mimicked in vitro by a 5 sec application of high K<sup>+</sup> ASW (CS) fol-lowed by a 15 sec exposure to 5x10<sup>-0</sup>M 5-HT (US). In the paired treatment (CS+) exposure to high K<sup>+</sup> ASW immediately preceded 5-HT exposure; in the unpaired treatment (CS-) 5-HT exposure was deexposure; in the unpaired treatment (CS-) 5-HT exposure was de-layed for 2.5 min. Each CS+ treatment had a CS- control in the contralateral isolated cluster from the same animal. In all cases 10<sup>-4</sup> M RO 20-1724 was included in the bath. After the ap-plication of 5-HT the samples were immediately shelf frozen. Paired application (CS+) of high K<sup>+</sup> ASW and 5-HT resulted in a significant elevation of cAMP levels in the sensory neuron clus-ters compared to the unpaired application (CS-) (p<.025, N=15, double blind). In contrast a similar pairing procedure produced no significant differences in cAMP levels of the abdominal gang-lia (N=15) or the pleural ganglia remnants (N=14). These results indicate that the activity-dependent neuromodu-lation underlying associative conditioning of the tail sensory neurons produces pairing specific increases in cAMP levels and

Tation underlying associative conditioning of the tail sensory neurons produces pairing specific increases in CAMP levels and supports the possibility that such increases may be a biochemical substrate for associative effects and the possible involvement of  $Ca^{++}$  in amplifying the CAMP response are currently under investigation. tigation.

ASSOCIATIVE LEARNING IN AN IN VITRO APLYSIA PREPARATION: FACILITATION AT A SENSORY MOTOR NEURON SYNAPSE. Ken Lukowiak\* (SPON: G. Mptisos). Dept. of Medical Physiology, Faculty of Medicine, Univ. of Calgary, Calgary, Alberta, Canada T2N 4N1. The in vitro siphon, mantle, gill and abdominal ganglion preparation of Aplysia can be classically conditioned using as a 51.10 CS a weak tactile stimulus to the siphon and a stronger tactile stimulus to the gill as a UCS (Lukowiak, 1982). With classical conditioning training, the CS comes to elicit a gill withdrawal reflex (GWR) which was initially evoked by only the UCS. Presentation of the CS alone; the presentation of the UCS at

Presentation of the CS alone; the presentation of the UCS at some random internal following the UCS; and backward condition-ing all do not lead to the CS evoking a GWR. Intracellular recordings were made from central gill motor neurons  $L_7$ , LDG<sub>1</sub>, and  $L_6$  during the course of training. Initially, the CS evoked only a few AP's in these neurons; however, as training progressed the CS came to evoke a larger neuronal response. In control group preparations the CS evoked fewer AP's in subsequent trials.

An analysis was therefore made of the monosynaptic sensory motor neuron synapse to determine if the efficacy of this synapse was altered by the conditioning. Because of the nature of the UCS and the GWR it evokes, it was not possible to record of the UCS and the GWR it evokes, it was not possible to record simultaneously from an LE sensory neuron and a follower motor neuron during the course of the training. Synaptic transmission was initially evaluated by measuring the EPSPs evoked by a single LE AP separated by 20 min; there was no change in EPSP amplitude. The amplitude of the EPSP ranged between 0.8-2.2 mv in the 30 preparations tested. The electrodes were then with-drawn from the cells which were visually recognizable by their position (etc.). The preparation was then given classical conditioning training (n=10), the CS alone (n=10), or the random control procedure (n=10). Following the presentation of 40 trials (ITI 2 min) the LE sensory neuron and the follower motor neuron were reimpaled and synaptic transmission re-evaluated. It was found that the EPSP amplitude increase 2-3 fold in the classical conditioning group; sometimes even evoking APs in the follower cell. In the control groups EPSP amplitude decreased by at least 50%. Further in 2 of the 10 preparations which of a least of the second secon an increase in the synaptic efficacy at the sensory-motor neuron synapse. This could be a neural mechanism which underlies associative learning. Supported by MRC (Canada).

MEMORY OF OLFACTORY CONDITIONING MUTANTS OF <u>DROSOPHILA</u> FOLLOWING PROLONGED TRAINING RESEMBLES THAT OF NORMAL FLIES AFTER BRIEF TRAINING. <u>Yadin Dudai</u>, Dept. of Neurobiology, The Weizmann Insti-51.11 tute of Science, Rehovot 76100, Israel. Several X-linked mutants of <u>Drosophila</u>, that fail in an olfactory conditioned avoidance paradigm, have been shown to be capable of displaying a very brief memory of odorant avoidance responses (Dudai, J. Comp. Physiol. <u>130</u>, 271 (1979); Neurosci. Abstr. 7, 64 (1981)). This implies that the mutations do not abolish acquisit-ion but interfere with memory storage or expression. We have set 643 out to test whether alterations in the training schedule of the olfactory avoidance conditioning paradigm can improve the memory of two of the mutants,  $\underline{dunce}^1$  (Dudai et al., PNAS 73, 1684 (1976)) and  $\underline{rutabaga}$  (Duerr and Quinn, PNAS 79, 3646 (1982)). In the para-digm employed, the flies are presented with an odorant associated with electric shock (or with intense vibration) and are later tested for their choice between the shock-associated and a control odorant in a T-maze (the experimental design controls for odor bias and non-specific sensitization). Each 30 sec presentation with a shock-odorant comprises a training session. A short-lived acquired selective avoidance of odorants is detected in the mutants already after a single training session. We have previously demonstrated that for both mutants, following 3 training cycles, selective avoidance of the odorant presented during training is 60-70% of normal when tested 30 sec after training, but only 2-8% of normal when tested 7 min after training. We have now tested several training schedules and found that increasing the number of training sessions to 6 (presented successively, with 30 sec rest periods between sessions, and with no presentation of non-shock odorant in between), markedly improves memory (P<0.001, to about 40% of normal after 7 min). However, intensifying the trai-ning by various procedures does not improve the performance of the mutants immediately after training (maximum obtained was 70% of normal at 30 sec). Moreover, the immediate memory decay of the mutants following 6 training cycles resembles that of normal flies following a single training session in the same paradigm. Thus, by differentially varying the intensity of the single-odorant training paradigm, one can equate the performance of normal and mutants when tested several minutes after training. The results suggest that the machinery required to store and retrieve the selective avoidance memory for periods longer than tens of seconds does exist in the mutants, but the threshold for its activation is higher than normal. (Supported by a grant from the US-Israel Binational Science Foundation, Jerusalem.)

#### PEPTIDES: RECEPTORS I

RECEPTORS FOR NEUROPEPTIDE Y IN RAT BRAIN A. Unden<sup>\*</sup>, K. Tatemoto<sup>\*+</sup>and T. Bartfai<sup>\*</sup>(SPON:B. Hedlund) Dep. of Biochemistry, University of Stockholm, S-106 91 Stockholm Sweden, and <sup>+</sup> Dep. of Biochemistry, Karolinska Institutet, Box 604 00, S-104 01 Stockholm, Sweden. Neuropeptide Y, NPY, recently isolated, 36 amino acids residue long mentide with turnoping amide C torminal from proving horing. 52.1 long peptide with tyrosine amide C terminal from porcine brain containing 5 tyrosine (Tatemoto et.al., 1982; Nature 296, 659) was labeled with  $^{125}$ I by the chloramine-T method. The iodinated peptide (specific activity 1000 Ci/mmole) was found to bind in a saturable and reversible manner to membranes from various regions of the rat brain. The binding sites were sensitive to treatment of the membranes with proteolytic enzymes or to heat denaturaof the membranes with proteolytic enzymes or to heat denaturation. Unlabeled NPY competed for the binding sites with an  $1C_{50}$  value of 0.58 nM. Secretin, VIP, Substance P and PHI at 50 nM concentrations did not inhibit binding while a related peptide, parcreatic peptide, gave 25 % inhibition at the same concentration. A sharp PH optimum for the binding was detected between PH 7 and PH 7.7. The apparent  $B_{max}$  of  $1^{25}$ I-NPY was dependent on the concentrations of binding sites were found in the cerebral cortex (0.37 pmoles/mg protein), hypothalamus and hippicampus, while the cerebral cortex. Specific binding of  $1^{25}$ I-NPY was present in all subcellular fractions except the myelin fraction. myelin fraction.

Immunoreactive substances related to these peptides were found in noradrenergic neurons (Hökfelt et.al., 1983; Acta Phys. Scand. <u>117</u>, 315-318). In view of this it is noteworthy preincubation of membranes with  $\beta$ -agonists, at  $3^{n_{\rm C}}$  C for 30 minutes, did prevent the decline in the binding of  $12^{-2}$  I-NPY normally associated with preincubations under these conditions.

Supported by NIMH grant MH 31107 and by a grant from the Swedish Medical Research Council.

DESENSITIZATION OF SOMATOSTATIN RECEPTORS NEGATIVELY COUPLED TO 52.2

DESENSITIZATION OF SUMATOSTATIN RECEPTORS NEGATIVELY COUPLED TO ADENYLATE CYCLASE. <u>T. Reisine</u>. Sec. on Pharmacol., Lab. Clinical Sci., NIMH, Bethesda, MD 20205. Somatostatin (SRIF) is a 14-amino acid containing peptide known to inhibit hormone release from the anterior pituitary. Addition of SRIF to tumor cells of the mouse anterior pituitary (AtT-20/ D16-16) blocks corticotropin releasing factor (CRF)-stimulated adrenocorticotropin hormone (ACTH) secretion. In addition, SRIF prevents CRF and forskolin from stimulating cyclic AMP accumula-tion in these cells suggestion that SPIF recentors are negatively. prevents LKF and forskolin from stimulating cyclic AMP accumula-tion in these cells suggesting that SRIF receptors are negatively coupled to adenylate cyclase. Pretreatment of AtT-20 cells with SRIF induces two compensatory changes: a reduced ability of SRIF to antagonize stimulated cyclic AMP formation and ACTH secretion and an increase in forskolin-stimulated cyclic AMP synthesis and adenylate cyclase activity. SRIF desensitization is time and dose-dependent, reversible and induced by SRIF analogues. The cyclic AMP analogue 8-bromo-cyclic AMP stimulates ACTH release through a mechanism bypassing adenylate cyclase and it's effects are blocked by SRIF. However, SRIF pretreatment does not alter SRIF's inhibition of 8-bromo-cyclic AMP's effects suggesting that the SRIF desensitization either involves an uncoupling of SRIF the SRIF desensitization either involves an uncoupling of SRIF receptors from adenylate cyclase or a loss of those receptors. The enhanced cyclic AMP response to forskolin is also time and dose-dependent. Hormone-stimulated cyclic AMP accumulation increases following SRIF pretreatment although longer periods are required than for the increase in forskolin's effects. SRIF pretreatment increases NaF and Gpp(NH)<sub>D</sub>-stimulated adenylate cyclase activity, cyclic AMP synthesis, phosphodiesterase activity or cyclic GMP levels. The increased forskolin response is blocked by cycloheximide suggesting that SRIF treatment either induces new adenylate cyclase activation. cyclase activation.

IN VITRO BIOCHEMICAL CHARACTERIZATION AND AUTORADIOGRAPHIC DISTRI-BUTION OF <sup>3</sup>H-THYROTROPIN RELEASING HORMONE (TRH) RECEPTORS IN RAT BRAIN SECTIONS. <u>W.H. Rostene, J.L. Morgat, M. Dussaillant, T.C.</u> <u>Rainbow and A. Sarrieau</u>. INSERM U.55, Hopital St Antoine, 75012 52.3 Paris, France.

TRH, originally isolated from the hypothalamus, has been identified in other regions of the CNS where it exerts behavioral and physiological effects unrelated to its neuroendocrine role on the pituitary-thyroid axis. TRH receptors which may mediate these effects have only been characterized with membrane preparations. In the present study, we describe the biochemical characteristics and and The present study, we describe the biochemical characteristics and the autoradiographic distribution of TBH receptors in the rat CNS after incubation of brain slices with H-TRH (55 Ci/mmole, CEN Saclay, France) in 50 mM Tris-HCl buffer (pH 7.6) containing 5 mM MgCl<sub>2</sub>, 0.2% bovine serum albumin and 20 uM bacitracin at  $4^{\circ}$  C. After incubation, sections were washed in Tris-HCl buffer at  $4^{\circ}$  C. The specific to non-specific ratio (obtained with 100-fold higher concentrations of uplabelled TRH) was 3:1. Under these conditions, the equilibrium of H-TRH specific binding was reached by 90 min of incubation. Increasing concentrations of unlabelled TRH produced a dose-dependent inhibition of H-TRH binding with a maximum obtained with 0.5 uM unlabelled TRH, which represents 70% of the total binding. Scatchard analysis slowed that, in the range of concentrations tested (0.7-35 nM), 'H-TRH bound to a single class of receptors with an apparent dissociation constant of 2 nM and the number of binding sites was estimated to be 20 fmoles/mg protein. The only analogue as potent as TRH to displace 'H-TRH binding was 2-ME-TRH, whereas I-ME-TRH and TRH free-acid were ineffective. S-ME-IKH, whereas I-ME-IKH and IKH free-acid were ineffective. Neither LHRH, neurotensin, somatostatin, D-Ala-Met enkephalin nor VIP showed any significant affinity for TRH binding sites. Autoradiograms obtained by apposition of LKB 'H-Ultrofilm showed that the highest concentrations of H-TRH binding sites were found in the amygdala (medial, cortical and basolateral nuclei), the In the amygoala (medial, cortical and basolateral hucle), the external layer of the cingulate cortex, the paraventricular nucle-us of the thalamus and in the hippocampal formation in both dorsal and ventral gubiculum and dentate gyrus. The biochemical characte-rization of H-TRH binding in brain sections is in good agreement with previous reports on membrane preparations and the autoradiographic localization of the binding sites provides anatomical sup-port for the effects of TRH in the CNS.

USE OF A SELECTIVE SUPERAGONIST OF CENTRAL SP2 RECEPTORS TO STIMULATE CENTRAL SITES FOLLOWING PERIPHERAL INJECTIONS. M.F.Piercey, M.W.Moon\*, F.J.Einspahr\* and J.R.Blinn\*, CNS Research, The Upjohn Company, Kalamazoo, MI 49001. When directly injected into the intrathecal spaces of the mouse spinal cord, very low doses of substance P (SP) elicit a very intense two-sided biting and scratching syndrome, presumably through stimulation of SP2 receptors (Reg. Peptides 3:337, 1982) located in nociceptive pathways of the dorsal horn (Science 214:1061, 1981). However, when SP is injected intravenously, even high doses fail to elicit this dramatic behavioral syndrome. Thus, systemically-administered SP does not reach centrally located SP2 receptors either because it is rapidly degraded or it lacks the ability to penetrate the blood-brain barrier. We have now found that pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> can stimulate central SP2 receptors following periphe-ral administration. When directly injected into the cord, pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> no contrast, pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> only very weakly stimulated SP1 receptors of the guinea pig ileum and rat colon. To confirm the SP2 superagonist properties for pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub>, the compound was microiontophoresed onto single neurons of the nucleus caudalis of the rat trigeminal complex. Multibarrelled microelectrodes were used with at least one barrel containing nGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6</sub>. complex. Multibarrelled microelectrodes were used with at least one barrel containing pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> and at least one containing SP. Trigeminal location was verified by histological identification of dye Trigeminal location was verified by histological identification of dye spots ejected at the end of the experiment. Every cell excited by SP was also excited by pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub>. For the same ejection currents, pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> increased cell firing rates more than did SP and the response to pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> was also much more prolonged. In mice, <u>intravenously</u> injected pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub> elicited a scratching and biting syndrome identical in appearance to that observed with intrathecal injections of SP and pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub>. For pGlu<sup>6</sup>Pro<sup>9</sup>SP<sub>6-11</sub>, the ED<sub>50</sub> for scratching was 2 ng i.t. and 30 mg/kg i.v.

BINDING BY BENZODIAZEPINES: N. A. Sharif\* and D. R. Burt. and Experimental Therapeutics, INHIBITION OF TRH RECEPTOR PHARMACOLOGY AND DISTRIBUTION. RECEPTOR 52.4 Department of Pharmacolology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, Maryland 21201

Biochemical, pharmacological and behavioral studies suggest a neurotransmitter role for the tripeptide, thyrotropin-releasing hormone (TRH), in the vertebrate CNS and pituitary. TRH antagonizes many effects of barbiturates and benzodiazepines (BZ), but like chlordiazepoxide (CDE), it attenuates conflict behavior (J.P.E.T., <u>193</u>, 11; <u>212</u>, 153). These and other observations led us to study the possible interactions between TRH and a variety of psychoactive drugs using radioreceptor binding techniques. Washed resuspensions (50 mg ww/ml in 50 µl) of rat pervous tissues were incubated with 1 nM [<sup>3</sup>H](3-Me-His<sup>3</sup>)TRH ([<sup>3</sup>H]MeTRH) at 0°C for 5 h and filtered under vacuum. Specific binding was 70-80% of total with 10 µM TRH as blank. Although 47 neuroactive drugs (antidepressants, amino acids, Ga<sup>2+</sup>-antagonists, nucleotides) were inactive against [<sup>3</sup>H]MeTRH binding (IC<sub>50</sub> > 1 mM), numerous BZs were potent competitive inhibitors, though less active than TRH and MeTRH. The profile of activity (CDE > diazepam (DZM) > flurazepam > lurazepam > flunttrezepam (Flu)) was almost identical for pituitary (Pit), retina (Ret) and amygdala (Amyg); corresponding IC<sub>50</sub> values for Amyg were (µM): 0.5 ± 0.05, 4 ± 0.5, 24 ± 3, 108 ± 21, 420 ± 64 respectively (n3-5). However, apparent reduced potency, but the same rank order, was seen in spinal cord, hippocampus and hypothalamus. Scatchard analyses of competition experiments in all 6 regions, run in the presence of IC<sub>50</sub> concentratione of CDE revened dit te calcatively radius Biochemical, pharmacological and behavioral studies suggest a reduced potenty, but the same tank other, was seen in spinal cord, hippocampus and hypothalamus. Scatchard analyses of competition experiments in all 6 regions, run in the presence of  $IC_{50}$  concentrations of CDE, revealed it to selectively reduce TRH receptor affinity (= 3-fold, P < 0.02) without affecting receptor number. These results supported the competitive mechanism of action of BZs suggested previously by inhibition curves parallel to those of TRH and MeTRH. In kinetic experiments, CDE (100 µM) induced a rapid biphasic dissociation of [<sup>3</sup>H]MeTRH binding from amygdala membranes (t 1/2 of fast component = 2.5 min). In contrast, TRH (10<sup>-9</sup>-10<sup>-5</sup> M) did not compete with either [<sup>3</sup>H]DZM or [<sup>3</sup>H]Flu binding to forebrain membranes. However, since high- and low-affinity BZ binding sites exceed those for TRH (16-6500 times), it may not be possible to detect displacement of [<sup>3</sup>H]BZs by TRH even though the BZs appear to interact with TRH receptors. Our results may be of importance since clinical doses of BZs produce plasma/brain levels > 50 µM and because TRH and BZs interact to influence physiology and behavior. These studies were supported in part by NSF grant BNS 8025(69) USPHS grant MH-26671 and U.S. Army Research and Development Command contract DAMD-17-81-C1279. Army Research and Development Command contract DAMD-17-81-C1279.

IN VITRO CHARACTERIZATION AND AUTORADIOGRAPHIC LOCALI-

IN VITRO CHARACTERIZATION AND AUTORADIOGRAPHIC LOCALIZATION OF SUBSTANCE P RECEPTORS IN RAT BRAIN. C. W. Shults,\* R. Quiron, T. L. O'Donohue and T. N. Chase (SPON: S. Rapisardi). Laboratory of Experimental Therapeutics Branch, National Institutes of Health, Bethesda, MD 20205. A method has been developed for in vitro binding of both <sup>125</sup>-I substance P (SP) (Peptides 3:1073-1075, 1982) and <sup>3</sup>H SP (Nature, in press) to brain slices. Using this technique we have studied the pharmacology of the binding site in rat brain slices which contained primarily striatum and have mapped the SP binding sites in the rat brain. Saturation curves and Scatchard analysis indicate that <sup>3</sup>H SP binds to an apparently saturable single class of sites with a dissociation constant (Kd) of 0.52 nM, and a number of sites (B-max) of 21.6 fmol/mg protein. The IC<sub>50</sub>'s for <sup>3</sup>H SP (2.2 x 10<sup>-7</sup>) and <sup>125</sup>I SP user similar. HSP <sup>125</sup>I SP

	'H SP	<sup>12</sup> /I SI
SP	100	100
physalaemin	16	14
nona SD	3.1	7.6
eledoisin	0.8	2.6
hepta SP	0.3	1.9
hexa SP 70		.8
(D-Pro <sup>2</sup> ,DTrp <sup>7</sup> , <sup>7</sup> )SP	0.01	.03
SP COOH	0.01	.01
penta SP	0.02	.001

The amide group on the C terminal appears to be critical for binding as is shown by the weak displacement by SP-COOH. Also C-terminal fragments of fewer than six amino acids have relatively little affinity for the receptor.

Areas of highest binding are the olfactory bulb, olfactory tubercle, pyriform cortex, suprachiasmatic n., certain amygdaloid n., hippocampus, dentate gyrus, superior colliculus, locus coeruleus, dorsal para brachial n., n. of the tractis solitarius, n. of X, n. of XII, inferior olive, n. ambiguus.

Moderate density of binding was seen in the cingulate cortex, n. accumbens, striatum, globus pallidus, medial septal n., periventricular n. of thalamus, dorsomedial hypothalamic n., periaqueductal gray, dorsal raphe n., interpedunuclear n., cuneiform n., deep cerebellar vermis, and lamina I and II of the dorsal horn of the spinal cord. Surprisingly little binding could be demonstrated in the substantia nigra pars reticulata, an area of high SP concentration.

Although in many areas there is good correlation between SP concentration and amount of binding, in other areas there is disparity between SP concentration and amount of binding. These disparities may suggest new aspects of modulation of synaptic transmission or new functions of neuropeptides.

52.7 AUTORADIOGRAPHIC LOCALIZATION OF CHOLECYSTOKININ RECEPTORS IN THE PYLORIC SPHINCTER OF THE RAT. Gregory T. Smith\*, T. H. Moran\*, J. T. Coyle, M. J. Kuhar, T. L. O'Donohue and P. R. McHugh. Departments of Psychiatry and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205, NINCDS, NIH, Bethesda, MD 20205.

Systemic infusions of cholecystokinin (CCK) in physiological dosages produce an inhibition of gastric emptying and result in behaviors associated with satiety. The effect of gastric inhibition has been proposed as the mechanism for CCK-induced satiety. CCK receptors have been previously shown to be transported distally along the vagus nerve and selective gastric vagotomy has been shown to abolish the satiety effects of systemic CCK infusions. In an effort to elucidate target sites within the gastrointestinal (GI) tract through which CCK may directly exert its effects, the distribution of CCK receptors was mapped in the stomach and small bowel by in vitro autoradiography.

effects, the distribution of CCK receptors was mapped in the stomach and small bowel by in vitro autoradiography. Receptor sites for CCK were labelled with <sup>125</sup>I-Bolton Hunter CCK<sub>33</sub> (<sup>125</sup>I-CCK<sub>33</sub>). Binding was carried out on 25  $\mu$  slide-mounted serial cross-sections sampling the esophagus, cardia, fundus, corpus, antrum, pyloric canal, pyloric sphincter, proximal duodenum, and terminal ileum. Binding conditions for GI sections were the same as those demonstrated to provide saturable, reversible, and high affinity binding (Kd = 0.45nM) in brain sections with specific binding of 80-90%. Tissue sections were l) preincubated in 50 mM Tris HCl (pH 7.4) containing 0.5% bovine serum albumin (BSA) for 20 min at 24°C; 2) incubated in 50 mM NaCl, 4.7 mM KCl, 5mM MgCl<sub>2</sub>, ImM EGTA and 400 pM <sup>125</sup>I-CCK<sub>33</sub> for 2 hours at 24°C and 3) washed in 50mM Tris HCl (pH 7.4) for 90 min at 4°C. Autoradiographs were then obtained on LKB-Ultrafilm from dried sections.

Specific CCK receptor Binding was localized to the circular smooth muscle layer of the pyloric sphincter. Receptors were concentrated in discrete circumferential banding patterns in the distal most portion of the pyloric sphincter. Negligible specific binding was observed in oblique, circular or longitudinal muscle layers at the other GI levels sampled. Moderate nonspecific binding confined to the mucosa was observed in all gastric sections. The restriction of CCK receptors to the circular muscle layer of the pyloric sphincter suggests this location as the site through which CCK inhibits gastric emptying. The gastric distention secondary to this inhibition of gastric emptying may be the mechanism for CCK-induced satiety. (Supported by NIH grant 2-ROI-AMI9302). 52.8 BRADYKININ RECEPTOR BINDING AND BIOLOGICAL ACTIVITY IN MURINE NEUROBLASTOMA CLONE NIE-115 CELLS. <u>R. Michael Snider and Elliott</u> <u>Richelson</u>. Departments of Psychiatry and Pharmacology, Mayo <u>Clinic and Foundation</u>, Rochester, MN 55905. Injection of the nonapeptide bradykinin (Arg-Pro-Pro-Gly-Phe-

Injection of the nonapeptide bradykinin (Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg) into specific regions of the brain elicits pronounced systemic effects. Specifically, microinjection of bradykinin into the lateral septum (or lateral ventricles), periaqueductal gray, and medial or lateral hypothalmus elicits hypertension, analgesia and hyperthermia, respectively. Moreover, bradykinin-like immunoreactivity has been localized in these same areas in the rat brain suggesting a possible neurotransmitter role for this polypeptide. (Correa et al. P.N.A.S. <u>76</u>:1489, 1979). In spite of these findings, very little concerning the specific biological effects of bradykinin on nerve cells has as yet been reported.

reported. Incubation of bradykinin with intact neuroblastoma cells caused a concentration-dependent, Ca<sup>++</sup>-dependent stimulation of cyclic GMP synthesis. The response peaked at 45 sec - 1 min and returned to basal levels by 5 min. The EC50 for this response averaged (+ S.E.M.) 1.1  $\pm$  0.2 nM (range 0.63  $\pm$  1.39 nM) and the cyclic GMP levels increased by 5.2  $\pm$  13.5 fold over basal levels. The binding of [<sup>3</sup>H]bradykinin to intact neuroblastoma cells was carried out at 25°C in phosphate-buffered saline solution containing 140 µg/m bacitracin, 1 mM 1.10-phenanthroline and 0.1% bovine serum albumin (crystalized, lyophilized). Free [<sup>3</sup>H]bradykinin was separated from bound by filtration over Whatman GF/B filters metreated with 0.1% agueous polyethylenemine which was

The binding of [4H]bradykinin to intact neuroblastoma cells was carried out at 25 °C in phosphate-buffered saline solution containing 140 µg/ml bacitracin, 1 mM 1,10-phenanthroline and 0.1% bovine serum albumin (crystalized, lyophilized). Free [<sup>3</sup>H]bradykinin was separated from bound by filtration over Whatman GF/B filters pretreated with 0.1% aqueous polyethyleneimine which was determined to decrease binding of bradykinin to filters. Saturation experiments and Scatchard analysis by computer fit of the data revealed three classes of binding sites on intact cells with  $K_0$  of 0.83 pM, 1.0 nM and 4.9 nM with Bmax's for these sites of 11.6, 158 and 253 fmoles/10<sup>6</sup> cells, respectively. For the cyclic GMP response, it appears that the 1.0 nM binding site is physiologically relevant.

tion experiments and Scatchard analysis by computer fit of the data revealed three classes of binding sites on intact cells with  $\kappa_{\rm D}$  of 0.83 pM, 1.0 nM and 4.9 nM with Bmax's for these sites of 11.6, 158 and 253 fmoles/10<sup>6</sup> cells, respectively. For the cyclic GMP response, it appears that the 1.0 nM binding site is physiologically relevant. These data support the hypothesis that bradykinin has physiologically important effects on nerve cells and substantiates the possibility of a neurotransmitter role for bradykinin. We are currently attempting to evaluate other bradykinin analogues for similar activity in this preparation. (Supported by the Mayo Foundation and Grants MH 27692 and MH 08823 from the U.S.P.H.S.).

52.9 NIGRA NEUROTENSIN RECEPTORS: EFFECTS OF CHRONIC NEUROLEPTIC TREATMENT. <u>G. R. Uhl and M. J. Kuhar</u>. Depts. of Neuroscience, and Neurology, Johns Hopkins University, Sch. Med., Baltimore, MD 21205 and Dept. of Neurology, Massachusetts General Hospital, Boston, Massachusetts 02114

Anatomic studies suggest potentials for interaction between the peptide neurotransmitter candidate neurotensin and dopamine-containing systems at several loci in the neuraxis. Neurotensin may influence dopaminergic function in the substantia nigra. Dense nigral neurotensin receptors are depleted from human brain by Parkinson's disease and from rat brain by 6-hydroxydopamine lesions suggesting peptide receptor localization to dopaminergic cells. Microiontophoresed neurotensin excites nigral cells, suggesting that these receptors are physiologically relevant.

Effects of neurotensin on dopaminergic systems may be reciprocated. In a case of neuroleptic-induced Parkinsonism, we found apparent increases in nigral neurotensin receptors when compared to control brains. We have, therefore, examined the influence of chronic dopamine receptor blockade on neurotensin receptor binding in rats. Rats were treated daily for one month with 0.5 mg/kg

Rats were treated daily for one month with 0.5 mg/kg haloperidol or vehicle, subcutaneously. This regimen has been shown to increase dopamine receptor binding. Brains were processed for neurotensin receptor autoradiography, and specific grain densities determined by subtracting parallel values obtained from adjacent "blank" sections with  $5 \times 10^{-6}$  M unlabeled neurotensin added to the primary incubation. Haloperidol-treated rats showed increased specific neurotensin binding in the substantia nigra (ca. 200% of control values, p < .005). There was no significant difference between receptor densities in the cerebral cortex in the same sections.

Could these changes represent direct influences of haloperidol on neurotensin binding? High concentrations of haloperidol added directly to binding assays have shown no influence on binding. Conceivably, these alterations could represent homeostatic adaptations to chronic dopamine receptor blockade. It is possible that such increased receptivity to excitatory peptide influences could contribute to some of the motor sequelae of long-term neuroleptic use, such as tardive dyskinesia or to other dopaminerelated diseases.

Supported by grants MH00053, MH25951, DA00266, grants from the McKnight Foundation, and the American Parkinson's Disease Association.

52.10 DISTRIBUTION OF ANGIOTENSIN II RECEPTORS IN RAT BRAIN. F.A.O. Mendelsohn<sup>1</sup>\* R. Quirion<sup>2</sup>, J.M. Saavedra<sup>3</sup>, G. Aguilera<sup>1</sup>\* and K.J. Catt<sup>1</sup>\* (SPON: G. Stanton). <sup>1</sup>Endocrinology and Reproduction Research Branch, NICHD; <sup>2</sup>Section on Brain Biochemistry, NIMH; and <sup>3</sup>Laboratory of Clinical Science, NIMH, National Institutes of Health, Bethesda, MD 20205, U.S.A Angiotensin II (AII) has important CNS actions including stimulation of thirst, salt appetite, autonomic activity, blood pressure and pituitary hormone release. AII-containing nerve terminals in the CNS have been demonstrated by immunohisto chemical methods (Fuxe et al, Neurosci. Lett. 2:229,1976)

Angiotensin II (AII) has important CNS actions including stimulation of thirst, salt appetite, autonomic activity, blood pressure and pituitary hormone release. AII-containing nerve terminals in the CNS have been demonstrated by immunohistochemical methods (Fuxe et al, Neurosci. Lett. 2:22,1976) and binding sites for AII have been identified in homogenates of various brain regions (Bennett and Snyder, J.Biol.Chem. 251:7423, 1976; Sirett et al, Brain Res. 122: 299,1977). To determine the precise anatomical distribution of brain AII receptors, we performed in vitro autoradiographic localization of AII binding sites in brain sections. For this purpose, 25 µm sections were cut from snap frozen rat brain, applied to gelatin-coated slides and dehydrated in a vacuum dessicator at 4°C. The slide-mounted sections were incubated with  $^{125}_{1-labeled}$  [Sar1]AII, washed, dried and exposed to LKB Ultrofilm. The films were processed and grain density quantitated by computerized densitometry. The AII binding sites were characterized in membranes prepared from fresh brain tissue, incubated with  $^{125}_{1-lsar1}$ ]AII in the presence of peptidase inhibitors, with separation of free and bound radioactivity by filtration through glass filtred is for AII were detected at a concentration of ~13 fmol/mg protein. The relative potencies of AII analogs in displacing  $^{125}_{1-lAII}$  form the binding sites were as follows: [Sar1]AII, 1.00; AII, 0.17; des-Asp1-AII, 0.12; AI, 0.0017. Autoradiographic visualization of  $^{125}_{1-lSar1}$ ]AII binding distribution shows a very high density of sites in the subformical organ, periventricular and paraventricular nuclei of the hypothalamus, lateral olfactory tract and nucleus of the tractus solitarius. Moderate levels of receptors are present in the suberor collic-ulus, suprachiasmatic nucleus, lateral septum, habenula, subiculum and inferior olivary nuclei. Low densities of receptors are found in most of the remaining areas.

ulum and inferior olivary nuclei. Low densities of receptors are found in most of the remaining areas. These studies provide the first demonstration of the anatomical distribution of AII receptors in brain. Specific receptors are concentrated in a number of physiologically relevant sites suggesting multiple roles for angiotensin II in the CNS.

SECRETIN RECEPTORS ON NEUROBLASTOMA CELL MEMBRANES. Bryan L. 52.11 Roth\*, Margery C. Beinfeld\* and Allyn C. Howlett\* (SPON: N. Connors), Dept. of Pharmacology, St. Louis Univ. Med. School, 1402 S. Grand Blvd., St. Louis, MO 63104.

Secretin (Sec) is a 27-amino acid peptide known to be present in the gut and in the central nervous system. Although Sec's role in the regulation of pancreatic secretion is well established, the function of Sec in the brain remains obscure. Recent studies utilizing cultured astrocytes and neuroblastoma X glioma hybrids indicated the presence of a Sec-stimulated adenylate cyclase. These studies suggested to us that there might be Sec receptors in neuronally-derived tissue.

Initial studies with neuroblastoma cells (N18TG2) indicated the presence of a peptide-activated adenylate cyclase. In general, Sec elicited an 8-10 fold elevation of cAMP in both intact cells and in a plasma membrane fraction. Interestingly, Vasoactive Intestinal Peptide (VIP) also activated adenylate cyclase although Intestinal Peptide (VIP) also activated adenylate cyclase although it had about one-tenth the affinity for the cyclase ( $K_{act}$ =300 nM for VIP and 30 nM for Sec). For a series of peptides, the rank-order potency was Sec>VIP>PHI>>Glucagon, hGRP. We also analyzed the binding of labelled Sec to the peptide receptor. We found that ( $^{125}$ I)Secretin bound to both intact cells

and plasma membranes with high affinity (k<sub>D</sub>=1.06+0.6 nM, B<sub>max</sub> 3200+800 fmole/mg protein). Kinetic analysis indicated that th binding was time-dependent and reversible at 25°C. Competition the binding assays revealed that the rank-order potency for inhibition of Sec binding was similar to that obtained in the adenylate cyclase assays.

We wondered whether there might be a distinct VIP receptor, but direct binding studies with labelled VIP did not reveal any specific binding. This suggested that VIP and Sec might be bind-ing to the same site. Indeed, computerized analysis of the competition binding data revealed a single site to which both VIP and Sec bound. Analysis of the data by a two-site model did not improve the fit. Further, the Hill Coefficients for activation of the adenylate cyclase approximated 1.0--consistent with the single site model.

Finally, we examined the sensitivity of the Sec receptor to nucleotides. As is seen in other systems, Gpp(NH)p inhibited Sec binding by accelerating the rate of dissociation. Other nucleotides were ineffective.

In conclusion, we have demonstrated a novel peptide binding site in a neuronally derived cell line. The Sec receptor appears to be coupled to adenylate cyclase in a positive manner in a guanine-nucleotide-sensitive fashion. N18TG2 cells thus provide a model system for analyzing the role of Sec in the nervous system. Supported by NS-16513 (AH), NS-18335 (MCB) and a grant from the American Parkinson Disease Foundation (MCB).

52.12 BRAIN INSULIN BINDING AND BRAIN INSULIN CONTENT IN THE

BRAIN INSULIN BINDING AND BRAIN INSULIN CONTENT IN THE HYPERINSULINEMIC ZUCKER (fa/fa) RAT. D.P. Figlewicz\*, D. Dorsa\*, H. Ikeda\*, L.J. Stein\*, D. Baskin\*, S.C. Woods and D. Porte, Jr.\* (SPON: W. Catterall). Depts. of Psychology, Pharmacology, and Medicine, Univ. of Washington, Seattle, WA 98195. We examined the brain insulin content and the regulation of insulin receptors in the hyperinsulinemic Zucker fa/fa rat. Fasting plasma and CSF insulin was measured in 4-mo. old female fa/fa (fatty) and lean (Fa/fa and Fa/Fa) littermates and age-matched Wistars. Plasma insulin was significantly elevated in the fa/fa's (201±35  $\mu$ U/ml; n = 9) as compared to either the Fa/fa (18±2.4  $\mu$ U/ml; n = 7) or the Wistar (12±2.4; n = 7). CSF insulin was also significantly elevated in the fa/fa's (1.59±0.19 vs. 0.23±0.11 and 0.20±0.13  $\mu$ U/ml). However, insulin content in the olfactory bub (OB). cerebral cortex elevated in the fa/fa's (1.59±0.19 vs. 0.23±0.11 and 0.20±0.13  $\mu$ U/ml). However, insulin content in the olfactory bulb (OB), cerebral cortex (CC), and hypothalamus (H) was significantly lower in the fa/fa's (2.1±0.4, 1.8±0.6, and 2.1±0.5  $\mu$ U/gm, respectively) as compared to control (10.3±1.0, 5.6±0.6, and 4.9±0.4  $\mu$ U/gm). To determine whether lowered insulin content could be explained by decreased insulin binding, we measured liver and brain insulin receptors in 8 mo. old Zucker and Wistar rats. Membrane particles were prepared from liver and 4 brain regions. Binding of 0.1 nM <sup>125</sup> l-insulin (alone or in the presence of 0.1 mM to 10 uM unphaled input) was measured at the presence of 0.1 nM to 10  $\mu$ M unlabeled insulin) was measured at 25°C, pH 8, for 2 hr.

Insulin binding in the livers of hyperinsulinemic fa/fa rats was lower (67.64% of the dose of trace <sup>25</sup>I-insulin) than binding in controls (84.92% and 85.09% in Fa/Fa's and Wistars); binding in the presence of 10  $\mu$ M insulin ("non-specific") was between 6 and 8% in all groups. In contrast, insulin binding by OB membranes in fa/fa, Fa/fa, Fa/Fa, and Wistaryzats was <u>not</u> different (33%, 26%, 26%, and 27% of a dose of trace '1-insulin/mg protein). In addition, binding in CC, medial H, and lateral H was not different in fa/fa's vs. control rats. Conclusions: Liver insulin receptors in the hyperinsulinemic fa/fa rat were decreased; brain insulin receptors did not "down-regulate." We conclude that reduced receptor numbers cannot account for decreased brain insulin in these animals.

## **REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS I**

SEROTONIN RECEPTORS (S1) IN THE SPINAL CORD: CHARACTERIZATION IN THE RAT DURING DEVELOPMENT AND MATURITY. D. Martínez-Fong\*, M.P. Fillion<sup>+</sup>, G. Fillion<sup>+</sup>, G. Chagoya\*, J. Hernández R., Lab. Neurociencias, Centro de Investigación I.P.N., Ap. 53.1 Postal 14-740, México, D. F. 07000\*, Lab. Neuropharmacologie, Inst Pasteur, 28 Rue du Dr. Roux, F-75724, Paris Cedex 15 France<sup>+</sup>. A system of serotonin receptors has been described in the brain

of various animal species, characterized as being post-synaptic specific and of high affinity. It is possibly coupled to a speci-fic adenylate-cyclase and GTP-dependent, classified as S<sub>1</sub>, in confic adenylate-cyclase and GTP-dependent, classified as  $S_1$ , in con-trast to other sites known as  $S_2$ , which recognize specifically  $|^3\text{H}|$ -spiperone. We have measured the specific binding of  $|^3\text{H}|$ 5-HT (serotonin) to neuronal membranes of the spinal cord, in the pre-sence of 10 µM GTP, 2 to 30 nM  $|^3\text{H}|$ 5-HT, and 10 µM unlabeled 5-HT. Bound radioactive ligand was separated by filtration. The related affinity constant and maximal binding were measured at various a-ges after birth. In the adult spinal cord  $|^3\text{H}|$ 5-HT binding was liges after birth. In the adult spinal cord  $|{}^{3}H|$  5-HT binding was linear up to 1.5 mg of tissue protein. Specific binding showed a typical association and dissociation kinetics reaching half maximal value at one minute and equilibrium at 10 minutes. The rate association constant (K<sub>1</sub>) was 1.955 x 10<sup>-5</sup> M<sup>-1</sup> seconds<sup>-1</sup> and rate dissociation constant (K<sub>2</sub>) 2.663 x 10<sup>-3</sup> seconds<sup>-1</sup>. K<sub>D</sub> calculated from these constants was 13.6 nM which is similar to that obtained from saturation curves and Hill plots. Bound ligand was dissociated by an excess of cold 5-HT. 5-HT agonists like Quipazine displace bound  $|{}^{3}H|$  5-HT with IC<sub>50</sub> from 5 to 30 nM. 5-Hydroxyindole-acetic acid did not displace bound  $|{}^{3}H|$  5-HT, indicating a specific binding. 5-HT agarties were methyservide and cyprohetradine. tic acid did not displace bound  $|^{\circ}H|_{5}$ -HT, indicating a specific binding. 5-HT antagonists methysergide and cyproheptadine, were less potent to displace bound  $|^{\circ}H|_{5}$ -HT with IC<sub>50</sub> of 300 to 500 nM. The system is saturable with the following constants:  $K_{D}$  19  $\pm$  9 nM spinal cord synaptosomes, and 17  $\pm$  7 nM in homogenates: Bmax of 0.1  $\pm$  0.04 pmol/mg protein, and 1.26  $\pm$  0.06 pmol/sp. cord in the homogenate, and 0.15  $\pm$  0.05 pmol/mg protein in synaptosomes. At 0 days (day of birth)  $|^{3}H|_{5}$ -HT binding was present with a  $K_{D}$  of 11.5 nM, and Bmax of 0.24 pmol/mg protein or 0.117  $\pm$  0.029 pmol/sp. cord. Bmax increased with age, being about four times as much on day 10 and eight times on day 21 when it reached adult values. Affinity did not change with age. The activity of tryptophan-5-hydroxylase (T5-H), a presynaptic marker of 5-HT pathways was determined at different ages. The developmental pattern of T5-H was parallel to postsynaptic receptors. Our results establish the presence of a postsynaptic receptors. Our results establish the presence of a system of specific  $|{}^{3}H|$ 5-HT recognizing sites in the spinal cord of the adult rat, saturable, reversible, GTP dependent, with a high affinity, possibly belonging to the S<sub>1</sub> group of sites. These receptors are already present at birth in a mature state. Previous results from our laboratory showed that the developmental pattern of  $|\,^{3}{\rm H}|\,^{5}{\rm -HT}$  sites in the brain is similar to that observed in the spinal cord.

MUSCARINIC ANTAGONIST BINDING SITE HETEROGENEITY AS EVIDENCED BY AUTORADIOGRAPHY AFTER DIRECT LABELING WITH  $[^{3}H]$ -QNB and  $[^{3}H]$ -PI-RENZEPINE. D. R. Gehlert, J. K. Wamsley, W. R. Roeske\* and H. I. Yamamura . (SPON: B. Grosser.) Dept. of Psychiatry, University Yamamura . of Utah, Salt Lake City, UT 84132 and Dept. of Pharmacology, University of Arizona, Tucson, AZ 85724. The binding of tritiated forms of "classical" muscarinic anta-

The binding of tritiated forms of "classical" muscarinic antia-gonists are consistent with the law of mass action indicating a single class of independent receptors (Hulme et al., Mol. Pharma-col. 14:737-750, 1978). However, pirenzepine, a novel muscarinic antagonist, appears to recognize subpopulations of muscarinic re-ceptors (Hammer et al., Nature 283:90-92, 1980). Recently, a tri-tiated form of pirenzepine  $([^{3}H]-PZ)$  was prepared and used to dir-cetly identify a population of muscarinic the brain ectly identify a population of muscarinic receptors in the brain which bound the ligand with high affinity (Watson et al., Life Sci. 31:2019-2023, 1982). Receptor autoradiographic techniques utilizing  $[^{3}H]$ -PZ and  $[^{3}H]$ -QNB have now been employed to microscopically differentiate the location of the binding sites for these two muscarinic antagonists. Slide mounted sections of rat brain were pre-incubated for 20

minutes at room temperature in Krebs phosphate buffer, pH 7.4 This was followed by a 60 minute room temperature incubation in the same buffer plus 20nM  $[\,^3{\rm H}]\text{-PZ}$  and a subsequent 5 minute rinse in fresh buffer at 0-4°C. Adjacent sections were labeled using lnM concentrations of  $[^{3}\mathrm{H}]-\mathrm{QNB}$  with a 120 minute room temperature incubation followed by two 5 minute rises in fresh ice cold Krebs phosphate buffer. The labeled sections were then quickly dried and apposed to sheets of LKB Ultrofilm in X-ray cassettes. After an appropriate exposure period, the films were developed and the autoradiograms were analyzed by computer assisted microdensito-

While most areas were labeled equally with both ligands, there were several distinct brain regions heavily labeled with  $[{}^{3}\mathrm{H}]-\mathrm{ONB}$  and <u>not</u> labeled with  $[{}^{3}\mathrm{H}]-\mathrm{PZ}$ . These sites include the ventral horn of the spinal cord, hypoglossal nucleus, cerebellum, nucleus tractus solitarius, nucleus of the facial nerve, superficial layer of the superior colliculus, diagonal tract of Broca and lamina IV of the cerebral cortex.

Thus,  $[^{3}H]$ -PZ recognizes only a subset of the muscarinic receptors labeled with  $[^{3}H]$ -QNB. Interestingly, the sites not labeled to is labeled with  $[^{+}H]$ -QNS. Interestingly, the sites not labeled with  $[^{3}H]$ -PZ are those which have a large percentage of high af-finity agonist sites as evidenced by agonist displacement of  $[^{3}H]$ -antagonist binding (Wamsley et al., <u>Brain Res. 200</u>:1-12, 1980) and by direct  $[^{3}H]$ -agonist binding (Wamsley <u>et al.</u>, this meeting).  $[^{3}H]$ -PZ thus labels nuclei where a large concentration of low affinity agonist sites exist.

QUANTITATIVE AUTORADIOGRAPHY OF B, AND B, ADRENERGIC RECEPTOR SUBTYPES IN RAT BRAIN. <u>Thomas C. Rainbow</u>, <u>Bruce Parsons and Barry</u> <u>B. Wolfe.</u> Department of <u>Pharmacology</u>, University of Pennsylvania 53.3 B. Wolfe. Department of Pharmaco Medical School, Phila. PA 19104

Beta (B) adrenergic receptors can be divided into B<sub>1</sub> and B subtypes on the basis of different affinities for drugs. Wh it is known that  $B_1$  receptors predominate in the rat forebrain, and that  $B_2$  receptors are more numerous in the cerebellum, more detailed information is lacking about their anatomical distribution. In this study, we have combined the recent LKB film method of autoradiography with computer-iterative methods of receptor analysis to quantify  $B_1$  and  $B_2$  receptors in discrete regions of rat brain.

regions of rat brain. Our procedure was to label  $_{23}^{22}$  thick frozen sections of rat brain <u>in vitro</u> with 150 pM <sup>-1</sup> I pindolol (IP:2200 Ci/mmol), a non-selective beta antagonist. Sections were incubated with the ligand for 70 min at 23°. The relative amounts of B receptor subtypes were determined by co-incubating the sections with 10<sup>-11</sup> to 10° M of ICI 118,551, a selective B<sub>2</sub> antagonist. The sections were washed 3 x 20 min in 4° büffer, dried on a 60° slide warmer and applied against LKB Ultrofilm for 4.5 hr to generate autoradiograms. Obtical densities of the autoradiograms were sections were and applied against LKB Ultrofilm for 4.5 hr to generate autoradiograms. Optical densities of the autoradiograms were converted into fm ligand/mg protein using <sup>12</sup>J brain-mash standards. Using readings from autoradiograms generated in the presence of 18-25 different concentrations of ICI 118,551, the relative proportions of B<sub>1</sub> and B<sub>2</sub> receptors were determined for a variety of brain regions via computerized analysis of inhibition curves. Non-specific binding was determined separately for each brain region via computerized curve-fitting. Scatchard analysis of density readings from the caudate-putamen indicated that the binding of IP was saturable, specific and of a high-affinity (Bmax = 400fm/mg P, Kd = 60-90 pM). In contrast to the inhibition curve for 1-propranolol, which computer analysis modeled to a single affinity binding site, the inhibition of IP binding by ICI 118,551 was biphasic and corresponded with high significance with predictions made for a two-site model.

significance with predictions made for a two-site model. Computer analysis of optical density readings indicated that high levels of  $B_2$  receptors were found throughout the molecular, purkinje and granular layers of the cerebellum, with high levels of  $B_1$  receptors occurring in the reticular nucleus of the brainstem and such regions of rat forebrain as the lateral septum and layer I of frontal cortex. White matter regions of both forebrain and cerebellum exhibited mixed ratios of  $B_1$  and  $B_2$ forebrain and cerebellum exhibited mixed ratios of  $B_1$  and  $B_2$  receptors. Our results provide the first quantitative map of  $B_1$  and  $B_2$  receptors in rat brain and demonstrate the feasibility of using the LKB film method to localize receptor subtypes via inhibition analysis.

DIFFERENTIAL LOCALIZATION OF TYPE 1 AND TYPE 2 BENZODIAZEPINE (BZ) RECEPTOR SITES IN THE SUBSTANTIA NIGRA. <u>M.M.S. Lo<sup>1</sup>, D.L.</u> <u>Niehoff<sup>2</sup>, M.J. Kuhar<sup>1</sup> and S.H. Snyder<sup>1</sup>. <sup>1</sup>Johns Hopkins</u> <u>University, Depts. of Neuroscience, Pharmacology and Psychiatry,</u> School of Medicine, Baltimore, Maryland 21205. <sup>2</sup> MRC Neuroimmunology Res. Proj. Uni. College, Dept. of Zoology, London. England. 53.5 London, England.

London, England. Differential regional localizations of type 1 and type 2 BZ receptors have been reported from one of our laboratories using light microscopic autoradiography of  ${}^{3}\text{H-flunitrazepam}$ ( ${}^{3}\text{H-FNZ}$ ) binding in the presence and absence of CL218872 (a type 1 selective drug). We have now reexamined the location of type 1 and 2 receptors using (1) displacement of  ${}^{3}\text{H-FNZ}$  by (L218872, (2)  ${}^{3}\text{H-s}\text{-carboline}$  (a type 1 selective drug) and (3)  ${}^{3}\text{H-FNZ}$  binding to detergent treated brain section (this treatment selectively solubilizes type 2 sites) in conjunction with quantitative autoradiography with tritium sensitive film. In the substantia nigra after unilateral lesions of the

with quantitative autoradiography with tritium sensitive film. In the substantia nigra after unilateral lesions of the striatonigral pathway, shows increases of about  $50^{\prime}/^{\circ}$  occur for total GABA and BZ receptor binding. However, differential analysis of type 1 and 2 BZ receptors shows that the lesion elicits a  $100-150^{\circ}/^{\circ}$  increase of type 1 sites and a  $50-70^{\prime}/^{\circ}$  reduction in type 2 sites. Conversely, lesions of the substantia nigra evoke a  $>50^{\circ}/^{\circ}$  reduction in type 1 sites but no change in type 2 sites. In conclusion, our observations are consistent with a postsynaptic location of type 1 sites, whereas type 2 sites are located on axons or terminals of the striatonigral pathway. Other studies in our laboratory consistent with this idea will also be discussed.

53.4 QUANTITATIVE AUTORADIOGRAPHY OF SODIUM-DEPENDENT\_[35]S-CYSTEIC C. Rainbow(Spon: S.D. Erulkar) Dept. of Pharmacology, Univ. of Pennsylvania Medical School, Philadelphia PA 19104. Cysteine sulfinic acid (CSA) has been shown to be present in rat brain, to be transported into synaptosomes by a Na-dependent

high-affinity system, and to exert strong excitatory effects on the spinal cord. In this study, we have employed the LKB-film method of autoradiography to quantify in rat brain Na-dependent (and presumptive re-uptake) binding sites for [35]S-cysteic acid (CA), an analog of CSA.

(CA), an analog of CSA. Our procedure was to preincubate frozen brain sections (32u) for 20 min in ice-cold 50 mM Tris buffer containing 300 mM NaCl, pH 7.4. Binding sites were labeled for 20 min at 4C with 300 ul buffer containing 20 or 150 nM [35]S-CA (41.4 Ci/mmol), with or without ImM unlabeled CSA. A range of cgncentrations of unlabeled CA or concentrations (10<sup>-10<sup>-10</sup></sup> M) of unlabeled compounds were included in some experiments. After incubation, sections were washed twice for 5 min in 4°C buffer, and removed for scintillation counting or apposed against LKB film for 4 h. Optical density readings were converted into pm/mg protein using

To schnittice contring of appoint appoint prime to the firm of the firm of the firm of the second s

To test this hypothesis, we performed quantitative autoradiography on "staggerer" mice, mutants known to be autoradiography on "staggerer" mice, mutants known to be deficient in excitatory amino acid re-uptake. We found that cerebellums from "staggerer" mice showed a 40% decrease in [35]S-CA binding sites relative to controls. We also observed a 55-60% decrease in [35]S-CA transport in synaptosome preparations from "staggerer" cerebellums. These results suggest a homology between Na-dependent [35]S-CA binding sites and CSA re-uptake sites, and are consistent with the hypothesis that CSA may act as an excitatory transmitter in the CNS. 53.6 FURTHER CHARACTERIZATION OF THE SPECIFIC CNS <sup>3</sup>H.PHENYTOIN Format SITE. D.Kafka\* and L.Spers\* (SPON: J.F.MacDonald).Dept.
Pharmacology, University of Toronto, Toronto, Ontario, Canada.

Pharmacology, University of Toronto, Toronto, Ontario, Canada. In an attempt to determine the relationship between the phenytoin site (1) and the GABA-chloride ionophore-benzodiazepine complex we have examined the effect of chloride ions on phenytoin binding. Binding to both the high and low affinity sites is shifted to the left, and the magnitude of the high affinity site is increased. This shift is independant of the cation used (Na,NH<sub>4</sub>,or K). The IC<sub>50</sub>'s of a number of anticonvulsant barbiturates for the phenytoin site are also left shifted, and in the presence of loOmM chloride, there is a good correlation between anticonvulsant a good correlation between anticonvulsant potency and competition for the phenytoin site. This should be compared with binding to the picrotoxinin site where there is a correlation between binding and sedative potency but not anticonvulsant potency (2).

We have determined that diazepam and flunitrazepam both enhance H.phenytoin binding, but that other benzodiazepines tested did not. The benzodiazepine antagonist Ro 15-1788 had the observed und not the behavior which would therefore appear to have the characteristics of the "peripheral" type benzodiazepine receptor. We will test the effects of the "peripheral" benzo-diazepine antagonist Ro5-4864. These finding are in conflict with Bowling & De Lorenzo (3) who demonstrated competition between benzodiazepines and phenytoin, and Shah et al (4) who found that all benzodiazepines they tested enhanced phenytoin binding. The distribution of the <sup>3</sup>H.phenytoin binding site in human

The distribution of the "H.phenytoin binding site in numan brain has been examined. Scatchard analysis reveals two sites, K<sup>-</sup> 30-50nm, and K<sup>-</sup> 200-500nM. In the rat K<sup>-</sup> was 10nM, and K<sup>-</sup> was 700nm. The highest binding (B<sup>-</sup> was observed in amygdala (700 fmoles/mg), in the motor cortex (500 fmoles/mg) with lesser amounts in the hippocampus (230 fmoles/mg) and cerebellar cortex (150 fmoles/mg).

Using irradiation inactivation analysis of freeze dried synaptosomal membrane the two sites in both man and rat were shown to have different apparent molecular weights, WM approx 72,000,MM<sup>2</sup> approx 113,000.This work was supported by MRC grant MA 7119.

53.7 AUTORADIOGRAPHY OF SUBSTANCE P RECEPTORS USING 1251-PHYSALAEMIN.

AUTORADIOGRAPHY OF SUBSTANCE P RECEPTORS USING 1=51-PHYSALARMIN. S. Wolf\*, T. Moody, R. Quirion and T. O'Donohue. (SPON: B. Tempel). Dept. Biochem., GWU Med. Sch., Washington, D.C. 20037 and Expt. Ther. Branch, NINCDS, Bethesda, MD 20205. Substance P may function as a neurotransmitter in the CNS. While endogenous substance P is discretely distributed in certain brain nuclei, the regional distribution of substance P receptors has only been described recently (Shults, C. <u>et al.</u>, <u>Peptides</u>, <u>3</u>: 1075, 1982). Here the pharmacology and discrete regional distri-bution of central substance P receptors was investigated using bution of central substance P receptors was investigated using rat brain slices and  $^{12\rm S} \rm I$ -physalaemin, a potent structural analogue of substance P.

Binding studies were conducted using 12 µm coronal slices of unfixed rat brain (Wolf, S. <u>et al</u>., <u>Eur. J. Pharm.</u>, <u>87</u>: 163,1983). Forebrain slices bound <sup>125</sup>I-physalaemin reversibly, with high affinity (Kd, 0.3 nM) to a single class of sites (Bmax, 22 fmol/mg protein). The ratio of specific to nonspecific binding was 15 to 1. Pharmacology studies indicated that only peptides structurally The intractingly schules indicated that only periods schulturary related to physalaemin such as substance P and eledoisin competed for high affinity <sup>125</sup>I-physalaemin binding; peptides structurally unrelated to substance P such as bombesin,  $\beta$ -endorphin,  $\alpha$ -MSH, neurotensin or VIP did not compete for specific <sup>125</sup>I-physalaemin binding sites.

Autoradiographic studies were conducted using the method of Palacios et al. (Neurosci. Lett., 25: 101, 1931). Highest grain densities were present in the olfactory bulb, dentate gyrus, medial amygdala, superior colliculus, ventral subiculum, as well as the dorsal parabrachial and dorsal tegmental nuclei, locus coeruleus and dorsal horn of the spinal cord. Moderate grain densities were present in the nucleus accumbens, striatum, hippo-campus, olfactory tubercle and periaquaductal gray of the mid-brain. Low grain densities were present in most thalamic nuclei, the substantia nigra and cerebellum. The corpus callosum and con-trols treated with 1 µM unlabeled physalaemin had negligible levels of binding. The unique pharmacological and regional dis-tribution data obtained suggest that <sup>125</sup>I-physalaemin may serve as a valuable probe for central substance P receptors.

53.8 AUTORADIOGRAPHIC LOCALIZATION OF ANGIOTENSIN II

AUTORADIOGRAPHIC LOCALIZATION OF ANGIOTENSIN II RECOGNITION SITES IN THE DOG CNS. R.C. Speth, C.L. Chernicky, D.R. Gehlert\* and J.K. Wamsley. Cleveland Clinic, Res. Div., Cleveland, OH 44106 and Dept. of Psychiatry, Univ. Utah, Salt Lake City, UT 84132 The existence of angiotensin II (Ang II) receptor recognition sites in the CNS of bovine and rodent species is well established. Our radioligand binding studies using <sup>125</sup>I Ang II have established their exis-tence in discrete microdissected regions of the studies using <sup>163</sup> Ang 11 have established their exis-tence in discrete microdissected regions of the canine CNS. Due to the limitations of homogenate binding techniques for precise anatomical localization, it is essential to employ the method of localization, it is essential to employ the method of in vitro receptor autoradiography for a better resolution of Ang II recognition sites in the dog CNS. Frozen sections of selected regions of the brain from a dog perfused with 0.01% formalin were cut at 20  $\mu$ M in a cryostat and mounted onto subbed microscope slides. After a dessication period in a frost free freezer, the sections were thawed and preincubated in a sodium phosphate buffer medium containing dithiothreitol, EGTA, NaCl and MgCl with or without 1  $\mu$ M Ang II for 30 min at 22°C. The sections were then transferred into jars containing the same medium plus 1  $m^{125}$ I-Ang II and 0.4% bovine serum albumin with or without 1  $\mu$ M Ang II, for 45 min at 22°C. These conditions have previously been used serial albumin with of without 1 µM Ang 11, for 45 min at 22°C. These conditions have previously been used to demonstrate specific  $^{12}$ SI-Ang II recognition sites in homogenates of the dog CNS. The sections were rinsed for 2-3 min in fresh buffer at 4°C and dried with a cooled-dessicated stream of air. The sections where placed in X-ray cassettes in apposition to an autoradiographic film (Ultrofilm, LKB Instruments) for a 2 to 8 day exposure. The autoradiograms revealed several areas of dense, highly specific <sup>125</sup>I-Ang II recognition sites; the nucleus of the solitary tract, the dorsal motor nucleus of the vagus, the anterior pituitary, and the anteroventral third ventricle (AV3V) region. Moderate densities of vagus, the anterior pituitary, and the anteroventral third ventricle (AV3V) region. Moderate densities of specific <sup>125</sup>I-Ang II binding sites were also observed in the septum, the medial basal hypothalamus and cerebellar cortex. Little specific binding was observed in other brain regions examined. Further autoradiographic examination of the <sup>125</sup>I-Ang II recognition sites in dog CNS areas is in progress. Supported by NIH HL-27568 and HL-6835.

- autoradiography of  $^{3}\text{H}\text{-}\beta\text{-}\text{endorphin}$  binding in rat brain: evidence 53.9 Autokarlockarl or Sh-B-ENDOKARI BIADIKO IN KAI BKAIN' EVIDENCE FOR EPSILON SITES R.R. Goodman, R.A. Houghtenş and G.W. <u>Pasternak</u>. Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, N.Y.,N.Y. 10021 and Dept. Immunopathology, Sripps Clinic Research Foundation, La Jolla, CA 92037. The autoradiographic regional localization of 3H-B-endorphin The autoratographic regional localization of  $A_{-D}$ -endorphin binding in rat brain differed from that of either 3H-dihydromor-phine or 3H-D-ala-D-leu-enkephalin (DADL), determined by the comparison of sequential sections through three regions of rat brain: striatum, hypothalamus, and brain stem 3H- $\beta$ -End-orphin labeled some clusters as well as the subcallosal streak in the striatum, the nucleus accumbens, Lamina IV of the cortex, medial thalamus, hippocampus, hypothalamus, inferior colliculus, dorsal raphe, median raphe and pontine nuclei. White matter regions had little, in any, binding. Although many of these structures were also labeled by  $^{\rm 3H-}$  dihydromorphine and  $^{\rm 3H-}$  DADL the overall pattern of  $^{3}\text{H}\text{-}\beta\text{-}\text{endorphin}$  was unique, consistent with the proposal of central epsilon receptors. Detailed displacement experiments in homogenate binding assays suggested a site selective for  $\beta\text{-}$  endorphin, corresponding, perhaps, to the previously proposed epsilon receptor. Saturation studies studies demonstrated a high affinity binding component (KD 0.4-0.6 nM) as well as a lower affinity component (KD approximately 15 nM). The higher affinity component consisted of more than one type of The higher attributy component consisted of more than one type of site. Approximately half of the high affinity component was eliminated by naloxonazine treatment, suggesting that the lost binding corresponded to muj sites. This high affinity binding of  $\beta$ -endorphin to muj sites was interesting in view of the ability of naloxazone and naloxonazine to antagonize  $\beta$ -endorphin analgesia and catalepsy. The remaining high affinity binding component on Scatchard analysis probably represented epsilon binding. The affinity of  $\beta$ -endorphin for other sites, such as mug and delta The was much less. Thus, the lower affinity component probably represented cross-binding between  $\beta$ -endorphin and other classes of opioid binding sites.
- 53.10 TEMPERATURE-SENSITIVE REVERSIBLE LOSS OF <sup>3</sup>H-SEROTONIN BINDING SITES. K. Blaschuk\* and S.W. Tang. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Ontario, CANADA, M5T 1R8 Dramatic reversible changes in <sup>3</sup>H-serotonin (<sup>3</sup>H-5HT) binding in

Dramatic reversible changes in 'H-serotonin ('H-SHI) binding in rat cerebral cortex crude homogenates can be induced by temp-erature. With 10  $\mu$ M serotonin to define non-specific binding, <sup>3</sup>H-SHT binding at 37° C for 10 minutes with immediate filtration yielded a monophasic Scatchard profile, with K<sub>d</sub> of 4 MM and B<sub>max</sub> of 255 fmoles/mg, protein. The Scatchard plot became clearly nonlinear if the incubation tubes were immediately immersed in icewater for 30 to 60 minutes before filtration after the  $37\,^{\circ}$  C – 10 minute incubation. Computer analysis revealed two binding sites with  $K_{\rm d}$  values of 0.3 and 12nM and  $B_{\rm max}$  values of 190 and 360

The K<sub>d</sub> values of 0.5 and 12 m and 5 max values of 190 and 300 fmoles/m<sub>g</sub>, protein, respectively. 3 Temperature stability curves varied with the concentration of H-5HT used. At low concentration (eg. 0.40 nM), when the incubation tubes were immersed in ice-water following the normal 37° C - 10 minute incubation, <sup>3</sup>H-5HT binding reached a maximum of about 350% of binding at starting point (before immersion into ice-water), within 20 minutes, and remained stable for at least two -water) within 20 minutes, and remained stable for at least two hours. When the temperature of the incubation tubes was reduced to room temperature after the  $37^{\circ}$  C - 10 minute incubation,  $^{3}$ H-SHT also increased but reached a maximum of 250% instead of 350% described above. The increase was stable up to 40 minutes. Bind-ing of <sup>3</sup>H-5HT maintained at 37° C was not stable. Progressive loss of binding occurred and only 40% of binding remained after

loss of binding occurred and only 40% of binding remained after 2 hours. Part of the loss (50%) was recoverable when the temperature was reduced to 0° C by immersion in ice-water. Similar experiments using higher concentrations of <sup>3</sup>H-5HT (eg. 7.5nM) showed that the increase in binding was only half of that observed with lower concentrations. When the temperature of the incubation tubes was reduced to either 0° C or room temperature, maximum increases of 180% and 130% respectively were observed. Binding maintained at 37° C beyond the 10 minute incubation was more stable than with lower concentration of <sup>3</sup>H-5HT. After 60 minutes, 25% of binding was lost but completely recoverable if the temperature was reduced to 0° C. Two hours at 37° C resulted in a 50% loss of binding, about 70% of which was recoverable. Our results demonstrate the existence of at least two <sup>3</sup>H-5HT binding sites in rat crude cerebral cortex homogenate, the high

binding sites in rat crude cerebral cortex homogenate, the high affinity site of which is highly temperature-sensitive. Our results thus explain the varied  $K_d$  and  $B_{max}$  reported in the literature. The high affinity site being highly temperaturesensitive, may have been frequently missed under the previous assay conditions reported.

53.11 UPTAKE OF PUTATIVE NEUROTRANSMITTERS BY ISOLATED CATFISH HORI-ZONTAL CELLS. M. Christensen\* and B. N. Christensen. Dept. of Physiology & Biophysics, Univ. of Texas Med. Branch, Galveston, TX 77550.

We have recently been using preparations of horizontal cells enzymatically isolated from intact retina to examine the ionic basis of their physiological properties. These cells maintain many of the electrophysiological properties expected of excitable cells in spite of the enzymatic treatment. However, we have been interested in showing that other properties of these cells remain intact after dissociation. To this end, we have compared the ability of isolated horizontal cells to transport putative neurotransmitters when applied in the extracellular medium. Horizontal cells in the intact catfish retina have a high affinity uptake mechanism for GABA (Lam et al. Proc. Natl. Acad. Sci., 1978) and glutamate and glycine are taken up in only small amounts. The experiments reported on here were done to determine whether the high affinity uptake mechanism for GABA is still intact following enzymatic dissociation. Freshly dissociated horizontal cells have large resting

Freshly dissociated horizontal cells have large resting membrane potentials ranging from -55 to -70 mV and when activated by passing a depolarizing current pulse through an intracellular electrode produce a sodium and calcium dependent action potential (Shingai and Christensen, Neuroscience, in press). These cells also respond to glutamate when this substance is pressure ejected from a pipette. The reversal potential for glutamate is about +5 mV (Shingai and Christensen, abstr. Society for Neuroscience, 1983).

Horizontal cells were enzymatically dissociated from excised catfish retina and incubated in several putative radioactive neurotransmitters. Usually the contralateral retina was left intact and incubated in the same radioactive medium in order to compare results from the dissociated cells with intact retina. The isolated cells and intact retina were fixed, embedded in plastic, and processed for light microscopic autoradiography. Our results show that enzymatically dissociated horizontal cells retain high affinity uptake mechanisms for GABA and that glycine and glutamate are taken up in much smaller quantities by both isolated horizontal cells and cells in the intact retina. To exclude the possibility that isolated horizontal cells in radioactive sucrose. This substance was not taken up by either the isolated cells or the intact retina. We conclude that enzymatically isolated horizontal cells are able to maintain a membrane which retains its ionic conductances and high affinity uptake mechanisms. Supported by grant EY-01897.

53.13 DOPAMINE RECEPTORS: ELECTRON MICROSCOPIC LOCALIZATION IN MOUSE CORPUS STRIATUM. A.C. Church, J.E. Kleinman,\* and R.J. Wyatt. Adult Psychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

The dopamine systems of the mammalian brain have been implicated in a number of disease states. In fact, the clinical potency of the drugs presently used to treat schizophrenia closely parallels their potency in blocking the so-called dopamine type-2 (D-2) receptors. Although these D-2 receptors have been localized regionally using autoradiographic techniques, their organization at the cellular or subcellular level has remained unknown. In order to study D-2 receptors with the electron microscope, an immunocytochemical approach was taken.

Lisuride (Schering AG) is an agonist with a high affinity for the D-2 receptor ( $K_{D}$ =5 x 10<sup>10</sup>M). Antibodies to lisuride (Anti-L) were raised in rabbits by injection of a lisuride-protein conjugate. Vibratome sections of mouse corpus striatum were incubated in lisuride and then anti-L serum. Anti-L's were stained using the peroxidase-anti-peroxidase technique with diaminobenzidine as the chromophore. Corpus striatum tissue was embedded in plastic and sectioned for electron microscopy.

Electron-dense immunoreactivity was found to be localized at synaptic junctions in the striatal neuropil. The lisuride immunoreactivity appeared to be organized in pre- and postsynaptic pairs, with stain on the synaptic faces of both an axon terminal and its apposed dendritic process. Control material was prepared by incubating tissue in the presence of lisuride and excess subjride. The subjride treatment effectively eliminated most of the synaptic stain. Our results agree in large measure with binding studies of others who have suggested that about 50% of D-2 receptors in the striatum are on extrinsic axon terminals while the remainder are located on cells intrinsic to this region. The results suggest a novel synaptic arrangement for D-2 transmission in the corpus striatum.

53.12 MODULATION OF NEURONAL SEROTONIN (5-HT) UPTAKE BY <sup>3</sup>H-IMIPRAMINE RECOGNITION SITES: EVIDENCE FOR AN ENDOGENOUS LIGAND. M. L. Barbaccia,\* D. M. Chuang,\* and E. Costa. Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

D.C. 20032. Specific, high affinity binding sites for <sup>3</sup>H-imipramine located on serotonergic (5-HT) axons have been characterized in crude synaptic membrane preparations of mammalian brains. These sites are located in serotonergic (5-HT) axons have been characterized in crude synaptic membrane preparations of mammalian brains. These sites are located in serotonergic axons and appear to be functionally associated with a regulation of the serotonergic reuptake mechanisms. Though 5-HT is a weak displacer of H-imipramine, the regulatory site for 5-HT uptake where imipramine binds is not the regulatory site for 5-HT uptake where mechanisms. The number of H-imipramine recognition sites located in various rat brain structures is decreased by two daily injections of imiprampel minces when the Bmax of H-imipramine binding is decreased the Vmax of the neuronal reuptake of 5-HT is enhanced (+40%). Moreover when the number of H-imipramine recognition sites is decreased the efficiency of imipramine as blocker of the 5-HT uptake is attenuated. All these observations taken together suggest that the high affinity H-imipramine recognition sites may have physiological significance as a site where an endogenous effector was extracted and partially purified fram whole rat brain. It inhibits in a dose dependent manner the uptake of H-5-HT and it displaces H-imipramine regulatory sites foiled to displace H-flunitrazepam, H-imispramin as deficient yes ned appear to be a petide or a lipid. The inhibitory activity either on Himipramine binding or on H-5HT uptake could be eluted quantitatively from a AG-50Wx8 (0.7x4cm) eluted column with 2 M HCl, this acid fails to elute H-5-HT added to the tissue as an internal standard. This finding suggests that the biological activity detected in the brain extract was not due to endogenous 5-HT. Experiments are now in progress to characterize the chemical nature of this endogenous ligand of H-imipramine recognition site. This liggand might become a very important tool

- PASSIVE MOVEMENT SENSITIVITY AT THE INTERPHALANGEAL JOINT OF THE 54.1 INDEX FINGER. <u>H.L. Cohen and W.S. Battersby\*</u> Dept. of Physiol., Downstate Med. Ctr., Bklyn, N.Y. 11203 and Dept. of Psych., Queens College, Flushing, N.Y. 11367 Two experiments were conducted in order to parametrically evalu-

ate passive movement sensitivity in normal, young adults. A highly precise electromechanical system for the delivery of kinesthetic precise electromechanical system for the delivery of kinesthetic stimulation and for the measurement of angular displacement was used to assess bensitivity at the proximal IP joint of the right index finger. In Expt. 1, stimuli consisted of random presenta-tions of all combinations of seven velocities  $(.15 - 11.0^\circ)sec.)$ and two directions (up, down), blocked across three starting po-sitions of the joint (15°, 25° and 35° from the vertical). Move-ment detection was responded to by a keypress which terminated Movethe movement and by verbal identification of direction. Percent correct detection (PCD) was a monotonically, increasing function of log angular velocity, while response time (RT) was a negatively accelerating, decreasing function. Repeated measures ANOVAs in-dicated a significant effect of velocity, but not of starting position or direction. In Expt. 2, subjects received automatically position or direction. In Expt. 2, subjects received automatically timed movement presentations, in contrast to the subject termi-nated movements in Expt. 1. Stimuli consisted of random presenta-tions of all combinations of six velocities  $(.05 - 1.5^{\circ}/sec)$ , six durations (1 - 10 sec) and two directions (up, down). Starting position was kept constant at 25° from the vertical. Movement detection and direction identification were indicated by a verbal response. The results showed that when stimulus duration was kept constant ECD inpresent of the convolution in the start of response. The results showed that when stimutes duration are constant PCD increased as a function of log angular velocity, stimulus duration increased, both slope and PCD also increased. As When angular velocity was kept constant PCD increased as a function of stimulus duration. As velocity increased both slope and PCD also increased, but more gradually than when duration was increased. Repeated measures ANOVAs indicated significant effects of velocity, duration and direction, as well as the velocity by duration interaction. Each velocity-duration combination was then multiplied in order to obtain a range of angular displacements. PCD was shown to be a monotonically, increasing function of log angular displacement. These behavioral results complement both the velocity and displacement sensitive properties of peripheral (muscle, joint and cutaneous receptors) and central (thalamic and cortical) kinesthetic structures defined by unit recordings.

54.2 INTERMOVEMENT SENSORIMOTOR ACTIONS IN THE CONTROL OF COORDINATED FINGER-THUMB MOVEMENTS. <u>Kelly J. Cole,\* Vincent L. Gracco,\* and</u> James H. Abbs\* (SPON: G. Celesia). Speech Motor Control Labs., Waisman Center, University of Wisconsin, Madison, WI 53706.

Most investigations of sensorimotor mechanisms have focused on analyses of movements around a single joint, often involving the use of unanticipated perturbations to reveal underlying control processes. By virtue of the experimental paradigm, these inves-tigations of single joint control have primarily emphasized autogenic sensorimotor mechanisms. In the present investigation, unanticipated loads were applied to the distal joint of the thumb in human subjects during a coordinated thumb-finger "pinching" movement. Subjects were trained to produce this movement rapidly with a controlled thumb-contact pressure in response to a tone. Using a DC brushless torque motor under force feedback control, loads were introduced randomly on 10-15 percent of the movement trials at varying times prior to and following the onset of thumb flexor EMG. Thumb and finger movement, along with EMG from Flexor pollicis longus (FPL) and Flexor digitorum superficialis (FDS), were recorded simultaneously. Analyses of thumb EMG and movement revealed autogenic compen-

satory responses in the thumb flexor muscle, as reported by sev-eral previous investigators. However, index finger movement and FDS EMG revealed compensators, changes as well. Finger movement and tory responses were reflected in increased displacement and velocity of the movement as well as corresponding increases in PDS. The latencies of the PDS responses were as short as 45 msec, but varied with the timing of the thumb load relative to EMG onset. Compensatory changes in the finger movement and FDS appeared the first time a thumb perturbation was introduced. Moreover, subjects' comments indicated that this was not a typical reaction time response; viz., the finger compensation was not initiated intentionally.

The finger compensatory responses appear to suggest a sensorimotor control process that is open-loop. That is, the finger compensatory responses are disassociated from the thumb distur bance and further, this sensorimotor action does not act to cor-rect the error induced in the thumb. In this regard, these results are comparable to those obtained in our earlier investigations where unanticipated perturbations were applied to the lower lip during a combined upper lip-lower lip movement [Abbs and Gracco, Soc. Neuroscience Abstracts, 1982]. In that study, open-loop responses were observed in the upper lip to the lower lip loads. Results of these parallel experiments suggest that intermovement sensorimotor actions, operating open-loop, may play a role in the coordination of multiple movements Research supported by NIH grants NS-13274-07 and

EFFECT OF UNILATERAL NEOSTRIATAL LESION ON PHASIC LIMB MOVEMENT AND 54 3 ASSOCIATED POSTURAL ADJUSTMENT IN THE STANDING CAT. <u>R.P. Di Fab</u> Physical Therapy Res. Labs., Univ. of Iowa, College of Medicine, Iowa City, IA 52242, USA. Fabio.

During normal limb movement, body posture is coordinated with limb displacement so that potential disturbances in equilibrium are counter-balanced by anticipatory postural adjustments. The basal ganglia (BG) were previously thought to serve a regulat-ing function for preparatory response sets (Buchwald et al., Growth <u>& Develop. Brain</u>,1975). BC influence on postural strategies prior to initiation of movement is unknown. The purpose of this study was to investigate the effect of unilateral neostriatal lesion on goal-oriented movement and on postural adjustments associated with task performance.

Five cats were conditioned to stand, unsupported, with each paw placed on a corresponding fost-plate dynamometer. Each dynamometer measured the vertical reaction forces during quiet standing and task execution. The task involved pressing a bar spontaneously with the left(phasic) forelimb and returning to full standing (one movement cycle). Baseline EMG and force-plate data were col-lected during the first 500ms of a 1.5s interval preceding a change in phasic forelimb weight-bearing force. Subsequent changes in EMG activity of 6 postural muscles were referenced to their mean baseline values. Animals were evaluated in control and lesion conditions. Small electrolytic lesions were made in the caudate nucleus with a monopolar lesioning electrode 0.3mm diameter at 2.5ma/25s and were verified histologically.

Perseveration and spontaneous turning to the lesioned side were observed interrupting task performance. Mean movement cycle time increased after partial neostriatal exclusion(p <.01) and bar press frequency was reduced (p <.01). These findings paralled previously reported deficits with unilateral ablation of the caudate nucleus (Olmstead et al., <u>Exp. Neurol</u>, 53:670,1976). In contrast, when symmetrical pre-lift weight-bearing criteria were met, associated postural responses showed no deficit. There were no significant differences in onset and duration of soleus, rectus femoris, and triceps brachii ipsilateral to the phasic limb or lumbar paraspinal, triceps, and biceps brachii contralateral to the phasic extremity. Peak stabilizing force, rate of loadbearing, and preparatory movement time were also unchanged. Partial exclusion of the neostriatum affected sequencing of

phasic limb movement. However, when stance was symmetrical (prior to initiation of lift), criterion measures of preparatory postural adjustments did not differ from control values. A theoretical model localizing anticipatory balance behavior to a lower closed-loop neural circuit would be supported by the current study.

POSTURAL RESPONSES TO INDUCED SWAY IN NORMALS AND PATIENTS WITH 54.4

POSTURAL RESPONSES TO INDUCED SWAY IN NORMALS AND PATIENTS WITH ACUTE UNILATERAL VESTIBULAR LESIONS. J.H.J. Allum & C.R. Pfaltz -ORL-Department, University Hospital CH-4031 BASEL, Switzerland. Coordination of muscle activity in postural responses follow-ing direct ankle dorsi-flexion of standing subjects was compared between normals, and patients with either bilateral or acute uni-lateral peripheral vestibular lesions. EMG activity was recorded with surface electrodes bilaterally from the soleus (SOL) and tibialis anterior muscles (TA) as well as over neck muscles pitch-ing the head backwards. Previous research on normals (Brain Res. 1983, 264,p.297) showed that unexpected dorsiflexions averaging 36/s over 3' result in a segmental reflex excitation of SOL and in-hibition of TA, followed by sway stabizing responses in TA at ca. 80 and 130 ms from the onset of ankle rotation. A weak coactiva-tion of SOL commenced after\_130 ms. Head angular accelerations tion of SOL commenced after 130 ms. Head angular accelerations exceeded the threshold of  $5^{0}/s^{2}$  for vertical hystagmus within 20ms and thereafter consisted of accelerations due to the perturbation. Triceps surae reflex induced sway and forwards sway produced by TA activity. Maximum head accelerations occurred during forward sway and equalled, on average, 220/95. A marked reduction of both TA stabilising responses was noted

in patients with bilateral lesions. Their neck EMG activity was enhanced with respect to normals, always increasing during angular accelerations pitching the head forwards.

Dramatic discoordination of stabilising responses occurred in patients with unilateral lesions. An asymmetry in the early TA responses was always observed (mean ratio of EMG area 1.9 - 1.0 (s.d.), mean delay difference 4 ms; c.f. area 1.0 - 0.2 and delay 1 ms in normals) and in 9 of 11 cases the response was larger in area and earlier contralateral to the lesion. Segmental reflex responses in SOL were, on average, unaffected, though in patients with the largest TA asymmetry, a SOL asymmetry was also observed; While vision (eyes open v. closed) had no consistent effect on the TA responses at 130 ms in normals, in 5 patients, vision produced a significant improvement in the later TA response asymmetry. Head stabilizing performance was strongly affected, head accelerations exceeded 400  $^{/s}$  during forward sway and was characterised by a failure of neck EMG activity rotating the head backwards to be coincident with TA activity rotating the body forwards. Instead, neck EMG activity commenced once the head rotated forwards with the body.

Thus patients with acute unilateral lesions experience insta-bility not only because their ankle muscle responses tend to rotate the body towards the side of the lesion but also because centres coordinating neck muscle activity with reflex activity in TA malfunction. Presumably an imbalance of vertical semicircular canal input underlies this malfunction.

DOES THE HUMAN POSTURAL CONTROL SYSTEM ADAPT TO REPEATED PSEUDORANDOM STIMULI? C. Wall III and L.M. Nashner. Dept. of Otolaryng., Univ. Pittsburgh Sch. Med., Pittsburgh, PA 15213, and Neurological Sciences Institute, Portland, Oregon 97210. 54.5

We tested the hypothesis that the human postural control system, which displays response adaptation to simple predictable stimuli stimuli (repeated 0.2 sec 50 deg/sec anterior-posterior velocity pulses) given at random intervals, would also display response adaptation to a second stimulus that was mathematically equivalent but possibly less predictable. A pseudorandom binary sequence (PRBS) velocity stimulus of bandwidth 0.04 to 3.33 Hz, having a repeat period of 25.5 seconds, was used as the less predictable stimulus. This stimulus was presented for six stimulus repetition periods and the response was averaged to increase signal to noise ratio.

It is possible to calculate an impulse response to the PRBS stimulus that is directly comparable to the actual velocity pulse response under certain assumptions. For both stimuli, A-P sway measured at the pelvis was the measured response. As expected, all subjects demonstrated was the measured response. As expected, all subjects demonstrated rapid response adaptation to the time pulses which showed up as a decrease in the magnitude of the oscillatory aftercomponent of the response that occurred when the pulse was presented for the second or third time. By contrast, the PRBS impulse response averaged for six stimulus repetition periods showed no such adaptation and resembled the response to the first time pulse. In addition, the computed six individual impulse responses, although noisier than the average response, showed no Impuse responses, although noisier than the average response, showed no systematic trends that would indicate response adaptation. There was considerable intersubject variability as indicated by the degree of "ringing" of the nonadapted time pulse response, but the degree of "ringing" for each subject correlated well between the time and PRBS responses.

In addition, the PRBS impulse response in three out of four subjects demonstrated a "small signal" linear range with respect to the fast dynamics, but a progressively greater amount of damping which occurred with increasing stimulus. Thus, it appears that the postural control system must have a simple, predictable stimulus to which to adapt and that a pseudorandom stimulus, although it is repeated several times, cannot be predicted and it is therefore useful in the study of the unadapted state of the postural control system.

AMPLITUDE AND TIMING OF POSTURAL AND TASK MUSCLES IN UNILATERAL 54.6

ACTUITUDE AND TIMING OF POSTURAL AND TASK NUSCLES IN SKOLDER FLEXION IN STANDING HUMANS. W.A. Lee, T.S.Buchanan\*. Northwestern Univ. Dept. and Rehab. Inst. of Chicago, Chicao, IL 60611. the Coleman, Hearts, J.M.Joyce, Regenstein, Searle of Phsyiol. Supported by Searle Foundations, and the L. Lavins.

In recent motor control studies, invariant temporal ordering of muscle patterns used to produce intentional actions has been emphasized. This study tested whether electromyographic (DrG) patterns in postural (hamstring: IN); erector spinae: ES) and task (anterior deltoid: AD) muscles demonstated invariant invariant task (anterior deltoid: AD) muscles demonstated invariant temporal order for 90 degree flexions made over an eight-fold range of speeds.

range of speeds. Ten standing subjects performed 15 trials at 5 target speeds (40, 80, 160, 320  $^{\circ}$ /s and 'as fast as possible') in a unilateral shoulder flexion task. An oscilloscope displayed a constant velocity target to subjects. A shoulder potentiometer measured joint angle and provided feedback about the match between target and actual speeds. ENG activity from IP, DS, and AD muscles ipsilateral to the arm moved were also recorded. Trials at each movement speed were identified as showing either 'early' (pre-movement onset) or 'late' (post-movement) onset of IP1, DS, and AD activity; these trials were averaged for estimation of DAG lateration. D4G latencies.

Analysis of individual trials showed that proportions of trials 'late' HM or FS onsets were greatest for slowest movements with 'late' IN or ES onsets were greatest for slowest movements (25-100% of trials for all subjects). As movement speeds increased, proportions of these late trials decreased; for movement speeds greater than 00 degrees/sec, all trials showed IN; ES, and AD before movement onset. With respect to EXS phase relations, ES onset was invariably later than both IN: and AD, reqardless of movement speed. Order of 'N: and AD varied with movement speed. At low average speeds, IN: followed AD onset (lag of 300 to 20 ms); at higher speeds (> 100 /sec), IN tended to precede AD onset (lead of 5 to 15 ms).

precede AD onset (lead of 5 to 15 ms). For 3 subjects, the relationships between D\*G (latency, integrated values over the 100 ms after D\*G onset) and average acceleration (first 100 ms of movement) and peak velocity were analyzed from individual trials. For slow movements, latencies of IN varied greatly (-200 to 2000 ms); for faster novements, AD and B\*L latencies were constant (-200 to -60ms), except for one subject showed an exponential decrease of AD onset with speed. Integrated AD and D\* values increased linearly (r=.67-.22) with acceleration and peak velocity for all 2 subjects. Latencies and ISMG values for IN and AD were significantly correlated, suggesting commonlity of drive to the two muscles.

INTRAMUSCULAR PARTITIONING OF THE FACIAL MUSCLES DURING SPEECH 54.7 MOVEMENTS: POSSIBLE CORTICAL CORRELATES. J. H. Abbs, V. L. Gracco, \* and C. A. Blair. Speech Motor Control Labs., Waisman Center, University of Wisconsin, Madison, WI 53706. Most previous studies of functional intramuscular partitioning have focused upon the nature of these subdivisions at subcortical have focused upon the nature of these subdivisions at subcorti-levels. The present studies were aimed at discerning whether functional muscle partitioning is evident also in "voluntary" behaviors requiring motor cortical actions. The activity of intramuscular subdivisions of facial muscles in human subjects was examined during select speech motor tasks. The perioral/ facial muscles were chosen because these multifunctional muscles (1) participate in generating several different three-dimensional (2) receive monosynaptic projections from the face area of the motor cortex, and (3) do not appear to be influenced significantly by lower brainstem perioral reflex pathways during volun-tary speech movements; compensatory response latencies to unanticipated lip loads indicate long-loop sensorimotor pathways [Gracco and Abbs, <u>Soc. Neuroscience</u> Abstracts, 1982]. Collec-tively, these considerations suggest that if task-dependent par titioning is present in the facial muscles, these functional sub-divisions may reflect motor cortex organization.

Two sets of data were obtained to address this hypothesis. Both experiments involved recording from multiple sites in three facial muscles (Orbicularis oris inferior, Orbicularis oris superior, and Mentalis) using restricted field, intramuscular, bipo-lar electrodes. In the first experiment, observations were made for several static speech positions of the lips and for some simple speech movements. Analyses revealed task-dependent intramuscular differences in the magnitude and timing of the multiple site EMG signals. In a second experiment, unanticipated loads were applied to the lower lip during several different speech movement tasks (p, b, f). The multiple intramuscular sites were observed to respond differentially to these perturbations with latencies that implicated long-loop pathways. The results from these experiments, taken together, indicate functional, task-dependent, intramuscular partitioning of the facial muscles and likely representation of these subdivisions at cortical levels. These results raise an interesting guestion concerning whether multiple motor cortical representations are of whole muscles, or rather reflect independent, task-dependent muscle subdivisions. Research supported by NIH grants NS-13274-07 and 5-P30-HD-03352-14.

DIFFERENTIAL SENSORIMOTOR ACTIONS FOR MOTOR PROGRAMMING AND 54.8 CONTROL OF SPEECH MOVEMENTS. V. L. Gracco\* and J. H. Abbs\* (SPON: C. Welt). Speech Motor Control Labs., Waisman Center, University of Wisconsin, Madison, WI 53706.

Complex coordinated motor behaviors appear to involve momentto-moment variations in the contribution of sensorimotor pro-cesses. Our results on perturbations applied to lower lip movemovements during speech similarly indicated temporal variations in sensorimotor actions [Gracco and Abbs, <u>Soc. Neuroscience</u> <u>Abstracts</u>, 1982]. In that study, compensations occurred in dif-ferent combinations of multiple synergistic muscles of both the upper and lower lips with variable latencies (22-85 msec). In general, these compensatory responses were influenced by the tim-ing between the load perturbation onset and the initiation of movement-related muscle activation.

In the present study, we investigated these compensatory response variations further in relation to systematic changes in the velocity and displacement parameters of the lower lip loads. Inferiorly directed loads (35-50 gms) were delivered to the lower lip via a DC brushless torque motor.

Perturbation displacement and velocity parameters influenced lip muscle compensatory responses differentially as a function of load onset time. Perturbations occurring 20-60 msec prior to muscle activation resulted in lower lip muscle compensation proportional to the displacement of the perturbation. Compensations to these early loads were predominately in the lower lip muscles; upper lip muscle compensations were not sensitive to displacement. By contrast, later loads introduced immediately prior to or during muscle activation resulted in compensatory responses that were (1) related to the perturbation velocity and (2) most prominent in the upper lip muscles. These data appear to reflect differential sensorimotor processes operating prior to and during motor execution, respectively. Indeed, compensatory responses to perturbations occurring during the pre-execution interval resulted in modification of the motor program with latencies cor-responding to a rapid reaction time (65-100 msec). By contrast, responses to loads introduced later during the execution process were more suggestive of feedforward, sensorimotor actions; viz., velocity information from the lower lip load was used in an openloop manner to adjust the motor output in the upper lip. Latencies of these latter responses were usually less than even a rapid reaction time (22-60 msec).

We interpret these results to suggest that peripheral afferent inputs interact with central neuromotor centers initially to set up the motor program, and once execution is initiated, to shape the details of the action based upon the kinematics of the evolv-Research supported by NIH grants NS-13274-07 and ing movement. 5-P30-HD-03352-14.

PERIPHERAL REGULATION OF MUSCLE OUTPUT: INTERPLAY BETWEEN MOTOR 54.9 PERIPHERAL REGULATION OF MUSCLE OUTPUT: INTERFLAY BETWEEN MOTOR UNIT RECRUITMENT AND FIRING RATE. H. Broman\*, B. Mambrito\* and C. J. De Luca (SPON: J. J. Bouyer). NeuroMuscular Res. Lab., Dept. of Orthopaedic Surgery, Children's Hosp. Med. Ctr., Harvard Medical School, Boston, MA 02115; and Liberty Mutual Res. Ctr., Hopkinton, MA 01748

The modulated output of a muscle is relatively smooth because The modulated output of a muscle is relatively smooth because the active motor units generally discharge asynchronously and with different contraction times. In such a scheme, the force transition through a level where a motor unit is recruited or decruited could conceivably be associated with quantal tran-sitions. Such force behavior has rarely (if ever) been observed. an investigation was performed to observe the behavior Hence, the firing rates of previously activated motor units when a new motor unit is recruited during a gradual increase in the force output of a muscle. This investigation was made possible by our recently developed myoelectrical decomposition technique which provides a verifiably accurate separation of every action poten-tial of several simultaneously active motor units (LeFever and De Luca, <u>IFEE BME 29</u>:149-157, 1982). Experiments were performed motor units in 23 records from the first dorsal intervals of 49 tibialis anterior muscles were obtained while the subject grad-ually increased the force output of the monitored muscle. Force outputs ranged from 3 to 60% of the maximal level.

outputs ranged from 3 to 60% of the maximal level. In all 15 records from the tibialis anterior muscle and 5 of 8 records from the first dorsal interosseous muscle, the firing rate of one or more of the previously activated motor units decreased after the recruitment of an additional motor unit. The firing rate decrease was affected by the characteristics of the force developed by the newly recruited motor unit: In cases of recruitment associated with a smooth output force, the previously activated motor units decreased their firing rates gradually over one or several seconds. If the newly recruited motor unit was associated with a twitch contribution to the output force, the firing rates of the previously activated motor units decreased in a step-wise fashion. Similar effects have been noted in data from the deltoid, flexor pollicis longus and extensor pollicis longus muscles.

Our data indicates that more than one mechanism is responsible for the observed inhibitory effect of a newly recruited motor unit on the firing rates of those already active. Among the possible candidates, recurrent inhibition and stretch reflex mechanisms originating from the newly recruited motor unit are the most likely.

MOTOR EFFECT OF RUBROSPINAL AND PYRAMIDAL TRACT ACTIVITY IN 54 11 AWAKE CATS DEPENDS ON BEHAVIORAL CONTEXT. V.E. Amassian and D.E. Batson. Dept. of Physiol., SUNY, Downstate Med. Ctr., Bklyn, N.Y. 11203.

In the intact awake cat, flexors may be activated by stimulat-In the intact awake cat, flexors may be activated by stimulat-ing forepaw hairs only if the limb <u>hangs unsupported</u>, a precondi-tion for tactile placing. Possibly, depending on the behavioral context, spinal motor relays respond variably to a <u>given</u> de-scending discharge from the higher motor control centers. We tested this hypothesis as follows: 125 um nichrome wires insulated to the tip were implanted in the contralateral bulbar pyramid (PT), or ipsilateral rubrospinal tract (RT) in the medulla. Trains of 2.0 restrangues public cent 100 up in draming with restrict and the trained of 3-9 rectangular pulses, each 100 us in duration and with a frequency of 500-1,000 Hz were delivered to the PT or RT, usually through bipolar electrodes. Alternatively, the contralateral red n. was stimulated through a tungsten microelectrode, with moni-toring of the decussated RT response; prior destruction of the bulbar pyramid ipsilateral to red n. stimulation did not change the results described below.

The results described below. When the stimulus intensity to RT, red n. or PT was adjusted to evoke a short latency (8-10 msec) biceps EMG response in the hang-ing, unsupported forelimb, standing the limb on a solid abolished or markedly diminished the biceps response. Laying the forearm down so that the ventral surface was supported was less effective in diminishing the biceps response; in this position, the elbow was most flexed. If the stimulus train was triggered when the unsupported paw was brought gently into contact with a placing apparatus, the biceps response was greatly into contact with a placing apparatus, the biceps response was greatly enhanced and its latency reduced to, e.g., 6 msec with PT and 5 msec with RT stimulation. Such stimulus trains often <u>delayed</u> subsequent placing of the forelimb. Contact alone did not elicit a biceps response at the latency of the response to the unconditioned stimulus train.

In general, the above changes in amplitude of biceps response not paralleled by changes in the level of resting biceps activity immediately preceding the stimulus train, except when the train was delivered during a spontaneous movement. Such lack of coherence of resting and stimulated biceps activity implies That behavioral context affects the motor consequences of PT or RT activity not through interaction directly at the flexor motoneuron, but at the level of the spinal interneuronal relays.

Furthermore, both PT and RT activity elicited at short latency by tactile input would have its motor effect enhanced by tactile input <u>locally</u> relayed through spinal interneurons. Aided by USPHS, NIH grant NS 11219.

54.10 MOTOR CONTROL OF ANTAGONIST MUSCLES, B. Mambrito\*, C.J. De Luca and H. Broman\*. NeuroMuscular Res. Lab., Dept. of Orthopaedic Surgery, Children's Hosp. Med. Ctr., Harvard Med. School Boston, MA 02115; and Liberty Mutual Res. Ctr., Hopkinton, MA The electrical activity of several concurrently active motor units (MU) has been simultaneously recorded from the human Flexor Policis Longus (FPL) and Extensor Policis Longus (EPL) muscles, respectively sole flexor and sole extensor of the distal phalanx of the thumb. The detected multichannel mycolectric signals have been decomposed into their constituent motor unit action po-tential trains (MUAPT) using a computer assisted algorithm (LeFever and De Luca, IEEE BME 29: 149-157, 1982), allowing ac-curate calculation of the firing times of up to 8 concurrently active motor units.

tential trains (MLAPT) using a computer assisted algorithm (LeFever and De Luca, IEEE BME 29: 149-157, 1982), allowing ac-curate calculation of the firing times of up to 8 concurrently active motor units. The experimental protocol, designed to promote different ME behavioral modes in the two antagonist muscles included the fol-lowing isometric contractions: constant force, triangular force-varying, force tracking of unpredictable trajectories, and volun-tarily initiated and sustained co-contraction of FPL and EPL with negligible net torque output at the joint (joint stiffening). To date 11 contractions have been analyzed, including 56 de-composed MLAPTS. The following observation have been made: MUS in the FPL and EPL are recruited in an orderly fashion (size principle) as already reported for other human muscles (De Luca et. al. J. Physiol. 329: 113-128, 1982) During triangular force-varying isometric contractions, some MUS in the antagonist muscle may be recruited at the "apex" of the triangle when the slope of the force signal from positive (force increasing) becomes negative (force decreasing). This phenomenon is invariably evident when the subject has no prior knowledge of the force reversal. When tracking unpredictable force trajectories having small oscillations (less the 10% of maximal voluntary exerted force) about the zero force level, co-activation of FPL and EPL is ob-served, but the firing rates of MUS in the two different muscles are "out of phase" i.ee. when the firing rates of the observed MUS in the EPL are decreasing and vice-versa. During voluntarily exerted FPL and EPL co-contraction (joint stiftening), firing rates of MUS in the two different muscles any fluctuate "in phase". This common behavior of firing rates of simultaneously active MUS has been observed within one muscle at a time (De Luca et. al. J. Physiol. 329: 129-142, 1982) and described in terms of common drive the motor-neuron pool. How-ever, previously it had never been observed among firing rates of simultaneously

54.12 CONTROL OF MULTI-JOINT ARM POSTURE. S. Hocherman\*, F A. Mussa-Cambridge, MA 02139.

Cambridge, MA 02139. The purpose of these experiments is to understand some of the neural and biomechanical factors underlying multi-joint arm posture in monkeys and humans. It is known that, under static conditions, the force generated by a muscle is a function of length and the level of alpha and gamma activation. The combined spring-like behavior of all of the arm muscles results in a stiff-ness field defining force at the hand as a function of displace-ment. This field has a shape, an orientation and magnitude. Controlling the magnitude, the shape and the orientation of the stiffness field of the hand in different portions of the work space is one of the important ways in which the central nervous

Stiffness field of the nand in different portions of the work space is one of the important ways in which the central nervous system may control posture and interactions with the environment. The goals of these experiments have been: (1) to explore whether arm movements converging on a location of the work space from different directions set up stiffness fields which differ in shape and orientation and (2) to investigate the time varying pro-perties of the stiffness field after a given posture was reached. Subjects and monkeys grasped the vertical handle of a light-weight hand-nosition transducer and moved the handle to each of a series Subjects and monkeys grasped the vertical handle of a light-weight hand-position transducer and moved the handle to each of a series of visual targets. The arm was restricted to move in a horizontal plane and the wrist was braced. When the hand reached zero velo-city, a perturbing force of known magnitude and direction was applied to the handle resulting in a hand displacement. We measured the amplitude, peak velocity and direction of the dis-placement. We also varied the time of the application of the placement. we ai perturbing force.

The results indicate that in both humans and monkeys, the The results indicate that in both humans and monkeys, the direction of the preceding movement does not influence the shape and orientation of the stiffness field at the final position. These results were obtained for six targets placed in different locations of the work space. With respect to the question of the time varying properties of the stiffness field, we have found no significant variation in the shape and orientation of the field over with delay up to 950 more from the created of the field even with delays up to 850 msec from the onset of postural stability.

In conclusion, arm movements converging upon the same point of the work space from different directions set up stiffness fields which do not differ in any significant way in shape and orientawhich do not differ in any significant way in shape and orienta-tion. This unexpected result represents a contribution to our understanding of the processes occurring during the transition between the end of the trajectory and the beginning of postural stability. INHIBITION OF SYMPATHETIC PREGANGLIONIC NEURONS DURING HEMORRHAGIC HYPOTENSION IN THE ANESTHETIZED CAT, Paul 55.1

HEMORRHAGIC HYPOTENSION IN THE ANESTHETIZED CAT. Paul S. Blum and James A. Spath, Jr.\*. Department of Physiology, Jefferson Medical College, Thomas Jefferson University, Philadelphia, PA 19107. Experiments were performed to investigate the interaction of serotonin (5-HT) and opiate pathways on mean arterial blood pressure (MABP) and preganglionic sympathetic neurons in hypotensive cats. Groups of animals were anesthetized with sodium pentobarbital (30 mg/kg, i.v.), paralyzed with gallamine, and prepared for recording splanchnic nerve (SPN) activity and MABP. Positive pressure respiration was adjusted to maintain normal blood gas values. Seven animals were pretreated with para-chlorophenylalanine (p-CPA, 300 mg/kg) 48 hr before the experiment. In these cats, 5-HT in the medulla and spinal cord was reduced more than 85%. Following baseline measurements, cats were hemorrhaged to a MABP of 40 ± 1 mm Hg for 1 hr. At that time, 12 intact cats and the cats pretreated with p-CPA were given cats were hemorrhaged to a MABP of 40 ± 1 mm Hg tor 1 hr. At that time, 12 intact cats and the cats pretreated with p-CPA were given the opiate antagonist naloxone (NAL, 2 mg/kg bolus followed by 2 mg/kg/hr). An additional 8 cats were given saline. The MABP and SPN activity are summarized below for 60 min, 65 min (5 min post NAL), and 80 min (20 min post NAL).

		Minu	tes of Olig	emia		
60 min		nin	65 min		80 min	
oups	MABP	SPN*	MABP	SPN	MABP	SPN
ine	39 ± 1	75 ± 6	38 ± 1	71 ± 6	33 ± 1	70 ± 7

NAL	41 ± 1	67 ± 4	51 ± 2+	69 ± 6	47 ± 3	70 ± 8
p-CPA/NAL	40 ± 1	53 ± 13	$60 \pm 4^+$	$58 \pm 13^+$	56 ± 5+	66 ± 7
*Activity expressed as percent of maximum.						

+ p<0.05 paired t test, compared to 60 min.

These data suggest that preganglionic sympathetic neurons were inhibited by an opiate-mediated pathway and a 5-HT mediated pathway during by an opiate-mediated pathway and a 5-HI mediated pathway during hemorrhagic hypotension. When both pathways were blocked (p-CPA/NAL group), there was a sustained increase in MABP with a concomitant increase in SPN activity. Administration of NAL in intact animals resulted in a small pressor effect at 5 min but SPN activity was unchanged and the pressor effect must be at a nonsympathetic site, perhaps in the periphery. (Supported in part by NIH grant #GM 30473, the American Heart Avecidation of Delaware and Ende Laboratorice.) Heart Association of Delaware, and Endo Laboratories.)

PNEUMOTAXIC CENTER INFLUENCES ON THE RESPIRATORY PERIODICITY OF 55.2 SYMPATHETIC NERVES. <u>C. A. Connelly and R. D. Wurster</u>. Dept. of Physiology, Loyola University Medical Center, Maywood, IL 60153.

Pneumotaxic center stimulation causes excitation or inhibition of phrenic activity, while ablation results in an apneustic breathing pattern in anesthetized, vagotomized cats. Pneumotaxic center stimulation also elicits cardiovascular pressor responses. (Mraovitch, Kumada and Reis,  $B\pi a (n Res., 232:57-75, 1982)$ . Th present study was conducted to 1) investigate effects of ipsi-and contralateral pneumotaxic center stimulations on the The and contralateral pneumotaxic center stimulations on the respiratory modulation of sympathetic activity, and 2) determine the effect of the apneustic breathing pattern, resulting from bilateral pneumotaxic lesions, on the rhythmic activity of sympathetic nerves. Phrenic and inferior cardiac sympathetic nerve activities were recorded in alpha-chloralose anesthetized, paralyzed, ventilated, vagotomized cats. pH, blood gases, end-tidal  $\rm CO_2$ , and rectal temperature were regulated within normal limits. Both ipsi- and contralateral stimulations (10- $100~\mu A$  ) of the parabrachial areas by stereotaxically positioned coaxial electrodes evoked activation (60 msec delay) followed by inhibition of sympathetic nerve activity. Evoked activity predominated over the intrinsic respiratory modulation of predominated over the intrinsic respiratory modulation of sympathetic activity, irrespective of the phase of respiration. Following direct current (DC) lesions of the stimulated areas, evoked responses were eliminated. An apneustic breathing pattern was acquired when lesions were optimally extensive. All lesions were histologically verified. During the apneustic phrenic pattern, sympathetic activity was enhanced at the onset and inhibited at the termination of inspiration. When blood pressure oscillations were coordinated with sympathetic extinution during componence cleur physics (Del)(min) were A11 activation during apneusis, slow rhythmic waves (9-15/min) were superimposed on the phrenic-linked activation and inhibition of superimposed on the phrenic-linked activation and inhibition of sympathetic activity. In conclusion, parabrachial areas have strong biphasic bilateral influences on sympathetic activity. Further studies are necessary to assess the nature of the slow sympathetic rhythms superimposed on the respiratory related sympathetic pattern during apneusis. (Supported by NIH Grant HL 27612)

IDENTIFICATION OF SPINAL SYMPATHETIC INTERNEURONS IN BARORECEPTOR-DENERVATED CATS. <u>Susan M. Barman</u>, Dept. of Pharmacology and Toxicology, Michigan State University, East Lansing, 55 3 MI 48824.

Do bulbospinal neurons mediate their effects directly on pregangli-onic sympathetic neurons (PSNs) or indirectly via spinal interneurons (INs)? Regarding this question, two types of neurons with cardiac-related (INS)? Regarding this question, two types of neurons with cardiac-related activity were identified in the vicinity of the intermediolateral nucleus (IML) of the upper thoracic spinal cord of the cat by Gebber and McCall (Am. J. Physiol. 231: 722-733, 1976). Type 1 neurons were classified as PSNs since they were antidromically activated by electrical stimulation of their axons in the cervical sympathetic nerve. Type 2 neurons could not be antidromically activated by stimulation of the cervical sympathe-tic nerve and, thus, were considered to be INs in a spinal sympathetic network (i.e. merusthetic D). Thet is the neuroinfolder. network (i.e., sympathetic INs). That is, the possibility was raised that the cardiac-related activity in sympathetic nerves is transmitted from the brain stem to PSNs via a pathway that contains INs in IML. This interesting proposal requires further testing for two reasons. First, type 2 neurons may have been elements of a nonsympathetic network that shared baroreceptor input with PSNs. Second, these neurons may have been PSNs whose axons were not distributed to the cervical sympathetic nerve. Thus, this study was initiated to evaluate more critically the proposal that The Study was initiated to evaluate more critically the proposal that the IML region contains sympathetic INs. The second thoracic IML was searched for neurons whose spontaneous discharges were correlated to 2-6 c/s slow wave activity in the inferior cardiac postganglionic sympathetic nerve of baroreceptor-denervated cats. Bilateral section of the carotid sinus, aortic depressor and vagus nerves eliminated the coupling of sympathetic and nonsympathetic networks via shared baroreceptor input. Spike-triggered averaging revealed two types of neurons in the IML region with activity synchronized to the 2-6 c/s sympathetic nerve slow wave. PSNs (n=13) were identified antidromically by activation of their axons in The T<sub>2</sub> white ramus. PSNs exhibited minimum interspike intervals of  $126\pm31$  ms and mean firing rates of  $0.9\pm0.2$  Hz. The second group of neurons with sympathetic nerve-related activity (n=13) had minimum interspite intervals of 27+7 ms and mean firing rates of 2.840.5 Hz. These neurons could not be antidromically activated by stimulation of the segmental preganglionic nerve. Thus, these neurons were classified as sympathetic INs antecedent to PSNs. Furthermore, the observation that the discharges of both PSNs and INs were synchronized to a point near the peak of the 2-6 c/s inferior cardiac nerve slow wave supports the view that the INs subserve a sympathoexcitatory function. (Supported by a Michigan Heart Association Grant-in-Aid and PHS Grant HL-13187.)

MEDULLARY RAPHE NEURONS WITH SYMPATHETIC NERVE-RE-LATED ACTIVITY: BARORECEPTOR INPUT AND SPINAL CONNEC-LATED ACTIVITY: BARORECEPTOR INFOT AND SPINAL CONREC-TIONS. S.F. Morrison and G.L. Gebber. Depts. of Pharmacol./Toxicol. and Physiol./Biophys., Michigan State Univ., East Lansing, MI 48824. We have previously used crosscorrelation analysis to identify single neurons in the cat medullary raphe nuclei with spontaneous activity related to inferior cardiac postganglionic sympathetic nerve discharge (NND). In the prevent study, we have algorified these neurons inter

(SND). In the present study, we have classified these neurons into 3 groups on the bases of their spinal connections and responses to barore-

ceptor reflex activation. Group 1 neurons were excited during 5 s periods of elevated carotid sinus pressure (i.e., baroreceptor reflex activation). Critically time-controlled collision tests demonstrated that these neurons could be driven antidromically by stimuli applied to the lateral funiculus of the cervical spinal cord and intermediolateral nucleus (IML) of the thoracic spinal cord. Threshold current for antidromic activation was as low as  $20 \mu A$ . Axonal conduction velocity of group 1 neurons (n=34) was  $1.9\pm0.7$  m/s. These observations lead to the conclusion that group 1 neurons are involved in mediating spinal sympathoinhibition of baroreceptor reflex Involved in mediating spinal sympathoinhibition of baroreceptor reflex origin. Group 2 neurons also were excited during baroreceptor reflex activation. However, group 2 neurons could not be driven antidromically from the spinal cord. Thus, these neurons may be involved in mediating supraspinal sympathoinhibition of baroreceptor reflex origin. Nine of 28 group 2 neurons were orthodromically activated with constant onset latencies by stimuli applied to regions of the cervical spinal cord from which group 1 neurons could be antidromically driven. The onset latencies of antidomic and orthodromic responses of group 1 and 2 neurons of antifaromic and orthodromic responses of group 1 and 2 neurons, respectively, were indistinguishable. These observations raise the possi-bility that group 1 and 2 neurons are synaptically interconnected.

The discharges of group 1 and 2 neurons were synchronized to the 2-6 c/s rhythm in inferior cardiac nerve activity when blood pressure was lowered so as to disrupt the phase relations between SND and the cardiac cycle (i.e., functional baroreceptor denervation). This observation indi-cates that raphe neurons in the baroreceptor reflex pathway also are

cates that raphe neurons in the baroreceptor reflex pathway also are contained in or receive input from the brain stem oscillator responsible for the 2-6 c/s rhythm in basal SND. Thus, these neurons mediate sympathoinhibition of non-baroreceptor as well as baroreceptor origin. Group 3 neurons were inhibited during periods of elevated carotid sinus pressure. These neurons could be driven antidromically from the lateral funiculus of the cervical spinal cord but not from the thoracic IML. Axonal conduction velocity of Group 3 neurons (n=18) was  $1.8\pm0.6$  m/s. Whether these neurons subserve sympathoexcitatory function remains to be determined. (Supported by PHS Grants HL-13187 and NS-06693.) 06693.)

NEURONS IN THE VENTROLATERAL MEDULLA PROJECTING DIRECTLY TO THE 55.5 INTERMEDIOLATERAL NUCLEUS RECEIVE BARORECEPTOR AND CHEMORECEPTOR AFFERENT INPUTS. <u>M. M. Caverson</u>, J. Ciriello and F. R. Calaresu. Department of Physiology, The University of Western Ontario, London, Canada, N6A 5C1. It has been shown that neurons in the ventrolateral medulla

(VLM) projecting directly to the region of the intermediolateral nucleus (IML) of the thoracic cord respond to electrical stimula-tion of the carotid sinus and aortic depressor nerves and of pressor sites in the paraventricular nucleus of the hypothalamus (Soc Neurosci. Abstr. 8:722, 1982). The present study was done to de-termine the response of VLM units that project directly to the (Soc. region of the IML to selective activation of peripheral barorecep-tors or chemoreceptors. Experiments were done in four chloralosed, paralyzed and artificially ventilated cats. Silent and spontan-eously active single units were identified in the reticular formation of the VLM by antidromic excitation to stimulation of function of the VLM by antidromic excitation to stimulation of func-tionally and histologically verified sites in the region of the IML at the level of  $T_2$ . Antidromically identified units were further tested for their response to activation of baroreceptors (2 ug/kg phenylephrine in 0.5 ml saline, i.v.) and chemoreceptors (20-60 ug sodium cyanide/0.1-0.3 ml saline via a cannula in the medial thyroid artery). Sixty-three units were antiformically excited in the VLM, of which 53 were spontaneously active and 10 silent. The firing frequency of 67% (42/63) of the units tested was altered by selective activation of either baroreceptors or chemoreceptors and 21 did not respond. Of the 42 responsive units, 27 increased their frequency of firing during chemorecepton acti-vation and also either decreased their firing frequency (n=5), increased their firing frequency (n=3), or were not affected (n= vation and also either decreased their firing frequency (n=3), increased their firing frequency (n=3), or were not affected (n= 19) by stimulation of baroreceptors. Fourteen of the 42 units de-creased their frequency of firing during chemoreceptor activation and also either increased their firing frequency (n=5), decreased their firing frequency (n=1), or were unaffected (n=8) by baro-receptor activation. One unit increased its firing frequency to stimulation of baroreceptors but was unaffected by chemoreceptor estimution. These results demonstrate that selective activation activation. of baroreceptors and chemoreceptors alter the activity of VLM neurons which send axons directly to the region of the IML, and suggest that these neurons are involved in complex integrative mechanisms in the control of the circulation.

RELATIONSHIP BETWEEN ARTERIAL PRESSURE (AP) AND ACTIVITY OF SPI-55.6 NALLY-PROJECTING NEURONS IN THE VENTROLATERAL MEDULLA (VLM) D.

Les Brown and Parrice G. Guyenet, Univ. of Virginia, School of Medicine, Dept. of Pharmacology, Charlottesville, VA 22908 The intermediate portion of the VLM contains a population of adremergic neurons which project to the lateral horn and are thought to be involved in regulation of the sympathetic nervous system. The present electrophysiological experiments were under-taken to explore the VLM for neurons with spinal projections and with discharge characteristics suggesting a role in the control of AP. Experiments were performed in Sprague-Dawley rats, anesthetized with urethane (1.5-2.0 g/kg), paralyzed and artificially respirated. End-tidal CO<sub>2</sub> was kept at 3.5-4.5%. AP was recorded via the femoral artery. Drugs were administered through the tail vein. Mean AP was 88 mmHg and could be lowered to 55 mmHg with the ganglionic blocker trimethaphan (1.2 mg/kg), suggesting the presence of sympathetic nervous system activity.

An area 0.2 to 1.0 mm posterior to the caudal end of the facial nucleus (identified with field potentials), 0.2 to 0.8 mm above the ventral brain surface, and 1.4 to 2.0 mm lateral to the midline was systematically explored for cells antidromically activa-ted with a stimulating electrode positioned in the cervical or thoracic spinal cord. Recording sites were verified by histolog-ical localization of fast green deposits and electrode tracks.

In 9 animals, the activity of 31 cells were studied in detail. Antidromic-orthodromic spike collision was demonstrated in 13 cells. Axonal conduction velocities ranged from 1.8 to 23.2 m/s. One group of cells (n=6) exhibited changes in firing rate oppo-site to spontaneous and drug-induced fluctuations in AP. Drugs used to modify AP were norepinephrine (50  $\mu$ g/kg), arg-vasopressin (3  $\mu$ g/kg), trimethaphan (750  $\mu$ g/kg), and sodium nitroprusside (75  $\mu$ g/kg). Five additional cells, which could not be antidromically activated, showed similar responses to changes in AP Two cells were completely silent at AP above 130 mmHg. Other cells were nearly silent when AP was raised to 90-150 mmHg. The effect of clonidine (20  $\mu$ g/kg) was tested on four cells. Activity was or cionidine (20  $\mu g/kg$ ) was tested on rour cells. Activity was decreased approximately 50%, based on estimates of expected firing rates during the lower AP which clonidine produced. During clonidine inhibition, activity remained sensitive to changes in AP. A second group of cells ( $\pi$ =4) exhibited changes in firing rate similar in direction to fluctuations in AP. Only one of the cells could not be antidromically activated. Three cells were completely silenced by lowering AP to 40-80 mmHg. These data show the presence in the VLM of at least two types

of spinally-projecting neurons which exhibit prominent changes in activity in response to changes in AP: one of these types may represent the Cl adrenergic neurons. Supported by NIH HL28785.

# ADRENALINE NEURONS OF ROSTRAL VENTROLATERAL MEDILLA 557

ADRENALINE NEURONS OF ROSTRAL VENTROLATERAL MEDULA MEDIATE BARO- AND CARDIOPULMONARY REFLEXES. A.R. Granata, D.A. Ruggiero, D.H. Park, T.H. Joh and D.J. Reis, Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 Adrenaline neurons of the Cl group of the rostroventrolateral medulla (RVL) project bilaterally to the intermediolateral column of the spinal cord (Ross et al., Brain Res., in press); they are also directly innervated by an ipsilateral projection from cardiovascular nucleus reacture collection: (NS) (Purefrage et al. Neuropic Abet, 1029). Wie innervated by an ipsilateral projection from cardiovascular nucleus tractus solitarius (NTS) (Ruggiero et al., Neurosci. Abst., 1982). We sought to determine if the NTS-C1 projection mediates the vasodepressor reflex (VDR) elicited by carotid sinus stretch (CSS) or electrical stimulation of the central end of the vagus nerve (VS). Rats were anesthetized, paralyzed and ventilated. Arterial pressure (AP) and heart rate (HR) was recorded. Lesions were placed electrolytically, and agents were microinjected into the brain in volumes of 0.1  $\mu$ l, delivared from a microinette. delivered from a micropipette. C1 neurons were localized immunocytochemically with antibody to PNMT. After bilateral electrolytic lesions of C1, MAP and HR fell to (from 99.8 + 6.2 mmHg were localized electrolytic lesions of C1, MAP and HR fell to (from 99.8 + 6.2 mmHg and 375.5 + 30 bpm to 50.1 + 5.2 mmHg and 223.6 + 15.0 bpm; n=8, p(.001), levels comparable to those produced by spinal cord transection. The VDR to CSS and VS were abolished. In all cases, the lesions destroyed the majority of C1 adrenaline neurons on both sides. To isolate the left NTS-C1 pathway and yet maintain MAP, a lesion was placed in the right (r) NTS. This lesion elevated MAP and reduced the VDR to CSS or VS by only 37% (before -31.7 + 2.8 mmHg; after lesion -18.9 + 3.5 mmHg. VDR to CSS of VS by only 37% (before  $-31.7 \pm 2.8$  mining; after lesion  $-19.9 \pm 3.5$  mmHg, -8.8, p < 0.5). The combined rNTS plus subsequent left  $\overline{C1}$  area lesions maintained MAP at normal levels ( $95.1 \pm 3.3$  mmHg before lesion  $87.4 \pm 3.5$  mmHg after lesion, n=9, NS). After the lesion of rNTS, a microinjection of tetrodotxin (TTX) (10 pmoles) or a lesion of the left C1 area abolished the VDR to CSS or VS (before,  $-30.6 \pm 4.1$ mmHg; after NTS/C1 lesions,  $-1.1 \pm 0.8$  mmHg, n=8, p $\langle 0.001 \rangle$ . A rNTS lesion was followed by a microinjection in the C1 area of kainic acid (400 pmole; n=6) or glutamic acid (200 nmole; n=6) which block neuronal (400 pmole; n=5) or glutamic acid (200 nmole; n=6) which block neuronal activity by persistant depolarization of neurons but not fibers. Both agents transiently increased AP during the first 15 min after the injection. Both abolished the VDRs 30 min after the injection when AP had returned to control levels. Complete blockade of the VDR was also achieved by lesioning the C1-spinal pathway in the dorsomedial medulla. Lesions avoiding both the C1 pathway and C1 perikarya, i.e. nucleus gigantocellularis pars dorsalis and ventralis (n=4), lateral or ventral event of the lateral termental field (n=3), spinel trigoninal ventral aspect of the lateral tegmental field (n=3), spinal trigeminal nucleus (n=3), vestibular complex (n=2), inferior olive (n=3), adjacent medullary serotonergic nuclei (n=3), or A1 area (n=3) did not alter VDR. The results are consistent with the hypothesis that: (a) CI neurons mediate the vasodepressor responses to stimulation of cardiopulmonary and arterial baroreceptors. (b) Afferent information reaches CI by an ipsilateral projection from NTS. (Supported by Grant HL18974).

ELECTROPHYSIOLOGICAL IDENTIFICATION OF NEURONS IN THE VENTROLAT-55.8 ERAL MEDULLA THAT SEND COLLATERAL AXONS TO THE PARAVENTRICULAR AND SUPRAOPTIC NUCLEI AND RECEIVE CARDIOVASCULAR AFFERENT INPUTS IN THE CAT. J. ciriello and M. M. Caverson. Department of Phys-iology, The University of Western Ontario, London, Canada N6A 5C1. Direct projections from neurons in the ventrolateral medulla (VLM) to the paraventricular (PVH) and supraoptic (SON) nuclei of (VLM) to the paraventricular (PVH) and supraoptic (SON) nuclei of the hypothalamus have recently been demonstrated both anatomically and electrophysiologically. The finding in these previous stud-ies that the anatomical distribution of neurons in the VLM pro-jecting directly to the PVH and SON overlapped, suggested the jecting directly to the rvH and Sok overlapped, suggested the possibility that some of these VLM neurons may send collateral axons to both hypothalamic structures. This possibility was in-vestigated in a series of experiments done in chloralosed, para-lyzed and artificially ventilated cats. The region of the VLM was initially explored for single units antidromically activated but attimized for single units antidromically activated by stimulation of histologically verified sites in the SON. Anti-dromically identified units were then tested for antidromic activation to stimulation of histologically verified sites in the PVH. Single units antidromically activated by stimulation of both sites were then tested for their orthodromic response to stimulation of the carotid sinus (CSN) and aortic depressor (ADN) nerves. Twenty-one units were identified in the VLM which were antidromically activated by stimulation of both the PVH and SON. Each unit followed similar frequencies of stimulation and had similar conduction velocities to stimulation of the PVH and SON. In add In addition, the antidromic spike evoked by stimulation of the PVH was always cancelled by the previously evoked spike to stimulation of always cancering by the previously evoked spike to stimulation of the SON. These units responded with latencies corresponding to conduction velocities of 1.4-11.4 m/s. Of the 21 antidromically identified units, 4 responded orthodromically by excitation only to stimulation of the CSN (mean latency, 9.0  $\pm$  2.1 ms) and 5 units were excited orthodromically to stimulation of only the ADN (mean latency) 1.2  $\pm$  2.0 ms) (mean latency,  $11.2 \pm 2.8$  ms). The remaining 12 units did not respond to either buffer nerve input. These data provide electrophysiological evidence of neurons in the VLM sending collateral axons to both the PVH and SON, and suggest that these neurons are involved in the release of vasopressin by SON and PVH magnocellular neurosecretory neurons during activation of cardiovascular afferent fibers.

55.9 RELEASE OF SUBSTANCE P FROM RAT SPINAL CORD AFTER KAINIC ACID INJECTIONS INTO THE VENTRAL MEDULLA. Y. TAKANO\*, J.E. MARTIN, S. LEEMAN\*, A.D. LOEWY. Depts. of Anatomy & Neurobiology and Pharmacology, Washington University School of Medicine, St. Louis, MO 63110 and †Dept. Physiology, University of

Massachusetts Medical School, Worcester, MA 01605 The ventral medulla plays a critical role in maintaining blood pressure by providing tonic excitation of sympathetic vasomotor neurons. Both serotonergic-like (Brain Res. 211:146, 1981) and substance P-like (Brain Res. 243:147, 1982) neurons of the ventral medulla project mainly to the intermediolateral cell column (and to a lesser degree to the ventral horn).

In the present study, we have measured the release of endogenous substance P or a substance P-like peptide (SP) from rat spinal cord after activating the ventral medulla with a unilateral  $1-\mu l$  microinjection of 40 mM kainic acid. These injections were centered on the area of the nucleus interfacicularis hypoglossi but spread approximately 1 mm rostrally and caudally. The spinal cords (the T1-L1 spinal segments) of rats anesthetized with sodium pentobarbital (35 mg/kg) were superfused in vivo at which solution periods balance (35 mg/kg) were superioused in vivo at a rate of 50  $\mu$ /min with phosphate buffered saline (Physiat Behav. <u>17</u>:1031, 1976). Every 10 minutes, a fraction was collected, freeze-dried, and subsequently assayed for SP by radioimmunoassay. Assay sensitivity was 6.5-9.0 gg/tube. Kainic acid injections caused an almost immediate elevation in mean arterial pressure which reached a maximum after 10-20 min. This is mediated by a descending pathway (Brain Res. 243:147, 1982) which excites the sympathetic preganglionic neurons. This re-sponse can be blocked by intravenous injections of a ganglionic blocker, hexamethonium (2 mg/kg). Concomitant with this rise in blood pressure is a 2-fold increase in the amount of SP in the superfusion samples which lasts for 20 minutes. In order to measure basal levels of SP, 10-min fractions from two rats had to be pooled (~10 pg/10 min). After kainic acid, the SP levels reached approximately 20 pg/10 min.

There are several possible neural pathways that could be the source of the increased SP-immunoreactivity that appears in the cerebrospinal fluid. The most likely pathway is the descending SP-like pathway from the ventral medulla to the sympathetic preganglionic cell column and ventral horn (Brain Res. 243:147, 1982). However, it is possible that intrinsic SP interneurons of the spinal cord could be activated by descending medullary pathways (Soc. Neurosci. Abstr. <u>8</u>:584, 1982). (Supported by USPHS Grants HL 25449 and AM 29876.)

LESIONS OF A1 AREA OF RAT VENTROLATERAL MEDULLA INCREASE CARDIAC OUTPUT AND ARTERIAL PRESSURE WITHOUT MODIF VING MECHANORECEPTOR REFLEXES. T. Imaizumi\*, A.R. Granata, A.F. Sved, E. Benarroch\* and D.J.Reis, (SPON, JOANNE CARROLL) Lab of Neurobiology, Cornell Univ. Med. Coll., New York, 55.11 NY 10021

NY 10021 In rabbits and rats, bilateral electrolytic lesions of the area of the caudal ventrolateral medulla containing A1 noradrenergic neurons (A1 area) produces fulminating hypertension (A1 hypertension) dependent, in part, on release of vasopressin (Blessing et al., Science, 1983; Imaizumi et al., Fed. Proc., 1983). We sought to characterize the hemodynamics of A1 hypertension and to determine if the area is involved in the mediating baro- and cardiopulmonary mechanoreceptor reflexes. Rats were anesthetized with halothane and the femoral artery and right jugular vein cannulated. A thermoprobe (YSI 520) was introduced from the right carotid artery to the aprice root. Cardiac output (CO) was International vehicular that a thermoprobe (1st 3st) was introduced from the right carotid artery to the aortic root. Cardiac output (CO) was measured by the thermodilution method. Basal values of mean arterial pressure (MAP), HR and CO were measured 30 minutes after discontinuation of halothane in the awake animal (control). Rats were then re-anesthetized, paralyzed and mechanically ventilated. Bilateral then re-anesthetized, paralyzed and mechanically ventilated. Bilateral electrolytic lesions were placed in the A1 area or nucleus tractus solitarius (NTS). Halothane and mechanical ventilation were discontinued. All measurements were done 60 min after lesion in the awake animal. After A1 lesions (n=5), MAP increased from 118 + 5 to 158 + 3 mmHg (p<0.005) while HR did not change (424 + 19 to 374 + 10 bpm; ns). CO increased from 4.13 + 2.1 to 4.99 + 2.8 (ml/min/100g); p<0.001) consequent to increased stroke volume (SV) (1.12 + 0.07X10<sup>-1</sup> to 1.25 + 0.11x1<sup>-1</sup> (mg/koat/100 cp. pc/0.05). remained unchanged  $(0.74 \pm 0.05 \text{ to } 0.035)$ . Vascular resistance (VR) remained unchanged  $(0.74 \pm 0.05 \text{ to } 0.83 \pm 0.11; \text{ ns})$ . The vasodepressor response elicited by supermaximal electrical stimulation of the central response elicited by supermaximal electrical stimulation of the central end of the transected vagus nerve (.8MA 2 msec pulse, 10 sec train) was examined in four anesthetized rats. Before A1 lesions, vagal stimulation decreased MAP by  $-33 \pm 7$  mmHg and after lesions, vagal stimulation decreased MAP by  $-33 \pm 7$  mmHg and after lesions, vagal produced by lesions of the NTS. In NTS hypertension (n=5), MAP increased from 118 + 3 to 176 + 2 mmHg (p<0.005); HR from 398 + 11 to 456 + 14 bpm (p<0.005); CO decreased from 39.0 + 2.0 to 24.8 ± 2.6 (ml/min/100g) (p<0.005) and SV from 0.92 to  $0.04 \times 10^{-1}$  to  $0.55 \pm 0.06 \times 1^{-1}$  (ml/beat/100g) (p<0.005). We conclude that: (a) A1 hypertension is largely due to increased CO in contrast to NTS hypertension in which CO is decreased while peripheral resistance is enhanced; (b) A1 hypertension is not the result of impairment of vasodepressor reflexes. (Supported by Grant HL18974). 55.10 CARDIOVASCULAR EFFECTS OF ELEVATED VASOPRESSIN AND NOREPINEPHRINE 

Electrolytic lesions of the ventrolateral medulia coinciding with the Al group of norepinephrine cells (Al lesions) produce acute hypertension, bradycardia and in some animals pulmonary oedema. Since Al neurons project to regions of the hypothalamus rich in vasopressin (AVP)-synthesizing cells, and since they were also able to demonstrate an increase in plasma AVP after Al lesions, Blessing et al (<u>Science 217</u>, 661, 1982) suggested that the increase in blood pressure after Al lesions is dependent on the release of AVP into the systemic circulation. In this study we have examined the effects of the vasopressin antagonist (VA; (CH<sub>2</sub>)<sub>5</sub>Tyr(Me)AVP) on the cardiovascular response to Al lesions and compared the responses after Al lesions with those produced by infusions of AVP. Arterial pressure, heart rate and cardiac output (Doppler

flow velocity) were monitored in conscious animals befor e and for one hour following Al lesions or infusions of AVP (2.0 ng/kg/min). In some animals VA was given prior to Al lesions (40 ug/kg iv) or to AVP infusions (10 ug/kg iv). Other animals were pretreated with propranolol and scopolamine so as to produce cardiac autonomic block. Blood samples were taken to

measure plasma AVP and norpinephrine (NE) levels. After typical Al lesions the animals developed the usual hypertension and bradycardia with a 25% fall in cardiac output and a 100% increase in peripheral resistance; in these animals and a 100% increase in peripheral resistance; in these animals plasma NE levels doubled and plasma AVP levels rose 10-20 fold. In other animals with less complete lesions, which developed the usual bradycardia without any hypertension, plasma NE did not rise but plasma AVP again rose 10-20 fold. Administration not rise but plasma AVP again rose 10-20 fold. Administr of VA before Al lesions had no effect on the hypertensive response but reduced the bradycardia by 50%.

Other rabbits not subjected to Al lesions received infusions of AVP which raised the plasma concentration of AVP some 10-20 fold to levels seen after Al lesions. The infusions depressed the heart rate and cardiac output by 10%, but did not elevate arterial pressure though peripheral resistance rose by 15%. These effects of AVP infusions were blocked by pretreatment with VA but were unaffected by administration of propranolol plus scopolamine.

Increased levels of plasma NE after Al lesions probably reflect increased activity of peripheral sympathetic nerves contributing to the vasoconstriction and hypertension. In contrast, the increased AVP levels may be more important in relation to the bradycardia than the hypertension and may be exerting a direct depressant effect on the heart.

55.12 NEURAL PROJECTIONS FROM PARAVENTRICULAR NUCLEUS RESPONSIBLE FOR CARDIOVASCULAR FUNCTION PASS THROUGH THE VENTROLATERAL MEDULLA.

NEURAL PROJECTIONS FROM PARAVENERICULAR NUCLEUS RESPONSIBLE FOR CARDIOVASCULAR FUNCTION PARAVENERICULAR NUCLEUS RESPONSIBLE FOR CARDIOVASCULAR FUNCTION PARAVENERIC THE VENTROLATERAL MEDULLA J.P. Porter\* and M.J. Brody. Dept of Pharmacology and the Cardiovascular Center, University of Iowa, Iowa City, IA. 52242. Previous studies in our laboratory showed that the cardio-vascular response produced by right PVN stimulation was not affected by a medullary knife cut designed to interrupt the neural connections of the right NTS. These data suggested that the neural pathways from the PVN which are responsible for car-diovascular control pass through the ventral medulla. Since these experiments were performed unilaterally, the possibility remains that crossing fibers mediated the effect. In the pre-sent investigation, studies were carried out to identify more clearly the pathway taken by projections from the PVN which subserve cardiovascular function by 1) eliminating crossing fibers with a medullary knife cut and 2) directly blocking neural conduction by injecting a local anesthetic into the pro-posed projection site; ventrolateral medulla. Rats were instrumented with miniaturized Doppler flow probes and a femoral arterial catheter. Changes in arterial pressure and mesenteric, renal, and hindquarter resistances were

pressure and mesenteric, renal, and hindquarter resistances were determined during right PVN stimulation before and after a total determined during right rvw stimulation before and after a total left medullary hemisection and after an additional right NTS undercut. The undercut was made by lowering an L-shaped knife 1.5 mm below calamus scriptorius on the midline and rotating it  $180^{\circ}$  to the right. Stimulation of the right PVN increased arterial pressure 15  $\pm$  4 mmHg, mesenteric and renal resistances arterial pressure 15  $\pm$  4 mmHg, mesenteric and renal resistances 261  $\pm$  40 and 69  $\pm$  22% respectively, and decreased hindquarter resistance 29  $\pm$  8%. Total left medullary hemisection lowered pressure from 94  $\pm$  3 to 69  $\pm$  4 mmHg but the response to PVN stimulation was unaffected. Right NTS undercut, in addition to the left medullary hemisection, did not affect baseline pressure and the response to right PVN stimulation was essentially intact except for a reduction in mesenteric constriction. In separate experiments, the left medulla was transected using the ventral approach. Injection of lidocaine (200 nl of 4% solution) into the right ventrolateral medulla reduced pres-sure and the response to PVN stimulation was significantly

sure and the response to PVN stimulation was significantly attenuated. Twenty min after lidocaine the response returned to control values.

These data support our original observation that the projec-tions from PVN which subserve vasomotor functions pass through the ventrolateral medulla. Monosynaptic projections pass through intermediolateral column of the spinal cord have been demonstra-ted to pass through ventrolateral medulla. We hypothesize that this monosynaptic projection subserves cardiovascular functions.

SELECTIVE ACTIVATION OF VASOCONSTRICTION AND VASODILATION BY MICROELECTRODE STIMULATION OF DISCRETE NUCLEI WITHIN THE AV3V 55.13

MICRORLECTRODE STIMULATION OF DISCRETE NUCLEI WITHIN THE AV3V REGION. M.J. Brody and M.L. Mangiapane, Dept. of Pharmacol. and the Cardiovasc. Center, U. of Iowa, Iowa City, IA 52242. Flectrical stimulation of the AV3V region with constant volt-age and large bipolar electrodes results in a complex pattern of hemodynamic responses: a small decrease in arterial pressure, hindquarter vasodilation, and mesenteric and renal vasoconstriction. The overall decrease in arterial pressure is not consis-tent with the protective effects of AV3V lesions against many tent with the protective effects of AV3V lesions against many forms of experimental hypertension. However, since separate constrictor and dilator projections could be simultaneously activated by AV3V stimulation, the purpose of the present exper-iments was to determine the regional blood flow and arterial pressure responses stemming from microelectrode stimulation of discrete nuclei within the AV3V region. Urethane-anesthetized rats were instrumented with femoral arterial catheters and with pulsed Doppler flow probes on the renal and superior mesenteric arteries and on the abdominal aorta. Constant-current stimula-tion (100 µamps) was delivered to the dorsal (DNM), anterior (ANM), and ventral (VNM) nucleus medianus, periventricular pre-optic nucleus (POP), and organum vasculosum-lamina terminalis (OVLT) region using stereotaxically-placed tungsten microelec-(001) region using screbolaritary-placed clugster microelectrodes. The following table summarizes the changes in hindquarter (HQ R), mesenteric (M R), and renal (R R) vascular resistance and arterial pressure (AP) produced by stimulation of these nuclei (NS = no significant change):

		PERCENT	CHANGE	
	AP(mmHG)	HQ R	RR	MR
OP	-13	-30	NS	NS
NM	-12	-33	NS	NS
NM	-13	-29	NS	NS
NM	+9	+16	+15	+15
VLT	+13	NS	NS	+120

These results indicate that the OVLT area of the AV3V region can generate an increase in arterial pressure. This is consistent with the findings that AV3V lesions attenuate or eliminate many forms of experimental hypertension. In addition, the finding that DMN stimulation elicits a pressor response and uniform vasoconstriction shows that stimulation of DNM evokes responses qualitatively similar to those elicited by subfornical organ (SFO) stimulation. This suggests that efferents of the SFO are (SFO) stimulation. This suggests that efferents of the SFO are activated by DNM stimulation, since these efferents are known to pass through the DNM en route to the AV3V and more caudal hypo-thalamic regions. Finally, the data indicate that vasodilator responses can be activated selectively within the AV3V region and that these effects are responsible for the overall depressor response elicited by AV3V stimulation.

MECHANISMS OF THE HEMODYNAMIC RESPONSES TO ELECTRICAL STIMU-LATION OF SUBFORNICAL ORGAN (SFO) IN NORMAL AND SINOAORTIC-55 14 DENERVATED RATS. M.L. Mangiapane and M.J. Brody, Dept. of Pharmacology and the Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242. SPON: Phillip G. Schmid, M.D.

Along with other circumventricular organs, the SFO has been anong with other circumventricular organs, the bronds been implicated in the mediation of pressor responses to circulating angiotensin II. We recently described increases in arterial pressure and regional vasoconstrictor responses produced by electrical stimulation (ES) of the SFO. The purpose of the electrical stimulation (ES) of the SFO. The purpose of the present experiments was to investigate the mechanisms and cen-tral pathways involved in the pressor and regional hemodynamic responses to SFO-ES in normal rats and in rats with sinoaortic responses to SFO-ES in normal rats and in rats with sinoaortic baroreceptor denervation. Rats were anesthetized with urethane and instrumented with femoral artery catheters and with pulsed Doppler flow probes on the superior mesenteric and renal arteries and on the abdominal aorta. Constant-current stimula-tion (200 µamps) was delivered to the SFO via stereotaxically placed tungsten microelectrodes. SFO-ES resulted in frequency-dependent pressor responses and vasoconstriction in all vascular beds tested. At 32 hz, these responses were: a 14 mmHg increase beds tested. At 32 hz, these responses were: a 14 mmHg increase in arterial pressure and resistance increases of 26% in the hindquarters, 33% in the mesenteric, and 13% in the renal bed. Movement of the electrode away from the SFO produced signifi-cantly smaller responses. Intravenous administration of a specific antagonist of the pressor activity of vasopressin significantly attenuated the responses to SFO-ES, while intra-venous administration of the ganglionic blocker chlorisondamine completely eliminated the responses. Corronal krife cute placed venous administration of the ganglionic blocker chlorisondamine completely eliminated the responses. Coronal knife cuts placed in the area of the lateral hypothalamus-medial forebrain bundle also attenuated the responses, while dorsally placed control cuts had no effect. Rats given sinoaortic denervation one week before the experiment had resting arterial pressure under urethane anesthesia which was similar to normal rats but yielded pressor and regional vasoconstrictor resonses more than twice as In addition, these sinoaortic-denervated rats responded large. to current levels as low as 30  $\mu$ amps. These results indicate that (1) electrical stimulation of the SFO elicits uniform vaso-These results indicate that (1) electrical stimulation of the 550 elicits uniform vaso-constriction which is most pronounced in the mesenteric bed; (2) the sympathetic nervous system is responsible for the effects but there may be facilitation of the responses by vasopressin; (3) a significant portion of the response is mediated through the medial forebrain bundle; (4) sinoaortic denervation greatly enhances the responses to SFO stimulation.

### FEEDING AND DRINKING: CENTRAL MECHANISMS I

56 1 BOMBESIN: ANOTHER PEPTIDE THAT INHIBITS FEEDING IN MAN. N.E.

Murahainen\*, H.R. Kissilef, J. Thornton\* and F.X. Pi-Sunyers, Obesity Research Center, St. Luke's Hosp. and Columbia University Institute of Human Nutrition, New York, N.Y. 10025 Exogenously administered bombesin (BBS) and cholecystokinin (CCK) produce a dose-related inhibition of food intake in animals without overt malaise. However, these neurogastrointestinal peptides are distributed differently and appear to modulate food in-

tides are distributed differently and appear to modulate food in-take by separate mechanisms, (1). To determine whether BBS, like CCK, also reduces food intake in man, eight lean healthy men received intravenous infusions of either .15 M saline or BBS (4.0 ng.kg. $-^1\min^{-1}$ ) during single course meals. The dosage of the synthetic BBS tetradecapeptide was esti-mated to be within physiological range. On 6 nonconsecutive days, each subject ate a 300 kcal breakfast 2.5 h before a saline infu-cion une started. Tan minutes affect the seline infusion began sion was started. Ten minutes after the saline infusion began, subjects received a 200 kcal preload of crackers and jelly. Seven minutes after the preload a switch was made to a second I.V. reservoir which contained either BBS or saline. On the first 2 days (adaptation) the second reservoir contained saline. On the last four days (test) it contained either BBS or S in a double-blind counterbalanced sequence such that each subject received 2 days of infusion with each. The design enabled measurement of both direct effect and residual effect (effect of treatment on succeeding days, e.g. by learning).

At the time either BBS or S from the second reservoir entered the vein (12 min. after consuming the preload) a liquified test meal of yogurt and fruit (0.91 kcal/g; 18% protein, 65% carbohy-drate and 17% fat) was consumed by straw. The infusion continued until 5 min. after the subject voluntarily stopped eating.

For the test days, intake was significantly for (5) less by 135.5 g  $\pm$  34.3 SE (direct effect) during BBS (722.9 g) than during S (858.4 g). Reductions in intake due to residual effect (82.8 g  $\pm$  41.4 SE) were not significant (p>.05). Meal duration was 1.63 min ( $\pm$ .87) less during BBS (7.45 min) than during S (9.10 min). There were no overt side effects, but in a postmeal questionnaire, the subjects reported a sick sensation in the stomach (where 0=none the subjects reported a sick sensation in the stomach (where onlone l=slightly, 2=moderately, 3=very, and 4=extremely) of greater magnitude (1.0  $\pm$  .23 SED) after BBS ( $\bar{x}$ =1.25) than after saline ( $\bar{x}$ =0.25). Reduction of food intake was not significantly related to the magnitude of the sick sensation ( $\mathbf{r}$ =47,  $\mathbf{p}$ >.05). These results are similar to those we observed with CCK (2,3). BBS may be

a natural appetite suppressant in man. (1) Stein and Woods <u>Peptides</u> 2:431, 1981, (2) Kissileff et al <u>Am. J.Clin. Nutr.</u> 34:154, 1981, (3) Pi-Sunyer et al <u>Physiol</u>. and <u>Behav</u>. 29:627, 1982.

THE ROLE OF DYNORPHIN (1-17) AND KAPPA OPLATE RECEPTORS IN THE REGULATION OF FEEDING. J.E. Morley and A.S. Levine. Neuroendocrine Research Lab, Minneapolis VAMC, Minneapolis, MN, 56.2 55417.

A growing body of evidence has suggested a role for endogenous A growing mody of evidence has suggested a role for endogeno opioid peptides in the modulation of feeding. Dynorphin is the putative endogenous ligand for the kappa opioid receptor. Much evidence has suggested a role for the kappa receptor in the regulation of food intake. We have examined the effect of ICV administration of dynorphin (1-17) and a variety of dynorphin formerstice of food intake. fragments on food intake. Also we examined the effect of the highly selective kappa opioid agonist U-50,488 on food intake and highly selective kappa opioid agonist U-50,488 on food intake and compared its effects to morphine and other opiate agonists. Dynorphin (1-17) ICV  $(20 \ \mu g)$  is a potent inducer of food intake with a latency of 17.2  $\pm$  3.1 minutes. This effect is highly specific as it is not accompanied by any significant changes in fluid ingestion, or time spent resting, grooming or moving. Dynorphin (1-17) did produce a slight increase in rearing behavior during the first 60 minutes following administration. This effect on feeding is blocked by naloxone. Neither dynorphin (1-8) or (1-9) increased food increasion. (1-8) or (1-9) increased food ingestion. Dynorphin fragments (1-10), (1-11) and (1-13) all increased feeding, but were not as potent as (1-17). Dynorphin (3-13) also increased feeding whereas the effect of (6-17) was not statistically significant. These studies suggest an important role for the non-opioid as well as the opioid moeity of dynorphin inducing feeding. Dynorphin B (rimorphin) also enhances food intake.

Dynorphin B (rimorphin) also enhances food intake. U-50,488 increases food intake after subcutaneous administration and its effect is blocked by naloxone in a stepwise manner. The early effects of U-50,488 were more marked than morphine and were produced at lower doses. The other kappa agonists, butorphanol, ketocyclazocine and tifluadom all significantly increased feeding. These studies suggest that the kappa opioid receptor is involved in modulation of food ingestion.

Ingestion. Based on these contradictory findings we suggest that the dynorphin receptor involved in the modulation of feeding consists of two segments (the "double-lock" concept). The non-opioid moeity of dynorphin acts as a key allowing access of the opioid moeity to the kappa-like feeding receptor. These studies confirm the highly specific role of dynorphin (1-17) in the induction of feeding and suggest a central role for kappa opioid receptors in the conid modulation of feeding. the opioid modulation of feeding.

BEHAVIORAL AND IMMUNOHISTOCHEMICAL ANALYSIS OF THE FUNCTION OF 56.3 CHOLECYSTOKININ IN THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS. P.L.Faris\*, A.C.Scallet, J.W.Olney, M.A.Della-Fera and C.A.Baile Depts Pathology, Psychiatry & Preventive Med, Washington Univ, and Monsanto Co, St. Louis, MO

The hypothalamic paraventricular nucleus (PVN) has been suggested by several investigators to be a critical site for the control of food intake. Both norepinephrine (NE) and opiate microinjections into this region increase food intake, whereas Suggested by several investigators to be a critical site for the control of food intake. Both norepinephrine (NE) and opiate microinjections into this region increase food intake, whereas cholecystokinin (CCK) injected directly into the PVN has been shown to inhibit NE-induced feeding (MCCaleb & Meyers, Peptides 1, 1980). Although it is generally believed that CCK does not play an important role in the central control of food intake in the rat, the action of CCK on NE-induced feeding and the fact that CCK immunoreactive cell bodies and fibers are numerous in the PVN prompted us to examine the effect of CCK microinjected into this region on spontaneous feeding. Following recovery from unilateral implantation of chronic indwelling cannulae in PVN, each rat received saline and CCK octapeptide (5 ng/ $\mu$ I) on alternate days in a counterbalanced fashion. Immediately following injection, animals were presented with a wet mash of powdered lab chow. The uneaten food and spillage was weighed one hour later. CCK significantly attenuated feeding (25%/pC0.05) under these circumstances. This finding suggests that either local circuit CCK neurons in PVN or extrinsic CCK inputs to PVN may play a role in the physiological regulation of food intake. Since CCK and opiates have been shown to be physiological antagonists of each other in several systems, including the guinea pig ileum assay, (Jurna & Zetler, Eur J Pharmacol 73, 1981) and opiate analgesia (Itoh & Katsura, Eur J Pharmacol 73, 1981) and opiate analgesia (Itoh & CK neurons might be anatomically connected in this region. Using standard immunohistochemical techniques, we have stained CCK and projate and CCK and projate and CCK and projate and CCK and projate and CCK and projate mathed as the of intages the region of the PVN. In superimposed drawings of these sections made using a drawing tube attachment to a light microscope, POMC nerve fibers arising from the arcuate nucleus appear to abut CCK cell bodies in the PVN. We have also employed double-staining techniques usi employed double-staining techniques Using a PAP-immunofluores-cence combination to demonstrate this same neural pattern of interaction between CCK and opiate-containing neurons. More definitive evaluation of POMC/CCK neuroanatomical connections in PVN awaits electron-microscopic application of double labeling methods. Supported in part by DA-00259, NS-20000 and RSA MH-38894 (JWO).

RATS RENDERED OBESE BY PARASAGITTAL HYPOTHALAMIC KNIFE-CUTS (KCs) DISPLAY NORMAL BROWN ADIPOSE TISSUE (BAT) RESPONSES TO ACUTE COLD. D.V. Coscina, J.W. Chambers\*, S. Hogan\* and J. Himms-Hagen\*. Sect. of Biopsychol., Clarke Inst. of Psychiatry, Toronto, MSI TR8; and Dept. of Biochem., Univ. of Ottawa, KIH BM5; Ontario, Canada. BAT is recognized as the major metabolic compartment for main-taining body temperature in response to environmental cold. BAT also appears to play a significant role in the thermogenic res-ponse which occurs after ingesting high-calorie foods. Recent research from our group suggests that the CNS mediation of these BAT responses may be dissociable. We have found that bilateral heat lesions of the medial hypothalamus (MH) which induce overeat-ing and obesity impair BAT responses to high-calorie foods but not cold. The present experiment was conducted to begin determining if BAT from rats made obses by KCs shows similar responses. Sub-jects were 48 adult female Holtzman rats housed singly with ad lib access to Purina Lab Chow and water. After 1 wk adaptation, 24 rats received stereotaxically-placed 3x3 mm bilateral to the mid-line and 6.5-9.5 mm below the dura. Another 12 rats received sham cuts in which the guide shaft was lowered without the knife extend ed; another 12 rats served as unoperated controls. Three wks after or unoper of 24 control bates were are one proced to 56.5 line and 6.5-9.5 mm below the dura. Another 12 rats received sham cuts in which the guide shaft was lowered without the knife extend ed; another 12 rats served as unoperated controls. Three wks after surgery, groups of 3 KC and 3 control rats were exposed to  $4^{\circ}$  C for 21 hrs before sacrifice; equivalent numbers remained at 28° C. KC rats ate 50% more food than controls and became very obese (200 + 8 g vs. 40 + 3 g gained by controls). Interscapular BAT weighed 50% more in KC rats, which was largely attributable to increased white fat content. Cold exposure enhanced BAT weight for both KCs and controls. Functional indices of BAT response (protein content, DNA content, cytochrome oxidase activity and mitochondrial GDP binding) indicated that tissue from KC rats was normal at 28° C. Exposure to  $4^{\circ}$  C elicited the same enhanced res-ponses in both groups. These findings imply that BAT responses to cold are not impaired by KCs, much as we found after MH lesions (Hogan et al., Am. J. Physiol., 243: E338, 1982). However, since both types of hypothalamic injury produced overeating and obesity, it might have been expected that BAT responses would have been en-hanced at 28° C. The lack of such increases suggests that BAT responses to high-calorie foods would be impaired. This latter prediction has been substantiated recently for MH-lesioned rats (Himms-Hagen et al., unpublished observations). Given the similar BAT profiles between MH-lesioned and KC rats, we would predict comparable impairments to high-calorie foods after KCs. Taken to-gether, the results of this work show an important role for neural pathways at the level of the hypothalamus in the regulation of BAT responses to diet-induced thermogenesis.

VENTROMEDIAL HYPOTHALAMIC LESIONS REDUCE BRAIN B-ENDORPHIN IN THE 56.4 RAT. C.W. Richard III, K.K. Vaswani\*, G.A. Tejwani, and J.R. Bianchine. Department of Pharmacology, The Ohio State University, College of Medicine, Columbus, Ohio 43210

Recent research has focused on the role of altered autonomic tone in the ventromedial hypothalamic (VMH) syndrome of obesity. VHM-lesioned animals exhibit increased parasympthetic tone (PT)

vnn-testoned animals exhibit increased parasympthetic tone (rf) and decreased sympathetic tone (ST). Deficits in brain neuro-transmitter systems after lesioning have not been identified. Intracerebroventricular (ICV) administration of β-endorphin (BE) has been shown to increase plasma glucose and catecholamines. This increased sympathetic outflow is blocked by chlorisonamine and bilateral adrenal sympathetcomy. ICV BE also decreases gastric acid secretion suggesting an inhibitory effect of BE on PT.

BE cell bodies are confined to the medial BE cell bodies are confined to the medial basal hypothalamus (MBH), immediately ventral to the VMH. BE fibers from this area project dorsally and anteriorally, innervating hypothalamic nuclei and the lateral septum. BE fibers turn caudally at the level of the thalamus, entering the pons mostly ventral to the cerebral aqueduct in midline peri-ventricular structures. Fibers spread laterally to innervate dorsal and lateral regions of the peri-aqueductal grav (PAG), locus coeruleus, n. solitary tract and dorsal motor n. vagus X. Thus, since exogenous ICV BE is associated with increased ST and decreased PT. and VMH lesions are associated with decreased

Thus, since exogenous ICV BE is associated with increased ST and decreased PT, and VMH lesions are associated with decreased ST and increased PT, we hypothesize that VMH-lesions causing obesity may destroy BE fibers en passage emanating from the MBH. In another animal model of obesity, injection of monosodium glutamate in neonatal animals causes gross obesity and is associated with destruction of hypothalamic and extrahypothalamic BE and up-regulation of opiate receptors. Ventromedial hypothalamic lesions were placed in five female Sprague-Dawley rats and sham lesions in six control rats. Animals were maintained on regular rat chow ad lib, with 12 hr light dark cycles. At the end of thirty days brains were dissected and the following brain parts assayed for BE by RIA: hypothalamus, PAG, and medulla. BE was reduced in the hypothalamus, PAG and medulla and medulla. BE was reduced in the hypothalamus, PAG and medulla by 64%, 71% and 66%, respectively. No change in pituitary BE was found.

In conclusion, VMH lesions causing hyperphagia and weight gain are associated with reduction in brain BE. This reduction in BE may be causally related to the altered autonomic tone found in this syndrome. (C.R. is supported by an O.S.U. Pre-doctoral Neuroscience

Research Fellowship Award).

PEPTIDERGIC MODULATION OF FEEDING IN THE NORMAL AND DIABETIC CHINESE HAMSTER. C.J. Billington\*, J.E. Morley, A.S. Levine and G.C. Gerritsen\*. Neuroendocrine Research Laboratory, Minneapolis VANC, MN and the Upjohn Co., Kalamazoo, MI. Diabetes mellitus is often associated with hyperphagia. Diabetes mellitus is often associated with hyperphagia. Diabetes has been shown to affect the opiate receptors involved in feeding and pain. Prompted by these observations, we sought to examine the feeding and satiety systems in the Chinese hamster, an animal that spontaneously develops diabetes mellitus in certain inbred strains. We used forty diabetic hamsters that were pair-matched to forty normal animals in these experiments. Quantitation of food eaten in baseline condition revealed that the diabetic animals were hyperphagic, consuming nearly twice as the diabetic animals were hyperphagic, consuming nearly twice as much dry food as the normals. The circadian variation in feeding much dry food as the normals. The circadian variation in feeding was maintained, though the diabetics ate more than normals at all times of the day. Both normal and diabetic animals were able to respond to variable degrees of starvation by transiently increasing eating, but this increase was seen principally in the first hour after restoring access to food and the animals do not make up for the degree of food deprivation. Putative satiety agents were examined using feeding driven by the natural peak in hunger augmented by six hours of starvation. In this system, a number of neuropeptides that inhibit feeding in other animals failed to show an effect: cholecystokinin, bombesin, somatostatin, glucagon, and pencreatic polyceptide. Calcitonin somatostatin, glucagon, and pancreatic polypeptide. Calcitonin suppressed feeding, and was more effective in the diabetics; an effect seen also in the diabetic rat. The dopamine antagonist, haloperidol, also suppressed feeding very effectively, and diabetics were much more sensitive to its effect - both as

56.6 PEPTIDERGIC MODULATION OF FEEDING IN THE NORMAL AND DIABETIC

- audocucs were much more sensitive to its effect both as percent inhibition relative to control and in absolute amount of food eaten. The opioid feeding system was found to be quite different than that found in the rat. Naloxone did not suppress eating in the peak feeding minimal starvation paradigm described above. Further, the opiate agonist, butorphanol, the most pottent minimal feeding in the rat could be induce rest potent opiate feeding inducer in the rat, could not induce feeding. However, normetazocine, a sigma opiate receptor agonist, did provoke feeding in the diabetic but not the normal Chinese hamsters. In vitro opiate receptor studies on brain membranes showed minimal H-naloxone and H-EKC binding over the 0.1 to 10 nM range. We conclude that the feeding and satiety systems in the
- Chinese hamster are markedly different from the well-described rat model and that diabetes appears to produce alterations in the appetite regulation system of these animals. The lack of high affinity opiate binding sites may explain the absence of a classical opioid feeding system in these animals.

DEFICIENCIES HYPOTHALAMIC HYPERPHAGIA. 56.7 IN

DEFICIENCIES IN HYPOTHALAMIC HYPERPHAGIA, NOREPINEPHRINE-INDUCED FEEDING, AND GLUCOPRIVIC FEEDING IN BRATTLEBORO RATS LACKING VASOPRESSIN. Paul F. Aravich\* and Celia D. Sladek (SPON: Gloria E. Hoffman). Departments of Neurology and Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642. The Brattleboro rat is characterized by a complete absence of vasopressin (VP), diabetes insipidus (DI), and several other physiological and behavioral abnormalities. We now report that the DI rat responds abnormally to three treatments that produce feeding in normal rats: parasagittal knife cuts in the perifornical hypothalamus, norepinephrine (NE) injections into the paraventricular hypothalamus (PVH), and glucoprivation induced by systemic injections of 2-deoxy-D-glucose (2DG). Adult female rats (Blue Spruce Animal Farms, Altamont, NY) served as subjects in two experiments. DI rats (age, 19-22 weeks; weight, 227.9 +3.4 g) and normal Long Evans (LE) rats (age, 13-15 weeks; weight, 266.5  $\pm$  4.8 g) participated in each experiment. Experiment 1 examined the effects of perifornical cuts on food intake and body weight; Experiment 2 evaluated the orexigenic effects of varying doses of NE (injected into the PVH) and 2DG (administered systemically). The of NE (injected into the PVH) and 2DG (administered systemically). The maintenance diets in Experiment 1 were a Purina chow diet followed by a 33% fat diet. Purina chow was the maintenance and test diet in Experiment 2. A 1-hr. test period followed the NE injections while a 3-hr. test period followed the 2DG injections. Experiment 1 revealed the hr. test period followed the 2DG injections. Experiment I revealed the following: When maintained on the Purina chow diet and observed for 30 days, the knife cuts failed to increase body weight in the DI rats in contradistinction to their effects in the LE group. The cuts did, however, produce an increase in caloric consumption by the DI group, though this effect was smaller and more transitory than that observed in the LE-cut group. When switched to the fat diet, the DI-cut group, but not the DI-sham group, was virtually indistinguishable from the LE-cut group in terms of weight gain and caloric intake. Experiment 2 found that the DI rat was deficient in NE feeding with respect to percent change from saline levels. A similar trend appears to exist (experiment in progress) with regard to 2DG-induced feeding. Three possible explanations for these findings are: a) VP directly influences feeding behavior perhaps via an interaction with the pituitary-adrenal axis; b) chronic vasopressin deficiency produces secondary changes in adrenal chronic vasopressin deficiency produces secondary changes in adrenal cortical function which, in turn, alter feeding; and/or c) other secondary changes resulting from chronic VP insufficiency (e.g., impaired water balance, excess oxytocin) account for the abnormalities. (Supported by NIMH Fellowship 1-F32-MH08872-01 and NIH Grant R01-AM-1976.)

THE EFFECT OF SEX STEROID HORMONES ON OPIOID MODULATION OF 56.8 FEEDING. A.S. Levine, B.A. Gosnell, M. Grace\*, J. Kneip\*, a J.E. Morley (SPON: S. Hsiao). Neuroendocrine Research Lab, and

Minneapolis, VAMC, Minneapolis, MN, 55417. Numerous studies have suggested a role for the endogenous opioid system in the modulation of appetite. Gonadal steroids play a role in food ingestion and weight gain and have been demonstrated to alter the concentrations of endogenous opioids in the CNS and to modulate opioid receptor number. For these reasons we investigated the effect of female gonadal steroids reasons we investigated the errect of remain gonadal steroids on the opioid feeding system. We used 4 groups of female rats: ovariectomized (ovx); ovx + estradiol 2  $\mu g/kg$  (ovx +  $E_2$ ); ovx +  $E_2$  + progesterone 2 mg/kg (ovx +  $E_2$  + P); ovx + P; and sham operated. In comparison to the ovx controls the  $E_2$ treated animals were 20 times less sensitive to naloxone. The the addition of the share to the sensitive to halo one as the overcontrols to suppress food intake and were 10 times more sensitive to halo one than the  $E_2$ 's. The addition of P to the  $E_2$  treatment improved the sensitivity of the animals to halo one but did not return it to the level of the share. Ketocyclazocine (CC) increased food intake significantly at 2 hours at both the 35 and the 3.5  $\mu$ M/kg doses in both the shams and E<sub>2</sub> + P groups without there being a significant effect in the ovx. At 4 hours the shams and the E<sub>2</sub> + P treated animals again showed significantly increased food intake at a lower dose than any of the other groups. At 6 hours, the highest KC dose signifi-cantly increased food intake in the ovx controls, shams and cantly increased food intake in the ovx controls, shams and E, treated animals. In order to further define the reason for the increased sensitivity to naloxone and decreased sensi-tivity to KC in ovx animals we measured ir-dynorphin in the cortex, striatum, hypothalamus, thalamus and brain stem in all of the animals following sacrifice. Ovx had decreased ir-dynorphin in the cortex compared to the sham and this was partially reversed by E, + P. P treatments tended to increase brain stem ir-dynorphin. In view of the finding that ir-dynorphin levels are decreased in ovx animals, it seems that altered receptor sensitivity is the most likely explanation for the observed effects of female sex hormones on coincid modulathe observed effects of female sex hormones on opioid modula-tion of feeding. These studies add to a growing body of litera-ture suggesting a role for the peripheral endocrine system in the modulation of opioid feeding systems. The alterations in the sensitivity of the opioid feeding system appear capable of explaining, in part, some of the effects of sex steroid hormones on feeding.

BEHAVIORAL COMPONENTS OF AREA POSTREMA LESIONS CAN BE PRODUCED SEPARATELY BY PARABRACHIAL LESIONS. R.C. Ritter and E.E. Ladenheim.\* College of Veterinary Medicine, Washington State University, Pullman, WA 99164 and WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 56.9 83843.

83843. Lesions of the area postrema (AP) and the adjacent nucleus of the solitary tract (NST) produce a constellation of behav-ioral changes which include loss of feeding in response to 2-deoxyglucose (2DG), overconsumption of highly palatable foods and exaggerated drinking in response to angiotensin II. We reasoned that by making lesions of anatomically distinct projections of the AP and NST, it might be possible to separate the individual behavioral components of lesions involving the projections of the AP and NSI, it might be possible to separate the individual behavioral components of lesions involving the AP and NST. The NST and the AP send projections to the parabrachial nuclei. In fact, Ohman and Johnson have reported that lesions which involve the lateral parabrachial nucleus cause rats to overdrink in response to angiotensin II. We compared the behavioral effects of lesions of the lateral (LPN) and the medial (MPN) parabrachial nuclei. We found that lesions of the MPN abolish or attenuate the increase in feeding lesions of the MPN abolish or attenuate the increase in feeding elicited by 20G administration. When food intake was monitored for six hours following 20G injection (200 mg/kg), sham-lesioned rats ate significantly more food  $(4.0\pm1.0 \text{ g})$  than they ate following a control injection of saline. Likewise, rats with lesions of the LPN also increased their intake in response to 20G  $(3.9\pm0.8 \text{ g})$ . Nevertheless, rats with MPN lesions did not increase their food intake significantly following 20G injection  $(0.5\pm0.3 \text{ g})$ . Our lesions of the parabrachial nuclei did not cause rats to overconsume palatable foods, such as cookies. When offered cookies for two hours, the consumption of all three groups was statistically indistinguisbable (shams cookies. When offered cookies for two hours, the consumption of all three groups was statistically indistinguishable (shams,  $6.5\pm0.3$  g; MPN-lesions,  $6.8\pm1.1$  g; LPN-lesions,  $7.1\pm0.8$  g). When injected subcutaneously with angiotensin II (0.5 mg/kg), sham-lesioned and rats with MPN lesions drank  $5.2 \pm 1.0$  g and  $8.6\pm1.1$  g, respectively. However, rats with lesions of the LPN drank significantly more ( $17.6\pm3.2$  g). Drinking by the three groups was indistinguishable following control injections. Our data demonstrate that lesions of discrete portions of the parabrachial nuclei produce some of the behavioral changes parabrachial nuclei produce some of the behavioral changes observed after lesions of the AP and adjacent NST. The parabrachial nuclei contain ascending projections and fibers of passage from the AP and NST. Therefore, these results suggest that the AP and adjacent NST may exert their effects on ingestive behavior via several different ascending projections.

AREA POSTREMA LESIONS INCREASE INTAKE OF PALATABLE FOOD IN VAGOTOMIZED RATS. <u>G.L. Edwards and R.C. Ritter</u>. Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164 and WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 83843.

We have previously demonstrated that lesions which destroy the area postrema  $\left(AP\right)$  and damage the adjacent nucleus of the solitary tract (NST) cause rats to overconsume highly palatable foods (Edwards and Ritter, Brain Res., 216: 265-276, 1981). Both the AP and the NST receive primary afferent terminals from the vagus nerve. Therefore, it is possible that overingestion of palatable foods by AP-NST-lesioned rats simply is due to the loss of abdominal vagal afferents. To test this hypothesis, we performed total subdiaphragmatic vagotomies on AP-NST-lesioned rats and on sham-lesioned rats. All of the rats were then tested for their response to a highly palatable solid food (cookies). Vagotomized, AP-NST-lesioned rats consumed signifi-(contes). Vagotimized, Ar-Asi-restoned rats consided significantly more cookies than hid vagotomized, sham-lesioned rats (p<.02) (see table). Vagotomized, sham-lesioned rats did not consume more than non-vagotomized, sham-lesioned rats. The fact that vagotomized hesioned rats consumed less than lesioned rats which were not vagotomized may be the result of damage to vagal efferents to the esophagus and stomach.

Consumption	of	Highly	Pal	atable	Food (	g)

	AP-NST-Lesioned	Sham-Lesioned
Vagotomized	$7.7 \pm 0.8$	$4.7 \pm 0.6$
Sham-Vagotomized	13.0 $\pm 0.9$	5.8 ± 1.1

Since the satiety effect of CCK-8 is mediated by the gastric vagus, we used the response to CCK-8 as a test for completeness of our vagotomies. Lesioned and sham-lesioned rats with intact vagi significantly reduced their food intake after injection of CCK-8. However, none of the vagotomized rats reduced their intake after CCK-8. This finding, taken together with post-mortem gross and histological examination, indicates that our vagotomise were successful vagotomies were successful. Our results demonstrate that overconsumption of palatable

foods by rats with lesions of the AP and NST is not due to loss of abdominal vagal afferents. The fact that rats with lesions of the AP and adjacent NST only overconsume highly palatable foods, suggest that this phenomenon results from altered responsiveness to gustatory cues.

57.1 LATERAL HYPOTHALAMIC LESIONS IMPAIR THE FEEDING OF RATS EXPOSED TO CHRONIC COLD. Gretchen L. Snyder\*, Edward M. Stricker and Michæel J. Zigmond. Psychobiology Program, Dept. of Psychology, Univ. of J. Zigmond. Psychobiology Program Pittsburgh, Pittsburgh, PA 15260.

Pittsburgh, Pittsburgh, PA 15260. Rats given bilateral lesions of the lateral hypothalamic (LH) area become aphagic and adipsic. Although these animals may gradually recover ingestive behaviors, they do not eat normally during acute glucoprivation or drink during acute dehydration. On the other hand, they increase their food intakes as control rats do when exposed to cold (Epstein & Teitelbaum, <u>Am. J. Physiol.</u> 213: 1159, 1967). The present experiments determined whether this response was in fact appropriate to their needs.

Twenty male Sprague-Dawley rats (300-350 g), each given LH lesions (1-2 mAmp, 10-15 sec), were tested 3-4 weeks after their recovery of ingestive behavior. Six weight-matched control rats recovery of ingestive behavior. Six weight-matched control fact also were studied. Body weights and intakes of Purina chow and water were monitored daily while animals were maintained in the colony room  $(22^{\circ}C)$  and after they were transferred to the cold  $(5^{\circ}C)$ . They were housed individually in stainless steel cages.

The control animals increased caloric intake by 40-50 kcal/day within 7 days and steadily gained body weight (+50 g by Day 20). Fourteen of the 20 rats with LH lesions also became hyperphagic in the cold, as reported previously. However, none of them gained weight normally; six simply maintained body weight while the other eight continually lost weight (-70 g by Day 20). Because their increases in caloric intake were comparable to those of controls, it appears that rats with LH lesions lost more calories as heat than did controls. In this regard, control animals decreased their tail temperatures from  $28^{\circ}$ C to  $17^{\circ}$ C when exposed to cold whereas the brain-damaged rats showed smaller and less consistent evidence of vasoconstriction. We conclude that rats with LH lesions have impaired feeding responses to cold stress, as revealed not by comparison with the intakes of control rats but by comparison with their own caloric needs.

The feeding deficits were more pronounced in the other six brain-damaged animals, which included the rats taking the longest brain-damaged animals, which included the rats taking the longest period of time to recover ingestive behavior after LH lesions. When placed in the cold, they did not become hyperphagic and lost body weight rapidly (-70 g by 4 days). However, when 5% sucrose solution was available instead of tap water, these animals increased their intake of ochow and were able to maintain their body weights. Thus, although LH lesions clearly impair both the physiological and behavioral responses to cold stress, minor edimensional contracts and the tartier conditions are allow the physiological and behavioral responses to cold stress, minor adjustments in the testing conditions may allow thermal homeostasis to continue even in rats with large brain lesions. (Supported by USPHS grants NS-16359 and MH-29670.)

57.2 INFLUENCE OF SURGICAL AND CHEMICAL SYMPATHECTOMIES ON THE LATERAL HYPOTHALAMIC LESION SYNDROME - 1, ACUTE EFFECTS. <u>Michael G.</u> Tordoff, Carlos V. Grijalva, Kalin A. Robinson,\* Larry L. Butcher, Donald Novin, Xavier Pi-Sunyer,\*\* Dennis A. VanderWeele.<sup>3</sup> "Dept. Psychology, UCLA, 2St. Luke's Hosp. Ctr., Columbia Univ., and "Dept. Psychology, Occidental College. Lateral hypothalamic (LH) lesions produce acute symptoms such are hypothalamic (LH). Dept.

Psychology, OLLA, "St. Luke's hosp. ttr., Columbia Univ., and "Dept. Psychology, Occidental College. Lateral hypothalamic (LH) lesions produce acute symptoms such as hyperthermia, hyperglycemia, hypoinsulinemia, diarrhea, and gastric pathology. The present research attempted to discover if the sympathetic nervous system (SNS) mediates these effects. In one series of studies, groups of 13-17 adult male Long Evans rats received adrenal demedullation (MDL), adrenalectomy (ADL), splanchnicectomy (SPL), celiac ganglionectomy (GAN) or a sham operation (SHM). Ten days later, following overnight food depriv-ation, they were given either LH lesions (1.2 mA x 15 sec, anodal current) or control (CON) surgery. Rectal temperatures and symp-toms were recorded prior to, 6 hr after, and 24 hr after surgery. Following the last observation, the rats were sacrificed, their stomachs analyzed for gastric pathology, blood taken for glucose and insulin assay, and tissue samples collected for verification of sympathectomy by catecholamine histofluorescence. The various sympathectomy procedures (MDL, SPL, GAN) had no effect on lesion-induced hyperthermia, gastric pathology, insulin levels or external symptoms. However, lesion-induced hyperglycem-ia was attenuated by SPL and blocked by GAN. (Glucose Xs (mg/dl): CON: SHH=108.6, MDL=107.2, SPL=106.8, GAN=102.9, LH: SHH=123.5, MDL=123.9, SPL=113.1, GAN=99.0). ADL-LH rats were hypothermic, showed greater gastric pathology and displayed lower levels of plasma insulin and glucose than the other groups. However, these effects were present in some ADL-CON rats, suggesting a general morbidity caused by surgical stress and food deprivation. In parallel studies, male rats neonatally sympathectomized by treatment with guarethidine (GUA) or given saline control inject-ions (SAL) were subjected to LH lesions when 70-90 days old. In one study, GUA rats displayed lower body temperatures prior to the lesion (GUA=7.3°C, SAL=37.3°C) and less increase in temper-ature after it (GUA=+1.0°C, SAL=+2.0°

These experiments found no role for circulating catecholamines in acute aspects of the LH syndrome. The SNS innervation of the abdominal viscera, as judged by surgical sympathectic denervation may be important in lesion-induced hyperglycemia. The attenuated hyperthermia and high fatality rate in lesioned rats with extensive denervation by chemical sympathectomy may argue for a role of the entire SNS in adaptation to the effects of the lesion.

INFLUENCE OF SURGICAL AND CHEMICAL SYMPATHECTOMIES ON THE LATERAL HYPOTHALAMIC LESION SYNDROME - II. CHRONIC EFFECTS. Donald Novin 57.3 Donald Novin, Michael G. Tordoff, and Carlos Grijalva. Dept. Psychology, UCLA, 90024

CA 90024. To determine if the sympathetic nervous system (SNS) is import-ant in long-term adaptation to the lateral hypothalamic (LH) lesion syndrome, adult male Long Evans rats were given surgical sympathectomies and LH lesions. Rats received adrenal demulla-tion (MDL), splanchnicectomy (SPL), celiac ganglionectomy (GAN), or a sham operation (SHM). As GAN surgery resulted in a loss of body weight, weight matched controls (GCON) were also included. Ten days later, the rats received either LH lesions (1.2 mA x 15 sec, anodal current) or control surgery (CON). LH rats were ini-tially tube-fed and then fed moist palatable foods to allow them to recover. The duration of each stage of recovery, food intake, and body weight were recorded. Sympathectomized-LH rats did not differ from SHM-LH rats in

and body weight were recorded.
Sympathectomized-LH rats did not differ from SHM-LH rats in rate of recovery, food intake, or body weight during the 90 days postlesion. (X body weights (N) on Day 90: CON: SHM=499.7 (9), MDL=504.6 (7), SPL=497.6 (7), GAN=473.7 (6), LH: SHM=279.5 (11), MDL=287.5 (11), SPL=316.2 (9), GAN=307.1 (11), GCON=289.0 (10)). To test the hypothesis that the impaired responsiveness of LH rats to glucopenia was due to lesion-induced SNS hyperactivity, all subjects received intraperitoneal injections of 2-deoxy-D-glucose (206). As some of the LH rats could not maintain themeselves on solid chow at this time, all rats were adapted to wet mash for 10 days. They were then given counterbalanced injection. Despite a large suppression of 2DG-induced eating in LH animals, no differences were present between sympathectomized and SHM LH groups at any time.

no differences were present between sympathectomized and SHM LH groups at any time. Although surgical sympathectomy had little effect on body weight or food intake, it might be argued that insufficient SNS destruction was present to produce noticeable effects. As an attempt to test this possibility some of the rats in the SHM and NDL groups received 25 40-mg/kg injections of the adrenergic neurotoxin guanethidine (GUA) over a 5-week period. The rest received saline (SAL) injections. Both LH and CON rats treated with GUA displayed severe diarrhea during, and for several weeks after, the treatment. Despite relatively high mash intakes, GUA-treated animals lost weight and most LH rats died, even when given access to a variety of palatable foods. The few LH rats that survived GUA treatment eventually regained weight to that of SAL-LH rats, but did not surpass it.

SAL-LH rats, but did not surpass it. In summary, no evidence was found to suggest that the SHS is involved in chronic aspects of the LH-lesion syndrome.

FAILURE TO ALTER BODY WEIGHT AND FAT, LINEAR GROWTH AND CALORIC INTAKE AND EPIDIDYMAL AND BROWN (BAT) ADIPOSE TISSUE WEIGHT BY FEEDING OF JUNK FOOD IN WEANLING RATS WITH VENTROMEDIAL HYPOTHALA-MICLESIONS (WMAL RATS). Lee L. Bernardis and Paul J. Davis\*. Div. Endocrinology, VA Med. Ctr., and Dept. of Med., SUNY at Buf-falo, Buffalo NY 14215.

Weanling male VMNL rats and sham-operated controls were maintained on lab chow for two post-operative weeks. The WNNL rats became obese (Lee Index) in the presence of normal food intake and body weight gains. The two groups were then divided into two sub-groups each: one subgroup continued to receive lab chow, whereas groups each: one subgroup continued to receive lab ChOW, Whereas the other subgroup was in addition fed various junk food items for 72 days. Rats from each group were killed weekly, beginning 51 days post-operatively. As expected, VMNL rats showed higher car-cass fat, epididymal fat pad weights, BAT lipid, and fat deposited per kcal eaten. They also exhibited reduced linear growth and provided more and propaging. per kar eaten. They also exhibited reduced there grown and epididymal and BAT protein. Unexpectedly, they also showed in-creased body weight and body weight gained per kcal ingested. Whereas no diet effect was noted in body weight, length, fat, cal-oric intake, epididymal weight and BAT weight, lipid and protein, diet effects were evident in reduced carcass and epididymal pair protein in junk-fed rats as well as fat deposited per kcal eaten. A time effect was noted in body weight and length, carcass fat, total kcal ingested, epididymal weight and protein, BAT protein and fat deposited per kcal eaten. Quite notably, an interaction between diet and lesion effect was noted in only one parameter, i.e., epididymal protein. A diet and time interaction was noted in body weight, total calories eaten, epididymal weight and BAT protein. An effect of lesion x time was seen in body weight and linear growth, carcass fat, epididymal weight and protein and fat deposited per kcal eaten. Finally, an interaction diet x lesion x time was evident in body weight and epididymal weight. Positive correlations were calculated between carcass fat and body weight, Positive total caloric intake and epididymal pad weight for all groups ex-cept the junk food-fed controls. Highly significant correlations were also found between carcass fat and Lee Index, but only in the WML rats is Negative correlations were observed between carcass fat and BAT protein, again only in the two VML groups. The data show that, in contrast to mature rats, weanling VML rats will not increase their caloric intake when fed palatable junk foods, will not gain weight and deposit fat in excess of VML rats fed lab Not gain weight and depositiat in excess of VMNL facts led lab chow and will not show gross changes in BAT. The efficiency of food utilization appears enhanced in both VMNL groups, as shown by the increased amount of fat deposited per kcal eaten. In con-trast to one report, neither intact nor VMNL rats will show an increase in linear growth when fed the junk food diet.

57.5 HYPOTHALAMIC-HINDBRAIN FEEDING INHIBITORY SYSTEM. AN EXAMINATION UTILIZING ASYMMETRICAL KNIFE CUTS AND HRP HISTOCHEMISTRY. A. L. Kirchgessner\* and A. Sclafani, Dept. Brooklyn College of CUNY and Biopsychology Pn Medical Center of SUNY, Brooklyn, New York 11210. Dept. of Psychology, ogy Program, Downstate

Extensive evidence indicates that the hyperphagic-obesity syndrome results from the i hypothalamic interruption of a fiber system interconnecting the anteromedial hypothalamus with the caudal brainstem. This system extends caudally from the area of the paraventricular nucleus (PVN) to at least the level area of the paraventricular nucleus (PVN) to at least the level of the midbrain. From this region the trajectory of the system has not been determined. In an attempt to extend the mapping of this feeding inhibitory system knife cuts were made in the following groups of female rats: Group UNILATERAL (n=8) received a unilateral parasagittal knife cut through the medial hypothalamus (MH cut); Group PONS (n=8) received a unilateral coronal knife cut through the caudal pons combined with a contralateral MH cut; Group MEDULLA (n=5) received a unilateral coronal knife cut through the rostral medulla combined with a contralateral MH cut; Group SHAM (n=8) received sham surgery. Food intake (high fat diet) and body weight were recorded for 21 days postoperatively. The rats in the PONS group were hyperphagic following surgery, and their postoperative weight gain exceeded (p<.05) that of the UNILATERAL rats, as well as that of the SHAM animals

surgery, and their postoperative weight gain exceeded (p<.05) that of the UNILATERAL rats, as well as that of the SHAM animals (100 vs. 53 and 22 g/21 days). The rats in the MEDULLA group, on the other hand, failed to overeat or gain reliably more weight than did the SHAM rats (38 vs. 22 g). To identify the location of the cell bodies whose fibers were severed by the pontine knife cut, similar cuts were made in additional rats using an HRP-coated knife. The results of this experiment implicate PVN efferents as part of the hypothalamic -hindbrain feeding inhibitory system. This is further indicated by the results of a third experiment in which hyperphagia was produced by small pontine knife cuts placed in the trajectory of the PVN efferents. These findings demonstrate that the hypothalamic feeding

findings demonstrate that the hypothalamic feeding These findings demonstrate that the hypothalamic feeding -inhibitory system extends to the level of the caudal pons, and follows the path of PVN efferents. The failure of the medullary knife cut, which was only 1 mm caudal to the pontine cut, to produce overeating and obesity indicates that either the feeding inhibitory fibers do not extend into the rostral medulla or that the medullary cut produced additional damage which interfered with the expression of the hyperphagia syndrome. This issue is currently being input interfered currently being investigated.

RELATIONSHIP OF HYPERINSULINEMIA TO HYPERPHAGIA IN RATS WITH 577

RELATIONSHIP OF HYPERINSULINEMIA TO HYPERPHAGIA IN RATS WITH VENTROMEDIAL HYPOTHALAMIC LESIONS. Bruce M. King, Randy L. Smith, and Lawrence A. Frohman. Department of Psychology, University of New Orleans, New Orleans, LA 70148, and Division of Endocrinology and Metabolism, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267. Animals with lesions of the ventromedial hypothalamus (VMH) are hyperinsulinemic both after a fast and in response to an oral glucose load (King & Frohman, <u>Neurosci.</u> <u>Biobehav. Rev.</u> 6: 205-214, 1982). Basal hyperinsulinemia is abolished by both subdiaphragmatic vagotomy (King, Phelps, & Frohman, <u>Am. J. Physiol.</u> 239: E437-E441, 1980) and adrenalectomy (King, Banta, Tharel, Bruce, and Frohman, <u>Am. J. Physiol.</u>, in press), but the hyperphagia, obesity, and postabsorptive hyperinsulinemia persist after the vagal transections and after corticosterone administration in adrenalectomized animals. The present experiment tested the hypothesis that postabsorptive hyperinsulinemia is due in part to pancreatic β-cells made hyperresponsive on the basis of hyperphagia. Plasma insulin and glucose levels were assayed after a 4-hr fast and 17 minutes after the initiation of a meal (6 ml sweetened milk in 7 minutes) in animals with sham lesions (SVMH, n=8), VMH animals maintained at preoperative body weight by food restriction (LVMH, n=7), and VMH animals fed ad libitum (OVMH, n=6). The OVMH animals displayed a mean weight gain of 8.1  $\pm$  0.7 g/day during the first 12 days after surgery. The LVMH animals displayed a mean weight gain of 9.6  $\pm$  1.0 g/day when fed ad libitum for 10 days at the conclusion of the experiment. The basal and postabsorptive

weight gain of 8.1  $\pm$  0.7 g/day during the first 12 days atter surgery. The LVMH animals displayed a mean weight gain of 9.6  $\pm$  1.0 g/day when fed ad libitum for 10 days at the conclusion of the experiment. The basal and postabsorptive insulin levels of the LVMH animals were significantly lower than in OVMH rats, but significantly greater than in SVMH animals (P<0.005). Plasma glucose levels did not significantly differ under the basal condition, but the postabsorptive glucose levels of the OVMH rats were significantly lower than the other two groups (P<0.05). It is concluded that the postabsorptive insulin responsiveness, as well as the basal hyperinsulinemia, is the result of both a primary effect of the lesion and of hyperbhagia. hyperphagia.

VENTROMEDIAL HYPOTHALAMIC AREA LESIONS INDUCE GRADUAL CLIMBING OF THE SET-POINT FOR BODY WEIGHT IN RATS. J. D. Hallonquist and J. S. Brandes. Dept. of Psychiatry, Mount Sinai Hospital, Toronto, Ontario, Canada M5G 1X5. We recently reported (Physiol. Behav. 27: 709-713, 1981) that electrolytic (DC) lesions in the area of the ventromedial hypo-thalamus (VMH) in adult rats produce not one, but two abnormal stages of weight gain; a linear phase of fattening rather than a plateau of body weight was found to follow the dynamic phase. The present experiment supports our previous speculation that the continuous, post-dynamic fattening may reflect a lesion-induced gradual elevation of the set-point for body weight. In adult female rats maintained on ad lib Purina Lab Chow pellets, bilateral DC or radiofrequency (RF) lesions of the VMH area produced a negatively-accelerated curvilinear phase of fattening which lasted 10 weeks, followed by a linear phase of

fattening which continued at a rate approximately double that of operated control rats of the same age (DC lesions, p < .001; operated control rats of the same age (DC lesions, p < .001; RF lesions, p < .01). There was no significant correlation (p > .05) between the weight gained during the first 10 post-lesion weeks and the rate of weight gain over the 10th to 20th week postlesion period, across either DC or RF-lesioned rats. During the second, linear phase of fattening, we food-restricted the lesioned rats between the 20th and 26th weeks postlesion. Compared to the rate of weight gain in the linear phase prior to food restriction, the rate over the same weight range following release from food restriction was significantly greater (p <.001) for both DC and RF-lesioned rats. Furthermore, by the 40th postlesion week, the lesioned rats had approached the weight 40th postlesion week, the lesioned rats. Furthermore, by the Hoth postlesion week, the lesioned rats had approached the weight they would have been if not food-restricted. These findings suggest that both DC and RF lesions of the VMH

which either follows or is superimposed on an immediate elevation of the set-point for body weight, and which either follows or is superimposed on an immediate elevation of the set-point responsible for the initial, curvilinear phase of weight gain. Consistent with two separate effects of such of the set-point responsible for the initial, curvilinear phase of weight gain. Consistent with two separate effects of such lesions is the lack of a significant correlation between dynamic phase weight gain and post-dynamic rate of weight gain. VMH area lesions may initiate a primary, slowly developing adipocyte proliferation and/or preadipocyte recruitment in at least some fat depots of adult rats. Thus, the steadily climbing set-point for body weight in our lesioned rats may reflect a gradual hyper-plasia beginning immediately postlesion. Furthermore, this mechanism may prove to be a useful model for human idiopathic obesity which also reflects a continuous upward shift in the level at which fat stores are regulated. 57.8 CHANGES IN CONSUMATORY BEHAVIOR OF THE RAT FOLLOWING LESIONS OF THE TRIGEMINAL LEMNISCUS AT THE LEVEL OF THE VENTROBASAL THALAMUS. <u>D. E. Reddick\* and S. H.</u> <u>Hobbs</u> (SPON: R. K. Thomas). Dept. of Psychology, Univ. of Georgia, Athens, GA 30602 and Dept. of Psychology, Augusta Coll., Augusta, GA 30910. Recent research has produced results differing over the prospace of pertamentive consumptions deficits.

the presence of postoperative consumatory deficits following damage to the rat trigeminal lemniscus (LTr). In the present study, placement of lesions at the LTr's terminal coursing within and beneath the thalamic medial ventrobasal complex (VBm) was followed (body weight, food and water consumption), but also by behavioral observations of feeding. Significant dif-ferences occurred between lesion and control groups on postsurgically recorded measures of body weight and postsurgically recorded measures of body weight and water consumption. Differences in the measure of food utilized were non-significant. However, observed aphagia (no feeding) following food deprivation was significantly greater for the lesion group than the control group. These findings imply that lesion-induced food consumption deficits were here hidden by inefficiencies which produce sometimes massive spill-age and suggest that terminal LTr lesions within the VBm adversely affect rat consumatory sensory processes. 57.9 ANORECTIC EFFECT OF CALCITONIN: LOCALIZATION TO THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS. <u>R. de</u> <u>Beaurepaire\*, and W.J. Freed.</u> Preclinical Neurosciences Section, Adult Psychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.
