ADENOSINE RECEPTOR SITES IN PURIFIED ATRIAL SARCOLEMMAL 166.11 MEMBRANES. M.L. Michaelis, T.E. Kitos\*, and T. Mooney\*, Ctr. Biomedical Research, Univ. of Kansas, Lawrence, Kansas 66045. Adenosine (Ado) has multiple regulatory actions in many organ systems. It has marked depressant actions in the CNS and potent negative inotropic effects in the heart. Ado receptors may be coupled to adenylate cyclases which in some cells are inhibited and in others stimulated by the ligand's interaction with its receptor sites. The properties of Ado receptors in CNS have been studied through analysis of the binding interactions between Ado analog and Ado recognition sites in particulate fractions. The studies reported here involve the use of radioligand binding assays to delineate the basic characteristics of Ado binding sites in a preparation of highly purified sarcolemmal membranes from bovine atria. Binding of the stable Ado analog [3H] 2-chloroadenosine

Binding of the stable Ado analog [9H] 2-chloroadenosine (2-ClAdo) to atrial myocyte membranes was measured in 20 mM potassium phosphate buffer, pH 7.4, at 4°C for 120 min, and incubations were terminated either by rapid filtration or by centrifugation at 4°C. Specific [9H] 2-ClAdo binding was determined by subtraction of the radioactivity present in samples incubated in the presence of 100  $\mu$ M L-phenylisopropyladenosine (L-PIA), a potent adenosine agonist. Scatchard analysis of the data obtained over a ligand concentration range from 0.5-750 nM indicated the presence of multiple binding sites, and the best indicated the presence of multiple binding sites, and the best least squares fit of the data to the Scatchard equation required least squares fit of the data to the Scatchard equation requiried the assumption of 3 classes of binding sites with interactions among the sites. The estimated  $B_{max}$  and  $K_D$  values for the 3 sets of sites were: 40 fmol/mg protein and 4 nM; 260 fmol/mg protein and 63 nM; and 5,500 fmol/mg protein and 667 nM. The displacement of bound [<sup>3</sup>H] 2-ClAdo by several N<sup>6</sup>-substituted Ado agonists also confirmed the presence of at least 2 classes of binding sites. The relative order of notencies for various exonists in The relative order of potencies for various agonists in displacing [<sup>3</sup>H] 2-ClA4o was: 2-ClAdo > N<sup>6</sup>-cyclohexyladenosine > L-PIA > N<sup>6</sup>-methyladenosine > D-PIA. The IC50 for two xanthines believed to be receptor antagonists were: isobutylmethylxanthine, 0.6  $\mu\text{M}$ , and theophylline, 2.1  $\mu\text{M}$ . Adenosine uptake inhibitors such as papaverine and desmethyldiazepam required concentrations greater than 100  $\mu\text{M}$  to produce 50% inhibition. These studies greater than too un to produce 50% inhibition. These studies confirm the presence of specific Ado binding sites in atrial sarcolemmal membranes, and the preliminary pharmacological characterization suggests that these sites may be of the  $A_1$  type which are generally associated with inhibition of adenylate cyclase activity. (Supported by the Amer. Heart Assoc., Ks. Affiliate, NS 16364, and BRSG RR5606.)

166.13 DISCRIMINATION OF MULTIPLE S-2 BINDING SITES BY METHYSERGIDE IN CORTICAL TISSUES OF MOUSE AND HUMAN BRAIN, <u>DC Morgan</u>, J <u>Marcusson</u>, and <u>CE Finch</u>. Andrus Gerontology Center and Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191.

Serotonin binding sites in the CNS have been classified as S-1 sites (labeled by H-serotonin) and S-2 sites (cortical sites labeled by H-spiperone) (Peroutka and Snyder, Fed. Proc. 42:213).

labeled by <sup>3</sup>H-spiperone) (Peroutka and Snyder, Fed. Proc. 42:213). We report here the resolution of two previously unidentified S-2 binding components which we designate S-2A and S-2B. Membrane preparations of 3whole mouse cortex or human frontal cortex were incubated with <sup>3</sup>H-spiperone in 10 mM MOPS/TRIS buffer (pH 7.2) and 4 mM CaCl with or without competing drugs, for 30 minutes at 25<sup>o</sup> and separated from free ligand by filtration. Ketanserin, a selective S-2 antagonist, pgoduced biphasic displacement curves. The initial phase (10<sup>o</sup> - 10<sup>o</sup> M ketanserin) displaced approximately 40% of the total binding. A second phase occured at ketanserin concentrations in excess of 10<sup>o</sup> M because at the transition concentrations in excess of 10 m excession of the set with extensively boiled tissue preparations. Hence, this second phase was assumed to represent displaceable nonspecific binding. A concentration<sub>3</sub> of  $0.5 \ \mu\text{M}$  ketanserin was subsequently used to define S-2 specific <sup>3</sup>H-spiperone binding.

Methysergide, a more general serotonin antagonist, also produced biphasic displacement curves. However, unlike ketanserin, the initial phase  $(10^{-} - 10^{-} \text{ M})$  displaced only 20% of the total binding, and no displacement from boiled membranes was obtained with methysergide. When methysergide competitions were conducted in the presence of a saturating concentration of ketanserin (0.5  $\mu$ M), no additional displacement by methysergide was observed. Thus the two phases of methysergide competition involve the same the two phases of methysergide competition involve the same binding sites as the S-2 specific phase of ketanserin displacement. We refer to the fraction of H-spiperone binding with high affinity for methysergide as S-2A binding sites, and that fraction with a lower affinity as the S-2B subtype.

Saturation analyses using 0.3  $\mu$ M methysergide to discriminate S-2A from S-2B indicated equal densities of S-2A and S-2B binding sites in human frontal cortex (130 fmoles/mg protein) and whole mouse cortex (50 fmoles/mg protein). The affinity of H-spiperone for S-2A sites was twice that for S-2B sites (K<sub>d</sub> = 0.67 and 1.45 nM respectively) nM respectively)

The biphasic displacement of <sup>3</sup>H-spiperone by methysergide was unaffected by guanine nucleotides, protease inhibitors, or the ionic constituents of the assay and wash buffers. Other experiments reported at this meeting indicate age related reductions in S-2A binding density with no change in S-2B recognition sites (Marcusson et al). (Glenn Fndn & NIA AG-03272)

GLUCOCORTICOIDS ENHANCE PGE1-STIMULATED CYCLIC AMP FORMATION IN CULTURED MURINE NEUROBLASTOMA CELLS (CLONE NIE-115). Carlos Forray\* and Elliott Richelson. (SPON: R. Weinshilboum) Depts. of Psychiatry and Pharmacology, Mayo Clinic & Fdn., Rochester, MN 166.12 55905

Adrenal glucocorticoids have been shown to regulate adrenergic receptor-mediated adenylate cyclase stimulation in brain tissue and in glial cells in culture. This finding has led to the hypo-thesis that glucocorticoids play an important role in endocrine-mediated receptor sensitivity changes. We determined whether these effects could be generalized to other receptors coupled to adenylate cyclase. To do these studies, we used murine neuroblas-toma clone NLE-115 cells possess prostaglandin E1 (PGE1) receptors coupled to adenylate cyclase, since several neuroblas-toma clones had been shown to be sensitive to induction of enzymes by glucocorticoids. Corticosterone (Cort) or dexamethasone (Dex) added to the incu-bation medium of NLE-115 cells, induced a 40% increase in PGE1-stimulated AMP (cAMP) formation. This increase was due to an increase in the maximum response without an apparent change in the ED50. The time course of the facilitation of the PGE1 response had a latency of 18 to 24 hrs and remained constant for at least 72 hrs following Dex or Cort incubation. The dose response curve for the steroids gave an ED50 of 2.6 µM for Adrenal glucocorticoids have been shown to regulate adrenergic

at least 72 hrs following Dex or Cort incubation. The dose response curve for the steroids gave an ED<sub>50</sub> of 2.6  $\mu$ M for Cort and of 0.08  $\mu$ M for Dex, suggesting that these hormones were active within the range of physiological concentrations. Other steroids such as progesterone,  $\beta$ -estradiol and testosterone had no significant effect on the PGE<sub>1</sub> response or in altering the glucocorticoid effects. Inhibitors of RNA or protein synthesis actinomycin-D (1  $\mu$ g/ml) or cycloheximide (30  $\mu$ M), respectively, blocked the effect of glucocorticoids.

blocked the effect of glucocorticoids. These results suggest that glucocorticoids alter receptor regulation in neural cells through a genomic mechanism of action and that these effects may be functioning for other receptors coupled to adenylate cyclase. Furthermore, this study suggests that cells in culture may be a suitable model for studying these hormonal effects at the molecular level. (Supported by Mayo Foundation and USPHS Grant MH27692.)

167.1 CO-LOCALIZATION OF VASOPRESSIN, NEUROPHYSIN AND NORADRENALIN CO-DOCALIZATION OF VASORESSIN, NEOROFHISIN AND NORADAEMALIN IMMUNOREACTIVITY IN SUBPOPULATIONS OF RAT LOCUS COERULEUS AND SUBCOERULEUS. <u>A.R.Caffé<sup>\*</sup></u>, <u>F.W.van Leeuwen<sup>\*</sup></u> and <u>H.W.M.Steinbusch<sup>+</sup></u>, Netherlands Institute for Brain Research, 28, JJdijk, 1095 KJ Amsterdam; <sup>+</sup>Free University, Medical Faculty, Dept. of Pharmacol., Van der Boechorststraat 7, 1081 BT Amsterdam, The Netherlands. It was recently shown that vasopressin (VP) and neurophysin (NF) immunoreactive cell bodies are present not only in the supraoptic, paraventricular and suprachiasmatic nuclei, but also in a variety of perikarya within the bed nucleus of the stria terminalis (BST), medial anygdaloid nucleus (AME), dorsomedial hypothalamus (DMH) and locus coeruleus (LC). In the BST, AME and DMH, parvocellular VP and NF elements are present while mediumsized, multipolar cells (width 15-20  $\mu$ , length 24-30  $\mu$ ) are prom inent in the LC and subcoeruleus (Van Leeuwen and Caffé, 1983; Caffé and Van Leeuwen, 1983).

In order to reveal whether or not noradrenalin (NA) and VP co-exist within perikarya of the LC,  $10 \sqcup$  thick cryostat sections were collected. The rats had been treated with colchicine 24-48 h prior to fixation with 4% paraformaldehyde and 0.5% glutaraldehyde. Consecutive sections were incubated according to the unlabeled antibody enzyme method, using antibodies raised against VP, NA and NF.

NA immuno-reactive cell bodies could be demonstrated throughout the entire LC and subcoerulear area. A considerable number of NA-immunoreactive cells within the LC was also immunoreactive for VP or NF, suggesting co-localization of these compounds. With regard to the biological relevance of such co-existence,

it is of interest that vasopressin appears to facilitate memory consolidation processes, via modulation of noradrenergic transmission in limbic midbrain terminals of the dorsal noradrenergic bundle (Kovács et al., 1979). The mechanism of this interaction is still unknown.

Caffé, A.R., Van Leeuwen, F.W., Cell Tiss. Res., in press. Kovács, G.L., Bohus, B., Versteeg, D.H.G., Neurosci. 4,1529,1979. Van Leeuwen, F.W., Caffé, A.R., Cell Tiss. Res. 228, 525, 1983.

167.2 LEU-ENKEPHALIN, DYNORPHIN AND BOMBESIN CONTENTS OF PURIFIED NOR-ADRENERGIC VESICLES. R. L. Klein<sup>1</sup>, R. Day<sup>2\*</sup> and S. Lemaire<sup>2</sup>. Depts. of Pharmacology, U. Miss. Med. Ctr.<sup>1</sup>, Jackson, MS 39216 and U. Sherbrooke<sup>2</sup>, Quebec, Canada JH 5N4.

Antibodies specific to Leu-enkephalin(L-ENK), Dynorphin 1-13 (DIN), Bombesin(BOM), Vasoactive intestinal polypeptide(VIP), neurotensin(NT) and Substance P(Sub-P) were used to analyse by RIA a highly purified fraction of large dense cored noradrenergic vesicles(LDVs) which can be prepared from the bovine splenic nerve. Preliminary data indicate that VIP, NT and Sub-P were not

nerve. Preliminary data indicate that VIP, NT and Sub-P were not above detection limits in the purest LDV fractions, but traces of VIP occurred in the whole nerve homogenate. LDV fractions contained L-ENK at 1.3-1.7 nmol/mg protein, representing a 69-fold purification from the 10,500xg for 15 min supernatant of the nerve homogenate in which > 85% L-ENK was particulate. The data are uncorrected for peptide losses during processing or for non-specifically adsorbed protein in the vesicle function of for monial content. fraction or for vesicle purity. LDV fractions contained DYN at 0.19-0.25 nmol/mg protein repre-

senting an average 66-fold purification and > 87% DYN was particulate in the nerve homogenate.

LDV fractions contained BOM at 0.83-0.95 nmol/mg protein representing an average 77-fold purification and > 95% BOM was particulate in the nerve homogenate.

A preliminary ratio of L-ENK: DYN: BOM in the purest LDV fraction is  $\sim$  7:1:4. By radioreceptor and HPLC assays, approximately equal amounts of L-ENK and M-ENK have been shown to co-exist with noramounts of L-ENK and M-ENK have been shown to co-exist with nor-adrenaline(NA) in the LDVs (Wilson et al., 1980) and have been calculated at 0.4-0.8 mool ENKs/mg protein(corrected) which is equivalent to 58-100 molecules ENKs/LDV (Klein et al., 1982). After trypsin treatment, cryptic ENK activity can be unmasked to double the value by radioreceptor assay. The present RIA data confirm about a two-fold higher content of L-ENK compared to the radioreceptor assay and that DYN accounts for a portion of the  $0.00^{\circ}$  UV coiedda ef > 600 but < 5000 belevation in the content of the con 40-60% LDV opioids of > 600 but < 5000 Daltons in size. Thus, least two synthesis pathways for opioids can be inferred to be Thus, at present in the splenic nerve, estimated to consist of  $\sim$  98% sympathetic C-fibers.

167.3 DIFFERENTIAL RELEASE OF SOMATOSTATIN-14 AND SOMATOSTATIN-28(1-12) FROM RAT HYPOTHALAMUS. C. Bakhit, L. Koda, R. Benoit\*, J.H. Morrison and F.E. Bloom. A.V. Davis Center, The Salk Institute, La Jolla, CA 92037 and \*Laboratories of Neuroendocrinology, The Salk Institute.

Recent investigations aimed at identifying the pro-somatostatin precursor have resulted in the characterization of two somatostatin-related peptides: somatostatin-28 (SS28), which contains the original tetradecapeptide somatostatin-14, and the dodecapeptide somatostatin-28(1-12) which corresponds to the NH2-terminal portion of \$528. In an effort to investigate how the somatostatin-related

repetides are stored and released we have examined the in vitro release of SS14 and SS28(1-12)-like immunoreactivity (LI) from rat hypothalamic slices following in vivo or in vitro treatment rat hypothalamic slices following in vivo or in vitro treatment with cysteamine, a drug previously shown to have specific depleting effects of SS14 but which does not influence the tissue stores of SS28 or SS28(1-12)-L1 (Bakhit et al, Regulatory Peptides, in press, 1983). Cysteamine (300 mg/kg, s.c. 4 hrs) administration to rats resulted in a marked depletion of hypothalamic SS14 and a profound decrease in the potassium evoked in vitro release of SS-14 without a significant change in the content or release of SS2(1-12)-L1. Further, cysteamine (1mM) administered in vitro enhances the spontaneous release and markedly potentiates the potassium evoked release of SS14. In vitro erosure to cysteamine, however, does not alter either the warkedly potentiates the potassium evoked release of Sola. In vitro exposure to cysteamine, however, does not alter either the spontaneous or potassium evoked release of SS28(1-12)-LI. Selective immunohistochemical visualization of hypothalamic neuronal cell bodies and fibers following cysteamine administration shows a marked disappearance of the SS14 immunoreactive fibers and cell bodies with no apparent change in the SS28(1-12) immunoreactive fibers or cell bodies. These data suggest, that in rat hypothalamus, SS14 and SS28(1-12) are either stored and released separately from the same terminals or are released from different neuronal systems. This work supported by USPHS HL 25457, AA 07273, AA 03504, and MRC (Canada) fellowship to R.B.

ACETYLCHOLINESTERASE AND SOMATOSTATIN-LIKE-IMMUNOREACTIVITY COEXIST IN A SUBPOPULATION OF NEURONS IN CULTURES FROM RAT CEREBRUM. J. R. DELFS. C. H. ZHU\* AND M. A. DICHTER. DIVISION OF 1674 ACETICLANESIANES AND SOMAIOSTAING-THEE IMMUNOREACTIVITY COEXIST IN A SUBPOPULATION OF NEURONS IN CULTURES FROM RAT CEREBRUM. J. R. DELFS. C. H. ZHU\* AND M. A. DICHTER. DIVISION OF NEUROSCIENCE, CHILDREN'S HOSPITAL, BOSTON, MA 02115. In brains of persons with senile dementia of the Alzheimer type, there are low levels of both choline acetyltransferase and of somatostatin (Davies et al. Nature 288:279-280, 1980). These abnormalities suggest that somatostatinergic and cholinergic systems may interrelate in the brain. In cultures of rat cerebrum, somatostatin-like-immunoreactivity (SOM-LI) can be localized by histochemistry to neurons (Delfs et al. Nature 283:676-677, 1980). Other studies have shown that neurons in these cultures stain for acetylcholinesterase (AChE) (Dichter and Mesulam, J.Histochem. Cytochem.29:306-308, 1981). In the present study, we asked whether SOM-LI and AChE might coexist in individual neurons. For cultures, 15 to 16 day fetal rat cerebri were dissected, mechanically and enzymatically dissociat-ed, and grown in a modified MEM with 5% rat serum. At 5 to 6 weeks cultures were treated with 100 nM colchicine for 24 hours, then fixed, and stained, first for AChE by the acetylthicholine-copper sulfate method of Koelle, and then by the indirect immunofluorescent method of Coons with a rabbit anti-SOM antibody (furnished by Seymour Reichlin). Out of 391 neurons identified prospectively to contain AChE, 59 (15%) were also seen to stain for SOM-LI. Out of 140 neurons identified prospectively as staining for SOM-LI, 31 (22%) were also seen to stain for AChE. Of the neurons staining for both SOM-LI and AChE, 13% were monopolar, 18% were bipolar or bitufted, 17% were stellate, and 13% resembled pyramidal neurons.

pyramidal neurons. When an identical double staining procedure was

when an identical double staining procedure was carried out for cholecystokinin-octapeptide-LI (CCK-8-LI) and AChE, simultaneous staining for both substances in the same neuron was never observed. These results demonstrate that in cultures of rat cerebrum there exists a subpopulation of neurons in which SOM-LI and AChE coexist. Whether the AChE activity in these neurons signifies cholinergic or a cholinocentive neurons must await further studies

COEXISTENCE OF SUBSTANCE P. CORTICOTROPIN RELEASING FACTOR AND 167.5 COEXISTENCE OF SUBSTANCE F, CONTICUTRUFIN RELEASING FACTOR AND ACETYLCHOLINESTERASE IN NEURONS OF THE NUCLEUS TEGMENTI DORSALIS LATERALIS, J. A. Olschowka, D. I. Diz\* and D. M. Jacobowitz, Lab. of Clinical Science, NIMH and NIGMS, Bethesda, MD 20205. The two neuropeptides, substance P (SP) and corticotropin re-leasing factor (CRF), have both been described as having a wide distribution throughout the rat central nervous system. The patterns of terminal arborization and location of immunoreactive cell bodies are similar for these two peptides in a number of regions, e.g. medial frontal cortex (MFC), septum, thalamus, nucleus tegmenti dorsalis lateralis (ntdl), etc. The cell bodies of the ntdl are particularly interesting for they have been shown to contain acetylcholinesterase (AChE) and project to the MFC, septum and thalamus. The purpose of the present study is to 1) determine if SP, CRF and AChE coexist within neurons of the ntdl and 2) determine to what areas they may project.

To determine the coexistence of SP, GRF and AChE, male rats were given colchicine (100  $\mu$ g, intracisternal), perfused 2 days later and processed for the indirect immunohistochemical procedure. Cryostat sections of the ntdl were stained first for CRF, photographed and then the antiserum was removed by elution with acidified KMnO, (Tramu, G. et al., J. Histochem. Cytochem. 26: 322, 1978). The sections were then restained for SP and photographed. Alternatively, sections were stained for AChE and then SP.

The projections of ntdl neurons were determined by injecting rats with either True Blue (2.5%, 42-300 nl) or Fast Blue (5%, 33-300 nl) into the MFC, anterior cingulate cortex, parietal cortex, septum or dorsal thalamus. After 4-7 days, the rats were given colchicine (100 µg, intracisternal), perfused 2 days later and processed for either SP or CRF immunofluorescence or ACLE histochemistry

Following the staining of the same ntdl section for both SP and CRF, there appeared to be complete coexistence of the two peptides. CRF, there appeared to be complete coexistence of the two perides AChE histochemistry revealed a larger number of neurons within the ntdl, a small proportion of which also contained SP. Following the injection of True Blue or Fast Blue into the MFC, septum or thalamus, moderate numbers of cells within the ipsilateral ntdl were labeled, as well as a few neurons contralaterally. A small proportion (20-50%) of these dye-labeled neurons were observed to also contain AChE, SP or CRF. However, not all AChE, SP or CRF cells contained the fluorecent dye. Dwe injections into the also contain Acht, SF or CKF. However, not all Acht, SF or CKF cells contained the fluorescent dye. Dye injections into the anterior cingulate or parietal cortices, areas with no SF or CKF inmervation, failed to label ntdl neurons. These results suggest that SF, CKF and Acht coexist within a subpopulation of ntdl neurons and that these cells project to a number of forebrain regions.

167.PO VIP. VIP, CCK, AND MET-ENKEPHALIN IN PIA ARACHNOID AND CEREBRAL ARTERIES AFTER UNILATERAL LESIONS OF CAT TRIGEMINAL GANGLIA. M.A. Moskowitz, T.V. Norregaard\*, L.-Y. Liu-Chen, R. Weatherwax, \* S. Michener\*, V.L.W. Go\*. Neurology and Neurosurgery Ser-vices, Mass Gen Hosp, Harvard Medical School, Boston, MA 02114; Gastroenterology Dept, Mayo Clinic, Rochester, MN 55905. Trigeminovascular projections to cat cerebral arteries com-

rigeminovascular projections to cat cerebral arteries com-prising the circle of Willis have been identified by axonal transport studies using horseradish peroxidase histochemistry (Mayberg et al, Science '81). The neurotransmitter, substance P has been found in some of these perivascular fibers as deter-mined by immunohistochemical and RIA data following unilateral trigeminal ganglionectomy (see Abst.: Liu-Chen, et al; Norregaard, et al). The neuropeptides, vasoactive intestinal poly-peptide (VIP), cholecystokinin (CCK), and met-enkephalin (m-ENK) have also been localized in primary sensory neurons where may function as putative neurotransmitters or neurothev modulators.

In this report, we examined the pia arachnoid and its accompanying arteries for the presence of iVIP, iCCK and im-ENK cat by RIA; when found, we then determined by lesioning studies, whether or not iVIP was contained within sensory scuales, whether of not PIP was contained within sensory neurons projecting from triggminal ganglia. Levels of VIP were approximately 35 and 1 fm/mg protein in cat cerebral arteries and triggminal ganglia, respectively; immunoreactivity ex-hibited parallel displacement over a 100-fold dilution. The authenticity of VIP was determined by gel filtration chroma-tereactive (cerebrate CSE) authenticity of VIP was determined by gel filtration chroma-tography (Sephadex G-50 resin) and co-elution of VIP-like activity with synthetic peptide. Trigeminal lesions were per-formed surgically in 13 cats using an extradural approach and microsurgical methods. Three to six weeks later, animals were sacrificed, pia arachnoid harvested from each hemisphere, and account performed on extraduce of bioma becomenter. assays performed on extracts of tissue homogenates. IVIP levels in cat vessels decreased by approximately 35% on the side of the lesion. Decreases of similar magnitude were measured for im-ENK but not iCCK. Levels of this peptide increased significantly in pia and arachnoid ipsilateral to the lesion. These preliminary findings indicate that iVIP and im-ENK arise in part from trigeminal nerve fibers which surround and invest arteries of the circle of Willis. ICCK, shown recently to coexist with iSP in primary sensory neurons, did not appear to be contained within perivascular trigeminal fibers, at least as reflected by increases in levels measured after unilateral tri-geminal lesions. Other sources of iVIP, im-ENK and iCCK in addition to the trigeminal ganglia remain to be determined.

SUBSTANCE P IN THE ASCENDING CHOLINERGIC RETICULAR SYSTEM. 167.6 SUBSIANCE P IN THE ASCENDING CHOLINERGIC RELICULAR SYSTEM. S.R. Vincent, K. Satoh and H.C. Fibiger. Depts. of Psychiatry and Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5. The existence of an ascending cholinergic reticular system

has been postulated by Shute and Lewis to arise from cells in the midbrain and pontine tegmentum. These cholinergic neurons have recently been identified immunohistochemically using antibodies to choline acetyltransferase. We have found that pharmacohistoto choiline acetyltransterase. We have found that pharmaconisto-chemical protocol for acetylcholinesterase utilizing diisopropyl-fluorophosphate (DFP) can also be used to visualize selectively these cells. In the rat, the neurons in this cell group begin in the midbrain reticular formation just caudal to the substantia nigra and extend dorsocaudally in the lateral portion of the nigra and extend dorsocaudally in the lateral portion of the mesencephalic and pontine reticular formation. In the rostral pons they extend medially in the dorsolateral tegmentum and enter the periventricular gray, forming a dense cluster in the latero-dorsal tegmental nucleus of Castaldi, just medial to the rostral pole of the locus coeruleus. We have discovered that all of the bolies of the focus coertains, we have discovered that all of the cholinergic neurons in this particular cell group can also be specifically stained by a novel enzyme histochemical technique based on NADPH-diaphorase activity. This method stains the cell bodies, dendrites and fibers of these cholinergic neurons making possible detailed morphological studies of this cell group. Also Also. NADPH-diaphorase histochemistry can be readily combined with immunohistochemistry. A population of substance P neurons has been found in the midbrain and pontine tegmentum, in particular within the laterodorsal tegmental nucleus. Some of these substance P cells appear to project to forebrain areas such as the septum and prefrontal cortex. By combining the indirect immunofluorescence technique for substance P with NADPH-diaphoimmunofluorescence technique for substance P with NADPH-diapho-rase histochemistry or acetylcholinesterase pharmacohisto-chemistry, we have found that about one third of the cholinergic neurons in these tegmental areas display substance P immunoreac-tivity. Thus substance P and acetylcholine coexist in a popula-tion of neurons in the midbrain and pontine tegmentum that project to the forebrain. Supported by the Medical Pescarch Council of Condo

CHARACTERIZATION OF A PUTATIVE NICOTINIC ACETYL CHOLINE RECEPTOR FROM RAT BRAIN, G. Kemp\*, L. Stone\*, B. Morley and M. McNamee, Neurosciences Program, Univ. of Alabama in Birmingham, Boy's Town Institute, Omaha, Neb., and the Dept. of Biochem. and Biophysics, University of California, Davis, California. <sup>127</sup>I-a-Bungarotoxin (<sup>127</sup>I-BGT) is known to bind with high affinity and almost absolute specificity to nicotinic acetylcholine receptors (AChRs) 168.1

almost absolute specificity to neoring acetyclosing receptors and in a solution and from the mammalian neuromuscular junction and from the second state of electronic second seco Isolated from the mammatian neuronnactuar junction and Login the electric organs of a variety of elasmobranches and teleosts. <sup>125</sup> I-BGT also binds to a closely related protein found in mammalian autonomic ganglia and CNS tissue. It has been suggested that the identity of this protein is that of the ganglionic nicotinic AChR long known to be responsible for primary synaptic connections in the autonomic nervous system.

Using a protocol developed to purify AChR from mammalian skeletal muscle, this protein has been purified to apparent homogeneity. Purifimuscle, this protein has been purified to apparent homogeneity. Purifi-cation steps include Naja naja siamensis  $\alpha$ -toxin (cobratoxin) biospecific adsorption, DEAE-Sephadex ion exchange chromatography, and con-canavalin A-Sepharose 4B-adsorption. The purified product binds ap-proximately 3 pholes of <sup>122</sup>I-BGT per µg of protein. Denaturing polyacrylamide gel electrophoresis reveals polypeptide chains 47,000, 50,000, 57,000, and 62,000 datons. The affinity ligand ('H)-maleimidobenzyl trimethylammonium iodide ('H) MRTab hore hore used to establish that the ligand binding site in

The attinuty figand ( 1/2-inaterinational transformation 1/2, 1/2the 50K chain.

It is well documented that peripheral A ChRs bind BGT at sites on each of two  $\alpha$ -chains. When bound to a cobratoxin-Sepharose 4B biospecific adsorption matrix, it can be shown that only one of these sites adsorption matrix, it can be shown that only one of these sites participates in the interaction with the affinity, resin, leaving the second site free to interact stoichiometrically with <sup>22</sup>1-BGT. In contrast, brain AChR adsorbed to the same affinity resin is unable to bind <sup>22</sup>1-BGT. This result suggests that brain AChR has only one  $\alpha$ -toxin binding site per molecule. If an additional ligand site or sites are present on brain CChR actions for the site of the second brain th AChR, as is the case for peripheral AChRs, then these sites are not blocked by BGT. Activation by nicotinic agonists acting at these proposed but undocumented sites may be responsible for the known inability of a-toxins to block agonist mediated conductance in neuronal tissues.

(Supported in part by NIH grant 14262.)

IN VIVO REGULATION OF <sup>3</sup>H-ACETYLCHOLINE BINDING SITES IN BRAIN 168.2

IN VIVO REGULATION OF <sup>3</sup>H-ACETYLCHOLINE BINDING SITES IN BRAIN BY NICOTINIC CHOLINERGIC DRUGS. <u>Rochelle D</u> Schwartz and Kenneth J. Kellar. Department of Pharmacology Georgetown University Schools of Medicine and Dentistry, Washington, DC Nicotinic cholinergic receptors in rat brain have been studied using [3H]-acetylcholine ([3H]Ach) of high specific activity (Schwartz et al., Mol. Pharmacol. <u>22</u>, 56-62, 1982). In the presence of a cholinesterase inhibitor to prevent hy-drolysis and atropine to block muscarinic cholinergic recep-tors, [3H]Ach bindis rapidly, reversibly and with high affinity to rat brain membranes associated with the synaptosomal frac-tion. The [3H]Ach binding sites are unevenly distributed throughout the brain; the highest levels of binding are found in the thalamus, cortex and striatum. Nicotinic cholinergic agonists such as (-)nicotine, cytisine and carbachol are at least 10-1000 times more potent (K<sub>I</sub> = 1-13 M) than nicotinic cholinergic antagonists in displacing [<sup>3</sup>H]Ach binding. Recently we have shown that [<sup>3</sup>H]Ach binding sites in rat brain are down-regulated after chronic treatment of rats with the cholinesterase inhibitor disporopyl fluorophosphate

brain are considered at the children the children of rats with the cholinesterase inhibitor diisopropyl fluorophosphate (Schwartz and Kellar, Science 220, 214-216, 1983). In addition,  $[^{3}H]$ Ach binding sites were shown to up-regulate after repeated nicotine administration. In the present study, we compared the effects of repeated administration of cotinine, Compared the effects of repeated administration of cotinning, the major metabolise of nicotine, and of the nicotinic agonist, cytisine with those of nicotine on [ $^{3}$ H]Ach binding sites in several areas of rat brain. All drugs were injected (6.3 umol/ kg) SC twice daily for 10 days. Repeated nicotine administra-tion resulted in a 38%, 18% and 25% increase in [ $^{3}$ H]Ach binding is the entry theorem. tion resulted in a 38%, 18% and 25% increase in [ $^{3}$ H]Ach binding in the cortex, thalamus and striatum, respectively. However, nicotine decreased [ $^{3}$ H]Ach binding in the hypothalamus by 47%. Cotinine had no effect in the cortex or thalamus, but decreased [ $^{3}$ H]Ach binding 25% and 29% in the striatum and hypothalamus, respectively. Cytisine had similar effects to nicotine in the cortex (25% increase), thalamus (18% increase) and hypothalamus (53% decrease). However, repeated administration of cytisine (53% decrease). However, repeated administration of cytisine decreased [3H]Ach binding in the striatum by 25%. While nico-tine is most likely not acting via its metabolite, cotinine, it is known to have both agonist and antagonist properties. (The same is true for cytisine.) Up-regulation could be explained by an antagonistic action of nicotine and cytisine at [3H]Ach recognition sites. In addition, the different effects of these two drugs in different brain regions suggest the existence of sub-populations of [3H]Ach binding sites in different areas of the brain.

CHRONIC REGULATION OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS OF CULTURED CELLS BY AGONIST OCCUPANCY. D.E. Robinson\* and 168.3

OF CULTURED CELLS BY AGONIST OCCUPANCY. D.E. Robinson\* and R. McGee, Jr., Dept. of Pharmacology, Georgetown Univ. Sch. of Med., Washington, D.C. 20007 In many receptor systems chronic changes in the cell in an attempt to maintain homeostasis. However, it is unknown if such factors also regulate the neuronal nicotinic acetylcholine (ACh) receptor. This question has been studied using a model system, the clonal pheochromocytoma cell line, PC12, which possesses functional "neuronal" nicotinic acetylcholine receptors. An ion flux assay using  $86Rb^+$  as the tracer ion was used to monitor the cellular response to receptor stimulation by agonists. Monolayer cultures of the cells were pretreated with ouabain to inhibit Na<sup>+</sup>, K<sup>+</sup>-ATPase, and then stimulated for 20 sec with the agonist in Na<sup>+</sup>,K<sup>+</sup>-ATPase, and then stimulated for 20 sec with the agonist in the presence of tracer amounts of  $86\text{Rb}^+$  in a Na<sup>+</sup>-depleted salt solution. Initial experiments have examined the changes in the presence of tracer amounts of 86Rb+ in a Nat-depleted salt solution. Initial experiments have examined the changes in receptor function that occur upon chronic treatment with the non-hydrolyzable agonist, carbamylcholine (carbachol). Following chronic treatments carbachol was removed from the cultures for 30 min, sufficient time to allow complete resensitization of the receptors. A time-dependent decrease in the maximal response to carbachol was observed after treatment with carbachol for 1 to 10 days. The extent of decreased responsiveness of the receptors was dependent on the concentration of carbachol between 50 uM and 1 mM, concentrations very similar to those which activate the receptors. Upon removal of the carbachol from the culture medium, receptor function began to return towards control values within 24 hr and was completely recovered by 4 days. This down-regulation of receptor activity occurred without any changes in regulation of receptor activity occurred without any changes in the  $C_{50}$  for receptor activation, suggesting that the receptors which remained functional were unaltered. Mecamylamine, a which remained functional were unaltered. Mecamylamine, a nicotinic ganglionic antagonist which potently blocked acute receptor stimulation by carbachol, antagonized the carbachol-induced functional down-regulation of the receptors. In contrast d-tubocurarine, a neuromuscular antagonist which is thought to act as a channel blocker, did not antagonize the chronic effects of carbachol. The simplest interpretation of these results is that chronic treatment with an agonist results in a change in the number of functional nicotinic acetylcholine receptors in the membranes of these cells. Since a channel blocker did not inhibit down-regulation, the results also suggest that receptor occupancy alone directly triggers down-regulation. In contrast. 168.4 MONOCLONAL ANTIBODIES TO TORPEDO NICOTINIC ACETYLCHOLINE RECEPTOR

MONOCLONAL ANTIBODIES TO TORPEDO NICOTINIC ACETYLCHOLINE RECEPTOR THAT CROSS-REACT WITH SPECIFIC SUBSETS OF MAMMALIAN PERIPHERAL NEURONS AND SMOOTH MUSCLE. <u>Edward Hawrot</u>, <u>Janet Holliday\*</u>, <u>Barry Schweitzer\*</u>, <u>and Linda L.Y. Chun\*</u>. Dept. of Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510 and Dept. of Neurology, Mass. General Hospital, Boston, MA 02114. Two mouse monoclonal antibodies (mAb) generated against <u>Torpedo</u> electric organ nicotinic acetylcholine receptor (AChR) but with considerable cross-species recognition of skeletal muscle AChR have been further characterized. One antibody (27.43.37) immunoprecipitates both murine muscle AChR and <u>Torpedo</u> AChR labeled with <sup>12</sup>J- $\alpha$ -bungarotoxin (<sup>12</sup>J-BuTX). It binds primarily to the  $\alpha$ -subunit of <u>Torpedo</u> AChR on immunoblots with Acta labeled with  $-1-\alpha$ -bungarotoxin  $(-1-\beta UTX)$ . It binds primarily to the  $\alpha$ -subunit of <u>Torpedo</u> ACRA on immunollots with some minor cross-reactivity to the  $\beta$ -subunit. Recognition of the  $\alpha$ -subunit is not reduced by prior treatment of ACRA with endoglycosidase-H. Immunofluorescence studies with frozen sections indicate that mAb 27.43.37 binds to mouse and rat skeletal muscle endplates, to the longitudinal and circular smooth muscle layers of guinea pig ileum, to rat superior cervical ganglion (SCG) neurons, and to subsets of rat sensory neurons.

A second mAb (23.12.18) also immunoprecipitates <sup>125</sup>I-BuTX-A second mAD (22.12.16) also immunoprecipitates - islin-labeled AChR from both mouse muscle and <u>Torpedo</u>. Its subunit specificity is unknown since antigen recognition is lost upon SDS-denaturation of AChR. In frozen sections, mAb 23.12.18 binds mouse and rat skeletal muscle endplates, rat SCG neurons, subsets of rat sensory neurons, rat myenteric plexus neurons, and rat sciatic nerve. The rat pheochromocytoma cell line, PCl2, is also stained by mAb 23.12.18.

In order to characterize the nature of the recognized antigens, PC12 cells and SCG explants obtained from meonatal rats were metabolically labeled with  $^{35}$ S-methionine. In addition, membrane fractions prepared from guinea pig ileal smooth muscle were labeled with <sup>125</sup>I using lactoperoxidase. Detergent extracts of the labeled proteins were immunoprecipitated with the mAbs covalently bound to Sepharose beads. Analysis of the immunoprecipitates by SDS-gel electrophoresis has led to the identification of 3 or 4 prominently labeled bands in the molecular weight range of 45 to 70 kd. The interrelationship between the labeled proteins being immunoprecipitated from the various tissue sources is under investigation as is the further characterization of the properties of the neuronal and smooth

168.7

- ULTRASTRUCTURAL LOCALIZATION OF 43K PROTEIN IN TORPEDO POSTSYNAPTIC MEMBRANES WITH MONOCLONAL ANTIBODIES. <u>Stanley C. Froehner, Barnaby E. Wray\*,</u> and <u>Robert Sealock\*</u>. Department of Biochemistry, Dartmouth Medical School, Hanover, N. H. 03756 and \*Department of Physiology and The Neurobiology Program, University of North Carolina, Chapel Hill, N. C. 27514 168.5 Program, University of North Carolina, Unaper ....., N. C. 27514. In addition to the subunits of the acetylcholine
  - receptor, other proteins that may play important roles in synaptic function are present in highly-purified postsynaptic membranes from Torpedo electric organ. The major non-receptor component of these membranes (43% protein) has an apparent mol. these membranes (43K protein) has an apparent mol. wt. of 43,000 and displays the properties of a peripheral membrane protein. We have prepared monoclonal antibodies (mabs) to this protein and have used them to investigate the localization of this component at the electrocyte synapse. Receptor-rich membranes were extracted with 10mM lithium diiodosalicylate and the solubilized proteins (predominantly 43K protein) were used to immunize mice. Spleen cells were fused with NS-1 myeloma cells and hybridomas secreting active antibodies were cloned. The specificity of the mabs was determined by an immunoblot technique. Five hybridomas secrete mabs that react with a 43K protein of Torpedo membranes. Immunoblots of membrane proteins separated by two-dimensional gel electrophoresis show that the reactive 43K components have isoelectric points of 7.5-8.0. The anti-43K mabs do not recognize either the acetylcholine receptor or points of 7.5-8.0. The anti-43K mabs do not recognize either the acetylcholine receptor or Torpedo muscle actin. Ultrastructural studies on Torpedo electric organ using these anti-43K mabs indicate that the 43K protein is restricted to the cytoplasmic surface of the postsynaptic membrane. Furthermore, the distribution of the 43K protein and the receptor appear to be very similar and possibly coextensive. This work was supported by a grant from the Muscular Dystrophy Association (S.C.F.) and by N.I.H. grants NS-14871 (S.C.F.) and NS-15293 (R.S.).
- COMPARISON OF LIGHT AND HEAVY, EMBRYONIC AND ADULT FORMS OF THE 168.6 TORPEDO ACETYLCHOLINE RECEPTOR USING MONOCLONAL ANTIBODIES.

TORFEDO ACETICHOLINE RECEITOR USING MONOCLONAL ANTIBODIES. B. Holton, S.J. Tzartos and J.-P. Changeux. Neurobiologie Moléculaire, Institut Pasteur, 75724 Paris-Cedex 15, FRANCE. The acetylcholine receptor (AChR) from adult <u>Torpedo marmorata</u> electric organ exists in a Light form ( $\alpha_2\beta_3\phi_3$ ) of apparent molec-ular weight 250,000. The association of two Light forms via an intermolecular  $\delta$ - $\delta$  disulfide bridge results in the AChR Heavy form, which predominates in vivo. With the aim of distinguishing between such states, we screened a library of 38 monoclonal antibodies for the ability to immunoprecipitate the 125I-a-bungarotoxin-labeled Heavy or Light forms. None of the nine anti  $\alpha$ -sub-unit mAbs tested distinguished between the two forms. On the other hand, the 29 anti  $\beta$ ,  $\gamma$  and  $\delta$  subunit mAbs precipitated more Heavy than Light form.

The Heavy and Light forms also exist in embryonic electric organ. We tested the same collection of mAbs against extracts of embryonic tissue. Most of the anti  $\beta$ ,  $\gamma$  and  $\delta$  subunit antibodies precipitated more adult than embryonic AChR, but the anti  $\alpha$ -subprecipitated more adult than embryonic AChR, but the anti  $\alpha$ -sub-unit mAbs made no distinction. Parallel measurements of the Heavy to Light form ratios in extracts from embryonic and adult electric organs revealed only 35% Heavy form in the embryo against 78% in the adult. Addition of the alkylating agent, N-ethyl maleimide (NEM) to electric organ preparations increased the percentage of Heavy forms in embryonic but not in adult extracts. When 125-1toxin-labelled adult AChR was mixed with embryonic electric organs and present throwbut the membryon extraction the Neavy to and present throughout the membrane preparation, the Heavy to Light receptor ratio did not change. In addition, a carefull Light receptor ratio did not change. In addition, a carefull study of embryonic and adult Light forms and of embryonic and adult Heavy forms did not reveal any difference in their reac-tivity towards the 38 mAbs tested. Thus, we conclude that our mAbs can not distinguish <u>Torpedo</u> embryonic and adult AChR by intrinsic structural differences but by the Light/Heavy form ratio. The ability of the anti- $\beta,~\gamma$  and  $\delta$  subunit mAbs to differentiate between the two forms may serve as a tool for their localization.

- ACUTE ELEVATION OF CAMP DOES NOT EFFECT THE FUNCTIONAL PROPERTIES OF A NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR. R. McGee, Jr. and B. Liepe\* (SPON: F. G. Standaert), Dept. of Pharmacology, Georgetown Univ. Sch. of Med., Washington, D.C. 20007 Nicotinic acetylcholine (ACh) receptors from Torpedo electric organs (models of muscle receptors) have been shown to be phos-phorylated by processes dependent on cAMP or Ca<sup>++</sup>, as well as processes independent of these modulators. However, it is unknown whether or not these phosphorylations influence receptor function. For neuronal nicotinic ACh receptors, it is unknown whether similar phosphorylations occur, and, if so, whether they alter receptor function. Although the neuronal receptors are not readily amenable to direct analysis of their state of phosphoryl-ation, their functional properties can be investigated under conditions known to alter cellular rates of phosphorylation. readily amenable to direct analysis of their state of phosphoryl-ation, their functional properties can be investigated under conditions known to alter cellular rates of phosphorylation. We have begun these studies by looking for CAMP-dependent alterations in receptor functions. Intact phochromocytoma cells (clone PC12) were exposed to concentrations of forskolin (10-3 to 10-5 M) which produced 2-100 fold increases in cellular cAMP and increased cAMP-dependent protein phosphorylation. The responsiveness of the neuronal nicotinic ACh receptors then was assessed as agonist-induced uptake of 86Rb<sup>+</sup> into the cells. The uptake assay was conducted in a Na<sup>+</sup>-depleted salt solution containing ouabain to inhibit Na<sup>+</sup>,K<sup>+</sup>-ATPase. At 37°C 86Rb<sup>+</sup> uptake induced by activation of the receptors with carbamyl-choline was linear for at least 20 sec. Under all conditions of elevated CAMP (2-100 fold increases, 1-40 min elevation of cAMP, prior to stimulation) no changes in receptor-mediated uptake of 86Rb<sup>+</sup> were observed. Neither the maximal response elicited by saturating agonist concentrations nor the agonist concentration, receptor response relationship was altered by elevation of cAMP. The rapid desensitization of the receptors also was not changed by elevation of cAMP; the entire time course for agonist-induced uptake of 86Rb<sup>+</sup> was the same in the presence and absence of forskolin. Finally, even the distribution between desensitized and excitable receptors achieved upon prolonged exposure to the agonist was unchanged by elevation of cAMP. Thus, within the time frame of 1 to 40 min the functioning of a neuronal nicotinic ACh receptor is unaltered by conditions known to enhance cAMP-dependent protein phosphorylation. It remains to be determined if alterations in cAMP may play a role in long-term adaptive responses. Supported by NIH grant NS 16777.
- 168.8 PHOSPHORYLATION OF THE NICOTINIC ACETYLCHOLINE RECEPTOR BY Ca<sup>2+</sup>/ PHOSPHORVLATION OF THE NICOTINIC ACETYLCHOLINE RECEPTOR BY Ca<sup>+/</sup> PHOSPHOLIPID-DEPENDENT PROTEIN KINASE, AND COMPARISON WITH ITS PHOSPHORVLATION BY CAMP-DEPENDENT PROTEIN KINASE. R. L. Huganir, K. A. Albert<sup>\*</sup> and P. Greengard. Dept. Pharmacology, Yale Univer-sity School of Medicine, New Haven, CT 06510. We have found that the purified nicotinic acetylcholine recep-tor from <u>Torpedo californica</u> is phosphorylated by a Ca<sup>2+</sup>/phospho-lipid-dependent protein kinase purified from bovine brain. We showed previously that the receptor is phosphorylated by the cata-lytic submit of cAMP-dependent protein kinase purified from

showed previously that the receptor is phosphorylated by the catalytic subunit of cAMP-dependent protein kinase purified from bovine heart. The Ca<sup>2+</sup>/phospholipid-dependent protein kinase phosphorylates only the  $\delta$  subunit of the receptor, whereas the catalytic subunit of the cAMP-dependent protein kinase phosphorylates the  $\gamma$  and  $\delta$  subunits. The stoichiometry of phosphorylation under the conditions used was 0.3 mol phosphate/mol of  $\delta$  subunit for the Ca<sup>2+</sup>/phospholipid-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and 1.0 mol phosphate/mol of  $\gamma$  or  $\delta$  subunit for the cAMP-dependent protein kinase and phosphate/mol phosphat Phosphorylation of the receptor by the cAMP-dependent kinase. Kinase. Phosphorylation of the receptor by the cAMP-dependent protein kinase appears to be of physiological significance (Huga-nir and Greengard, PNAS, <u>80</u>, 1130-1134, 1983). We are currently attempting to determine the physiological significance of the phosphorylation of the receptor by the Ca<sup>2+</sup>/phospholipid-dependent protein kinase, by comparing the relative rates and specificities of the phosphorylation of the receptor by the two kinases.

of the phosphorylation of the receptor by the two kinases. We have also studied the phosphorylation of the nicotinic acetylcholine receptor by endogenous protein kinases in subcellu-lar fractions from Torpedo electric organ. Endogenous membrane-bound and cytosolic cAMP-dependent protein kinase phosphorylates the  $\gamma$  and  $\delta$  subunits of the receptor. We are currently attempting to demonstrate endogenous Ca<sup>2+</sup>/phospholipid-dependent phosphoryla-tion of the  $\delta$  subunit of the receptor. The possible effects of the phosphorylation of the receptor. The possible effects of the phosphorylation of the acetylcholine receptor by the two kinases on the function of the receptor and its associated channel are also being investigated. (Supported by USPHS Grants MH-17387 and NS-08440 (P.G.). R.L.H. is the recipient of a Muscular Dystrophy Association Fellowship.) 168.9 KAPPA-BUNGAROTOXIN: AN UNUSUAL SNAKE NEUROTOXIN WHICH BLOCKS NICOTINIC TRANSMISSION IN MAMMALIAN AND AVIAN AUTONOMIC GANGLIA. V. A. Chiappinelli and S. E. Dryer\*. Dept. of Pharmacology,
 St. Louis Univ. Sch. of Med., St. Louis, MO 63104.
 Kappa-Bungarotoxin (KBgT) is a minor α-neurotoxin present in

the venom of the snake Bungarus multicinctus. The major  $\alpha$ -neuro-toxin contained in the venom is the well-known  $\alpha$ -bungarotoxin (ABgT). KBgT has been purified to apparent homogeneity via a series of cation-exchange columns (1).

<u>Electrophysiology</u>. Both extracellular and intracellular re-cording from isolated ganglia have been used to characterize the physiological effects of KBgT. In the chick ciliary ganglion By Storogical effects of RSgT. In the chick cillary ganglion KBgT blocks nicotinic transmission at a dose of 75 nM. In the rat superior cervical ganglion a blockade is observed only at consid-erably higher doses (800 nM). In both ganglia, nicotinic trans-mission recovers after several hours of washing out the toxin. <u>Biochemistry</u>. KBgT is a highly basic polypeptide (pI=9.1). It

appears to be purified in a dimerized state, with a molecular weight for the dimer of approximately 12,500 daltons as determined by gel filtration on Sephacryl 200 or by sedimentation equilibrium centrifugation. The dimer is physiologically active. The dimer is broken down by treatment with the detergent sodium dodecyl sulfate, yielding a weight for the monomer of 6,500 daltons as determined by gel electrophoresis or by gel filtration in the presence of sodium dodecyl sulfate. The amino acid composition of

presence of soluminable sufficiency sufface. The main order to composition of KBgT indicates that it is not a cleavage product of ABgT. <u>Binding Experiments</u>. While most  $\alpha$ -neurotoxins (e.g. ABgT) bind with high affinity (K<sub>d</sub>=1 nM) to a nicotinic site in both the chick ciliary ganglion and the rat superior cervical ganglion,  $\alpha$ -neurotoxins frequently have no effect on nicotinic transmission through these ganglia at concentrations which saturate this site (2,3). Using <sup>125</sup>I-labeled KBgT, a search for sites other than those seen by ABgT was initiated. In the chick ciliary ganglion, such a site was identified, which may be associated with the physiological nicotinic receptor in the ganglion. In contrast, when binding was studied in the chick optic lobe, where ABgT blocks nicotinic transmission (4), <sup>125</sup>I-KBgT did not identify any additional nicotinic binding sites.

These results indicate that an unusual snake  $\alpha$ -neurotoxin, KBgT, may be a useful probe for the physiological nicotinic receptor in several neuronal systems. (Supported by NIH Grant NS 17574.)

  Chiappinelli, Cohen and Zigmond (1981) Brain Res. 211, 107.
- 4. Oswald and Freeman (1981) Neuroscience 6, 1.

Although the neuronal  $\alpha$ -bungarotoxin ( $\alpha$ -BGT) binding site has the properties of a nicotinic acetylcholine receptor, its nature remains controversial because  $\alpha$ -BGT does not block the physio-logical functions mediated by nicotinic receptors. This could suggest that the  $\alpha$ -BGT site, although regulated by nicotinic cholinergic drugs, is the target for an as yet unidentified endo-genous ligand, which plays a role in other aspects of receptor regulation. Evidence that a factor which competes with  $\alpha$ -BGT for its binding site, exists in brain supernatant has previously been obtained (Brain Res. 245:57, 1982). Experiments to partially purify and characterize this factor are now presented. A 45.000 xg supernatant was prebared from rat or hovine brain. purify and characterize this factor are now presented. A 45,000 xg supernatant was prepared from rat or bovine brain. This supernatant was heated and subsequently centrifuged at 100,000 xg. The factor, which competed for  $\alpha$ -BGT binding, was active after this procedure and present in both the supernatant and sedimented material. Attempts to purify the 100,000 xg supernatant by gel chromatography or other conventional purifi-cation techniques resulted in minimal recovery of an anagrent low supernatant by get chromatography or other conventional purity cation techniques resulted in minimal recovery of an apparent low molecular weight material. These observations suggested that the factor in supernatant is in a soluble, possibly low molecular weight form, which is readily adsorbed. On the other hand, a purification of the endogenous material, which competed for  $\alpha$ -BGT purification of the endogenous material, which competed for  $\alpha$ -BGT binding, could be achieved after an acetonitrile/trifluoroacetic acid extraction of the 100,000 xg pellet. A 50% inhibition of  $\alpha$ -BGT binding occurred using 50 µg/ml of this extract; this represents an approximate one hundred fold purification. The effect of the factor on  $\alpha$ -BGT binding was approximately linear with protein and was not altered by prior exposure of the extract to peptidase, neuraminidase, phospholipase or lipase activity. No activity was recovered after passage of the 100,000 xg acetonitrile/trifluoroacetic acid extract through a gel filtration column, although the activity associated with the original 100,000 xg pellet could be eluted from the column in the void volume. volume.

These results suggest that the endogenous ligand which competes for the  $\alpha\text{-BGI}$  binding site is a fairly stable factor. It appears to exist in a soluble form of possibly low molecular weight which is readily absorbed, and also in a higher molecular weight or aggregated state.

LECTIN SENSITIVITY OF NICOTINIC ACETYLCHOLINE RECEPTORS IN 168.11 CULTURED CHICK CILIARY GANGLION NEURONS. <u>A. Messing and N. K.</u> Gonatas. Div. of Neuropathology, Univ. of Penn. Sch. of Med., Philadelphia, PA 19104.

The effects of various lectins and toxins on neuronal nicotinic acetylcholine receptor function have been studied in primary cultures of chick ciliary ganglion neurons.

Dissociated monolayer cultures from 8-day chick embryos were prepared as in Messing (Brain Res., 232:479, 1982) and were used for experiments between days 5 through 9 in vitro. Neuronal For experiments between uays a through 3 in vitro, we notice response to acetylcholine receptor activation was measured as influx of radioactive ions by a modification of the method of Huang, Catterall and Ehrenstein (J. Gen. Physiol., 71:397, 1978). Ion influx was measured at  $4^{\circ}$ C in a high potensium low sodium medium designed to stabilize membrane potential near zero, with nearbylcholine ac the accelered and receiver 127 at the two sets of the stabilize of the stabilize of the stabilize of the stabilize the stabilize of the stabilize the stabilize the stabilize of the stabilize the stabiliz acetylcholine as the agonist and cesium-137 as the tracer ion. Non-specific influx was assessed in parallel cultures by incubation in medium lacking acetylcholine.

Exposure to 1 mM acetylcholine for 30 seconds (within the linear range of the time course) produced a 5-10-fold stimulation of cesium-137 influx. Acetylcholine-stimulated influx was in-hibited more than 95% by 10 µM d-tubocurarine, but was insensitive

hibited more than 95% by 10  $\mu$ M d-tubocurarine, but was insensitive to both 1  $\mu$ M tetrodotoxin and 1  $\mu$ M  $\alpha$ -bungarotoxin. Cultures were exposed to 50  $\mu$ g/ml of concanavalin A, wheat germ agglutinin, lentil lectin, cholera toxin or 10  $\mu$ g/ml tetanus toxin for one hour at either 4°C or 37°C, then assayed for acetyl-choline-stimulated cesium-137 influx at 4°C. Concanavalin A inhibited agonist-induced ion flux by 80% at both temperatures; the other lectins and toxins were without effect. Succinyl-concanavalin A was ineffective at concentrations up to 125  $\mu$ g/ml, and could not protect against the concanavalin A inhibition. Concentrations are not according to the second and could not protect against the concentrations and to be the second and the second according to the nicotinic acetylcholine receptors. (Supported by U.S.P.H.S. grants NS-05572-19 and NS-07064-03).

168.12 BENZOMORPHAN INTERACTIONS WITH ACETYLCHOLINE RECEPTOR-ION CHANNEL SERZMORHAN INTERACTIONS WITH ACCITICALITIE RECEPTOR CONTINUES COMPLEXES FROM TORPEDO CALIFORNICA. Coleman T. King, Jr.\* and Robert S. Aronstam. Department of Pharmacology, Medical College of Georgia, Augusta, GA 30912. Benzomorphan interactions with acetylcholine receptor complex-

es from Torpedo california electric organ were investigated using radiolabelled probes for receptor and ion channel binding sites, and compared to their selectivity for various opiate receptor subtypes.

Alpha-bungarotoxin binding to the ACh receptor was not decreased by more than 10% by any of the benzomorphans at a concentration of 100 uM. All of the benzomorphans competitvely inhibited phencyclidine  $([^{3}H]PCP)$  and perhydrohistrionicotoxin  $([^{1}H]WIW to ion observed vites The benzomorphans competitively$ ([H]]HTX) to ion channel sites. The benzomorphans can be divided into 2 groups on the basis of their affinity for the divided into 2 groups on the basis of their affinity for the ion channel: Phenazocine, N-allylnormetazocine, pentazocine and cyclazocine inhibited ion channel binding with high affinity (IC50's = 1 to 5 uM), while ketacyclazocine and ethylketocyclazo-cine were substantially less active. With each drug, benzomor-phan affinity was increased when 1 uM carbarnylcholine was included in the incubation medium. Thus, ion channel affinity is not strictly limited to benzomorphans which stimulate sigma opiate receptors, and is not a certain indication of psychoto-mimetic potency. mimetic potency.

168.13 THE SPECIFICITY OF A MYASTHENIC SERUM FOR DEVELOPMENTALLY DIFFERENT FORMS OF THE ACETYLCHOLINE RECEPTOR. <u>Marie-Paule</u> <u>Roisin\*, Yong Gu\* and Zach W. Hall, Div. Neurobiol. Dept.</u> Physiol., Univ. Calif., San Francisco, CA 94143 During development of the neuromuscular junction, the ace-

During development of the neuromuscular junction, the acetylcholine receptor (AChR) undergoes changes in its functional and biochemical properties that occur in several stages before and after birth. We have previously shown (Weinberg and Hall, 1979) that many patients with myasthenia gravis have antibodies in their sera that distinguish two developmental forms of the AChR. We have found one serum that shows remarkable specificity when tested with AChR from rat or mouse muscle. Antibodies in this serum recognize only an  $\alpha$ -bungarotoxin ( $\alpha$ -BuTx) binding site on AChRs partially purified from denervated or embryonic muscles; they do not bind to other sites on these receptors nor do they bind to receptors purified from adult muscle (Gorin et al. 1982).

We have used this serum to determine when during development the Immunological reactivity of the AChR at endplates changes. Immunocytochemical experiments on frozen sections of rat muscle show that AChRs at endplates in neonatal animals bind the antibodies, but that during the second and third postnatal weeks, the AChRs at endplates cease to be recognized by the antibodies. This immunological transition occurs during the same developopmental period in which the mean channel open time of the AChRs changes and in which postsynaptic folds appear. We have characterized the biochemical specificity of the

We have characterized the biochemical specificity of the anti-AChR antibodies in this serum in two ways. First, we have examined the effect of the antibody on toxin-binding to intact myotubes of the  $C_2$  mouse muscle cell line. The AChRs in  $C_2$  myotubes have two binding sites for  $\alpha$ -BuTX that can be distinguished by their different affinities for d-tubocurarine (dTC). Our experiments show that the antibodies specifically block binding of toxin to the high-affinity dTC site. Thus a maximum of 50% inhibition of toxin-binding is obtained. We have also found that the antibodies slock 50% of toxin-

We have also found that the antibodies block 50% of toxinbinding to solubilized AChR from <u>Torpedo</u> electric organ. The effect of the antibodies on the <u>Torpedo</u> receptor and on the AChR from denervated rat leg muscle can be completely inhibited by N-acetylglucosamine, but is unaffected by N-acetylgalactosamine, sialic acid, mannose, galactose or glucose. Our results thus suggest that during the postnatal maturation of endplates in rat muscle, the AChR undergoes a change in glycosylation near one of the toxin-binding sites. Supported by grants from the NIH and MDA.

168.15 A SIMPLE DEVICE FOR PERFORMING LARGE NUMBERS OF CENTRIFUGAL GEL FILTRATION RECEPTOR BINDING ASSAYS SIMULTANEOUSLY. J. A. Lewis and S. A. McLafferty. Dept. of Biological Sciences, Univ. of Missouri-Columbia, Columbia, MO 65211. Ligand binding to a detergent-solubilized receptor can be

Ligand binding to a detergent-solubilized receptor can be assayed by centrifuging ligand-receptor solutions through minicolumns of G-25 Sephadex to separate receptor-bound ligand from free ligand. A limitation of this standard technique is that during the time required to load a series of columns, bound ligand may begin dissociating from receptor on the first-loaded columns while additional columns are being loaded. We find that Becton-Dickinson 26 gauge syringe needles clipped or bent to remove the beveled point can be used as loading caps in the tops of assay columns (l cc. B-D tuberculin syringe barrels) to hold each assay aliquot above its column until the start of centrifugation loads all columns simultaneously by forcing liquid through the needle openings onto the top of each column. Up to 72 assays can be loaded, equilibrated, and run simultaneously in one set of centrifuge adapters. With extra sets of adapters, one person can easily perform several hundred binding assays a day. The height to which Sephadex columns are packed and the speed of initial centrifugation turn out to be important variables in achieving precise reproducibility. We demonstrate the usefulness and reliability of our modified technique in assaying the Triton X-100 solubilized levamisole receptor of the nematode <u>Caenorhabditis elegans</u> by  $[^3H] -meta-aminolevamisole binding. The receptor assayed is one for which a number of receptor-deficient mutants have been obtained by selection for levamisole resistance.$ 

168.14 MECHANISM OF PHENCYCLIDINE BINDING TO THE <u>TORPEDO</u> <u>CALIFORNICA ACEFYICHOLINE RECEPTOR. R. E. Oswald, M. J.</u> <u>Bamberger\* and J. T. McLaughlin\*. Department of</u> Pharmacology, Cornell University, Ithaca, NY 14853. Phencyclidine (PCP) binds to the acetylcholine receptor

Pharmacology, Cornell University, Ithaca, NY 14853. Phencyclidine (PCP) binds to the acetylcholine receptor (ACRR) and inhibits ion flux at a site distinct from the acetylcholine binding site. This high affinity site seems to be present in one copy per 250 000 dalton acetylcholine receptor monomer (Heidmann, T., Oswald, R. E. & Changeux, J. P., <u>Biochemistry</u>, in press). The nature of this site remains unresolved; however, the voltage-dependence of inhibition of ion flux suggests that these agents may sterically block the ion channel (Albuquerque et al., PNAS, 77,124, 1980). The kinetics of ['H]ECP association are 10<sup>3</sup> - to 10<sup>4</sup>-fold more rapid when PCP and carbamylcholine (carb) are added simultaneously to the ACRR (presence of a large proportion of open channels) than when PCP is added to ACAR which has been previously equilibrated with carb (mainly desensitized ACIR) or ACAR in the absence of carb (mainly desensitized ACIR) or ACAR in the absence of carb (mainly "resting" ACRR). The mechanism of PCP binding to the ACAR previously equilibrated with carb was investigated with thermodynamic, viscosity and kinetic experiments. The thermodynamic data suggested that both association and dissociation rates in the presence and absence of carb were highly dependent upon temperature with transition state enthalpies on the order of 25 kcal/mole and O<sub>10</sub>'s (20° to 30°) of 4 to 6. Viscosity had no effect on association rates but increased dissociation rates. The interpretation of the thermodynamic and viscosity studies was that the binding is not limited by diffusion but rather by an energy barrier associated with the interaction between the ACAR and PCP. The pseudofirst order association rate was linearly dependent on ACAR concentration and virtually insensitive to PCP concentration. In the absence of carb, the association rate seemed to be a hyperbolic function of both PCP and ACAR concentration. The minimal model capable of explaining the data is a mechanism by which PCP binds to

EFFECT OF SHORT-TERM DESENSITIZATION ON MUSCARINIC RECEPTOR 169.1 EFFECT OF SHORT-TERM DESENSITIZATION ON MUSCARINIC RECEPTOR BINDING IN INTACT MURINE NEUROBLASTOMA CELLS (CLONE NIE-115). Michael McKinney\*, Scott Stenstrom\* and Elliott Richelson (SPON: J. W. McLaren). Depts. of Psychiatry and Pharmaco-logy, Mayo Foundation, Rochester, MN 55905. Muscarinic agonist binding sites in intact NIE-115 cells were studied with the equilibrium binding of  $[^3H]$ quinucli-dinyl benzilate ( $[^3H]$ QNB) and carbachol. The data were analyzed with an interative non-linear computer fitting pro-gram emloying models for multiple independent aconcit bind.

gram employing models for multiple independent agonist binding sub-types.

Ing sub-types. Intact naive NIE-115 cells at 15°C exhibited three agonist sites with dissociation constants for carbachol of 2.7 nM, 1.35 µM, and 56 µM, with relative proportions of 29%, 24% and 47%, respectively. These sites correlate with the "super-high", "high", and "low" agonist sites in the literature. The super-high site appeared to be absent when the binding was performed with homogenates of NIE-115 cells.

was performed with homogenates of NIE-115 cells. Confluent NIE-115 cells were desensitized with 1 mM carba-chol for 20 minutes at 37°C. After three washes with cold medium, the binding of [<sup>3</sup>H]QNB and its displacement by car-bachol was performed at 15°C to prevent resensitization. Neither the total receptor number nor the receptor's affinity for [<sup>3</sup>H]QNB was changed by short-term desensitization. Conversely, the curve for agonist displacement of [<sup>3</sup>H]QNB was markedly shifted to the right. Computer analysis revealed that the major change occurred in the binding affin-ities of all three agonist binding sites with the new disso-ciation constants as follows: super-high=141 nM, high=109 µM, low=855 µM. low=855 uM.

The data suggest that muscarinic receptor binding in homogenates differs from that in intact cells in that the propor-tions of agonist sites may change. However, in either homotions of agonist sites may change. However, in either homo-genates or intact cells there were two sites with dissocia-tion constants near the  $ED_{50}$ 's for inhibition of PGE<sub>1</sub> mediated cAMP formation and stimulation of cGMP formation, respectively. The decrease in agonist binding affinity of the muscarinic receptor that occurred during prolonged treat-ment with agonists may be part of the mechanism whereby cells become desensitized.

169.2

COMPARISON OF <sup>3</sup>H-PIRENZEPINE AND <sup>3</sup>H-QNB BINDING TO MUSCARINIC RECEPTORS IN RAT BRAIN. <u>Gary R. Luthin\* and Barry</u> <u>B. Wolfe</u> (Spon: M. Wax) Dept. Pharmacol., Univ. Pennsylvania Sch. Med., Philadelphia, PA 19104 Pirenzepine (Pz) is an antagonist at muscarinic cholinergic receptors and inhibits the effects of muscarinic receptor agoinsts (Gil and Wolfe, Neurosci. Abs. 1983). Pz, as well as atropine and scopolamine, inhibit the binding of <sup>3</sup>H-antagonists to muscarinic receptors. Atropine inhibition curves of <sup>3</sup>H-QNB binding have Hill coefficients of 1, suggesting that atropine and <sup>3</sup>H-QNB interact with one site, or with multiple sites having equal affinities. Pz also inhibits (<sup>3</sup>H)-QNB binding, but Hill coefficients of competition curves are less than one in some tissues. This is consistent with the presence of either receptor subtypes suggesting that atropine and "H-QNB interact with one site, or with multiple sites having equal affinities. Pz also inhibits (<sup>4</sup>H)-QNB binding, but Hill coefficients of competition curves are less than one in some tissues. This is consistent with the presence of either receptor subtypes or different affinity states of muscarinic receptors. Watson et al. (Life Sci. 31:2019, 1982) recently have demonstrated binding of <sup>4</sup>H-Pz to rat brain membranes. In this study, we have characterized <sup>4</sup>H-Pz binding in rat brain and compared the binding profile of <sup>4</sup>H-Pz to that of <sup>4</sup>H-QNB. Initial experiments were performed in rat cerebral cortex. At  $32^{\circ}$ C, the binding of <sup>4</sup>H-Pz was rapid, with a k<sub>1</sub> of  $8.75 \times 10^{6}$ M<sup>-1</sup>min<sup>-1</sup>, reversible, with a k<sub>-1</sub> of 0.128 min<sup>-1</sup>, and of high affinity and saturable. Scatchard plots of equilibrium <sup>4</sup>H-Pz binding data were linear over the range 0.3-75 nM <sup>4</sup>H-Pz. The Kd calculated from the saturation data was 15.2 nM, which agrees with the value of 14.6 nM calculated from the ratio k<sub>-1</sub>/k<sub>1</sub>. The pharmacological profile of <sup>4</sup>H-Pz binding was identical to that of (<sup>4</sup>H)-QNB binding. The rank order of potencies of muscarinic drugs to compete with both ligands was QNB > atropine-scopolamine > pienzepine > oxotremorine > carbachol. All antagonists inhibited <sup>4</sup>H-Pz and <sup>4</sup>H-QNB binding with Hill coefficients of 1 (except Pz vs <sup>4</sup>H-QNB). The Hill coefficients for agonists were all less than one. The Hill coefficients for agonists were increased in the presence of 5 mM magnesium plus 100 µM GTP for both ligands. Saturation experiments with both ligands revealed the concentration of (<sup>4</sup>H)-QNB binding sites in cortex, striatum, and hippocampus. However, in pons-medulla, the ratio of <sup>3</sup>H-Pz<sup>3</sup>H-QNB binding sites was 0.2, and in cerebellum, no <sup>3</sup>H-Pz binding sites were detectable. We postulate that Pz interacts with both a high- and low-Kd recognition site in brain, and that the high-Kd site is not detectable in direct binding assays using <sup>3</sup>H-Pz. In cortex, Pz interacted with

DIFFERENT PHARMACOLOGICAL PROFILES FOR TWO MUSCARINIC-MEDIATED RESPONSES. <u>Daniel W. Gil<sup>\*</sup> and Barry B. Wolfe</u>. Dept. of Pharmacology, University of Pennsylvania School of Medicine, 169.3 Pharmacology, Univer Philadelphia, PA 19104.

Several hormones modulate phosphatidylinositol (PI) turnover, associated with cytosolic calcium mobilization, and adenylate cyclase activity through separate receptor subtypes. This arrangement has been best demonstrated for catecholamines, with  $\alpha_1$ -adrenergic receptors mediating an increase in PI turnover and calcium fluxes and  $\alpha_2$ -adrenergic receptors mediating an inhibition of adenylate cyclase activity (Fain, J.N. and Garcia-Sainz, J.A., Life Sci. <u>26</u>:1183, 1980). Muscarinic cholinergic receptors also modulate these biochemical responses and analogy with  $\alpha$ receptors suggests that muscarinic receptors may exist as two subtypes, each modulating a distinct biochemical response. We have therefore investigated the pharmacological profiles of muscarinic receptorstimulated PI turnover and muscarinic receptor-inhibited adenylate cyclase activity.

The cleavage of the phosphorylated inositol head group from the glycerol backbone is the receptor-linked step in PI turnover, so the accumulation of inositol 1-phosphate (I  $1-PO_4$ ) is a measure of receptor-mediated PI turnover. 10 mM LiCl maximally inhibited the enzyme, mediated PI turnover. 10 mM LiCI maximally inhibited the enzyme, inositol 1-phosphate phosphatase, and I 1-PO<sub>4</sub> accumulation remained linear for over 80 min. We have measured the 60-min muscarinic-stimulated accumulation of <sup>3</sup>H-I 1-PO<sub>4</sub> in rat parotid slices preincubated with <sup>3</sup>H-inositol. Adenylate cyclase activity was studied in rat ventricle homogenates by measuring the production of <sup>32</sup>P-cAMP during a 500-sec incubation with <sup>32</sup>P-ATP. Adenylate cyclase activity was increased with either 7.5  $\mu$ M isoproterenol or 100  $\mu$ M forskolin and its activity remained linear for at least 12 min.

The potencies of several muscarinic drugs in the two assay systems have The potencies of several muscarinic drugs in the two assay systems have been determined. The potency of the agonist, oxotremorine, was similar in both assay systems. Using Schild analysis, however, the potencies of some muscarinic antagonists differed. Pirenzepine was a more potent (16x) blocker of muscarinic-stimulated PI breakdown than muscarinic-mediated in bibliotics of edenviate available activity. Attenies was also mediated inhibition of adenylate cyclase activity. Atropine was also a more potent (5x) inhibitor of the muscarinic-mediated PI effect than the muscarinic-mediated adenylate cyclase effect. The antagonist potencies were not altered by using different muscarinic agonists, different were not altered by using different muscarinic agonists, different temperatures, or by stimulating adenylate cyclase with forskolin rather than isoproterenol. The ganglionic stimulant, McN A343, was a weak partial agonist for  $1-PO_4$  accumulation, but a full agonist for adenylate cyclase inhibition. While the reason that the muscarinic antagonists appear to be selective is not yet clear, the differences in potencies are consistent with the existence of separate muscarinic receptor subtypes modulating PI turpover and denylate activity. (Supported by NII modulating PI turnover and adenylate cyclase activity. (Supported by NIH GM-31155 and NSF SPE-82-64157).

## $^{\rm EFFECT}$ OF ZINC ON $^{\rm 3H-OXOTREMORINE}$ DISPLACEMENT BY MUSCARINIC AGONISTS AND ANTAGONISTS. C.P.Smith and F.P.Huger Dept. of 169.4 Biochemistry, Hoechst-Roussel Pharmaceuticals, Somerville, NJ 08876

Muscarinic receptor heterogeneity has been explained by the presence of three different agonist binding sites (SH, H and L) which bind agonists at widely different affinities but bind antagonists at equal affinities. The ability of guanine nucleotides, ions and sulfhydryl reagents to alter the relative proportions of agonist binding sites indicate that these proportions are probably not due to the existence of molecularly heterogeneous non-interconvertible sites. The finding that  $Zn^{+2}$  enhances the ability of muscarinic agonists to displace  ${}^{3}\text{H}$ -antagonists from muscarinic receptors prompted us to investigate the effect of InM ZnS04 on  ${}^{3}\text{H}$ -oxotremorine was captured by centrifugation after a 15-minute incubation at 30°C, then washed, dried, solubilized and measured by liquid scintillation. Nonspecific binding, measured in 2 µM atropine sulfate or 2 µM oxotremorine binding, measured in 2  $\mu$ M attropine suitate of 2  $\mu$ M oxotremorine sesquifumerate, did not differ, either in the presence or absence of 1  $\mu$ M 2nSO<sub>4</sub>. The results indicate that homogenization and incubation in 1  $\mu$ M 2nSO<sub>4</sub> can effectively enhance <sup>3</sup>H-oxotremorine binding, apparently through an increase in binding sites. A saturation experiment showed a 10-fold increase in the number of binding that the theorement of 1  $\mu$ M 2FO saturation experiment showed a 10-rold increase in the number of binding sites due to the presence of 1 mM ZnSQ4. At low <sup>3</sup>II-ligand concentrations (3-7nM), zinc-treated rat forebrain mem-branes showed nearly a three-fold increase in bound <sup>3</sup>H-oxotrem-orine as compared to control membranes. Under these conditions, agonist affinities were not affected by zinc-treatment, but muscarinic antagonists showed a 10-fold decrease in ability to displace bound <sup>3</sup>H-oxotremorine in 1 mM ZnSO<sub>4</sub>. The selective, high-affinity antagonist pirenzepine and McN-A-343, a unique agonist, were not distinguished from classical agonists (oxotrem-orine, carbachol) or antagonists (atropine, scopolamine), but pilocarpine, a partial agonist of low efficacy, had an inter-mediate decrease in ability to displace  ${}^{3}$ H-oxotremorine in the presence of 1 mM ZnSO,.

169.5 CHARACTERIZATION OF THE EFFECT OF ZINC ON THE DISPLACEMENT OF <sup>3</sup>H-QNB BY MUSCARINIC AGONISTS AND ANTAGONISTS. <u>F.P.Huger and</u> <u>C.P.Smith.</u> Dept. of Biochemistry, Hoechst-Roussel Pharmaceuticals, Inc., Somerville, NJ 08876

The effects of certain heavy metals and sulfhydryl agents on muscarinic cholinergic receptor binding have been reported by several laboratories. We have shown that incubation of membranes from rat forebrain in the presence of  $1 \, \rm m M \ Zn^{24}$  shifts the agonist displacement curves of  $^3 \rm H-QNB$  to the left, with little or no effect on antagonist displacement curves. Further studies were done to optimize and characterize the effect of zinc on muscarinic receptor binding.

Experiments were performed with membranes isolated from discrete brain regions (frontal cortex, striatum, hippocampus and cerebellum) showed that the effect of zinc on muscarinic agonist affinity for QNB-labeled sites was consistent in all regions tested. The effect of zinc was concentration-dependent up to 1 mM. At a concentration of 10 mM Zn<sup>2+</sup>, there was no specific binding of <sup>3</sup>H-QNB. This loss of specific binding was associated with a loss of membrane protein. The possibility of an anion effect was ruled out by comparing treatments with ZnSO<sub>4</sub>, ZnCL<sub>2</sub>, Zn(NO<sub>3</sub>)<sub>2</sub> and Zn(C2H<sub>3</sub>O<sub>2</sub>)<sub>2</sub>. All of these salts shifted the concentration-response curves for carbachol, with no effect on atropine. Evaluation of several other heavy metals revealed that Cd<sup>2+</sup> (.01 mM) and Cu<sup>2+</sup> (.10 mM) alls oshifted the agonist displacement curve, while Co<sup>2+</sup> (1 mM) and Hg<sup>2+</sup> (.001 mM) had no effect. Like zinc, none of these metals affected the displacement curves of atropine. Reincubation of zinc-treated membranes with dithiothreitol reversed the zinc effect on agonist affinity. These data support the hypothesis that zinc increases muscarinic agonist affinity by binding to critical sulfhydryl groups which control the conformation of the receptor.

169.6 DISTRIBUTION AND FUNCTION OF M1 AND M2 MUSCARINE RECEPTORS IN DIFFERENT TISSUES. <u>L.T. Potter and J. Luber-Narod</u>. University of Miami School of Medicine, P.O. Box 016189, Miami, Florida 33101.

Measurement of the prevalence of M1 and M2 receptors is facilitated by agents which uncouple high-affinity agonist-receptor complexes, and by conditions which maximize the different binding properties of the two remaining populations of uncoupled receptors. These goals are achieved in 20 mM Tris-1 mM MnCl\_pDus 0.1 mM GpRNB at 37°C, or in 50 mM sodium phosphate-1 mM EDTA plus 1 mM NEM at 25°C. The latter is much less expensive. Membranes were prepared in 50 mM phosphate-10 mM EDTA plus 0.1 m NEM at 20-fold excess of 1 nM (-)  $^{3}$ H-quinuclidiny1 benzilate, by competition with carbachol and/or pirenzepine.

assayed with a 20-fold excess of l nM  $(-)^{3}$ H-quinuclidinyl benzilate, by competition with carbachol and/or pirenzepine. From all mammals so far studied (human, rat, rabbit, dog, monkey, cat, guinea pig, sheep) M1 and M2 receptors show the same affinities and very similar prevalences. There are two clear patterns. 75-90% of the sites in the forebrain (cortex, striatum, hippocampus etc.), ganglia and various glands (including intestinal lining) are of the M1 type, which shows -100-fold lower affinity for carbachol and - 15-fold higher affinity for pirenzepine than M2. The conducting system of the heart has many of these sites, which may lie on cholinergic cell bodies. M1 receptors appear to regulate neural firing (Mcurrents) and glandular secretion. In contrast, 80-90% of the sites in the brainstem and lower midbrain (medulla, pons, cerebellum, superior colliculus), forebrain cholinergic nuclei, smooth muscle and heart are of the M2 type, which is sensitive to GppNHp or NEM. Activation of these receptors attenuates activation of adenylate cyclase. Both receptors are used postsynaptically. M2 sites predominate in cholinergic neurons. Drugs can be selected for the regulation of specific tissues.

Supported by the National Parkinson Foundation.

169.7 CHANGES IN M1 AND M2 MUSCARINE RECEPTORS IN ALZHEIMER'S DISEASE AND AGING, AND WITH LESIONS OF CHOLINERGIC NEURONS IN ANIMALS. D.C. Mash and L.T. Potter. University of Miami School of Medicine, P.O. Box 016189, Miami, Florida 33101.

Our autoradiographs of muscarine receptors in rat and human brains demonstrate that regions rich in cholinergic cell bodies (magnocellular neurons in the basal forebrain of the rat, nucleus basalis of Meynert in humans, and the medial septum/diagonal band of Broca) are heavily labelled with <sup>3</sup>Hquinuclidinyl benzilate in the presence of enough pirenzepine to prevent binding to M1 receptors. Carbachol prevents this labelling at concentrations which occlude M2 receptors. Although most cortical receptors are M1 in type (labelled in carbachol but not pirenzepine), M2 receptors are apparent in laminae having the highest levels of choline acetyltransferase. In the hippocampus there is a striking correspondence between the localization of M2 receptors, the distribution of the septal-hippocampal projection, and acetylcholinesterase. Evidence that M2 receptors are transported in cholinergic nerves further favors the idea that M2 receptors are neurochemical markers for localizing cholinergic tracts. Acetylcholine is known to inhibit its own release, while receptor antagonists increase release. Our working hypothesis, therefore, is that M2 receptors and that a centrallyacting M2-selective antagonist may prove useful for increasing acetylcholine release in people with diminished numbers of cholinergic terminals.

We are seeking evidence for a decrease in M2 receptors in the cerebral cortex with Alzheimer's disease, with aging in humans, and in rats with kainic acid lesions in the ventral globus pallidus. So far, test tube data have yielded a consistent picture: there is a moderate (~ 20%) loss of total QNB sites in the frontal cortex, with a smaller loss in M2 sites. These changes are being correlated with changes in choline acetyltransferase. The localization of changes in receptors is being studied by autoradiography. If enough terminals remain in all layers of the cortex, there will be reason to focus further on drugs which work via these terminals. In any case, drugs which block MI receptors (e.g., scopolamine, trihexyphenidyl, antihistamines, and prochlorperazine) should be used with great care in demented patients, including those with Parkinson's disease.

Supported by NIH HL-07188 and the National Parkinson Foundation.

169.8 SELECTIVITY OF DRUGS FOR M1 AND M2 MUSCARINE RECEPTORS. J. Luber-Narod and L.T. Potter. University of Miami School of Medicine, P.O. Box 016189, Miami, Florida 33101.

We have examined - 30 commonly-used clinical and laboratory drugs which block or activate muscarine receptors, for their M1/M2 selectivity, by conducting competition assays against (-)<sup>3</sup>H-quinuclidinyl benzilate. Two sets of conditions were used. In 50 mM sodium phosphate-1 mM EDTA at 37°C, and in physiological media (Krebs) with added GpgNHp or NEM, ligands bind to only two populations of uncoupled receptors, analyses are easy, and quantitative data are obtained. The results are particularly applicable to laboratory work. In physiological media without uncoupling agents, analyses are complicated by the presence of high- and low-affinity agonist-receptor complexes; however the results are relevant for the selection of drugs in medicine, and for distinguishing physiological effects. Potency and selectivity series were obtained in both conditions, with complex results.

errects. Potency and selectivity series were obtained in both conditions, with complex results. Scopolamine is an example of a highly potent antagonist which is M1-selective only in EDTA. Oxotremorine is a highly potent agonist with little selectivity. McN-A-343 is a moderately potent agonist which is M1-selective only in physiological media. Carbachol is highly M2-selective in general. Dicyclomine (Bentyl) is - 100-fold more potent and slightly more M1-selective than the prototype antagonist, pirenzepine, (which is available only in Europe). It would appear to have advantages for treating ulcers over less selective drugs like propantheline (Pro-Banthine). Trihexyphenidyl (Artane) is one of the most M1-selective anti-Parkinson drugs. The nicotine receptor antagonists, gallamine and pancuronium, are also weakly M2-selective drugs are clearly needed and possible

N-ETHYL MALEIMIDE DISTINGUISHES M1 AND M2 MUSCARINE RECEPTORS. 169.9 D.D. Flynn and L.T. Potter. University of Miami School of Medicine, P.O. Box 016189, Miami, Florida 33101.

The binding of  $(-)^{3}H$ -quinuclidinyl benzilate to unselected membranes from the hippocampus and brainstem of the rat was examined in the presence and absence of NEM. NEM has two clear effects. Low concentrations (1  $\mu$ M at 37°, 10  $\mu$ M at 25°C) maximally diminished the high affinity of brainstem receptors (which are ~ 90% M2) for carbachol, moving competition curves to the right and almost to isotherms. The only effect on hippocampal receptors (which are ~ 75% M1) was to uncouple high-affinity carbachol binding to M2 sites. Thus low con-centrations of NEM diminish selectivity between M1 and M2. More NEM progressively increased the affinity of both receptors, especially M2, such that in 1 mM NEM at 25<sup>o</sup>C the carbachol affinity of M2 became ~ 100 times that of M1, greatly facilitating distinction between the uncoupled receptors. This effect was slightly facilitated by freezing membranes before effect was slightly facilitated by freezing membranes before assays. NEM had no effect on competition curves for the MI-selective antagonist, pirenzepine. The mechanism whereby NEM uncouples agonist-M2 complexes was apparent from dissociation rate experiments: NEM increased the rate of loss of <sup>3</sup>H-oxo-tremorine-M from M2 more than 20-fold, with little or no effect on M1. GppNHp has a similar effect. NEM probably uncouples high affinity agonist-M2 complexes by interacting with a guanine nucleotide binding protein. Presumably it increases affinities at high concentrations by direct actions on both receptors. receptors.

16910 BIOCHEMICAL CHARACTERIZATION OF CHOLINERGIC MUSCARINIC RECEPTORS IN MEMBRANE FRACTIONS FROM BOVINE AIR-WAY SMOOTH MUSCLE.

A. Ponte Sucre<sup>\*</sup>, <u>I.L. de Becemberg</u><sup>\*</sup> and <u>M. Alfonzo<sup>\*</sup></u>. (SPON: T. Koch).Seccion de Biomembranas, Instituto de Medicina Experimental, Universidad Central de Venezuela, Apartado 50587 Sabana Grande, Caracas, Venezuela.

The air-way caliber in many species including humans is regulated by the parasympathetic nervous system via the vagus nerve. This physiological regulation is effected by the contraction of the air way smooth muscle, which is blocked by atropine indicating thus that muscarinic receptors are involved. Most of the data regarding muscarinic receptors in air-way

smooth muscle are concerned with their pharmacological characteri-zation. In this work we have used [<sup>3</sup>H]-QNB binding to study some biochemical properties of muscarinic receptors associated to highbiochemical properties of muscarinic receptors associated to high-ly purified membrane fractions obtained by subcellular fractio-nation of bovine air-way smooth muscle. [H = 0KB binding shows high affinity, specificity and saturability, with an estimated Kd of 1.6nM and a Hill number (HN) of about 1 in the absence of experimental ions. Incubation of membrane fractions in the pre-sence of monovalent cations (0.154M) increased the specific bin-ding about 20% when KCl was used and 40% when either Nacl or LiCl was used. In addition, when KCl was used, Kd=1.8nM and HN=1.39t018 (slopetSD); when NaCl was used Kd=2.66nM and HN=1.84t0.12; and when LiCl was used Kd=2.66nM and HN=2.00t0.13. Incubation of membrane fractions with Tris (PO. or Wares(Midzeol instead of Tris Hel Mel used Melcour and Melcours interferences interference in the number of This /HCl, did not modify the effect of NaCl. Our results suggest that an increase in the number of receptors

and/or the cooperativity among them can be produced by the incu-bation of membrane fractions in the presence of monovalent cations. Furthermore, the specific binding and the HN increases as the atomic radius of the cation used decreases (K Na Li). This suggest that the functional properties of the muscarinic receptor are influenced by its environment, i.e., that there are specific interactions which depend on the ion's radius and are thus subjec-ted to physical restrictions. At NACI concentrations similar to those present in the extracellular fluid the specific binding to membrane fractions shows optimal values and the HN increases from near 1 to 1.84, thus indicating an increased cooperativity among the receptors. Indeed Ghosh (1981) has pointed out that in those The receptors. Indeed drosh (1961) has pointed out that in these systems where positive cooperativity exists and depends on the presence of a cofactor, such cooperativity shows optimal values at the physiological concentrations of the cofactor. 169.12 'LIGAND-BINDING CHARACTERIZATION OF INSECT ACETYLCHOLINE

'LIGAND-BINDING CHARACTERIZATION OF INSECT ACETYLCHOLINE RECEPTORS. <u>Sarah C.R. Lummis\* and David B. Sattelle\*</u>. (SPON: A. Taylor). <u>ARC</u> Unit of Insect Neurophysiology and Pharmacology, Dept. of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, U.K. Radiolabelled ligand-binding studies have been used to investigate acetylcholine receptors in the central nervous system of the cockroach <u>Periplaneta americana</u>. In studies using the nicotinic cholinergic receptor ligand, <u>A</u>-bungarotoxin and the muscarinic cholinergic receptor ligand, <u>quinuclidinyl</u> benzilate, particulate preparations of cockroach nerve cords were shown to contain distinct saturable components of specific binding. L-[benzilic-4, 4'-H]-quinuclidinyl benzilate bound to a single class of non-cooperative binding sites. Scatchard binding. L-(benzilic-4, 4'-H)-quinuclidinyl benzilate bound to a single class of non-cooperative binding sites. Scatchard analysis yielded a K, of 8nM and a B of 138pmol/mg. The dissociation constant calculated from the association and dissociation rate constants was 1.9nM. The pharmacological profile of the binding component was that expected for a muscarinic acetylcholine receptor: dexetimide, atropine, scopolamine and unlabelled quinuclidinyl benzilate were the most potent inhibitors of binding, whilst  $\propto$  -bungarotoxin and nicotine were ineffective. The N-[propiony1-]H]-Interface were interfective. The w-(propionyl-nj-propionylated  $\ll$ -bungarotoxin binding component was saturable (B<sub>m</sub> = 910pmol/mg) and of high affinity (K<sub>s</sub> = 4.4nM). Rate constants for association and dissociation yielded a Raher constants for association and dissociation yielded a dissociation constant of 0.6nM. Specific  $\propto$  -bungarotoxin binding was displaced most effectively by the nicotinic ligands d-tubocurarine (K\_=8.5 x 10<sup>-</sup>M), nicotine (K\_=3.4 x 10<sup>-</sup>M) and unlabelled  $\propto$  -bungarotoxin (K\_=7.7 x 10<sup>-</sup>M). The muscarinic ligands quinuclidinyl benžilate (K\_=1.4 x 10<sup>-</sup>M) and atropine (K\_=2.0 x 10<sup>-</sup>M) were much less effective. Decamethonium (K\_=1.3 x 10<sup>-</sup>M) was a weak inhibitor. The cell body membrane of the fast coxal depressor motoneurone (D\_{f}) of the cockroach metathoracic ganglion was particularly sensitive to nicotinic cholinergic ligands (David J.A. & Sattelle D.B., J. Exp. Biol., 1983, in press):  $\propto$  particularly sensitive to nicotinic cholinergic ligands (David J.A. & Sattelle D.B., J. Exp. Biol., 1983, in press):  $\propto$  -Bungarotoxin was much more effective (I<sub>50</sub> = 6.4 x 10 <sup>M</sup>) in blocking the depolarization resulting from ionophoretic application of acetylcholine, than either quinuclidinyl benzilate (I<sub>50</sub> = 1.0 x 10 <sup>M</sup>) or decamethonium (I<sub>50</sub> = 2.8 x 10 <sup>M</sup>). It is concluded that the membrane component characterized in  $\propto$ -bungarotoxin binding studies is a constituent of a cell body acetylcholine receptor of an identiconstituent of a cell body acetylcholine receptor of an identified motoneurone.

169.11 PROPERTIES OF A SOLUBILIZED GUANYL NUCLEOTIDE SENSITIVE MUSCARINIC ACETYLCHOLINE RECEPTOR. M.W. Gainer and N.M. Nathanson. Dept of Pharma-cology, Univ. of Washington, Seattle, WA 98195. Extensive studies on membrane homogenates have Extensive studies on membrane homogenates have shown that muscarinic receptors consist of at least two classes of sites which have similar high affini-ties for antagonists but differ in their affinities for agonists. Previous attempts to solubilize muscar-inic receptors have yielded preparations which retain specific high affinity binding of antagonists but bind agonists to only a single class of low affinity sites and thus have lost the heterogeneity of agonist binding characteristic of the membrane bound receptor.

of agon1st binding characteristic of the membrane bound receptor. In this study, a combination of 10 mM CHAPS and 1 M NaCl solubilized 15-40% of the specific receptor binding sites from bovine brain membranes. This sol-ubilized receptor preparation binds the muscarinic antagonist, [3H] QNB, with high affinity to a single class of sites ( $K_D$ =301 pM). Moreover, this solubilized preparation exhibits heterogeneity in the binding of the agonist, carbachol, as well as guanyl nucleotide regulation of agonist binding, identical to that of the membrane bound receptor. Therefore, CHAPS can solubilize muscarinic receptors from bovine brain membranes which retain the agonist and antagonist membranes which retain the agonist and antagonist binding properties characteristic of the membrane bound receptor.

The solubilized receptor preparation can be adsorbed to wheat germ lectin sepharose and specifically eluted with N-acetylglucosamine with a several-fold increase in specific activity, suggesting that lectin chromotography may be a useful step in

the purification of the receptor. Sucrose gradient sedimentation analysis of the solubilized receptor showed that the receptor sedimented in a single peak with a sedimentation coefficient of 5S.

Sepharose 4B chromotography of the solubilized receptor preparation resulted in an elution profile containing two peaks of activity. Studies are being undertaken to determine if the receptor in these two peaks exhibit similar biochemical properties.

170.1 CHARACTERIZATION OF ENKEPHALIN-LIKE PEPTIDES IN BOVINE SPLANCHNIC NERVE, <u>T.D. Hexum</u>. Dept. Pharmacology, Univ. Neb. Med. Ctr., Omaha, NE 68105

Chromaffin cells from the adrenal medulla contain opiate well as cholinergic receptors. Acetylcholine-induced catecholamine secretion can be reduced by opiate agonists such as etorphine. The source of the endogenous opiate material that can interact with these receptors may be either the adreno-medullary interact with these receptors may be either the alreadomedulisry chromafing granules or the splanchnic nerve both of which contain enkephalin-like peptide (ELP) material (Schultzberg et al., 1978 Neurosci. 3, 1169-1186). The ELP content of adrenal chromafin granules has been well-characterized and found to exist primarily as polymeric forms of met<sup>2</sup>- and leu<sup>2</sup>-enkephalin (high MW) with lesser amounts of the pentapeptides and related compounds (low MW). The nature of the ELP content of splanchnic nerves has not been determined.

been determined. Splanchnic nerves from pigs were desheathed, minced and homogenized in 1 N acetic acid containing 0.02 N HCl and 0.1 % 2-mercaptoethanol. The homogenate was subjected to a chloroform:methanol extraction procedure (1:2). <sup>3</sup>H-Met<sup>5</sup>-enkephalin added to the extraction mixture was recovered in the methanol layer (93% recovery). The ELP content of pig splanchnic nerve, determined radioimmunochemically using a C-terminal directed antiserum to met<sup>5</sup>-enkephalin, was 1.4 pmoles ELP/mg protein. Trypsinization followed by treatment with carboxypeptidase B increased the immunoreactivity to 5.2 pmoles ELP/me protein indicating the presence of precursor (hish MW) CRLOWSYPEPLIURSE D INCREASED IN INTERPRETATION OF A CONTRACT OF A CONTRA pattern is similar to that reported for other nervous tissue such as the striatum but unlike that observed in adrenal chromaffin granules.

- 170.2 OPIOID PEPTIDES IN RAT PITUITARY\_ANTERIOR LOBE.
  - C.J. Molineaux. J.G. Rosenberger and B.M. Cox. Department of Pharmacology, Uniformed Services University, Bethesda, MD 20814.

The presence in pituitary corticotrophs of pro-opiomelano-cortin and the opioid peptide  $\beta$ -endorphin derived from it, is well established. However, peptides derived from the two other known opioid peptide gene products, prodynorphin and proenkeph-alin, are also present in anterior lobe (AL), suggesting a possible local role for endogenous opioids in pituitary function in addition to their probable function in pituitary regulation at the level of the hypothalamus. We have measured by RIA the levels of several dynorphin-

(Dyn-) and enkephalin-like periods in rat AL. The level of ir-Dyn A-(1-13) in AL was 2.32 pmol/gland, an amount comparable to that found in the neurointermediate lobe. The total irto that four in the herbilitermediate fold. Into that  $11^{-1}$  and  $-neo-onder hin (a-nEND) concentration was lower (0.42 pmol/gland. However, gel filtration analysis indicated that there was very little authentic Dyn A-(1-17) and <math>\alpha$ -nEND present. The level of  $\underline{j_1}$ -Dyn A-(1-8), another small peptide derived from prodynorphin, was also very low (0.08 pmol/gland). Most of the Dyn A and  $\alpha$ -nEND immunoreactivity in AL extracts eluted with apparent M in the range 6-10 kdaltons. The absolute amounts of these peptides cannot be determined because the RIA cross-reactivities of these putative precursor peptides are unknown.

 $\underline{ir}$ -Leucine-enkephalin (LE) is also present in AL, at a level of 1.18 pmol/gland. LE might be generated from either prodynorphin or proenkephalin. We have therefore measured the concentration of the C-terminal fragment of proenkephalin,  $[{\tt Met}^5]$ -enkephalin-Arg-Phe (ME-RF), with an antiserum which has negligible cross-reactivity with the other opioid peptides known to be present in AL, but which apparently also recognizes enke-phalin precursors. The <u>ir-MR-RF</u> level in AL was 5.52 pmol/ gland. Gel filtration analysis suggests that <u>ir-ME-RF</u> in AL is also present largely in a high molecular weight form. Thus, it appears that the low levels in AL of the small molecular weight forms of opioids derived from prodynorphin and proenke-

phalin do not result from a deficiency of precursor peptides. In initial experiments examining dynamic changes in opioid peptide levels in AL, levels of each of the peptide immunopeptide levels in AL, levels of each of the peptide immuno-reactivities were measured at intervals throughout a 24 hr period. A significant circadian variation was observed in the level of <u>ir-ME-RF</u>, with the level at 0100 hr being approximately twice that found at 1300 hr. Other peptide immunoreactivities remained relatively stable. (Supported by USUHS Research Protocol R07542).

- EXAMINATION AND CHARACTERIZATION BY COLUMN COUPLED RADIORECEPTOR 170.3 ASSAYS OF ENDORPHINS RELEASED FROM THE SPINAL CORD OF THE CAT DURING CONTROL AND HIGH INTENSITY STIMULATION OF THE SCIATIC DURING CONTROL AND INTERSTIT STITUTION OF THE SCHWICK and K. Jhamandas\* (SPON: P.J. Dyck). Dept. of Neurosurg. Res., Mayo Clinic, Rochester, MN; Depts. of Pharmacol., Uppsala Univ., Uppsala, Sweden; Queens Univ., Kingston, Ontario, Canada. We have previously shown that met-enkephalin like immunoreactivity is released from the spinal cord by high intensity stimulation of the sciatic nerves (J. Neurophysiol. 46:1056,1981). We have extended these experiments to determine if other materials acting at opiate binding sites are released. Cats are anesthetized (chloralose-urethane), prepared for spinal superfusion with a (chloralose-urethane), prepared for spinal superlusion with a concentric polyethylene catheter inserted through the cisternal membrane. Artificial CSF with albumin (120  $\mu$ g/ml) and bacitracin (30  $\mu$ g/ml) was infused at 100  $\mu$ l/min through the inner catheter (PE-10) which extended to the sacral cord (35 cm). The outflow was collected through the outer catheter (PE-90) which extended to the mid-thoracic cord (15 cm). Samples were lyophilized and reconstituted in 0.2 M acetic acid, and passed through an Amicon PM-10 filter prior to passing over a Sephadex G-10. Further separation was achieved using column electrophoresis in agarose suspension. Opiate displacement activity was examined using brain synaptosomes and <sup>3</sup>H-dihydromorphine (<sup>3</sup>H-DHM) as described elsewhere (Life Sci. 16:1759, 1975). Separation of activity on the G-10 column revealed two fractions (I and II) which appear before and after the solt fractions and account for over 70% of before and after the salt fractions (1 and 11) which appear before and after the salt fractions and account for over 70% of 3H-DHM displacing activity. Sciatic nerve stimulation resulted in a 30 and 5 fold increase in FI and FII, respectively. Electro-phoretic separation of FI at alkaline and acid pH revealed 2 major pools which co-migrated with  $\alpha$ -neoendorphin and dynorphin 1-13. FII activity was isographic with enkephalin hexapeptides. Radioimmunoassays revealed the presence of dynorphin. Though relatively little activity co-migrated with met-enkephalin radio-immunoassays revealed low levels comparable to that previously reported in spinal superfusates. In all cases, the activity peaks identified on the agarose columns was elevated by sciatic nerve stimulation. These observations confirm the stimulated release of non-enkephalin activity which co-migrates with extended enkephalin and dynorphin fragments. Whether these several fractions represent neurotransmitters or metabolic by-products is rractions represent neurotransmitters or metabolic by-products is not known, but as they derive from metabolically distinct pre-cursors, their increase in the extracellular fluid by sciatic nerve stimulation suggests that they may serve as markers for activity in different populations of endorphin releasing neurons. Can we now determine what is the effective physiological drive for the several populations of neurons from which these markers are derived? (NSI6541/TLY; DA01502, B83-04X-03766-12C/LT)
- 170.4 CHARACTERIZATION OF IN VITRO β-ENDORPHIN PROCESSING IN THE BRAIN AND GUT: IMPLICATIONS. <u>Thomas P. Davis</u>, Alison J. Culling<sup>\*</sup> and Hans Schoemaker<sup>\*</sup>. Dept. of Pharmacology, University of Arizona College of Medicine, Tucson, Arizona 85724.

In vitro, central, proteolytic processing of  $\beta$ -endorphin ( $\beta$ E;  $\beta$ E 1-31) by membrane-bound enzymes results in the formation of among others  $_{\Omega E}$  (BE 1-16),  $_{YE}$  (BE 1-17) and their des-tyrosine-analogs. Clinical studies suggest that these endorphins may analogs. United studies suggest that these enotypins may function in brain homeostases and a variety of behavioral adaptive processes due to their amphetamine ( $\alpha E$ ) and neuroleptic  $(\gamma E)$ -like activities.

Recent evidence from our laboratory indicates that  $\beta E$  is also recent evidence rise out and and the sine while significantly increasing motility. Analysis of the venous effluent identified, among others, several  $\alpha$ - and  $\gamma$ -type endorphins. Upon testing these peptide fragments, it was noted that  $\alpha S$ ,  $\gamma E$  and their descent of the several  $\alpha$ - and  $\gamma$ -type endorphins. tyrosine-analogs significantly increased motility at doses of l $\mu g/ml.$  These responses were characterized by increases in phasic contractions of constant amplitude and frequency.

phasic contractions of constant amplitude and frequency. These observations led to the hypothesis that a balance exists between  $\alpha^-$ ,  $\beta^-$  and  $\gamma^-$ type endorphins in specific tissues that is necessary for "normal" physiological activity. To address this hypothesis, a new, improved HPLC procedure, capable of separating 28 different  $\beta E$  related fragments in a single chromatographic analysis, was developed. In vitro  $\beta E$  metabolism by membrane-bound enzymes from post-mortem brain and regions of the small intention where the fourth of the second process of the small bound enzymes from post-mortem brain and regions of the small intestine were studied. BE (20µM) was incubated in PBS buffer at 37°C with twice-washed membrane preparations. After 30-120 min time-course incubations, samples were boiled for 15 min and centrifuged for 60 min at 15,000 kg. The supernatant was assayed for SE related peptide fragments by HPLC. The peptides were separagE related peptide fragments by HPLC. The peptides were separa-ted on a ODS-5 $\mu$  column using a series of curvelinear gradients of acetonitrile against 0.1M NaH\_PO, buffer (pH 2.1) with detection at 210nm. The most striking difference was between the mucosa and nerve/muscle regions of the small intestine. The mucosa metabolized  $\beta$ E very rapidly with a T\_2 of 22 min, whereas  $\beta$ E in the muscle had a half-life of 82 min. The mucosa also exhibited a very random rate of fragment formation which differed qualita-tively and quartitatival. Score the neuroference are the tively and quantitatively from the nerve/muscle region and the brain. The brain was very similar to the nerve/muscle region of the small intestine in that it metabolized  $\beta E$  slowly (T\_2^1=141 min brain. vs 82 min) and yielded a very similar pattern and ratio of  $\alpha-$  and  $\gamma-type$  endorphins. Therefore, these data suggest that  $\beta E$  processing in the nerve/muscle region may be occurring at the nerve and that a specific balance of  $\alpha-$  and  $\gamma-type$  endorphins does exist in different tissues. The question of whether this balance in the gut is altered in pathological states, as we have shown centrally in schizophrenia, remains to be established.(Supp. by PMA Grant)

170.5 THE ACTION OF ENDOPEPTIDASE OF BRAIN MEMBRANES WITH DYNORPHIN-RELATED PEPTIDES. <u>M. Knight, L. Steardo, C.A. Tamminga, T.N.</u> <u>Chase.</u> NINCDS ETB, Bethesda, Maryland 20205. <u>An enkephalin-generating endopeptidase (ECE) purified from</u> rat brain membranes has been previously shown to form enkephalin from peptides containing the amino-terminal enkephalin sequence. Although the tryptic fragment of Beta endorphin, Beta-LPH61-69 was initially used as the assay for this peptidase, ECE also produces enkephalin from enkephalin Arg<sup>6</sup> and generates enkephalin and Leu-enkephalin from precursors in striatal extracts of rat. Thus, this endopeptidase may function in brain as the final processing enzyme in enkephalin biosynthesis from proenkephalin procursors. The possibility exists that ECE may metabolize the dynorphin-

The possibility exists that but may metabolize the dynorphinalpha-neoendorphin precursor and fragment peptides. Since the known specificity of the enzyme is to cleave a medium chain peptide sequence after a Met or Leu amino acid, Leu-enkephalin could be cleaved from alpha-neoendorphin and dynorphin, or dynorphin 1-8 could be generated directly by proteolysis of the Ile<sup>6</sup> peptide bond in dynorphin 1-17, 1-13, or 1-11. To answer this question, dynorphin peptides at 10<sup>-5</sup>M were reacted with 6 ug/ml EGE enzyme at 37°; at progressively longer reaction times the products were analyzed by HPLC and radioimmunoassay for the products of Leu-enkephalin and dynorphin 1-8. There was no formation of Leu-enkephalin or dynorphin 1-8 from dynorphin 1-13 and 1-17 at times up to 90 min. Thus, the enzyme apparently lacks affinity for these peptides. However, when the EGE was reacted with dynorphin 1-8 and with alpha-neoendorphin octapeptide amide, a rapid production of Leu-enkephalin from the suggest a role for EGE in generating Leu-enkephalin from the dynorphin-alpha neoendorphin system. Also, the enzyme could function as the inactivating enzyme for dynorphin 1-8. Indeed, the presence of EGE in either synthetic granules or on the nerve ending cell membrane may define the neurochemistry of a neuron as a functional enkephalin cell.

- 170.6 PHENCYCLIDINE-INDUCED INHIBITION OF STRIATAL ACETYLCHOLINE RELEASE: COMPARISONS WITH MU, KAPPA, AND SIGMA OPIATE AGONISTS. <u>S.M. Leventer\* and K.M. Johnson</u>. Dept. of Pharmacol. and Toxicol. Univ. Tex. Med. Br., Galveston, TX 77550. Phencyclidine (PCP) has been shown to share a number of characteristics with certain psychotomimetic opioids. In the rat, cyclazocine and PCP produced a similar behavioral pattern, including backwards walking and side-to-side head movements. In the chronic spinal dog, both SKF10047 and PCP increased pulse
  - Tate, dilated pupils, and decreased the flexor reflex. Finally, in rats trained to discriminate PCP from saline, SKF10047 and cyclazocine elicited PCP-appropriate responding. Previous studies in our laboratory have shown that PCP produced a concentration-dependent inhibition of K<sup>+</sup>-stimulated acetyl-

choice studies in our laboratory have show that for produced a concentration-dependent inhibition of K<sup>-</sup>-stimulated acetylcholine (ACh) release from rat striatal slices. In order to further characterize the similarities between PCP and the opiates, the present study compared the effects of PCP to those of morphine, ethylketocyclazocine (EKC) and SKF10047, putative agonists at mu, kappa and sigma binding sites respectively. EKC and the (+)-isomer of SKF10047, like PCP, inhibited K<sup>+</sup>-

EKC and the (+)-isomer of SKF10047, like PCP, inhibited K<sup>-</sup>stimulated ACh release in a concentration-dependent manner. This effect was antagonized by 0.1  $\mu$ M naloxone and 0.1  $\mu$ M haloperidol. Since it is probable that naloxone is not an antagonist at the sigma/PCP receptor, but is an antagonist at the mu and kappa receptor, these data indicate that the effect of PCP and SKF10047 may result from interaction with mu and/or kappa receptors. Morphine, however, had no effect on ACh release in this preparation, suggesting that the inhibition of ACh release observed in this study may be mediated via kappa opiate receptors. The reversal of this effect by haloperidol suggests that EKC and SKF10047, like PCP, may inhibit ACh release indirectly by stimulating straital dopamine release. This work was supported by ADAMHA grant #DA 02073.

170.7 PHOSPHORYLATION STATE OF 45-49 kD PROTEINS IN MONKEY CEREBRAL CORTEX: CORRESPONDENCE WITH OPIOID RECEPTOR GRADIENTS. <u>R. Nelson\*, D.</u> <u>Friedman, J. B. O'Neill, M. Lewis, M. Mishkin, and A. Routtenberg.</u> Cresap Neuroscience Laboratory, Northwestern University, Evanston, IL 60201, and Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205.

Stereospecific 3H-naloxone binding sites in rhesus monkey cerebral cortex, which represent one or more classes of opioid receptors, increase in density along cortical pathways which sequentially process modality-specific sensory information (Fig.la; Lewis, et al., <u>Science</u>, 1981). Since certain opioid peptides affect protein phosphorylation (Bar et al., <u>Eur.J.Pharm.</u>, 1980), we examined endogenous phosphorylation of electrophoretically separated proteins from cerebral cortex of 3 rhesus monkeys. We now report: (a) an inverse correlation (Fig. lb) across 22 cortical regions between the density of 3H-naloxone binding sites and the <u>in vitro</u> phosphate incorporation of Band F1, a 45 kD protein (r=-0.609,df=20,pQ,01); (b) the presence of a 47 kD protein with similar properties to the 45 kD band (Ca++-stimulated, cAMP-stimulated phosphorylation) found only in cortical regions of highest 3H-naloxone binding levels (r=40.564,df=20,pQ.01). These findings suggest a local control of protein phosphorylation in monkey cerebral cortex corresponding to opioid receptor levels.

A 48 kD brain phosphoprotein termed B-50 proteolytically cleaves following dialysis to a 46 kD phosphoprotein, B-60 (Zwiers et al., <u>FEBS Letters</u>, 1981). B-50 phosphorylation is also sensitive to dynorphin (Zwiers et al., <u>Life Sci.</u>, 1981). The 45-49 kD phosphoproteins observed in monkey cortex may correspond to B-50 and B-60, suggesting that these 2 proteins may occur physiologically and that endogenous opioids may determine which form predominates. (Supported by MH25281 and MH263-MD-229713 to A.R.)

170.8 ISOLATION AND CHARACTERIZATION OF METORPHAMIDE, A NOVEL AMIDATED OPIOID OCTAPEPTIDE FROM BOVINE BRAIN. <u>E. Weber, F. Esch\*, P.</u> Bohlen\*, J. D. Barchas and C. J. Evans. Nancy Pritzker Lab., Dept. Psychiatry, Stanford Univ. Med. Sch., Stanford, CA 94305, and Labs. for Neuroendocrinology, Salk Institute for Biological Studies, La Jolla, CA 92037

Studies, La Jolla, CA 92037 Recent studies have begun to yield information on the posttranslational proteolytic processing of opioid peptide precursors in brain. Most work has been done on pro-dynorphin whose processing appears to be unusual in that at least two peptides, dynorphin A(1-8) and dynorphin B, are generated from this precursor by proteolytic cleavages at single arginine residues rather than at classical double basic amino acid residues thought to be primarily involved in peptide precursor processing (1,2). In order to examine whether pro-enkephalin, the second major privide meruperson also given prior to conside that are

In order to examine whether pro-enkepnalin, the second major opioid peptide precursor, also gives rise to opioids that are generated by a single arginine cleavage, we have begun to examine brain tissue from several species for the presence of such cleavage products. Here we show that extracts from bovine caudate contain a midated opioid octapeptide with the following following structure: Tyr-Gly-Gly-Phe-Met-Arg-Arg-Val-NH<sub>2</sub>. The peptide has been named metorphamide. Metorphamide is contained within pro-enkephalin and is apparently generated by a single arginine cleavage followed by transformation of a carboxyterminal glycine into an amide group. Metorphamide was detected by a specific RIA and purified to homogeneity by gel-filtration chromatography and reverse phase HPLC. The purified peptide was chemically characterized by amino acid composition analysis and automated Edman degradation in the gas/liquid phase peptide

Weber, E., Evans, C.J., Barchas, J.D. <u>Nature 299</u>, 77, 1982.

HIGH-PERFORMANCE LIQUID CHROMATOGRAPHIC STUDIES OF ENKEPHALIN-LIKE PEPTIDES IN HIPPOCAMPUS, RETINA, AND COCHLEA. <u>Douglas W. Hoffman</u> LNO, Bldg 36, Rm. 5008 National Institutes of Health, Bethesda, MD 20205 Previous studies from this lab have reported the 170.9 Previous studies from this lab have reported the presence of enkephalin-like peptides in the guinea pig cochlea, retina and hippocampus, using immunofluorescent, chromatographic, and radioimmunoassay techniques. The high-performance liquid chromatographic (HPLC) studies, utilizing an isocratic elution of trifluoroacetic acid (TFA) in acetonitrile from a reversed phase column, demonstrated the presence of three enkephalin-like fractions in these tissues as determined by fractions in these tissues, as determined by radioimmunoassay (RIA) of the HPLC fractions. Two of these fractions can be identified by retention time in HPLC as met- and leu-enkephalin, respectively. The third immunoreactive HPLC fraction elutes earlier than met- or leu-enkephalin standards from the reversed-phase column, and, like the fractions identified as met- and leu-enkephalin, co-elutes from a Biogel P-2 column with synthetic enkephalin standards, and is active in inhibiting the binding of labeled opiate ligands to rat brain membranes. It appears likely that this earlier eluting fraction contains a chemically modified or extended leu-enkephalin-like molecule, possibly a dynorphin fragment, although neither dynorphin (1-8) or alpha-neo-endorphin (1-8) have the retention time of this fraction.

Gradient elution of tissue sonicates, utilizing a shallow gradient from 20% to 30% acetonitrile in 0.05% TFA, indicates that the earlier eluting fraction is composed of two or more immunoreactive and bioactive peptides, as determined by RIA and radioreceptor assays of HPLC gradient fractions. Further studies are directed toward purification and Further studies are directed toward purification and identification of these chromatographically separated enkephalin-like peptides. 170.10 ISOLATION AND AMINO ACID SEQUENCE OF A PRO-DYNORPHIN C-TERMINAL FRAGMENT FROM BOVINE CAUDATE NUCLEUS. C. J. Evans, F. Esch\*, P. Bohlen\*, J. D. Barchas and E. Weber. Nancy Pritzker Lab., Dept. Psychiatry, Stanford Univ. Med. Sch., Stanford, CA 94305, and Labs. for Neuroendocrinology, Salk Institute for Biological Studies La Jalla CO 02027

Studies, La Jolla, CA 92037. The complete primary structure of the common precursor to neo-endorphins and dynorphins was recently determined. The precursor contains the amino acid sequences of  $\alpha$ -neo-endorphin, dynorphin A and dynorphin B (rimorphin). Dynorphin B is located near the carboxyterminus of the precursor. The release of dynorphin B involves cleavage at a single

The release of dynorphin B involves cleavage at a single arginine residue. This processing site is 16 residues from the C-terminus of the precursor. One would predict that cleavage at this site results not only in the release of dynorphin B but also a fragment constituting the C-terminus of the precursor (pro-dynorphin C-fragment). We have raised antibodies to a synthetic decapentapeptide fragment representing the C-terminus of pro-dynorphin as predicted from the porcine mRNA nucleotide sequence. Using radioimmunoassay as detection system, we isolated and characterized natural pro-dynorphin-C-fragment immunoreactive material from bovine caudate nucleus. Amino acid composition analysis showed that the peptide consisted of 15 amino acid residues. Microsequencing in the gas/liquid phase sequenator demonstrated that bovine pro-dynorphin-C-fragment sequenator demonstrated that bovine pro-dynorphin-C-fragment differed by one amino acid from the porcine peptide as predicted from the mRNA sequence (serine was substituted for the asparagine residue at position 6). The N-terminal amino acid was serine (an arginine as predicted from the mRNA sequence was missing from the N-terminus) showing that the processing enzyme(s) cleave(s) on the carboxyl side of the arginine residue. Dynorphin-B was also isolated from bovine caudate nucleus. Amino acid composition analysis confirmed its structure (i.e., no arginine was present at the C-terminus of dynorphin B). Since the arginine residue at the cleavage site dynorphin B). Since the arginine residue at the cleavage site is not present on either dynorphin-B or pro-dynorphin-C-fragment, it must be eliminated during the processing. The cleavage at this single arginine residue is therefore analogous to those at double basic residues and is consistent with a trypsin-like cleavage followed by carboxypeptidase-B-like activity. The pro-dynorphin C-fragment that we have isolated may be a good marker peptide for the presence of pro-dynorphin in neuronal tissues.

170.11 POMC IN RHESUS ANTERIOR PITUITARY + PLASMA: EVIDENCE OF

PONC IN RHESUS ANTERIOR PITUITARY + PLASMA: EVIDENCE OF N-ACETYLATED  $\beta$ -ENDORPHIN AND  $\alpha$ -MSH <u>C. Cahill<sup>\*</sup>, S. Watson</u>, <u>M. Knobloch<sup>\*</sup> and H. Akil</u> (SPON: G. Goldstein). Mental Health Res. Insti., Univ. of Michigan, Ann Arbor, Michigan 48109 Pro-opiomelanocortin (PONC) related peptides have been extensively studied in rat tissue and plasma. Yet, in rhesus monkey pituitary and plasma they have not been well characterized. We have characterized POMC related peptides by immunocytochem-istry, multiple radioimmunoassays (RIA's), molecular sieving and HPLC. HPLC.

Immunocytochemical staining of the pituitary demonstrated N-acetyl- $\beta$ -endorphin and  $\alpha$ -MSH in some of the anterior lobe (AL) corticotrophs. The AL was carefully separated from the thin band corticotrophs. The AL was carefully separated from the thin band of the intermediate lobe (IL) seen in monkey. The dissection was conservative to avoid contamination from IL. RIA's of extracted AL has shown N-acetyl-B-endorphin-like and  $\alpha$ -MSH-like immunoreac-tivity. Molecular sieving chromatography of the extracted AL has shown that the B-endorphin-sized peak is larger than the B-LPH peak with a ratio of 1.7:1 unlike the situation in the rat where the B-endorphin/B-LPH ratio is 0.5:1. Further, a significant proportion of the B-endorphin-sized peak is N-acetylated (33%), whereas less than 8% acetylation is seen in rat B-endorphin-sized material derived from the AL. Overall less than 3% of the total material derived from the AL. Overall, less than 3% of the total  $\beta$ -endorphin-like immunoreactivity in the rat AL is N-acetylated whereas, over 20% of the immunoreactivity is N-acetylated in monkey AL. This pattern along with the presence of  $\alpha$ -MSH-like immunoreactivity suggests that post-translational events more immunoreactivity suggests that post-translational events more similar to the rodent intermediate lobe, and is mirrored by the plasma profiles. Molecular sieving chromatography of extracted plasma demonstrated a pattern similar to that seen in the AL. N-acetyl- $\beta$ -endorphin forms and  $\alpha$ -MSH peaks are clearly identifiable with 40% of the  $\beta$ -endorphin-sized material being N-acetylated. After pretreatment with intraventricular colchicine, N-acetyl- $\beta$ -endorphin and  $\alpha$ -MSH-like immunoreactivity disappears from plasma. These data suggest that rhesus monkey corticotrophs process POMC differently than rat with a pattern falling between AL and IL patterns of the rodent. 170.12 ISOLATION OF MULTIPLE-SIZED IMMUNOREACTIVE FORMS OF DYNORPHIN-A IN ISULATION OF INDEFINITE COLLEGE AND A COLLEG 48109

Immunocytochemical studies indicate that pro-dynorphin, the common precursor for and  $\alpha$ -neo-endorphin, dynorphin A and dynorphin B, has a distribution distinct from either the enkephalin or  $\beta$ -endorphin opioid networks in the central nervous system of the B-endorphin optoin networks in the central nervous system of the rat (Khachaturian et al., <u>Peptides</u>, <u>3</u>:941-54, 1982). Two anatom-ically distinct terminal field regions in the pro-dynorphin system are the posterior lobe of the pituitary, a neuroendorcine region and the substantia nigra, the major dopaminergic cell group in the CNS.

In order to assess whether dynorphin A is differentially processed in these regions acid/acetone extracts of the posterior pituitary and substantia nigra were separately fractionated by gel filtration chromatography on a Sephadex G-50 column equilibrated Interaction from to graphy on a separate 0-50 contain equilibrium [Leu]enkephalin.

Three peaks of dynorphin A-related material were detected in the extracts of both regions: a 4K peak of DYN A(1-17)-related material, a peak of DYN A(1-17)-sized material, and a peak of DYN A(1-8)-sized material. In the substantia nigra these peaks represented respectively 1%, 3%, and 96% of the total immunoreactivity, while in the posterior pituitary these peaks represented 11%, 28%, and 61% of the total immunoreactivity. These results argue that the dynorphin A region of pro-dynorphin is differentially processed in these regions to yield DYN A(1-8)-sized material as a major end product in the substantia nigra, and a mixture of DNN A(1-17)- and DNN A(1-8)-sized material as major end products in the posterior pituitary. Experiments are in progress to analyze the forms of dynorphin A present in the cell bodies associated with these distinct terminal regions

170.13 B-ENDORPHIN IMMUNOREACTIVITY IN THE RAT PITUITARY: POSTNATAL DEVELOPMENT. N.E. Alessi, H. Khachaturian, S.J. Watson and H. Akil. Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109. Previous studies of β-endorphin ontogeny have focused mainly on

developmental changes in content of different brain regions (Bayon, A., et al., <u>Brain Res.</u> <u>1793-101</u>, 1979). Little attention has been given to the <u>ontogeny</u> of <sub>β</sub>-endorphin in the pituitary gland. Specifically, post-translational alterations of the <sub>β</sub>-endorphin molecule which may occur at different developmental stages, such as changes in the ratio of multiple forms or in acetylation of  $\beta$ -endorphin, have not been studied. Our current studies of the postnatal development of  $\beta$ -endorphin in the anterior (AL) and intermediate (IL) lobes of the rat pituitary have begun to address these issues.

Postnatal (P1, P7, P14, P21 days) and adult male Sprague-Dawley rats were sacrificed, and the pituitaries were immediately separ-ated into AL and IL (also containing neural lobe). The region of the AL in contact with the IL was discarded. Tissue was extracted in acid-acetone with iodoacetamide and phenylmethylsulfonyl fluor-ide as inhibitors. Radioimmunoassays were performed utilizing antibodies which recognize  $\beta$ -endorphin immunoreactivity (i.r.) and N-acetylated- $\beta$ -endorphin i.r. The preliminary results are summarized in the following table. Values of  $\beta$ -endorphin i.r. are expressed in pmol/lobe (mean + SEM).

	<u>P1</u>	<u>P7</u>	P14	<u>P21</u>	Adult
AL	1.8 <u>+</u> 0.0 (n=5)	6.1 <u>+</u> 1.7 (n=5)	10.4 <u>+</u> 0.4 (n=6)	16.2 <u>+</u> 4.5 (n=6)	164 <u>+</u> 40 (n=5)
			<pre></pre>		

 $\frac{\text{IL}}{(n=5)} \begin{array}{c} 2.3 \pm 0.4 & 5.6 \pm 0.6 \\ (n=6) \end{array}$ 12.4 <u>+</u> 5.8 (n=4) 1,010 + 308(n=4) 6.5 <u>+</u> 0.8 (n=5)

From P1 to P21, the total g-endorphin i.r. increased 9 fold in AL and 5 fold in IL. From P21 to adult,  $\beta$ -endorphin i.r. increased i.r. increased more than 50 fold in IL and 10 fold in the AL. Therefore, the quantity of  $\beta$ -endorphin i.r. increased more than 250 fold from P1 to adulthood in the IL and more than 90 fold in the AL. On the other hand, acetylated  $\beta$  -endorphin i.r. increased only 30 fold in the IL and 10 fold in the AL.

Ongoing work at this time involves the characterization of  $\beta$ -endorphin i.r. and N-acetylated  $\beta$ -endorphin i.r. following the molecular sieving of pooled AL and IL extracts at selected postnatal dates. These studies will provide information on the ontogeny of multiple forms of  $\beta$ -endorphin and its post-translational processing during development.

170.15 BETA-ENDORPHIN IN DEPRESSION. J. Matthews\*, S.J. Watson, J. Greden\* and H. Akil (SPON: J.A. Taren). Dept. of Psychiatry, University of Michigan, Ann Arbor, Michigan 48109.

For several years it has been clear that at least fifty percent of endogenously depressed (ED) patients exhibit abnormal regula-tion of their hypothalamo-pituitary-adrenal axis (HPA). The dexamethasone suppression test (DST) has been useful in demonstrating this abnormal regulation by showing that ED patients tend to suppress plasma cortisol less postdexamethasone challenge as compared to either normal or psychiatric control subjects. In addition, circadian rhythm studies show that ED patients secrete more cortisol over a 24 hour period than controls. These cortisol measures reflect adrenal activity and thus implicate abnormal adrenal function. We however have been studying changes in plasma POMC peptides in ED patients in order to see whether these pitui-tary products exhibit analogous regulatory defects thus suggesting that either pituitary or brain is the source of the regulatory defect defect.

Patients were catheterized and four plasma samples were col-lected around the 4 p.m. time period on the baseline day as well on the day following 1 mg oral dexamethasone (given at 11 p.m.). Plasma was assayed for  $_{\beta}\text{-END/}$   $_{\beta}\text{-LPH}$  and cortisol across 35 patients.

We have found that dexamethasone can suppress  $\,_{\beta}\text{-END}/_{\beta}\text{-LPH}\,$  in We have found that dexamethasone can suppress  $\beta$ -END/ $\beta$ -LPH in plasma of normal subjects and psychiatric controls at 16 hours postadministration. The ED patients as a group suppressed  $\beta$ -END/ $\beta$ -LPH less than control groups. Further, those ED patients which escaped suppression of  $\beta$ -END/ $\beta$ -LPH were not necessarily the same as those whose cortisol escaped suppression. The general conclusion is that plasma POMC peptide measures postdexamethasone point to an abnormality in either pituitary or brain regulation in ED patients and suppression for  $\beta$ -END/ $\beta$ -LPH and  $\beta$ -CND/ $\beta$ -LPH were not necessarily the same point to an abnormality in either pituitary or brain regulation in ED patients and such measures may be a sensative marker for diagnosis. Furthermore, a combination of  $\beta$ -END or cortisol abnormalities tends to be seen in a reasonably large percent of ED patients.

Studies in progress involve circadian rhythm studies of  $\beta\text{-}\text{END}$ /β-LPH and ACTH, ACTH plasma responses to the DST, and CRF challenge tests.

170.14 SOME NEW INSIGHTS IN THE REGULATION OF BETA-ENDORPHIN BIOSYNTHESIS AND RELEASE. <u>H. Akil, H-L. Lin and Y. Ueda</u>. Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109. While numerous studies have examined the effects of various manipulations on brain beta-endorphin ( $\beta$ E) levels, few have uncovered substantial changes in content. Clearly, we need to develop strategies for more dynamic measures and their validation in given models. In our laboratory we have attempted this by studying  $\beta E$  systems in pluitary and in brain and the effects of drugs or of acute and chronic stress. The biochemical tools for more dynamic measure include: 1) pulse-chase experiments, involving labeling peptides and their purification on immunoaf-finity columns. 2) Measurement of the pre- prohormone/prohormone ratio, using specific signal peptide,  $\beta E$  and ACTH antibody affinity columns. 3) Studies of multiple forms of E (N-acetylated and C-terminus cleaved) using HPLC /RIA.

Our studies suggest two new insights into the system: 1) activation of the system (with stress or drugs) which causes release of  $\beta E$  leads to increases not only in the biosynthesis of the precursor, but in the processing of it, resulting in shorter half lives of the precursors and intermediates. This may be due to some induction of the enzymes involved in cleavage and in post-translation modification. 2) There is some suggestion that post-translation modification. 2) There is some suggestion that the most modified, highly processed material is preferentially released, at least in the case of the neurointermediate lobe. Whether these observations apply to all brain areas under other behavioral or pharmacological models remains to be established. This work was supported by NIDA grant DA02265 to HA.

170.16 RELEASE OF ENDOGENOUS DOPAMINE (DA) FROM RAT STRIATUM IN VITRO: EFFECTS OF L-GUITADIS DOFAMINE (DA) FROM RAI SIRIAIDH IN VIRO Marc Marien\* and Khem Jhamandas\* (SPON: J.V. Milligan). Department of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada K7L 3N6. Previous investigations of opioid effects on striatal DA

release in vitro have focused on the release of exogenous or newly-synthesized radiolabelled transmitter. We have observed here y synthesized rationabelled transmitter. We have observed that morphine depresses the L-GLU-evoked release of preloaded <sup>3</sup> H-DA from superfused slices of the rat striatum (Marien et al., Can. J. Physiol. Pharmacol. <u>61</u>, 43, 1983). The aim of the present study was to determine if opioids modify the release of endogenous striatal DA <u>in vitro</u>. These experiments examined the effects of D-Ala<sup>2</sup>-D-Leu<sup>3</sup> emkephalin (DADL), a delta opioid the effects of D-Ala-D-Let enkephalin (AADL), a defta opioid receptor agonist, on the spontaneous and the L-GLU-stimulated release of endogenous DA in rat striatal slice superfusates. Slices ( $300 \ \mu m$  thickness, 50 mg weight) were placed in 1.0 mL chambers and superfused for 70 min with a modified Kreb's-Henseleit medium ( $0.5 \ mL/min$ ). The DA in 10-min superfusate samples was isolated by alumina adsorption and cation-exchange samples was isolated by alumina adsolption and carton-exche-chromatography, and quantitated by high performance liquid chromatography with electrochemical detection (HPLC-ED). 7 limit of sensitivity of this method was 40-50 pg DA per mL The superfusate. The baseline rate of DA release from the slices was superfusate. The baseline rate of DA release from the slices was 330 pg DA/g tissue/min; this basal release rate was not affected by a 30-min exposure to DADL (5 mM). Nomifensine (10  $\mu$ M), a blocker of DA reuptake, increased the basal DA release rate 10-fold. In the presence of nomifensine, L-GLU (1 mM, 5-min exposure) increased the basal release of DA by 530%; in these experiments, DADL (50 nM, 50-min exposure) had no effect on the baseline (unstimulated) release of DA, but significantly reduced the L-GLU-evoked release to 420%. The post-superfusion tissue levels of DA and the DA metabolite dihydroxyphenylacetic acid (DOPAC) were not significantly chanced by DADL. (DOPAC) were not significantly changed by DADL. This study demonstrates that the release of endogenous

striatal DA in vitro, under the experimental conditions employed, is measurable by HPLC-ED; the release of DA in this system is stimulated by L-GLU and this action is modulated by a delta receptor agonist.

170.17 Co-release of enkephalins and precursors with catecholamines from the perfused cat adrenal in situ. J. Rossier, M. Chaminade, A.S. <u>Foutz, G. Patey and P.E. Chabrier<sup>\*</sup>, C.N.R.S. Physiologie Nerveuse</u>, 91190 Gif-sur-Yvette, and \*Institut Beaufour, Les Ulis, France.

Several studies have indicated that enkephalin immunoreactive products or opiate-like products are coreleased with catecholamiproducts or oplate-like products are coreleased with categoriam-nes from the adrenal medulla. In the present study we have care-fully characterized the nature of the released enkephalins (E). Met-enkephalin (ME), Leu-enkephalin (LE), the octapeptide (OE) and the heptapeptide (HE) are released from perfused adrenals in a mo-lar ratio similar to that found in the biosynthetic precursor, proenkephalin. The left adrenal of anesthetized cats was perfused with Krebs solution. Catecholamines (CA), ME, LE, OE, HE and large E containing peptides (ECP) were assayed in the perfusate by various specific assays. Electrical stimulation (St) of the left rious specific assays. Electrical stimulation (St) of the left splanchnic nerve (N) at 15 Hz induced an immediate release (10 to 20 times over baseline values) of these various molecules. During St, 2.17 nmole of CA (about 1.2 % of the gland content) are released per min with 0.87 pmole of ME (1.3 %), 2.41 pmole of ECO (1.%) and 0.34 pmole of HE (1.5 %). Perfusion of the gland with Ach (0.1mM) or K<sup>+</sup> (50mM) induced an even greater release, about 70 times over baseline for all the molecules. During K<sup>+</sup> St the release her which was 10.41 nmole (5.6 %) CA, 3.45 pmole (5.%) ME, 19.4 pmo-le (7.6 %) ECP and 1.02 pmole (4.9 %) HE. As for CA, a rapid fati-gue of the secretion of various E was noticed during a 10 min St by N, Ach or K<sup>+</sup>. During the first 2.5 min period output was always 2 to 3 times higher than the output during the fourth 2.5 min period. During the four 2.5 min periods of the N St the molar ra-tios of CA/ME (2420), CA/HE (9500) and CA/ECP (1025) were quite stable and close to the ratios found in extracts of the gland stable and close to the ratios found in extracts of the gland (2690, 7930 and 720 respectively). We examined the ratios of ECP/ ME during N and K<sup>+</sup> St. This ratio was 2 fold greater during K<sup>+</sup> than during N St. When a second 10 min K<sup>+</sup> St was repeated the ECP/ ME increased 4 fold as compared to N St. When perfusates obtained during N or K<sup>+</sup> stimulation were analysed on gel filtration, their elution profiles were strikingly different. With N St the main peak of ECP has Mr 4000, with K<sup>+</sup> St the main peak had Mr between 20.000 explore the relation between it is the second to relate the relation between its in the second to relate the relation between the second to relate the relation between the second to relate the relation between the second to relate the relation between the second to relate the relation between the second to relate the relation between the second to relate the relation between the second to relate the relation between the relation between the relation to relate the relation between the relation between the relation to relate the relation between the relation to the relation between the relation to the relation between the relation to the relation to the relation to the relation between the relation to the relation between the relation to the relation 20,000 and 5000. These results may indicate a heterogeneity in the population of chromaffin granules. They may be classified into ma-ture granules in which proenkephalin is fully processed into ME, LE, OE and HE, and in immature granules containing partially pro-cessed precursors. Physiological stimulation by the splanchnic nerve will induce the release of mature granules. When intense K<sup>+</sup> St are repeated immature granules containing the partially processed precursors are also released. Abbreviations: N St, Nerve stimulation; ECP, enkephalin containing peptides; HE,heptapeptide ;0E,Octapeptide; ME,Met-enkephalin.

170.19 IN VIVO ENKEPHALIN RELEASE FROM THE GLOBUS PALLIDUS OF THE RAT. DIURNAL RHYTHM AND RELATIONSHIP WITH GABA RELEASING SYSTEMS. <u>A. Bayon, B. Anton\* and D. Diaz-Pontones\*</u>. Instituto de Investigaciones Biomedicas. Universidad Nacional Autonoma de Mexico, 04510 Mexico D. F. Mexico.

We have previously shown that endogenous immunoreactive enke We have pieceforms invoit from the globus pallidus and that this release is tonically inhibited by endogenous GABA (Bayon <u>et al</u>; <u>Neurosci.</u> letts., 24:65, 1981, Bayon <u>et al</u>; Soc. <u>Neurosci.</u> Abstr. Vol. 7, p. 800, 1981). During those investigations it was inci-dentally observed that enkephalin release was higher in the evening than in the morning hours. Given the link observed be-tween GABA and enkephalin systems in the pallidum, we decided to study and compare the diurnal variation in the in vivo release of these messengers. Methodological details of the push-pullcannula perfusion technique used in these experiments have been reported elsewhere (Bayon <u>et al</u>, Neurosci, Letts, 24.65, 1981). Fifteen min. after cannula insertion <sup>3</sup>H-GABA was perfused for 30 minutes (4 x 10<sup>6</sup> cpm in 750 µl Ringers) and 15 min-fractions were collected thereafter. <sup>3</sup>H-GABA washout and release was determined by direct scintillation counting and endogenous enkephalin release was measured by a Leu-enkephalin RIA. Six perfusion sessions were carried out from 8.00 AM to 2.30 PM (daytime) and six from 4.00 PM to 10.30 PM (evening). Resting enkephalin release increased 100% between 2.00 PM and 10.00 PM, while  ${}^{3}$ H-GABA resting release decreased 60%. Similarly, K<sup>+</sup>-stimulated enkephalin release increased 6fold while K<sup>+</sup>-stimulated  $^{3}\text{H}$ -GABA release decreased more than 10 fold within that time. In relation to the opposed diurnal rhythms of enkephalin and GABA release from the globus pallidus it is noteworthy that enkephalin and GABA trans-mission in this region also have opposite actions on the motor activity of the rat. Bilateral injection of enkephalin analogs in the pallidum leads to hyperactivity, an action which is block-ed by naloxone (Joyce <u>et al</u>, <u>Brain Res</u>, 221.359, 1981). In con-trast, bilateral pallidal administration of drugs promoting GARA-ergic transmission produces akinesia, while the opposite is found for drugs antagonizing this transmitter (Pycock et al, Brain Res, 116.353, 1976). Being the rat a nocturnal animal, the evening increase of enkephalin release and the decrease of GABA release in the pallidum parallel these psychopharmacological observations, Thus, we suggest that the coordinated GABA-enkephalin transmission in the pallidum may be an important link in the neural con-trol of the motor activity rhythms in the rat. (Supported by grants from CONACYT, Mex. the FONEIN, Mex. and the Instituto Mexicano de Psiquiatria).

170.18 LC-EC OF NEUROPEPTIDES. L.H. Fleming\* and N.C. Reynolds, Jr., Dept. of Neurol. (Milwaukee Clinical Campus), Univ. of wI Med. School and Sect. of Neurol.-Dept. of Med., Mt. Sinai Med. Cntr., Milwaukee, WI 53201.

The existence of many closely-related neuropeptides has complicated research efforts to clearly establish their functional significance in normal and disease states (Panerai, A.E. et al., In: Regulatory Peptides: From Molecular Biology to Function, ed. by E. Costa and M. Trabucchi, p. 139. Raven Press, New York, 1982). Highly specific and sensitive techniques are required to quantify neuropeptides present in physiological fluids and tissues at low concentrations. Radioimmunoassay (RIA) is frequently used to quantify methionine (ME) and leucine enkephalin (LE) (Przewlocki, R. et al., <u>Br. Res.</u> 174: 357, 1979) but has been limited for some neuropeptides by the lack of highly specific antibodies. Because of its selectivity, high performance liquid chromatography (LC) has been used to separate neuropeptides in biological samples. Chromatographic fractions are quantitated by RIA for each peptide of interest because the concentration of neuropeptides (pico-to-femto-molar) is below the limits of detection by far UV spectroscopy (Loeber, J.G. and J. Verhoef, <u>Meth. Enzmol</u>. 73: 261, 1981). This procedure is time consuming, expensive and introduces additional experimental variables.

LC with electrochemical detection (LC-EC) has been used to identify and quantify catechol- and indol-amines from small samples of brain, blood, urine and CSF (Kissinger, P. T. et al., <u>Life Sci</u>. 28: 455, 1981). The observation of the electroactivity of ME and LE (Meek, J.L. et al., <u>Neuropharmac</u>. 16: 151, 1977) prompted us to explore the possible usefulness of electrochemical detection for neuropeptide standards. In an effort to optimize the separation of ME and LE from other closely-related peptides (i.e. Dynorphin 1-6, 6, 8-Neo-endorphin, etc.), several different reverse phase columns and isocratic mobile phases were used. ME and LE were chromatographed on 5µ Ultrasphere-Octyl, 10µ Aquapore 300, 10µ µBondapak and 5µ Biophase ODS columns using various dilutions of phosphate buffer, pH 2.3 containing acetonitrile. Hydrodynamic voltammograms showed that in this mobile phase, ME and LE are oxidized by a glassy carbon working electrode at relatively high potentials, > + .90v relative to Ag/AgCl reference electrode. Dynorphin 1-6,  $\alpha$ -Neo-endorphin 1-10,  $\beta$ -Neo-endorphin etc. are also oxidized at these potentials permitting their simultaneous measurement. LC-EC offers an efficient and inexpensive alternative to the use of RIA for studies of neuropeptides in selected brain regions.

170.20 THE OPIOID OCTAPEPTIDE MET<sup>5</sup>-ENKEPHALIN-ARG<sup>6</sup>-GLY<sup>7</sup>-LEU<sup>8</sup> IN RAT SPINAL CORD: BIOCHEMICAL CHARACTERIZATION, DISTRIBU-TION, RELEASE AND ANALGESIC ACTIVITY. M. J. ladarola, J. Tang\*, P. Panula\*, J. Chou\*, H.-Y.T. Yang and E. Costa. Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032, The content and biochemical characteristics of met<sup>-</sup>-enkephalin-arg<sup>6</sup>gly'-leu<sup>9</sup> (met-enk-arg-gly-leu) immunoreactive material were analyzed in rat spinal cord using a sensitive and specific antibody directed against the C-terminal of this octapeptide. Sacral and lumbar cord contained two-fold more immunoreactive material than thoracic or cervical cord. The concentration of immunoreactivity in dorsal cord was greater (3-4 fold) than that in ventral cord at all spinal levels. Lowest levels of metenk-arg-gly-leu were observed in ventral thoracic cord (0.7 picomol/mg prot); highest levels were observed in dorsal lumbo-sacral cord (5-6 picomol/mg prot). Biochemical characterization of the immunoreactive material by gel

Biochemical characterization of the immunoreactive material by gel filtration revealed two distinct species: that with high molecular weight (~8,000d on Biogel P-30) represented half of the total immunoreactivity measured in acid extracts of cord tissue; the low molecular weight material was shown to be identical with synthetic met-enk-arg-gly-leu by reverse phase HPLC.

Finer details of met-enk-arg-gly-leu localization were obtained by peroxidase-antiperoxidase immunohistochemistry using the same antiserum as in the RIA. The densest staining was observed in laminae lll. Numerous densely stained fibers were observed in the dorsal lateral fasciculus. This pattern is similar to observations made with antisera against met enkephalin and met enkephalin-arg enter Cell bodies could be observed in Lamina I through V and around the central canal but not in the ventral horn. Ventral horn contained only fibers. These fibers mainly innervated neuronal somata which in some cases were clearly outlined by the reaction product.

outlined by the reaction product. The octapeptide was released in vivo into a spinal perfusate containing  $10^{-6}$ M substance P using the intrathecal perfusion system described by Yaksh et al. (Brain Res. 242:279, 1982). The subarachnoid space was perfused at a rate of .1 ml/min with artificial CSF containing  $10^{-6}$ M captopril. Under these conditions both the octapeptide and its high molecular weight component were recovered in the perfusate. This suggests that both high molecular weight material and met-enk-arg-gly-lev are released from nerve terminals.

met-enk-arg-gly-leu are released from nerve terminals. Met-enk-arg-gly-leu was a potent analgesic. Intrathecal injection of 270 ng (in  $30_{\rm H}$  l of artificial CSF containing bestatin and captopril) increased tail flick latency within 5 min; peak activity occurred by 10 min. Tail flick latency returned to predrug values by 25 min. Analgesia produced by met-enk-arg-gly-leu was reversed by naloxone ( $30_{\rm H}$  l of 2x10<sup>-7</sup> M intrathecally). These data suggest that the opioid octapeptide met-enk-arg-gly-leu which is derived from preproenkephalin A may function as a neuromodulator.

AUTORADIOGRAPHY OF RECEPTORS FOR BOMBESIN IN MAMMALIAN BRAIN M. Zarbin, M. Kuhar, T. O'Donohue, S. Wolf and T. Moody. Dept. Neuroscience, Johns Hopkins Med. Sch., Baltimore, MD 21205, Expt. Ther. Branch, NINCDS, Bethesda, MD 20205 and Dept. Biochem., GWU 171.1

Med. Sch., Washington, D.C. 20037. The peptide bombesin (BN) is a potent hypothermic and hyper-glycemic agent after central injection. These biological activities may be mediated by the endogenous BN-like peptides which have been detected in discrete brain regions (Moody, T. et al., Peptides, 2: 75, 1981). Upon release from certain brain neurons, endogenous BN-like peptides presumably activate specific receptors which have been demonstrated using rat brain homogenate (Moody, T. et al., PNAS, 75: 5372, 1978). Here, using in vitro autoradiographic techniques, the discrete regional distribution

autoradiographic techniques, the discrete regional distribution of binding sites for BN-like peptides was investigated. Binding studies were conducted using the method of Wolf <u>et al.</u> (<u>Eur. J. Pharm., 87</u>: 163, 1983). Unfixed 12  $\mu$ m coronal slices derived from the forebrain bound ( $1^{25}$ I-Tyr<sup>4</sup>)BN reversibly and with high affinity (Kd, 5 nM) to a single class of sites (B<sub>max</sub>, 130 fmol/mg protein); the ratio of specific/nonspecific binding was 6/1. Also, pharmacological studies indicated that only peptides which have a C-terminal similar to that of BN compete for specific (<sup>125</sup>I-Tyr<sup>4</sup>)BN binding sites. In vitro autoradiographic studies were conducted using the

The office and the state of the second state o thalamus, dorsomedial thalamic nucleus, hippocampus, locus coeruleus, facial nuclei and nucleus tractus solitarius of the hindbrain and substantia gelatinosa of the spinal cord. Moderate grain densities were observed in the pyriform cortex, deep layers of the neocortex, rhinal sulcus and striatum. Negligible grain densities were present in the cerebellum, white matter and sections treated with 1 µM unlabeled BN. The presence of high concentrations of binding sites and immunoreactive BN in discrete regions, such as the suprachiasmatic and solitary nuclei as well as the substantia gelatinosa, suggests that BN-like peptides may function as important neuroregulatory agents in these brain loci. This research supported in part by grants GM 07309, MH 00053, MH 25951 and NS 17073.

DISTRIBUTION OF SOMATOSTATIN RECEPTORS IN RAT BRAIN AS DETERMINED 171.3 BY IN VITRO RADIOAUTOGRAPHY. P. Leroux\* and G. Pelletier (SPON: A. Dupont). MRC Group in Molecular Endocrinology, CHUL, Quebec, Canada.

Somatostatin is a neuropeptide which is widely distributed throughout the brain. By radioreceptor assays performed in macroscopically dissected brain structures, somatostatin receptors have been shown in many brain areas, especially cortex, thalamus, hypothalamus and striatum (Srikant, C.B. and Patel, Y.C., <u>Proc.</u> <u>Natl. Acad. Sci. USA</u> 78:3930, 1981). In an attempt to precisely determine brain localization of somatostatin binding sites, we determine brain localization of somatostatin binding sites, we have used <u>in vitro</u> radioautography performed on slide mounted frozen brain sections as previously described for brain oplate receptors (Herkenham, M. and Pert, C.B., <u>J. Neurosci.</u> 2:1129, 1982). The somatostatin agonist, [Tyr<sup>0</sup>, DTrp<sup>5</sup>]somatostatin (supplied by Dr. D.H. Coy), was iodinated by the lactoperoxydase method and purified on a Vydac Cl8 RP-HPLC system using a gradient TEAP-acetonitrile as mobil phase. The specificity of the binding was investigated by competition with 10<sup>-6</sup>M/1 native compatostatin within the invubation buffer. somatostatin within the incubation buffer. High specific binding was observed mainly in the claustrum, the median and lateral amygdalian nucleus, the olfactory bulb, the deep layers of the amygdalian nucleus, the olfactory bulb, the deep layers of the cerebral cortex, the periventricular nucleus of the thalamus, the hippocampus, the gyrus dentatus and the locus coeruleus. Moderate binding was detected in the septal medial nucleus and amygdalian anterior area whereas low binding could also be observed in the caudate-putamen nucleus. Worthy of note is the complete lack of binding in the hypothalamus and ventral premamillary bodies, two areas known to contain very high concentration of immunoreactive somatostatin in the rat brain. However, with a few exceptions, our data show a good correlation between somatostatin binding sites and immunohistochemically identified somatostatin pathways in rat brain.

171.2 PICOMOLAR AFFINITY SOMATOSTATIN RECEPTORS IN THE CNS AND PERIPHERY LABELLED WITH A METABOLICALLY STABLE SS-28 ANALOG. D.C. Perryl, D.C. Manningl, J. Rivier<sup>2</sup>, W. Vale<sup>2</sup> and S.H. Snyder<sup>1</sup>. Johns Hopkins Univ., Depts. of Neuroscience, Pharmacology and Psychiatry, Sch. of Med., Baltimore, MD 21209 2Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 9037 MD 21205 92037.

Somatostatin, originally identified as a somatotropin release inhibiting factor, has since been demonstrated to be a potent modulator of numerous endocrine and neuronal functions. Several molecular forms have been localized to neurosecretory cells in the hypothalamus, neurons in the CNS and periphery and endocrine cells in the pancreas and G.I. tract. Using <sup>125</sup>I-labeled SS-14 analogs, several groups have identified SS binding sites in preparations from brain, pituitary, pancreas and adrenal; (Reubi et.al., Life Sci. 25:219I-8, 1981) used a metabolically stable analog of SS-28 (<sup>125</sup>I-leuß, D-Trp<sup>22</sup>, Tyr<sup>25</sup>J-SS-28, to label sites in brain, pituitary and pancreatic  $\beta$ -cells. We have refined the binding assay with this probe and now report the presence of a very high affinity site in rat cortex (KD 20 pM, B<sub>max</sub> 200 fmole/mg protein). A lower affinity site (KD > 1 mM) is also observed. These results were obtained by increasing the incubation volume while lowering both the receptor and ligand concentrations. Briefly, aliguots of crude membrane preparation (0.33 mg wet

and ligand concentrations. Briefly, aliquots of crude membrane preparation (0.33 mg wet weight tissue) were incubated with 1-5 pM ligand in 4 ml Hepes buffer (10 mM, pH 7.6) for 90 min at room temperature. The mixture was filtered over GF/B filters pre-soaked in 0.25°/° polyethyleneimine HCl; the filters are rinsed with 3 x 4 ml cold buffer and radioactivity on the filters is measured with a gamma counter. Specific binding was defined as that remaining in the presence of 10-9 or 10-7 M somatostatin-28. In a typical assay with rat cortical membranes, 32,000 cpm were added: total binding was 3600 cpm and pon-specific binding 1200

In a typical assay with rat cortical memoranes, 32,000 cpm wer added; total bindng was 3600 cpm, and non-specific binding 1200 cpm (of which 800 cpm represented non-displaceable binding to filters). Using this assay, we have specifically labeled sites in several brain regions (highest in cortex), as well as membranes from pituitary, pancreas, adrenal, stomach and intestine.

intestine. Through the use of this refined binding assay we will examine the potency of a number of SS analogues to determine if more than one distinguishable SS receptor exists in the CNS. The ability to label receptors in the periphery now provides the opportunity to compare the properties of central and peripheral receptors. Comparison studies have already revealed pharmacological differences between pancreatic pituitary and CNS SS receptors (Reubi et al., <u>Endocrinol.</u>, <u>110</u>:1049-1057, 1982).

EVIDENCE THAT  $[D-Trp^8]$ -SOMATOSTATIN INHIBITS SYNAPTIC PLASMA MEM-BRANE PROTEIN PHOSPHORYLATION BY INTERACTION WITH A SPECIFIC MEM-BRANE BINDING SITE. L.A. Dokas, M. Klis\*, A. Liauw\* and D.H. Coy\*. Depts. of Neurosciences and Biochemistry, Medical College 171.4 of Ohio, Toledo, OH 43699 and Dept. of Medicine, Tulane Univer-sity, New Orleans, LA 70112

Somatostatin and related peptides inhibit protein phosphorylation in the synaptic plasma membrane (SPM) fraction from rat brain with characteristics that suggest a receptor-mediated mechbrain which characteristics that suggest a receptor-mediated mechanism (Dokas et al., <u>Eur. 1</u>). <u>Pharm.</u> 88:185). We now report fur-ther characterization of this <u>effect</u>, using [D-Trp<sup>8</sup>]-somatostatin, ([D-Trp<sup>8</sup>]-SS), the most potent of the peptides examined previous-ly. The SPM fraction was prepared from rat hippocampus and incu-bated with ATP<sup>32</sup> to phosphorylate endogenous proteins. The stanbated with AIP-2 to phosphorylate endogenous proteins. The stan-dard assay was an incubation of 25 µg of membrane protein for 20 sec at  $30^{9}$ C in an acetate buffer, pH 6.5, containing 1 mM calcium and 7.5 µM ATP<sup>32</sup>. The major phosphorylated protein of the SPM was BSO (48,000 daitons). When  $10^{-4}$ M [D-Trp<sup>3</sup>]-SS was added for 15 sec prior to addition of ATP<sup>32</sup>, a subsequent inhibition of -44.3 $\pm$ 2.6% was seen in the phosphorylation of B50. Increasing the preincubation with [D-Trp<sup>8</sup>]-SS to 30 min resulted in virtually complete (-92.9±1.0%) inhibition of B50 phosphorylation. This time course is consistent with that required for somatostatin-re-lated peptides to reach maximal binding to membrane sites. Preincubation of the SPM fraction for 30 min in the absence of [D-Trp<sup>8</sup>]-SS had no effect on basal protein phosphorylation. Similar inhibition by [D-Trp<sup>8</sup>]-SS after 30 min was seen in the presence inhibition by [D-Trp<sup>0</sup>]-SS after 30 min was seen in the presence of 200 µM leupeptin or 1 mg/ml bacitracin, suggesting the loss of BSO phosphorylation was not due to substrate protein degradation during the preincubation. The effect of  $[D-Trp^8]$ -SS was compared to that of  $10^{-4}$ M ACTH or  $\beta$ -endorphin. After 15 sec of preincuba-tion ACTH inhibited BSO phosphorylation by -68.5±7.3%. This ap-parently was a maximal effect, since increasing the preincubation with ACTH to 30 min produced no greater inhibition (-69.9±8.1%).  $\beta$ -endorphin inhibited BSO phosphorylation slightly (-9.3±6.3%) after 15 sec of preincubation. Increasing the preincubation with  $\beta$ -endorphin to 30 min resulted in more inhibition of BSO phos- $\beta$ -endorphin to 30 min resulted in more inhibition of B50 phos-phorylation (-23.8±6.4%), but the % effect was much smaller than that seen in response to [D-Trp<sup>8</sup>]-SS. The effect of [D-Trp<sup>8</sup>]-SS on protein phosphorylation was also examined in the cytosolic fraction. Preincubation for 15 sec with  $[D-Trp^8]$ -SS had no effect fraction. Preincubation for 15 sec with [D-Trp<sup>0</sup>]-SS had no effect on the phosphorylation of a protein of approx.85,000 daltons. The phosphorylation of an approx.52,000 dalton band was inhibited by [D-Trp<sup>8</sup>]-SS equally after a 15 sec or 30 min preincubation. This evidence suggests that [D-Trp<sup>8</sup>]-SS interacts with specific SPM binding sites in the rat hippocampus to produce inhibition of B50 phosphorylation.  $^{3}$ H-BRADYKININ RECEPTOR LOCALIZATION IN SPINAL CORD AND SENSORY GANGLIA - EVIDENCE FOR A ROLE IN PRIMARY AFFERENT FUNCTION. D.C. Manning and S.H. Snyder. Johns Hopkins University, Depts. of Neuroscience, Pharmacology and Psychiatry, School of Medicine, Baltimore, Maryland 21205. Bradykinin (BK), an endogenous nonapeptide, is a extremely potent algesic substance causing stimulation of small diameter afferent fibres and is often used for experimental production of pain. The great potency of BK suggests that specific BK receptors exist on primary afferent fibres. We have investigated this proposal using  $^{3}$ H-BK receptor autoradiography.

investigated this proposal using <sup>3</sup>H-BK receptor autoradiography. <sup>3</sup>H-BKadykinin receptor binding sites were localized autoradiographically in nervous tissue of the guinea pig and dog using a modified version of Young and Kuhar's conversijp method (Young, W.S. and Kuhar, M.J. Br. Res., 179:255-270, 1979). Tissues were perfusion fixed with 0.1°7° formaldehyde/10 /\* sucrose in phosphate buffered saline adjusted to isotonicity. Ten micron frozen tissue sections were cut and incubated for 120 min at 4°C in a media containing 25 mM TES pH 6.8, 1 mM 1.10 phenanthroline, 0.2° /\* BSA 1 mM dithiothreitol, 140 ug/ml Bacitracin, 1 µM captopril (S014,225), 300 mM sucrose and 0.2 nM <sup>3</sup>H-BK (52 Ci/mmole). Nonspecific binding was defined in the presence of 1 µM unlabelled BK. After incubation the tissue sections were dried rapidly and NTB3

300 mM sucrose and 0.2 nM  $^{3}$ H-BK (52 Ci/mmole). Nonspecific binding was defined in the presence of 1  $_{\rm M}$  unlabelled BK. After incubation the tissue sections were dried rapidly and NTB3 emulsion coated coverslips were apposed and exposed for 3 months.  $^{3}$ H-Bradykinin receptors in the guinea pig spinal cord are concentrated in the dorsal horn in the approximate area of Rexed's lamina I and II. Bradykinin receptors in the dorsal root and trigeminal ganglia of the guinea pig are highly concentrated on a small subpopulation of ganglia cells. Receptors for  $^{3}$ H-BK in the dog stellate ganglia display a streaking pattern consistent with ganglionic fibre tracts. The nervous system localization of  $^{3}$ H-BK binding sites supports the contention that bradykinin is further supported by a localization of binding sites in the dorsal root and trigeminal ganglia. The ganglia receptors may represent newly synthesized binding sites ready for axonal transport. The stellate ganglion contains the cell bodies of sympathetic afferent fibres that supply the heart. The localization of  $^{3}$ H-BK binding sites to the stellate ganglion may support a role for bradykinin in cardiac afferent function.

171.6 CHOLECYSTOKININ RECEPTORS IN THE STRIATUM AND SUBSTANTIA NIGRA ARE FOUND ON INTRINSIC NON-DOPAMINERGIC NEURONS. P. Gaudreau, R.T. Jensen, S. St-Pierre, C.B. Pert and A. Pert. (SP Bennett). Biological Psychiatry Branch and Clinical (SPON: C.T. Neuroscience Branch, NIMH; Digestive Diseases Branch, NIADDK; Department of Pharmacology, University of Sherbrooke, Sherbrooke, Canada.

Comparative autoradiographic distribution of cholecystokinin (CCK) receptors in rat brain using  $[{}^{3}\text{H}]$  pentagastrin or  $N^{\alpha}[{}^{12}\text{SI}$  desaminotyrosyl] CCK-33 has been studied. The two probes showed high densities of CCK receptors in the nucleus accumbes, especially its medial part, moderate levels in the striatum and substantia nigra, and very low levels in the ventral tegmental area. Since these brain areas contain dopamine terminals and cell bodies, respectively, it was of interest to ascertain the precise localization of CCK receptors in relation to mesolimbic and nigrostriatal dopamine neurons. Nigrostriatal dopaminergic projections were lesioned

unilaterally by intranigral injections of 6-hydroxydopamine (G-OHDA) (9 ug). Mesolimbic dopaminergic projections were lesioned unilaterally by injection of G-OHDA (7.5 ug) into the ventral tegmental area. Unilateral lesions of the medial forebrain bundle (MFB) were also made by injections of 6-OHDAinto this fiber bundle at the level of the lateral hypothalamus. Intrinsic neurons in the striatum and substantia nigra (SN) were destroyed by unilateral injections of ibotenic acid (10 ug). On One month later the animals were killed and their brains removed. Serial 25 um sections were taken through the forebrain region encompassing the nucleus accumbens and caudate nucleus and the midbrain region encompassing the substantia nigra and ventral tegmental areas. These sections were then exposed to  $[{}^{3}\text{H}]$  pentagastrin or N<sup>a</sup>[ ${}^{125}\text{I}$  des- aminotyrosyl] CCK-33 and

 $[^{3}H]$ pentagastrin or NQ[<sup>12-5</sup>I des- aminotyrosyl] CCK-33 and processed for autoradiography using a tritium-sensitive film. 6-OHDA lesions of the SN failed to alter CCK binding in either the ipsilateral striatum or SN. A-10 lesions were also ineffective in this regard. MFB lesions, which produce retrograde degeneration of DA neurons in the zona compacta of the SN, were also ineffective in modifying CCK binding in the SN. Injections of ibotenic acid into the striatum and SN, on the other hand, effectively decreased CCK binding at the site of injection.

Altogether, these results suggest that CCK receptors are localized on intrinsic non-dopaminergic cell bodies in the striatum and SN and that DA terminals in the striatum and nucleus accumbens are devoid of CCK receptors.

171.7 HIGH AFFINITY BINDING OF GLUCAGON TO RAT BRAIN MEMBRANES. N. M. Honsein<sup>\*</sup> and R. S. Gurd. Medical Sciences Program and Dept. of Chemistry, Indiana Univ., Bloomington, IN 47405. Glucagon, a 29 amino acid peptide usually found in the pancreas

Clucagon, a 29 amino acid peptide usually found in the pancreas and gastrointestinal tract, has been detected in canine brain ex-tracts by radioimmunoassay (Unger, R. et al., <u>Diabetes 28:700</u>, <u>1979</u>). Also immunocytochemical studies have localized higher mol-ecular weight forms of glucagon in the rat hypothalamus and thala-mus (Tager, H. et al., <u>Proc. Natl. Acad. Sci. U.S.A. 77:6229</u>, <u>1980</u>, and Loren, I. et al., <u>Histochemistry 61:335</u>, <u>1979</u>). To de-termine the possible presence of glucagon receptors in rat brain, the rader birden of radiological concerns to the brain mombranes in-vitro binding of radiolabeled glucagon to rat brain membranes

was investigated. Mono[<sup>125</sup>I]iodoglucagon bound to rat brain membranes with high affinity ( $K_d = 5.0$  nM). Regional distribution studies indicated higher specific binding to olfactory tubercule, hippocampus and higher specific binding to olfactory tubercule, hippocampus and pituitary membranes with somewhat lower binding to those from me-dulla, thalamus, olfactory bulb and hypothalamus. Regions whose membranes did not bind significant amounts of radiolabeled gluca-gon were cerebral cortex, cerebellum, colliculii, striatum and mid-brain. The specific binding per mg. of protein was of the order of that for insulin but differed in distribution (Havrankova, J. et al., <u>Nature 272:829, 1978</u>). Binding assays performed with subcellular fractions showed a greater density of binding sites in the currenteement. the synaptosomal fraction relative to mitochondrial or myelin fractions. Insulin, vasoactive intestinal polypeptide and vaso pressin did not inhibit binding of radiolabeled glucagon to lysed  $P_2$  fractions obtained from pituitary gland. To further characterize brain glucagon binding sites the ef-

To further characterize brain glucagon binding sites the er-fects of time, pH, GTP and glucagon analogues were examined. At  $30^{\circ}$ C, steady state binding was attained within 20 min. at an op-timum pH of 6.8 - 7.5. In analogy to the regulation of hepatic glucagon receptors by nucleotides, inclusion of 0.1 mM GTP in the binding assay reduced the binding affinity (K<sub>D</sub> = 44.5 nM). Com-petition assays performed with 3 different glucagon analogues re-vealed lowered affinities with the order of affinity differing from the target for hepatone to receptor. from that for hepatocyte receptors.

These data suggest the existence of receptors in rat brain which bind glucagon with characteristics that may differ from those of hepatic glucagon receptors. (Supported by NIH Grant AM21121.)

SOLUBILIZATION AND CHARACTERIZATION OF THYROTROPIN-RELEASING 171.8

SOLUBILIZATION AND CHARACTERIZATION OF THYROTROPIN-RELEASING HORMONE RECEPTORS FROM RAT BRAIN. W.A. Johnson and A. Horita\* (SPON: P. Prinz). Dept. of Pharmacology, University of Washington, Seattle, WA. 98195. The binding site for thyrotropin-releasing hormone(TRH) was successfully solubilized from rat brain in a stable unbound form. The three amino acid neuropeptide, TRH (pyroGlu-His-Pro-NH<sub>2</sub>), has been shown in membrane binding studies using the labeled ahalogue  $^{3}$ H-(3MeHis<sup>2</sup>)TRH to bind to specific saturable sites in the extra-hypothalamic brain of various mammalian species. The natural glycoside, digitonin, in 20 mM TrisHCl, pH 7.4, was the only agent out of a variety of ionic and non-ionic detergents tested capable of solubilizing the binding site for  $^{3}$ H-(3MeHis<sup>2</sup>)TRH in its unbound form. The solubilized site extinabilited binding kinetics virtually identical to the membrane preparation and responded with a similar order of potency to a series of TRH-analogues that inhibit binding of the labeled ligand. Gel exclusion chromatography on Sepharose 6B indicated M<sub>Y</sub> 230,000 for the receptor-digitonin complex. The solubilized preparation was kept frozen at  $-20^{\circ}$ C for 48 hours resulted in a significant loss of activity. activity.

EFFECTS OF INTRAVENTRICULAR ANGIOTENSIN II ANTAGONIST INFUSION ON <sup>12</sup>51-ANG II BINDING IN RAT BRAIN. R. Singh\*, C.M. Perrario and R.C.Speth (SPON: R. Smeby). Cleveland Clinic, Res. Div., Cleveland, OH 44106. 171.9

Cleveland, OH 44106. Our previous studies have demonstrated that brain Angiotensin II (Ang II) receptors are unresponsive to chronic intraventricular (IVT) infusion of [Ile<sup>5</sup>] Ang II (Physiologist 25: 297, 1982). Here, we report the effects of IVT infusion of [Sar<sup>1</sup>, Ile<sup>8</sup>] Ang II, an Ang II antagonist. Male Sprague Dawley rats (350-400 g) were infused with either [Sar<sup>1</sup>, Ile<sup>8</sup>] Ang II at 500 ng/hr (AIIA, n=10) or 0.9% saline vehicle at 1  $\mu$ /hr (SV, n=10) for 6 days using subcutaneously implanted osmotic pumps. Specific <sup>125</sup>I Ang II binding to brain and adrenal Ang II receptors was determined at 5 concentrations of <sup>125</sup>I Ang II (0.1 nM - 1.0 nM) in the presence and absence of 1  $\mu$ M unlabeled Ang II. The <sup>125</sup>I Ang II receptor binding site density in the hypothalamus-thalamus-septum-midbrain (HTSM) region was 13.1 ± 0.68 fm/mg protein in AIIA rats vs\_15.1 ± The trial ang 11 receptor binding site density in the hypothalamus-thalamus-septum-midbrain (HTSM) region was 13.1  $\pm$  0.68 fm/mg protein in AIIA rats vs 15.1  $\pm$  1.06 fm/mg protein in SV rats. Although HTSM <sup>125</sup>I Ang II binding was decreased by 13.3% in the AIIA group, it was not statistically significant. There was no change in brain <sup>125</sup>I Ang II binding affinity. In a separate group of AIIA infused rats we found that the drinking response to centrally injected Ang II (1-2  $\mu$ g) was blunted through day 7 of infusion, whereas similar injections evoked equal drinking responses in AIIA and SV rats on day 10 when the pumps were spent. In AIIA rats, <sup>125</sup>I Ang II binding to the adrenal cortex was significantly reduced (986  $\pm$  151 vs 1972  $\pm$  413 fm/mg protein, p < 0.05) with no change in binding affinity. This reduction might be due to leakage of Ang II ecceptors in the adrenal cortex. Ang II antagonist into the circulation and subsequent occupation of Ang II receptors in the adrenal cortex. The <sup>125</sup>I Ang II binding to the adrenal medulla did not differ between the two groups. Systolic blood pressure, daily water consumption, urine output and urine sodium excretion did not change in AIIA rats as compared to either pre-infusion level or SV rats. Thus, chronic Ang II antagonist infusion did not appear to cause significant alterations in HTSM receptor number or affinity. These results further indicate that brain Ang II receptors do not undergo homologous regulation. Supported by Am. Heart Assn. N.E. Ohio Affil., NIH HL-27568 and NIH HL-6835.

171.11 EFFECT OF INTRACEREBROVENTRICULAR Sar<sup>1</sup>-Ile<sup>8</sup>-ANGIOTENSIN II ON INTRACEREBROVENTRICULAR ANGIOTENSIN II AND III INDUCED BLOOD PRESSURE ELEVATIONS. S.L. Morseth, M. L. Mills\*, G. G. Deffenbough\*, J.W. Harding, and J. W. Wright. Departments of Psychology and Veterinary Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164. Departments backdemontated that determined the second secon

Previous research has demonstrated that intracerebroventricular (icv) pretreatment with the specific angiotensin competular (1cv) pretreatment with the specific anglotensin compet-itive antagonist saralasin acetate (Sar<sup>1</sup>-Ala<sup>8</sup>-Anglotensin II), prevented the pressor effects of icv anglotensin II (Hoffman & Phillips, <u>Brain Res.</u>, <u>109</u>: 541-552, 1976). Our laboratory recently discovered high specific binding for  $[^{125}I]$ -Anglotensin III in rat circumventricular organs (Harding et al., <u>Soc.</u> <u>Neurosci. Abst.</u>, <u>8</u>: 902, 1982). This raised the possibility that anglotensin III, or a metabolite, may be the active ligand for centrally mediated blood pressure control. In the present investigation pretreatment with icv injections the present investigation pretreatment with icv injections The present investigation pretreatment with icv injections of  $\operatorname{Sar}^1$ -Ile<sup>8</sup>-Angiotensin II and several peptidase inhibitors were effective in blocking the pressure effects induced by icv injections of angiotensin II and angiotensin III in rats. These data suggest that angiotensin III, or a smaller fragment, may be responsible for at least a portion of the centrally mediated pressor effects observed following icv angiotensin II injections.

171.10 INFLUENCE OF INTRACEREBROVENTRICULAR Sar<sup>1</sup>-Ile<sup>8</sup>-ANGIOTENSIN II ON SYSTEMIC ANGIOTENSIN III INDUCED BLOOD PRESSURE CHANGES.
 J. W. Wright, S. L. Morseth, M. L. Mills\* and J. W. Harding.
 Departments of Psychology and Veterinary Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164.
 Investigations utilizing [<sup>125</sup>1] Angiotenein II (ALL) have

 Phalman, WA 99164.
 Investigations utilizing [<sup>125</sup>I]-Angiotensin II (AII) have indicated significant binding in several circumventricular organs (CVOs) of the rat (Bennett & Snyder, J. Biol. Chem., 251: 7423-7430, 1976; Sirett et al., Brain Res., 166: 139-148, 1979). Our laboratory recently discovered similar high specific binding for [<sup>125</sup>I]-Angiotensin III (AIII) in rat CVOs (Harding et al., Soc. Neurosci. Abst., 8: 902, 1982). This raised the possibility that AIII or a metabolite, may be the active ligand for centrally mediated blood pressure control. The present investigation initially measured pressor responses to systemically administered AIII in rats. We next attempted to prevent these AIII induced elevations in systemic blood pressure by intracerebroventricular (icv) pretreatment with the specific angiotensin competitive antagonist the specific angiotensin competitive antagonist

 ${\rm Sa}^{1}\text{-}11e^{8}\text{-}AII$  , and several peptidase inhibitors. Previous research has established that icv pretreatment with a function-

ally equivalent compound, saralasin acetate (Sar<sup>1</sup>-Ala<sup>8</sup>-AII), prevented the pressor effect of icv infused AII (e.g. Hoffman & Phillips, <u>Brain Res., 109</u>: 541-552, 1976). Presently,

& Phillips, <u>Drain Res.</u>, <u>105</u>, 031-052, 1707. Including, Sar<sup>1</sup>-Ile<sup>8</sup>-AII and several peptidase inhibitors were effective in reducing systemic AIII induced pressor effects. These results suggest that AIII is a potent peripheral pressor agent, and that its pressor effects can be signifi-cantly reduced by icv pretreatment with these compounds. These findings also suggest that the pressor effects previously attributed to AII may be due to its degradation product AIII, or a metabolite. These or a metabolite.

171.12 LOCALIZATION OF NEUROTENSIN RECEPTORS IN GUINEA PIG BRAIN. R. Quirion. Section on Brain Biochem, NSB, NIMH, and Expt1 Ther Branch, NINCDS, NIH, Bethesda MD 20205.

Branch, NINCDS, NIH, Bethesda MD 20205. Recent studies have shown some differences between rat and guinea pig neurotensin (NT) receptors (Quirion et al., Br. J. Pharmacol., <u>68</u>, 83, 1980; Checler <u>et al.</u>, Life <u>Sci.</u>, <u>31</u>, 1145, 1982). Thus, I decided to investigate NT receptor distribution in guinea pig brain using an autoradiographic technique (Herkenham and Pert, J. Neurosci., <u>2</u>, 1129, 1982), which permits precise anatomi-cal localization of binding sites. Slide-mounted guinea pig brain sections were preincubated in 50 mM Tris-HCl, pH 7.4, at 4°C for 15 min and then incubated in the same buffer plus 0.5 mg/ml bacitracin, 0.1% BSA, and 4.0 MM [<sup>3</sup>H]NT at 4°C for 60 min. At the end of the incubation, slides were transferred sequentially through 4 rinses (2 min in each) of cold incubation buffer. Specific binding was calculated as the difference in cpm bound in presence and absence of 1.0 µM NT. Autoradiograms were generated by placing slides against tritium-

the uncudation burler. Specific binding was calculated as the difference in cpm bound in presence and absence of 1.0  $\mu$ M NT. Autoradiograms were generated by placing slides against tritium-sensitive film in cassettes for at least 8 wks. In preliminary experiments, saturation curves and Scatchard analysis show that [34]NT binds to an apparent single saturable class of receptor (K<sub>D</sub> = 4.7 nM) in guinea pig brain. Structure-activity studies reveal a ligand selectivity pattern similar to rat brain (Quirion <u>et al.</u>, Peptides, 3, 757, 1982), except for [Trp11]NT which is at least 10 times weaker in guinea pig brain. These results confirmed those obtained by Checler <u>et al.</u> (Life Sci., 31, 1145, 1982) using brain membrane preparations. The autoradiographic distribution of [34]NT binding sites in guinea pig brain is similar to the one observed in rat brain (Young and Kuhar, Brain Res., 206, 273, 1981, Quirion <u>et al.</u>, Peptides, 3, 757, 1982). For example, high densities of [34]NT binding sites are found in the external plexiform layers of the olfactory bulb, cingulate cortex, medial and cortical nuclei of amygdala, substan-tia nigra, pars compacta, and ventral tegmental area. Low densi-ties are observed in caudate-putamen and nucleus accumbens. Howtia nigra, pars compacta, and ventral tegmental area. Low densi-ties are observed in caudate-putamen and nucleus accumbens. How-ever, some difference in  $[{}^{3}H]NT$  receptor distribution between rat and guinea pig brain are noted. In guinea pig brain, layer I of cortex and dendate gyrus contain more  $[{}^{3}H]NT$  binding sites than rat brain. Also, very little  $[{}^{3}H]NT$  binding is observed in lateral septum and zona incerta of guinea pig compared to rat brain. In summary,  $[{}^{3}H]NT$  binding pharmacology and autoradio-graphic localization appear to be slightly different in guinea pig brain as compared to rat brain. brain as compared to rat brain.

172.1 SPONTANEOUS DISCHARGES IN RAT SENSORY NEURONS CAUSED BY HERPES SIMPLEX VIRUS. <u>P. H. Lima\*, G. Anderson-Beckman\*, D. J. Forbes</u>, and R. S. Pozos. Depts. of Physiology and Anatomy, Univ. of Minn., Duluth, MN 55812. Sensory neurons in dissociated cell cultures prepared from

Sensory neurons in dissociated cell cultures prepared from embryonic rat dorsal root and trigeminal ganglia were infected with herpes simplex virus (HSV). Changes in the electrical properties were examined by intracellular electrophysiological techniques. The most prominent change is the appearance of repetitive spontaneous discharges in many of the neurons by 10-12 hours post infection. Initially the discharges are small, 5-10 mV spikes which occur at low frequency (20-30/min). Gradually both the frequency and amplitude of the spikes increase. At the maximum discharge rate, full sized action potentials with amplitudes averaging -60 to -70 mV occur at a frequency of 3-4/sec.

This spontaneous activity was associated with infections by both HSV type 1 (HFEM strain) and type 2 (R2 strain). The R2 was somewhat more virulent than the HFEM. Cultures infected with R2 at a concentration of  $10^5$  pfu rarely survive longer than 30 hours while those infected with HFEM ( $10^5$  pfu) typically survived at least 60 hours. Spontaneous firing could be recorded as long as the neuron was able to maintain a resting membrane potential of at least -35 to -40 mV. HFEM is the wild parent strain for tsB5, a temperature sensi-

HFEM is the wild parent strain for tsB5, a temperature sensitive mutant deficient in a glycoprotein required for the virus to penetrate through the cell membrane. HFEM grown at  $34^{\circ}$  and  $38.5^{\circ}$ C as well as the tsB5 grown at  $34^{\circ}$ C all cause similar spontaneous activity but tsB5 grown at 38.5 did not cause any spontaneous activity or other changes in the electrical properties of the neurons.

The antiherpetic drug acyclovir (ACG) inhibits HSV by interfering with the HSV DNA polymerase preventing viral DNA replication. Cultures were first infected with the virus and then continuously treated with ACG (20-40  $\mu$ M). In most of the treated neurons there was no spontaneous activity and the cells demonstrated normal action potentials for up to 60 hours. In approximately 5% of the R2 infected neurons there was some spontaneous firing. Spontaneous discharge would appear in all the cultures 10-12 hours after removal of the ACG.

172.3 UNCONVENTIONAL PROPERTIES OF PAIRED HELICAL FILAMENTS IN HUMAN NEURONS IN AGINO AND ALZHEIMER'S DISEASE. D. J. Selkoe, C. Abraham\*, L. K. Duffy\* and C. G. Rasool. Harvard Medical School, McLean Hospital, Belmont, MA 02178. The principal ultrastructural change of human cerebral neur-

The principal ultrastructural change of human cerebral neurons during normal aging and in Alzheimer's disease is the formation of helically wound pairs of intermediate filaments, known as paired helical filaments (PHF), in many cell bodies and neurites. We have found that PHF remain insoluble and structurally intact in sodium dodecyl sulfate, urea and other conventional protein solvents. Further studies now demonstrate that certain strongly chaotropic salts, viz. guanidine thiocyanate (7M) and lithium bromide (10M), can denature PHF conformation so that it is no longer recognizable by electron microscopy while apparently failing to depolymerize the fibers and release soluble polypeptide subunits. Furthermore, the insoluble fibrous material remaining after such harsh solvent extraction can still be immunolabeled by rabbit antibodies raised against intact PHF; these antibodies are highly specific for PHF and fail to react with neurofilaments or any other native brain cytoskeletal proteins. PHF also display considerable resistance to digestion by specific and nonspecific proteases (e.g., trypsin, pepsin, pronase). Similarly, the fibers are not significantly digested (as judged by gel electrophoresis) and retain their reactivity with QHF antibodies following cyanogen bromide cleavage in 70% formic acid. The specificity of our QHF antibodies recommends them for immunoaffinity purification of PHF to homogeneity, a prerequisite to breaking them down by limited acid hydrolysis and elucidating their composition and origin. Initial results using this strategy will be presented. Our results to date indicate that the paired helical

Our results to date indicate that the paired helical filaments which accumulate progressively with age in selected human neurons are unconventional, highly stable macromolecules that (1) contain determinants which are highly modified from normal neuronal proteins and (2) are held together by strong noncovalent interactions and apparently by covalent crosslinks, properties without precedent among known neuronal proteins. 172.2 PRESERVATION OF CATECHOLAMINE UPTAKE AND RELEASE IN HERPES SIMPLEX VIRUS TYPE 1-INFECTED PC12 CELLS. <u>R. Rubenstein\* and R. W. Price</u>. Cotzias Lab. of Neuro-Oncology. <u>Memorial Sloan-Kettering</u> Cancer Center, New York, NY 10021.

Kettering Cancer Center, New York, NY 10021. Although the peripheral nervous system plays a critical role in the ecology of herpes simplex virus type 1 (HSV-1) infections and the central nervous system is a target of severe HSV-1 infection, little is known of the effects of infection on neuronal cell metabolism other than eventual cell death. To address this issue we have undertaken a series of studies evaluating the effects of HSV-1 infection on "specialized" neuronal functions using the PC12 cell as a model system. We now report the effects of infection on catecholamine uptake, content and K<sup>+</sup>stimulated release following inoculation of the PC12 cells with the F-strain of HSV-1. During a 24-hour period of productive infection we found little alteration in these aspects of catecholamine metabolism despite production of viral progeny and marked morphological cytopathology. Thus, uptake of <sup>3</sup>H-norepinephrine paralleled that of mock-infected cultures, and in both cases the specificity of this uptake was confirmed by desmethylimipramine inhibition. Similarly, throughout the course of infection, endogenous dopamine and norepinephrine stores evaluated by thin-layer chromatography did not differ between HSV-1-infected and mock-infected cells. Likewise, content of these amines was reduced to a similar extent on exposure of infected and uninfected cells to 51.5 mKC1 added to the medium. These studies reveal a remarkable preservation of catecholamine uptake, content and release despite conversion of PC12 cells to virus production, suggesting that neurons may retain a measure of functional capacity for an unexpectedly prolonged period during the course of viral infection.

172.4 EFFECTS OF EXPERIMENTAL SUBARACHNOID HEMORRHAGE (SAH) ON THE MORPHOLOGY AND METABOLITE UPTAKE IN THE RABBIT CHOROID PLEXUS T.M. Liszczak, P.McL. Black, L. Foley\* A. Tzouras,\* Neurosurgical Service, Massachusetts General Hospital and Harvard Medical School, Boston, Mass. 02114. Autologous nonheparinized blood (0.5 ml) was injected into the cisterna magna of anesthetized adult rabbits on days, 1, 7, and 14. Control animals had injections of saline or artificial CSF but were otherwise treated identically. The animals were sacrificed 7 days after the last blood injection. Isotopes 0.5 ml. of 14C linoleic acid specific activity of 900 mCi/mmol and 0.2 ml. 3H leucine specific activity of 158 ci/mmol were injected into the cisterna magna in 9 animals. Two hours later the animals were sacrificed by aldehyde perfusion and tissues were examined for isotope incorporation by scintillation counting. The choroid plexus from 15 different animals using the same experimental protocol was examined by scanning and transmission electron microscopy. Linoleic acid incorporated/gram dry weight before and after SAH are: basilar artery from 1731 + 123 to 148 + 14, arachnoid from 1079 + 3 to 100 <u>+</u> 8, optic nerve from 24 <u>+</u> 3 to 1 <u>+</u> 0, choroid plexus from 417 +71 to 2 <u>+</u> 0, frontal gray matter from 12 <u>±</u> 2 to 0, and the frontal white matter from 12 <u>±</u> 10. Leucine incorporation was significantly increased in basilar arteries from 2268 <u>±</u> 103 to 8292 ± 1011 nanomoles/gram dry weight and choroid plexus from 170 <u>+</u> 74 to 1224 <u>±</u> 18, optic nerve from 75 <u>±</u> 5 to 40 <u>+</u> 1, frontal gray from 37 <u>±</u> 4 to 349 <u>±</u> 34. Pathological changes were ebserved in 50% of the animals. Dilation of the choroid plexus lateral and basal intercellular spaces were seen in 25% and erythrocytes in lysosomes were present in the choroid epithelium of 50% of the experimental animals when compared with controls.

- RECOVERY OR MALFORMATION (HYDROCEPHALUS) FOLLOWING X-IRRADIATION: NEUROEPITHELIAL-MESENCHYMAL BASAL LAMINA RELATIONS. R. A. Glover\*, C. J. D'Amato and S. P. <u>Hicks</u>. Depts. of Anatomy and Cell Biology, and Pathol-ogy, Univ. of Michigan Med. Ctr., Ann Arbor, MI 48109. We showed earlier that 6-L4 somite-pair rat fetuses recover substantially from devastating cell-killing by 150R rivaling amphibia in regulative regenerative ca-pacity, and also demonstrated that 35 somite-pair fe-tuses sometimes recover so well as to be indistinguish-able as adults from normals (D'Amato 1982). We now re-port that 16-24 somite-pair fetuses (11th day) recover remarkably well after 150R, with substantial regenera-tion accomplished in 12-18 hours. Maximum regulation is attained by 48-72 hours, but complete success is marred by eye defects. Fetuses are removed by succes-RECOVERY OR MALFORMATION (HYDROCEPHALUS) FOLLOWING X 172.5 marred by eye defects. Fetuses are removed by succes-sive caesarian sections for light and electron micros-copy. Regulation failed after 225R given on the llth fetal day, characterized by late fetal stenosis of the midbrain-thalamic junction (MTJ) (D'Amato, Hicks 1981). Because a mutant rat also displays stenosis with hydro-cephalus, which we attribute, in part, to an incomplete basal lamina (BL) between the MTJ neuroepithel-ium and mesenchyme appearing around the llth fetal day (Glover, D'Amato, Hicks 1983), we explored whether a similar situation occurred in 225R llth day fetuses. Several hours after 225R, the BL of the MTJ showed dis discontinuities, allowing contact between neuro-pithelium and mesenchyme. By 24 to 48 hours extrusions of neuro-epithelium into the mesenchyme developed leading to mi-nute neural ectopias, as in the mutant. Focally disnute neural ectopias, as in the mutant. Focally dis-turbed orientation of neuroepithelial cells lining the MTJ ventricle also occurred. In contrast, there was no disturbance of the BL in 150R 11th day fetuses, d despite cell-killing. We conclude, with Hay (1982), the the integrity of the BL is crucial to normal develop-ment and, in our experiments, appears essential for that regulative success of the neuropeithelium and mesen-chyme. The precise mechanisms involved in the two forms of failed regulation characterized by the aque-duct stenosis syndrome are unknown; they take on added interest because B12 and folate deficiency also pro-duce the syndrome (Newberne, O'Dell 1961). USPHS Univ. of Michigan Biomedical Research Council 10531. 2S07RR05383-22.
- 172.7 OPTIC NERVE CHANGES IN THE SPONTANEOUSLY HYPERTENSIVE RAT. <u>R. L. Bondar\*</u> (SPON: J. Fullard). Div. of Neurology, McMaster Univ. Med. Ctr., Hamilton, Ont., Can. L8N 325. Hypertension frequently has been found in association with idiopathic ischemic optic neuropathy (ION). Human clinical pathological correlation is lacking in these "non-arteritic" forms. Alterations in optic nerve morphology-physiology in genetic models of hypertension have received little investigation to date. The present study was initiated to assess morphological changes in blood vessels in the optic nerve of spontaneous hypertensive rats and to document pathological changes in the optic nerve secondary to altered vascular supply. Spontaneous hypertensive rats (SHR) 28 weeks old and age-matched Wistar Kyoto (WKY) rats were perfused through the carotid artery with glutaraldehyde and paraformaldehyde following a vascular rinse under nembutal anesthesia. The optic nerves were removed, post-fixed with osmium tetroxide and processed for electron microscopy. Toluidene blue statind 1 µ sections and silver-gold thin sections were analyzed. Blood vessels within the septa of the optic nerve of SHR rats showed a marked increase in cross-sectional diameter, with changes in the endothelial cells, thickening of the basement membrane and accumulation of collagen. Infarction of the optic nerve was present around several of the severely affected blood vessels. These changes were not present in the control rats. At least in this genetic model of hypertension, optic nerve infarction can occur as a consequence of alterations in the vascular supply of the optic nerve.

172.6 IMMUNE DEVELOPMENTAL PATHOLOGY OF THE FRONTAL CORTEX AND SELECTED AREAS OF THE VISUAL SYSTEM FOLLOWING LCMV INFECTION. M.F. Kritzer and M. del Cerro (SPON: J. Ison). Center for Brain Research, University of Rochester, Rochester, N.Y. 14642.

Lymphocytic choriomeningitis virus (LCMV) induces autoimmune disorders in the nervous and sensory systems of mice and rats. The present study concerns histopathological changes in the frontal cortex, the superior colliculus, and the lateral geniculate nucleus of developing rats neonatally infected with the virus. Preliminary results indicate a characteristic evolution of pathology depicting non-specific and specific immune responses in these central nervous system regions.

In ease central nervous system regions, In ease that nervous system regions, (PND)) marginated monocytes in superficial vessels and activated macrophages in meninges and superficial neuropil are evident. From that time on, macrophages from the meninges infiltrate the superficial neuropil and continue migration in a ventro-medial direction. In deeper neuropil, these cells become satellite to neuronal somas. Macrophages then migrate to the ventral limits of the structures and appear to exit brain tissue via the ventricular system. As development continues, fewer macrophages enter the regions, neuronal-macrophage contacts are lost, and ventral migration of these cells increases. With this waning of macrophage involvement, a concommitant increase in plasma cell populations is observed. Plasma cell distributions display an evolving pattern similar to that of macrophages found earlier, as an apparent site for site replacement of macrophage populations by plasma cells takes place.

plasma cells takes place. One interpretation of data depicts LCMV associated pathology in structures studied as being representative of an immune reaction within the brain to the spreading of surface and cytoplasmic neo-antigens of viral origin. The LCMV disease offers a safe, and highly reliable animal model for the study of inflammation in the developing brain.

172.8 THE CHRONIC EFFECTS OF METHYLMERCURY ON THE INTRAMUSCULAR NERVES AND MOTOR ENDPLATES OF THE EXTENSOR DIGITORUM LONGUS MUSCLE OF THE RAT. R.K. Yip and D.A. Riley. Dept. of Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226. Methylmercury (MeHg) is a potent neurotoxin. Due to th

Methylmercury (MeHg) is a potent neurotoxin. Due to the severity of the neurological symptoms, many studies have focused attention on the central nervous system (CNS) as the primary target after MeHg exposure. The peripheral nervous system (PNS) has not been thoroughly investigated. Ataxia and paretic gait observed in humans and experimental animals after MeHg poisoning are generally attributed to the lesions in the cerebellar cortex. Recent electrophysiological studies revealed that MeHg inhibits neuromuscular activities, raising the possibility that the ataxia and paresis are due in part to neuromuscular dysfunctions. The present study sought to examine the effects of chronic MeHg treatment on the motor and sensory axons of mammalian skeletal muscle.

Six male Sprague-Dawley rats (175-200 g) were gavaged daily for approximately six weeks with an aqueous solution of methylmercuric chloride (2 mg/kg body weight). Controls received equal volumes of 0.9% saline solution. When the MeHgtreated rats were sacrificed, they exhibited abnormal crossing reflexes of their hindlimbs, ataxia, and paresis. Intramuscular nerves and extrafusal motor endplates were examined in longitudinal sections (100  $\mu$ m) of extensor digitorum longus (EDL) muscles stained with a combined acetylcholinesterase (for extrafusal motor endplates) and silver impregnation technique (for nerve fibers). In the MeHd-treated animals, coaquiative degeneration was

In the MeHg-treated animals, coagulative degeneration was found in 16% of the extrafusal motor endplates (n=1000/muscle). In these animals, nerve fiber fragmentation and axonal debris were found in 22% of the 1 afferents while frank necrosis was observed in 90% of the  $\vec{l}_{\rm b}$  afferents. Moreover, there were varying degrees of fiber loss and degeneration within the intramuscular nerve bundles of EDL from the intoxicated animals. All of the aforementioned changes were absent in the controls.

Present results demonstrated that chronic MeHg administration caused degeneration of the intramuscular motor and sensory axons. These changes could explain the ataxia and paresis associated with MeHg poisoning as impairment of neuromuscular function rather than attributing these deficits solely as a result of the CNS lesions.

This work is supported by NASA Ames University Consortium NCA-OR665-102. 172.9 THYROID STATUS IN AN INHERITED CANINE NEUROMUSCULAR DISORDER ACCOMPANIED BY TYPE II SKELETAL MUSCLE FIBER DEFICIENCY. G. A. Hegreberg, M. J. Hamilton\*, R. H. Abhold\*, and J. A. Magnuson\*. Depts. Veterinary Microbiology and Pathology and Chemistry, Wash. State Univ., Pullman, WA 99164.

Several parameters were examined to evaluate thyroid status in a genetically transmitted neuromuscular disorder of Labrador retriever dogs which is characterized by muscle weakness and atrophy, intolerance to exercise and cold, loss of glycolytic fibers from skeletal muscle, and an autosomal recessive mode of inheritance. Total and free T3, reverse T3, total and free T4, and total serum levels of cortisol, cholesterol, calcium, and lactate dehydrogenase (LDH) were measured on 14 adult affected dogs (7 males and 7 females) and 7 adult nonaffected dogs (4 males and 3 females). Total and free levels of both T3 and T4 were measured by radioimmunoassay methods in fasting serum. Reverse T3 was measured by radioimmunoassay in plasma. Free T3, reverse T3, and free T4 levels were significantly elevated in the affected dogs as compared to the nonaffected dogs (free T3, affected - .305 pg%, nonaffected - .024 ng/ml; free T4, affected 1.73 ng%, nonaffected - 1.02 ng%). No significant differences were found in total T3 and total T4 levels comparing affected with nonaffected dogs. Total LDH was significantly elevated in the affected dogs (affected - 80 Ul/dl). Total serum cholesterol was also significantly elevated in the affected dogs (affected - 231 mg%, nonaffected - 164 mg%). No significant differences were found in total T3 and total LDH was significantly elevated in the affected dogs (affected - 231 mg%, nonaffected - 164 mg%). No significant differences were found in total serum calcium and cortisol levels comparing affected work with nonaffected dogs.

Muscle atrophy, weakness, and cold intolerance are often associated with hypothyroidism. Elevated serum cholesterol and serum LDH are also indicators associated with a hypothyroid state. On the other hand, the elevated free T3, reverse T3, and free T4 levels in the affected dogs indicate that they are hyperthyroid. The dichotomous results suggest an enhanced thyroid hormone production but improper utilization of the hormone with the subsequent clinical appearance of a hypothyroid state. Current studies are underway to further define the role of the thyroid in this disorder.

INTERACTIONS BETWEEN MACROPHAGES AND MOUSE ONS MONOLAYER

172.10 HYPOPHYSECTOMY-INDUCED GROWTH RETARDATION MITIGATES THE PREVALENCE OF SKELETAL MUSCLE FIBER NECROSIS IN GENETICALLY DYSTROPHIC HAMSTERS. <u>G. Karpati, P. Jacob\*, S. Carpenter\* and S. Prescott\*</u>. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4.

Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4. Peripheral nerve section and high thoracic cordotomy performed in the prenecrotic stage prevent muscle fiber necrosis in the appropriate muscles of genetically dystrophic hamsters (Muscle & Nerve 5: 369, 1982.). We have suggested that these procedures cause an immature state of muscle fibers in which the necrotizing effect of the dystrophic gene is negated, possibly by the persistence of a fetal isoenzyme or isoprotein which is functionally equivalent to the product of the gene that is the site of the mutation. We have created impaired growth (and presumably immature state) of muscle fibers in dystrophic hamsters by growth hormone deficiency induced by surgical ablation of the pituitary at 22 days of age. Corticotropin and thyroid stimulating hormone were injected daily into these animals. Shamoperated dystrophic hamsters served as controls. At 33 and 45 days, the prevalence of centronucleated fibers (which is a valid cumulative index of all necrosis that had taken place) was found to be markedly reduced in quadriceps muscles of effectively hypophysectomized dystrophic hamsters as compared to controls (5% and 12.5% versus 23% and 60%). In those hypophysectomized animals whose growth retardation was only partial (as ascertained by several indices including length of femurs) the prevalence of centronucleated fibers appeared directly proportional to growth. These experiments indicate that mitigation of the necrotizing effect of the dystrophic gene can be achieved without apparent reduction of the mechanical activity of muscles. This avenue may be exploited therapeutically in human muscular dystrophy.

172.12 HISTOCHEMICAL STUDIES OF PHOSPHATASE ACTIVITIES IN NERVES UNDER-GOING WALLERIAN DEGENERATION. <u>G. Szumanska\*, A. Vorbrodt\*, H. M.</u> <u>Wisniewski\* and R. M. Gould</u>. Institute for Basic Research in Developmental Disabilities, Staten Island, New York 10314.

Wallerian degeneration of peripheral nerves includes the destruction of myelin sheaths surrounding degenerating axons. This destruction includes the breakdown of myelin into ovoids and the digestion of myelin lipids and protein components. In order to characterize the sites where hydrolytic activity is increasing, we are using histochemistry with water soluble phosphate-containing substrates, including some related to the breakdown of myelin phospholipids. We are comparing the hydrolysis of phosphoryl-choline, myo-inositol 2-phosphate, and cytidine 5'-monophosphate with other substrate commonly used in histochemical studies,  $\beta$ -glycerophosphate, inosine diphosphate, thiamine pyrophosphate, adenosine monophosphate, and pyridoxyl phosphate. The sciatic nerves of adult rats were crushed and ligated.

The sociatic nerves of adult rats were crushed and ligated. After 4, 24 or 72 hrs, the rats were perfused with 2% paraformaldehyde and 1% glutaraldehyde in 0.1 M cacodylate buffer pH 7.3. The degenerating nerve and contralateral control were removed and left in fixative for 90 min, before storing overnight (4°C) in cacodylate buffer. The reactions were carried out for 1-3 hrs on longitudinally-sectioned (40  $\mu$ ) pieces of nerve. Saponin (0.025%) was included in some incubations and lead was the primary trapping agent. Cerium was used in a few studies. Liver, brain and dorsal root ganglia were used in some experiments to test enzyme activities, and incubations without substrate were included as controls.

Our results so far demonstrate that some but not all activities appear or are enhanced in degenerating nerve compared with control. Among those that appear are acid phosphatase for  $\beta$ -glycerophosphate and cytidine monophosphate, but not phosphorylcholine (results with myo-inositol 2-phosphate are equivocal). Activities that are enhanced include alkaline phosphatase ( $\beta$ -glycerophosphate), inosine diphosphatase, thiamine-pyrophosphatase and 5'-nucleotidase (adenosine monophosphate). We plan to report the localization of these activities at the light microscopic level in teased fiber preparations and in electron micrographs.

CULTURES AFTER NEURITE AMPUTATION VIA LASER MICROBEAM SURGERY. C.R. Gardner\* and G.W. Gross, Dept. of Biology, Texas Woman's University, Denton, TX 76204 (SON: J.P. Hines). We have cocultured macrophages with neurons and glia to investigate interactions of those cells after neuronal or glial injury. Mouse macrophages were isolated via peritoneal lavage and seeded on established embryonic mouse spinal cord cultures grown on glass coverslips. Within 2 hours the macrophages were firmly established on the substrate but produced no obvious morphological damage within a seven day observation period. Cell process transections were carried out at 337nm either with single l2ns shots from a nitrogen laser at  $4-6_{\rm DJ}/{\rm m}^2$  or multiple shots at 4Hz and energy densities ranging from  $1-3\mu J/{\rm m}^2$ . The latter technique resulted in a slow pinching of the process followed by transection or recovery, depending on the cumulative energy density applied (1). The minimum focus diameter of the laser beam was 2.2m. Preliminary data indicate that many macrophages within 25µm of a transection site will migrate to the site of the lesion and begin to phagocytize the process. Within minutes, other macrophages in the vicinity of the target process will approach and attack seemingly intact segments of the process both proximal and distal to the actual lesion. Maximal response distances of 50µm have been observed. Initial response times from the time of lesion to detected macrophage movement towards the lesion range from 30sec. to 5min. The length of time of attack for any given macrophage is based partially on its size and can last between 15 and 45min. Thereafter, the macrophage retracts and enters a refractory period during which it is unable to respond to another lesion in the vicinity. Macrophage attack has also been observed after process lasing that resulted in cytoplasmic pinching without actual process transection. This indicates that a chemotactic substance may be released during cytoplasmic contraction at the lase

173.1 GLYCEROL INHIBITS THE SYNTHESIS OF THE 71 KILODALTON "STRESS PROTEIN" IN BRAIN SLICES. F.P. White, S.R. White, and R.W. Currie . Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland. AlB 3V6 Telencephalon slices, incubated in vitro, synthesize a 71 kilodalton protein which can constitute up to 20% of the newly synthesized protein produced by the slices. This protein has been referred to as a 'stress protein' (SP71) because, although it is not normally present in mammalian brain or most other organs in vivo, it is induced in vivo following stresses such as hyperThermia and ischemia, as well as beng induced when brain or other organs are sliced and incubated in vitro (White & Currie, in Heat Shock From Bacteria to Man, ed. Schlesinger et al, 1982). In rat brain, SP71 synthesis in response to hyperthermia or slicing appears to be restricted to endothelial cells of the microvasculature.

We are currently investigating the effects of various manipulations of the brain slice incubation media in an attempt to determine what factors influence SP71 synthesis in stressed tissue. Salicylate (10 mM) nonspecifically inhibits the synthesis of all proteins including SP71. Altering concentrations of ionic gradients, known to be important as cellular signals (Ca<sup>+</sup>, Na<sup>+</sup>, H<sup>+</sup> and K<sup>+</sup>), and drugs which inhibit those systems (papaverine, chlorpromazine, and trifluoperazine), altering levels of cyclic nucleotides (caffeine, dBCAMP, dBCMP and theophylline), and addition of anti-inflammatory agents (dipyridamole, ibuprofen, indomethocin and PG1<sub>2</sub>) had little or no specific effect on SP71 synthesis. However, IM glycerol specifically inhibited SP71 synthesis in brain slices. Glycerol (1M) also prevents induction of SP71 in rat embryo cell cultures stressed with cadmium, heat, or canavanine (S. Whelan & L. Hightower, personal communication). Interestingly, glycerol has been used to treat cerebral edema. It is possible that there is a relationship between this therapeutic effect of glycerol and glycerol's ability to prevent induction of SP71 in stressed tissue. We are currently examining whether intraperitoneal injections of glycerol can inhibit the synthesis of SP71 in response to hyperthermia. (This research is supported by grants from the Canadian Heart Foundation and MRC (Canada)). 173.2 PROTEINS OF THE BRAIN EXTRACELLULAR FLUID (ECF): EVIDENCE FOR RELEASE OF S-100 PROTEIN INTO ECF OF RAT HIPPOCAMPUS. B. W. Moore\*, V. E. Shashoua and G. W. Hesse\*. (SPON: A. Pope). Dept. of Biol. Chem., Harvard Med. School, Mailman Res. Center, McLean Hospital, Belmont, MA 02178, & Dept. of Psych., Pharm. and Anat., Washington Univ., School of Medicine, St. Louis, MO 63110 S-100 is an acidic brain protein that is highly localized in a certain class of astrocytes. It has been reported to bind to compare the section of

Washington Univ., School of Medicine, St. Louis, MO 63110 S-100 is an acidic brain protein that is highly localized in a certain class of astrocytes. It has been reported to bind to synaptic membranes in vitro. Such a property, if it occurs in vivo, requires the availability of S-100 in the extracellular fluid. We have devised a procedure for isolating proteins from the brain extracellular fluid (Neurochem Res. 6:1129, 1981; J. Neurochem. 40:1448, 1983). The method uses isotonic media to selectively extract ECF proteins from perfused brains at 0°C without disrupting the integrity of the tissue. The use of the low temperature conditions avoids leakage of cytoplasmic proteins into the extracts from which the cytoplasmic fraction marker, tyrosine hydroxylase, is virtually absent.

Electroblots of ECF proteins isolated from rat brain hippocampus were found to contain a single staining band with antiserum to S-100. Immunoelectrophoresis and RIA measurements indicate that ECF contains about 2.5  $\mu g$  S-100/mg protein. This is S-fold higher than the S-100 protein content of the cytoplasmic fraction and suggests that the protein may be released into the ECF.

Suggests that the protein may be released into the ECF. Direct confirmation of this possibility was obtained in studies of protein release from viable slices of rat brain hippocampus in vitro. Superfusion of the slices results in a release of about  $2 \mu g$  protein/mg tissue/hr. That the released proteins were not due to products of cell lysis was established by assays of the cytoplasmic enzyme marker, lactate dehydrogenase. Using an ELISA procedure and specific antisera for S-100, the superfusion fluids were found to contain 4.1  $\mu g$  S-100/mg protein (the cytoplasmic fraction of the tissue had 0.8  $\mu g$  S-100/mg protein). Thus, S-100 in the released fraction is again 5-fold higher than that retained in the tissue cytoplasm.

ELISA analyses show the presence of 1.8 ug S-100/mg protein in rat brain CSF, indicating that in vivo release of the protein also occurs. This result is of the same order of magnitude as that obtained by RIA of ECF and the in vitor studies of protein release. These findings suggest that S-100 is normally released into the brain extracellular fluid and raise the possibility that its functional role in the CNS may involve loci other than the site of its synthesis. (This research was supported by NINCDS grant No. 09407.)

173.3 PROTEIN RELEASE FROM HIPPOCAMPUS IN VITRO. G. W. Hesse\* and V. E. <u>Shashoua</u> (SPON: G. Hauser). Dept. of Biological Chemistry, Harvard Medical School, Mailman Research Center, McLean Hospital, Belmont, MA 02178

There is growing evidence that the proteins released into the extracellular spaces of the CNS may have a variety of significant roles in brain function. We have begun to investigate this process in mammalian brain using the hippocampal slice preparation as a model system. Using physiologically viable slices of rat hippocampus we find that, after an initial rinse and recovery period, protein release from unstimulated slices is relatively constant for several hours at about 2  $\mu$ g/mg tissue/hr. Assays of a cytoplasmic marker enzyme (lactate dehydrogenase) indicate that this material is not the result of cell lysis. Pulse-chase experiments using [<sup>3</sup>H]valine indicate that a sub-

Pulse-chase experiments using  $[{}^{3}H]$ valine indicate that a substantial fraction of the newly synthesized proteins eventually appears in the incubation medium (18.7% ± 3% of the total TCA precipitable radioactivity during a 6-hr superfusion) and that the releasable protein pool has an apparent half-life of about 4 hr. This apparently rapid rate of export is comparable to export rates reported for proteins released from various cell cultures derived from nervous system tissue.

For nervous system tissue. Simultaneous labeling of newly synthesized proteins with  $[{}^{3}H]$ -fucose and  $[{}^{14}C]$ valine showed a 3-fold higher ratio of  $[{}^{3}H]$ fucose to  $[{}^{14}C]$ valine in the released protein fraction in comparison to the soluble cytoplasmic fraction and the crude membrane fraction of the tissue. This suggests that the soluble released fraction is more highly glycosylated than either the soluble or membrane proteins of the tissue.

Electrophoretic patterns on SDS-polyacrylamide gels show differences between the soluble cytoplasmic proteins of the tissue and the released proteins. While the released fraction contains a broad spectrum of molecular weights, several bands between 42 kD and 68 kD appear to be characteristic of the released protein fraction.

These results suggest that a distinct group of proteins and glycoproteins exists in hippocampal tissue which is destined to be selectively released into the extracellular space. (This research was supported by NINCDS grant No. 09407.) 173.4 MODULATION OF BRAIN PROTEIN PHOSPHORYLATION BY THE S-100 PROTEIN. J. Patel.\* and P. J. Marangos. Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

The S-100 is an acidic protein localized primarily in the nervous system of mammals. Although S-100 protein has been implicated in the process of learning and memory, little is known of its interactions at a blochemical level. The S-100 protein characteristics of particular interest are that it shares a number of properties with calmodultn, including similarities in amino acid sequence and the ability to specifically interact with calcium. In this report, we have investigated the effect of the S-100 protein of brain proteins. Our results demonstrate the S-100 protein of be an effective inhibitor of phosphorylation of a number of proteins. The most potent effect exhibited by S-100 was on the phosphorylation of a protein having a molecular weight of 73,000. S-100 concentrations of 5  $\mu$ g/ml caused significant inhibition of the phosphorylation of the S-100 molecular weight protein was strictly dependent on the presence of calcium. The phosphorylation of the 73K protein was not cyclic AMP, calmodulin us to believe that the inhibitory effects of solution of calcium of the studies lead us to believe that the inhibiting the phosphorylation of a number of membranal proteins. The data suggest that the putative actions of the S-100 protein may involve a calcium dependent modulated inhibition of the fact of effect of the sphorylation of a number of the 73K protein was not cyclic number of encode of calcium. The phosphorylation of the nervous system. More recent studies lead us to believe that the inhibitory effects of solve of suggest that the putative actions of the S-100 protein may involve a calcium dependent modulation of proteins. EFFECTS OF PROTEIN CARBOXYLMETHYLATION ON  $(\alpha^{32}P)$ -8-AZIDO-ATP 173.5 BINDING IN RAT BRAIN. Melvin L. Billingsley, Paul A. Velletri, Donald M. Kuhn, Robert A. Levine and Walter Lovenberg. Section on Biochemical Pharmacology, NHLBI, NIH, Bethesda, MD 20205.

20205. Cytosol prepared from rat brain exhibits Ca<sup>++</sup>-Calmodulin (CaM)-dependent protein kinase activity. Our laboratory has investigated the possibility that carboxylmethylation of Ca<sup>++</sup>-CaM protein kinase by the enzyme protein-O-methyltransferase (PCM; E.C. 2.1.1.24) modulates  ${\rm Ca}^{++}-{\rm CaM}-{\rm dependent}$  phosphory-(row, F.C. 2.11.24) modulates care-care-appendent phosphoty-lation. Using purified PCM and 100  $\mu$ M S-adenosylmethionine (AdoMet), we found that methylation of whole brain cytosol reduced subsequent Ca<sup>++</sup>-CaM-dependent protein phosphorylation. Since CaM itself is methylated by PCM, we depleted whole brain cytosol of CaM using chromatography over fluphenazine-Sepharose or DEAE-Sephacryl. CaM-depletion was determined using SDS-gel electrophoresis. CaM-deficient cytosol was incubated with PCM and AdoMet (100  $\mu\,M$  ), and the reaction stopped with 100  $\mu\,M$  Sand automet (by ph), and the reaction stopped with hot ph of PCM adenosylhomocysteing, a potent competitive inhibitor of PCM ( $K_i = 1.0 \mu$ M). ( $\gamma^{-2}$ P)-ATP ( $5 \mu$ M) was added to this reaction, along with native CaM (1-5.0  $\mu$ g) and Ca<sup>++</sup> (150  $\mu$ M), to initiate phosphorylation. CaM-depleted cytosol phosphorylations were phosphorylation. Can-depleted cytosol phosphorylations were inhibited by carboxylmethylation, presumably due to the inacti-vation of protein kinase as other factors participating in the phosphorylation reaction. We utilized the photbaffinity probe [a<sup>-2</sup>P]-B-azido-ATP to examine possible effects of carboxyl-methylation on ATP binding in the protein kinase preparations. methylation on AlP binding in the protein kinase preparations. CaN-depleted and whole brain cytosol had several prominent bands that bound the photoaffinity label. Exposure of these cytosolic preparations to carboxylmethylating conditions significantly inhibited the binding of  $[x^{3/2}]$ -8-azido-ATP to various proteins with a prominent reduction in a 49,000 dalton protein common to with a prominent reduction in a 49,000 dalton protein common to all preparations. Further purification of cytosol by chromato-graphy over CaM-Sepharose yielded a preparation highly enriched in Ca<sup>++</sup>-CaM-induced protein kinase activity. This preparation contained one band ( $M_{\star}$  = 49,000) that bound [ $a^{-2}P$ ]-8-azido-ATP. Carboxylmethylation of this specific CaM-binding fraction inhibited the binding of the photoaffinity probe to the 49,000 dalton protein. Thus, this 49,000 dalton protein may be a subunit of Ca<sup>++</sup>-CaM protein kinase, and its state of activity may be resulted by carboxylmethylation. may be regulated by carboxylmethylation.

173.6 ENZYMATIC DETERMINATION OF SUBPICOMOLE QUANTITIES OF PHOSPHOLARGININE AND ADENOSINE 5'-TRIPHOSPHATE IN AXOPLASM. E.M. Lieberman and J. Pascarella\*. Dept. of Physiology, East Carolina U. Sch. of Med., Greenville, NC 27834. An ultramicro ATP and phospho-L-arginine (Arg-P) assay and techniques for handling nanoliter volume biological samples are described. A glass cannula attached to an oil-filled syringe was used to remove nanoliter samples of axoplasm from an intact functioning medial giant axon of the crayfish, Procambarus clarkii. The sample was ejected onto a 25 µm wire held under oil and its volume measured optically. The sample, while still in the oil-filled chamber, was prepared for the enzymatic determination of ATP and Arg-P. The assay for Arg-P is based on the ATP:L-Arginine phosphotransferase (E.C. 2.7.3.3.) catalyzed phosphorylation of ADP to ATP. The generated ATP is measured with the luciferin-luciferase bioluminescence method. Standard curves of ATP vs. scintillation counts and the generated [ATP] vs. [Arg-P] in the reaction medium were linear when plotted on full log paper over a 3 decade range, representing ATP and Arg-P contents of 10<sup>-14</sup> moles per sample. ATP and Arg-P concentrations of pure axoplasmic samples, from resting nerve, were found to be approximately 2 mM and 13 mM, respectively. Following Iodoacetic acid and cyanide poisoning, preliminary studies have shown that the axon consumes approximately 50%/hr studies have shown that the axon consumes approximately 50%/mof its available high energy phosphate (sum of ATP + Arg-P) for all cellular functions. The high energy phosphate consumed was shown to be at the expense of the axoplasmic concentration of All cellular functions. The high energy phosphate consumed was shown to be at the expense of the axoplasmic concentration of Arg-P. The ATP concentration was relatively constant, near 100% of its control value, until Arg-P was significantly reduced. It is presumed that ATP is the directly utilized energy substrate but is regenerated by the conversion of ADP to ATP using Arg-P as the phosphate donor. After addition of ouabain, energy consumption falls to 20%/hr indicating that Na-K exchange accounts for approximately 60% of the energy utilized by this axon. There was no evidence that substances present in the biological sample interfered with the assay. Recovery of added ATP and Arg-P was approximately 100%. ATP and Arg-P concentration of isolated biological samples was found to be stable for one hour a room temperature. The assay and method was demonstrated to be reliable and reproducible for the detection of subpicomole quantities of ATP and Arg-P in serial samples of cytoplasm from single isolated giant nerve fibers. The techniques described here could be easily modified for the study of a variety of metabolic intermediates in situ in functioning tissues and organs. Supported in part by grants from the US Army Research office #DAAG29-82-K-O182 and NSF grant INT-8117183. INT-8117183.

173.7 EFFECTS OF MEMBRANE FATTY-ACID MODIFICATION ON [3H]ADTN BINDING AND DOPAMINE-SENSITIVE ADENYLATE CYCLASE OF NIE-11 NEUROBLASTOMA. M.G.Murphy\* and P. Pehtla\*. (SponJ.G. Rutherford) Dept. of Pharmacology, Dalhousie University, Halifax, N. S. Canada B3H 4H7

Cultured neuroblastoma cells provide an excellent model for studying the role of membrane lipids in cell-surface receptor function. Complex lipid components can be extensively modified by media supplementation without compromising cell viability and radioligand binding properties and intracellular responses can be examined in the intact cell system. Mouse neuroblastoma (clone N1E-115) have been supplemented with fatty acids which (clone NLE-115) have been supplemented with fatty acids which increase membrane fluidity. Subsequently, the binding of the dopamine agonist,  $[{}^{3}H]ADTN$ , and the activity of dopamine-sensitive adenylate cyclase have been examined. Linoleic (18:2 $\omega$ 6), linolenic (18:3 $\omega$ 3) and <u>cis-vaccenic (19:1 $\omega$ 7)</u> acids were all taken up by the cells and <u>incorporated</u> into membrane phospholipids (either directly or after metabolism). Fatty-acid profiles of the supplemented cultures were distinct for each culture condition, with major differences being observed in relative proportions of individual PUFA and of 18:1 observed in relative proportions of individual PUFA and of 18:1 isomers. The density of dopamine receptors on N1E-115 was isomers. The density of dopamine receptors on NLE-115 was significantly (p < 0.03) increased in cells fed linoleic acid, with an average  $B_{max}$  of 352.9 ± 54.96 pmol [ ${}^{3}H$ ]ADTN specifically bound/mg protein. Linolenic acid-fed cells also had a higher  $B_{max}$  than control cells (275.1 ± 53.8 and 156.6 ± 9.1 pmol/mg protein, respectively). By contrast, the binding profile in cultures supplemented with cis-vaccenic acid (17% phospholipid fatty acids were 18:1 $\omega$ 7) was the same as that for controle avecantic the the supplemented with cis-vaccenic for a superscript of the superscript of controls, suggesting that non-specific "fluidizing" of a membrane does not enhance the extent of ligand-receptor interaction. The affinity of [<sup>3</sup>H]ADTN for binding sites on interaction. The attinity of [<sup>3</sup>H]ADIN for binding sites on NIE-115 did not change with culture conditions, and membrane fatty-acid modification did not alter the pattern of displacement of the agonist (apomorphine> dopamine > noradren-aline). Supplementation with 18:2 and 18:3 resulted in elevated (1.5 to 2.5 fold) basal levels of intracellular cAMP; adenylate cyclase in 18:2-fed cells was less sensitive to stimulation by dopamine than was the control enzyme. (Supported by the Medical Research Council of Canada).

173.8 INCREASED ADENYLATE LEVELS IN TERMINAL AXON REGIONS COUPLED TO SYNAPTIC TRANSMISSION. <u>C. A. Lindgren, C. T. Gibson\*, and D. O.</u> Smith. Department of Physiology, University of Wisconsin, Madison, WI 53706. High-energy phosphates were studied in single identified

After exposing the excitor axon innervating the opener axons. axons. After exposing the excitor axon innervating the opener muscle, the entire preparation was placed in a bath of well-oxygenated saline for 20 min. The tissue was then quick frozen in liquid nitrogen either immediately (nonstimulated) or after nerve stimulation (stimulated) for 1 min. at 50 Hz. After lyophilization, the terminal axon region was removed by micro-dissection and weighed. High-peneru phosphates were then assay After dissection and weighed. High-energy phosphates were then assayed using the luciferin-luciferase method.

using the luciferin-luciferase method. Following stimulation, the ATP content increased from 13.34 to 18.16 nmol/mg dry weight; this difference, 36%, is statistically significant at the 0.05 level. The ADP and AMP levels also rose. These changes are expressed as a significant increase in the total adenylates. In contrast, the calculated energy charge did not differ significantly; average values were 0.86 and 0.88 in the nonstimulated and the stimulated tissue, respectively. The rise in ATP could not result from rapid glycolysis or oxidative phosphorylation. for there was not a corresponding derease in rise in ATP could not result from rapid glycolysis or oxidative phosphorylation, for there was not a corresponding decrease in ADP levels. An immediate source of the increased ATP might be the phosphagen, phosphoarginine (PArg). Thus, its levels were also assayed. The results indicated that the PArg content did not change significantly during the 1 minute stimulation. Thus some other less direct pathway must be involved. To test whether the underlying muscle is the source of the increased adenylates synaptic transmission was blocked and ATP levels again measured. In separate experiments transmission was Thus,

Increased adenyiates synaptic transmission was blocked and ATP levels again measured. In separate experiments transmission was blocked by addition of the calcium-current blockers  $Co^2^*$ , verapamil, D-600, and Ruthenium Red, and the glutamate antagonist  $\gamma$ -methyl-glutamate to the bath. There were no significant changes in ATP levels following stimulation in any of these cases indicating that synaptic transmission, and consequent muscle activity, is neresarily related to elavated advaccing level

Indicating that synaptic transmission, and consequent muscle activity, is necessarily related to elevated adenosine levels. Possible release by muscle was tested by measuring ATP levels in the bath saline following nerve stimuation. We estimate that at least 0.70 pmol were released. This increase was not detected when synaptic transmission was blocked. Furthermore, addition of ATP to the bath (1 to 10 mM) caused ATP levels assayed in non-stimulated tissue to rise significantly. Our tentative constimulated tissue to rise significantly. Our tentative con-clusion is that ATP derived from the muscle becomes associated with the presynaptic nerve. Supported by grants from NIH (NS13600 and NS00380) and the Whitehall Foundation.
STUDIES ON THE SUBCELLULAR LOCALIZATION OF CNPase IN CAT PERIPHERAL NERVE. <u>S.M. Ross\*, M.I. Sabri and P.S. Spencer</u>, Institute of Neurotoxicology, Departments of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY. 10461. <u>2',3'-Cyclic nucleotide 3'-phosphohydrolase (CNPase) is present in CNS</u> 173.9

myelin, in plasma membranes of myelin-free oligodendrocytes and in murine glial tumor cells grown in culture. Little is known about the subcellular localization of CNPase in the PNS. Several previous studies have indicated only marginal enrichment of CNPase in the heavy myelin Subcellular localization of CNPase in the PNS. Several previous studies have indicated only marginal enrichment of CNPase in the heavy myelin fraction (0.85M sucrose phase) over that of the crude homogenate (CH) prepared from peripheral nerve. CNS myelin isolation procedures are usually used to prepare PNS myelin, in which the meniscus between the 0.32M:0.85M sucrose interface is collected as the crude myelin fraction. To produce purified light myelin and to facilitate localization of CNPase in peripheral nerve, a 0.6M sucrose phase was introduced into our discontinuous sucrose gradient (DSG) system (0.25M:0.6M.0.6SM). Subcellular fractions from cat sciatic nerve were prepared according to the method of Ross et al., (J. Neurochem., 1983). CNPase specific activity was highest in membranes floating above the 0.6M and 0.25M sucrose phases 2.5- and 2.0-fold over the CH, respectively. Activity in membranes 2.5- and 2.0-fold over the CH, respectively. Activity in membranes douting above the 0.25M.0.5M interface floating above the 0.25M.0.5M sucrose phase secific activity declined in heavier fractions. Taken together, CNPase activity in the material floating above the 0.25M.0.5M.0.5M.0.5M sucrose phase sucrific activity was enterial activity in the material floating above the 0.25M.0.5M.0.5M.0.5M sucrose phase activity in the material floating above the 0.25M.0.5M.0.5M.0.5M sucrose phase activity in the material floating above the 0.25M.0.5M.0.5M sucrose phase constituted 70% of the total activity, while membranes floating above the 0.6M interface accounted the total activity, while membranes above the 0.6M interface accounted the total activity, while membranes above the 0.6M interface accounted for 51% of total activity. A second osmotic shock of these membranes (0.6M sucrose phase) and relayering of the material over a second DSG resulted in reduction of the specific activity by 11% and of total activity to 34% in this fraction. SDS-PAGE of membrane proteins individually harvested from the 0.25M:0.6M:0.85M interfaces indicated the presence of P<sub>0</sub>, P<sub>1</sub>, and P<sub>2</sub> myelin-specific proteins, and electron microscope examination revealed typical multilamellar myelin membranes. In summary, CNPase specific activity was increased in membranes. In summary, CNPase specific activity was activity. Typical myelin lamallae and myelin-specific proteins are resident in these fractions. These data indicate, based on morphological and biochemical criteria, that CNPase in cat peripheral nerves is associated with purified light myelin which floats above 0.6M and 0.25M sucrose interfaces. POLYPEPTIDE PATTERNS FROM IN VITRO SYNTHESIS BY BRAIN MITOCHONDRIA AND SYNAPTOSOMES. C.C. Irwin\* (SPON: G. Adelman). Dept. of Biochem., Shriver Center for Mental Retardation, 200 Trapelo Rd., Waltham, MA 02254
 Protein synthesis in brain mitochondria and synaptosomes has

been a matter of some controversy, partly because of difficulty in interpreting the quantitative effects of cycloheximide, an inhibitor of cytoplasmic protein synthesis, and chloramphenicol, an inhibitor of mitochondrial protein synthesis. To help resolve an inhibitor of mitoenondrial protein synthesis. To help resolve this issue, qualitative aspects of protein synthesis in brain mitochondria and synaptosomes were studied. Mitochondria and synaptosomes were isolated by discontinuous Ficoll-sucrose gradients from 10-14 d. rat brain cortexes and incubated in an amino acid incorporation system with 200  $\mu$ Ci <sup>35</sup>S-methionine. After 1 h incubation at 37°, mitochondria and synaptosomes were washed, dissolved in SDS-containing medium and electrophoresed on gradient SDS-polyacrylamide slab gels. Autoradiography of the gels revealed that both mitochondria and synaptosomes synthesize gels revealed that both mitochondria and synaptosomes synthesize a large population of polypeptides in the absence of inhibitors (50 or more in the molecular weight range 3,000-200,000) with only minor variations in the overall pattern. In the presence of cycloheximide, fewer bands appeared (at least 10-12), primarily in the lover molecular weight region (3,000-43,000) with 5 bands predominating (molecular weights 19000, 25000, 30000, 33000, 40000). Incubation with chloramphenicol reduced or eliminated those bands. Thus, provide that ine differences eliminated these bands. Thus, no major qualitative differences in protein synthesis occur in brain mitochondria and synaptosomes by one-dimensional analysis. Furthermore, the polypeptide patterns from cycloheximide-inhibited organelles corresponded closely to patterns obtained from rat liver mitochondria and intact neural cells (cultured neuroblastoma and glioma). The results are consistent with the idea that brain mitochondria. including intraterminal mitochondria, synthesize a conventional array of proteins inhibitable by chloramphenicol. Furthermore, both mitochondrial and synaptosomal preparations, isolated by traditional methods, also synthesize a broader range of proteins, inhibitable by cycloheximide, that may reflect intrasynaptosomal non-mitochondrial, or extrasynaptosomal vesicular, protein synthesis, as suggested by others.

173.11 RATE OF CHANGE OF OXIDATION OF NADH IN THE RESPIRATORY CHAIN BY CO<sub>2</sub> IN DORSAL ROOT GANGLION NEURONS SOMAS, <u>Carlos Rodríguez-Estrada</u>. Cátedra de Fisiología I.M.E. Facultad de Medicina, U.C.V., Caracas, Venezuela. Previous reports (Rodríguez-Estrada, Carlos, Neuro-science Abs. 3:321,1977; 8:992,1982) have shown that carbon dioxide blocked the metabolic response after a chort period of nerripheral nerve stimulation and that Previous reports (Rodríguez-Estrada, Carlos, Neuro-science Abs. 3:321,1977; 8:992,1982) have shown that carbon dioxide blocked the metabolic response after a short period of peripheral nerve stimulation and that it is a critical CO2 concentration need to block the oxidation of NADH after a short period of anoxia. In this work the rate of change of oxidation of NADH and the per cent change of NADH was measured. Fluoro-metric determinations of NADH were done on <u>in vitro</u> preparations of dorsal root ganglion ( Rana palmipes spix as previously described, and pH was measured in the Ringer's solution bathing the preparation (Bee-trode\*), also pO2 of the gas circulating the chamber was measured simultaneously, (25°C). The preparation in O2 was alternated with N2 or CO2-N2 mixtures for 7 min duration. In half the preparations following this se-quence: O2, N2, O2, CO2-N2, O2 (N2), the other half O2, CO2-N2, O2, N2, O2. Results reported here are from changes observed in preparations subjected either (N2) or (CO2-N2) sequence. The rate of change was the per cent change of oxidation during a period of time meas-ured from the beginning of oxidation to its half oxida tion (t<sub>1</sub>/2). In each preparation the oxidation change (%f1) and the rate of change of oxidation (t<sub>1</sub>/2) were larger, without exception, after N2 than after CO2-N2. A group of three series performed in the same prepara-tion (N2). (2.5%CO2-N2), (5%CO2-N2) the values observed were: (N2) "%f1, N=10, M=1.454, SD=.579, R=.183, R=.66 -2.52"; (2.5%CO2-N2), "%f1, N=10, M=.657, SD=.207, SE=.065, R=.28-.85"; (5%CO2-N2), "%f1, N=10, M=.338, SD= .260, SE=.082, R=.2-.78". The t(ratio) of t\_{1/2} for (N2) and for (2.5%CO2-N2), a r=.47 and .06 respectively, but a r=.97 for (5%CO2-N2), a r=.47 and .06 respectively, but a r=.97 for (5%CO2-N2), a r=.47 and .06 respectively, but a r=.97 for (5%CO2-N2), a r=.47 and .06 respectively, but a r=.97 for (5%CO2-N2), a r=.47 and .06 respectively, but a r=.97 for (5%CO2-N2), a r=.47 and .06 respectively, but a r=.97 for (5%CO2-N2

173.12 EFFECT OF INTRAVENOUS FEEDING ON BRAIN AND PLASMA METABOLITE ABNORMALITIES AFTER PORTACAVAL ANASTOMOSIS. <u>A. Mans\*, J.</u> <u>Biebuyck\*, D. Davis\* and R. Hawkins</u> (SPON: R. Bryan). Depart-ments of Anesthesia and Physiology, Hershey Medical Center, The Fennsylvania State University, Hershey, PA 17033. Rats with a portacaval anastomosis show several characteristic metabolic abnormalities: brain content of glutamine, ammonia, tryptophan, tyrosine and phenylalanine are elevated, blood ammonia is high, and there is an abnormal pattern of plasma amino acids. Transport of neutral amino acids into brain is increased.

acids. Transport of neutral amino acids into brain is increased. In patients with liver failure and encephalopathy, both oral and intravenous amino acid mixtures have been administered, in an attempt to improve mental status by altering entry of those amino acids into brain which are neurotransmitter precursors. So far, reports on effects on brain function have been conflicting. We have studied the effect of nutrition on brain amino acid content and the altered blood-brain barrier transport systems. Rats with portacaval shunts were deprived of food (except controls) and given either oral dextrose, intravenous dextrose, or intravenous given either oral dextrose, intravenous dextrose, or intravenous dextrose plus leucine, valine and isoleucine (in amounts adequate to provide caloric need). Four days of treatment lowered blood ammonia concentration especially in the group given oral glucose. Brain glutamine content decreased remarkably from about 14 µmol/g to about 8 µmol/g (normal 6 µmol/g). This effect was seen with all three regimens and is presumably due to the absence of oral protein intake and subsequent production of ammonia. In general, protein intake and subsequent production of ammonia. In general, most plasma amino acid concentrations were lower after treatment. The high henylalanine was reduced whereas tyrosine was unaffect-ed in all three groups. The low branched-chain amino acids were further decreased by administration of dextrose alone, either orally or intravenously. In all three treated groups, the resulting plasma amino acid pattern led, in theory, to decreased competition for tryptophan transport into brain (calculated from the neutral amino acid concentrations and their inhibitor con-stants). Thus, based on consideration of competition between neutral amino acids, the entry of tryptophan into brain was predicted to be greater after all three treatments. Furthermore, the brain uptake index of tryptophan, which was 45% higher after shunting, was not lowered in the treated groups. Interestingly, in spite of these findings, brain content of tryptophan, phensummering, was not rowered in the treated groups. Interestingly, in spite of these findings, brain content of tryptophan, phen-ylalanine and tyrosine was decreased by intravenous dextrose plus amino acids. Thus, a partial reversal of several abnormalities found after portacaval shunting was obtained by removal of oral protein and administration of glucose. The addition of branched chain amino acids to the glucose infusion had the greatest effect on brain aromatic amino acids, although the mechanism remains to be clarified.

INCREASED GLYCOLYSIS IN GOLDTHIOGLUCOSE-INDUCED LESIONS 173.13 OF CIRCUMVENTRICULAR ORGANS. R.J. DirAccco and E.E. Coms. Monell Chemical Senses Center, Philadelphia, PA 19104. Psychology Department, New York University, New York, N.Y. (SPON: L.A. Palmer) We have recently reported that inflammatory brain lesions of experimental allergic encephalomyelitis (EAE) in rats are accompanied by the intense stimulation of glycolysis. One interpretation of this result is the intense stimulation of glycolysis. One interpretation of this result is that it represents anaerobic glycolysis, as the culmination of inflammatory events beginning with increased capillary permeability followed by exudation, edema, hemoconcentration, hemostasis and ischemic hypoxia in the lesion sites. Another contributing factor may be the high metabolic rate of sensitized T-cells which aggregate to produce these foci of inflammation. Unlike EAE lesions, however, goldthioglucose (GTG)-induced lesions of circumventricular organs (CVO's) are not accompanied by the infiltration of significant numbers of lymphocytes. Moreover, macronhages are not evident in CVO's until several days after Moreover, macrophages are not evident in CVO's until several days after GTG injection. Therefore, any increase in glycolysis that occurs before this time could not easily be attributed to high metabolic rates in

this time could not easily be attributed to high metabolic rates in aggregated leukocytes, microglia or macrophages of peripheral origin. CBA/Ki mice were injected (I.P.) with GTG (0.4 mg/g). <sup>14</sup>C-deoxy-glucose (100 $\mathcal{A}$  (C/kg) was injected (I.P.) 1,3,5, and 7 hrs, as well as 2,8 and 12 days after GTG administration. Mice were sacrificed 45 minutes after <sup>14</sup>C-2DG injection and autoradiograms were prepared from frozen brain sections obtained with a cryostat. Autoradiograms obtained one hour after GTG were normal, however by 3 hours glycolysis in the ventromedial region of the hypothalamus (VMH) including the median eminence was intensely stimulated. By 5 hours, the involved region was larger but the lesion was characterized by a leading edge of metabolic activity surrounding a central quiescent zone. Seven hours after GTG, all CVO's were involved. This pattern of activity persisted for two days. By 8 days after GTG, however, the region of VMH metabolic involvement had diminished in size to a sharply demarcated area of intense metabolic activity corresponding to scar formation. Other CVO's appeared normal at this time. Twelve days after GTG, all circumventricular regions appeared normal by visual examination of the autoradiograms.

Intense glycolysis in GTG-induced CVO lesions as early as three hours post GTG occurs well before significant accumulation of leukocytes and macrophages, and therefore cannot be explained in terms of a high metabolic rate of these cells. This observation supports the hypothesis that ischemic hypoxia leading to anaerobic glycolysis is a cause of the increased metabolic rate of glucose in inflamed regions of the central nervous system.

173.14 APPARENT ACTIVATION OF [3H]2-DEOXYGLUCOSE UPTAKE BY SLICES OF CEREBRAL CORTEX AFTER EXPOSURE TO LOW GLUCOSE INCUBATION MEDIA.

CEREBRAL CORTEX AFTER EXPOSURE TO LOW GLUCOSE INCUBATION MEDIA. B. I. Gold and J. Kyle-Lillégard. Dept. Pharmacol. Uniformed Services Univ. Sch. Med., Bethesda, MD 20814 We have been using the uptake of [<sup>3</sup>H]2-deoxyglucose ([<sup>3</sup>H]2DG) by brain slices to model glucose transport by brain. With this model we have shown that [<sup>3</sup>H]2DG is taken up selectively and ste-reospecifically. Uptake is saturable and it displays a tempera-ture dependence that is consistent with a carrier-mediated pro-cose. We new report data from proliminary emperiments designed to the new report data from proliminary emperiments designed to the new report data from proliminary emperiments designed to the new report data from proliminary emperiments designed to the new report data from proliminary emperiments designed to the new report data from proliminary emperiments designed to the new report data from proliminary emperiments designed to the new report data from the new report data from the new report data for the new reperatore data for the new report data for the new report dat cess. We now report data from preliminary experiments designed to question whether glucose uptake in the brain is regulated in part as a function of glucose availability. Slices of cerebral cortex from freshly-killed rats were rou-

tinely incubated in oxygenated Krebs-Ringer-bicarbonate media (KRB). After a 30 min equilibration in KRB with 10.4 mM D-glucose (D-glc), slices were transferred and incubated for up to 1 h in KRB which contained 10.4 mM L-glucose (L-glc), the inactive ste-reoisomer of D-glc, or 10.4 mM choline Chloride. Control slices were incubated in parallel in 10.4 mM D-glc. After exposure to L-glc or to choline Cl, slices were filtered, rinsed, and resus-L-gic or to confine C1, sinces were filtered, finsed, and resus-pended in D-glc-free KRB. Uptake was initiated with 0.5 mM [<sup>3</sup>H]2DG and after 2 min slices were filtered again, rinsed, sol-ublized in Protosol and radioactivity was estimated. These steps have been described in detail (Neurochem. Res. 6:949; 8:473). [<sup>3</sup>H]2DG uptake by slices exposed to L-glc or choline C1, was

 $[^{3}H]2DG$  uptake by slices exposed to L-glc or choline Cl, was increased up to threefold as compared to controls. In separate experiments,  $[^{3}H]2DG$  uptake was halted by filtration but samples were extracted in 0.4N HClO4. The extracts were neutralized with KOH, they were centrifuged and the supernatants were applied to small anion exchange columns. Two fractions were collected, a neutral fraction containing  $[^{3}H]2DG$  and an acidic fraction con-taining  $[^{3}H]2-DG-6-phosphate ([^{3}H]2DGP)$ . In slices that had been taining ['H]2-DG-6-phosphate (['H]2DGP). In slices that had been exposed for 1 h to 10.4 mM choline Cl, not only was total <sup>3</sup>H uptake increased, but the amount of <sup>3</sup>H that eluted in the acid fraction increased almost fivefold as compared to slices incubated for 1 h in 10.4 mM D-glc. In similar experiments, [<sup>3</sup>H]2DG uptake by slices exposed to 10.4 mM 3-0-methylglucose, an analogue that is not a substrate for hexokinase increased twofold as compared to control but uptake by slices exposed for 1 h to 10.4 mM 2DG was not increased and actually showed a 40% decrease. [ $^{3}$ H]2DG upwas not intreased and actuary showed a to declass. I intro the take by slices exposed for 1 h to 2.0 mM D-glc, analagous to hypo-glycemic plasma levels, increased about 30% as compared to con-trol slices exposed for 1 h to 10.4 mM D-glc. These results suggest that brain glucose uptake at the cellular

level responds to decreased glucose availability by increasing the rate or the capacity of glucose transport. New data are re-quired, however, to determine if increased uptake is secondary to or driving the increased glc metabolism. (USUHS protocol #107528)

173.15 AN IN VIVO MODEL FOR ISOLATING THE PHOTORECEPTOR CELL LAYER IN THE RAT. S. Y. Schmidt\*, J. C. Blanks and M. A. Sandberg\*. Berman-Gund Laboratory, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA, and Estelle Doheny Eye Foundation, Los Angeles, CA. A model system was developed to obtain a retina rich in photo-

receptor cells. Neonatal rats (postnatal days 5-11) were sub-jected to a series of 12-13 subcutaneous and intraperitoneal injections of a combination of neurotoxic agents, including glutamate, aspartate and 6-hydroxydopamine. The photoreceptor cells were not affected by these injections and underwent normal cells were not affected by these injections and underwent normal differentiation and growth. On day 26, photoreceptor cell func-tion was evaluated by electroretinography (ERG) and photorecep-tor cell metabolism by the capacity for RNA synthesis in vivo and in vitro and by the cells' ability to restrict the entry of sodium in light but not in dark. ERGs showed a normal a-wave and a greatly reduced b-wave; the capacity of photoreceptor cells for RNA synthesis and excluding sodium in light was com-parable to that in unpiciented literates controls. In come are cells for RNA synthesis and excluding sodium in light was com-parable to that in uninjected littermate controls. In some ex-periments, rats were given an additional intraocular injection of alpha-aminoadipic acid (AAA); 20 hours later ERG responses showed further reductions in the b-wave, a normal a-wave and the retina was composed almost entirely of photoreceptor cell layers with nearly complete disappearance of inner retinal neurons and Müller cells. The photoreceptor cells remained intact and their capacity for RNA synthesis was normal as shown by biochemical and autoradiographic analyses shown by biochemical and autoradiographic analyses. These studies establish that such photoreceptor-rich retinas

provide an <u>in vivo</u> system for electrophysiological analysis of the isolated a-wave of the ERG and an <u>in vitro</u> system for de-fining RNA synthesis and exploring the molecular biology of photoreceptor cells.

173.16 METHIONINE SULFOXIMINE EFFECT ON N-ACETYL-L-ASPARTATE LEVELS IN SYNAPTOSOMES. <u>G. Massieu and K.Aoki</u>. Depart-ment of Neuroscience. CINVESTAV del IPN. Apartado Postal 14-740, México 07000, D.F.

tal 14-740, México 07000, D.F. There is growing evidence that N-acetyl-L-aspartate (NAA) is not an inert metabolite, but rather is utili-zed in the lipid biosynthesis in the developing rat brain (D'Adamo et al, 1968). On the other hand, Tapia et al (1967) showed that administration of methionine sulfoximine (MS) to mice decreases the brain levels of glutamic and aspartic acid, GABA and glutamine. It was therefore of interest to examine the effects of MS on the NAA levels in the mice and rat cerebral cortex as vell as the influence of MS-treatment on NAA content of The NAA levels in the mice and rat cerebral cortex as well as the influence of MS-treatment on NAA content of synaptosomes obtained from rat brain cortex. In the normal cortex of mice, the contents of NAA are of  $81.1^{\pm}$  9.38 (mean  $\pm$  S.D. n=4) mµmoles per mg of protein. 24 hours after the injection of 150 mg/kg of MS, the content of NAA in the cerebral cortex was changed to 66.5  $\pm$  4.42 mµmoles per mg of protein. This difference was not significant. However, in the remainder of the brain there was a significant reduction of NAA (P<0.02) from 67.9  $\pm$  3.08 control (n=4) to 53.2  $\pm$  2.52 (n=5). In the rat cortex, MS also reduced the levels of NAA (from control values of 101.5  $\pm$  3.59 n=4 to 89.4  $\pm$  8.09 (n=5) after MS), but was without significant effects in the remainder of the brain (79.6  $\pm$  1.61, n=4 control to 77.4  $\pm$  4.84, n=5 after MS). Similar decreases of NAA after (100 mg/Kg MS) were

Similar decreases of NAA after (100 mg/Kg MS) were observed in synaptosomal preparations obtained from rat cerebral cortex. Control values were  $78.01 \pm 1.74$  (n=7) and were changed to  $54.7 \pm 1.92$  (n=7) after 100 mg of MS.

In another series of experiments we compared the ac-In another series of experiments we compared the ac-tion of MS (100 mg/Kg) administered together with me-thionine (372 mg/kg). There was practically no differ-ence between the NAA content of the synaptosomes of MS-treated rats ( $54.9 \pm 1.65$ , n=18) as compared with the MS + methionine treated rats ( $58.2 \pm 2.14$ ) which were significantly smaller (P<0.05) than controls (76.0  $\pm$ 2.09 n=30) 2.09, n=30).

It is concluded that NS-treatment induces a moderate decrease of the NAA content of brain tissue. In the case of synaptosomes the falling of NAA is more significant. These findings support the view that NAA metabolism is active.

173.17 ESTIMATION OF THE LEVEL OF NOREPINEPHRINE AND ASCORBATE AUTOXIDA-TION INHIBITING ACTIVITY IN THE CNS AND SERUM OF GUINEA PIG, RAT G.B. Kovachich\* and O.P. Mishra\* (Spon: AND HUMANS. A. Winokur). Dept. of Pharmacology and Inst. for Environmental Medicine, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104. During the past year evidence has been presented that the rat brain cortex contains 2 heat stable, nondialyzable substances with potent inhibitory effect on the <u>in vitro</u> autoxidation reactions of ascorbate (ASC) and norepinephrine (NE) (Kovachich and Mishra, Neurosci. Lett. 34:83, 1982, Neurosci. Lett. in press.) Data presented below indicate that these antioxidants are distributed widely in the CNS and beyond, with uniform activity levels.

ASC autoxidation was determined by spectrophotometric measurements at 265 nm, NE autoxidation was estimated by spectrophotometric detection of noradrenochrome at 480 nm in buffered reaction media. Rat and guniea pig brain areas (brain stem, midbrain, cerebellum and cortex) and spinal cord samples were dis-sected from adult animals, human frontal lobe sections were obtained from the University Hospital morgue 6-8 hours post mortem. Tests showed no change in rat brain antioxidant activi-ties <u>post</u> mortem for at least one day. Serum samples were pre-pared from rats and guniea pigs after Nembutal anesthesia directly from the heart, human serum through I.V. puncture. CNS samples were homogenized in 10% w/v 10mM TRIS or 16mM NaPi pH7.4 and 100,000g supernatant was used for assay. The choice of buffers did not effect the assay results. Serum samples were diluted 10-fold with buffer and all samples were dialized over-night (m.w. cut off at 8,000).

The inhibitory activities on ASC and NE autoxidation were determined using 1-100 ul aliquots in 2 or 4 ml buffered reaction mixtures against various concentrations of ASC and NE. All samples were active. Although there were minor variations in the potency of the samples, the uniformity of the results were more striking than the differences. Experiments with EDTA verified previous findings that the inhibitory effect of the extracts is far greater than the maximum effects that could be obtained by the use of EDTA.

Precise quantitative generalizations are difficult to obtain without further measurements, however, the inhibitory effect of tissue extracts on both the ASC and NE autoxidations were discremable at up to  $5\times10^4$ -fold dilution of the original tissue Cernaple at up to SALO Flow of the term of the second second activity. Maximal inhibitory effect was obtained at approximately  $10^3$ -fold dilution. The substances responsible for these effects appear to be in considerable excess of what is required for inhibition of autoxidation. This suggests that the physiological role of these entities is yet to be identified. Supported by NII: Grant HL-08899 and ONR Contract N00014-7-00248.

#### ACUTE CHANGES IN REGIONAL CEREBRAL METABOLITE CONCENTRATIONS 173.19 ACTIVE CHARGES IN ALECTORIAL CERESKAL HEIMBOLITE CONCENTRATIONS FOLLOWING EXPERIMENTAL BLUNT HEAD TRAUMA. K. R. Wagner and P. A. Tornheim. Departments of Neurology and Anatomy and Cell Biology, University of Cincinnati, VA Medical Center, and Cell Biology,

Cincinnati, OH 45220. The present study asks whether mechanical head injury alters cerebral metabolite concentrations and, if so, whether these effects: 1) relate topographically to tissue hemorrhage; and 2) vary for gray versus white matter. Ketamine-anesthetized cats monitored for arterial and intracranial pressures and blood gases were subjected to impact to the skull with a Remington Humane Stunner. Controls were handled identically except for Humane Stunner. Controls were handled identically except for the injury. Brain metabolite concentrations were fixed by  $\frac{1}{10}$ situ freezing of the head at 15 min after impact. Only injured animals with unilateral cerebral contusions were studied. Metabolite concentrations were assayed by enzymatic-Metabolite concentrations were assayed by enzymatic-fluorometric methods on samples from cerebral cortex and deep white matter neighboring, distant (ipsilateral), and contralateral to tissue hemorrhage. Tissue density was measured with an organic gradient to correct for dilution of metabolite concentrations by edema fluid.

metabolite concentrations by edema fluid. For 5 control cats, concentrations of ATP, phosphocreatine (PCr) and lactate were 2.20±0.06, 4.10±0.25 and 1.29±0.15 µmoles/g (Mean±SEM) respectively in white matter and 2.57±0.09, 5.76±0.48 and 2.14±0.41 µmoles/g respectively in cortex. For 8 head-injured cats, white matter neighboring contusion had substantial metabolic changes (corrected values for ATP, PCr and lactate of 1.37±0.33, 1.79±0.49 and 8.26±1.55 µmoles/g respectively). Distant white matter had smaller alterations; contralateral white matter values were similar to controls. By contralateral white matter values were similar to controls. contrast, cortex meighboring contrusion had lesser changes in metabolites (corrected ATP, PCr and lactate of 1.93 $\pm$ 0.39, 3.56 $\pm$ 0.79 and 6.94 $\pm$ 2.53 µmoles/g respectively) than white matter, with variable responses distant and contralateral to contusion. Systemic responses to trauma do not explain the topography or magnitude of metabolic changes seen with our model.

The present results demonstrate, at 15 min following head injury, marked metabolic changes in deep white matter that decrease with distance from contusion. We conclude that the metabolism of the white matter compartment is particularly vulnerable to trauma and that acute metabolic insults may contribute to the white matter edema frequently seen following severe head injury in man.

This study was supported by NIH Grant #R01 NS17975.

# 173.18 EFFECTS OF EXPERIMENTAL HEAD INJURY ON TISSUE DENSITY AND

EFFECTS OF EXPERIMENTAL HEAD INJURY ON TISSUE DENSITY AND VASCULAR PERMEABILITY TO PROTEIN IN WHITE MATTER. P. A. TOTNheim, K. R. Wagner, R. L. McLaurin\*. Depts. of Anat. & Cell Biol, Neurol., and Surgery, Univ. of Cincinnati; VAMC, Cincinnati, OH 45267.

Although the characteristics of the spread of edema fluid from thermal insults to cerebral cortex (cold injury) have been well described, the early development of edema after mechanical injury to the brain has received little investigative attention. The purpose of the present study was to determine the topography of white matter edema following experimental mechanical head trauma. Ketamine-anesthetized cats were injected intravenously with Evans Blue dye (25 mg/kg), followed by impact to the exposed skull with a Remington Humane Stunner. At 15 min and 6 hr after injury the head was frozen in liquid nitrogen, followed by coronal slicing on a band saw. Only head-injured cats with unilateral contusions of the lateral frontotemporal area were studied. Frozen slices were examined for white matter Evans Blue dye, indicating the location of protein-rich (vasogenic) edema fluid. Each slice was thawed under kerosene and serial white matter samples were taken 1-10 mm medial to the edge of contusion as well as bilaterally from the deep white matter (centrum semiovale) 0-15 mm caudal to the level of tissue hemorrhage. Samples were measured for tissue density with an organic gradient. Density data from head-injured animals were compared with those from uninjured control cats to

estimate change in tissue water content (edema). At 15 min after injury, a narrow rim (0.2-1.5 mm) of Evans Blue dye was visible in white matter deep to contusions. White matter from this area had substantial decrease in density from control values. At 2.5-10 mm deep to contusion, outside of the vasogenic edema front, there was a small but significant decrease in density from control values. Deep white matter 0-7 mm caudal to contusion had slight hypodensity. Extremely caudal and contralateral white matter had normal density. At 6 h after injury there was a substantial Evans Blue

territory medial to contusion, usually with sparing of dorsal subcortical white matter and arcuate fibers. The deep white matter was stained up to 8 mm caudal to contusion. Substantial decrease in density occurred in the subcortical and deep white matter medial and up to 8 mm caudal to contusion, but not contralaterally. The present results document, at 15 min after injury, changes in white matter density in a widespread area peripheral to the vasogenic edema front surrounding contusions. These findings contrast with those seen with cold injury. We conclude that events in addition to spread of fluid from sites of tissue hemorrhage contribute to the white matter edema of mechanical trauma.

173.20 31-PHOSPHORUS NUCLEAR MAGNETIC RESONANCE OF DECAPITATED RAT BRAIN, J.A. Helpern, J.R. Ewing\*, K.M.A. Welch, S.J. McGee\*. Nuclear Magnetic Resonance Lab., Dept. of Neurology, Henry Ford Hospital, Detroit. MI 48202

31-Phosphorus Nuclear Magnetic Resonance (NMR) has been used 31-PhoSphorus Nuclear Magnetic Resonance (NNR) has been used to measure high-energy phosphate metabolism during global ische-mia in the decapitated rat brain. Brains from rats (male, Sprague-Dawley, 325-350 gm) were isolated post-decapitation and immediately placed over an insulated NMR surface coil, tuned to the 31-P resonance frequency of 32.5 MHz. NMR parameters (pulse interval) worm or insulate for the detection of phorphosphice the 31-P resonance frequency of 32.5 MHz. NMR parameters (pulse intervals) were optimized for the detection of phosphocreatine. Data acquisition began within 40 seconds of decapitation, at a rate of 120 scans per 49 seconds, and continued for at least 5 minutes. No phosphocreatine or ATP/ADP peaks were detectable in any of the subsequent spectra. These parameters were also used to detect phosphocreatine in anesthetized rats with a signal-to-noise ratio 24. Since our first data point is the accumulation of individual cone during the time from of AL98 seconds postindividual scans during the time frame of 40-89 seconds postdecapitation, we conclude that any phosphocreatine in rat brain after global ischemia of > 1 minute in duration is not detectable by NMR. These results seem to contradict the findings of Norwood et al (Norwood WI, et al, Am J Physiol, 244(3):205, 1983), who recently demonstrated the presence of phosphocreatine in perfused adult and neonatal rat brain well after 5 minutes of ischemia. In order to clarify these findings, whole decapitated rat heads, as well as decapitated rat heads which had been cleaned of extra-neous skin and muscle were placed in the NMP with the surface neous skin and muscle, were placed in the NMR with the surface coil located directly over the calvarium. Whole decapitated rat heads as well as those that had been cleaned of some but not all extraneous tissue demonstrated the presence of phosphocreatine extraneous tissue demonstrated the presence of phosphocreatine and ATP/ADP peaks lasting for up to 25 minutes post-decapitation. However, rat heads which had been thoroughly cleaned of extraneous tissue showed no indication of any presence of phosphocreatine or ATP/ADP. As further evidence that any detectable levels of phos-phocreatine or ATP/ADP after global ischemia of > 1 minute in duration result from tissue other than brain, the brains were removed from the skull, replaced with a sack of water, and the head placed in the MMR. Subsequent NMR spectra confirmed that the phosphocreatine and ATP/ADP peaks originally thought to be resulting from brain actually result from the surrounding tissue of the skull. of the skull.

SYMPOSIUM. THE DYNORPHIN PEPTIDES. <u>A. Goldstein</u>, Stanford Univ. (Chairman); <u>S. Numa\*</u>, Kyoto Univ.; <u>E. Weber\*</u>, Stanford Univ.; <u>F. Bloom</u>, Salk Institute; <u>A. Herz\*</u>, Max Planck Institut fur 175 Psychiatrie.

The dynorphin peptides comprise the third known family of opioid gene products in the mammalian nervous system. There are three main opioid peptides within the dynorphin message -- neoendorphin, dynorphin A, and dynorphin B (rimorphin).

The structures of the messages and genes encoding the opioid peptide families will be compared, and their physiological and evolutionary significance will be discussed (Numa).

The evidence for a high degree of selectivity of the dynorphin peptides for the kappa opioid receptor will be presented (Goldstein).

The several pathways of post-translational proteolysis will be the several pathways of post-translational proceedysis will discussed, especially the unusual cleavages that lead to dynor-phin A-(1-8) and dynorphin B (Weber).

The hippocampus provides an interesting opportunity to compare release and function in dynorphin and enkephalin circuits, and to study specificity of action of these peptides on their target neurons (Bloom).

Finally, the possible involvement of dynorphin peptides in gross physiologic and behavioral functions -- e.g., pain modula-tion, neuroendocrine effects, food and water intake -- will be discussed (Herz).

177 SYMPOSIUM. FUNCTIONAL RECONSTRUCTION OF NEURONAL SYSTEMS.

Co-chairmen: Donald <u>H. Perkel</u>, Stanford Univ.; <u>Peter A. Getting</u>, Univ. of Iowa. Other speakers: <u>John P. Miller</u>, Univ. of Cali-fornia, Berkeley; <u>Ronald Joyner</u>\*, Univ. of Iowa; <u>W. Otto Friesen</u>, Univ. of Virginia; <u>Daniel K. Hartline</u>, Univ. of Hawaii. Panelists: <u>Jack D. Cowan</u>, Univ. of Chicago; John <u>W. Moore</u>, Duke Univ. Med. Center; <u>Wilfrid Rall</u>, National Institutes of Health; <u>Stephen G. Waxman</u>, V.A. Med. Center, Palo Alto.

The availability and power of present-day computers have made practical the realistic simulation of neurons and circuits, taking advantage of the quantitative morphological and physiological data provided by cellular neuroanatomy, voltage-clamp techniques, and neuropharmacological studies. Functional recon-struction is soundly based on mechanisms of gating dynamics for ion channels, neurotransmitter release and uptake kinetics, cytoplasmic current flow in realistically described cellular morphology, and modulation of conductances by neurotransmitters, calcium ion, "second messengers", and the like. Use of func-tional reconstruction for neuronal systems provides a quantitative, predictive framework for organizing and comparing experimental data and for testing higher-level theories of neural functioning.

Speakers in the symposium will describe a variety of approaches and applications of functional reconstruction. Perkel will discuss overall aims, mathematical formulations, and types of implementation. Getting will describe applications of funcof implementation. Getting will describe applications of func-tional reconstruction to specific neuronal circuits. Miller will illustrate the use of program packages for electrical networks to simulate integrative properties of dendritic structures. Joyner will describe simulations of interacting pacemaker neurons. Friesen will discuss use of analog methods to simulate networks. Hartline will describe digital simulation of lobster stomatogastric ganglion.

Following the speakers' presentations, the panelists will compare approaches, implementations, and techniques for func-tional reconstruction. They will attempt to evaluate the utility of various degrees of morphological and physiological realism as well as practical considerations of system size and computational speed. This round-table discussion should be illuminating for both the experienced and novice modeler, and should clarify present and future capabilities of this approach.

SYMPOSIUM: THE ACIDIC INTERIOR OF SECRETORY VESICLES: MECHA-NISMS AND IMPLICATIONS FOR NEUROBIOLOGY. J.T. Russell, NIMH, 176

NISMS AND IMPLICATIONS FOR NEUROBIOLOGY. J.T. Russell, NIMH, and R.W. Holz, Univ. Michigan (Chairmen); D. Njus, Wayne State Univ.; R.L. Pedersen, Johns Hopkins Univ; I. Mellman, Yale Univ. In recent years it has become clear that many subcellular mem-brane systems possess H<sup>+</sup> translocating ATP-ases. Among these systems are mitochondria, chloroplasts, secretory vesicles, lisosomes, endosomes, and sperm acrosomes. In secretory vesicles and other vesicular organelles, this enzyme electrogenically transports protons into the lumen rendering them acidic with respect to the cytosol. Such a phenomenon has been found in secretory vesicles from various neuronal and nonneuronal tissues, secretory vesicles from various neuronal and nonneuronal tissues, eg. chromaffin vesicles, neurosecretory vesicles, anterior pitu-itary vesicles, secretory vesicles from platelets, pancreatic islets, parathyroid, etc. This proton translocating enzyme is a Mg<sup>++</sup>-dependent ATP-ase and is similar, but not identical, to the F1/F0\_type proton pump found on mitochondria. Unlike the mito-chondrial enzyme, the H<sup>+</sup>-ATP-ases in secretory vesicle membranes are not fully biochemically characterized as yet. With the mito-chondrial enzyme as the model, the relationship between the macromolecular structure of the protein and the proton translo-cation will be discussed. In the chromaffin vesicle the pH pradient (AnH) and the membrane potential (Au) drive the untake macromolecular structure of the protein and the proton translocation will be discussed. In the chromaffin vesicle the pH gradient (ApH) and the membrane potential ( $\Delta\psi$ ) drive the uptake of catecholamines which are transported into the vesicles in exchange for H<sup>+</sup>. The  $\Delta\mu$ H and  $\Delta\psi$  also drive electrons in, through a membrane-bound cytochrome b561. In the neurosecretory vesicle the acidic interior provides the optimal environment for post-translational modification of newly synthesized secretory peptides. The proteolytic enzymes involved in this process have acidic pH optima (pH<5.5). The binding of neuropeptides vaso-pressin and oxytocin to their respective neurophysins also is optimal at pH 5.5. Thus the internal organization of these vesicles may also depend upon the acidification. The question of whether the large H<sup>+</sup> electrochemical potential plays an important role in exocytotic secretion will be addressed in the chromaffin cell model system. The H<sup>+</sup> pumps identified in endosomes, liposomes and coated vesicles are similar to the H<sup>+</sup>-translocating enzyme found in secretory vesicles. The ApH of endocytic vesicles has important implications for uptake and delivery of macromolecules and membrane recycling. Further, numerous pathogens (viruses, bacterial toxins) make use of this acidic environment to penetrate into cells. The possible significance of these phenomena for the normal function and pathology of the nervous tissue will be discussed.

ADAPTATION OF ACTION POTENTIAL FREQUENCY IN HIPPOCAMPAL PYRAMIDAL CELLS IS REGULATED BY CALCIUM-ACTIVATED POTASSIUM CONDUCTANCE AND M-CURRENT. D.V. Madison and R.A. Nicoll. Depts. of Pharmacology and Physiology; and Graduate Program in 178.1 Neuroscience, University of California, San Francisco, CA. 94143.

Adaptation of action potential frequency in response to a tonic excitatory stimulus is characteristic of many neuronal cell types. Since adaptation determines the frequency at which the cell discharges, it plays a fundamental role in controlling the output of the neuron. It has been frequently reported that adaptation occurs in neurons of the central nervous system, however, little is known of the mechanisms of this adaptation. nowever, little is known of the mechanisms of this adaptation. Using the in vitro hippocampal slice preparation of the rat, and intracellular recording, we have found that the action potential discharge of CAI pyramidal cells also shows adaptation in response to excitatory stimuli. While the cells respond to a long depolarizing current pulse (600-800ms) with an initial a long depolarizing current pulse (600-800ms) with an initial high rate of action potential discharge, the frequency of this discharge rapidly decays until the cell falls completely silent. Associated with this adaptation is a prominent "sag" in the underlying membrane voltage, and an afterhyperpolarization (AHP), which is known to be due primarily to calcium-activated potassium conductance ( $C_{K}(Ca)$ ). Blocking  $C_{K}(Ca)$ , either by injecting EGTA into the cell, or by bathing the slice in the calcium channel blocker, cadmium, greatly reduces the "sag", the AHP, and the adaptation seen in response to a depolarizing the AHP, and the adaptation seen in response to a depolarizing stimulus. Dentate granule cells in the slice also exhibit adaptation and calcium-activated potassium AHPs, both of which are reduced by cadmium. In pyramidal cells, adaptation, and the remaining "sag", can be further reduced by bathing the slice in low concentrations (lµM) of the muscarinic agonist, carbachol, which is believed to block another potassium current, the M-current (I<sub>M</sub>). Thus, we propose that adaptation in pyramidal cells is caused by two potassium currents: The M-current and the calcium-activated potassium current. At least current and the calcium-activated potassium current. At least one of these currents, the calcium-activated potassium current, causes adaptation in dentate granule cells. These intrinsic currents are turned on by depolarization, and exert a braking influence on further discharge. Blocking these currents re-moves their inhibitory influence, increasing the output of the cell to a given stimulus. Thus, these two currents play a critical role in regulating the input/output function of the cell. This role gains much greater significance in light of the fact that LM and GK(Ca) are blocked by the neurotransmitters acetylcholine and norepinephrine, respectively. This research was supported by NIH Grant NS-16485, NS-15764, RCDA MH00437 and the Klingenstein Fund to R.A.N.

ADAPTATION OF THE ELECTRICAL ACTIVITY OF SINGLE ELEMENTS IN THE OPTIC TECTUM OF GUINEA PIGS IN VITRO: ITS POSSIBLE ROLE IN Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., Dept. New York, NY 10016.

Intracellular recordings from the large neurons stratum griseus medium of the optic tectum in guinea pigs were obtained in vitro following coronal slicing of the brainstem. Direct stimulation produced repetitive firing, the frequency of Direct stimulation produced repetitive firing, the frequency of which reduced rapidly with repeated stimulation. The action potentials generated by these current pulses are characterized by a rapid rate of rise and a break in their falling phase due to a fast after-depolarization which increases in amplitude during the spike train. Replacement of calcium by barium in the extracellular fluid increased this after-depolarization which was blocked by the addition of cadmium to the extra-collular madium that a calcium spike most which was blocked by the autorition to calmid to the extra-cellular medium, indicating that it is a calcium spike, most probably of dendritic origin. Also characteristic of these cells is the observation that with repeated current injections of 500 msec duration at frequencies from 1/sec to 1 every 5 sec for a period of 20 sec, a long-term adaptation of the repetitive response is observed which recovers to control level in approximately 60 sec. The adaptation is accompanied by a small hyperpolarization and a decreased input resistance due to an hyperpolarization and a decreased input resistance due to an increased potassium conductance  $(g_R)$  which is spike frequency dependent. Adaptation as well as the  $g_{K(Ca)}$  are blocked by barium and by ions known to block calcium conductance such as cadmium, all of which indicate that a calcium-dependent  $g_R$  of rather long duration is responsible for the long-term excitability dependent that barium the source that the second se bility change. These results demonstrate that optic tectal neurons possess intrinsic properties which allow them to adapt to repetitive stimuli independently of the properties of the neuronal circuit in which they are embedded. The time course of this adaptation is very similar to that observed for the habituation of the neuronal firing in rabbit tectum following physiological stimulation (Oyster & Takahashi, J. Neurophysiol. 38: 301, 1975). As in their case, four criteria for habitua-tion were observed in these experiments: (a) the responses are the same if separated by sufficient time, (b) the response decreases gradually with each stimulus, (c) the rate of re-sponse decrease is stimulus- and spike frequency-dependent, and (d) the response recovers with time after the cessation of the stimuli. We propose that this adaptation is a significant comstimuli. ponent of the visual habituation in the tectum. Supported by USPHS grant NS13742 and NIH international postdoctoral fellowship 0303201.

178.2 THREE COMPONENTS OF OUTWARD CURRENT IN ISOLATED MAMMALIAN CORTICAL NEURONS. Robert B. Clark\*

K\* and Robert K.S. Wong, (SPON: W.D. Knowles) Biophys., University of Texas Medical Branch, Dept. Physiol. Biop Galveston, TX 77550.

Single neurons were isolated from slices of adult guinea pig hippocampus (microdissected to remove granule cell layer) using an enzymatic (papain) digestion and mechanical dispersion using an enzymatic (papain) digestion and mechanical dispersion procedure. The majority of cells, probably pyramidal, had a pear-shaped soma 15-30 µm across and apical dendrite stump of 50-150 µm in length. Intracellular recordings were made using the "whole-cell" gigaseal technique of Hamili <u>et. al.</u> (Pflugrs Arch. (1981), <u>391</u>, 85). Temperature was about <u>22°C</u>.

Neurons selected had resting potentials in the range -45 to -60 mV and apparent input resistances at rest of 200-800 MC. Action potentials, either spontaneous or evoked by injected Action potentials, either spontaneous or levoked by injected current, were 80-90 mV in amplitude and 1-2 ms duration (dt ½ amplitude). In TTX-containing saline (1 µgm/ml), voltage-clamp currents evoked by depolarizing steps from -35 to +20 mV (holding potentials -45 to -55 mV) were outward (see Fig.). (a) shows transient outward current with an inactivation time constant of  $\sim 20ms$  (Vm = -20 to 0 mV), and similar rate of removal of inactivation by hyperpolarization to -60 to -70 mV. In some cells, transient current was largely inactivated at holding potential but was revealed by pre-hyperpolarization. 4-AP (1 mM) reversibly abolished the current. (b) Delayed outward current appeared to consist of two components. The delayed current was "noisy" in many cells; the noise\_and amplitude of the current was substantially reduced in Mn<sup>2+</sup> (1 mM)<sub>4</sub> or Co<sup>-</sup> (2 mM) containing salines (which hlock an inward Ca<sup>2+</sup> current in these cells), suggesting a Ca<sup>2+</sup>-dependent K<sup>2</sup> current. A delayed voltage\_dependent outward current was and amplitude of the current outward current was substantially reduced in Mn<sup>2+</sup> (1 mM) reversibly abolished to current was a cells; the noise cells). current. A delayed voltage-dependent outward current was also present in 0 Ca<sup>2+</sup>, 1 mM Mn<sup>2+</sup> saline. This current activated at about -35 mV, the rate of activation increasing with increased depolarization. Both delayed components were considerably depolarization.

reduced by TEA (10-20 mM), but not 4-AP. In most cells, the current tail on repolarization to the holding potential (c) was outward. The reversal potential of the tail was determined using a b' c of the tail was determined using a two-pulse clamp protocol and was between -55 to -65 mV. All components of outward current were blocked if Cs replaced K' in the recording pipette, suggesting that the currents are probably carried by K'. Foundation.

LOCUS COERULEUS ACTIVITY IN VITRO: INTRINSIC REGULATION BY A CALCIUM-DEPENDENT POTASSIUM CONDUCTANCE BUT NOT  $\alpha_2$ -ADRENOCEPTORS. <u>R. Andrade and G.K. Aghajanian</u> Depts. of Pharmacology and Psychiatry, Yale Univ. School of Medicine, New Haven, CT 06508 1784

Haven, CI 0508 Previous in vivo studies have shown that locus coeruleus (LC) neurons exhibit a pronounced afterhyperpolarization (AHP) and a long-lasting suppression of spontaneous activity following a burst of spikes. Two mechanisms have been proposed to account for the AHP: the activation of  $\alpha_2$ -adrenergic "autoreceptors" through the release of norepinephrine by recurrent collaterals or dendrites or the activation of a Ca<sup>2+</sup>-dependent K<sup>+</sup> conductance. The present study was undertaken to distimuish between these mechanisms in the in without here a distinguish between these mechanisms in the <u>in</u> <u>vitro</u> brain slice.

Pontine brain stem slices from albino rats (150-250 g) were Pontine brain stem slices from albino rats (150-250 g) were cut using a Sorvall Tissue Sectioner. They were continuously perfused in a slice chamber with ACSF (in mM: NaCl 130; KCl 5; NaH2PO4 +H2O 1.25; NaHCO3 24; CaCl2 2.5; MgSO4 1.5; D-Glucose 10) at 32 to 37°C. 95% O2 and 5% CO2 continuously flowed over the slices. Extracellular and intracellular recordings were obtained from the visually identified LC using standard electrophysiological techniques.

electrophysiological techniques. As previously observed in vivo, LC neurons in vitro exhibit a prolonged AHP and a marked post activation inhibition (PAI) following a burst of spikes. This AHP has a reversal potential  $(E_{rev})$  in the hyperpolarizing direction and is associated with an increase in membrane conductance. Since the  $E_{rev}$  for the AHP was virtually identical when recorded with KCl or K-acetate AHP was virtually identical when recorded with KCl or K-acetate electrodes and shifted in the hyperpolarizing and depolarizing direction with decreases and increases in  $[{\rm K}^+_{\ 0},$  it appears that the AHP following a burst of spikes is mediated by an increase in K<sup>+</sup> conductance. Moreover, since the AHP was greatly attenuated by reducing Ca<sup>2+</sup> influx (i.e., by reducing extracellular Ca<sup>2+</sup> or blocking Ca<sup>2+</sup> channels with Mn<sup>2+</sup> or Cd<sup>2+</sup>) LC neurons appear to possess a Ca<sup>2+</sup>-dependent K<sup>+</sup> conductance whose activation by calcium entry during the burst results in the observed AHP and PAI. In contrast to in vivo where the  $\alpha_2$ -antagonist piperoxane increases spontaneous activity and reduces the AHP, its administration in vitro failed to reduce reduces the AHP, its administration in vitro failed to reduce the AHP or the PAI even when norepinephrine synthesis was stimulated by supplementing the ACSF with L-tyrosine. Thus it submatch of supports that the AHP and postactivation inhibition in the LC in  $\frac{vitro}{vitro}$  is mediated principally by a  $Ca^{2+}$ -dependent  $K^+$  conductance. CONTROL OF EXCITABILITY IN ISOLATED HIPPOCAMPAL DENDRITES. 178.5 Leona M. Masukawa and David A. Prince. Neurology Department, Stanford University School of Medicine, Palo Alto, CA. 94305. The apical dendrites of CAl pyramidal cells were isolated from their cell bodies by making cuts through proximal stratum radiatum of transverse hippocampal slices from the guinea pig. This lesion separated the distal apical dendritic elements from the somata, basal dendrites, and 50-100 microns of the proximal apical dendritic tree. Orthodromic stimuli in stratum radiatum evoked excitatory synaptic responses in isolated dendrites, but no inhibitory components could be detected. In spite of this surgically produced disinhibition, orthodromic stimuli did not elicit burst activity at the resting membrane potential. Howe However. isolated dendrites and intact dendrites could generate multiple slow spike activity when directly stimulated with depolarizing current pulses. When isolated dendrites were depolarizing current, EPSPs could evoke subthreshold intrinsic slow depolar-izations, or repetitive slow spikes, similar to responses elicited by depolarizing current pulses alone. Afterhyperpolar-izing potentials associated with an increase in conductance occurred in isolated dendrites following repetitive slow spikes After exposure to bicuculline(5LM), both intact and isolated dendrites generated bursts of activity following synaptic activation. A possible mechanism for this action of bicuculline is blockade of a residual GABA-mediated inhibition which was not expressed as a postsynaptic hyperpolarization in isolated dendrites. This bicuculline-sensitive event was capable of depressing dendritic excitability in the absence of the recurrent inhibitory synaptic input and was very effective in controlling burst activity. Dendritic behavior is therefore dependent on a complex interaction between synaptic and voltage sensitive events.

178.6 DEPOLARIZATION-INDUCED EFFECTS OF INTRACELLULARLY APPLIED CALCIUM-CALMODULIN DEPENDENT PROTEIN KINASE IN MEURONS OF THE MOTOR CORTEX OF CATS. <u>C. D. Woody<sup>a</sup>, D. I. Alkon and B. Hay</u><sup>\*</sup>, Laboratory of Biophysics, Natl. Inst. Health at the Marine Biological Laboratory, Woods Hole, NA 02543. Sixteen cells of the motor cortex of awake cats were given

intracelular ionophoretic application of calcium-calmodulin dependent protein kinase (CaPK) followed by a 30 sec period of steady depolarization (1.0 nA). These cells showed an increase in steady depolarization (1.0 m/). These certs showed an increase in input resistance in comparison with a control group of fifteen cells given depolarization only, without application of CaPK. The difference between groups was significant (p < 0.05, Student's t test, two-tailed). The increase of input resistance did not occur after injection of CaPK alone. Post-ionophoretic measurements of input resistance in twenty-six cells given CaPK alone were no different from those in seven cells given equivalent negative currents through electrodes containing only KC1, nor were levels of resistance increased after injection of CaPK in the cells that subsequently showed increases in input resistance after CaPK plus depolarization. We conclude that intracellular injection of calcium-calmodulin dependent protein kinase followed by depolarization and depolarization-elicited impulse activity transiently increases input resistance of neurons of the motor cortex of cats. The magnitude of increase in input resistance in cells responding to CaPK plus depolarization averaged  $+5.0 \pm 10^{-1}$ 2.5 (s.e.m.) megohms. Protein kinase alone or weak depolarization in the absence of protein kinase did not produce this effect. An analogous increase of input resistance can be produced in the Type B photoreceptor of <u>Hermissenda</u> by applying protein kinase sufficient depolarization paired with light to increase calcium conductance and internal calcium concentration. This observation led us to perform the present experiments. Given observation led us to perform the present experiments. Given previous studies linking changes in both types of neurons to the development of conditioning, the results suggest the possibility of shared biochemical steps during the acquisition of conditioned behavior by vertebrate and invertebrate species. (Supported by AFOSR and USPHS.)

178.7 CELLULAR PHYSIOLOGY OF THE DEVELOPING RAT NEOCORTEX IN VITRO. A.R. Kriegstein\*, T. Suppes and D. Prince (SPON: D. Purpura). Dept of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305. We have investigated voltage-dependent membrane properties and synaptic physiology of developing rat neocortex which is rela-tively immature at birth and undergoes considerable structural Dept. tively immature at birth and undergoes Sensorimotor cortex slices (300-400  $\mu$ m) were prepared from rat pups aged 3-26 days postnatal (PN) and maintained in vitro at 37°C using standard techniques. Slices from animals under 5 days were maintained at 34°C. Stable intracellular current clamp recordings were obtained from neurons of all cortical layers (n=42) in slices from animals as young as 3 days PN.

Very immature cells, < 6 days PN had resting potentials ( $V_m$ S) from -40 to -70 mV and peak action potential (AP) amplitudes from 40 to 78 mV (n=1) which were followed by hyperpolarizing after-potentials. Cells with the highest V s had AP amplitudes greater than 65 mV and AP durations < 2 msec.<sup>m</sup> Young neurons also tended to have high input resistances (mean  $R_M = 70~M\Omega$ ). The steady-state current voltage curves in cells < 6 days PN were strikingly linear with a steep slope around the resting potential. In cells 12-20 days PN (n=26) the V<sub>m</sub> ranged from -52 to -70 mV, peak AP amplitude ranged from 60 to 80 mV, and mean R, was lower (35 MQ). The I-V curve became less steep, and non-linearities were present. Tetrodotoxin (10 M) blocked the APs in cells at all ages suggest-ing that a significant Na<sup>+</sup> current underlies the AP. Labelled cells from recordings with HRP-filled electrodes (n=7) were mostly pyramidal neurons, suggesting that our data applies primarily to pyramidal neurons, suggesting that our data applies primarily to this cell type.

We examined synaptic responses to stimulation at the pial sur-We examined synaptic responses to stimulation at the plai sur-face or in the subcortical white matter. Extracellular stimula-tion in animals < 1 week PN evoked long-lasting post-synaptic responses that underwent marked attenuation with repetitive stimu-lation even at frequencies as low as 0.1 Hz. The PSP attenuation to stimulus frequency decreased with age. No IPSPs were seen in cells < 5 days PN (n=11). Stimulation in cells older than 10 days PN often led to complex responses that contained IPSPs. It is astronative that (RAP accorder binding and GAD ctaining become noteworthy that GABA receptor binding and GAD staining become prominent in rat brain at 7-10 days PN (Coyle, J.T. and Enna, S.J., Brain Res. 111:119-133, 1976).

These results indicate that physiological properties of rat neocortical neurons undergo maturational changes during the post-natal period, and may be studied <u>in vitro</u>.

178.8 SINGLE K<sup>+</sup> CHANNEL CURRENTS FROM HIPPOCAMPAL PYRAMIDAL CELLS OF ADULT GUINEA PIG. R.K.S. Wong and R.B. Clark\*. Physiology and Biophysics U.T.M.B. Galveston, TX 77550. ADULT GUINEA PIG. Dept. of

Experiments were carried out using individual neurons isolated from guinea pig hippocampus. Single channel currents were recorded from giga-seal patch recordings from whole cells. When the recording pipettes were filled with isotonic (150mM) KCl or K-gluconate solutions, inward current steps of unitary could be observed from the membrane patch. The amplitude size of these single channel currents increased markedly when the transmembrane potential across the patch was hyperpolarized. The single channel conductance derived from this I-V relation-ship was 250 pS. The conductance of these single channels was ship was 250 pS. The conductance of these single channels was not significantly different when recorded from  $_{\rm K}$ Cl or K-gluconate containing electrodes suggesting that K<sup>+</sup> is the charge carrier. We observed that the kinetic properties of these single channel current showed no obvious dependency on the transmembrane potential. When the patch membrane was depolarized, the inward current reduced in size and often with an application of -30mV to the pipette (effectively depolarizing the patch membrane by 30mV to about -20mV transmembrane potential) current event can no longer be observed. Additional depolarization beyond -20mV transmembrane potential (Vm) did not cause an inversion of the single channel current and no events cause an inversion of the single channel current and no events were recorded when Vm was in the range of -20mV to +60mV. Often, when Vm was depolarized above +60mV, large amplitude unitary outward currents were again recorded. These unitary outward current events differ from the events recorded at the resting or hyperpolarized membrane potentials in that (1) the open time of the depolarization-activated single channels markedly increased with additional depolarization and (2) their frequency of occurrence also increased with depolarization. The data suggest that single  $K^+$  channels recorded at resting and hyperpolarized Vm may show inward rectification.

178.9 ALTERED TRANSMISSION AT SPARED SYNAPSES AFTER MAUTHNER-CELL AXOTOMY. <u>M. Titmus and D.S. Faber</u>. Div. Neurobiology, Dept. Physiology, SUNYAB, Buffalo, NY 14214. Each goldfish Mauthner (M-) axon monosynaptically activates 3 or more cranial relay neurons (CRN) (Hackett & Faber, <u>Brain</u>

Each goldfish Mauthner (M-) axon monosynaptically activates 3 or more cranial relay neurons (CRN) (Hackett & Faber, <u>Brain</u> <u>Res. 264</u>:302-306,1983). These in turn project to interneurons which mediate feedback inhibitions of the M-cell, including a chemically-mediated IPSP, called the late collateral inhibition (LCI). We were interested to see if long term axotomy (35-211 days), at a level which spared output synapses to CRNs, altered LCI.

In control and spinal cord-transected fish (8-10mm caudal to the M-cell soma) the LCI was evoked by either 1) antidromic (AD) impulses elicited by current injection into the M-axon, or 2) surface stimulation of the medulla 5-7mm caudal to the Mcell. LCI magnitude was quantified as the \$ reduction in amplitude of AD spikes or EPSPs (produced via posterior VIII nerve stimulation) evoked during the LCI relative to controls. In 10 cells from control fish, LCI magnitude ranged from 30-75\$; for any one cell, it was essentially equal for both methods of stimulation. Low intensity medullary surface stimulation menueled story is a modations in inbibition.

In 10 cells from control fish, LCI magnitude ranged from 30-75%; for any one cell, it was essentially equal for both methods of stimulation. Low intensity medullary surface stimulation revealed stepwise gradations in inhibition, with some components occurring at voltages subthreshold to M-cell activation. This fractionated LCI may result from direct activation of individual CRNs. In contrast, intra-axonal or more caudal spinal cord stimulation activated the LCI in an all-or-none fashion at threshold for an M-cell spike which is consistent with the notion that CRN axons do not project to the spinal cord. Three cells tested before and after acute axotomy (up to 2 hrs) showed no change in LCI strength.

In long term axotomized fish, 10 of 15 M-cells tested exhibited frequent failure of LCI following AD stimulation, while surface stimulation still evoked maximal inhibition comparable to that observed in controls. As in controls, low intensities of stimulation produced graded steps of inhibition. For 2 Mcells, AD-evoked LCI was less than half that produced following surface stimulation.

These results demonstrate there is a decrease in LCI in long term axotomized M-cells which most likely occurs at the level of M-cell synapses onto cranial relay interneurons. The apparent destabilization of M-axon output synapses is not a simple consequence of axonal dieback and may reflect loss of a trophic influence of the distal axon on regional specialization at more proximal sites. (Supported by grant NS 15335.) 178.10 REPETITIVE FIRING PROPERTIES OF CAT NEOCORTICAL LAYER V NEURONS <u>IN VITRO. C.E. Stafstrom, P.C. Schwindt, and W.E. Crill.</u> Depts. of Physiology & Biophysics, and Medicine, Univ. Wash. Sch. Med. and V.A. Med. Ctr., Seattle, WA 98195.

Repetitive firing characteristics of layer V neurons were studied in slices of cat sensorimotor cortex, using current clamp techniques and a single-electrode voltage clamp. In response to steps of intracellularly injected current, neuronal firing rate adapts to a steady level with an approximately exponential time course. The relation between firing rate and injected current was linear (range of slopes 11-36 imp/s/nA) for steady firing and for early interspike intervals (ISIs) during adaptation.

The behavior of voltage threshold for spike initiation  $(V_T)$  and mean depolarization during the ISI (V) were examined during adaptation and steady firing.  $V_T$  and V increase with injected current (and thus with firing rate). Even at the slowest firing rates, V during the ISI is sufficient to activate a previously described persistent subthreshold sodium current ( $I_{INAP}$ ; Brain Res. 236:221, 1982). Thus  $I_{NAP}$  is available to counter outward currents and to boost depolarization throughout the whole firing range of the neocortical neurons.

Injection of current ramps showed that layer V neurons are sensitive to the rate of change of current (dI/dt) as well as its amplitude (1). The use of ramps followed by steady currents demonstrated that the repetitive response lags behind changes in stimulus parameters and does not reach a steady state, even during slow ramps; i.e., the response depends on time as well as on I and dI/dt. Instantaneous firing rates during the ramp increase linearly with time for a wide range of ramp slopes (dI/dt). The instantaneous firing rate of early interspike intervals is also linearly related to ramp slope, for small ramp slopes. Quantitative analysis indicated that the repetitive response during ramp stimulation cannot, in general, be described by a linear combination of amplitude- and rate-dependence, but the use of a time-varying rate-dependence roughly approximates the ramp response in many cells.

178.11 MECHANISMS OF IFSP DEPRESSION INDUCED BY REPETITIVE ACTIVATION STUDIED IN THE PAT HIPPOCAMPAL SLICE N. MCCarten and F.F. Alex

MEDIATION THE RAT EIROSIDA TRADECED WALL THE ADJUNCTION TO THE RAT EIROSIDA TRADECED AND ALL TRADECED AND

vate the role of IPSP plasticity in tetanic potentiation induced by stimulus trains of IC Pz lasting 5 sec.
Since GABA-mediated IPSPs can be evoked by orthodromic (0) or antidromic (A) stimuli, repetitive 0 or A stimulation should produce similar clanges of the IPSP if these changes are specific to the IPSP pathways. Responses to A or to subthreshold 0 trains were similar (pak IPSP amplitudes decreased from approximately 5 mV to 2.5 mV). However, during a suprathreshold 0 train, the IPSP was usually abolished or inverted and the cell often became deporalrized with respect to the resting membrane potential (RMP).
Because antidromic IPSPs are relatively uncontaminated by FPSPs, the depression of this IPSP indicates the maximal specific de-

pression of IPSPs. To assess what factors can account for the greater changes in suprathreshold O IPSPs we first prevented occurrence of depolarizing potentials during the train by recording with CSCI filled electrodes and depolarizing the cells to approximately O mV. In these cases IPSPs persisted throughout the train and were depressed from approximately 35 mV to 24 mV. This suggests that alteration of suprathreshold O IPSPs at RMP is not entirely specific. The use of potencier sensitive microelectrodes showed that

tion of suprathreshold O IPSPs at RMP is not entirely specific. The use of potassium sensitive microelectrodes showed that suprathreshold O trains were associated with much greater increases in extracellular K ([K]) than A trains and that increases in [K] were directly proportional to concurrently measured shifts in peak IPSPs during a train. Changes in both [K] and suprathreshold O IPSPs were augmented by increases in stimulus intensity, frequency of stimulation and length of trains. We conclude that alterations in the efficiency of GAFA mediated

We conclude that alterations in the efficacy of GAEA mediated synaptic transmission can account for not more than a 50% decrease in IPSP. The greater apparent effects on suprathreshold 0 IPSPs are probably due in part to their being obscured by burst potentials, and to the effects of K on the cells. We are investigating the degree to which K contributes to changes in A and subthreshold 0 IPSPs. Supported by NIH Grant NS17539 and the McKnight Foundation.

178.12 EFFECTS ON INPUT CURRENTS OF LOCAL INCREASES IN MEMBRANE RESISTANCE IN CORTICAL PYRAMIDAL CELL DENDRITES EXPLORED USING A PASSIVE CABLE MODEL FOR DETERMINING THE TRANSIENT POTENTIAL IN A DENDRITIC TREE OF KNOWN GEOMETRY. W. R. Holmes\* and C. D. Woody (SPON: R. G. Pay). Depts. of Biomathematics and Biobehavioral Sciences, UCLA, Los Angeles, CA 90024.

Changed neuronal responsiveness observed after conditioning may result from increased membrane resistance since the neurons show increased excitability to intracellularly injected constant (+) current pulses. Rall has proposed that changes in the spine stem resistance may alter the potency of spine synaptic input response and so affect neural excitability. Changes in membrane resistance in the dendritic trunks themselves might also alter excitability. The present study explores this latter possibility by modeling the effects of injecting constant currents in dendrites of known morphology. The morphology was obtained from a montage composed of photomicrographs taken at different, overlapping areas within serial sections of an HRP-injected, layer V pyramidal cell of the cat motor cortex.

A passive cable model which can determine the transient potential in dendritic trees of arbitrary geometry was used to examine the efficacy of different loci of increased membrane resistance for given loci of current injection. The model used the passive cable equation to express the potential for each interbranch segment of the dendritic tree. By matching boundary conditions at branch points and terminations, a system of equations was readily obtained for the Laplace transform of the potential at the ends of each segment. The inverse transform could then be quickly computed for any arbitrary time point. Since only one equation is required for each interbranch segment, this approach uses far fewer equations than the compartmental approach. The method can be used to model voltage clamping or any of a number of current inputs including constant current,  $\delta$ -function current, or repetitive trains of  $\delta$ -function current into any or all terminal segments or branch points.

Using the model described above, it was found that an increase in membrane resistance in the region immediately proximal to the point of current input was more effective in increasing soma potential than an increase in a comparable membrane area of a more proximal dendritic region. Under certain circumstances a distal increase in membrane resistance could be more effective than a comparable proximal increase depending on the locus of current injection and the morphology of the dendritic tree. (This research was supported in part by AFOSR F49620-83-C-0077.)

- EFFECT OF EYESTALK REMOVAL ON GLUCAGON-INDUCED HYPERGLYCEMIA IN CRAYFISH. R. H. Leinen\* and A. J. Giannini. Northeastern Ohio College of Medicine, P. O. Box 2169, Youngstown, Ohio 44504. Administration of 0.5 mg glucagon by injection at a coxal membrane caused significant (p 0.05) hyper-glycemia in intermolt-stage crayfish Orconectes virilis within two hours (increase to  $17.40 \pm 5.53$  mg glucose/100 ml blood filtrate, over normal and vehicle-treated values of  $3.87 \pm 1.87$  and  $3.98 \pm 1.32$  mg glucose/100 ml blood filtrate, respec-tively). Early premolt-stage animals, in which stage transformation had been initiated by eyestalk removal 20-24 hours previous to treatment, did not respond to glucagon. In contrast, epinephrine pro-duced a hyperglycemic effect in both stages, showing the availability of a carbohydrate reserve. It is suggested that the action of glucagon depends upon intact eyestalk neuroendocrine function. 179.1
- HEART ARRHYTHMIAS IN JUVENILE HORSESHOE CRABS (LIMULUS POLYPHEMUS) MAY BE CAUSED BY POSTEMBRYONIC INCREASES IN THE NUMBER OF CARDIAC 179.2 NEURONS. D. Gil Hole, MA 02536. Gibson. Woods Hole Oceanographic Institution, Woods

Intracellular recordings from heart muscle fibers of Limulus larvae and juveniles show that the neurogenic heart rhythm is well coordinated when the larvae hatch, but becomes irregular after the first juvenile molt. The rhythm stabilizes after subsequent molts but out-of-phase EJPs are still more frequent than they were in the larval heart.

\_\_\_\_10 mV ha 1.0 5 -65 mV

lst juvenile molt 3rd juvenile molt

The **arrh**ythmia at the first juvenile molt may occur as addi-tional neurons become wired into the cardiac ganglion. At the first juvenile stage, the ganglion contains about 75 neurons; by the next molt, the number has doubled (whole mounts, cresyl violet Nissl stain), still short of the average 231 neurons in the adult cardiac ganglion (Bursey and Pax, 1970. J. Morph. 130:385). In the lobster embryo, all four pacemaker and five follower neurons are present when heartbeat begins, and these cells grow larger during embryogeny (Burrage and Sherman, 1978. Cell Tiss. Res. 188:171). In contrast, a first-molt <u>Limulus</u> juvenile has less than a third of the adult number of cardiac neurons, and these do not increase in size with the next few molts; instead, these do not increase in size with the next few molts; instead, their <u>numbers</u> increase in size with the next few molts; instead, their <u>numbers</u> increase. Neurons at these stages are too small to be recognized as pacemakers or followers by size as they can in the adult (40 µm vs. 60-120 µm; Bursey and Pax, 1970). It is clear that many <u>Limulus</u> cardiac neurons arise during post-embryonic growth; exactly how this occurs has not been

determined.

179.3 RECEPTOR POSITION ON THE CERCUS DETERMINES SYNAPTIC CONNECTIVITY Jonathan Bacon and R.K. Murphey, Department of Biology, SUNY, Albany, NY 12222.

The cercus-to-giant system of the cricket has become a focus of considerable attention for developmental neurobiologists, the problem being the familiar one of connecting an array of sensory neurons to their interneuronal targets in an orderly fashion. In this system, the presynaptic elements are the sensory neurons of this system, the presynaptic elements are the sensory neurons of the wind-sensitive cercal filiform hairs, and the postsynaptic elements are the giant interneurones. Previous work had established that there are 4 main types of filiform receptor, each of which responds to wind from a different direction; the location of these hair types on the cercus was not known. However, it was known that the interneurons derive their directional selectivity by making specific connections with some directional selectivity by making specific connections with some of these cells (Tobias and Murphey, J.c.Physiol. 129;51, 1979). With this knowledge, we began our analysis by mapping the location of receptors of different type and found that receptors

of the same directional preference are localised on the cercus in longitudinal strips. Straight borders occur between fields of different hair type; adjacent receptor fields can be sensitive to wind from polar opposite directions. We've known for some time that afferents project into the cercal glomerulus in a topographic fashion. We now provide a functional interpretation of this topographic mapping function by showing that each receptor type terminates in a different region of the glomerulus - in other words, the glomerulus is functionally divided into 4 regions concerned with the processing of wind information from different directions.

In order to test the significance of this finding, we needed to show monosynaptic connections between the sensory cells and wind-sensitive interneurons in the CNS. We have used the anatomy to guide the search for connections. We made simultaneous recordings from interneuron 10-3 and from a sensory neuron whose terminal overlaps the interneuron's dendrites. In approximately 25% of the cases where we knew there was anatomical overlap, we observed unitary synaptic potentials synchronised with the sensory neuron action potentials. These synaptic potentials occurred at a constant latency and were highly susceptible to fatigue. In cases where sensory neurons did not anatomically overlap 10-3's dendrites, we saw no such potentials. We conclude that the position of an interneuron's dendrites within the sensory projection determines synaptic connectivity. When sensory neuron and interneuron overlap, connections are made on a probabilistic basis. These connections shape the receptive fields of the first order interneurones and ultimately shape the behavior of the animal.

POSITIONAL INFORMATION DIRECTS SYNAPTOGENESIS BETWEEN SENSORY MUTPHER NUMBER AND THEIR TARGETS. W.W. Walthall, J.P. Bacon, and R.K. Murphey. Neurobiology Research Center, SUNY Albany, Albany, N.Y. 12222.

The theory of positional information attempts to explain how biological patterns are formed. It is based upon the idea that a series of chemical gradients uniquely specifies cells within a developmental field.

The positional information model predicts certain types of regeneration where tissues from non-adjacent locations are brought together. Where the appostion occurs epidermal cells begin to proliferate and, through a process called intercalation, restores normal neighbors. The cricket cercus is such a developmental field and the sensilla on the cercus form a highly acveropmental field and the sensifie on the cercus form a highly ordered receptor pattern. Work from this laboratory has established that sensory neurons project from the periphery to the central nervous system in an orderly way. Here we provide evidence that positional information not only determines the organization of the periphery but also determines the formation of orderly synapses between sensory neurons and their interneuronal targets.

In order to test the positional information hypothesis, strips of cercal tissue from a black cricket were transplanted to a different position on the cercus of a white cricket. These chimera make it possible to distinguish graft from host derived chimera make it possible to distinguish graft from host derived receptors. Such grafts induce the generation of new receptors near the graft margin. The transplant contained receptors that would never synapse with a particular interneuron. However, the graft was selected so that if the positional information graft was selected so that if the positional information hypothesis were true, the graft tissue should generate new receptors that would synapse with the interneuron. After the graft had healed and intercalation occurred, newly generated afferents near the graft boundary were examined. When assessed physiologically unitary postsynaptic potentials were detected between a newly generated, graft derived sensory neuron and the appropriate target. When assessed anatomically, the terminal arbor of the sensory neuron was seen to overlap the interneuron of interest.

These results are consistent with other experiments that suggest positional information underlies the construction of orderly patterns of receptors. They go one step further by directly implicating positional information in the formation of orderly synaptic connections. Supported by NIH grant #NS15571.

179.5 CHOICE OF SYNAPTIC PARTNERS BY SENSORY NEURONS IN THE CRICKET. R.K. Murphey, Neurobiology Res. Ctr., SUNYA, Albany, Albany, N.Y. 12222.

Numerous studies of the insect nervous system focus on the way in which sensory systems are assembled: either by examining the initial choices the growth comes of sensory neurons make embryonically or by observing the effects of surgical or genetic maneuvers which displace them. Studies of the cercal system of crickets have revealed two main regions of neuropil which receive cercal sensory afferents. By staining the sensory cells with cobalt, it was possible to show that all of the "bristle hairs" on the cercus, which are multiply innervated, project to an anterior, ventral region of neuropil. It has been shown elsewhere that the other hair types (filiform and clavate) project to a separate region which has become known as the cercal glomerulus. I have located six previously unidentified interneurons whose dendrites are located in the neuropil innervated by the bristle hairs. These newly discovered interneurons are sensitive to touching the body surface and are insensitive to stimulating other receptors on the cercus due as the filiform hairs. Thus when cercal sensory neurons first reach the nervous system during development, they make a crucial choice between two target areas. This dichotomous choice determines their synaptic partners since different subsets of interneurons are available for synaptic contact in the two regions.

This choice is repeated in every ganglion. For example, when cerci were transplanted to the thorax, bristle hair sensory cells from the cercus arborized in a ventral region of neuropil which is distinct from the region which receives the fillform afferents (Johnson and Murphey, this volume). Thus a multitude of external insect receptors can be assigned to only two categories based on their target area.

Thus a multitude of external insect receptors can be assigned to only two categories based on their target area. What is it about these two categories of sensory cells that distinguishes them? One obvious difference is that most hairs which I have called "bristles" are multiply innervated while the filliform and clavate hairs are singly innervated. Thus they have different lineages; bristles have an extra round of division in their lineage. This lineage difference may determine the growth of their processes and thereby their choice of synaptic partners. Supported by NIH Grant #NS 15571 179.6 CELLULAR INTERACTIONS BETWEEN A MUSCLE AND ITS MOTOR NEURON ARE NOT INVOLVED IN THEIR ENDOCRING-MEDIATED DEATHS DURING METAMORPHOSIS IN THE TOBACCO HORNWORM MANDUCA SEXTA. Janis C. Weeks and James W. Truman. Dept. Zoology Univ. of WA, Seattle, WA 98195. Metamorphosis in Manduca involves the reorganization of the musculature as well as of central motor circuits. Some undergo programmed death at specific times, and some muscles arise anew from retained myoblasts during adult development. Individual motor neurons also undergo different metamorphic fates: some innervate the same muscle throughout whereas others experience the death of their original larval target muscle. In the latter case, the targetless motor neurons either persist and come to innervate newly generated muscles or else they die(Levine & Truman, 1982). We have examined an example in the last class, in which a motor neuron and its muscle die together. The muscle is the principal planta retractor muscle (PPRM) of the caterpillar, contraction of which retracts the planta (the distal tip of the abdominal proleg) and disengages the proleg from the substrate. PPRM is innervated by a homosegmental motor neuron, PPR. During the larval-pupal transformation the prolegs are lost and both PPRM and PPR die. Using electrophysiological and anatomical techniques combined with hormonal manipulations we have investigated the cues responsible for these events in order to determine if the fates of the muscle and motor neuron are linked, or whether their deaths are triggered independently. Our results show that a rise in the blood ecdysteroid titer 3 d. prior to pupation triggers the degeneration and death of PPRM as well as some initial dendritic loss in PPR. However, PPR survives the death of iPRN, as chronic removal of the muscle does not die util 2 d. after pupation. This delay occurs because PPR becomes committed to the death of PPRM, as chronic renoval of the muscle does not die util 2 d. after pupation. This delay occurs decause PPR becomes committed to

179.7 DEVELOPMENT OF LEECH SEROTONIN NEURONS EXAMINED WITH SEROTONIN ANTIBODY, CELL LINEAGE TRACER, AND CELL KILLING. Duncan K. Stuart, Joel C. Glover\*, Seth S. Blair\*, and David A. Weisblat. Dept. of Molecular Biology, University of California, Berkeley, CA 94720. Antisera against serotonin was used to follow the origin and differentiation of identifiable serotonin-containing neurons in two glossiphoniid leeches. Antibody staining combined with cell lineage tracers shows that all these cells are derived from a bilateral pair of blastomeres, the N teloblasts. These neurons start staining in a specific order, but some subsequently disappear and are not seen in the adult. Ablation studies suggest that competitive interactions determine which cells disappear. Each of the first three unfused segmental ganglia of the adult (Haementeria ghilianii or Helobdella triserialis) has nine serotonin neurons: one giant Retzius cell pair; three smaller pairs, the anteromedial pair, the sex ganglia [86] lack one lateral pair, and the posterior 14 (8-21) lack the unpaired neuron. The embryonic origin of these neurons was determined by injecting early blastomeres with a rhodamine-labeled lineage tracer, then raising the embryos to nervous system differentiation (stage 10-11), staining for serotonin with a fluorescein labeled second antibody and examining the nerve cord for double labeling; we find all serotonin cells are derived from the N teloblast pair;

During any splotonin (stage 9) the serotonin neurons begin to stain in a specific order. In any given ganglion the Retzius cells appear first, followed shortly thereafter by the lateral cell pairs and, in ganglia 1-3, the anteromedial pair. The posteromedial neuron appears last, at the end of stage 9. However, initially a <u>pair</u> of posteromedial neurons is seen in the first seven ganglia, one of each pair ceases to stain shortly thereafter. Also, one of the two lateral pairs disappears in the sex ganglia. Thus, some neurons which first show serotonin staining either die or cease to synthesize or sequestor serotonin.

Two lines of evidence suggest that competitive interactions may be involved in determining which of the two embryonic posteromedial neurons survive to become the unpaired cell of the adult. First, lineage tracer studies show that in each of ganglia 1-7 the unpaired cell of the adult arises with equal likelihood from either N teloblast. So, this disappearance is not determined strictly by lineage. Secondly, if a single N teloblast is killed by DNase I injection, so that only one posteromedial cell appears, this cell always survives and contains serotonin. This implies that interactions between the N-derived cells on the two sides of the nerve cord, possibly between the pair of posteromedial neurons themselves, are involved in the disappearance of one of each pair. 179.8 A MONOCLONAL ANTIBODY SPECIFIC TO THE LEECH PRESSURE-SENSITIVE MECHANOSENSORY NEURONS. <u>C. Loer\*, C. Schley\*, B. Zipser</u>, and <u>W. Kristan</u>. (SPON: J. Lamborghini) Dept. of Biology, Univ. of California, San Diego, La Jolla, CA 92093 and Cold Spring Harbor Laboratory, NY 11724.

Two pairs of pressure-sensitive mechanosensory neurons (P cells) are found in the standard midbody ganglion of the glossophoniid leech, <u>Haementeria</u> (Kramer and Goldman, J. Comp. Physiol. <u>144</u>:435, 1981). We have produced a monoclonal antibody specific to the somata and neurites of these cells and to a small number of unidentified fibers. The antibodies were prepared by immunizing Balb-C mice with lightly-fixed, homogenized <u>Haementeria</u> nerve cords. Their spleen cells were fused with myeloma cells to produce hybridomas. After a standard HAT selection, the clones were screened on paraformaldehyde-fixed ganglia of adult <u>Haementeria</u> using an HRP-conjugated secondary antibody and staining with DAB and H<sub>2</sub>O<sub>2</sub>. Four large cell bodies stain in the standard adult ganglion along with their neurites in the neuropil, peripheral nerves, and connectives. A few as yet unidentified fibers are found more medially in the neuropil astain differently: the two sex ganglia have only one pair of cell bodies staining, the last two unfused ganglia have one pair of large cell bodies and one pair of small cell bodies which stain. The tail brain, composed of 7 fused ganglia, has cells staining the lass custof 7 fused ganglia and a supraesophogeal ganglion, segmental homologues are again apparent as well as a few additional cell bodies.

few additional cell bodies. We have found as well that the antibody cross-reacts with another glossophonid leech, <u>Helobdella triserialis</u>, in which experimental manipulations of P cell progenitors are possible. We are now using the antibody to examine the consequences of ablations and other experimental manipulations of P cell progenitors. We are investigating the possible function of the antigen by a variety of means. First, the antigen appears by light microscopic observations to be located both on the surface and inside the cell; these observations will be confirmed by other means. Second, the molecular weight of the antigen will be sought. Third, the antibody will be applied to live ganglia

while recording from the P cells and their postsynaptic targets. Research sponsored by an NSF Predoctoral Fellowship to C.L., NIH 50R01NS17984-02 to C.S. and B.Z., and NSF BNS79-23459 and PHSNS14410 to W. K.

DIFFERENTIATION OF SEROTONIN-CONTAINING NEURONS IN THE LEECH. 179.9 J.C. Glover\* & D.K. Stuart (Spon: L. Henderson). Grad. Group in Neurobiology & Dept. of Molecular Biology, UCB, Berkeley, CA 94720.

The leech Haementeria ghilianii contains 5 types of segmentally iterated serotonin-containing neurons in the ventral nerve cord. In the adult, neurons of each type contain serotonin in high concentrations, sequester serotonin with a high-affinity uptake system, and have characteristic morphologies. Determining the temporal sequence of appearance and maturation of such pro-perties lends insight into the mechanisms whereby neurons differ-entiate. Consequently, the development of these properties has been examined during embryonic life. The appearance of trans-mitter store has been investigated using commercially available serum antibodies against serotonin. Because these neurons stain very early, it has also been possible to use these antibodies to study morphological development. The appearance of the high-affinity uptake system has been examined with autoradiography following exposure to <sup>3</sup>H-serotonin.

As described in the previous abstract (Stuart, et al.) there is a type-specific sequence of appearance of transmitter store in these neurons. The appearance of the uptake system follows this antibody staining. This appearance of the update system formously with the antibody staining. This is supported by the observation that bathing embryos in  $10^{-5} - 10^{-3}$  M serotonin before immunohistological processing leads to an overall increase in intensity of staining without labelling any additional cells. At the time antibody staining is first detectable, the Retzius cells are morphologically immature, having extended only a short neurite ending in a growth cone within the ganglion. This entire struc-ture labels with both antibody and <sup>3</sup>H-serotonin. It is tempting to speculate that in addition to containing and sequestering serotonin, the Retzius cell may be able to release serotonin at this early stage as well.

Further morphological development of the Retzius cell involves progressive branching of the initial neurite such that axons are extended in both ipsilateral connectives and all ipsilateral are extended in both ipsilateral connectives and all ipsilateral peripheral nerves. Although the Retzius cells in all segments undergo this morphological sequence, in the adult there are seg-mental differences. In segments 5 and 6 the Retzius cells have much smaller somata and are missing many of their axons. The former difference occurs during embryogenesis and is due to an early termination of somal growth. It is not yet known when or how the latter difference arises, but it is clear that at some point during development the original morphology is modified. point during development the original morphology is modified. The factors responsible for this modification are being sought.

179.10 DEVELOPMENT OF AFTERDISCHARGE IN THE BAG CELLS OF Development of AFTERDISCHARGE IN THE BAG CELLS OF JUVENILE <u>APLYSIA</u>. <u>D. Leibowitz\* and V.F. Castellucci</u> (SPON: C. D. Toran-Allerand). Center for Neurobiology and Behavior, Columbia University, College of Physicians & Surgeons, and New York State Psychiatric Institute, New York, N. Y. 10032. The bag cells of <u>Aplysia californica</u> reared in the laboratory have been studied with intracellular and extracellular techniques in order to produce the observe in their calculate physicial properties during

analyze the changes in their electrophysiological properties during maturation.

Individual bag cells of <u>A. californica</u> are responsive at least 2½ weeks prior to sexual maturity. As in the adult, immature bag cells in the isolated abdominal ganglion are normally electrically silent. In marked contrast to the adult, bag cells in immature animals always show depolarizations associated with each suprathreshold shock to the ipsilateral and contralateral connective nerves. Their apparent absence in mature animals may be due to increasing distance between synapses and recording sites, or to a reorganization of the synapses themselves. Also in contrast to the adult, the bag cells of immature animals are not electrophysiologically homogeneous but fall into two classes. Cells of the first class can be caused to spike by injection of depolarizing current. Upon repetitive stimulation of the connectives the evoked depolarizations show potentiation and can give rise to full regenerative spikes of brief duration (less than 10 msec). The firing of these cells can outlast the triggering shock, older animals being capable of longer bursts. This appears to be the precursor of the adult-type afterdischarge. This firing is correlated with extracellular compound spikes, localized to a single cluster, which are of lower amplitude than those of the second class of bag cells which may fire concurrently. These extracellular spikes show a progressive increase in amplitude (from 1  $\mu$ V to adult values), duration of afterdischarge, and degree of bilateral synchrony during development. lateral and contralateral connective nerves. Their apparent absence in synchrony during development. A second physiological class of bag cells, prominent in immature

animals and still present in recently-matured animals, shows no poten-tiation of the post-shock depolarizations. Temporal summation to threshold can trigger an intracellular spike of relatively long duration. These spikes occur only one at a time, never repetitively, and the cells become readily refractory to further spiking. The spikes are correlated with extracellular spikes relatively high in amplitude; both clusters usually participate simultaneously, although the low amplitude spiking by the same cluster is unilateral. Cells of both classes have been observed in a cluster is unilateral. in a single cluster, and neither shows intracellular depolarization correlated with extracellular spikes due to the other class.

We intend to extend these observations to younger juveniles, characterize the ionic requirements of these two classes of action potentials, and investigate their fate and functional significance.

## CEREBELLUM: OLIVO-CEREBELLAR FUNCTION

180.1

SENSORY-OCULOMOTOR INTERACTIONS IN PRIMATE CEREBELLAR VERMIS: A ROLE IN SMOOTH PURSUIT CONTROL. <u>D.A. Suzuki</u> <u>E.L. Keller</u>. Smith-Kettlewell Inst. Visual Sciences, San Francisco, CA 94115. Neuronal activity related to the sensory and oculomotor information necessary for an internal construct of angular target velocity has been recorded in the vermis, but the component signals were studied as dissociated vestibular, vision, and eye movement-related activities. Since smooth eye movements seldom occur dissociated from sensory information, it was of interest to clarify how the vermis processes concurrent sensory and clarify how the vermis processes concurrent sensory and oculomotor information.

Monkeys were trained to track a 0.5 deg spot during simultaneous presentation of vestibular or visual stimuli. simultaneous presentation of vestibular or visual stimuli. During the performance of these tasks, extracellular recordings were made from Purkinje cells (Pc) in lobules VI and VII of the cerebellar vermis (vermis-6,7). In addition, the affect of lesions of vermis-6,7 on smooth-pursuit eye movements was investigated. Out of 42 units that were tested, 37 (88%) exhibited some kind of interaction. Nineteen (out of 22) exhibited modulations in discharge rate related to all three components of target velocity, i.e., eye, head, and retinal slip velocities. Fifteen (out of 16) exhibited interactions between eye and head velocity-related signals, and 3 (out of 4) showed interactions between eye and vision-related signals. intereactions between eye and vision-related signals.

A monotonic relationship was observed between the amplitude of modulation of Pc activity and the magnitude of eye velocity during concomitant smooth pursuit and vestibular stimulation that were in or out of phase to various degrees. Cells that exhibited responses of differring directional preferences to smooth pursuit and background pattern movement, exhibited a predictable, facilitated response during tracking of a target on a stationary, random dot background pattern. Vermis-6,7 is similar to the flocculus in its processing of eye and head movementrelated information, but differs in its additional role in the processing of eye and vision-related activity. While the flocculus supplies a gaze velocity signal, vermis-6,7 generates a target velocity signal. Removal of the posterior vermis resulted in the expected

Kemoval of the posterior vermis resulted in the expected saccadic dysmetria, but also caused a significant drop in smooth-pursuit gain. Over the range 0.1 to 0.75 Hz,  $\pm$  10 deg, a 30-50% reduction in smooth pursuit gain was observed. These gain reductions are similar in magnitude to those observed with floccular lesions (Zee et al.). The results compliment the extracellar recording studies in supporting a role for vermis-6,7 in the resulation of smooth pursuit eve movements. in the regulation of smooth pursuit eye movements. Supported by NSF Grant BNS-8107111.

180.2 TASK-ORIENTED ADAPTATIONS OF COCONTRACTION OF OPPOSING MUSCLES (TUNING) DEPEND ON THE NEOCEREBELLUM, V. B. Brooks and S. Watts Department of Physiology, University of Western Ontario, London, Watts\*. Canada, N6A 5C1.

Performance of a step-tracking task made by fascicularis mon-keys was studied. The animals guided a handle into alternating target zones by making elbow flexions and extensions in the horizontal plane. During task learning accelerations and decelera-tions are scaled together, so that velocities assume 'continuous' single-peaked profiles without oscillations. These movements called 'programmed' because they can be made from memory, once These movements are learned.

Accurately made, programmed movements become faster during Accurately made, programmed movements become laster during training, even though the animals are not rewarded for speeding-up. Speed is increased (by about 1 rad/s) through strengthening of initial agonist muscle bursts and weakening of antagonist pre-movement cocontraction. This 'tuning' increase of reciprocal inhibition of accurately programmed flexions and extensions pre-sumably optimizes muscle use, within the limits of task condi-tions. Charges carry over an average from one training session sumably optimizes muscle use, within the limits of task contain tions. Changes carry over on average from one training session to the next. Joints are 're-tuned' towards greater or lesser cocontraction (and thus joint stiffness) as the need arises, for instance after alterations of targets or loads. These task-oriented adaptations of patterns and intensities of

reciprocal muscle actions are likely to be mediated through con-trols descending to spinal la-interneurons. It is well known that control of adaptability is lost after neocerebellar damage in human patients. The same was found to be true during reversi-ble neocerebellar dysfunction in monkeys.

Cooling of the neocerebellar output through the dentate nu-cleus, or input through the principal nucleus of the inferior olive, reversibly diminishes the number of accurately programmed movements. Those that remain during cooling however, are made at speeds reduced by about 1 rad/s, as if the joints have reverted to pre-tuning stiffness. (calculated from data published with A. D. Miller, and with P. R. Kennedy and H.-G. Ross, in Exp. Brain Res. 1982, 45: 328-332 and 47: 95-104. It is concluded that task-oriented adaptations of joint stiff-

ness before movement onset (tuning) are routine parts of motor learning, which may be a means of acquiring greater motor skill. This depends on neocerebellar adjustments, including the functions of its olivary input.

180.4

SIMULTANEOUS SAMPLING OF THE RESPONSES OF MULTIPLE, CLOSELY ADJACENT, PURKINJE CELLS RESPONDING TO CLIMBING FIBER ACTIVATION

<u>J. Bower and R. Llinás.</u> Dept. Physiol. Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016. <u>In vitro</u> studies of the inferior olive (IO) have demon-strated that changes in the membrane potential in IO neurons generate a sequence of electrophysiological responses that produce oscillatory spiking. This oscillatory behavior is en-hanced by the alkaloid, harmaline (Llinás & Yarom, J. Physiol. 315: 549, 1981; Yarom & Llinás, Soc. Neurosci. Abst., 1981). Furthermore, in vitro as well as in vivo experiments have shown electrotonic coupling between IO neurons.

We have investigated the significance of these biophysical properties on the global organization of the IO by sampling the climbing fiber (CF) responses recorded in cerebellar Purkinje cells using a recently developed method for simultaneous sampling and analysis of extracellular action potentials (Bower & Llinás, Soc. Neurosci. Abst., 1982). Recordings have been made of spontaneous as well as tactile evoked activity of multiple, closely adjacent Purkinje cell complex spikes in crus IIA of the cerebellar cortex of rats. Autocorrelations of single CF activations reveal that these cerebellar afferents fire spontaneously with an average minimum interburst interval of 100-125 ms. Harmaline (25 mg/kg, IV) increases the number of such activations without changing the average minimum interval. The spatial distribution of cross correlation between different units demonstrates a preferred parasagittal orientation, indi-Units demonstrates a preferred parasagital of interaction, indi-cating a non-isotropic distribution of the relatedness of CF activity over the cerebellar cortex. These crosscorrelelograms have peaks at 0 and 100-125 ms. Thus, CFs projecting to a given area of cerebellar cortex tend to burst simultaneously at regular, repeated intervals. Investigation of interaction beregular, repeated intervals. Investigation of intervals to tween this inherent group oscillation and peripheral tactile stimuli (e.g. upper lip) indicates a phase relation between stimuli (e.g. upper lip) indicates a phase relation between intrinsic oscillatory pattern and the probability of a CF response. Because adjacent CFs tend to fire simultaneously (same oscillatory phase), a given successfully timed stimulus is likely to be simultaneously activating many CF afferents. Conversely, the intrinsic oscillatory behavior of the IO may in turn be influenced by robust peripheral stimuli which can reset the oscillatory activity of the CF activation to a given Purkinje cell 'group'. Because the specific CFs constituting such a 'group' vary with time and stimulus condition, with some CFs missing a given interval while others join transiently. grouping represents more a functional state than an anatomical constraint of the IO, suggesting modulation of electrotonic coupling in this nucleus (Llinás, The Physiologist 17: 19, 1974). Supported by USPHS grants NS13742 and NS06958.

Sensory and Motor Properties of the Inferior Olive of Alert Cats, 180.6

Sensory and motor properties of the interior office of Alert Car Reuben <u>Gellman</u>, Alan <u>Cibson</u>, and J.C. <u>Houk</u>, Northwestern University Medical School, Chicago, IL. <u>60611</u> We have recorded 226 cells in the inferior olive of 5 alert cats, and determined their responses to sensory stimuli. Somatosensory cells, which were found in all major olivary regions, were more responsive than in the aneshetized animal (see Gellman et al., J. Comp. Neur., in press), only 10% of cells being classified as unresponsive. Of somatosensory cells 51% were classified as receiving cutaneous input, and 47% as proprioceptive. It is probable that many of the former received

proprioceptive input as well. Cells responding to light tactile stimuli were found primarily in the dorsal accessory olive (DAO) (72% of 67 cells in this area), and such cells were frequently encountered in the medial accessory nucleus (MAO; 32% of 90) as well as in the principal nucleus (PO; 31% of 51). The response to a stimulus usually consisted of one spike. The receptive fields of 90% of cells with cutaneous input were strictly contralateral, and were usually restricted to a small part of one limb. Although many cells were very sensitive and responded whenever the limb contacted an obstacle, cells with receptive fields on the plantar surface of the paw generally failed to respond when the animal

placed its paw on the surface on which it was standing. Cells responsive to proprioceptive input were usually activated by rotation at a joint or small displacements of the platform on which the cat was standing. For most cells tested one direction of displacement produced an optimal response; the opposite direction failed to evoke a response; and displacements in other directions produced responses of intermediate probability. It was usually from the contralateral limb, but 18% of cells had Input ipsilateral or bilateral input. In no case did we note a reliable response to active movement by the cat, although some cells seemed to be weakly modulated during movement. We microstimulated (20-50 uA, 100-200 usec pulses, 1-5 sec,

10-60/sec) in all olivary subdivisions (20 locations) while the animal was at rest and during active movement. In no case was a movement produced, interrupted or modified in any noticeable way by the stimulus.

It appears that the inferior olive reliably transmits sensory stimuli produced by an external agent, but not those produced as an intentional consequence of the animal's movement. Supported by 1-P01-NS17489-02.

THE RELATIONSHIP BETWEEN SIMPLE AND COMPLEX SPIKE RESPONSES OF CEREBELLAR PURKINJE CELLS LOCATED IN IDENTIFIED CORTICONUCLEAR ZONES. <u>T.J. Ebner</u>, <u>Q. Yu\* and J.R. Bloedel</u>. Depts. of Neuro-surgery and Physiology, Univ. of Minnesota, Mpls., NN 55455. In decerebrate, unanesthetized cats the relationship between the responses of Purkinje cells to natural forepaw stimuli and their location in identified corticonuclear zones was examined. 180.3 their location in identified corticonuclear zones was examined. Purkinje cells recorded extracellularly with glass microelec-trodes on the surface folia of lobules Va-c were identified by the presence of spontaneous complex spikes. Each cell's site of termination was determined by the location within the fasti-gial (F), anterior interposed (AI) and posterior interposed (PI) nuclei from which they could be antidromically activated. In most experiments cells were convertibly inlated at 100 200 most experiments cells were sequentially isolated at 100-300 micron intervals in the sagittal direction. Each cell's simple and complex spike responses to a brief flexion of the ipsilateral forepaw were discriminated and used to construct peristim-ulus histograms. Contour maps of the simple and complex spike responses of several Purkinje cells recorded on the same folium were constructed to visualize the relationship between response amplitudes and the boundaries of the corticonuclear zones. The results obtained from over 350 Purkinje cells reveal an extrem-ely strict boundary between the cells projecting to the fasti-gial (F zone) and anterior interposed nuclei (AI zone) at 2.1 mm from the midline. The border between the zones projecting to the anterior and posterior interposed nuclei (PI zone) was located between 3.5 and 3.8 mm from the midline. The contour maps of the simple spike responses revealed areas of simple spike modulation beginning at the border of the F and AI zones and ex-tending throughout the AI zone. Usually a second locus of sim-ple spike modulation was present in the F zone. Similarly in the PI zone the simple spike activity exhibited extensive mod-ulation. The complex spike contour maps showed loci of increased activity at the same locations as the regions where simple spike activity was well modulated. These results sug-gest that Purkinje cells in all of the corticonuclear zones examined, F, AI and PI zones, receive and process information concerning the same forepaw stimulus. Furthermore, the tight spatial coupling between the location of simple spike and climbing fiber responses suggest mutual interaction between these two afferent systems. Supported by NIH Grants ROI-NS 18338 and ROI-NS 09447.

INCREASED RESPONSIVENESS OF PURKINJE CELLS TO PARALLEL FIBER 180.5 STIMUL ASSOCIATED WITH SPONTANEOUS CLIMBING FIBER INPUTS. <u>J.R.</u> <u>Bloedel and T.J. Ebner</u>. Depts. of Neurosurgery and Physiology, Univ. of Minnesota, Mpls., MN 55455.

Univ. of Minnesota, Mpls., MN 55455. Recent work in our laboratory has demonstrated that the occur-rence of spontaneous or evoked climbing fiber inputs is associat-ed with an increased responsiveness of Purkinje cells to mossy fiber inputs activated by natural peripheral stimuli. These ex-periments were designed to evaluate the hypothesis that this change in responsiveness to mossy fiber inputs results from in-teractions occurring in the cerebellar cortex. In decerebrate unanesthetized cats Purkinje cells identified by their depth and presence of spontaneous complex spikes were isolated on the surface folia of lobule V using conventional electrophysiological techniques. The discriminated simple spike responses to a sur-Surface folia of lobule V using conventional electrophysiological techniques. The discriminated simple spike responses to a surface electrical stimulus (LOC) were used to construct peristimulus time histograms (N=100) under two conditions. In the first or 'random' paradigm, the LOC stimulus was applied randomly with respect to the occurrence of spontaneous complex spikes in the same neuron. In the second or 'climbing fiber conditioning' paradigm LOC stimulation of the same stimulus intensity was timed to course of the same stimulus intensity was timed to occur at fixed intervals (20-100 msec) after the occurrence of spontaneous complex spikes. Comparing the response amplitude to the LOC stimulus in the random and climbing fiber conditioned to the LOC stimulus in the random and climbing fiber conditioned paradigm showed that the simple spike response amplitude was in-creased when the response to the surface stimulus occurred 30 msec after a complex spike. This increase in responsiveness was independent of the type of simple spike modification produced by the LOC stimuli. In Purkinje cells where the response to the LOC stimulation consisted of an increase in the simple spike dis-charge rate, climbing fiber conditioning augmented the amplitude of the excitatory response. In cells responding to the LOC stimulus with a decrease in simple spike discharge rate, climb-ing fiber conditioning resulted in a further reduction of acti-vity, accentuating the inhibitory response. These results sup-port the hypothesis that a change in the gain of the simple spike response is associated with a climbing fiber input and that this gain change results from interactions in the cere-bellar cortex. 180.7 EFFECTS OF REVERSIBLE LESIONS AND STIMULATION OF THE INFERIOR OLIVE ON FLOCCULUS PURKINJE CELL ACTIVITY IN THE CAT. <u>b. A.</u> Echelman\*, J. L. Demer\* and D. A. Robinson (SPON: R. J. Leigh). Johns Hopkins University School of Médicine, Baltimore, MD 21205. Reversible lesions and electrical stimulation of the inferior olive (IO) or climbing fiber (CF) decussation (dec.) rapidly alter CF input to the cerebellum, and reversibly alter vestibulo-ocular reflex gain. Alteration of Purkinje cell (P-cell) activity during these lesions would be inconsistent with Marr's hypothesis that CF activity selectively modifies the efficacy of parallel fiber synapses on P-cells during motor learning.

Synapses on P-cells during motor learning. We recorded simple-spikes (SSs) and complex spikes (CSs) of isolated P-cells in the flocculus of 13 cats for 1-4 hr periods. Results were obtained using ketamine/acepromazine anesthesia. An electrode cannula assembly was positioned in the IO or CF dec. to evoke CSs at 50-300 µA. Then 1-10 µL injections of saturated lidocaine were made to reversibly abolish CSs for periods of 10-50 min. Electrode and cannula sites were later verified histologically.

Before CF lesions, mean SS rate over 5 min for 11 cells was 23 Hz (range 10-51), but the rate during the lesions was 40 Hz (range 23-84), a mean increase of 98%. These changes are larger than those observed in a study using smaller injections in rabbits (Leonard & Simpson, <u>Soc. Neurosci. Abstr.</u>, 1982). To investigate SS rate variability, we computed the standard deviation (SD) of SS rate (10 s bins) for each of these P-cells. SD decreased from a mean of 6,9 Hz (range 3.0-12.0) before to 3.5 Hz (range 0.8-7.2) during the lesions. Peak SS rate (200 ms bins) increased from 63 Hz (range 30-100) before to 86 Hz (range 35-135, n = 9) during the lesions. CSs recovered gradually after lesions, and repeated lidocaine injections reproduced the above effects. As a control, after CF axons were mechanically severed using the cannula for 2 cells in 1 cat, mean SS rates increased from 65 to 71 Hz and 66 to 85 Hz, but did not change further following injection of lidocaine into the CF dec. The effect of evoked CSs on SS rate was studied in 15 P-cells by electrically stimulating the CF dec. Rates of evoked CSs at or above thresholds of  $5 \pm 2$  Hz (mean  $\pm$  SD) completely inhibited SSs, and threshold had a weak positive correlation to spontaneous SS rate. For comparison with SS activity during anesthesia, 6 P-cells were isolated in the cerebellum of 1 alert cat. Mean SS rate was 39 Hz (range 20-72), with a mean SD for each cell of 10 Hz (range 6-18).

Because P-cell activity and variability are altered during CS rate enchancement or abolition, our results favor a role for climbing fiber activity in modulating ongoing P-cell responsiveness, rather than in plastically altering the efficacy of P-cell synapses. (Supported by MSTP 5-T32-GM07309. 5-R01-EY00598, & So.Med.Assoc.) 180.8 SHORT-TERM AND LONG-TERM EFFECTS OF FLOCCULAR LESIONS ON OPTOKINETIC AND VESTIBULOOCULAR REFLEXES OF RABBITS. N. H. Barmack, Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, OR.

The role of the cerebellar flocculus in the modulation of optokinetic and vestibuloocular reflexes has been examined in rabbits which have received unilateral suction ablations of the left flocculus using three different surgical approaches: 1) A dorsal approach, which causes partial damage to the ansiform and paramedian lobes, 2) A caudal approach, which damages the paraflocculus and lateral cerebellar nucleus, and 3) A lateral approach, which causes no damage to other cerebellar structures. The horizontal vestibuloocular reflex (HVOR) ( $\pm$ 10 deg, 02-.80 Hz) and the monocular optokinetic reflex (HVOR) ( $\pm$ 0 deg, 00.1-50.0 deg/sec) were tested in a group of 19 pigmented and albino rabbits before, immediately after (within 24 hr) and at least 50 days after unilateral suction ablations were made of the left cerebellar flocculus. Eye movements were recorded with an infrared light projection technique.

The immediate effect, observed within 15 min following placement of a floccular lesion, was a conjugate nystagmus with the slow phase toward the side opposite to the lesion when the animal was placed in total darkness. This spontaneous nystagmus lasted from several hours to two days depending on the extent of other cerebellar structures damaged. This nystagmus was <u>reversed in sign</u> if the subjacent vestibular nuclei or vestibular nerve were damaged by the operation. The nystagmus did not appear if the unilateral floccular lesions were made in animals which had been previously bilaterally labyrinthectomized. This spontaneous drift of the eyes observed immediately postoperatively caused a bias in measurements of the HVOR and caused a near-normal gain of the HOKR of the left eye measured in the posterior-anterior direction (same direction as the slow phase of the nystagmus) immediately postoperatively. This rightward bias of the eyes was frequency dependent; less evident at higher stimulus frequencies. When measured 50 days postoperatively, the HVOR had a normal gain and normal bias. When measured 50 days postoperatively, the monocular HOKR (posterior-anterior stimulation of the left eye) was significantly reduced in gain at stimulus velocities below 5 deg/sec. A quantitative anatomical analysis of the floccular lesions revealed

A quantitative anatomical analysis of the floccular lesions revealed that they caused degeneration of neurons in the contralateral dorsal cap of the inferior olive. This cell loss accounted for as much as 65% of the dorsal cap neuronal population. Cell loss was evident in animals sacrificed more than two days after the floccular lesion was placed and the degeneration was complete within seven days.

These data reveal a <u>permanent</u> deficit in the HOKR, but not the HVOR following unilateral floccular lesions and are consistent with the idea that the flocculus contributes to the visual regulation of low velocity eye movements through the inhibitory modulation of the activity of the subjacent vestibular nuclei. (Supported by EY04167).

180.10 TWO NEURONAL GROUPS ASSOCIATED WITH THE MEDIAL LONGITUDINAL FASCICULUS (MLF) OF CAT AND RAT THAT CONVEY VESTIBULAR IMPULSES TO THE CEREBELLAR FLOCCULUS. <u>R.H.I. Blanks and Y. Torigoe</u><sup>+</sup> Depts. of Anatomy and Surgery (Otolaryngology), Univ. Calif. Irvine, Irvine, CA 92717.

The vestibular and cerebellar connections of neurons intercalated among the pontine and medullary portions of the MLF in cat and rat were studied using anterograde and retrograde horseradish peroxidase (HRP) techniques following iontophoretic injections into the flocculus and medial vestibular (MVN) and prepositus hypoglossi (ph) nuclei. An analysis of Nissl-stained material in both species reveals the presence of three groups of neurons within, or associated with, the MLF. One eye movement-related group termed the rostral interstitial nucleus of the MLF (rostral i MLF) (Büttner-Ennever and Büttner, Brain Res. <u>151</u>:31, 1978) arises within the MLF rostral to the IIIrd nucleus. In the present report, we identify two other high density populations which retrogradely label with HRP injections into the flocculus and receive collateral projections from axons traveling with the MLF. We term these the intermediate and caudal i MLF to designate their position within, and association with, the MLF. The intermediate i MLF extends anteroventrally (1-3 mm in cat; 1-1.5 mm in rat) from the rostral border of the abducens nucleus and is adjacent to the superior pole of the nucleus reticularis tegmenti pontis (NRTP). The small-to-medium fusiform neurons comprising this population are largely distributed to the medial and dorsomedial portions of the MLF and are distinct in location from the adjacent raphe central superior nucleus, nucleus raphe dorsalis and NRTP. In contrast, the caudal i MLF is of lower cellular density and extends from the rostral pole of the hypoglossal nuclei to the genu of the facial nerve.

Our anterograde studies with HRP reveal that the intermediate iMLF of both species receives a dense collateral projection from vestibulo-ocular reflex neurons of the MVN and ph. These projections densely cover the neurons of the intermediate i MLF along its full extent and are primarily crossed, though an uncrossed projection also exists. The MVN and ph connections of the caudal i MLF are less dense, and there are indications that these are provided by collaterals of MLF axons comprising the descending limb of the MLF.

limb of the MLF. Receiving projections from the MVN and ph, the intermediate and caudal i MLF may serve as a feedback pathway to the flocculus conveying head velocity and position signals. Interestingly, the region comprising the intermediate i MLF in the cat (Curthoys et al., Brain Res. <u>222</u>:75, 1981) contains medium-lead burst and burst-tonic neurons, suggesting that this pathway may also convey information related to saccades or eye position to the flocculus.

ROTATIONAL POLARITY OF PURKINJE CELL ACTIVITY IN THE RABBIT FLOCCULUS. <u>C.S. LEONARD and J.I. SIMPSON</u>. Dept. Physiol. Biophys., 550 First Ave., New York Univ. Med. Ctr., New York 10016

Rabbit floccular Purkinje cells (PCs) receive visual and vestibular input via mossy and climbing fiber (CF) pathways. Recently we identified a striking rotational polarity in the representation of visual world movement by direction and speed selective visual CFs in the rabbit flocculus. CFs with ipsilateral receptive fields and horizontal preferred directions, respond to large, slow moving, textured patterns with an increased activity for nasal movement and a decreased activity for temporal movement. Since no CFs have been found that increase and decrease their firing rate for stimuli moving in the opposite sense, the CFs as a group can be said to have a response polarity. Here we report that PC simple spike (SS) response polarity, but opposite to the CF polarity. Extracellular recordings were made from floccular PCs in chronically prepared, unanesthetized, paralyzed rabbits during visual, vestibular and combined visual-vestibular stimulation. 78 PCs having CF responses with ipsilateral receptive fields and horizontal preferred directions were studied. Of the 42 PCs tested with a constant speed stimulus (.1°/s to  $30^{\circ}$ /s), the majority (40/42) increased their SS firing rate for temporal movement and decreased their firing rate for nasal movement, opposite to the response pattern of the CFs. Similarly, of 36 PCs tested with sinusoidal whole-body rotation (0.05 to lHz;  $\pm$ 1° to 30°) about an earth vertical axis in the dark, 35/36increased and decreased their SS firing rate for contralaterally and ipsilaterally directed rotation respectively (type II). All PCs whose SS were modulated by vision showed markedly greater modulation for sinusoidal rotation in the light than in the dark (n=27). Although floccular PCs are known to inhibit some second-order vestibular neurons of the vestibulo-ocular reflex (VOR), their role in the VOR is unresolved, especially across species. Several lines of evidence make it reasonable to assume that PCs receiving input from 'horizontal' CFs inhibit some second-order vestibular neurons projecting to the ipsilateral medial and lateral rectus motoneurons, and that these vestibular neurons have type  ${\rm I}$ responses to vestibular stimulation. Therefore, it appears that during head rotations about the earth vertical axis with the horizontal canals in the earth horizontal plane, the rabbit flocculus can enhance the modulation of these second-order vestibular neurons. Supported by USPHS Grant NS-13742.

- 180.11 VISUAL INPUT FIBERS IN THE MACAQUE FLOCCULUS.
- VISUAL INPUT FIBERS IN THE MACAQUE FLOCCULUS. <u>M. Ohno\*, H. Noda,</u> <u>T. Fujikado\* and D. Belknap</u>\*(SPON: R. D. DeVoe). Sch. of Optometry, Indiana Univ., Bloomington, IN 47405. In a class of Purkinje cells in the macaque flocculus, res-ponses to retinal stimulation within 10° of the fixation point were excitatory and stimulation applied to a wide area of the were excitatory and stimulation applied to a wide area of the peripheral retina resulted in deep depression of Purkinje cell activity (1). To elucidate the underlying neuronal mechanisms for the dual visual inputs to the flocculus, discharges of mossy and climbing fiber units were tested under the same paradigms as used to study the Purkinje cells. In addition, visual input fibers were tested with vestibular stimulation by rotating the primate chair sinusoidally around the vertical axis.

Among 53 mossy fiber units studied, 13 responded to moving visual stimulation. Five units discharged when the pattern was moved toward the direction of recording side and 6 units responded during contralateral stimulus movement. These units were sup-pressed when the pattern was moving in the non-preferred direction. Discharges were depressed in 2 units during stimulus movement in both directions. Showing cyclic modulation in activity responding to sinusoidal changes in the stimulus velocity, ll units did not increase the peak activity with an increase of the frequency in a range from 0.1 Hz ( $3.1^\circ$ /sec) to 0.8 Hz. In the majority of the range from 0.1 Hz (3.1 /Sec) to 0.8 Hz. In the majority of the units, therefore, the responses seemed to saturate at a lower frequency. Receptive fields of all 13 units were found in the peripheral retina. Of the 5 units discharging with ipsilateral visual stimulus movements, 3 units showed peak activity during ipsilateral head movements and none responded to movements in the opposite direction. Of the 6 units showing contralateral visual responses, 2 units responded to contralateral and none to ipsiresponses, 2 units responded to contralateral and nome to ipsi-lateral head movements. One unit which was depressed by bilateral visual stimulus movements showed also bilateral suppression during head movements. One climbing fiber unit showed peak firing at the peak velocity of the stimulus movements toward the recording side. Its receptive field was located in the peripheral retina. The response was enhanced when the stimulus frequency was increased, but it did not respond to head rotation.

Although we have not yet discovered input fibers which convey visual information from the central retina, it is shown that a sub-population of visual mossy fibers which transmit peripheral retinal information have parent cells in structures which are related to the vestibular function. These neurons may play an important role during optokinetic nystagmus. (1) Warabi, T and Noda, H. Exp. Brain Res. 41:A35.

180.13 THE RELATIONSHIP BETWEEN SIMULTANEOUSLY RECORDED RESPONSES OF THE RELATIONSHIP BEIWEEN SIMULTAREOUSLT RECORDED RESPONSES OF ANATOMICALLY RELATED ANTERIOR INTERPOSITUS NEURONS AND PURKINJE CELLS TO NATURAL PERIPHERAL STIMULI. <u>C.J. McDevitt, T.J. Ebner</u> and J.R. Bloedel. Depts. of Physiology and Neurosurgery, Univ-ersity of Minnesota, Mpls., MN 55455. Several experiments have demonstrated that the projection of Ducking cells to pourger in the cordealian nuclei is capitally

Several experiments have demonstrated that the projection of Purkinje cells to neurons in the cerebellar nuclei is sagittally organized with a specific region in the nucleus receiving inputs from zones of Purkinje cells localized in narrow antero-posterior strips. The purpose of these experiments was to examine the re-lationships of the responses of anatomically related Purkinje cells and nuclear neurons recorded simultaneously. In decere-brate unanesthetized cats concentric bipolar stimulating electrodes were positioned stereotaxically within the red nucleus to antidromically identify neurons recorded in the contralateral anterior interposed nucleus with a tungsten electrode (z=6 Mohm). After isolating and identifying an anterior interposed neuron the appropriate zone of lobule V was searched for Purkinje cells responding antidromically to microstimuli (0.5-75 uA) applied with the same electrode in the interposed nuclei used to record the activity of the nuclear neuron. Following successful isola-tion of a Purkinje cell and nuclear neuron the unitary responses to sinusoidal and square wave displacement of the wrist joint at various amplitudes and frequencies were determined. The sim-ultaneous activity of twenty-six pairs of Purkinje cells and in-terposed neurons was analyzed using histograms, autocorrelograms and cross correlograms. When reciprocal activity was observed in a pair of neurons in response to square wave stimuli, nuclear neurons responded with a phasic increase in discharge rate rap-idly followed by a more prolonged decrease below background trodes were positioned stereotaxically within the red nucleus to neurons responded with a phasic increase in discharge rate rap-idly followed by a more prolonged decrease below background level. Coincident with the decrease in the impulse activity of the nuclear neuron, there was an increase in the discharge of the associated Purkinje cell. However, this relationship was highly dependent on stimulus parameters. In general, the rela-tionship between the two cells' responses to sinusoidal stimuli differed from the relationship observed for square wave stimuli. In some cases one cell of a pair was modulated while the other neuron was unmodulated. For pairs whose activity was modulated by the sinusoidal input the modulation of the two cells could be either in or out of phase. Cross correlograms of the spon-taneous activity demonstrated little correlation. Although these data are preliminary, the results suggest that the func-tional relationship between Purkinje cells and anatomically re-lated interposed neurons depends on the features of the afferent input. 180.12 UNIT ACTIVITY AND RESPONSES TO MICROSTIMULATION IN THE MACAQUE FLOCCULUS DURING SMOOTH PURSUIT EYE MOVEMENTS. D. Belknap' Noda and M. Ohno\*. oomington, IN 47405 School of Optometry, Indiana University Bloomington, IN

Purkinje cells in the primate flocculus are known to modu late their simple spike activity during smooth pursuit. In order to understand the role of the flocculus in smooth pursuit, we to understand the role of the flocculus in smooth pursuit, we have applied microstimulation to the flocculus in conjunction with single unit recordings from Purkinje cells. We are extend-ing our earlier results to the situation of ongoing smooth pursuit. Slow eye movements were evoked by stimulation of the macaque flocculus. Trains of brief negative pulses of 20 µA or less were effective at approximately 40% of the sites tested in the floccular cortex. This percentage was not increased by choosing sites near isolated units which modulated their activity during smooth pursuit. 10 µA or less was effective at 20% of the sites tested. When the histological layers were identified by their characteristic unit and background activity, micro-stimulation was found to be most effective in the granular layer and least effective at the Purkinie cell layer.

stimulation was found to be most effective in the granular layer and least effective at the Purkinje cell layer. Pulse trains having a duration of one-half second applied during a steady fixation evoked slow eye movements in all directions with amplitudes of up to 5 degrees and sometimes including quick phases. After the end of a pulse train, the eyes slowly returned in the direction opposite to the evoked eye movement. Eye velocity increased with increasing stimulus frequency and increasing current. Increasing the current above threshold caused the return eye movement to increase in amplitude and velocity and to begin before the end of the pulse train. train

Purinje cell simple spike activity was modulated during sinusoidal smooth pursuit in the vertical and horizontal planes. Directional preferences were predominantly downward in the verticle plane. Eye movements evoked by microstimulation usually had upward vertical components. In samples from some regions of several flocculi the direction of the horizontal component of several flocculi the direction of the horizontal component of the evoked eye movement was predominantly ipsilateral and in others contralateral responses prevailed, suggesting that the horizontal component is, to some extent, dependent on the area stimulated within the flocculus. Microstimulation during smooth pursuit reduced eye velocity as would be predicted by the vector sum of the intended eye velocity and the eye movement evoked during fixation by the same stimulus. Supported by NIH grant EY04063.

THE FUNCTION OF EFFERENT PROJECTIONS FROM THE LUMBOSACRAL SYMPA-THETIC CHAIN TO THE URINARY BLADDER OF THE CAT. <u>D.C.Kuo, and</u> <u>W.C.de Groat</u>, Dept. of Pharmacology, University of Pittsburgh, 181.1

IHELIC CHAIN TO THE URINARY BLADDER OF THE CAT. D.C.Kuo, and W.C.de Groat, Dept. of Pharmacology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261 Previous anatomical studies in the cat identified a prominent efferent postganglionic pathway from the caudal (S<sub>1</sub> and S<sub>2</sub>) sym-pathetic chain ganglia (SCG) to the pelvic nerves which provide the parasympathetic (PSYM) innervation to the uninary bladder and colon. The present every undertaken to identify and colon. The present experiments were undertaken to identify the destination and function of these sympathetic (SYMP) post-

and colon. The present experiments were undertaken to identify the destination and function of these sympathetic (SYMP) post-ganglionic axons in the pelvic nerve. In chloralose or barbiturate anesthetized cats, various nerves were isolated for stimulation or recording including: postganglio-nic nerves on the surface of the colon and bladder, pelvic and hypogastric nerves, and lumbar sympathetic chains (LSC) bilater-ally. Electrical stimulation (thresholds 2-4V) of the LSC evoked firing in the pelvic nerve and in colon and bladder postganglionic nerves at latencies of 60-150 msec. The responses were unaffected by decentralization, i.e., cutting the chain one segment rostral to the site of stimulation on the vere abolished by the administra-tion of ganglionic blocking agents (tetraethylammonium or hexa-methonium). The conduction velocity in the sympathetic postgang-lionic axons was approximately 1 mysec. Electrical stimulation of the LSC at L<sub>2</sub>-L<sub>2</sub> also elicited responses in the bladder and bladder ganglia similar to the effects elicited by stimulation of the hypogastric nerves (HGN). For example, spontaneous bladder contractions and those elicited by stimulation of PSYM-preganglionic axons in the pelvic nerve were reduced by repetitive stimulation of the LSC (10-30 Hz, 3-30 V). The inhibition was preceded by a transient rise in bladder pressure which most likely represents a contraction of the blad-der neck. This inhibition was ont affected by decentralization, but was blocked by ganglionic blocking agent (tetraethylammonium) and by beta adrenergic blocking agent (propanolol). Transmission in bladder ganglia was also depressed (30-40%) by stimulation (10-30 Hz) of the LSC or the HGN. The inhibition was unaffected by decentralization, but was completely antagonized by injection of dihydroergotamine (DHE, 20-50 ug/kg, i.v.) an alpha adrenergic blocking agent. After DHE ganglionic transmission was facilitated by stimulation of the LSC. In summary, electrical stimulation of preganglionic pathways by stimulation of the LSC.

by stimulation of the LSC. In summary, electrical stimulation of preganglionic pathways in the LSC elicits postganglionic firing in nerves innervating the pelvic viscera and evokes responses in the urinary bladder which duplicate the effects produced by stimulation of the HGN. Thus, it seems likely that efferent projections from the lumbo-sacral sympathetic chain may play a similar role as the hypogas-tric nerve in the regulation of lower urinary tract function.

181.3 THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) REGION IN EXPERIMENTAL THE ANIEKUVENIKAL INIKU VENIKILE (AV37) REVIEW IN EARDEATHDATE SHOCK, G. Feuerstein, R. L. Zerbe#, A. K. Johnson## and A. I. Faden. Neurobiology Research Unit, Uniformed Services University of the Health Sciences, Bethesda, Maryland 20814 and #Department of Psychology, University of Iowa, Iowa City, Iowa 52242, ##Eli Lily Lab, Wishard Memorial Hospital, Indianapolis, Indiana 46202.

The AV3V region was previously shown to be a site of central integration of autonomic and sympathetic responses. In addition, the AV3V was shown to be the site for central pressor and vasothe AV3V was shown to be the site for central pressor and vaso-pressin (VP) release by angiotensin (AII) (Brody & Johnson, <u>Am.</u> <u>Physiol. Soc.</u>, 7:105, 1981). Since the AV3V area seems to have an important role in regulation of the three major pressor systems (sympathetic, AII, VP) and in the development and mainten-ance of several models of experimental hypertension, we investi-gated the role of the AV3V region in the cardiovascular recovery after severe hemorrhage, the latter being a known stimulus for sympathetic, AII and VP release. AV3V lesioned (n=19) and control (n=14) rats were implanted with indwelling catheters in both femoral arteries. Twenty-four hours later, conscious, unrestrained rats were exposed to hyporoplemic hyportension ((AC2)) both remota arteries. Twenty-four motifs fatter, conscious, unrestrained rats were exposed to hypovolemic hypotension (40%) by bleeding 8 ml/300 gm over 5 min. Mean BP (MBP) and heart rate (HR) were continuously recorded for 60 min and at 24 hr. Plasma catecholamines (CA, radioenzymatic-TLC) and vasopressin (VP, RIA) were determined at the control period and at 5 min, 1 hr and 24 hr after the bleeding. Water consumption and hematocrit were also monitored. The exact site of lesion was confirmed by microscopic examination of thionine (0.1%) stained sections (50  $\mu$ ). MBP of AV3V lesioned and control rats fell to 28 ± 4 and 47 ± 6 mmHg, (p < 0.05) but no further differences were found throughout the rest of the experimental period respectively (ANOVA with repeated measures). Heart rate response consisted of 4 phases: tachycardia (1 min), bradycardia (2-5 min), tachycardia (20-30 min) and normal rate (24 hr) but no differences were seen between the groups. Plasma norepinephrine, epidneprine and VP between the groups, the end of the hemorrhage, up to  $6.4\pm1.2$ ,  $23.4\pm6.3$  and  $1.5\pm0.3$  ng/ml, respectively, but at each time point there 6.3 and 1.5±0.3 ng/ml, respectively, but at each time point there was no significant difference between the two groups; water consumption 24 hr after the hemorrhage was 38±7 and 44±5 ml in the control and AV3V lesioned rats (p = n.s.). Hematocrit dropped from 42±2 in the control period to 31±1, 28±2 and 24±1% at 5 min, 1 and 24 hr after the hemorrhage but no significant differences were found between the groups. The AV3V lesioned rats had a higher mortality rate (p < 0.05). These data indicate that the AV3V is important in recuperation and survival from acute hypovolemic hypotension through mechanisms unrelated to acute hypovolemic hypotension through mechanisms unrelated to sympathetic activation, VP release or water consumption and not directly related to MBP and heart rate responses.

DIFFERENTIAL DISTRIBUTION OF TRANSMITTER BINDING SITES IN THE INTERMEDIOLATERAL CELL COLUMN (IML) OF THE RAT. V. Seybold and <u>R. Elde</u>, Dept. of Anatomy, Univ. of MN, Minneapolis, MN 55455 By combining retrograde transport of Fast Blue (FB) with immunohistochemistry, earlier work determined a close relation-ship of serotonin- and enkephalin-containing varicosities with cells in IML which project to the adrenal gland (Holets and Elde, Neurosci. 7:1155-1174, 1982). As an extension of this work, we determined whether specific binding sites for these and other transmitters could also be correlated with the distribution of sympatho-adrenal preganglinging reprose. 181.2

transmitters could also be correlated with the distribution of sympatho-adrenal preganglionic neurons. In order to localize sympatho-adrenal preganglionic neurons, the left adrenal medulla of 4 rats was injected with FB. Five days later, the animals were perfused with 0.1% paraformaldehyde, and the left adrenal gland and spinal cord segments T7-10 were were defined former converted cord segments T7-10 were and the left adrenal gland and spinal cord segments T7-10 were rapidly excised and frozen. Cryostat sections (10  $\mu$ m) were cut from these tissues, and the location of FB-labeled cells in each section was recorded with a fluorescence microscope equipped with an X-Y stage digitizer. The sections containing FB-labeled cells were then processed with <sup>3</sup>H-ligands for receptor autoradio-graphy using the <u>in vitro</u> method with emulsion-coated coverslips. D-Lysergic acid (LSD) was used for visualization of serotonin binding sites, dihydromorphine (DHM) for opiate binding sites, quinuclidinyl benzilate (QNB) for muscarinic cholinergic binding sites and p-aminoclonidine (PAC) for alpha-2 noradrenergic binding sites. After development of autoradiograms, the number of silver grains/1600  $\mu$ <sup>2</sup> over regions of Fast Blue labeled cells was counted using the previous maps for orientation. Each of the ligands displayed a unique pattern of binding

Each of the ligands displayed a unique pattern of binding in the intermediate regions of the thoracic spinal cord. Distinct densities of PAC binding sites were seen within IML with a high correlation with FB-labeled cells such that den-sity of grains over FB-cells other regions of IML/adjacent sity of grains over FB-cells>other regions of IML>adjacent intermediate gray matter. LSD binding showed the same general pattern, although dense clusterings of grains were not apparent in IML. Dense clusterings of grains as with PAC were also observed in IML with QNB binding, but there was no correlation with FB-labeled cells and no consistent difference between grain densities over FB-labeled cells and the adjacent intermediate gray matter. DHM binding was most homogeneous with no signifi-cant difference within IML or the adjacent gray matter. These results indicate that receptor autoradiography can be effectively combined with tract-tracing techniques to determine the distribution of transmitter binding sites over retrogradely-

the distribution of transmitter binding sites over retrogradely-labeled cells. In particular, serotonin and alpha-2 adrenergic receptors had a higher association with the sympatho-adrenal pre-ganglionic neurons in 17-10 of the rat spinal cord than with other regions in the intermediate gray matter.(Support: DA-02148)

181.4 SYMPATHETIC NERVOUS SYSTEM AND ADRENOCORTICAL INTERACTIONS.

M.R. Brown, L.A. Fisher and W.H. Vale. Peptide Biology Lab, The Salk Institute, La Jolla, CA 92037. Corticotropin releasing factor (CRF) stimulates pituitary se-cretion of ACTH and is a physiologic regulator of ACTH release following stress. CRF also acts within the brain to increase the activity of the sympathetic nervous system (SNS). Glucocorticoids (GLC) inhibit stress-induced release of CRF from the hypothalamus into the hypophyseal portal system and in addition an-tagonize CRF's action on the pituitary gland. To assess the physiologic role of CRF in regulating the SNS, studies were car-ried out to determine the effects of altered plasma GLC levels on CRF- and stress-induced elevations of plasma levels of epine-

on CH- and SITESS-INDUCED Elevations of plasme levels of opinio-phrine (E) and norepinephrine (NE). Experiments were carried out in unanesthesized rats bearing chronic jugular venous and brain lateral ventricular cannula (icv). Plasma E and NE levels were determined using a radioenzymatic method. Dexamethasone (dex) was given subcutaneously and CRF was given icv. Dex (0.1-1 mg/kg 2-hour pretreatment) pro-duced a dose dependent lowering of basal levels of plasma (E) and (NE), and suppression of CRF (1.9 nmole)-induced elevation of plasma E and NE.

Restraint and exposure to ether vapor (stress) for 3 minutes resulted in elevations of plasma E and NE. Dex (1 mg/ kg) given 2, 4 and 6 hours prior to stress suppressed plasma levels of E and NE. Dex (0.001-1 mg 2-hour pretreatment) suppressed stress-induced rise in E and NE with a minimal effective dose <u>ca</u>. 0.01 mg/kg. The dose of dex required to produce 50% inhibition of stress-induced E and NE is similar to the dose for inhibition of ACTH secretion.

To determine the effects of decreased endogenous plasma levels of GLC on the E and NE response to stress, animals were pretreated with antisera against CRF. This treatment (CRF antipretreated with antisera against CRF. This treatment (CRF anti-sera given iv) prevented stress-induced elevations of plasma ACTH and corticosterone, but accentuated the stress-induced rise<sup>o</sup> of plasma E and NE. CRF antisera given iv does not gain access to those brain areas where CRF may possibly be involved in regu-lating the SNS. This conclusion is based on the observation that CRF antisera given iv did not prevent the rise in plasma E and NE following CRF given icv. Removal of endogenous GLC by acute adrenalectomy elevated plasma NE. These results, however, are confounded by the removal of adrenal E. To avoid this prob-lem studies are currently underway using the steroid synthesis inhibitor, aminoelutethinide, to lower plasma GLC levels.

Tem studies are currently underway using the storoid synthesis inhibitor, aminoglutethinide, to lower plasma GLC levels. These studies suggest that GLC may exert an inhibitory effect on the activity of the SNS. We propose the hypothesis that this inhibitory effect of GLC on SNS function may be mediated through GLC inhibition of the secretion and/or action of CRF.

181.5 RELATIONSHIPS BETWEEN NEURONS IN THE PARAVENTRICULAR AND SUPRA-OPTIC NUCLEI AND SYMPATHETIC PREGANGLIONIC NEURONS. K. Koizumi, M. Kollai\*, H. Yamashita\* and K. Inenaga\*. Department of Physiology, State University of New York, Downstate Medical Center, Brooklyn, New York, and University of Occupational and Environmental Health, School of Medicine, Kitakyushu, Japan.

Morphological studies have shown the presence of monosynaptic connections between cells in the paraventricular nucleus (PVN) and the intermediolateral cell column (ILC) of the spinal cord. In order to clarify their functional implications, we approached the problem with 3 experimental procedures using electrophysics logical techniques in chloralose anesthetized cats and dogs. 1) Electrical stimulation of certain regions in and near the PVN and the supraoptic nuclei (SON) with repetitive pulses (20-100 Hz) produced changes in blood pressure, heart rate and muscle blood flow very similar to the pattern observed in the "defense reactions." Such areas were very restricted but mingled with those from which "depressor response" was obtained by similar stimulations. 2) Recordings from the thoracic white ramus (Th II or III) revealed that stimulations of the PVN and SON regions with a short train of pulses evoked clear discharges. The latencies varied between 20 to 70 msec and the threshold 10 to 30 µA, depending on sites of stimulation. 3) Responses of "identified" and "non-identified" neurosecretory cells in the PVN and SON were recorded following microstimulation of the ILC of Th I or Th II with a short train of pulses. Antidromically evoked action potentials were recorded in 9 out of 297 neurons tested. They were located in both anterior and dorsal parts of the PVN as well as near but not within the SON. Among these 9 neurons 2 were antidromically excited also by the pituitary stalk stimulation, 5 were orthodromically excited by the same stimulus and the last 2 were not excited by the stalk stimulation. These results indicate that, although neurons in or near the PVN and the SON are very much involved in cardiovascular reactions, a very few neurosecretory cells send axons to the ILC of the cord and their specific function, if any, must be sought in the future. - 181.6 FASTING DECREASES ARTERIAL PRESSURE AND CYTOCHROME OXIDASE ACTIVI-
  - TY OF THE PARAVENTRICULAR NUCLEUS IN THE SPONTANEOUSLY HYPERTEN-SIVE RAT. <u>T.L. Krukoff\* and F.R. Calaresu</u>. Dept. of Physiology, Univ. of Western Ontario, London, Canada. N6A 5C1 The spontaneously hypertensive rat (SHR) exhibits a genetically transmitted state of elevated arterial pressure (AP). There is experimental evidence suggesting that the CNS, by increasing the activity of the sympathetic nervous system, may play a role in the development and/or maintenance of the elevated AP. The additional observation that fasting in SHRs reduces both sympathetic nervous activity (SNA) and AP (Young & Landsberg, Science 196: 1473, 1977) has suggested that specific CNS sites, in particular the paraven-tricular nucleus of the hypothalamus (PVH), may play an important role in the control of SNA and the development of elevated AP in the SHR (Zhang et al., Fed. Proc. 42: 495, 1983). These experi-ments were done to investigate the metabolic activity of hypothalamic nuclei, and particularly of the PVH, in adult SHRs, before and after fasting, by using the technique for the histochemical localization of cytochrome oxidase (COX). Adult male SHRs and normotensive adult male WKYs (250-300 g) were divided into 2 groups each. The experimental group in each strain was fasted for days; water intake, AP, and weight were recorded before and dur-ing the fast. Control groups of each strain were treated in the same manner except that they were not fasted. At the end of the Same manual except that they were not rested. At the end of the fast or control periods, rats were anesthetized and their brains prepared for COX histochemistry as previously described (Wong-Riley, Brain Res. <u>171</u>: 11, 1979). The decrease in body weight of fasted rats of both strain was similar. However, the water intake in fasted SNRs (SNR-f) was significantly less than that of fasted WW (WY f). WKYs (WKY-f). AP of SHR-f was significantly lower than the AP of non-fasted SHRs (SHR-nf). With regard to COX activity in the hypothalamus, it was shown that (1) activity of neurons in the PVH of SHR-nf was greater than that of non-fasted WKYs (WKY-nf); (2) activity in the PVH of SHR-f was decreased to a level between that of SHR-nf and WKY-nf; and (3) no obvious differences in COX activity within other hypothalamic nuclei were found between control and experimental animals. These results suggest that metabo-lic activity of the PVH is related to the level of AP in the SHR and provide additional evidence for an important role of this nuc-leus in the control of AP in this model of hypertension. Supported by the Medical Research Council of Canada.

181.7 THE CENTRAL DISTRIBUTION OF VAGAL SUBDIAPHRAGMATIC BRANCHES IN THE RAT. <u>R. Norgren and G.P. Smith</u>, Penn State Univ. Col. of Medi-cine, Hershey, PA, 17033 and Dept. Psychiatry, Cornell Univ. Med. Col., White Plains, NY 10605.

We used retrograde and transganglionic transport of horseradish peroxidase (HRP) to examine the central distribution of afferent axons and efferent somata from the major branches of the subdiaphragmatic vagus nerve (SDX). Successful transport occurred in 11 preparations: bilateral SDX, n=3; gastric branches, n=3; coeliac, n=2; hepatic, n=3. In each case, the nerve branch(es) was dissected free, cut, and exposed to crystalline HRP for 6 hr. After 60-65 hr. survival, the brains and vagal ganglia were fixed and reacted ice cold. Sections through the medulla and upper cervical cord were mounted in alternate series, one unstained and one stained with neutral red, and stored at  $4^{\circ}$ C (Kalia & Mesulam, 1980; Hamilton & Norgren, 1981). Cases in which both SDX trunks were exposed to HRP confirmed previous descriptions (Coil & Norgren, 1978; Gwyn et al., 1979). Anterograde label occurred in the dorsal half of the medial nucleus of the solitary tract (mNST) beginning 0.4-0.5mm rostral to the area postrema (AP) and continued caudally ventral to AP. This bilateral distribution connected across the midline in the commissural nucleus. Caudal to AP (obex) only this midline anterograde distribution remained, and it faded within 0.3-0.5mm. Weak label occurred in AP, but not in the lateral NST beyond the labeled axons in the solitary tract. sparse reaction product in the ventral half of mNST can be attri-buted at lease in part to labeled dendrites of DMX neurons. Retrogradely labeled somata filled the dorsal motor nucleus of the vagus (DMX) from 2.0mm rostral to 2.0+mm caudal to obex. Nucleus ambiguus contained many fewer labeled neurons. The anterograde distribution resulting from incubating individual branches indi-cated some degree of localization with the SDX projection area in mNST. First, the anterior gastric and hepatic branches distributed primarily on the left side of the medulla, while the posterior gastric and coeliac branches were concentrated on the right. When the accessory coeliac was incubated along with the main coe-liac branch, the right bias was less obvious. Second, gastric branch label concentrated in the lateral and anterior aspects of mNST. Virtually no anterograde reaction product remained at the level of the obex. The coeliac and hepatic branch label began at the same A-P level as the gastric branches, but was more medial and continued caudally under AP to the level of the obex. The vast majority of retrogradely labeled neurons in DMX and nucleus ambiguus sent axons into the gastric branches. The coeliac branch had a few efferents in the lateral tip of DMX, but the hepatic branch labeled fewer than 100 efferent neurons

181.8 PROJECTIONS OF THE SUPERIOR LARYNGEAL NERVE TO THE SOLITARY COMP-LEX IN THE RAT. L. D'Ippolito\* and J. Ciriello (SPON: V. Hachin-ski). Department of Physiology, The University of Western Ontario, London, Canada, N6A 5C1.

It is well known that the superior laryngeal nerve (SLN) plays an important role in the regulation of respiration and arterial pressure. However, the primary sites of termination of SLN affer-ent fibers in the brainstem has not been adequately described. In the present study the central projections of the SLN were studied using the transganglionic transport of horseradish peroxidase (HRP). After application of crystalline HRP to the cut central end of the SLN for 6-8 hrs, the rats were allowed to survive for a period of 2-3 days, and then transverse frozen sections of the brainstem were processed according to the tetramethyl benzidine method. Labelled axons were found to enter the ipsilateral medulla by multiple rootlets approximately 2-3 mm rostral to the obex. After joining the solitary tract, the majority of labelled axons turned caudally and coursed within the lateral half of the tract. At this level, a small component of the labelled fibers appeared to terminate within the ventrolateral subnucleus of the nucleus of the solitary tract (NTS). The terminal labelling in the NTS increased in intensity towards the obex, and was densest in the interstitial subnucleus of the NTS. Additional labelling was pre-sent in the dorsolateral, ventral and medial subnuclei. Some labelled axons coursing through the dorsolateral subnucleus were traced into the ventrolateral aspect of the area postrema where they appeared to terminate. Further caudally, the intensity of labelling remained greatest in the interstitial subnucleus, although some labelling was also found in the medial and commissural subnuclei. Labelled axons crossed the midline above the central canal in the commissural subnucleus and terminated in the contralateral medial and dorsolateral subnuclei. These data provide evidence that SLN afferent fibers project to restricted regions of the solitary complex and suggest that several regions of the NTS have physiological roles in the homeostatic regulation of respiration and arterial pressure.

SINGLE UNITS IN THE AMYGDALA OF THE CAT RESPONDING TO ACTIVATION 181.9 OF BARORECEPTORS AND CHEMORECEPTORS. D. F. Cechetto and F. Calaresu, Dept. of Physiology, University of Western Ontario, London, Canada, N6A 5C1.

Electrical stimulation of the carotid sinus and aortic depressor nerves has been shown to alter the firing frequency of units in the amygdala (Soc. Neurosci. Abs. 7:365, 1981) but the distriin the amygdala (Soc. Neurosci. Abs. /:305, 1981) but the distri-bution of neurons within the amygdala responding to selective ac-tivation of baro- and chemoreceptors and the input to these neurons from other CNS nuclei involved in cardiovascular and respiratory control are not known. Experiments were done to investigate both the specificity of separate projections to different portions of the amygdala and convergence on neurons in the amygdala of inputs from baro- and chemoreceptor afferents and from the paraventricular nucleus of the hypothalamus (PVH) and parabrachial nuclei (PB), CNS locations with known involvement in central control of circulation and respiration. In 12 chloralosed, paralyzed and artificially ventilated cats electrical activity of spontaneously active units in histologically verified sites in the amygdala was monitored for changes in firing frequency during activation of baroreceptors (BA, phenylephrine, 2  $\mu g/kg$ , i.v.) and activation of carotid chemoreceptors (CA, sodium cyanide 25  $\mu g$  in 0.1 ml saline into the medial thyroid artery). Units responding to BA and CA were also tested for responses to electrical stimulation of the Were also tested for response to electrical stimulation with the PVH and PB. CA altered the firing frequency of 23% (35/154) of the units in the amygdala of which 37% (13/35) were excited while 63% (22/35) were inhibited. Of the 13 units excited by CA, 2 were also excited by PVH stimulation and 4 were excited by PB stimulaalso excited by PVH stimulation and 4 were excited by PS stimula-tion. Of the 22 units inhibited by CA 5 were excited and 2 were inhibited by PVH stimulation while 6 were excited and 1 was inhib-ited by PB stimulation. BA altered the firing frequency of 16%(24/154) of the units in the amygdala of which 71% (17/24) were excited while 29% (7/24) were inhibited. Of the units responding to BA only 2 of the inhibited units responded to PB stimulation while none responded to PVH stimulation. No units responded to both BA and CA. Units responsive to BA and CA were located primarily in the central, lateral and basal nuclei. The units res-ponsive to CA were located primarily medial and dorsal to the units responsive to BA. These experiments show that about half of the units responding to CA also received converging input from the PVH or PB, whereas only a very small number of the units responding to BA also responded to PVH and PB. In addition it has been shown that baro- and chemoreceptor information appears to project to separate functional neuronal pools in the amygdala with a cer-This demonstrated separatain degree of anatomical separation. tion of inputs may have functional implications in the role these separate areas play in integrating the autonomic components of behavioral responses. 181.11 REFLEX RESPONSES. OF SPLENIC AND RENAL NERVES TO SELECTIVE ACTIVATION OF SPLENIC RECEPTORS IN THE CAT. <u>F.R. Calaresu, J.C.</u> Tobey<sup>\*</sup>, and L.C. Weaver. Dept. of Physiol., Mich. St. Univ., E. Lansing, MI 48824.

Experiments were done to investigate the reflex responses of splenic and renal efferent nerves to selective activation of receptors within the spleen. Adult cats, under 80 mg/kg of  $\alpha-$  chloralose i.v., were paralyzed, artificially ventilated, and the vagus, aortic depressor, and carotid sinus nerves were sectioned. The spleen was exposed, and all vascular connectives to other organs were ligated. The splenic artery and vein were cannulated through branches of these vessels and prepared for occlusion by a snare. Evidence that all vascular connections between the spleen and other visceral organs had been eliminated was obtained at the beginning of each experiment by the injection of Evans blue dye beginning of each experiment by the injection of Evans blue dye into the splenic artery after occlusion of the splenic vein and artery. The following variables were monitored: 1) integrated electrical activity from efferent splenic and renal nerves, 2) splenic venous pressure (SVP), 3) systemic arterial pressure (SAP), and 4) heart rate (HR). The following substances were injected into the splenic artery while both splenic artery and vein were occluded: 1) warm physiological saline (PS, 3-20 ml) to increase intrasplenic pressure; 2) capsaicin (CAPS, 5-25 µg); 3) bradykinin (BK, 1-10 µg); and norepinephrine (NE, 1 µg). Congestion of the spleen with PS increased splenic nerve activity (SNA) 40 + 9%, renal nerve activity (RNA) 15 + 6%, SVP 26 + 6 mm Hg, SAP 27 + 8 mm Hg, and HR 4 + 2 bpm (n = 6). Stimulation of splenic receptors by CAPS increased SNA 139 + 132%, RNA 49 + 11%, SVP 14 + 3 mm Hg, SAP 68 + 16 mm Hg, and HR 14 + 3 bpm (n = 7). Responses to BK were similar to those to CAPS. In contrast, although injection of NE caused increases in SVP of 38 + 6 mm Hg (n = 4). The neural reflexes, HR responses, and a part of the SAP responses caused by these stimuli were demonstrated to be reflex in nature because they were abolished consistently by into the splenic artery after occlusion of the splenic vein and SAP responses caused by these stimuli were demonstrated to be reflex in nature because they were abolished consistently by splenic denervation. These results indicate that 1) splenic receptors are activated by congestion and by algogenic sub-stances; 2) selective stimulation of splenic receptors causes sympathetic excitation leading to cardiovascular responses; this excitation affects SNA more than RNA; 3) contraction of the spleen induced by NE does not evoke reflexes, suggesting that responses to concestion and perhaps to the noxious agents were responses to congestion and perhaps to the noxious agents were initiated by stimulation of stretch receptors. Supported by grant HL 21436.

181.10 MYELINATED RENAL AFFERENTS PROJECT DIRECTLY TO NUCLEUS GRACILIS AND NUCLEUS SOLITARIUS IN THE RAT. L.P. Schramm, O.R. Simon\* The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205

A variety of autonomic responses have been attributed to the activation of afferent fibers from the kidney. Several recent studies have shown that the majority of renal afferents synapse in the dorsal or intermediate spinal gray at low thoracic and high lumbar levels. However, we have noticed that renal nerve fibers with conduction velocities characteristic of the A-delta group could be antidromically activated from high cervical levels in the The present study traced these fibers from their site of spinal entry to their termination.

Female Sprague-Dawley rats were anesthetized with alpha-chloralose, paralyzed, and artificially respired. The caudal medulla, cervical spinal cord, and lumbar spinal cord were exposed. Record-ings using hook electrodes were made from unsplit bundles of nerves dissected from the left renal artery. Electrical stimula-tion (2-20  $\mu$ a, 0.3 ms duration) elicited single (or, more rarely, several) action potentials in the renal nerve at conduction velo-cities of approximately 15 M/s. Responses had sharp thresholds and constant latencies, and they followed stimulation to approximately 300/s, confirming their antidromic nature. Antidromic responses to spinal stimulation could be abolished

by sectioning a T10, T11, or T12 dorsal root, indicating entry of the myelinated fibers at these segments. At high cervical levels, minimum thresholds for antidromic activation were located medially in the faciculus gracilis, approximately 0.5 mm below the dorsal surface of the spinal cord. Fibers were also located medially at the level of nucleus commissuralis. However, at the level of the obex, minimum thresholds were observed more laterally in nucleus gracilis and nucleus solitarius. Activation threshold vs depth characteristics indicated widely ramifying terminals in these nuclei.

Myelinated renal nerve afferents could be activated by pressure on the renal hilus, and the resulting action potentials collided with potentials antidromically-evoked from cervical levels. There these afferents project from the renal parenchema itself and

fore, these afterents project from the form presentation of from surrounding tissue. We conclude that myelinated renal afferents enter the spinal cord between T10 and T12 and project via the medial faciculus gracilis directly to the nucleus gracilis and the nucleus solitarius. Supported by NIH Grant HL16315

181.12 SIMULTANEOUS MEASUREMENT OF BEHAVIORAL AND CORE TEMPERATURE: EFFECTS OF PROSTAGLANDIN E1 AND DOPAMINE. Spencer, R. L\*.. Marques, P. R\*., McDougal, J. N., & Burks, T. F. Depts. of Psychology and Pharmacology, Univ. Arizona, Tucson, AZ 85724.

These studies show the autonomic and behavioral temperature effects of compounds believed to be endogenous hypothalamic mediators of temperature regulation. Three days before the experiments, 34 rats were implanted with ICV cannulas and intraexperiments, 34 rats were implanted with 100 canulas and intraperitoneal temperature sensitive AM transmitters. The emitters send a signal to an AM receiver which is converted by a microcomputer to degrees C. Preferred ambient temperature (Ta) is determined in a temperature gradient, that ranges from  $8-38^{\circ}C$ . Infrared sensors detect the location of a rat within this 5/long Infrared sensors detect the location of a rat within this 5'long opaque thermocline. The change in a rat's location provides a derived measure of motor activity. The computer continuously monitors the rat's position, activity and core temperature (Tc) printing a 5 min mean of 20 15 sec readings. Prostaglandin E1 (PGEI) was studied at 5 doese (0, 1, .2, .5, 1.0, ug) with both gradient ON (G+) and OFF (G-), totaling 10 combinations. PGE1 in 5 uL produced significant dose related increases in Tc ranging from 1.1 to 2.4°C above basal. Time to peak was also significantly dose-related with a low mean peak of 17 min (0.1 ug) and a high peak of 22.5 min (1.0 ug) for both G+ and G- conditions. Analyses of 4 10 min intervals post injection showed a dose related peak of 22.5 min (1:0 gg) for both of all of controls. Marses of 4.10 min intervals post injection showed a dose related selection of a warm Ta  $(32.5 \,^{\circ}\text{C})$  for the 3 highest doses  $(0.2-1.0 \,$ ug) while controls selected 27.5  $^{\circ}\text{C}$  Ta. During the next 20 min ef PGE1 injected rats moved back to a neutral Ta. PGE1 did not alter motor behavior in these studies. ICV injections of dopamine (DA) motor behavior in these studies. ICV injections of dopamine (DA) (50, 100, 200, 400 ug in 10 uL water) produced a dose-dependent decrease in Tc ranging from a mean  $-1.64^{\circ}C$  (50 ug) to a mean  $-2.85^{\circ}C$  (400 ug). The time to peak hypothermia increased with dose. The DA induced hypothermia was greater in the Ge condition. In G+, the rats spent the first 10 min after DA at the cold end of the thermocline, at a mean Ta of  $16.4^{\circ}C$ . This was significantly different from the control selected Ta (23.9°C). This cold seeking persisted 20 min after 200 and 400 ug. This behavioral response may explain the lower Tc after DA in the G+ condition. At 30-40 min after 200 and 400 ug DA, rats selected a significantly warmer (31.7°C) location than controls ( $26.9^{\circ}C$ ). Motor activity increased significantly for the first 20 min after DA; at 400 ug this increase continued for 40 min. A significant hyperthermic rebound was seen in the G+ condition, but not G-, possibly due to an active compensatory selection of heat when the possibly due to an active compensatory selection of heat when the gradient was available. The time to peak rebound hyperthermia increased with dose of DA (49 min for 50 ug, 83 min for 400 ug). The results emphasize the importance of measuring behavior in studies of temperature regulation. Supported by NS15420.

181.13 THE BICUCULLINE-LIKE EFFECTS OF CENTRAL DOPAMINE SULFATE IN THE CONSCIOUS RAT. POSSIBLE ANTAGONISM OF GABA RECEPTOR BY DOPAMINE SULFATE. N.T. Buu\*, J. Duhaime\*, O. Kuchel\* (SPON: A. Barbeau), Institut de Recherches Cliniques de Montréal, Montréal, Quebec (H2W 1R7), Canada. Dopamine (DA) sulfate and bicuculline belong to two diffe-rent neuropathways. The first, present in discrete areas of rat brain (J. Neurochem. 36:769, 1981; Karoum, 1983) and in human CSF, is a metabolite of free DA, while the second is an antagonist of central GABA receptors. However, both agents evhibited similar action. At low does they increase arterial exhibited similar action. At low doses they increase arterial blood pressure (BP); at high doses they become convulsant agents. The present study was undertaken to compare their effects in the conscious rat in order to better understand their mechanism.

Rats were implanted under Nembutal anesthesia with permanent catheter in the left lateral ventricle. BP was measured through a femoral artery catheter. Intraventricular (IVT) injections of low doses of bicuculline (0.2 - 1.0  $\mu$ g) or DA sulfate (5-30  $\mu$ g) caused increases in BP (15-40 mmHg) which sulfate  $(5-30 \ \mu g)$  caused increases in BP  $(15-40 \ \text{mHHg})$  which were not blocked by DA antagonists haloperidol and metoclopra-mide. Sympathectomy (80%) by 6-hydroxydopamine, or pretreatment with angiotensin II antagonist saralazin did not affect the response to bicuculline or DA sulfate suggesting that the central sympathector provous system, and central angiotensin II receptors are not directly involved. Intraventricular injec-tions of larger doses of DA sulfate  $(60 \ g)$  or bicuculline  $(1.2 \ \mu g)$  caused generalized convulsions. The effect of DA sulfate was additive to that of bicuculline: half of a convul-sive dose of DA sulfate injected after half a convulsive dose of bicuculline provoked seizure, suggesting that their convul-sive effect may be through a common mechanism. Both convulsive and cardiovascular effects of bicuculline and DA sulfate could be blocked or reduced by GABA agonists, diazepam and muscimol. be blocked or reduced by GABA agonists, diazepam and muscimol. In another experiment, the possible interaction of DA sul-

In another experiment, the possible interaction of DA sulfate with central GABA receptor, suggested also by structural resemblance between GABA and DA sulfate molecules, was investigated. The results showed that DA sulfate could displace sodium independent <sup>3</sup> H GABA binding to synaptic membranes from rat brain (IC =  $2 \times 10^{-6}$  M).

It is concluded that DA sulfate exhibiting bicuculline -like biological activities in rat brain may act as a GABA antagonist in raising BP and causing convulsions. It may therefore serve as a link between central GABAergic and dopami-nergic neuropathways. (Supported by grants from the MRC and Canadian Heart Foundation.)

#### DEVELOPMENT AND PLASTICITY: TROPHIC AGENTS I

- NGF-MEDIATED ENZYME INDUCTION IN CULTURED ADRENAL CHROMAFFIN CELLS: SPECIFICITY AND LEVEL OF REGULATION. A. Acheson and H. Thoenen. Max-Planck-Institute for Psychiatry, Dept. Neurochemistry, 8033 Martinsried, FRG While many effects of nerve growth factor (NGF) on its target cells have been established (eg. survival, neurite outgrowth, enzyme induction), little is known about the mechanism of action of NGF beyond its inter-action with specific plasma membrane receptors and the involvement of a (so far unknown) second messenger. Primary cultures of calf adrenal chromaffin cells have proved to be suitable for investigating such problems. They are available in large quantities, and they respond to NGF with a pattern of enzyme induction which is representative of that found in physiological target cells <u>in vivo</u>. We have examined NGF-mediated tyrosine hydroxylase (TH) and acetylcholinesterase (AChE) induction in more detail, and since cAMP has been suggested as a possible second messenger for NGF, we have compared its effects with those of NGF. The continuous presence of NGF for 48 hrs was required for TH induction, whereas AChE could be induced by shorter (24 hr) exposures. A 12 hr exposure of cells to cAMP was sufficient to elicit the full effect on both enzymes. a-Amanitin, an inhibitor of RNA polymerase II, did not block NGF-mediated TH induction, while in the same cells AChE induction was completely abolished. cAMP-mediated induction of both enzymes was blocked by this treatment. 9-B-Arabinofuranosyladenine, a poly-adenylation inhibitor, blocked the effect of NGF on both TH and AChE, as well as the effects of cAMP. Thus, it can be concluded that the NGF-mediated TH induction is regulated at the post-transcriptional level, perhaps involving a polyadenylation-dependent event. In con-NGF-MEDIATED ENZYME INDUCTION IN CULTURED ADRENAL 182.1 CHROMAFFIN CELLS: SPECIFICITY AND LEVEL OF REGULATION. is regulated at the post-transcriptional level, perhaps involving a polyadenylation-dependent event. In con-trast, the induction of AChE is transcription-depen-dent. This, in combination with the different time courses of TH and AChE induction, suggests that NGF mediated enzyme induction involves several mechanisms. cAMP cannot be the second messenger for NGF-mediated CAMP cannot be the second messenger for NGP-mediated enzyme induction for the following reasons: in con-trast to the effect of NGF, cAMP-mediated TH induction is abolished by  $\alpha$ -amanitin. In addition, both the patterns and the times of exposure required for enzyme induction differ between cAMP and NGF-treated cells.
- 182.2 NEURITE-PROMOTING ACTIVITIES FOR CHICKEN SPINAL NEURONS: CHANGES DURING DEVELOPMENT AND AFTER DENERVATION. C.E.Henderson

M.Huchet<sup>\*</sup> and J.-P.Changeux. Neurobiologie Moléculaire, Institut Pasteur, 75724 Paris XV, France. Spinal motoneurons may depend on muscle-derived growth factors for axon outgrowth and stabilisation at two principal stages of their development: during the initial invasion of the differentiating muscle masses and during the perinatal regression of mul-tiple innervation. Using a bidassay involving the measurement of neurite outgrowth from 4.5-day embryonic chick spinal neurons in dissociated cell culture, neurite-promoting activity was detected both in medium conditioned over embryonic myotubes in vitro (emb-ryonic muscle-conditioned medium, "ECM") and in soluble extracts of chick leg muscle prepared 3 to 5 days after hatching (postnatal muscle extract, "PNME").

The molecules responsible for these two activities had physicochemical properties that distinguished them both from each other and from reported polyornithine-attached neurite-promoting factors. The former (in ECM) was active on uncoated plastic dishes but did not bind to them under cell culture conditions. It was inactivated by trypsin and was essentially found only in media conditioned by muscle and liver cells (spec. act. 550 units per mg protein). The activity in PNME, on the other hand, bound to tissue culture plastic, was more resistant to high trypsin

The levels of this factor in postnatal leg muscle were develop-mentally regulated: the specific activity increased 10-fold mentally regulated: the specific activity increased 10-fold between hatching and day 3 (max. value 3200 units/mg protein) and fell back to nearly its original levels by day 7. Cultures of embryonic myotubes "aged" for 2 weeks in vitro secreted into the medium a factor having some of the properties of that in PNME. Following sciatic nerve transection in 6-day chicks, the spec-

ific activity in extracts of muscles of the lower leg increased up to 15-fold compared to controls (max. value 10,000 units/mg). The time-course of appearance of this activity (3 to 6 days after denervation) correlates well with the period that elapses in partially denervated mammalian muscles before sprouts appear.

Under all culture conditions, more than 92% of total spinal cord cells contained neurofilaments, as revealed by indirect immunofluorescence. Cells cultured for 26 h in nonconditioned medium retained their capacity to develop neurites in response to ECM. When ECM and PNME were assayed together, the maximum value attained in the neurite outgrowth assay did not increase. It is likely, therefore, that the observed effects of the two activ-ities did not result from differential survival <u>in vitro</u> of different cell sub-populations.

182.3 DEPOLARIZING AGENTS INCREASED TYROSINE HYDROXYLASE IN THE DEVELOPING BRAIN LOCUS COERULEUS (L.C.) IN CULTURE. C.F. Dreyfus, K.A. Markey and I.B. Black. Division of Developmental Neurology, Cornell Univ. Med. Coll., New York, NY 10021. While abundant evidence indicates that differentiation of peripheral neurons is regulated by epigenetic factors, the regulation of brain neuronal development is largely undefined. To begin approaching this problem at the molecular level, we have been examining development of the mouse 1.c. in explant culture. Previous studies indicated that tyrosine hydroxylase (TH) and dopamine-β-hydroxylase (DBH), noradrenergic biosynthetic enzymes, increase markedly during development of this embryonic catecholaminergic nucleus over 3 weeks in vitro. In the present study we examined the influence of membrane depolarization on TH.

dopamine-B-hydroxylase (DBH), noradrenergic biosynthetic enzymes, increase markedly during development of this embryonic catecholaminergic nucleus over 3 weeks in vitro. In the present study we examined the influence of membrane depolarization on TH. Exposure to veratridine (1.5 x 10 M for 7 days) which elicits depolarization by increasing sodium influx, significantly increased TH activity. This effect was prevented by tetrodotoxin (10 M) which blocks the sodium channel effects of veratridine, suggesting that depolarization and transmembrane sodium flux increase TH development. To help determine whether depolarization itself evoked the increase in TH, a structurally dissimilar depolarizing agent, K (20mM) was used. Exposure to elevated K also caused a significant increase in TH in the cultured 1.c.

Our experiments suggest that membrane depolarization influences development of brain catecholaminergic neurons. More generally, epigenetic factors may regulate the ontogeny of specific transmitter phenotypic characters in brain neurons, as in the periphery (Supported by NSF grant BNS 8024081 and NIH grants NS 10259 and HD 12108.) 182.4 SEPTAL CHOLINERGIC NEURONS IN CULTURE: IMMUNOCYTOCHEMICAL VISUAL-IZATION OF CHOLINE ACETYLITRANSFERASE, AND REACTION TO NERVE GROWTH FACTOR, GLIAL CELLS, AND THYROXINE. F. Hefti, J. Hartikka\*, F. Eckenstein\*, H. Gnahn\*, R. Heumann\*, M. Schwab, and H. Thoenen. Sandoz Ltd., Preclinical Research, Basel, Switzerland, and Max Planck - Institute, Martinsried/Munich, West Germany. Cholinergic neurons of the forebrain appear to specifically de-

Cholinergic neurons of the forebrain appear to specifically degenerate in Alzheimer's disease. Understanding their cell biology should facilitate the search for cause and treatment of this disease. We therefore decided to study cholinergic neurons in culture and to investigate their requirements for survival, growth, and expression of transmitter-specific enzymes.

The septal area was dissected from rat embryos (E17). Cells were dissociated and plated in poly-ornithin-coated dishes and grown for 10-12 days in a modified L-15 medium. Cultures free of glial cells were obtained by adding cytosine arabinoside to the medium. Under these conditions, 95% of the cells were identified as neurons by positive labelling with tetanus toxin.

Cholinergic neurons were identified by immunocytochemical staining of choline acetyltransferase (ChAT) and histochemical staining of acetyl cholinesterase (AChE). Immunocytochemical visualization of ChAT was obtained with both, a rat serum against pig brain ChAT in conjunction with a FITC-labelled second antibody, and a monoclonal antibody followed by a biotinylated second antibody and avidin-peroxidase. Positive ChAT staining was only observed, when septal neurons were grown in the presence of glial cells. Both immunocytochemical methods stained cell bodies and proximal processes. Staining intensity of cell bodies was increased by NGF (100ng/ml) and thyroxine  $(10^{-7}M)$ , in confirmation of earlier findings obtained with biochemical measurements of ChAT activity in these cultures (Gnahn et al., Develop. Brain Res., in press).

ChAT-positive neurons identified with the FITC-method were double stained for AChE. The histochemical staining was the more sensitive method and enabled us to visualize cholinergic neurons in cultures free of glial cells. App. 5% of the cells in such cultures were identified as cholinergic neurons. NGF and antibodies to NGF failed to affect survival of or fiber outgrowth from cholinergic neurons.

In conclusion, cholinergic neurons were identified in cultures of dissociated neurons from the rat septum. Glial cells, NGF, and thyroxine have a trophic influence on these neurons, inasmuch as they enhance ChAT levels. The effect of NGF seems to be limited to a stimulation of ChAT synthesis and does not affect survival and fiber outgrowth of these neurons.

182.5 STUDIES ON THE CHOLINERGIC DIFFERENTIATION FACTOR FOR SYMPATHETIC NEURONS. <u>Keiko Fukada</u>, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

Recent studies by S. Landis and collaborators have shown that certain cholinergic sympathetic neurons innervating specific targets such as sweat glands undergo a transition from noradernergic to cholinergic as part of their normal development. In order to understand the molecular mechanism of such a plasticity in neuronal development, it is essential to study developmental signals which control it. The existence of such a developmental signal has been shown from culture studies on dissociated rat sympathetic neurons that certain non-neuronal cells produce a diffusible factor (cholinergic factor) which induces cholinergic differentiation in the neurons while inhibiting the development of a variety of noradrenergic properties. This factor influences the transmitter decision but has no effect on survival or growth. The cholinergic factor is being purified from conditioned medium (CM) prepared by incubation of serum-free, hormone-supplemented medium on cultures of rat heart cells (Fukada, Nature 287, 555 1090). Using acouncitioned biological tophicance on in 287.

The cholinergic factor is being purified from conditioned medium (CM) prepared by incubation of serum-free, hormone-supplemented medium on cultures of rat heart cells (Fukada, Nature 287, 555, 1980). Using conventional biochemical techniques, an increase in specific activity of more than 10,000-fold has been achieved with a reasonable recovery. The most purified activity is highly sensitive to trypsin and chromatographs on Sephadex at a molecular weight of  $\sim$ 45,000 daltons. This preparation still possesses the ability to both inhibit the development of noradrenergic characteristics as well as to induce cholinergic differentiation.

Since the factor was found not to be inactivated by the treatment with 1% sodium dodecylsulfate (SDS), further purification of the factor was pursued by preparative SDS-polyacrylamide gel electrophoresis under non-reducing conditions. High recovery of the activity was obtained at a molecular weight of  $\sim$ 50,000 daltons, which corresponds to the molecular weight determined by chromatography on Sephadex under native conditions. Thus the active form of the factor is a monomer (possible subunits may be held together by disulfide bonds, however). Moreover, high recovery of the activity with the good resolution this method affords makes this technique promising as a further purification step. In addition to these blochemical methods another approach is

In addition to these biochemical methods another approach is in progress. A partially purified CM fraction was injected into mice in an effort to raise monoclonal antibodies. Twenty-three hybridomas were selected for their ability to bind preferentially to the most purified fraction. Several of these antibodies were found to bind to major impurities in the CM preparation and may therefore be useful in further purification. One monoclonal antibody specifically precipitated a significant fraction of the cholinergic activity. (Supported by the Dysautonomia, McKnight and Rita Allen Foundations, and the NINCDS) 182.6 BIOCHEMICAL AND ANATOMICAL EFFECTS OF ANTIBODIES AGAINST NERVE GROWTH FACTOR ON DEVELOPING RAT DORSAL ROOT GANGLIA. U. H. Otten, M. Goedert\*, S. P. Hunt\*, L. L. Iversen\*, M. Schlumpf and W. Lichtensteiger. Dept. of Pharmacology, Biocenter of the University, Basel, Switzerland; MRC Neurochemical Pharmacology Unit, Cambridge, UK and Inst. Pharmacol. Univ. Zürich, Switzerland.

The protein nerve growth factor (NGF) is essential for the development of peripheral adrenergic neurons, as shown by the fact that the administration of anti NGF-antibodies to newborn animals leads to an irreversible destruction of their peripheral sympathetic nervous system. The same treatment results in a marked but reversible reduction in substance P-like immunoreactivity in dorsal root ganglia, spinal cord and skin. In the present study, we have examined the development of rat dorsal root ganglia following prenatal exposure to anti NGF-antibodies. Rat foetuses (day 16.5 of gestation) received a single intramuscular injection of a monospecific NGF-antiserum and were killed at the age of four months. Control animals were treated with preimmune serum. The anti NGF-antibody treatment produced a reduction of greater than 80% in the number of unmyelinated dorsal root fibers. Substance P- and somatostatin-like immunoreactivities were decreased by over 80% in dorsal root ganglia and skin, as determined by radioimmunoassay. Substance P-like immunoreactivity a 12% reduction in the spinal cord. These results were supported by immunohistochemical findings which showed a substantial depletion of both substance P- and somatostatin-like immunoreactivities in dorsal root ganglia and in the dorsal horn. In addition, fluoride-restistant acid phosphatase was depleted in both structures, as shown by a histochemical technique. These results indicate that NGF is a natural trophic factor for both sympathetic and dorsal root ganglia. However, whereas anti NGF-antibodies produce a destruction of rat sympathetic and dorsal root ganglia. However, whereas anti NGF-antibodies produce a destruction of rat sympathetic ganglia is limited to the prenatal period.

GANGLIOSIDE MEDIATION OF NGE ENHANCED NEURONAL MATURATION. 182.7 Fred J. Roisen, Maurice M. Rapport, Yung-Yu Huang\* and Glee Yorke\*. Department of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854 and Division of Neuroscience, New York State

Yorke\*. Department of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854 and Division of Neuroscience, New York State Psychiatric Institute, NY, NY 10032. We have reported previously (Science, 214:577, 1981) that exogenous bovine brain ganglisdes (BBG) induce in vitro neurito-genesis of chick embryonic dorsal root ganglia (DRG) and murine Neuro 2a neuroblastoma (N<sub>2</sub>A). The mechanism through which BBG enhances neuritogenesis is unknown. We and others have suggested that gangliosides incorporated into neuronal plasma membranes may function as "acceptor" molecules for growth factors. To examine this possibility we have been studying the relationship between gangliosides and Nerve Growth Factor (NGF). Four pure bovine brain ganglioside species (GM, GD<sub>1</sub>, GD<sub>1</sub>, and GT<sub>1</sub>, Fidia Res. Labs., Abano Terme, Italy) were found to enhance N<sub>2</sub>A and DRG neuritic sprouting. Affinity purified antibodies to GM<sub>1</sub> were prepared and used to probe NGF's ability to increase neurito-genesis of DRG <u>in vitro</u>. The antibodies diminished specifically NGF's capacity to increase neurite length and number but had no effect on the radial migration of accompanying non-neuronal cells. Another consequence of NGF's activity of ornithine decarboxy-lase (DDC) (MacDonnell <u>et al</u>., PNAS, 74:4681, 1977), the rate-limiting enzyme in the polyamine biosynthetic pathway. ODC acti-vity of DRG is independent of neurite outgrowth. Accordingly, we have examined the effects of antibodies to GM<sub>1</sub> alone, or in combi-nation with NGF on the ODC levels of DRG and a cloned NGF-responsive pheochromocytoma cell line (PC-12). NGF's elevation of ODC activity was reduced in a dose-dependent manner when NGF and antibodies to GM, were administered simultaneously to DRG or PC-12 OCC activity was reduced in a dose-dependent manner when NGF and antibodies to GM, were administered simultaneously to DRG or PC-12 cultures. The ODC activities were reduced to levels below that found in untreated controls when antibodies to GM, were applied in the absence of additional treatment. Furthermore, NGF-induced The absence of adultional treatment. Furthermore, were induced in the mean neurite elongation was enhanced by exogenous GM<sub>1</sub>. These studies are consistent with the possibility that gangliosides in the membrane play a key role in trophic regulation and demonstrate specifically that NGF interacts with GM<sub>1</sub>, in some as yet undefined manner, to increase both ODC activity and neurite elongation. Supported by NIH grants NS11299 and NS11605.

PARTIAL PURIFICATION OF A CHOLINERGIC TROPHIC FACTOR FROM ADULT 182.8 HUMAN MUSCLE. <u>Ken Vaca\* and Stan Appel</u>. Dept. of Neurology, Program in Neurosciences, Baylor College of Medicine, Houston, Texas 77030.

Trophic substances which affect spinal and parasympathetic motor neurons have been extracted from a variety of sources, with some differences in their reported properties. If some neuromuscular disorders are a consequence of aberrant trophic interac-tions, it would be desirable to be able to identify the trophic molecules active in human. Cultured chick ciliary ganglion neurons provide a sensitive system to assay for such trophic factors. The 100,000 g supernatants of muscle extracts from more than 10 human (vastus lateralis) muscle biopsies typically induced a 4 to 5 fold increase in  $^{3}$ H-ACh synthesis after to 3 to 4 days in culture, roughly comparable to that produced by fetal calf or embryonic chick muscle extracts. However, in contrast to the embryonic extracts which elicited tremendous neurite extension, the adult muscle extract had minimal effect on cell morphologies. (Psoas) muscle extracts from autopsy material were usually nearly as active as the biopsy specimens on cholinergic activity and as active as the biopy spectments on chain length activity and were used for further purification. Activity was precipitated in 60-85% ammonium sulfate. The active material was present in both high (>100,000) and low (<20,000) molecular weight forms, the former being favored when the 60-85% pellet was resuspended at high concentration. The lower molecular weight activity was separated and concentrated by consecutive ultrafiltration steps. separated and concentrated by consecutive ultratilitation steps. By gel filtration, the apparent molecular weight of the choliner-gic factor was approximately 10-12,000, which increased  ${}^{3}\text{H-ACh}$ synthesis more than 2-fold at 1 µg/mL. Preparative isoelectric focusing produced activity with a pI of approximately 7.5. The active fraction did not increase  ${}^{3}\text{H-thymidine incorporation and}$ thus was not mitogenic for supporting cells. This cholinergic trophic factor contained in adult muscle may play a role in maintaining motor neurons in their active, fully differentiated state.

(We thank Dr. Scott Stewart for help in obtaining autopsy speci-mens. Supported in part by grants from the John A. Hartford Foundation and the Robert J. Kleberg and Helen C. Kleberg Foundation).

INITIAL PARTIAL CHARACTERIZATION OF A GROWTH FACTOR FOR <u>APLYSIA</u> NEURONS IN TISSUE CULTURE. <u>S.M.Fredman and R.</u> <u>Waziri</u>. Dept. of Psychiat., Univ. of Iowa, Col. of Medicine, Iowa City, IA, 52242. The blood of <u>Aplysia</u> contains a factor or factors that is/are necessary for and promotes the extension of neurites in culture of dissociated neurons. We now report the partial characterization of this factor. Our assay system consisted of the cell bodies of neurons from the CNS of immature <u>Aplysia</u> (weighing 12-50g) in culture. The neurons were mechanically dissociated without the use of enzymes and plated on poly-L-lysine coated culture dishes in L-15 medium (GIBCO) supplemented with additional salts and antibiotics. With 10-40% (vol/vol) blood added, neurons typically put out processes in 12-24 hours. Neurons cultured without blood, or with blood inactivated by boiling or trypsin failed to extend neurites. This suggests that the growth promoting factor(s) is/are protein(s). The growth promoting factor was retained by a membrane filter (Amicon) with a cut-off of 300,000 MW. More precise size estimation by gel chromatography indicted that the factor has a molecular weight of approximately 500,000 Daltons. Further characterization and purification of the growth promoting factor() is non characterization and purification of the growth promoting factor(s) is now in progress.

PROCEDURES THAT ENHANCE NEURONAL GROWTH PROMOTING FACTOR(S) IN APLYSIA BLOOD. R. Waziri and S.M.Fredman Dept. of Psychiat., Univ. of Iowa, Col. of Medicine, Iowa City, IA 182.10 52242

The extension of neurites by <u>Aplysia</u> neurons in tissue culture requires "growth factor(s)" which is normally present in the blood. We have found that surgical manipulation can enhance the growth promoting abilities of <u>Aplysia</u> blood. Neurons from immature <u>Aplysia</u> (27g average weight) were mechanically dissociated without enzymes and grown on poly-L-lysine coated dishes using L-15 medium plus 5-10% (vol/vol) <u>Aplysia</u> blood. Blood was obtained from adult animals which had: i) an additional CNS implanted; ii) bilateral crush of the cerebro-pleural connectives; iii) CNS implant + connective crush. Blood from size-matched sham-operated and unoperated animals served as controls as did blood taken from the experimental animals controls as did blood taken from the experimental animals prior to surgery. The growth promoting ability of blood from animals with nerve crush + implant was > implant alone > than crush alone > controls. The blood from crush + implant animals not only stimulated more neurons to sprout processes but also promoted more extensive neuritic arborization. This indicated that when combined the two procedures had a synergistic and non-linear effect. These results lead to the conclusion that the CNS of <u>Aplysia</u> is the source of blood borne neuronal growth promoting factors. the source of blood borne neuronal growth promoting factors which are enhanced in response to injury. Our data are in agreement with results of Wong et al. (J. Neurosci 1, 1008-1021, 1981) that CNS "conditioned" medium supports the growth of cultured molluscan neurons.

COMPARISON OF THE NEURITOGENIC ACTIVITIES OF CYCLIC NUCLEOTIDES AND STRIATED MUSCLE-CONDITIONED MEDIUM ON CILIARY GANGLIA IN VITRO. Glenn M. Monastersky\* and Fred J. Roisen (SPON: R. Duvoisin), Dept. of Anatomy, UMDNJ-Rutgers Medical School, 182.11 IN VITRO. Glenn M. Monastersky\* and Fred J. Roisen (SPON: R. Duvoisin). Dept. of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854. We reported recently that cyclic adenosine-3',5'-monophosphate (cAMP) and its dibutyryl derivative [(But)<sub>2</sub>cAMP] stimulated neurite formation in embryonic chick ciliary ganglia (CG) in <u>vitro</u> in a dose-dependent fashion. Growth cones (gc) produced in response to exogenously applied cAMP were not associated with neighboring non-neuronal cells as they grew out from CG explants on a collagen-coated substratum. This lack of non-neuronal association exhibited by nucleotide-induced gc was in sharp contrast to the consistent non-neuronal association observed for produced by treatment with striated muscle-conditioned medium (StCM). Cyclic nucleotides maintained neurites for up to 72h, whereas StCM supported neurites for more than one week. We have examined further the responses of CG to cAMP and StCM. Simul-taneous treatment of CG with (But)<sub>2</sub>CAMP and StCM had non-additive effects on neurite number and length as well as non-neuronal effects on neurite number and length as well as non-neuronal outgrowth. The gc of neurites in these cultures were either directly associated with non-neuronal cells or isolated. Se-quential treatment of CG with StCM for 48h followed by treatment with (But)\_cAMP resulted in displacement of the non-neuronal-gc associations formed in response to StCM. To examine the effects of cAMP and StCM on polyamine biosynthesis in CG, the levels of ornithine decarboxylase (ODC), the rate-limiting enzyme in this synthetic pathway, were determined. Treatment with (But)\_cAMP elevated CG ODC activity whereas StCM, although highly neurito-genic, did not. We have been examining the effects of several substrata on CG neuritogenesis, including primary and established genic, did not. We have been examining the effects of several substrata on CG neuritogenesis, including primary and established monolayers. To investigate the role of non-neuronal cells in CG neuritogenesis and to test the specificity of the non-neuronal cell association of StCM-stimulated gc, organized and dissociated CG were plated on monolayers of 1929 fibroblasts in the presence or absence of StCM. In these experiments, no neuritogenesis was observed. StCM pre-treatment of L929 monolayers for 24h to parmit adcorption of neurito-promotion factors did not enhance observed. StCM pre-treatment of L929 monolayers for 24h to permit adsorption of neurite-promoting factors did not enhance CG neuritogenesis, as has been shown for poly-DL-ornithine (PORN) substrata. Currently, we are comparing the neurite pro-moting activity of cAMP with the PORN-adsorbable component of StCM. Although StCM and cAMP both stimulate CG neuritogenesis, our evidence suggests that they are acting via divergent morbanisme mechanisms Supported by NIH grant NS11299.

192.12 EVIDENCE FOR BIOCHEMICAL SEPARATION OF MORPHOLOGIC AND CHOLIN-ERGIC-ACTIVE TROPHIC FACTORS FROM EXTRACTS OF NEWBORN RAT

SKELETAL MUSCLE, R.G. Smith\*, J. McManaman\*, and S.H. Appel. Dept. of Neurology, Baylor College of Med., Houston, TX 77030. We have previously reported the existence of trophic substances extracted from newborn rat skeletal muscle that promote neurite elongation and enhance cholinergic activity in cultures neurite erongation and enhance choinergic activity in cultures of dissociated 14-day embryonal rat ventral spinal cord. We have also described how these factor-stimulated activities are differentially regulated as a function of the age and innerva-tion-denervation state of the rat from which the extract is prepared. We now report that polypeptides mediating morpho-

logical and cholinergic effects are biochemically distinct. The morphological and cholinergic factors are quantitatively The morphological and cholinergic factors are quantitatively different with respect to their sensitivities to inactivation by heat and trypsin. The neurite inducing activity is labile to heating at 60°C with half-maximal loss at 10 minutes, and to trypsin (0.1 mg/ml at 37°C) with a  $t_2$  of approximately 45 minutes. In the same skeletal muscle extracts, at the same test concentrations, the cholinergic factor activity is lost at 60°C with a  $t_2$  of 30 minutes, and inactivated by trypsin with a  $t_2$  of 15 minutes. At pH between 8 and 10, the cholinergic factor is stable, while the morphological factor is ranidly inactivated 15 minutes. At pn between o and 10, the thornergic factor is stable, while the morphological factor is rapidly inactivated. Following chromatography on Sephacryl S-200, a single peak of Following chromatography on Sephacryl S-200, a single peak of neurite inducing activity is recovered, with an apparent molecu-lar weight of 33-37,000 d. On isoelectric focusing, this activity peak elutes at a pI of 4.8. There is no cholinergic inducing activity associated with these fractions. At present, the neurite inducing activity has been purified more than 10,000-fold over the crude extract. The cholinergic stimulating activity is eluted in three different peaks, both by gel chroma-tography, and by isoelectric focusing. These cholinergically active factors are presently being further purified and charac-terized. (Supported in part by grants from the John A. Hartford Foundation and the Robert J. Kleberg and Helen C. Kleberg Foun-dation.) dation.)

# VISUAL CORTEX: INTRINSIC ORGANIZATION II

UPTAKE AND LAMINAR DISTRIBUTION OF TRITIATED ASPARTATE, GLUTAMATE, GABA AND GLYCINE BY NEURONS IN THE VISUAL CORTEX OF SQUIRREL MONKEYS: CORRELATION WITH LEVELS OF CYTOCHROME OXIDASE ACTIVITY. E.W. CARROLL\* and M. WONG-RILEY (SPON: R.L. Curtis). Dept. of Anat Med. Coll. of Wis., Milwaukee, WI 53226. The laminar distribution of four putative neurotransmitters was compared in the wingle control of four putative neurotransmitters was 183.1

The laminar distribution of four putative neurotransmitters was compared in the visual cortex of squirrel monkeys to determine if any correlation existed between the cytochrome oxidase-rich re-gions and the neuronal uptake of these amino acids. Each of the four tritium labeled (<sup>3</sup>H) compounds: aspartic acid (ASP), glutamic acid (GLU), GABA and glycine (GLY), at concentrations of 2.5 to  $6\mu$ Ci/O.1-0.2µl/site, was injected into restricted zones within areas 17 and 18 of different animals. Perfused brain tissues were reacted for cytochrome oxidase (C.O.) and subsequently pro-cessed for autoradiography.

Cessed for autoralography. In general, radioactively labeled neurons that were C.O.-react-ive  $(C.O./^{3}H^{+})$  and C.O.-nonreactive  $(^{3}H^{+})$  were present in all laminae with each amino acid tested. The laminar distribution and density of  $^{3}H^{+}$  and C.O./ $^{3}H^{+}$  neurons were similar for the putative excitatory transmitters ASP and GLU; however, differen-ces existed between ASP/GLU, GABA and another putative inhibitory transmitter CIV

ces existed between ASP/GLU, GABA and another putative inhibitory transmitter, GLY. ASP/GLU In lam II and III, few neurons ( ${}^{3}\text{H}$ + or C.0./ ${}^{3}\text{H}$ +) were labeled with either ASP or GLU. An increase in labeled neurons ( ${}^{3}\text{H}$ + and C.0./ ${}^{3}\text{H}$ + and so observed for both amino acids in lam IV. The greatest number of labeled neurons were found in lam V and VI, with C.0./ ${}^{3}\text{H}$ + neurons more abundant in lam VI. Labeled fusiform (7x14µm) and stellate shaped neurons (8-20µm in diameter) were becaused within the various laming as were large ( ${}^{2}\text{Cym}$  in diameter).

 $(7x14\mu m)$  and stellate shaped neurons  $(8-20\mu m$  in diameter) were observed within the various laminae, as were large  $(25\mu m$  in diam.)  $C.0./^{3H+}$  pyramidal neurons in laminae V and VI. <u>GABA-labeled</u> neurons  $(C.0./^{3}H+$  and  $^{3}H+)$  were more prevalent in lam II than III. Preliminary analysis indicated that there were more  $C.0./^{3}H+$  neurons within the cortical C.0.-rich puffs. An increase in GABA labeled neurons  $(C.0./^{3}H+$  and  $^{3}H+)$  was observed in lam IV to lam VI, with the most prominent increase in lam V and VI. Labeled neurons  $(C.0./^{3}H+$  and  $^{3}H+)$  in these and other laminae included fusiform  $(8x17\mu m)$  and stellate neurons  $(8-15\mu m)$ .

VI. Labeled neurons (C.0./<sup>3</sup>H+ and <sup>3</sup>H+) in these and other laminae included fusiform (8x17µm) and stellate neurons (8-15µm). <u>GLY</u> Significantly more neurons (C.0./<sup>3</sup>H+ and <sup>3</sup>H+) were labeled with <u>GLY</u> than with the other amino acids. These neurons were more uniformly distributed throughout all cortical laminae. They included fusiform and stellate neurons of all sizes from lam II to VI, a distinct row of large fusiform-shaped neurons (C.0./<sup>3</sup>H+) in lam IVB, and large C.0./<sup>3</sup>H+ pyramidal neurons at the V-VI border. Preliminary results in area 18 suggested that the distribution and differential uptake observed in area 17.

GLUTAMIC ACID DECARBOXYLASE IMMUNOREACTIVE NEURONS AND TERMINALS 183.2 IN THE VISUAL CORTEX OF MONKEY AND CAT. <u>D. Fitzpatrick\*</u>, <u>J.S. Lund, D. Schmechel</u>. Ophthalmology Research, Medical University of South Carolina, Charleston, South Carolina and Division of Neurology, Department of Medicine, Duke University, Durham, North Carolina 27706.

Considerable evidence supports the idea that GABA mediated inhibition plays an important role in shaping the response properties of visual cortical neurons, yet we know little about the morphology, distribution, frequency and connectional relations of GABAergic cortical neurons. In this study we have examined the distribution of neurons and terminals which are immunoreactive for glutamic acid decarboxylase (GAD), the synthesizing enzyme for GABA, with in the visual cortex of squirrel monkey and cat. GAD immunoreactive terminals and axon dilatations are found

in all layers of the cortex and are frequently found surrounding the somata of both immunoreactive and non-immunoreactive neurons. In both species, cytochrome rich geniculate recipient zones are distinguished from other cortical layers by the presence of distinctly larger immunoreactive terminals; and, in and, in

the squirrel monkey, this distinction also applies to the geniculate recipient patches of layer 3. GAD immunoreactive somata are present in all layers and constitute 8-15% of the neurons. No clearly identifiable glial cells appeared to be immunoreactive. The proportion of GAD immunoreactive neurons remains relatively constant across layers. For example, there is no significant difference in the proportion of GAD immunoreactive neurons in geniculate recipient vs. non-geniculate recipient zones (including the layer 3 vs. non-geniculate recipient zones (including the layer 3 patches in the monkey). However there are obvious laminar differences in the sizes of GAD immunoreactive neurons, with particularly large neurons occuring in layers 4A, 5 and 6 in the cat, and layers  $4C\alpha$  and 6 in the monkey. The largest neurons in monkey striate cortex (those in 4B and in the upper part of layer 6) are not found to be GAD immunoreactive. Laminar differences in the sizes of GAD immunoreactive terminals and cell bodies suggest that GAD neurons may comprise a batemore neuron of the size of the terminal section.

a heterogeneous population and may be the source of an inhibitory circuitry that is unique for different laminae. Supported by EY03221 and EY05543.

- 183.3 THE EFFECT OF IMPULSE BLOCKAGE ON CYTOCHROME OXIDASE ACTIVITY IN THE MONKEY VISUAL SYSTEM. <u>M. Wong-Riley and E. Carroll\*</u>. Dept. of Anat., Med. Coll. of Wis., <u>Milwaukee</u>, Wi 53226.
  - Neurons in the visual system are particularly sensitive to sensory deprivation and environmental alterations. Recently, we found that the blockage of impulse transmission with intravitreal injections of tetrodotoxin (TTX) could lead to significant though reversible changes in cytochrome oxidase (C.O.) activity in the <u>adult</u> cat visual system (Wong-Riley & Riley, '83). The present study sought to extend the findings to the primate, where C.O.-rich zones have been characterized by others (Horton & Hubel, '80, Humphrey and Hendrickson, '80) and ourselves.

present study sought to extend the findings to the primate, where C.O.-rick zones have been characterized by others (Horton & Hubel, '80, Humphrey and Hendrickson, '80) and ourselves. Adult Macaque monkeys were anesthetized and were monocularly injected with 19ug TIX in 10ul D.W. every 3-4 days. Survivals ranged from 3 days to 4 weeks. Perfused brains were then processed for cytochrome oxidase histochemistry. In the normal retina, the large ganglion cells were usually much more reactive than the medium and small ones. Sublamina b (presumed ONcenter; Nelson et al., '77) of the inner plexiform layer (IPL) was frequently more reactive than sublamina a (presumed OFcenter), with a relatively clear zone in between. Horizontal cells were highly reactive, as were the photoreceptor inner segments, the cone pedicles and the outer plexiform layer. The pattern of reactivity in TIX-treated retinae was similar to the normal, with a slight decrease in the ganglion cell axons which were previously quite reactive. In the normal lateral geniculate nucleus (LGN), magno layers 1 and 2 and parvo layer 6 were the most reactive, followed by layer 5, while layers 3 and 4 were the least reactive. Thus, the ON-center layers 3 and 6 (Schiller & Malpeli, '78) were more reactive than the OFF-center layers. TIXtreatment resulted in reduced C.O. activity in the LGN laminae innervated by the injected eye. However, changes were more marked on the lpsi - than the contral ateral slde. Within the strlate cortex, TIX treatment induced a pattern of alternating light and darkly reactive bands in lamina IV C, as well as alternating rows of dark puffs and smaller, lightly reactive puffs in laminae lilightly reactive puffs in 11-111 with light bands. In IVA and IV C, and the darkly reactive puffs with dark bands. Changes in the LGN and area 17 could be seen as early as 3 days post injection. Thus, neurons of the adult primate visual system remain extremely sensitive to the pattern of impulse activity arising at the primary afferent level. In th 183.4 TANGENTIAL ORGANIZATION OF THE SEROTONERGIC INNERVATION OF PRIMATE VISUAL CORTEX. B.E. Kosofsky, M.E. Molliver, M.S. Lewis\*, and H.G.W. Lidov. Department of Cell Biology and Anatomy, Johns

and H.G.W. Lidov. Department of Cell Biology and Anatomy, Johns Hopkins University School of Medicine, Baltimore, MD 21205. The cerebral neocortex consists of a tangentially continuous sheet of grey matter in which the neurons with a particular morphology and density form horizontal layers that have characteristic afferent and efferent connections. The functional units of cortical signal processing are vertical columns in which the cells of each layer subserve a particular role in cortical circuitry. In an effort to determine which neuron sets are directly influenced by raphe-cortical serotonergic axons we have employed PAP immunocytochemistry with an antibody directed agains 5hydroxytryptamine (5-HT) to investigate the axonal morphology and ultrastructural specializations which characterize the serotonergic innervation of the visual cortex of Cynomolgus monkeys.

In primary visual cortex, 5-HT-positive axons display a sharply demarcated laminar distribution that varies in the density, morphology and predominant orientation of constituent fibers, and that is in register with the cytoarchitectonic layers. Within each cortical layer the density of axons is uniform throughout area 17, and we were unable to detect tangential periodicity in the distribution of fibers. A dense plexus of finely ramified 5-HT processes in lamina IVA, IVB and IVCa suggests the presence of a localized zone of terminal innervation in these layers. This zone is bordered above by the lower density plexus of layers II-III where fibers of oblique orientation predominate, and below by the sparsely innervated layer IVC $\beta$  where the fibers are predominantly radial in orientation. In contrast to the low density in IVC $\beta$  there is a dense tangential plexus of fibers in VA. This distribution of 5-HT fibers contrasts with that in the Squirrel monkey where the highest density of 5-HT axons extends throughout layer IVC and no fibers are found in layer V (Morrison, et al. PNAS 79 (1982) 2401-2405). Varicosities are distributed along 5-HT fibers with much greater spacing in the primate than in the rat. In area 17 of Cynomolgus, we have observed laminar differences in the density of varicosities (e.g., high in VA; low in IVB); the density does not vary in direct proportion to axon density. Ultrastructural examination reveals that 5-HT varicosities form typical synaptic contacts with asymmetric membrane specializations. While there are species differences in the specific sites of termination, we conclude that in area 17 serotonin input selectively and differentially influences vertically restricted neuronal elements in a tangentially continuous fashion. The laminar precision in each species together with the presence of specialized synaptic contacts provide further support for a high degree of anatomic specificity in the sites of serotonergic action in the neocortex. 183.5 GENICULOCORTICAL AFFERENTS IN THE MINK: EVIDENCE FOR ON/OFF AND OCULAR DOMINANCE PATCHES. S.K. McConnell and S. LeVay, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The mink's lateral geniculate nucleus contains a pair of A layers innervated by the contralateral eye and a pair of Al layers innervated by the ipsilateral eye. Of each pair, one layer contains on-center cells and the other off-center cells (LeVay and McConnell, Nature 300:350, 1982). We have gone on to examine how these four sets of geniculate afferents terminate in area 17. The distribution of left and right eye afferents was first examined by autoradiography following transneuronal transport of <sup>3</sup>H=proline injected into one eye. In the binocular regions of areas 17 and 18, label was distributed in a patchy fashion, suggesting the presence of ocular dominance columns. Contralateral eye columns were wider than ipsilateral columns (500 µm vs. 300 µm), nervated layers of the LGN. The monocular region of area 17 was proportionately larger than that of the cat or monkey; this correlates with the mink's more extensive monocular field of view. To study the distribution of geniculate afferents physiolog-

To study the distribution of genicitate alternets physical ically, we recorded from their terminal arborizations in layer IV of area 17 after silencing all cortical neurons in the vicinity with injections of 0.1% kainic acid. (This technique was developed by Helen Sherk.) In this situation, neural activity was almost entirely restricted to layer IV. Here multiple units were commonly recorded simultaneously; these showed fast spikes and a high spontaneous level of firing. When single units could be distinguished, they were monocular and had a center-surround organization. This activity presumably arises from geniculate afferents in layer IV. During tangential penetrations through layer IV, aggregate receptive fields advanced in an orderly fashion through the visual field, often showing changes in position after steps of as little as 25 µm. In these penetrations we encountered periodic shifts in ocular dominance consistent with the results from autoradiography. Although the centers of ocular dominance patches were monocular, transitions from one eye to the other were gradual In addition, there were stretches during which responses were exclusively or predominantly on- or off-center. On and off patches were also found to alternate, with stretches of mixed activity between them. Reconstructions from parallel tangential penetrations indicated that these patches extended the full thickness of layer IV. They were about 100-300 µm in width, i.e. somewhat smaller than ocular dominance patches.

These results indicate that in the mink the segregation of responses according to both sign of contrast and eye of origin is maintained up to the level of layer IV of visual cortex. Supported by N.I.H. EY-ROI-1960 and N.S.F. SPI81-6637. 183.6 LAYER 6 CELLS PRIMARILY CONTACT SMOOTH AND SPARSELY SPINY NEURONS IN LAYER 4 OF CAT STRIATE CORTEX. B.A. McGuire, J.P. Hornung, C.D. Gibert and T.N. Wiesel. (Department of Neurobiology, Har-vard Medical School, 25 Shattuck St., Boston, MA 02115, U.S.A.) The main afferent input to layer 4 of striate cortex is from the lateral geniculate nucleus (LGN), but the neurons in this layer also receive a substantial input from axon collaterals of layer 6 cells. We have studied the layer 6 to layer 4 pathway ultrastructurally to help determine how this input may influence the functional properties of cells in layer 4. Intracellular recordings were made from layer 6 neurons, their receptive fields were characterized, and the cells were then injected with horse-radish peroxidase. After processing the tissue for light and electron microscopy, we reconstructed each cell and chose a por-tion of its axonal arbor in layer 4 for serial thin sectioning. Labeled axon terminals and their postsynaptic processes were identified by serial EM reconstruction. Compared to injected LGN terminals, which possessed repeated swellings making synaptic terminals, which possessed repeated swellings making synaptic contacts en passant, the layer 6 terminals were smaller, each typically projecting off the parent axon collateral by a narrow (0.1-0.2 um) stalk and making a single asymmetric synaptic con-tact containing round vesicles. Sampling 138 synapses made by axon collaterals of 2 cells, we found that 71% contacted dendri-tic shafts and 29% contacted spines. This pattern is the reverse of that seen for the geniculocortical afferents of which 80% end of that seen for the geniculocortical afferents, of which  $80\,$  end on spines and  $15\,$  on dendritic shafts . We have thus far characterized 57 postsynaptic dendrites and subdivided them into 3 classes based on differences in spine frequency, density of synaptic inputs, and dendritic morphology: (1) beaded dendrites (10 cases), (2) smooth and sparsely spiny dendrites (40 cases), and (3) spiny dendrites (7 cases). Our finding that layer 6 cells form asymmetric synapses, and the presence of high affinity uptake of aspartate suggest an excitatory effect on layer 4 cells. The great majority (50 out of 57) of the identified postsynaptic dendrites belonged to smooth and sparsely spiny stellate cells, which are thought to be inhibitory. Thus, the overall effect of the layer 6 to layer 4 pathway is likely to be inhibitory, even if there was also some direct excitatory input to spi-ny stellate cells. In this pathway, one possible role for layer 6 cells with very long receptive fields could be to produce the property of end-inhibition via non-spiny stellate cells. TWO RESTRICTED LAMINAR LOCI IN MACAQUES MAY ALONE SUBSERVE 183.7 THRESHOLD DETECTION OF MICROSTIMULATION IN STRIATE CORTEX.

TWO RESTRICTED LAYINAR LOCI IN MACADURS WAY ALONE SUBSENCE THRESHOLD DETECTION OF MICROSTIMULATION IN STRIATE CORTEX. <u>Eduar A. Devoe and Robert W. Doty</u>, Center for Brain Research, University of Rochester, Rochester, NY 14642 Electrical stimulation applied to the surface of striate cortex in man is known to elicit a simple, specific visual sensation, the phosphene. Since the physiological basis of this phenomenon is obscure, and since the macaque and human visual systems are so sinilar, we have investigated the physiological and behavioral effects of comparable stimulation applied within striate cortex of monkeys trained to respond when a detectable sensation(?) is thus electrically induced. Optimal, cathodal, constant current trains of 30, 0.2-msec. pulses, 100 Hz were presented via glass-insulated, Pt/Ir microelectrodes advanced "step-wise perpendicularly through cortex. At any location transition from non-detection (<10%) to complete detection (>90%) occurred over a current range  $\pm 16.5\%$  of threshold (50% detection). Electrode tip positions relative to the cortical laminae were determined with the aid of two electrophysiological indices: level of multiunit activity (taken as 2X the standard deviation of a 100-msec. sample a 16 KH2), which reached a maximum in layer 4C (terminology of Lund, J. Comp. Neurol. <u>147</u>: 455, 1973), and diminished abruptly in layer 5; and the appearance of an early positive peak in the flash evoked potential at the transition between layers 4 and 5. Consolidating these data with histological verification, two minima (1-5uA) in threshold for stimulus detection were revealed, one in lower these data with histological verification, two minima (1-5uA) in threshold for stimulus detection were revealed, one in lower layer 3/upper 4, the other in layer 5. In other layers, significantly higher currents (up to the maximum 25 uA tested) were required. In 16 complete penetrations, the average lowest and highest thresholds differed from the mean within a given penetration by -35% and +75%, respectively. Taking the data of Stoney et al. (J.Neurophysiol.<u>31</u>:659,1968) on the relative excitability of pyramidal cells as a function of distance from the source of microstimulation, it can be calculated that only two bands of excited elements, at the junction of layers 3 and 4, and in layer 5 could account for the average pattern of detection thresholds in the present experiments; all higher thresholds mercly reflecting current values required to affect these elements from a distance! The additional assumption of restricted "columns" of excited elements, perhaps related to the inhomogeneites revealed by cytochrone oxidase histochemistry (e.g. Humphrey and Hendrickson, J.Neurosci.<u>3</u>:345,1983), could account for significant absolute differences observed from one individual penetration to another. (Supported by NIH grant NS these data with histological verification, two minima (1-5uA) in individual penetration to another. (Supported by NIH grant NS 16180.)

183.8

DIFFERENTIAL EFFECTS OF UNIFORM AND RANDOM-NOISE BACKGROUNDS ON THE ONGOING ACTIVITY AND EVOKED RESPONSES OF NEURONS IN FOVEAL A17 AND A18 OF THE MACAQUE. Y. Trotter\*, S. Squatrito\*, B.C. Motter\* and G.F. Poggio, - Bard Laboratories of Neurophysiology, Dept. of Neuroscience, Johns Hopkins Sch. of Med., Baltimore, MD 21205. We have investigated the effects of uniform (dark & luminous) and dynamic random-dot backgrounds on the ongoing activity and binocular responses of neurons in foveal striate and prestriate cortex of rhesus monkeys trained to fixate on a small target. Background fields subtending 5° square were centered over the re-ceptive field of the neuron under observation. Stimulus bars of optimal size and orientation, moving bidirectionally across the field, were superimposed on the background which was continuously present both during and in between behaviorally controlled fixa-tion trials. The position of the eyes was routinely measured. Following onset of the monkey's attentive fixation of the tar-get, the ongoing activity of more than 50% of the cells (N = 238) was differentially affected by the background. More frequently (44%), the neuron's maintained discharge rate was considerably higher in the presence of a textured background than a uniform one. In only 9% of the neurons, the uniform background specifically affected the ongoing activity. Moreover, for many cells (35%), the activation by visual noise was present also in the intertrial period of relaxed uncontrolled oculomotor behavior. The effect of background on cortical activity may change when the animal shifts from the relaxed to the attending behavior. For noise background, we observed an increase in or the onset of high maintained activity at the time of the shift in 17% of foveal neurons, and changes to a higher or lower discharge rate were seen almost as frequently in other neurons to accompany the behavioral shifts in the presence of a uniform background. An effect of the dynamic visual noise on the response to a

shifts in the presence of a uniform background.

An effect of the dynamic visual noise on the response to a moving bar was observed for 60% of neurons. Most frequent and dramatic was a significant reduction or the complete disappearance of the response in the ongoing activity (48%). In a few neurons (8%) the response was enhanced by the noise, being larger and briskier when evoked on the textured background than on the uniform one. Rarely (4%) the noise background revealed an inhibitory response to a bar which evoked an excitatory response when presented on a uniform background.

These findings emphasize the importance of the whole visual scene on the activity of visual cortical neurons and the need to consider static and dynamic aspects of both the visual scene and the attending behavior in any attempt to interpret processing of visual information by neurons. (Supported by NIH grant EY02966.)

183.10 SPATIAL AND TEMPORAL FREQUENCY SELECTIVITY OF NEURONS IN V1 AND V2 OF THE MACAQUE MONKEY. <u>K.H. Foster\*</u>, J.P. Gaska\*, <u>M.</u> Nagler\*, and D.A. Pollen. Barrow Neurological Institute, Phoenix, AZ 85013. The spatial and temporal frequency selectivity of over 230

neurons in V1 and V2 of the macaque monkey (Macaca fascicularis) was studied using sine-wave gratings of suprathreshold contrast drifting over the receptive field at the preferred orientation and direction. Neurons in V1 and V2 were selective for different but partially overlapping ranges were selective for different but partially overlapping ranges of the spatial frequency spectrum. At a retinal eccentricity of  $2^{0}-5^{0}$  from the forea, the spatial frequency preferences for neurons in VI ranged from 0.5-8.0 c/deg with a distribution of spatial frequency preferences and bandwidths essentially similar to the results of De Valois et al. (Vision Res. 22, 545, 1982) based upon estimates of contrast sensitivity. However, spatial frequency preferences at this same retinal eccentricity in V2 word from (0.26 c/deg 28 c/deg on upon contract should 2) ranged from  $\langle 0.25 \rangle$  c/deg-2.8 c/deg and were, on average, about 2 octaves lower than in V1. Bandwidths in the two cortical areas were similar and ranged from 0.8-3.0 octaves.

Temporal frequency selectivity was low pass (down to 0.5 Hz) for 70% of neurons in V1 with little fall-off at high temporal frequencies until drift rates generally exceeded 4-5.6 Hz. Even the 30% of neurons in V1 with bandpass temporal tuning were most often very broadly tuned with a mean full bandwidth of 2.9 octaves. On the other hand, 70% of the neurons in V2 had bandpass temporal frequency characteristics with a mean full bandwidth of 1.8 octaves. Peak drift frequencies in V1 and V2 generally ranged from 1-8 Hz. Furthermore, at any given spatial frequency some examples of bandpass temporal frequency selectivity were found for neurons in V1 as well as in V2. The range of preferred temporal frequencies and their corresponding bandwidths suggest that there are at least two non-overlapping temporal filters at each spatial frequency.

These results in the macaque are surprisingly similar to those reported for the cat (Movshon et al., J. <u>Physiol.</u> 283, 101, 1978; Berardi et al., <u>J. Physiol.</u> 323, 603, 1982) in view of the differences in the <u>geniculocortical</u> projections within the two species. Moreover, the present results may provide a physiological substrate for psychophysical results in man which suggest several independent detector mechanisms centered at different temporal frequencies (Watson and Robson, <u>Vision Res.</u> <u>21</u>, 1115, 1981), especially at low spatial frequencies (Bowker and Tulunay-Keesey, <u>J. Opt. Soc. Am.</u> <u>73</u>, 427, 1983). Supported by NIH grant EY03290.

183.9 BINOCULAR INHIBITORY MECHANISMS IN STEREOSCOPIC PROCESSING. Jill <u>C. Gardner</u>, Research Laboratory of Electronics, Massachusetts Institute of Technology, Bldg. 36-864, Cambridge, Mass. 02139 In the combination of input from the two eyes, neurons in area 18 and the 17/18 border of the cat show widespread binocular inhibition. In normal animals, the large role played by inhibitory mechanisms in determining the disparity-sensitive response of visual cells was seen in binocular interactions to two types of depth-related stimulus motion. Stimuli moving in the same direc-tion on the two retinae (in-phase) represented sideways motion at different distances from the animal while stimuli moving in oppo-site directions on the two retinae (antiphase) represented motion toward or away from the animal or motion in depth. Examining disparity-sensitive responses across these two movement conditions showed that binocular interactions to in-phase moving stimuli were characterized by strong direction selective inhibition in the preferred direction of motion and that they were significantly larger than interactions to antiphase stimulus motion (p<.005). When the facilitatory and inhibitory components of the binocular responses were analyzed separately, it was seen that differences between the two movement conditions were due exclusively to differences in levels of binocular inhibition (p<.001). No differences were seen between the distributions of binocular facilitation.

The significance of binocular inhibitory mechanisms in the development and function of stereoscopic processing was further illustrated in experiments examining the disparity-sensitivity of cells in cats in which normal binocular connectivity had been dis-rupted. Units in area 18 of animals reared with a neonatallyrupted. induced strabismus and units along the 17/18 border of cats with unilateral lesions of the visual cortex showed a reduction in Unliteral lesions of the visual cortex showed a reduction in sensitivity to binocular retinal disparity in conjunction with significant decreases in the strength of binocular inhibition (px.01 and px.025 respectively). In all preparations studied, the distributions of binocular excitation were matching, and were cen-tered around the point of summation of the 2 eyes independent monocular responses. Inhibitory interactions were much more pro-nounced than facilitatory interactions and consistently reduced responses to below levels evoked by monocular stimulation. These results indicate that in the determination of disparity-specific responses, it is binccular inhibition which is the

crucial process. Although disparity signals may be generated by facilitatory responses, binocular inhibitory mechanisms appear to play a fundamental role in influencing the structure of stereo-scopic systems. Since a unit's selectivity for stimulus disparity can be modified by experience, the data suggest that during the cat's early development, it is the inhibitory binocular connec-tions which are the plantic unit. tions which are the plastic ones.

183.11 SPATIAL PHASE DEPENDENCE OF CORTICAL VISUAL NEURON RESPONSES TO CONTRAST REVERSAL GRATINGS IN THE CAT.

<u>S. Hochstein and H. Spitzer\*</u> Institute of Life Sciences, Hebrew University of Jerusalem, Jerusalem 91904 ISRAEL.

Cortical visual neurons have been classified as Simple or Complex on the basis of their performing linear or nonlinear spatial summation. This classification is analogeous to that of retinal ganglion and lateral geniculate neurons into the  ${f x}$ and Y cell types, respectively. We now demonstrate dramatic differences betweeen the receptive field characteristics of Y-cells and those of cortical Complex cells. Specifically all retinal ganglion and lateral geniculate Y-cells in the cat lack a spatial phase dependence in their responses to high spatial frequency contrast reversal gratings, though at low spatial frequencies a linear aspect of their receptive fields introduces some spatial phase dependence. In the cortex, on the other hand, a distinct spatial phase dependence was found for nearly all cells studied, even those classified as Complex because of nonlinear spatial summation. The degree of spatial phase dependence is often a function of the spatial frequency of stimulation. A receptive field model is presented which may explain the mechanism underlying these stimulation dependent effects.

183.12 DIRECTION SELECTIVITY IN VISUAL CORTICAL NEURONS OF THE IMMATURE RABBIT. E. H. Murphy, A. M. Grigonis\*, and G. J. Zingaro\*. Dept of Anatomy, The Med. Coll. of Pennsylvania, Phila., PA 19129. Previous studies from this laboratory have demonstrated that

Previous studies from this laboratory have demonstrated that many of the neurons of the primary visual cortex of the rabbit show orientation selectivity (OS), and virtually all (95%) of these cells also show direction selectivity (DS). Following early deprivation of visual experience, OS changes little, but the percentage of DS is significantly lower in strobe reared rabbits (40% DS), and in lid sutured rabbits (70% DS), compared with normals.

In the present study, in order to determine whether this reduced DS in deprived animals represents a failure in development or a breakdown of established organization, we have studied DS in visual cortical neurons of immature, normally reared pups. Some visually responsive cells are present at the time of eye opening (11 days), but OS is not observed until day 17. From the age of 17 days on, the percentage of cells with OS receptive fields increases rapidly, reaching adult levels by day 30, but the percentage of these cells which are also DS is approximately 70% throughout this time period. Thus, in normally reared animals aged less than 30 days, DS is significantly lower than that observed in the normal adult, significantly higher than that observed in the strobe reared adult.

observed in the lid sutured adult. The results suggest that the population of DS cells observed in the mature adult comprises several subsamples of cells which respond differently to experimental manipulation of sensory experience: some fail to develop DS, some lose DS, and some maintain DS despite abnormal early experience. The results also indicate that the normal development of DS in the rabbit visual cortex extends into the 2nd postnatal month, after the time that OS appears to have reached mature levels. Thus, DS develops later than OS and is more susceptible to the effects of early deprivation.

183.13 INFORMATION FLOW THROUGH SINGLE CELLS OF CAT STRIATE CORTEX. B. Bridgeman and J. Artim\*, Vision Research Laboratory, U. of Ca., Santa Cruz, CA 95064. Most studies of single neurons in sensory systems have failed to present stimuli with information value to the experimental animal. We have compared responses of cat striate cortex neurons to informative and to non-informative stimuli. A cat learned to press a pedal in response to a flashed stimulus (a 20 msec pattern of random lines) repeated every 10 sec, receiving a soymilk reward if the press was within a 0.5-1.5 sec post-stimulus window. After overtraining on this task, hardware was surgically implanted to allow extracellular single unit recording from the awake and behaving animal. There were 3 trial types: 50% of the trials had only the initial informative flash, 25% had an additional physically identical but unrewarded flash 3-5 sec after the informative flashs. Neurons were divided into two categories: 27 that exhibited a primary response (30-70 msec post-stimulus) and 17 that did not. The distinction was arbitrary since all cells were exposed to the same flashed stimulus.

Neural firing rates varied with stimulus information content, momentary state of alertness, and behavioral response. Cells which exhibited a primary response also showed enhanced responses for the rewarded flashes compared to the randomly timed unrewarded flashes. The latency to peak response for the rewarded presentations was 10 msec less than for the randomly interspersed unrewarded stimuli. Additionally, the informative flashes showed a 21% enhancement in peak firing rate compared to the 500 msec delayed flashes. Background activity also changed with reward contingencies. Backward averaging synchronized with the behavioral response showed a decrease in unit firing ranging from 34% to 74% in the 100 msec before the pedal press. The results show that firing of striate cortex neurons is modified by task variables and by information content of stimuli, even when stimulus parameters remain constant.

INCREASED TRANSLATIONAL PREINITIATION COMPLEX FORMATION 184.1 EFFICIENCY WITH S40 RIBOSOMAL SUBUNITS ISOLATED FROM INDUCED DIFFERENTIATED NEUROBLASTOMA CELLS. K. Fan, Depts. of Pathology and Medical Research, VA Medical Center, Little Rock, AR 72206.

Cultured neuroblastoma cells can be induced to morphological and biochemical differentiation by chemical such as dibutyryl cyclic-AMP (db-cAMP), cAMP or serum-deprivation. In an attempt to study whether there is translational regulatory mechanism in operation during the induction stage of differentiation, experiments were conducted to study the efficiency of the preinitiation complex (Met-tRNAf.eIF2.GTP.S40 subunits) formation using S40 subunits isolated from db-cAMP induced differentiated mouse neuroblastoma 2a cells, as compared with the S40 subunits isolated from neuroblastoma cells not exposed to db-cAMP, i.e., undifferentiated cells. The Met-tRNAf was isolated from Spraque-Dawley rat livers and in-vitro charged with <sup>35</sup>S-methionine, mediated by E. coli Met-tRNA synthetase. The initiation factor  $(eIF_2)$  was also purified from the rat livers. During experiments, two independent steps were carried out: Step 1 was to form the initiation ternary complex (355-Met-tRNAf.eIF2.GTP) in buffer (20 mM Tris-HCl, pH 7.2, 100 mM KCl, 1 mM dithicthreitol, 0.1 mM MgCl<sub>2</sub> containing 15 µg eIF<sub>2</sub>, 4.5 mM GTP and approximately 50,000 CPM <sup>35</sup>S-Met-tRNA<sup>4</sup> (3000 cpm pmol<sup>-1</sup>). After 7 minutes at 37°C, 2 0.D.<sub>260</sub> S40 ribosomal subunits isolated from differentiated and undifferentiated cells were added into the 0.2 ml reaction mixture (Step 2). After Mg<sup>++</sup> concentration was adjusted to 2 mM, the reaction mixtures were further incubated at  $37^{\circ}$ C for 15 minutes, then applied onto a 10-30 percent sucrose gradient (50 mM Tris-HCl, pH 7.6, 4 mM MgCl<sub>2</sub>, 50 mM KCl and 1 mM dithiothreitol). After centrifugation, the fractions contained the  $^{35}$ S-Met-tRNA<sub>f</sub> S40 complex were collected and the radioactivity determined. Alternately the reaction mixtures were washed onto Millipore HA type filters and the retainable radioactivity determined. Findings indicated that 3-fold higher preinitiation complex formation efficiency was observable when the S40 subunits isolated from db-cAMP induced differentiated cells were used, as compared with S40 subunits isolated from undifferentiated

cells. The findings suggest that there is a translational regulatory mechanism in operation during differentiation stage of neuro-blastoma; for the present study, probably via a cAMP-dependent phosphorylation of the S40 ribosomal subunits. Supported by VA Medical Research Service, Little Rock.

184.3 INTRODUCTION OF TORPEDO ACETYLCHOLINE RECEPTOR GENES INTO MAMMALIAN CELLS. T. Claudio\*, M.J. Palazzolo\* and R. Axel\* (SPON: J. Goodrich). Inst. of Cancer Res., Columbia Univ., New MAMMALIAN CELLS. York, N.Y. 10032.

We are using gene cloning and gene transfer to study the structure and function of individual acetylcholine receptor subunits as well as the biosynthesis, assembly and physiology of the nicotinic acetylcholine receptor complex. The expression of exogenous acetylcholine receptor genes in recipient cells first requires that we clone the genes encoding each of the four subunits, construct appropriate vectors which facilitate their expression and introduce these genes into recipient cells where their function may be analyzed. To this end we have constructed a library of CDNA clones synthesized from the messenger RNA of the electric organ of <u>Torpedo californica</u>. We have isolated clones which contain the entire structural gene sequence of each of the four subunits (probes for two of the genes were generously provided by D. Noonan, D. Hershey, K. Mixter and N. Davidson). These clones were then inserted into a eucaryotic expression We are using gene cloning and gene transfer to study the vector which places the genes under the control of the SV40 early promoter. This vector further contains an SV40 origin early promoter. This vector further contains an SV40 origin of replication allowing the replication of these recombinant molecules to high copy number in recipient cells which express T antigen. This gene transfer system allows for transient replication and transcription of donor genes and provides a rapid means of analysis of receptor gene expression. In a seperate series of experiments, we have constructed stable seperate series of experiments, we note constituted stable mouse cell lines containing the four exogenous Torpedo subunit genes by cotransformation. We are currently analyzing the expression of these genes. This system will allow us to analyze the various properties of wild type receptor as well as allow us to make specific mutations in the genes and unified their effects of protection for the set. examine their effects on receptor function.

MOLECULAR GENETICS OF THE MYELIN BASIC PROTEIN SYSTEM OF THE 184.2 Molecolar densities of the Might Barle Holer Noising of the RATY A. H. Roach\*, S. B. Frusiner<sup>1</sup> and L. E. Hood\* (SFON: F. Strumwasser). Div. of Biology, Calif. Inst. of Technology, Pasadena, CA 91125, and <sup>1</sup>Dept. of Neurology, Sch. of Medicine, Univ. of California, San Francisco, CA 94143. Myelin basic proteins (MEPs) are a family of highly basic

(pI>10), abundant proteins found in myelin, related in sequence but differing in size. They are thought to play a structural role, and are an autoimmune antigen in the demyelinative dis-ease multiple sclerosis. While many species appear to have a single MEP, rat and mouse have two major forms, differing only by the presence or absence of 40 amino acids at a site 13 res-idues from the C-terminus (reviewed in Carnegie, P. and Moore, W. in <u>Proteins of the Nervous System</u>, Bradshaw, R. and Schneider, D. (eds.) Raven Press, New York, 1980). Two additional minor D. (eds.) Rate frees, Ration (1997). The additional mining species in mouse have also been reported (Barbarese, E. et al, Proc. Nat. Acad. Sci. USA 74, 3360 (1977)). Synthetic oligonucleotides were used as a hybridization probe

to select CDNA clones encoding MBPs from a library constructed using brain RNA from myelinating 18-day-old rats. Several clones were examined in detail with the aim of understanding the origin of the multiple forms of MBP in the rat. cDNA clones of two classes were found, sharing homology by

restriction site mapping and nucleic acid hybridization over much of their length but being nonhomologous in their 5'-untranslated regions. A 1.5kb stretch from one of these 2kb cDNAs has been sequenced and contains the entire translated region for the small (M.W. 14,000) rat MBP, as well as more than 1kb of untranslated sequence. Sequencing of a cDNA clone of the other class is being undertaken to elucidate precisely the pattern of relat-

is being undertaken to elucidate precisely the pattern of relat-edness of the transcribed sequences. RNA blotting experiments show that MEP sequences are carried on polyadenylated RNAs of 2.1kb in length. In order to determine the gene organization, analysis of genomic sequences was performed by Southern blotting using cloned MBP-specific probes. These and other experiments dir-ected towards cloning the corresponding genomic sequences promise to explain the interesting relationship between the nroteins.

STRUCTURAL ANALYSIS OF THE GENES CODING FOR THE CATECHOLAMINE BIOSYNTHETIC ENZYMES. <u>E.E. Baetge, V.R.</u> Albert, H.M. Moon\*, D.H. Park, D.J. Reis and T.H. Joh, Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 1844

We have proposed that the catecholamine (CA) biosynthetic enzymes tyrosine hydroxylase (TH), dopamine-B-hydroxylase (DBH), and phenylethanolamine N-methyltransferase (PNMT) contain similarities in phenylethanolamine N-methyltransferase (PNMT) contain similarities in their primary protein structures, based on the following evidence: (a) antibodies specific for one CA enzyme <u>in vivo</u>, immunoprecipitated more than one enzyme from <u>in vitro</u> translation products, suggesting that the catecholamine <u>enzymes</u> possess common antigenic determinants, and implying similarities in protein structure. (b) Proteolytic fingerprinting and amino acid composition analysis of the purified enzymes revealed that the enzymes contain similar protein domains in their primary structure. domains in their primary structure. To further test this hypothesis, mRNAs for the CA enzymes DBH

and PNMT were partially purified from bovine adrenal and used for the synthesis of complementary DNA. Recombinant DNA molecules were Synthesis of complementary DNA. Recompliant DNA molecules were formed by annealing appropriately modified vector and cDNA, and these molecules used for bacterial transformation. Bacterial clones containing DBH and PNMT cDNA inserts were identified by positive hybrid selection. In addition to selecting mRNA coding for 31,000 dalton PNMT, a PNMT cDNA clone hybrid selected a small amount of DNA clones for the 2000 deltae DBH. mRNA coding for 72,000 dalton DBH. Similarly, DBH cDNA clones hybrid selected small amounts of mRNA coding for 31,000 dalton PNMT as well as mRNA coding for 72,000 dalton DBH. It was further demonstrated by Northern blot hybridization that a mRNA of 1100 nucleotides in length coded for PNMT and that a separate mRNA of 5500 nucleotides coded for DBH. Northern blot analysis with a PNMT cDNA probe under less stringent conditions revealed a significant cross-hybridization with a 5500 nucleotide mRNA, identical in size to DBH mRNA. Southern blot analysis of restricted bovine adrenal or rat brain DNA, using either DBH or PNMT cDNA probes, revealed hybridization to one or two restriction fragemtns per enzyme digest indicating that both enzymes exist as single copies in the genome. Comparison of DBH and PNMT Southern blots also showed hybridization of both cDNA probes to restriction fragments of common size, suggesting that the two genes are linked.

These results provide strong evidence that regions of homology exist in the genes coding for DBH and PNMT, and suggest that these CA enzymes may be coded for by genes which are members of a linked catecholamine enzyme gene family. (Supported by Grant HL 18974.)

EVIDENCE FOR THE EXISTENCE OF MULTIPLE mRNA SPECIES CODING FOR BOVINE DOPA DECARBOXYLASE. V.R. Albert, D.J. Reis, and T.H. Joh, Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 184.5

DOPA decarboxylase (DDC, EC 4.1.1.28, aromatic L-amino acid decarboxylase) catalyzes the conversion of L-dopa to dopamine and 5-OH tryptophan to serotonin. The enzyme also decarboxylates other aromatic amino acids including tyrosine and tryptophan, but a much slower rate. DDC is localized in neuronal cells, where its major function is the production of dopamine or serotonin, yet large amounts of this enzyme are also found in non-neuronal tissues such as liver and kidney, where no monoamines are produced. In the present studies, we present evidence to suggest that there are different mRNAs coding for DDC in neuronal and non-neuronal tissues.

DDC was purified to homogeneity from bovine adrenal medulla by ion-exchange chromatography, gel filtration and hydroxyapatite chromatography. Antibodies to the enzyme were raised in rabbits and determined to be specific by immunodiffusion, immunoelectrophoresis and Western blotting. Initial biochemical and immunochemical comparisons of the enzyme isolated from bovine kidney, liver, brain and adrenal showed no significant differences: the K of the enzymes for adrenal showed no significant differences: the K<sub>m</sub> of the enzymes for L-DOPA and tyrosine were essentially the same; immunochemical titration, immunodiffusion and immunoelectrophoresis experiments revealed identical cross-reactivities with the antibody directed against revealed identical cross-reactivities with the antibody directed against the adrenal enzyme. However, immunostaining of crude preparations of the enzyme from these tissues separated by SDS-slab gel electrophoresis (Western blot analysis) revealed very slight differences in molecular weight. The antibodies recognized a single 57,000 MW protein in bovine adrenal and brain, a single 56,000 MW protein in bovine liver, and a doublet of 57,000 and 60,000 daltons in bovine kidney. Even greater differences were found when mRNA translation products were compared. mRNA was isolated from bovine adrenal medulla, liver and kidney, and translated in a reticulocyte lysate cell-free translation system. Immunoprecipitation of translation products with DDC antibody demonstrated significant differences in the size of free translation system. Immunoprecipitation of translation products with DDC antibody demonstrated significant differences in the size of the newly synthesized DDC. The translation product from bovine adrenal has a MW of 55,000 daltons. Newly synthesized DDC from bovine liver appears to be only 53,000 daltons. Newly translated DDC from bovine kidney appears as a doublet of 54,000 and 53,000 daltons. These experiments indicate that DDC probably undergoes post-translational modification in vivo, possibly involving addition of carbohydrate, to increase its size by 2-4000 daltons. More importantly, the differences in size between the in vitro translation products suggests that there are separate mRAAs coding for the enzyme found in different tissues, and further raises the possibility that several genes code for this enzyme. (Supported by Grant MH 24285.)

EXPRESSION OF THE PRO-OPIOMELANOCORTIN GENE IN THE PITUITARY AND HYPOTHALAMUS. J.-P. Gagner, P. Burbach\*, J. Charron\*, L. Jean-notte\*, M. Nemer\* and J. Drouin\*. Lab. of Molecular Biology of Eukaryotes, Clinical Research Institute of Montreal, 110 Pine Ave W., Montreal, Quebec H2W 187, Canada. 184.7

We, Montreal, Quebec H2W 1R7, Canada. Pro-opiomelanocortin (POMC) is the precursor to ACTH,  $\beta$ -lipo-tropin,  $\beta$ -endorphin and the melanotropins. We are studying the structure and expression of the POMC gene in three rat and porci-ne tissues where it is expressed: the anterior and intermediate lobes of the pituitary and the arcuate nucleus of the hypothala-mus. We have isolated by molecular cloning from a rat genomic DNA library in bacteriophage  $\lambda 1059$  about 25 kilobases of DNA con-taining the entire POMC gene. The three exons of the gene and about 500 base pairs of upstream sequence have been sequenced; comparison of these sequences revealed a high homology with the human, bovine and porcine genes. Southern blot analysis suggest comparison of these sequences revealed a high homology with the human, bovine and porcine genes. Southern blot analysis suggest that there is only one POMC gene in the rat; this is born out in the fact that eight independent isolates of this gene contain the same genomic sequences. Northern blot analysis indicate that POMC mRNAs of similar size are found in pituitary lobes but that the arcuate nucleus mRNA is slightly bigger; this size difference can be accounted for by different lenghts of polyadenylate tails. Primer-extension studies suggest that the 5'-ends of POMC mRNAs

Primer-extension studies suggest that the 5'-ends of POMC mRNAs from the two pituitary lobes are similar. The processing of POMC differs in the anterior and intermediate lobes of the pituitary; the regulation of the POMC gene also seems to be different in these tissues. For example, glucocorticoids only decrease POMC mRNA levels in the anterior pituitary and do not affect these levels in the intermediate lobe. We have measu-red the effect of dexamethasone treatment of adrenalectomized rats on POMC transcription rates by incorporation of <sup>32</sup>P-labelled UTP into transcripts of isolated pituitary cell nuclei. The labelled RNAs encoding POMC and actin (an internal control) are selected and quantitated by hybridization to corresponding filter-bound RNAs encoding POMC and actin (an internal control) are selected and quantitated by hybridization to corresponding filter-bound genomic DNA fragments. The experiments suggest that glucocorti-coids inhibit within a few hours the transcription rate of the POMC, but not of the actin gene, in the anterior pituitary, which is in accordance with their effect on mRNA levels; on the other hand, glucocorticoids have little effect on POMC transcription in the intermediate lobe. There is a concomittant reduction of the plasma concentration of ACTH, a POMC maturation product characte-ristic of the anterior hypophysis. The glucocorticoid-responsive sequences new being dissected by reintroduction into cultured cells of the <u>in vitro-modified POMC</u> gene. (Supported by the Medical Research Council and the National Cancer Institute of Canada).

HORMONAL CONTROL OF PRO-OPIOMELANOCORTIN GENE EXPRESSION. 184.6 James Eberwine\*, and James L. Roberts. Columbia Universit Biochemistry Department 630 West 168th Street New York, NY Columbia University 10032.

Glucocorticoids suppress secretion of the peptide hormone pro-opiomelanocortin (POMC) in cultured mouse tumor cells and dispersed rat pituitary cells. Recently it has been shown that POMC mRNA levels decrease in the anterior lobe shown that POMC mRNA levels decrease in the anterior lobe of the rat pituitary, while remaining unchanged in the intermediate lobe, in response to the synthetic glucocorticoid, dexamethsone. We have investigated the effects of glucocorticoids on the rate of POMC gene transcription, utilizing a sensitive <u>in vitro</u> nuclear transcription assay. The results indicate, that in the rat anterior lobe there is a decrease of 2-fold in POMC transcription which occurs rapidly, within 45 minutes of intraperitoneal injection of dexamethasone or corticosterone. Over a time course of 6 hours after hormone injection, the transcription rates slowly increase to near normal levels after the initial decrease to the minimum value measured at 45 minutes. The intermediate lobe cells are unaffected by dexamethason administration. These results are confirmed via Northern blot analysis of POWC HNRNA as performed over the same time course. One week after adrenalectomy, the anterior lobe rate of transcription increased 5-fold while there is only a 3-fold increase after two weeks of adrenalectomy. Again the intermediate lobe POMC transcription rate remains unaffected. These rates of transcription in conjunction with the established values of the steady state level of POMC mRNA and protein production and secretion allow us to assess the relative contribution of each of these processes to the control of POMC gene expression.

The hormonal influences of corticotropin releasing hormone, haloperidol and ergocryptine are currently being examined to determine the relative contribution of each of these factors to the rate of POMC gene transcription. work is supported by NIH grant AM 274874). (This

REFINEMENT OF IN SITU HYBRIDIZATION AS A TOOL TO STUDY GENE EXPRESSION IN THE BRAIN. Josiah N. Wilcox\*, Connie Gee and James L. Roberts. Center for Reproductive Sciences, Columbia University College of Physicians and Surgeons, New York, NY 10032. (Spon: M. Blum)

In situ hybridization histochemistry is a procedure that has been developed for the visualization of specific mRNA's in individual cells. Fixed cryostat sectioned tissue is incubated with labelled CDNA probes under conditions allowing CDNA-mRNA hybrids to form. Unhybridized probe is washed off at the end of the incubation procedure and the tissue processed for autoradiography and counterstained to visualize cells. The distribution and density of silver grains after developing the slides then yields information regarding the presence of absence of mRNA's complementry to the CDNA probe used. This technique has been used to visualize specific mRNA's in various somatic tissues. Our laboratory has used in situ hybridization to demonstrate regulatory changes in growth hormone and proopionelanocortin (POMC) mRNA's in rat pituitary. We have also demonstrated that there are cells in the peri-arcuate region of the rat

This technique holds great promise for the study of gene expression in the brain in that it allows single cell resolution of the CDNA-mRNA hybridization, an important consideration given the heterogeneity of neural tissue. However, major problems associated with applying in situ hybridization to the brain have been unacceptably high backgrounds and variable success in visualizing positive cells. We have refined the in situ procedure as applied to the study of POMC gene expression in the as applied to the study of PONC gene expression in the brain reducing backgrounds and increasing the reli-ability of the signal. Using both 3H and 32P labelled cDNA probes we have been able to visualize the distri-bution of cells containing PONC mRNA in the arcuate nucleus of the rat hypothalamus. Eventually we hope to make this technique quantitative so that it can be used to study regulation of POMC gene expression in the brain. (This work was supported by NIH grant AM 27484).

184.9 CELL-FREE BIOSYNTHESIS OF RAT NEUROPHYSIN PRECURSOR POLYPEPTIDES FROM POLY(A)RNA ISOLATED FROM INDIVIDUAL HYPOTHALAMIC NUCLEI. <u>T.G. Sherman<sup>\*</sup> and J.F. McKelvy</u>. Dept. of Neurobiology and Behavior SUNY, Stony Brook, NY 11794.

Previous experiments have shown that total rat hypothalamic poly(A)RMA was capable of directing the active cell-free translation of multiple high molecular weight forms of neurophysin protein (Sherman & McKelvy, Ann. N.Y. Acad. Sci., <u>394</u>:82, 1982). In vitro translation studies which examine whether hypothalamic RNA may code for one or more neurophysin precursors beyond the vasopressin-neurophysin I (AVP-RNp I) and oxytocin-neurophysin II (OT-RNp II) common precursors were complicated by the fact that neurophysin proteins are synthesized within several different discrete hypothalamic nuclei. The supraoptic (SON), paraventricular (PVN) and suprachiasmatic (SON) nuclei are three principal neurophysin-containing cell groups in the rat hypothalamus. In an effort to more closely examine the number and nature of the neurophysin precursors synthesized in each of these hypothalamic nuclei and in an endeavor to study the effects of certain physiological manipulations (suckling, salt-loading, diabetes insipidus) on AVP-RNp I and OT-RNp II precursors synthesized within each of these nuclei, a method was developed wherein poly(A)RNA could be isolated from a single hypothalamic nucleus (PALkovits punch) and translated in a rabbit reticulocyte lysate (RRL) cell-free translation system.

Using a 1.0 mm I.D. punch, the SON, PVN and SCN were dissected from frozen coronal brain sections (1.0 mm thick) and homogenized immediately in 100 ul of a buffer containing 6M guanidinium isothiocyanate and 10 ug carrier tRNA. The RNA was fractionated from contaminating DNA and protein by ultracentrifugation through a 5.7M CSCl cushion. The poly(A)-containing RNAs were selected with oligo(dT)-cellulose using a micro-batch procedure and were ethanol precipitated from potassium acetate in the presence of carrier. It was extimated that a single FVN punch, weighing 1.0 mg wet weight, yielded approximately 0.4-0.6 ug total RNA and 20-25 ng poly(A)RNA. When translated in a RRL cell-free system, 12-14% of the [35S]-cysteine-containing protein was immunoprecipitable with anti-rat neurophysin IgG, resulting in two bands migrating at 17,000 and 18,500 MW on an SDS-polyacrylamide gel.

Thus, it is now possible for the first time, to study the transcriptional regulation of peptide hormone mRNAs and the heterogeneity of protein translation products from discrete brain regions in a cell-free translation assay: a functional assay correlative to mRNA quantitation by specific oligodeoxynucleotide probe dot-blot analysis.

This study is supported by a grant from University Genetics Co.

184.11 LOCALIZATION OF β-NGF mRNA IN TISSUE SECTIONS USING IN SITU HYBRIDIZATION. John E. Pintar\* and Axel Ullrich\* (SPON: Marie Gibson). Dept. Medicine and Anatomy, Mt. Sinai School of Med., New York, NY. 10029 and Genentech, Inc., South San Francisco, CA. 94080.

Nerve Growth Factor (NGF) is of critical importance for the development and maintenance of the peripheral nervous system and may have similar functions in the central nervous system as well. Although the amino acid sequence and biochemical properties of the bioactive  $\beta$ -subunit of NGF are relatively well understood, the physiological sites of NGF synthesis are unknown. We have begun to address this problem by using a recently isolated recombinant DNA probe to mouse  $\beta$ -NGF to localize cells containing  $\beta$ -NGF mRNA.

We have initially shown that <u>in situ</u> hybridization of male and female submaxillary gland tissue sections with radiolabelled NGF probes reflects the known difference in NGF mRNA between these tissues and, in addition, have demonstrated specific cell populations containing NGF mRNA. Submaxillary glands from male and female Swiss-Webster mice were excised, fixed in 4% formaldehyde and subsequently embedded in the same block. Single cryostat sections thus contained both male and female submaxillary gland tissue, which are easily distinguished histologically. Sections were then hybridized with <sup>32</sup>P-labelled NGF cDNA and subsequently exposed to X-ray film. Areas of the section containing male and female tissue showed dramatic differences in the amount of probe bound; film exposure was much greater over areas of the section containing male tissue. This difference was not seen if sections were hybridized with radiolabelled pBR DNA or with a radiolabeled probe to a portion of the proopiomelanccortin gene. To determine the cellular location of NGF mRNA in these tissues, slides were emulsion coated and exposed for autoradiography. Silver grains were concentrated in male secretory tubules and were essentially absent in the acini; this cellular distribution of grains correspons to the site of NGF storage in the submaxillary gland shown by immunocytochemistry.

These results suggest that in situ detection of NGF mRNA at the single cell level in embryonic and adult tissue sections should be feasible. Such experiments are presently in progress.

Supported in part by the Hazen Foundation (JP) and by a Hirschl Career Development Award (JP).

184.10 STRUCTURE OF THE GENE ENCODING RAT PRE-PROSOMATOSTATIN. M.R. Montminy\*, R.H. Goodman\*, J.F. Habener\*. Endocrine Div., Dept. of Med., New Engl. Med. Ctr. Hospital, Lab of Molec. Endocrinol., Mass. Gen. Hospital, Howard Hughes Med. Inst. Labs, Boston, MA 02114.

Somatostatin is a tetradecapeptide that regulates the release of pituitary, pancreatic, and gastrointestinal hormones. Rat somatostatin is synthesized in the form of a 116 amino acid precursor, pre-prosomatostatin. We have previously determined the amino acid sequence of rat pre-prosomatostatin from the nucleotide sequence of cloned cDNAs derived from a medulary thyroid carcinoma. We now report the use of this cDNA to isolate the gene encoding rat pre-prosomatostatin. Using plaque hybridization and reciprocal recombination (TWX) techniques, the rat somatostatin gene was isolated from a genomic library cloned in Charon 4A bacteriophages. The gene is approximately 1.3 kilobases in length, and is interrupted by a single intron of about 600 nucleotides located at base 200, near the middle of the pre-prosomatostatin coding sequence. The site of transcriptional initiation, identified by S-1 nuclease mapping, is located 102 bases upstream from the AUG codon that signals the start of translation. A variant promoter sequence (TTTAAAAA) is located 31 bases upstream from the transcriptional initiation (cap) site. The 5' region of the gene is flanked by two middle-repetitive sequences arranged in tandem. The structures of the recombinant bacteriophages are consistent with genomic Southern blotting data, indicating that these recombinants accurately represent their genomic counterparts. Restriction analysis of genomic DNA, hybridized with the cDNA obtained from the rat medullary thyroid carcinoma, is consistent with a single gene and a small number of additional bands which appear under low stringency hybridization conditions and might represent pseudogenes.

184.12 MOLECULAR CLONING OF 7S NERVE GROWTH FACTOR: ISOLATION AND CHARACTERIZATION OF A GENE CODING FOR THE ALPHA SUBUNIT, Margaret Fahnestock\* and Eric M. Shooter. (SPON: J. H. Pate Skene). Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Nerve growth factor (NGF), a polypeptide necessary for the growth and maintenance of sensory and some sympathetic neurons, is isolated from the male mouse submaxillary gland in a high molecular weight complex, 75 NGF, comprising the NGF dimer, a trypsin-like  $\gamma$  subunit, an acidic  $\alpha$  subunit and zinc ions. The  $\alpha$  subunit, whose function is unknown, has a molecular weight 26,500. A biosynthetic precursor of the  $\alpha$  subunit, of molecular weight 32,000, has been previously identified in incorporation experiments using mouse submaxillary gland slices followed by precipitation with specific anti- $\alpha$  antiserum. An antibody to highly purified  $\alpha$  subunit was prepared and

An antibody to highly purified  $\alpha$  subunit was prepared and used to characterize in <u>vitro</u> cell-free translation products of total male mouse submaxillary gland mRNA. Four polypeptides were precipitated ranging in molecular weight from 34,000 to 16,500. Furthermore, the  $\alpha$  subunit antiserum was used to differentially purify submaxillary gland polysomes and to prepare from them a fraction of mRNA molecules enriched in  $\alpha$  subunit sequences. This fraction was used as a probe to screen a male-specific cDNA library from the mouse submaxillary gland (obtained from James Scott and William J. Rutter). One clone from this library was isolated and shown to

One clone from this library was isolated and shown to contain CDNA coding for a subunit by its ability to hybridize and select mRNA which will direct the <u>in vitro</u> synthesis of the four antibody-precipitable proteins. Northern analysis indicated this clone hybridized to a single RNA of the expected size, and that this RNA, like the a subunit protein, was present in much higher amounts in male than in female glands. DNA sequencing is being carried out in order to confirm the identity of the isolated clone. 184.13 EXPRESSION OF THE MOUSE NERVE GROWTH FACTOR GENE: THE PROTEIN PRECURSORS OF NGF. T. Darling\*, P. Petrides\*, R. Sherman-Cold\*, S. Feinstein\*, E. Shooter; M. Selby\*, and W. Rutter.\* Dept. Neuro-biology, Stanford Univ. Sch. Med., Stanford CA 94305, VA Med. Cen., Washington, D.C. 20422; Dept. Bioch. and Biophys., Univ. California, San Francisco, CA 94143.

California, San Francisco, CA 94143. In the adult male mouse submaxillary gland the nerve growth factor (NGF) protein accumulates in a zinc ion stabilized multi-protein complex, 7S NGF, which is released into saliva by epine-phrine stimulation. The other proteins are the gamma subunit, a trypsin-like enzyme, and an acidic alpha subunit. Each protein is synthesized as a higher molecular weight precursor. Both incorporation studies in submaxillary gland slices and trans-lation of alord mPM in reinsulation large acounded with acadid Both incorporation studies in submaximary gland sinces and trans-lation of gland mRNA in reticulocyte lysates coupled with peptide mapping identifies preproNGF as an M\_ 34,000 proNGF peptide and of two lower molecular weight intermediates of M\_ 22,000 and 19,000 respectively, as well as the M\_ 13,300 NGF peptide chain. Pre-cursor peptides labeled with H-Valine in 60 minute incubations of tissue slices baye hear isolated with artibodies constants of tissue slices have been isolated with antibodies, separated by electrophoresis through polyacrylamide gels, in the presence of SDS, and detected by autoradiography. Each H-Val labeled SDS, and detected by autoradiography. Each  ${}^{3}$ H-Val labeled precursor peptide has been recovered in the appropriate section precursor peptide has been recovered in the appropriate section of dried gel, and subjected to proteolysis by trypsin. The radioactive tryptic peptides of each precursor have been analyzed by HPLC and shown to co-elute with authentic tryptic peptides of NGF, the latter having been identified by amino acid analysis. The sizes of the NGF precursor proteins are consistent with the nucleotide sequence of a cDNA derived from mouse mRNA (Scott et al, 1983, Nature 302:538), the positions of predictive proteolytic cleavance eiter in the converse and an energy reading from 1983, Nature 302:538), the positions of predictive proteolytic cleavage sites in the sequence and an open reading frame beginning 564 nucleotides upstream from the serine codon defining the N-terminus of NGF. The gamma subunit is postulated to specifically release the arg.gly dipeptide extension from the C-terminus of proNGF initiating the formation of the 7S NGF complex. (Supported by grants from NIH (NS 04270 and AM 21344) and NSF (BNS 791408).

184.14 SYNTHESIS AND CLONING OF COMPLEMENTARY DNA TO POLYADENYLATED RNA OF PERIPHERAL NERVE FROM NEONATAL RABBIT. H. D. Shine, P. R. Dobner\* and L. <u>Villa-Komaroff\*</u>, Departments of Neuroscience and Neuropathology, Children's Hospital and Harvard Medical School, Boston, MA 02115 and Department of Molecular Genetics and Microbiology, University of Massachusetts Medical Center, Worcester, MA 01605.

In order to study expression and regulation of genes involved in differentiation of Schwann cells we have produced a complementary DNA (cDNA) library to polyadenylated RNA (poly(A)<sup>+</sup> RNA) isolated from developing peripheral nerves of (poly(A)' RNA) isolated from developing peripheral nerves of neonatal rabbits. RNA was isolated from 3 g of frozen nerves dissected from 100 one day-old rabbits by phenol extraction and enriched for poly(A)<sup>†</sup> RNA by oligo-(dT)-cellulose affinity chromatography to yield 50 µg of RNA. Approximately 2 µg of double-stranded cDNA in sizes ranging from approximately 300 to 1,700 base pairs was synthesized from 10 µg of poly(A)<sup>†</sup> RNA with reverse transcriptase, polymerase I and S-1 nuclease. The cDNA was dC-tailed with terminal transferase and annealed to LCC which was out with Pet-I restriction enzyme and dG-tailed. COMA was detailed with terminal transferase and anneared to the pUCS which was cut with PSt-I restriction enzyme and defatiled. <u>E. coli</u> (strain HB101) was transformed with the annealed vector at a transformation efficiency of 3.0 x  $10^4$  transformants/ug DNA. This library is enriched in Schwann cell-specific, developmentally active mRNA sequences since (i) most cells in the nerve tissue were fibroblasts and Schwann cells and (ii) the nerve was dissected at a stage of rapid Schwann cell the herve was dissected at a stage of rapid Schwahn cell development. We are now using several methods to identify Schwahn cell-specific sequences in the library. Heterologous cDNA probes synthesized from poly (A)<sup>+</sup> RNA from cultured fibroblasts and non-neural tissues are being used to screen for colonies that contain sequences that are either common to Schwann cells and other cell types or specific to non-neural cells. Additionally, since pUC8 is a vector capable of expressing hybrid peptides coded by the cDNA insert cloned within a portion of the <u>lac7</u> gene, peptides of interest may be identified by immunoassay with antibodies to Schwann cellspecific antigens.

Supported by grants from the Dysautonomia Foundation, Charles King Foundation, NIH grants NS14768 and NS11237 to R.L. Sidman, GM26068 to L. Villa-Komaroff, and Institutional Core Grant HD06276.

## **BIOLOGICAL RHYTHMS I**

185.1

SURGICAL DISSECTION OF THE CIRCADIAN PACEMAKER AND BURST GEMER-ATING FUNCTIONS IN THE <u>PULLA AND APLYSIA</u> EYE. <u>G.D. Block and</u> <u>D.G. McMahon</u>, Dept. of Biology, University of Virginia, Charlottesville, VA 22901. The eyes of several opisthobranch molluscs express circadian rhythms in the frequency of optic nerve compound action poten-tials (CAPS). In <u>Bulla</u> (Block & Wallace, Science, 217: 1982) and in <u>Aplysia</u> (Strumwasser, Physiologist, 16: 1973) the pacemaking system resides among a small group of lower retinal neurons (LRNs--nomenclature of Strumwasser). In the present study we have attempted to localize further the circadian pacemaker by removing the somata of LRNs and then evaluating optic nerve impulse activity. This was accomplished by cutting, or in some cases ligating, the optic nerve at its insertion into the connec-tive tissue capsule surrounding the eye. Optic nerve/retinal fragments produced in this fashion remained spontaneously active, generating regular bursts of CAPs which resembled the patterning observed in intact <u>Bulla</u> and <u>Aplysia</u> eyes at their peak CAP frequency within the circadian cycle. There was no evidence of a circadian modulation, however. Subsequent histological examination of these fragments revealed an intact optic nerve with a small portion of lower retinal neuropil. There was no evidence of LRN cell bodies. Repeated at functed to the connective trained and provention the somata of evidence of LRN cell bodies.

Repeated attempts to record spike activity from the somata of LRNs in the retina separated from the optic nerve failed to show evidence of electrical excitability. While many cells within the severed retina exhibited substantial resting membrane potentials

severed retina exhibited substantial resting membrane potentials (40-80 mV), presumptive LRNs were uncharacteristically silent. These results suggest to us that CAP burst generation and the circadian pacemaker system are functionally discrete. Previous experiments in <u>Aplysia</u> by Woolum & Strumwasser (Proc. Natl. Acad. Sci., 77: 1980) using ionizing radiation, and tissue reduction studies by <u>Jacklet & Geronimo</u> (Science, 174: 1971) likewise suggest that these two functions are separate. Our current results provide evidence that these two properties of LRNs are anotonically discrete as well anatomically discrete as well. Since fragments of retinal tissue containing intact LRNs

Since fragments of retinal tissue containing intact LRNs generate CAP bursts modulated by a circadian pacemaker, while neuropil-only fragments support constant levels of CAP activity, a simple hypothesis can be formulated. The circadian pacemaker system is located in the LRN somata or immediately adjacent neurites and modulates CAP burst generators located in more remote regions of the neuron. If this hypothesis is correct, it should be possible to record circadian rhythms in membrane potential from non-spiking LRNs following removal of the optic nerve and associated neuropil. Membrane potential rhythms have been recorded from LRNs in intact eyes (McMahon & Block, this volume). Supported by NS15264.

185.2 LONG-TERM INTRACELLULAR RECORDING FROM LOWER RETINAL NEURONS IN THE BULLA EYE: RHYTHMS IN MEMBRANE POTENTIAL AND IMPULSE FREQUENCY FOLLOW CIRCADIAN RHYTHM. D.G. McMahon and G.D. Block. Dept. of Biol., University of Virginia, Charlottesville, VA 22901. The eye of the marine mollusc <u>Bulla gouldiana</u> expresses a circadian rhythm in the frequency of compound action potentials (CAPs) recorded from the optic nerve. Block and Wallace (1982, Science, <u>217</u>, 155-157) have shown that the entire circadian system, entrainment pathway, rhythm generation, and output pathway persists in retinal fragments containing as few as 30 lower retinal neurons (LENs, nomenclature of Strumwasser). LRNs exhibit action potentials one for one with CAPs recorded in the consistent includes the second secon

We now report that long-term intracellular recordings from We now report that long-term intracellular recordings from LRNs reveal rhythms in membrane potential and impulse frequency synchronized with the circadian rhythm in CAPs. Bulla eyes were dissected from the animal and maintained in FSW at 150C. LRNs were impaled with glass capillary microelectrodes (40-80 MQ) filled with 4M KCl. Following impalement, eyes were maintained in constant darkness. Stable recordings from LRNs yielded membrane potentials of -40 to -80mv and could be maintained for up to 20 hours. These records reveal two prominent features. First, LRNs exhibit a rhythm in impulse frequency corresponding to the CAP rhythm. Second, a rhythm in membrane potential underlies the rhythm in impulse frequency. During the subjective night LRNs are hyperpolarized and silent. They depolarize, initiating inpulse activity near projected dawn and are most

night LRNs are hyperpolarized and silent. They depolarize, initiating impulse activity near projected dawn and are most depolarized near peak impulse frequency. They repolarize as impulse frequency falls during the subjective day. The amplitude of the membrane potential rhythm is 7 to 13mv trough to peak. Importantly, the rise in membrane potential from its minimum preceeds initiation of impulse activity by about 1 hour. These results suggest that the circadian rhythm in CAPs recorded from the <u>Bulla</u> eye reflects the membrane potential rhythm in the LRNs. These experiments do not distinguish whether LRNs generate circadian rhythmicity in the <u>Bulla</u> eye or are merely an output pathway. They do, however, demonstrate rhythmicity in single neurons of a circadian system, and are an important first step in the cellular-level analysis of a neuronal circadian pacemaker. Supported by NS15264. circadian pacemaker. Supported by NS15264.

THE PROPERTIES OF THE BURSATELLA CIRCADIAN SYSTEM DIFFER FROM THE PROPERTIES OF THE CONTRIBUTING PACEMAKERS. M. H. Roberts and G. D. Block, Dept. of Biology, University of Virginia, Charlottesville, VA 22901. We have reported previously that the two ocular circadian properdemands of the previously that the two ocular circadian 185.3

We have reported previously that the two occular circadian pacemakers of the marine mollusc <u>Bulla gouldiana</u> are mutually coupled and that their interaction can be studied <u>in vitro</u> (Roberts and Block, <u>Soc. Neurosci. Abstr.</u>, vol. 8, p. <u>33</u>, 1982). We found that experimentally induced pacemaker desynchrony is reduced if the pacemakers are allowed to interact desynchrony is reduced if the pacemakers are allowed to interact for 48 hours. We recently evaluated ocular pacemaker coupling in another opisthobranch, <u>Bursatella leachi plei</u>. We were suspicious that the <u>Bursatella</u> ocular pacemakers might be coupled since, like <u>Bulla</u>, ocular phase information is transmitted from one eye to the other. Using our <u>in vitro</u> coupling assay we found that experimentally induced interocular phase differences of about 4 hours are reduced to one hour if the pacemakers are allowed to interact for 48 hours in darkness. Thus, like Bulla, the Burstella coular pacemakers darkness. Thus, like <u>Bulla</u>, the <u>Bursatella</u> ocular pacemakers appear to be coupled to one another.

appear to be coupled to one another. Intriguingly, we find that the ability of the <u>Bursatella</u> ocular pacemakers to sustain a free-running rhythm depends upon ocular coupling. Out of 20 isolated eyes evaluated, 13 rhythms damped out and failed to produce a second peak of activity <u>in</u> yitro. The remaining 7 eyes displayed extremely short free-running periods (21.7 hrs) confirming earlier results obtained in our laboratory (Block and Roberts, <u>J. Comp. Physiol.</u> 142:403, 1982). In contrast, when the two eyes remained attached to the cerebral ganglion, the free-running period was about 1.5 hours longer (23.0 hrs, n=12) and none of the eyes failed to produce a second peak. Furthermore, many eyes (n=8) exhibited a third peak of activity <u>in</u> yitro. This difference is not due to influence from the cerebral ganglion since single eyes which remained attached to the nervous system behaved eyes which remained attached to the nervous system behaved similarly to isolated eyes.

While additional control experiments need to be performed, these data indicate that two properties of the <u>Bursatella</u> circadian system (period and sustainability) differ from the properties of the contributing pacemakers. Supported by NS15264 to GDB.

185.4 CIRCADIAN PACEMAKER IN THE BULLA EYE CONTROLS LOCOMOTOR BEHAVIOR VIA A HUMORAL PATHWAY. <u>P.R. Raiford\* and G.D. Block</u>. (Spon: J. Bennet, Jr.) Dept. of Biol., University of Virginia,

VIA A HOBOLAL FARINAL FIG. FIG. 1010 and G.C. EDOK. (5001) J. Bennet, Jr.) Dept. of Eiol., University of Virginia, Charlottesville, VA 22901. The eyes of <u>Bulla gouldiana</u> contain circadian pacemakers which are involved in timing a nocturnal locomotor rhythm (Block and Davenport, J. Exp. Zool., 224, 1982). Eye removal leads to a permanent loss of free-running behavior in constant darkness and abolishment of the entrained nocturnal rhythm in animals exposed to light cycles. Many eyeless <u>Bulla</u> continue to exhibit a bout of diurnal activity for 1 - 2 hours after dawn. This period of activity seen sporadically in the records of intact <u>Bulla</u>, typically increases in regularity, intensity and duration in eyeless animals. It appears, however, to be a response to the onset of light, rather than initiated by the clock system. We presently find that intact optic nerves are not necessary for ocular control of the locomotor rhythm. In 4 <u>Bulla</u> where the optic nerves were severed during free-runs in continual darkness, there was a return of rhythmicity within 3 weeks after surgery. The recovery period was highly variable, ranging from 5 - 20 days. This recovery of rhythmicity hear been observed in eyeless <u>Bulla</u>.

when <u>Bulla</u> were maintained on light cycles, bilateral section of the optic nerves led initially to either a shift to diurnal behavior (N=3), disorganized activity records (N=5) or, in one case, persistence of the nocturnal rhythm. Within three weeks the nocturnal rhythm was reestablished in 5 of the <u>Bulla</u>

weeks the nocturnal rhythm was reestablished in 5 of the <u>Bulla</u> whose locomotor records were disrupted by surgery. Subsequent histological examination of these <u>Bulla</u> revealed no evidence of reconnection of the optic nerves: thus we conclude that humoral release is involved in ocular control of locomotor rhythmicity. Humoral coupling of the <u>Bulla</u> eve to locomotor centers is surprising since in a related mollusc, <u>Aplysia</u>, this connection is neural. Section of the optic nerves produces permanent alterations in locomotor timing identical to eye removal (Lickey <u>et al.</u>, Neurosci. Abstr., 1974). While these nerves in <u>Aplysia</u> are the critical pathways for locomotor control, it has been reported that the eye also exhibits a rhythmic release of several polypeptides which can influence central neurons (Strumwasser <u>et al</u>., Naito International Symposium, 1978). It is currently unknown whether similar polypeptides are released by the Bulla eye.

The presence of a humoral coupling pathway in <u>Fulla</u> provides an opportunity to perform transplantation experiments to further define the role of the ocular pacemakers in controlling locomotor behavior. Preliminary transplantation studies provide evidence that rhythmicity can be restored through the implantation of eyes. Supported by NS15264.

185.5 IDENDTIFICATION OF CIRCADIAN CLOCK FIBERS IN THE CNS OF <u>APLYSIA</u> <u>L. Olson\* and J.W.Jacklet</u> (SPON: S.B. Tieman). Dept of Biol. Sci., SUNY Albany, Albany, N.Y. 12222 Behavioral studies have shown that locomotion in <u>Aplysia</u> is Dept.

influenced by a circadian clock in the eye. The output of the clock is through an identified population of retinal neurons, the secondary cells, which send axons out the optic nerve (ON) to the cerebral ganglion (CG). The synchronous firing of these cells is seen as a compound action potential (CAP) in the ON whose frequency is modulated with a circadian period. Understanding the cellular mechanisms involved in clock modulation of behavior requires knowledge of the distribution of clock information from the eye to the CNS. To this end we are conducting studies to localize "clock" fibers in the CNS. We find that clock information is sent to almost the entire CNS. The ON contains afferents from secondary cells and

photoreceptors, and a small number of efferent axons. HRP fil: of the ON stain afferent axons and efferent cell bodies within the CG. This technique is being used for an ultrastructural HRP fills analysis of optic fiber terminations in the CG. However, incubation of the eye in  ${}^{3}\text{H}$  leucine with subsequent autoradiography of transported material best delineates the ON projection at the light level. Fibers ramify extensively throughout ipsi- and contra- CG neuropil. Large groups of fibers also project out of the CG: 1) the largest projection extends to ipsi- and contra- Pleural ganglia; 2) a smaller projection extends bilaterally to Pedal ganglia; 3) two much smaller extends bliaterally to redai gangila, s) two much smaller projections are seen in the ipsilateral Anterior and Posterior Tentacle nerves of the CG; and 4) a projection leaves the Pleural ganglia along the Pleural-Abdominal connectives. It is likely that this projection extends to the Abdominal ganglion. We are using two approaches to discriminate clock fibers from

photoreceptor afferents in the ON: 1) recordings from Pleural and Pedal connectives reveal a CAP coincident with that seen in the Conversly, an antidromic CAP is evoked in the ON after stimulation of these connectives, demonstrating that fibers from the secondary (clock) cells in the eye are bilaterally distributed to Cerebral, Pleural, Pedal and possibly Abdominal ganglia; 2) specific labeling of retinal secondary cells was accomplished with <sup>3</sup>H DOPA. Other studies have suggested that secondary cells, but not photoreceptors are dopaminergic. We find in fact that only the secondary cells specifically accumulate <sup>3</sup>H DOPA. <sup>3</sup>H DOPA transport studies in progress will confirm and extend the

specific location of clock pathways in the <u>Aplysia</u> CNS. Supported by: Grant #NSF BNS 8206245

185.6 EVIDENCE FOR A CIRCADIAN CLOCK IN THE EYE CONTROLLING RETINAL EVIDENCE FOR A CIRCADIAN CLOCK IN THE FIE CONTROLLING RELINAL SEROTONIN N-ACETYLITANSFERASE AND PHOTORECEPTOR DISC SHEDDING. P. M. Iuvone\*, J. C. Besharse\*, and D. A. Dunis\* (SPON: S. DeRossett). Depts. of Pharmacology, Anatomy, and Ophthalmology, Emory University School of Medicine, Atlanta, GA 30322. Recent evidence indicates that in several vertebrate species the beddynamic and the several vertebrate species

the shedding and phagocytosis of rod photoreceptor disc membranes and the biosynthesis of melatonin in retina occur as circadian rhythms (see Besharse, Prog. Retinal Res. <u>1</u>: 81, 1982). In order to gain insight into the localization of the circadian clock that regulates these rhythmic processes, we studied the regulation of retinal servicinity processes, we studied the regulation of retinal servicini Nacetyltransferase (NAT), a key enzyme in the biosynthesis of melatonin, and the relationship of melatonin to disc shedding in eyes of <u>Xenopus laevis</u>. NAT activity, which was localized to neural retina, fluctuated in vivo as a circadian rhythm with peak activity in subjective devices. in vivo as a circadian rhythm with peak activity in subjective darkness. To determine if the clock that regulates this rhythm is intrinsic to the eye, the activity of NAT was studied in an isolated, cultured, eye cup preparation. In eye cups cultured under a lighting schedule of 12h dark:12h light, NAT activity fluctuated as it did <u>in vivo</u>. Furthermore, the rhythm of NAT activity persisted for at least 80h in culture in constant dark-ness. Phase-reversal experiments were carried out <u>in vitro</u> to determine if the rhythm of NAT activity could be altered by a change in light cycle. Eye cups were first cultured for 48h on a 12h:12hD cycle that was opposite that which had been used to entrain the rhythm in vivo, and were then cultured for 30h in entrain the rhythm in vivo, and were then cultured for 30h in constant darkness. Samples taken during constant darkness indicated that the rhythm of NAT activity had completely reversed Thus, the circadian clock and the photoreceptor for its entrainment are intrinsic to the eye.

To determine if rhythmic disc shedding is related to rhythmic melatonin biosynthesis, the effect of melatonin on disc shedding was examined in eye cups. Light-evoked disc shedding was stimu lated by addition of melatonin in concentrations as low as 50nM to medium containing insufficient bicarbonate to support disc shedding (non-permissive medium). The response occurred in eye cups preincubated in darkness with melatonin prior to light onset, but not when added at the time of light onset. The related indoleamines, serotonin and N-acetylserotonin, had no effect. Our findings suggest that the rhythm of melatonin bioof disc shedding, and that the circadian clock that influences these processes is intrinsic to the eye.

ENDOGENOUS CIRCADIAN RHYTHM IN THE ERG OF THE DIURNAL LIZARD 185.7 ANOLIS CAROLINENSIS. D. H. Fowlkes, C. J. Karwoski and L. M. Proenza. Psychology Dept., University of Georgia, Athens, GA. roenza. 30602

Bilateral ERGs were recorded once per hour in constant dark (DD) for periods of 4-16 days from the diurnal lizard Anolis Carolinensis, which possesses an all-cone retina. Prior to testing, animals were maintained on the solar LD cycle for at least 3 weeks. Testing consisted of a 10 use flash of white light diffused by a translucent dome in which the animal was housed. Animals were allowed free range of movement within the dome, since physical restraint decreases ERG amplitude and abolishes ERC rhythms. Variations in ERG amplitude are not the surfaces, since 1) the animal's visual field is nearly homo-geneously illuminated by the stimulus flashes, and 2) the eyelids

of the animals were retracted for the duration of the experiment. A relatively weak rhythm is discernable in a-wave amplitude, but the amplitudes of b-wave components (both b1 and b2) exhibit robust free-running rhythms that have a period of approximately 24 hr and that peak near projected midday with amplitudes 2times greater than amplitudes during projected might tures 25 rhythms do not result from a modulation of pupil diameter, nor from any discernable morphological changes (e.g., retinomotor movements). Constant light (LL) disrupts the rhythms, as evidenced by phase delays and increased variability in period length.

Data were also obtained from the nocturnal lizard Gecko gecko, which possesses an all-rod retina, under conditions identical to those employed with Anolis. There is no evidence for an a-wave rhythm, and the bl and b2 amplitude rhythms peak shortly after projected superior and by amplitude injums peak shortly after projected superior. This phase difference in the rhythms exhibited by the 2 lizard species suggests that the ERG rhythms result from the modulation of visual mechanisms by processes endogenous to the animal, and not by processes exogenous to the animal.

In summary, (1) the Anolis EKG component amplitudes exhibit free-running rhythms in DD, (2) The rhythms are disrupted by LL, (3) The rhythms consist primarily of a modulation of post-re-ceptoral (b-wave) processes, and (4) The modulating mechanisms are endogenous to the animal. Thus, ERG component amplitude rhythms observed in Anolis can properly be considered circadian rhythms resulting from endogenous modulation of retinal mechanisms.

ENTRAINMENT OF CIRCADIAN RHYTHMS IN UTERO: ROLE OF THE MATERNAL 185.8 SUPRACHIASMATIC NUCLEUS. F.C. Davis\* and R.A.Gorski (SPON; A. Coquelin). Lab. of Neuroendocrinology, Brain Res. Inst. and Dept.

Anatomy, UCLA Sch. of Med., Los Angeles, CA 90024. There is strong evidence in rodents that rhythms which are controlled by the suprachiasmatic nucleus (SCN) can be entrained in utero. To determine precisely when and by what mechanism such entrainment occurs, it is important to identify the relevant zeitgeber. As a starting point, we have found that entrainment of the circadian mechanism underlying the activity/rest rhythm of weanling hamsters is mediated by the maternal SCN and that this enrainment may begin before day 14 of gestation. Beginning on day 1 of gestation, female hamsters were maintained in running-wheel cages in dim constant light. On day 7 of gestation the mothers were given electrolytic midline lesions (2mA, 15 secs) directed at the SCN. When the pups of these mothers were 18 days old, they were separated and placed in individual running-wheel cages, still maintained in dim constant light. The phase angles of their activity onsets on postnatal day 18 were determined from records col-lected over the subsequent three weeks. A distribution of phase angles within a litter which is significantly different from uniform (Rayleigh test) is taken as evidence that the pups had been entrained sometime prior to weaning. Four to 10 pups were taken from each of 13 mothers, one with a sham lesion and 12 with vari-ous amounts of damage to the SCN. A lesion which destroyed at least 70% of a mother's SCN disrupted entrainment of her litter, i.e., the distribution of phase angles within litters from seven such mothers were not significantly different from uniform. In contrast, six litters from mothers with less than 70% SCN destruc-tion showed phase angle distributions which were different from uniform indicating within-litter synchrony among pups. In addi-tion, the scatter in phase angles within a litter was correlated with the degree of SCN destruction in the mother (r=0.915). Thus, with the degree of SCN destruction in the mother (r=0.915). Thus entrainment of the pups within a litter, as measured by the syn-chrony of their activity rhythms at weaning, is disrupted by de-struction of the mother's SCN on day 7 of gestation. To determin if entrainment occurs prenatally, three mothers were lesioned on day 14 of gestation, two days before birth. The percent SCN destroyed in these mothers was 100, 98, and 48, and in all cases the litters showed phase angle distributions which were signifi-cartly different from uniform. Therefore, SCN lesions to the To determine cantly different from uniform. Therefore, SCN lesions to the mother which on day 7 of gestation disrupt entrainment do not do so when performed on day 14, suggesting that entrainment occurs before day 14. This is only one day after the termination of SCN neurogenesis suggesting that minimal SCN development is necessary for entrainment.

THE ROLE OF THE SCN IN THE REGULATION OF THE ESTROUS CYCLE, THE ACTIVITY RHYTHM AND THE LH SURGE. J.Swann, K.Anderson\* & F.Turek. Dept. Neurobiol. & Physiol., Northwestern U., Evanston, IL 60201.

185.9

The proestrus LH surge in rodents is regulated by an endogen-ous circadian oscillator. In ovariectomized (OVAX) estrogen-treated hamsters exposed to a light-dark (LD) cycle, constant light or constant darkness, the LH surge occurs daily about 4-5 hrs before the onset of activity. These results suggest that both the timing of the LH surge and the activity rhythm are reg ulated by the same circadian oscillator. Bilateral ablation of the suprachiasmatic nuclei (SCN), a putative circadian pacemaker, abolishes the circadian activity rhythm. Several studies have reported that both estrous cyclicity and the LH surge are also abolished following bilateral ablation of the SCN, but recent re-ports claim that estrous cyclicity and the LH surge are maintain-ed in rats and hamsters with SCN lesions and that the medial pre-optic nuclei (MPN) regulate the timing of the LH surge. We exam-ined the role of the SCN in the regulation of the LH surge, the estrous cycle and the activity rhythm in individual golden ham-sters. 18 adult, female hamsters were singly housed in running wheel cages and exposed to 16L:8D throughout the experiment. A A11 females were examined daily for the presence of vaginal discharge. After 4 weeks on 16L:8D 14 of the hamsters received lesions aimed at the SCN; 4 females received sham lesions (SH). 4 weeks after surgery, all hamsters were OVAXed and 2 weeks later each animal was fitted with an intra-atrial cannula and implanted with a 4 mm silastic capsule filled with extradiol benzoate. 48 hrs after implantation, each animal was bled once an hour for 24 hrs and Implantation, each animal was bled once an non-rol ry mis and histo-logically to determine the extent of the lesion. The SH hamsters lesioned hamsters with intact SCN, and 4 of the 5 hamsters with The SH hamsters, partial SCN lesions had entrained activity rhythms, a 4-day est-rous cycle, and an LH surge 4-5 hrs before the onset of activity. The fifth hamster with a partial SCN lesion ceased cycling and failed to show an LH surge, but the circadian activity rhythm per-sisted. In 5 of 6 hamsters with bilateral lesions of the SCN (SCNL), the activity rhythm and the estrous cycle were completely disrupted and there was no evidence of an LH surge. The sixth SCNL hamster had an entrained activity rhythm and a normal LH surge, but it did not show an estrus smear. In all of the lesion-ed hamsters, the lesion extended rostrally into the MPN. However, there was no clear correlation between the extent of the damage to the MPN and the expression of estrous cyclicity or the presto the MFN and the expression of estrous cyclicity of the pres-ence of an LH surge. These results indicate that the SCN plays an important role in the regulation of the estrous cycle, the activity rhythm and the LH surge, and that bilateral lesions of the SCN which disrupt the activity rhythm also eliminate the LH surge and the estrous cycle in the golden hamster.

185.10 MICROINJECTION OF NEUROPEPTIDES INTO THE SUPRACHIASMATIC REGION OF THE HYPOTHALAMUS PHASE-SHIFT CIRCADIAN ACTIVITY RHYTHMS OF SYRIAN THE HYPOTHALAMUS PHASE-SHIFT CIRCADIAN ACTIVITY RHYTHNS OF SYRIA HAMSTERS (Mesocrietus auratus). H.E. Albers, C.F. Ferris\*, S.E. Leeman and B.D. Goldman\*. Worcester Found. for Exp. Biol., Shrewsbury, MA 01545 and Dept. of Physiol., Univ. of Mass. Med. Ctr., Worcester, MA 01605

Neurons within the suprachiasmatic nuclei(SCN) are essential for the generation and entrainment by light-dark cycles of many mammalian circadian rhythms. Immunohistochemical analysis of the SCN has indicated the presence of a variety of peptides within specific cell subpopulations. Vasopressin (VP)-like reactivity occurs in perikarya of the dorsomedial SCN, while avain pancreatic polypeptide (APP)-like reactivity is observed in neurons that project from the ventral lateral geniculate nucleus (LGN) to the ventromedial SCN (Card & Moore, 1982). Studies were begun to examine the effects of these peptides on circadian rhythms following their microinjection into the suprachiasmatic region. Eleven intact and 4 blinded and castrated(BX) hamsters were implanted stereotaxically with chronic guide cannulae aimed at the SCN. Each hamster was then placed in a cage with an activity wheel to establish a stable free-running rhythm under constant light. 10-14 day intervals the unanesthetized hamsters were removed from their cages and injected with VP(50pm) or APP(10pm), in 200 nanoliters of 0.9% Nacl via a 33 gauge needle. Injection sites were verified histologically. Injection of VP at various timepoints during the subjective night in intact and BX hamsters had little or no effect on the timing of the activity rhythm; phase-shifts ranged from -0.44 to +0.31 hr. Injections of VP during the subjective day produced more variable results with phase-shifts ranging from -0.85 to +0.55 hr. No relationship was observed between the circadian phase of VP injection and the direction and/ or magnitude of the phase-shift. In contrast, injection of APP produced phase-shifts in activity whose direction and magnitude appeared to depend upon the phase of administration. During the subjective day APP consistently advanced the timing of activity (range= 0.45 to 1.08 hr), but during the late subjective night produced phase delays of up to 2.21 hr. The early subjective night appeared to be a transition period where APP resulted in either small phase advances or delays. The free-running circadian period was not altered by either VP ( $-0.03\pm0.03$  hr;X±SEM) or APP ( $0.02\pm0.02$ ). The present data demonstrating that APP but not VP can systematically alter the timing of circadian activity in a phase-dependent manner when injected into the suprachiasmatic region suggests that APP or an APP-like peptide may be involved in the transmission of photic information to SCN neurons.

185.11 METABOLIC MAPPING OF CIRCADIAN OSCILLATION IN THE RAT BRAIN: A C14-2DG AUTORADIOGRAPHIC STUDY. <u>Alan M. Rosenwasser, Gregory</u> <u>Trubowitsch</u>; and Norman T. Adler, Department of Psychology, Univ. of Pennsylvania, Philadelphia, PA 19104.

Previous studies by Schwartz and colleagues have demonstrated the existence of a circadian rhythm in the uptake of labeled 2deoxyglucose by the suprachiasmatic nucleus (SCN) of the hypothalamus. This rhythm persists under constant darkness or after blinding, with an amplitude which is reduced relative to that seen under light-dark conditions. Inouye and Kawamura have shown by multiunit population recording that the SCN also demonstrates a circadian rhythm in electrical activity. Both the metabolic and electrical SCN activity rhythms have maximum activity during the light or "subjective day" phase of the circadian day. Further, the electrophysiological studies, but not the 2-DG studies, have shown that numerous other brain regions show circadian rhythms in their activity which are dependent on neural connections with the SCN. In the present study, we sought to replicate and extend the metabolic results using 2-DG autoradiography in conjunction with a newly developed computer-assisted image processing system. Animals were blinded by orbital enucleation 24 hours before they were given a 30uCi dose of C14-2DG and sacrificed 45 min. later. Nine different time points throughout the day were sampled in this manner. The results closely matched those of the earlier studies, and demonstrated an approximately 75% increase in 2DG uptake in the SCN during the subjective day relative to the night phase. We further attempted to identify intra-SCN heterogeneity in the pattern of 2DG uptake. This analysis showed that the left and right SCN displayed identical circadian variation, while the rostral and caudal poles of the SCN showed lower amplitude rhythms than did the middle third of the nucleus showed the highest 2-DG uptake. However, the time of day effect was apparent a 11 rostral-caudal levels. We are currently extending these analyses by conducting a systematic survey of other neural structures in these same radiographs to search for non-SCN metabolic rhythms. This survey is guided by existing information concerning SC

- 185.12 ABLATION OF THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN) PRE-VENTS SHORT-DAY INDUCED GONADAL REGRESSION IN THE GOLDEN HAMSTER WITHOUT ELIMINATING THE CIRCADIAN RHYTHM OF LOCOMOTOR ACTIVITY. <u>Gary E. Pickard and Fred W. Turek.</u> Dept. of Psychology, University of California, Berkeley, CA. 94720 and Dept. of Neurobiology and Physiology, Northwestern University, Evanston, II1. 60201. Photoperiods of less than 12.5 hr of light/24 hr produce a well characterized neuroendocrine response in the golden hamster resul
  - characterized neuroendocrine response in the golden hamster resul-ting in gonadal regression after 8-10 weeks. Although this phenomenon has been studied for many years, the complete neural cir-cuitry underlying the response is unknown and the physiological cultry underlying the response is unknown and the physiological mechanisms remain obscure. Two well characterized components of the photoperiodic neural circuit include the hypothalamic supra-chiasmatic nucleus (SCN) and the pineal gland; ablation of either of these structures prevents short-day induced testicular regress-ion in hamsters. Photic information (i.e. day length) is relayed directly from the prevent the SCN a similar condition conditions which directly from the retina to the SCN, a circadian oscillator which regulates many circadian parameters including the circadian rhy-thms of pineal melatonin synthesis and locomotor activity. However, the complete neural circuit from the SCN to the pineal re-mains unspecified. Recently, we have demonstrated that different SCN circadian effector circuits regulate the photoperiodic test-icular response and the circadian rhythm of locomotor activity since lesions in the dorsal aspect of the SCN were found to disrupt short-day induced gonadal regression without eliminating the circadian rhythm of locomotor activity. In view of the recently established efferent projection from the SCN to the PVN which exits the SCN dorsally, we hypothesized that the PVN might act as an integral relay between the SCN and pineal. To demonstrate the possible role of the PVN in the photoperiodic response we examined both short-day induced gonadal regression and wheel-running activity in male golden hamsters with electrolytic lesions aimed at the PVN. After 8 weeks exposure to LD 6:18 (6 hr light:18 hr darkness) the testis width of sham lesioned animals (6.9± 0.6 mm; N=8) was significantly less (P<0.001) than long-day controls (l1.6 $\pm$ 0.6; N=7) housed in LD 14:10. The testis width of animals maintained for 8 weeks in LD 6:18 with bilateral lesions aimed at the PVN  $(9.9\pm0.7; N=12)$  were not significantly different from long-day controls (P>0.10) but were significantly larger (P<0.01) than Short-day animals. In at least 4 lesioned animals with large tes-tes, the circadian rhythm of wheel-running acticity was completely uneffected; the phase angle of entrainment was similar to sham lesioned animals. Thus, the gonadal response to short-days was prevented without eliminating the circadian rhythm of activity. The results suggest that short-day induced testicular regression is mediated at least in part, by a neural circuit which includes the PVN. This research was supported in part by NIH grant NS 19223 to GEP and NIH grants HD 09885 and HD 12622 to FWT.
- 185.13 BILATERAL VENTROLATERAL CORTICAL LESIONS SLOW AND ACCENTUATE ULTRADIAN ACTIVITY RHYTHMS IN RATS. S. Finklestein<sup>\*</sup>, M. Teicher, A. Campbell<sup>\*</sup>, and R.J. Baldessarini. Mailman Research Center, McLean Hospital, Belmont, MA 02178, and Massachusetts General Hospital, Boston, MA 02114. Motor activity rhythms were studied in male Sprague-Dawley rats with bildered verteclateral corpus and content logical contined particular.

Motor activity rhythms were studied in male Sprague-Dawley rats with bilateral ventrolateral cerebral cortical suction lesions (4 X 12 mm). Activity was measured continuously during 2 days before, and 5-7 days after surgery, in 10 min, epochs, using computer-interfaced electronic monitors. Rats moved freely in home cages with food and water freely available, under a 12:12 hr light:dark cycle. Sham-operated controls (N=9) showed no changes in activity levels or rhythms after surgery. Cortically lesioned rats (N=8), however, showed a 92.8  $\pm$  9.0% increase in post-operative mean activity (data are means  $\pm$  SEM; p<0.01), as well as a striking accentuation and slowing of ultradian activity trythms. In lesioned animals, Fourier-based spectral analysis showed a marked pre- to post-operative increase in the percentage of total variance in activity accounted for by "los frequency" (3-8 cycles per day, CPD) ultradian rhythms from 14.1  $\pm$  1.1 to 30.8  $\pm$  3.3 (p<0.003), a decrease in that accounted for by "fast frequency" (9-16 CPD) ultradian rhythms (16.4  $\pm$  3.0 vs. 21.0  $\pm$  2.4.) No change was found in the circadian rhythm (1 CPD) of lesioned rats. The behavioral changes observed may be related to widespread but specific alterations in cortical and subcortical levels of monoamines and their metabolites also found a week after such lesions are made (Finklestein, et al., Brain Research, 1983). They may also parallel disturbances of sleep, appetite, and other ultradian-modulated behaviors found in humans with focal cortical injury (Finklestein, et al., Ann. Neurol., 12:463-468, 1982).

185.14 PHASE SHIFTING AND ENTRAINMENT OF THE HAMSTER CIRCADIAN SYSTEM: ROLE FOR ACETYLCHOLINE IN MEDIATING THE EFFECTS OF LIGHT. <u>David</u> J. Earnest\* and Fred W. Turek (SPON: D. Ferster). Dept. of Neurobalacus, Buyaiolacus, Northwestern Univ. Function 11 60201

biology & Physiology, Northwestern Univ., Evanston, IL 60201. biology & Physiology, Northwestern Univ., Evanston, 1L 60201. The light:dark environment is an important cue for the synchro-nization of many circadian rhythms. Entrainment of the circadian system to the periodicity of a light cycle (usually 24 hr) is thought to occur through a summation of the phase advancing and phase delaying effects of light. Depending on the phase of the rhythm perturbed by light, a circadian rhythm free-running in con-stant darkness (DD) can be phase advanced or delayed by a single pulse of light. pulse of light. While the quantitative aspects of these responses to light have been examined in great detail, little is known about the neural events underlying the place shifting and entrainment of circadian rhythms by photic signals. Recent studies with rodents suggest that the neurotransmitter, acetylcholine, may be involved in mediating the effects of light on the circadian system. There fore, we sought to determine if carbachol, a cholinergic agonist, Therecould mimic the phase shifting and entraining actions of short light pulses. In the first study, adult male hamsters free-run-ning in DD were injected via a cannula implanted in the right lateral ventricle with either saline or 0.01 M carbachol (vol. = 2µ1) once every 12-20 days at various circadian times. Intraventricu-lar administration of saline failed to alter the free-running pattern of activity in DD. In contrast, injections of carbachol evoked phase shifts in the activity rhythm that were similar to those induced by brief light pulses; carbachol administered early in the subjective night induced discrete phase delays of the activ-In the subjective night indiced discrete phase derays of the activity hyperbolic and the subjective night advanced the phase of the latter half of the subjective night advanced the phase of the rhythm (max. amplitude = 5 hr). However, carbachol injections continued to elicit phase shifts at circadian times (i.e., subjective day) during which light pulses have no effect on the activity rhythm. In the second study, adult male hamsters were transferred Thythm. In the second study, adult male namelets were transferred from LD 14:10 to DD and injected intraventricularly with either saline or 0.01 M carbachol (vol. =  $l\mu l$ ) once every 23.33 hr or 24 hr for 9 weeks. Irrespective of the period length of the injec-tion cycle, all animals receiving saline exhibited a free-running pattern of activity in DD ( $\tau > 24$  hr). In contrast, entrainment of the activity thythm was observed in 6 out of 6 animals and 2 with 6 for index with period. out of 6 animals subjected to carbachol injection cycles with perout of 6 animals subjected to carbachol injection cycles with per-iod lengths of 23.33 hr and 24 hr, respectively. During entrain-ment to the 23.33 hr injection cycle, the onset of activity occur-red 8-9 hours before the injection time; this pattern of activity resembles that exhibited by hamsters exposed to light cycles (1 hr light/cycle) with the same period length. These results suggest that acetylcholine may play a key role in the mechanism underlying the photoentrainment of circadian rhythms.

185.15 A CHEMICAL GATING THEORY OF CIRCADIAN RHYTHMS IN NOCTURNAL AND DIURNAL MAMMALS: PHASE RESPONSE CURVES AND ASCHOFF'S RULE. Gail A. Carpenter, Northeastern University, Boston, MA 02115 and Stephen Grossberg, Boston University, Boston, MA 02215. A behaviorally, physiologically, and anatomically predictive model of how circadian rhythms are generated by each suprachiasmatic nucleus (SCN) of the mammalian hypothalamus is presented. This gated pacemaker model is defined in terms of competing oncell off-cell populations whose positive feedback signals are gated by slowly accumulating chemical transmitter substances. These components have also been used to model other hypothalamic circuits, notably the eating circuit. The complementary reactions to light of diurnal and nocturnal mammals as well as their similar phase response curves are obtained at the SCN level. The "dead zone" of the phase response curve during the subjective day of a nocturnal rodent is also explained. Oscillations are suppressed by high intensities of steady light. An augmented model, which included the effect of metabolic feedback via the bloodstream, accounts both for the consistent obedience to Aschoff's rule by nocturnal mammals (i.e., increased light implies increased period) and for the various responses of the periods of diurnal mammals with increasing light. The same model has previously been used to explain split rhythms, long-term after-effects, and effects of hormonal manipulations (Neuroscience Abstract 8, 1982).

### EPILEPSY: PHARMACOLOGY

- 186.1 INDIVIDUAL AND COMBINED EFFECTS OF CONVULSANT AND ANTICONVULSANT DRUGS ON REGIONAL BRAIN METABOLISM. M.A. Mirski<sup>\*</sup> and J.A. Ferrendelli. Dept. of Pharmacology, Washington Univ. Med. Schl., St. Louis, MO 63110. The effects of pentylenetetrazol (PTZ) alone, and in animals pretreated with ethosuximide (ESM) or phenytoin (PHT), on electroencephalographic activity and [1<sup>4</sup>C] 2-deoxy-D-glucose ([1<sup>4</sup>C]) DG) uptake in brain were examined. Guinea pigs (250-350 g), divided into 6 groups of 3-6 animals, were continuously administered convulsant and anticonvulsant furges at a rate of 4 mg/kg/ min, alone or in combination, via a venous catheter beginning 15 min prior to the I.V. bolus delivery of [1<sup>4</sup>C]DG (30 µCl). Animals receiving infusion of anticonvulsant were additionally pretreated 30 min prior to infusion with an I.P. injection of the same drug, either ESM (300 mg/kg) or PHT (100 mg/kg). The dosage of PTZ administered was sufficient to induce electroencephalographic seizures. ESM prevented these seizures, although the EEG still exhibited some occasional spike activity. PHT lacked any anticonvulsant activity and apparently had a facilitory effect by shortening the onset of the PTZ-induced seizures. Autoradiographs from animals treated with ESM or PHT alone user experiments in the start of the the test of test of the test of test of test of the test of the test of the test o
  - Autoradiographs from animals treated with ESM or PHT alone were qualitatively similar to controls. In these, the mammillary nucleus, ventral posterolateral nucleus of the thalamus, and both the medial and lateral geniculate nuclei had the greatest autoradiographic density. PTZ treatment alone enhanced uptake of label in all grey matter areas, especially the cortex, hippocampus, thalamus, globus pallidus (GP), and substantia nigra (SN). Pretreatment of PTZ-infused animals with ESM returned the autoradiographic density of most brain regions to control levels. Enhancement of  $[^{14}C]$  DG uptake was demonstrated, however, selectively involving the mammillary nucleus, the mammillothalamic tract, the anterior nucleus of the thalamus, and the ventral tegmental nucleus in the midbrain. These structures were, in fact, increased in density relative to those from animals treated with PTZ alone. If the pretreatment dose of ESM was increased to revert the EEG to control activity, the enhancement in these structures was lost. Autoradiographs of PTZ-infused animals given PTZ alone, with additional label uptake in the GP and SN. These data suggest that the mammillary nucleus and its projections to the anterior nucleus of the thalamus and to the ventral tearment of proventing the mammillary nucleus and its pro-
  - These data suggest that the mammillary nucleus and its projections to the anterior nucleus of the thalamus and to the ventral tegmental nucleus may be important in the generation of seizure activity induced with PTZ and/or in the anticonvulsant action of ESM in this seizure model. Augmented electroencephalographic activity coupled with enhanced [14c] DG incorporation into the GP and SN with PHT pretreatment of PTZ-infused animals supports the concept of the GP and SN involvement in seizure mechanisms. Supported, in part, by USPHS Grant NS-14834.

86.2 A LOSS OF INHIBITORY, GABA TERMINALS THAT SYNAPSE WITH AXON INITIAL SEGMENTS OF PYRAMIDAL CELLS IN EPILEPTIC FOCI. C.E. Ribak, Department of Anatomy, University of California, Irvine, CA 92717

Previous studies from this laboratory have shown that GABAergic, inhibitory axon terminals which form symmetric synapses with somata and dendrites of pyramidal neurons are preferentially lost at epileptic foci. Other GABAergic terminals in the neocortex form a dense plexus with the axon initial segments of pyramidal neurons, especially those in layers II and III. The cells that give rise to such an axonal plexus are called chandelier or axo-axonal cells. In the present study, the axon terminals of chandelier cells were analyzed in monkeys with cortical focal epilepsy produced by alumina gel to determine whether this type of GABAergic terminal is lost at epileptic foci. Epileptic and non-epileptic cortical tissue from monkeys used in a previous study were re-examined with the electron microscope. Axon initial segments of pyramidal neurons were identified by their characteristic origin from the base of these cells and by three ultrastructural features: fasciculations of microtubules, a multilayered electron dense subaxolemmal undercoating and numerous cisternal organelles. Some of the axon initial segments that were examined were traced for at least 40  $\mu$ m in serial thin sections and beyond this point were observed to become myelinated. In single sections, 10-15 axon terminals were found to form symmetric synapses throughout the entire length of the axon initial segments and were observed to synapse with only these structures and not adjacent dendrites or spines. In epileptic cortex, the axon initial segments of pyramidal neurons were apposed by glial profiles that contained clusters of filaments typical of reactive astrocytes. Few if any axon terminals were observed to form symmetric synapses through aneuros were apposed by glial profiles that contained clusters of filaments typical of reactive astrocytes. Few if any axon terminals were observed to form symmetric synapses that they exert a strong influence on the output of pyramidal cells. The near absence of these chandelier cell axons in tipil segments tof p

DISSOCIATION BETWEEN THE BEHAVIORAL AND ANTICONVULSANT ACTIONS OF INTRANIGRAL MUSCIMOL, <u>D.S. Garant\* and K. Gale</u>. (SPON: R. Sheridan) Dept. of Pharmacology, Georgetown Univ. Schools of Med-icine and Dentistry, Washington, D.C., 20007. GABA agonist- or lesion-induced inhibition of nigral efferent 186.3

GABA agonist- or lesion-induced innibition of higral efferent activity, produces stereotyped behavioral hyperactivity and pro-tects against a number of experimental seizure models (Iadarola and Gale, Science 218(1982)1237; Garant and Gale, Brain Res, in press). We are currently examining various nigral efferents to determine those responsible for mediating these effects.

A projection from SN to reticular formation territor terr really into PPN completely blocks all components of stereotypy induced by bilateral intranigral muscimol (J.A. Childs and K. Gale, this volume). We therefore were interested in determining whether the maintenance of GABAergic tone in the vicinity of PPN would counteract the anticonvulsant action of nigral manipulations.

tions. Muscimol was dissolved in saline and infused at a rate of 0.2 ul/min. Seizure activity was assessed using bicuculline (0.3 mg/kg iv) in 250-300 g rats, or by maximal electroshock in 90-120 g rats. 25 ng of muscimol was microinjected bilaterally into SN and either saline or 50 ng muscimol was injected bilaterally into PPN (coordinates for 300 g rats: AP, 5.8 mm caudal to bregma; 1.4 mm lateral to midline; 6.9 mm below dura; for 100 g rats: AP, 4.8 mm caudal to bregma; 1.3 mm lateral; 6.0 mm below dura). Rats receiving intranjaral muscimol alone displayed stereotyped AP, 4.5 mm caudal to pregna; 1.3 mm lateral; 5.0 mm below dura). Rats receiving intranigral muscimol alone displayed stereotyped sniffing and gnawing and seizure protection. Muscimol injections into PPN abolished the stereotyped behavior induced by intranigral muscimol; however, the PPN injections failed to antagonize the anticonvulsant action of intranigral muscimol in either seizure test.

Thus the hyperactivity and the anticonvulsant activity pro-duced by intranigral muscimol administration are separable phe-nomena. This suggests that the nigral efferents that mediate hyperactive, stereotyped behaviors and those that mediate anti-convulsant actions, while subject to similar neurotransmitter influences, are independent pathways.

186.4 EVIDENCE THAT MORPHINE POTENTIATES SEIZURES INDUCED BY GABA

EVIDENCE THAT MORPHINE POTENTIATES SEIZURES INDUCED BY GABA ANTAGONISTS. Frederick Foote\* and Karen Gale (SPON: D.Stoff) Dept. of Pharmacology, Georgetown U. Schools of Medicine and Dentistry, Washington. D.C. 20007 The effect of morphine sulfate was examined on several dif-ferent rat seizure models: (1) Maximal electroshock (MES), (2) Bicuculline (0.3mg/kg i.v.), (3) Isoniazid (350mg/kg i.p.) and 4) Picrotoxin (2.0mg/kg i.v.). Morphine was administered to male Sprague-Dawley rats in doses of 10-50 mg/kg i.p., 30 min prior to MES, bicuculline or picrotoxin and 15 min before isoniazid. In a dose-dependent manner, morphine pro-tected against seizures induced by MES and increased the incidence and severity of seizures induced by bicuculline. The dose-response characteristics of the two effects of mor-phine were similar and in the same range. For each effect, the The dose-response characteristics of the two effects of morphine were similar and in the same range. For each effect, the  $E0_{50}$  of morphine was approximately 20 mg/kg and the morphine-induced alteration of seizure susceptibility was antagonized by naloxone (2-10 mg/kg s.c.). In addition, morphine (30 mg/kg i.p.) markedly potentiated seizures induced by isoniazid and by picrotoxin. In the case of isoniazid, morphine pretreatment caused major clonic and/or tonic seizures following a subthreshold dose of isoniazid.

subthreshold dose of isoniazid. These results demonstrate that opiate activity may influ-ence the expression of seizures in contrasting ways dependent upon the mode of seizure generation. Morphine exerted an anticonvulsant effect on seizures induced by MES, a nonspeci-fic mode of seizure induction. In contrast, the effects of morphine were uniformly proconvulsant with respect to seizures induced by interference with GABA-transmission, either as a consequence of GABA-synthesis inhibition (isoniazid) or as a consequence of GABA-receptor antagonism (bicuculline and picrotoxin). GABAergic systems may therefore be of partic-ular significance for the elucidation of some of the complex and varied effects of morphine on seizure susceptibility.

186.5 THE EFFECT OF DIAZEPAM, VALPROIC ACID, OR CARBAMAZEPINE ON L-METH-IONINE-d, &-SULFOXIMINE INDUCED CONVULSIONS AND BRAIN LEVELS OF S-ADENO.YLMETHIONINE AND S-ADENOSYLHOMOCYSTEINE. <u>M.W. G111\*, C.</u> Ryan\*, B. Hassett\*, J. Bellino\*, and R.A. Schatz\*. (SPON: J. Hall). Grad. Sch. Pharm. Allied Health Prof., Toxicol. Prog., Northeastern Univ., Boston, MA 02115. The convulsant L-methionine-d, &-sulfoximine (MSO) has been shown to accelerate flux through cerebral methylation pathways. These methylation reactions utilize S-adenosyl-L-methionine (Ado-Met). as methyl donor and result in the formation of S-adenosyl-

Met), as methyl donor and result in the formation of S-adenosyl-L homocysteine (AdoHcy), an endogenous inhibitor of methylation re-actions. The ratio of AdoMet/AdoHcy has been used as an index of methylation, in vitro. (Increased ratios indicate accelerated methylation and decreased ratios indicate slowed methylation). The AdoMet/AdoHey ratio is increased after MSO and this is further reflected by increases in the activity of several methyltransfer-ase enzymes. The clinical anticonvulsants phenobarbital or pheny-toin decrease the AdoMet/AdoHey ratio, prevent MSO-induced altera-tions in methylation and protect against MSO seizures. We have extended these observations using valproate (VPA), diazepam (DZ), and carbamazepine (CBZ) to see if: 1) they protect against MSO seizures and 2) if the protective effect is modulated via alterations in the methylation pathway. Mice were injected i.p. with 25 or 50 mg/kg DZ, 250 or 500 mg/kg VPA, and 25 or 50 mg/kg CBZ. DZ significantly decreased both AdoMet and AdoHey levels 180 or 360 min after drug administration. VPA decreased brain levels of Ado-Met and AdoHey at 180 min. CBZ significantly decreased AdoMet lev-(BID x 7 day) VPA (250 mg/kg) and CBZ (50 mg/kg) on AdoMet and AdoHcy levels were also determined. CBZ significantly increased AdoHcy levels and blocked the MSO-induced decrease in brain AdoHcy. The effect of the anticonvulsants on AdoMet/AdoHcy ratios were Mixed. Acute and subacute CB2 treatment alone had no effect on this ratio, but did inhibit the MSO-induced increases in AdoMet/ AdoHcy. Acute treatment with VPA did not affect these ratios, but this ratio, but did initial the new index interest interest. AdoHcy. Acute treatment with VPA did not affect these ratios, but subacute VPA, as well as acute DZ, actually increased the AdoMet/ AdoHcy ratio. The protective effects of DZ and VPA against MSO-induced seizures either: 1) are not mediated via alterations in brain methylation or 2) the AdoMet/AdoHcy ratio does not necessar-ily reflect actual in vivo alterations in methylation (perhaps because of cellular commartmentalization of some components of the because of cellular compartmentalization of some components of the pathway). The protective effect of CBZ, like phenytoin and pheno-barbital, may involve inhibition of the MSO-induced increase in methylation reactions. The blochemical mechanism responsible for DZ, VPA, and the protective effect of CBZ in blocking MSO induced convulsions remains to be elucidated. Supported by N.U. Provost Grant to RAS.

EFFECTS OF 6-HYDROXYDOPAMINE ON PINEALECTOMY-INDUCED SEIZURES IN THE RAT. <u>C.A. Stockmeier</u>, <u>B.R. Larsen\* and D.E. Blask</u>. Depart-ment of Anatomy, University of Arizona, Tucson, AZ 85724. Norepinephrine (NE) levels are depressed in the brain of the 186.6

partially parathyroidectomized (PthX) rat induced to convulse by pinelactomy (PinX). To determine the role of NE in these seizures and whether changed NE levels are a cause or an effect of the convulsions we treated neonatal rats with 6-hydroxydopamine (6-OHDA) and observed them for various seizure parameters after Groups of neonatal male and female Long-Evans rats received PinX. s.c. injections of vehicle, 6-OHDA (100 mg/kg), desipramine (DMI) (25 mg/kg), or DMI plus 6-OHDA on each of the first three days after birth. At 21 days of age they were partially PthX under after birth. At 21 days of age they were partially PthX under Innovar anesthesia. One week later members of each group were either PinX or sham-PinX under ether anesthesia, and caged one per cage and observed for 8 hr for evidence of wild runs, clonic and/or tonic seizures. 6-OHDA caused a 42% reduction in the mean latency to onset of the first seizure when compared with controls; in the DMI- and DMI/6-OHDA-treated rats the latency was not In the DMI- and DMI/GOHDA-Treated rats the latency was not different from controls. Of the 6-OHDA-treated rats which con-vulsed 45% died during a seizure; none of the vehicle-, DMI- or DMI/6-OHDA-treated rats died during a seizure. Thus DMI appears to reverse the proconvulsant effects of 6-OHDA. With one excep-tion, sham-PinX rats did not convulse. At the end of the observation period the telencephalons and brain stems of the sham-PinX rats were removed and frozen; NE and DA were extracted with 70% ethanol and assayed using high-performance liquid-chromatography with electrochemical detection. Neonatal 6-OHDA treatment reduced NE levels by 24% (p<0.01) in the telencephalon and increased NE levels by 66% (p<0.0005) in the brain stem when compared with vehicle-injected controls. Telencephalic levels of DA were elevated 20% (p<0.01) by neonatal 6-OHDA. The alterations in central catecholamine levels by 6-OHDA were prevented by pretreatment with DMT, suggesting that the proconvulsant effect of 6-OHDA may be due to altered NE function. Elevations in telen-cephalic levels of DA, which we observed, are usually not report-ed to be correlated with proconvulsant behavior. NE and/or DA appear to play a strong role in modulating PinX-induced seizures, however, a deficit in their function per se does not seem to be the fundamental cause of the seizures since sham-pinealectomized rats having altered catecholamine function did not convulse. Supported in part by PHS Grant #CA-27653.

186.7 ANTICONVULSIVE EFFECT OF YOHIMBINE AND PHENTOLAMINE ON SEIZURE INDUCED LIDOCAINE K.C.Kim, M.D. Lab. Indiana University School of Medicine, Department of Anesthesia, Indianapolis, IN 46223. Administration of epinephrine and norepinephrine altered the seizure threshold induced by pentylentetrazol. Changes in brain monoamines varied after seizures depending upon the individual monoamines varied after seizures depending upon the individual drug. Depletion of norepinephrine in the brain tissue occurs often after drug induced seizures. Norepinephrine has an inhibitory effect on central nervous system activity(Swinyard,E.A., <u>J Pharm Exp Ther.</u>, 144:52,1964). Yohimbine increases norepinephrine levels in the central nervous system by blocking the alpha-2 adrenergic receptor site. The purpose of this study was to inves-tigate the effect of yohimbine and phentolamine on lidocaine-induced seizure. Female mice, CD-1 strain, weight 22:1 (M±SE) were used for this study. The drugs were injected intraperitoneal-ly into the right lower quadrant of the abdomen of mice. Saline or yohimbine or phentolamine was injected 5 minutes before administrwere used for this study. The drugs were injected intraperitoneally into the right lower quadrant of the abdomen of mice. Saline or yohimbine or phentolamine was injected 5 minutes before administration of lidocaine. Volume of injected drugs was 0.05 ml/10 Gram of weight and concentration of drug was adjusted to volume. The experiment was divided into three groups: saline, yohimbine, and phentolamine. Dosage of drug:yohimbine 0.1, 0.5,1,5, 10 mg/kg; pentolamine 1,5,10,30,50,100 mg/kg. Convulsion was defined by the following three symptoms: loss of righting reflex, tonic-chronic seizure, opisthotonus, and raising the tail. The CD50 was computed from the probit-log regression line using the method of Licifield and Wilcox. Parallelism and significance were tested by the CD50 for lidocaine in the control group was 66.2 mg/kg (table 1). Yohimbine was not statistically significant. The effective anticonvulsive dosage range for yohimbine and phentolamine was 10 times more effective than phentolamine. Phentolamine has  $J_{-1}$  and  $J_{-2}$  antagonism, and yohimbine is  $J_{-2}$  antagonist. Therefore, anti-convulsive mechanism of  $J_{-2}$  antagonism needs to be investigated. Table 1 investigated. Table 1

GROUP	TREATMENT	<sup>CD</sup> 50	95% CONFIDENCE LIMITS (MG/KG)
Control	Saline	66.2	60.7 - 72.4
Yohimbine	1 mg/kg	98.7	90-9 - 101.9
Pentolamine	10 mg/kg	91.2	91.1 - 100.6

186.9 EEG AND NEUROPATHOLOGICAL CONSEQUENCES OF INTRAHIPPOCAMPAL

EEG AND NEUROPATHOLOGICAL CONSEQUENCES OF INTRAHIPPOCAMPAL QUINOLINIC ACID. G.S. Brush\*, A. Vezzani\*, A.C. Foster, E.D. <u>French</u> and <u>R. Schwarcz</u> (SPON: W.O. Whetsell Jr.). Maryland Psychiatric Research Center, Baltimore, MD 21228. Quinolinic acid (QUIN), a hepatic tryptophan metabolite, is a structural analog of kainic acid, and has recently been demonstra-ted to occur in human and rat brain (Wolfensberger et al., this meeting). Upon intrahippocampal injection, QUIN produces a char-acteristic excitotoxic lesion similar to the local damage caused by kainic acid and the neuropathological features of Ammon's horn sclerosis. The present study was designed to examine the electro-encephalogranhic (EEG) and neuropathological consequences of OUIN encephalographic (EEG) and neuropathological consequences of QUIN injections into the hippocampus of unanesthetized rats.

injections into the hippocampus of unanesthetized rats. Unilateral injections of QUIN (30-300 nmol) were made into the dorsal hippocampus of freely-moving adult animals and EEG patterns continuously recorded from bilateral hippocampal and cortical electrodes. At all doses, QUIN-induced EEG changes consisted of fast activity (8-10 Hz), spiking in one or more leads or occasion-al seizures (characterized by such abnormal EEG-patterns in all leads). Some of these QUIN-related EEG-abnormalities were observ-ed in all animals tested. However, reliable precipitation of ictal episodes, recurring at regular intervals, required QUIN-dos-es of \$120 nmol. QUIN-induced seizures had an average latency of 25 min. This delay was not due to the slow accumulation of a con- $25~{\rm min}$ . This delay was not due to the slow accumulation of a convulsive QUIN-metabolite since virtually all radioactivity recovered 25 min after a test injection of  ${}^{3}\mathrm{H}-\mathrm{QUIN}$  could be identified as

unmetabolized QUIN. Injection of 120 nmol QUIN invariably resulted in neuronal depeneration on the injected side, while the contralateral hippocam-pus, which showed identical EEG changes, remained undamaged. Thus, it appears that the physical presence of QUIN is necessary for neuropathological changes to occur. Pre- and co-treatment with 12 nmol of (-)2-amino-7-phosphono-

heptanoic acid, a synthetic excitatory amino acid antagonist with known anticonvulsant properties (Science, <u>216</u>, 899, 1982), blocked the EEG changes and neurodegeneration caused by 120 nmol of QUIN. Similar blockade was also obtained by co-treatment of the endogen-ous tryptophan metabolite kynurenic acid (360 nmol) with QUIN (120

ous tryptophan metabolite kynurenic acid (Soo nmol) with QUN (L. nmol; cf. Foster and Schwarcz, this meeting). The data support and expand the earlier suggestion of Lapin (Epilepsia, 22, 257, 1981) that QUIN should be considered as a causative factor in seizure disorders. Moreover, our work indi-cates a possible role of kynurenic acid, a metabolically related substance, as an endogenous modulator of seizure phenomena. Supported by UBP45 grant NS 16102

Supported by USPHS grant NS 16102.

186.8 INHIBITION OF BRAIN THROMBOXANE BIOSYNTHESIS DOES NOT REDUCE SEIZURE THRESHOLD. <u>T.W. Lysz</u>. Dept. of Pharmacology, UMDNJ-New Jersey Medical School, Newark, N.J. 07103.

It has recently been reported that the inhibition of prostaglandin (PG) biosynthesis by nonsteroidal anti-inflammatory agents lowers the convulsant dose-50 to tonic convulsions in mice chal-lenged with pentylenetetrazol (PTZ) (Steinhauer and Hertting, Eur. J. Pharm. 69:(1981)199-204). These results suggest that a PG or other arachidonic acid metabolite has an anticonvulsant action. In an attempt to determine which PG may possess antiaction. In an accumption of elements which for may possess and epileptic activity, experiments were conducted to selectively inhibit the formation of thromboxane  $(TXB_2)$  in brain, one of the arachidonic acid metabolites elevated at the onset of clonic convulsions

Adult female Swiss Albino mice were pretreated with 20 mg/kg OKY-1581, a selective thromboxane synthetase inhibitor, followed one hour later with 100 mg/kg PTZ. Two minutes after the onset of clonic convulsions, the mice were decapitated and the head for orbit conditions, the mile were decapitated and the head dropped into liquid N<sub>2</sub>. Analysis of endogenous whole brain PG levels by RIA revealed a 92% decrease in TXB<sub>2</sub> levels (44.1 ng/Gm wet wgt. in controls versus 3.6 ng/Gm in the OKY-1581 treated animals). PGF<sub>2</sub> alpha levels were unaffected by drug pretreatment (133 ng/Gm wet wgt. versus 146 ng/Gm wet wgt. in the OKY-1581 treated mice)

treated mice). Despite the marked effect of OKY-1581 on TXB<sub>2</sub> brain levels, there was no effect on the tonic seizure threshold (77 mg/kg in OKY-1581 treated versus 75 mg/kg in controls). In contrast, 10 mg/kg ip indomethacin which also lowers TXB<sub>2</sub> as well as other PGs, reduced the tonic seizure threshold to 64 mg/kg. These data suggest that inhibition of TXB<sub>2</sub> levels in the CNS does not affect the seizure threshold in mice and that some other product of arachionic acid methadium has an entimenual cant as

product of arachidonic acid metabolism has an anticonvulsant ac-tion in mammalian brain. Supported by UMDNJ-Biomedical Research Support Grant (NIH 5 507 RR05393).

186.10 EFFECTS OF CORTICAL AND BRAIN STEM METRAZOL PERFUSIONS IN "ENCEPHALE ISOLE" CATS. F. Velasco, M. Velasco\* Sci. and M.T. Pacheco\*. Division of Neurophysiology. Res. Dept., Natl. Med. Ctr. IMSS. Mexico Cy. MEXICO. Cats with implanted electrodes for recording EEG, EMG of facial and extraocular muscles and push-pull cannula guides aiming different cortical and brain stem structures, underwent the following procedures: C2-C3 spinal cord transection to immobilize them in the stereotaxic frame, tracheostomy to maintain artificial respiration and arterial cannulation for blood sampling and blood pressure monitoring. These procedures were performed under general anesthesia. Upon recovering, a solution containing 10 mg/ml of metrazol was perfused through a push-pull cannula, at a rate of 0.05 ml/min, in one of the following structures: Cerebral cortex: suprasylvian, motor or orbitofrontal. Mesencephalon: reticular formation (MRF), colliculi, periaqueductal gray, pes pedunculi. Pons: reticular formation (PRF), pontine nuclei, floor of 4th ventricle.

Cortical perfusions induced: focal EEG spikes without EMG seizures at 0.6 ± 0.2 ml. Intermittent bilateral EEG spikes without clinical seizures at 1.1 + 0.4 ml, with EMG contralateral jerks at 1.3 ± 0.3 ml and generalized EEG and EMG tonic-clonic seizures more prominent in the contralateral muscles at 2.7 + 0.9 ml.

MRF perfusions induced: a) EEG and EMG generalized tonic-clonic seizures at 0.6  $\pm$  0.3 ml when cannula tip was placed in the dorsocaudal part of the nucleus. b) Bilateral EEG and EMG clonic discharges at 0.8  $\pm$  0.2 ml when located in the rostral part of the nucleus. c) Bilateral EMG tonic-clonic discharges without EEG seizures at 0.4 + 0.2 ml when located in the ventro

caudal part of the nucleus. PRF perfusions induced hypotonia and EEG spindle bursts. Outside these areas brain stem perfusions induced neither EEG nor EMG modifications but occasional nystagmus. Results suggest that primary generalized metrazol induced seizures are due to activation of MRF.

186.PO EFFECT OF PROSTAGLANDIN SYNTHETASE INHIBITOR PRETREATMENT ON PENTYLENETETRAZOL-INDUCED SEIZURES IN THE RAT. M.C. Wallenstein Dept. Physiology, New York University, NY, NY 10010. Prostaglandins (PGs) are present in mammalian nervous tissue

and are released in increased amounts during both spontaneous and experimental seizures. However, whether PGs have a role in induction of seizures is still unclear. In the present study, the effects of pretreatment with PG synthetase inhibitors on pentylenetetrazol (PTZ)-induced seizures were investigated. Both the electrocortical and motor manifestations of these seizures were examined in free-moving rats with chronically-implanted supracortical electrodes. It was found that the seizures produced by 60 mg/kg PTZ were:

a) significantly delayed after pretreatment with either 150 mg/kg paracetamol, 50 mg/kg meclofenamic acid, 30 mg/kg ibuprofen or 10 mg/kg indomethacin.

b) blocked after pretreatment with either 450 mg/kg paracetamol, 150 mg/kg sulindac or 90 mg/kg ibuprofen. These data were quantified through voltage integration and spectral analysis. The results suggest that PGs are involved

in the mechanism underlying PTZ-induced seizures. The author thanks: Warner-Lambert Co. (meclofenamic acid, mefenamic acid); The Upjohn Co. (ibuprofen); Merck, Sharp and Dohme (indomethacin, sulindac)

# CONTROL OF LIMB MOVEMENTS

187.1 ANTAGONIST MUSCLE ACTIVITY DURING RAPID FLEXION OF THE FOREARM IN

ANTAGONIST MUSCLE ACTIVITY DURING RAPID FLEXION OF THE FOREARM IN A FUNCTIONALLY DEAFFERENTED HUMAN SUBJECT. R. Forget\* and Y. Lamarre. Centre de recherche en sciences neurologiques, Dépt. de Physiologie, Univ. de Montréal, Mtl., Québec, Canada, H3C 3T8. Electromyographic activity (EMG) was recorded from the biceps (Ag) and triceps brachii during rapid flexion movements of the forearm (40 and 90 degrees) in ten normal subjects and one patient with a polyneuropathy affecting selectively the peripher-al sensory myelinated fibers. In response to a sound cue the subject had to move from a departure zone to a fixed target zone displayed on a cathode ray monitor. All normal subjects showed a trionbasic EMG pattern characterized by two bursts in the agonist triphasic EMG pattern characterized by two bursts in the agonist (Ag1 and Ag2) and a burst in the antagonist occurring between Ag1 and Ag2.

In a previous study, there was no obvious burst in the antag-onist of the deafferented patient (Soc. Neurosci. Abstr., 8:73, 1982). These experiments have been repeated one year later. At this time, the patient's motor performance was much improved (day to day activities) despite the fact that she was still function-ally totally deafferented. Along with a more accurate perfor-mance of the motor task, an antagonist burst was now present and was grossly appropriate to decelerate the arm in the region of the target end zone. The antagonist burst had a rather constant duration of 100 ms and ended precisely at the time of maximal deceleration (Dmax). The magnitude of the burst was significant-ly correlated with Dmax (P 0.01). In this study all movements, including those which over- and undershot the target, were analyzed. Analysis of individual In a previous study, there was no obvious burst in the antag

undershot the target, were analyzed. Analysis of individual movements revealed that most were discontinuous and lacked the precision found in the normals. When all movements were aver-aged, the mean position at which Dmax occurred and the mean end position of the movement were the same as in normal subjects. however, the variance around the mean was significantly greater in the patient resulting in an equal amount of overshoot and undershoot. This finding indicates a lack of precise adjustment of the antagonist burst in the deafferented subject as compared to normal controls. Further analysis showed this deficit to be attributable to improper adjustment of both the size and the timing of the antagonist burst. In normal subjects, the timing of the antagonist burst varied as a function of peak velocity and the size of the antagonist burst was strongly correlated with the size of the first agonist burst. In the patient, these relationships were absent or very weak, particularly for larger movements (90°). It is concluded that a central "program" can generate a triphasic pattern of muscle activity and that peripheral feedback is required for precise adjustment of the size and timing of the antagonist burst. (Supported by the Canadian MRC). 187.2 INACCURATE LIMB POSITIONING AFTER UNEXPECTED PERTURBATIONS DURING MOVEMENT. Jerome N. Sanes Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205.

It has at times been proposed that the brain controls muscles nearly independently of peripheral inputs and that the trajectory and end-point of a step movement can be executed and achieved, respectively, independently of processing of afferent inputs that occur during movement. This would imply that transient obstruc-tions would not impair attainment of a planned final position. Nevertheless, recent data (Day and Marsden, <u>J Physiol</u>, 1982, <u>327</u>; Sanes and Evarts, <u>J Neurosci</u>, 1983, <u>3</u>) have demonstrated the dis-ruptive effects of unexpected viscous loads and transient obstructions on final positioning of learned movements. The studies using viscous loads as a perturbing stimulus have shown that intact afferents were necessary to generate short latency muscle responses to compensate for unexpected changes in viscosity during performance of large movements. In the present work, these observations were extended by evaluating performance of large and small movements in intact subjects and patients with sensory loss when a viscous load was unexpectedly introduced or removed.

After training, subjects performed wrist flexion movements in a visual tracking task by moving a handle coupled to a torque motor. Discrete handle rotations of 3°, 10° and 30° were separately performed. Initially, handle movement was either unopposed or resisted by 1 of 3 viscous loads. For 50% of the trials visual guidance was removed and on 50% of these trials either 1 of 3 viscous loads was introduced or the initial viscosity was removed. Changes in visual guidance and viscosity occurred when movement began.

End-point error increased when visual guidance was removed and increased further when the initial viscosity conditions were The greatest increases of error were observed for both altered. the introduction and removal of the largest viscous load. Little change in error was observed for the smallest viscous loads. The overshooting of the intended position was relatively greater for small than for large movements. Short latency muscle responses were observed when viscous loads were unexpectedly changed. Patients with peripheral sensory neuropathy who do not detect changes in viscosity undershoot the learned end-point.

These findings demonstrate that achievement of an accurate learned position is disrupted by peripheral inputs much more for small than for large movements. Further, the short latency muscle responses resulting from unexpected changes in mechanical loads during limb movements do not always result in appropriate compensatory responses. The mechanisms responsible for inability to specify limb position may involve as yet unspecified interac-tions between the afferent input and central command in the motor neuronal pool.

TREMOR IN A "DEAFFERENTED" HUMAN SUBJECT, <u>B.T. Shahani</u>, Clinical Neurophysiology Laboratories, Neurology Depart 187.3 Massachusetts General Hospital and Harvard Medical School, Boston Massachusetts 02114.

We have previously demonstrated severe involvement of all sen-sory fibres with normal preservation of the function of alpha motor axons in a patient with pansensory neuropathy. Detailed electrophysiological evaluation including "proprioceptive silent period" and unloading reflex studies (which were both absent) confirmed our original impression that the stretch reflex arc was not functioning in this virtually "deafferented" human subject. Surface electromyographic recordings from a pair of antagonistic muscles (extensors and flexors of wrist) and accelerometric recordings showed normal continuous electromyographic activity and 10-12 Hz oscillations (features of normal physiological tremor) when the patient held his arms outstretched. Whereas holding a 1-2 kg weight produced synchronization of motor unit potentials and increase in the amplitude (the rate of underlying tremor remaining unchanged) in a normal control subject, such "enhanced physiological" tremor was not seen in the patient under similar physiological tremor was not seen in the patient under similar conditions. However during the task of holding the weight for 2 to 4 minutes, slow oscillations (1 to 3 Hz) were recorded due to movement at proximal joints. These findings in a "deafferent-ed" patient (1) confirm the findings of Hagbarth and Young who on the basis of direct microneurographic recordings showed that servo-loop and muscle spindles are essential for the production of enhanced physiological tremor but are not necessary for the normal physiological tremor present during mild to moderate voluntary effort (2) there are some central oscillatory mechanisms which are not dependent on segmental reflex pathways.

187.4 PRE-MOVEMENT EMG SILENCE IN PARKINSON'S DISEASE. <u>P. Eisenberg\*</u>, <u>S. Sawyer Palmer</u>, and J.A. Mortimer. Geriat. Res. Educ. Clin. Ctr., V.A. Med. Ctr., Minneapolis, MN 55417, and Department of Neurology, University of Minnesota, Minneapolis, MN 55455. Silencing of tonic EMG activity immediately preceding the in-itial agonist burst is a common observation in normal subjects making rapid voluntary movements. The occurrence of pre-movement silence (PMS) is correlated with the peak acceleration of the subsequent movement (Mortimer and Eisenberg, 1982). The purpose of the present study was to determine whether PMS occurs in of the present study was to determine whether PMS occurs in patients with Parkinson's disease instructed to make rapid ballistic movements and whether a similar relationship with movement acceleration is evident. Eight patients were studied. Seven had significant brady-

kinesia as assessed by clinical evaluation. Their right forearms were strapped to an arm support that rotated in a horizontal plane. Surface EMG was recorded from biceps and triceps. Patients maintained an initial elbow position of 90 degrees against a 1 Nm load on triceps and were instructed to initiate maximum effort arm extensions following tone cues. Movements were ar-rested by a karate bag, Each patient performed 25-35 trials. A computer algorithm was used to identify periods of PMS that dif-

computer algorithm was used to identify periods of PMS that dif-fered significantly from random variations in the baseline EMG. PMS was seen in all 8 patients. Its frequency of occurrence (range: 16-50%, mean =30%) was lower than that seen in healthy young subjects under similar experimental conditions (range: 37-91%, mean = 58%). In only 1 of 8 patients was there a signifi-cant correlation between the occurrence of PMS and acceleration. By contrast, 7 of 9 normal subjects studied previously showed such a relationship. During 68% of the trials made by Parkinson patients, a sequence of "segmented bursts" led up to or replaced the single initial agonist burst seen in normals. The presence of such segmented bursts was associated with lower acceleration. The such segmented bursts was associated with lower acceleration. The three Parkinson patients with the lowest mean accelerations had segmented bursts on 93-100% of their trials, whereas these bursts occurred on 3-88% (mean=51%) of trials in the other 5 patients.

In an earlier study, we hypothesized that the occurrence of PMS enables the motoneuron pool to become non-refractory and available for synchronous activation, producing higher movement available for synchronous activation, producing inginer movement acceleration. Although PMS was seen on many trials in Parkinson patients, little association was evident between its presence and movement acceleration. In Parkinson patients, the motor system appears to be constrained to a gradual and periodic recruitment of motor units over a longer time course than in normal subjects. Supported by the Veterans Administration.

187.5 CENTRAL AND PERIPHERAL FATIGUE OF INTERMITTENT SUBMAXIMAL VOLUNTARY CONTRACTONS. <u>B. Bigland-Ritchie, F. Bellemare\* and</u> <u>J.J. Woods</u>\*, (SPON. J.T. Stitt). John B. Pierce Foundation and Quinnipiac College, New Haven, CT. 06519.

During fatigue of a sustained maximal voluntary contraction (WC) we have previously concluded that, despite a decline in EMG, loss of force is not due to failure of either peripheral neuromuscular transmission, or of muscle activation by the central nervous system (central fatigue). Thus it must result mainly from muscle contractile failure. Similar methodology has now been applied to fatigue of sustained or intermittent submaximal contractions.

When single or multiple shocks are superimposed on ongoing voluntary contractions the force increment (Ts) declines as the voluntary force increases. If the muscle is fully activated by the CNS during a MVC then further stimulation results in no additional force; ie. Ts = 0 (Belanger and McComas). Submaximal contractions were repeated until the time that the target force (% initial MVC) could no longer be maintained (Tlim). Muscle contractile force (Tr) was monitored by periodically injecting single or multiple shocks between contractions. When these shocks were periodically superimposed on the ongoing voluntary contractions the decline in the consequent force increment (Ts) detects changes in muscle activation by the CNS. The evoked muscle potentials were monitored for failure of neuromuscular transmission. Initially, and at intervals, the force of brief MVCs was compared with the force during 50 Hz maximal nerve stimulation.

Preliminary results suggest that: a) endurance time (Tlim) can be predicted from the (% initial MVC x % contraction time per be predicted from the (% initial NVC  $\chi$  contraction time per cycle), as shown previously by Bellemare and Grassino for similar contractions of the human diaphragm; b) the MVC declines progressively; c) at Tlim the decline in MVC ( $\Delta$ MVC)  $\simeq \Delta F$  50 Hz; d)the  $\Lambda$ dTr $\times$   $\Lambda$ MVC ( $\simeq$  ) at Tlim, Tso(;f) little or no decline was seen in the evoked M waves. From this we suggest that fatigue is mainly due to muscle contractile failure. The substantial increase in M wave duration indicates a considerable slowing in muscle conduction velocity.

**PURCE (N)** The above figure shows the dramatic effect that four different levels of co-contraction can exert on the force-EMG relation during ramp contractions. The non-linear relation found for the biceps muscle appeared to be linearized by co-contraction during the step procedure. These results indicate that it is critical to monitor the level of co-contraction whenever the force-EMG relation is determined.

187.7 MUSCLE-REFLEX COMPLIANCE: ELASTICITY AND PLASTICITY AT THE HUMAN ELSOW. Gerald L. Gottlieb and Gyan C. Agarwal. Rush Medical College, Department of Physiology, Chicago, Illinois 60612

60612. Following the experimental paradigm of Fel'dman (1), step torques were applied to the elbow joints of human subjects who were maintaining a specified joint angle against a constant load. These torques were random sequences of varying ampli-tudes in both unloading (of the steadily contracting bicceps) and loading. This resulted in either shortening or lengthening of the active muscle while the subject was instructed not to react or "intervene voluntarily" after the perturbation. The joint would equilibrate at a new angle within 200-400 ms after the perturbation, depending upon its direction and ampli-tude. We would plot the equilibrium angle versus the per-turbing torque to generate a "characteristic curve" for the joint. Irrespective of the starting angle or torque, the char-

joint. Inrespective of the starting angle or torque, the char-acteristic curve was always S-shaped, decreasing in slope for larger amplitude perturbations, both in extension and contrac-tion. Thus, the characteristic curve demonstrates the often described short-range stiffness properties of isolated muscles and human isolate and human joints.

What was of most interest was that the characteristic curve always shifted with the operating point of the joint so that changing initial angle, torque or both together produced a new Changing initial angle, torque or both together produced a new characteristic curve centered at the new values. We confirmed Fel'dman's observation that the average slope of the character-istic curve was insensitive to the initial angle and propor-tional to the initial torque. The S-shaped curve is incom-patible with some of his conclusions concerning the linearity of the concernent to emultical publics.

patible with some of his conclusions concerning the linearity of the responses to multiple pulses. The mobility of the characteristic curve represents a funda-mental plasticity in the behavior of the joint under the exper-imental paradigm used. In this case such a nonlinearity may result in simplification of the control scheme because the joint always operates at the same place on the curve (the cen-tral inflection point), irrespective of shifts in torque or angle of either external or internal origin. This is one form of invariant property which can be exploited by the motor con-troller but the underlying mechanism is still uncertain. (1) Asatryan, G. and Fel'dman, A.G. 187.8 PASSIVE ELASTIC PROPERTIES OF MUSCLES MEASURED AT THE ELBOW IN MAN

A. W. Wiegner\* and R. L. Watts\* (SPON: R. R. Young). Clin. Neuro-physiology Lab., Massachusetts General Hospital, Boston, MA 02114 Recent theories of arm trajectory formation (Feldman; Bizzi and co-workers) emphasize the role of the motor control system in selecting, by means of appropriate activation, one of a set of length-tension relations for agonist and antagonist muscle pairs acting at a joint such that at equilibrium the arm is correctly positioned at the target. Still more basic is an appreciation of the role of passive elastic properties of these muscles in deter-mining flexibility and range of motion in the relaxed limb. The present studies were undertaken to assess some passive elastic properties at the elbow joint in the relaxed arm. Subjects were studied in a chair with the right arm supported

on a table at shoulder height and the forearm, wrist, and hand strapped to the lever arm of a printed motor (Axem MC19S) mounted below the table. Lever arm position and torque were measured by a potentiometer on the motor shaft and strain gages on the lever arm, respectively. In order to insure that reflex activity would arm, respectively. In order to insure that reflex activity would not obscure the passive elastic properties of the muscles acting about the elbow, a set of preliminary experiments were done with torque pulses of up to 7 N-m for 100 msec applied to the arm. Reflex responses were not seen when peak velocities at the joint were less than 100°/sec. Subsequently, slow bidirectional ramps in torque ( $\leq 0.11$  N-m/sec, producing velocities  $< 20^\circ$ /sec) were applied to the forearms of 10 normal subjects instructed to remain relaxed. Tricens EMG was monitored and any subjects decoestrating relaxed. Triceps EMG was monitored and any subjects demonstrating EMG activity or voluntary arm movement during the test were removed from the study. Data obtained during rising and falling torque ramps were combined to take into account the effects of limb hysteresis and 10 trials were averaged for each subject. We observed: (1) Even in relaxed muscle there are underlying

spring-like properties that, in the absense of friction and spring-like properties that, in the absense of friction and external torques, return the arm from a displaced position to neutral position  $(112\pm10^{\circ}(SD)$  at the elbow). (2) Curves obtained by plotting displacement vs. applied torque were remarkably linear over a range of  $\pm 30^{\circ}$  from neutral position, with linear regression r-values exceeding 0.98 in each subject. Elbow compliance ranged from 35 to 171  $^{\circ}$ /N-m, with a strong negative correlation (r=-0.80, P<0.01) between upper arm mass and compliance at the elbow.

Our results suggest that normal values for passive elbow posi-tion and compliance may be obtained for comparison to limbs of those with pathological conditions such as spasticity, rigidity, or mechanical changes caused by contractures or arthritis at the elbow. This may assist in differentiating enhanced reflex activity from changes in physical properties of muscle and in monitoring the progress of therapy.

187.9 RESPONSES OF FORELIMB MUSCLES TO SMALL WRIST PERTURBATIONS. E. M. Schmidt and J. S. McIntosh. Laboratory of Neural Control, NIH, Bethesda, MD 20205.

To further investigate the role of sensory information in the control of movement and posture, monkeys were trained to perform wrist flexion - extension movements. The hand was coupled to a torque motor that simulated a spring load with zero force at the torque motor that simulated a spring load with zero force at the mid-wrist position. With this device different background loads and small amplitude perturbations of 50 ms duration were produced at different times in the task. The perturbations produced wrist rotations of approximately 1 degree. EMG electrodes were inserted into forearm flexor and extensor muscles. Electrode placement was verified by stimulating through the electrodes at the end of the recording session.

Unloading perturbations applied to an active muscle produced a reduction in EMG at a latency of approximately 15 ms followed by rebound excitation after the pulse. Loading perturbations applied to an active muscle produced a slight increase in EMG during the pulse with suppression of EMG following the pulse. Responses to perturbations varied as a function of time of The largest response occurred near application during the task. the end of a 1 sec. hold period while a minimal response occurred at the beginning of movement. These results could be due to the different levels of motor pool excitability present at different times during the task, to sensory receptor sensitivity variations, or variations in central processing of the sensory information. In order to investigate the effects of motor pool excitability on response to perturbations, the load was varied while the perturbations were applied at the same time in the task. The level of motor pool excitability, as evidenced by different levels of EMG activity, did affect the magnitude of the responses, but could not account for the much larger variations seen at different times in the task. Although these tests do not evaluate possible changes in receptor sensitivity, the present results suggest that sensory feedback may have little effect at the beginning of movements, as if the movement control system was operating open loop, but during the later control system was operating open loop, but during the later phases of posture the control system operates closed loop

phases of posture the control system operates closed loop relying heavily on sensory information. Previously Schmidt, et al. (Soc. Neurosci., 8:150.3, 1982) have shown that small wrist unloading perturbations produce modifications of motor cortex neurons in as little'as 12.3 ms. This time is too long for peripherally modified cortical activity to influence the beginning of the observed EMG unloading response but it is short enough to participate in the later the EMC surpression renduced by the particupate later phase of the EMG suppression produced by the perturbation.

187.10 SHORTENING RESPONSES IN NORMAL, SPASTIC, AND RIGID MUSCLE. B.J. Norton\*, S.A. Sahrmann, (SPON: M.H. Clare) Appl. Kines Lab. PGM. in Physical Therapy. Sch. of Med., Washington Univ. St. Louis, MO 63110

Though first reported in 1918, responses elicited during passive muscle shortening have not been studied extensively. Preliminary studies suggest a possible role for SRs in normal motor control particularly as an element in muscle tone, and when absent or exaggerated, as an indicator of neuropathology The purpose of this study was to compare the following charac-teristics of SRs and stretch reflexes (STRs) in normal subjects, stroke, and Parkinson patients: 1) frequency of occurrence, 2) onset latency, 3) response to fast vs. slow movements, and 4) response to continuous vs interrupted movements.

A computer controlled electrohydraulic system designed to produce passive joint movement was used to elicit EMG activity during both stretch and shortening of the biceps (Bi) and brachioradialis (Br) muscles. A total of 24 normal subjects, 22 brachioradialis (BF) muscles. A total of 24 hormal subjects, 22 stroke, and 26 Parkinson patients were studied. The values for both total EMG elicited by passive elbow movement and onset latencies were used for analysis. The significance of the fre-quency of occurrences was analyzed with Chi square (p<.05); the differences between SR and STR onset latencies, the responses to

differences between SR and STK onset latencies, the responses to fast and slow movement, as well as continuous vs interrupted movements were assessed with the pared t-test (p <.05). In each group, more subjects demonstrated SRs than did not for both Bi and Br, but only in the patient groups did the majority of subjects demonstrate STRs. The latency of the SR was twice that of the STR. Fast movement elicited a significantly larger response than slow movement for 1) both SR and STR in the hemiplegic patients (2 muscles), 2) STR in the Parkinson patients (2 muscles), and 3) STR in the normal subjects (1 muscle). Interrupted movements (3 second pause between flexion and extension) did not significantly change the STRs in normals or spastic patients when compared to continuous movements. Interrupted movements did decrease STRs and SRs in rigid patients and SRs in spastic patients.

Stretch reflexes have been studied extensively in order to define their role in regulation of muscle tone and in the control of movement. Shortening responses have been the subject of only a few studies, yet the frequency of their occurrence in normals suggests the need to study their possible role in posture and movement. The patterns of SR behavior vary between normals and patients with disorders of the nervous system. The alteration in SR behavior may be related to specific disease processes that affect suprasegmental motor systems and may provide useful physiological insights into their mechanisms.
187.11 EFFECT OF VOLITIONAL SET ON THE CORTICAL EVOKED POTENTIAL TO WRIST PERTURBATIONS IN HUMANS. W.J. Becker\*, D.G. White\* and R.G. Lee. Dept. of Clinical Neurosciences, Univ. of Calgary Fac. of Med. Calgary, Alberta, Canada T2N 1N4 The long latency component of the EMG response to muscle stretch (M2) is dependent on prior instruction or "volitional set" (Hammond, J. Physiol. 132:17, 1956). M2 is well developed upon subjects are instructed to activate a parturbation

The long latency component of the EMG response to muscle stretch (M2) is dependent on prior instruction or "volitional set" (Hammond, J. Physiol. 132:17, 1956). M2 is well developed when subjects are instructed to actively oppose a perturbation, whereas it is small or even absent when they are instructed to "let go" and allow the limb to be passively displaced. It is believed that M2 is mediated, at least in part, by a transcortical feedback loop. In monkeys, perturbations of the forelimb produce short latency responses from motor cortical neurons which are appropriately timed for them to be participating in such a loop (Evarts, Science 179:501, 1973). The objectives of the present study were: 1) to define the cortical evoked potentials to sudden stretches of the wrist flexor muscles, 2) to determine the manner in which these potentials are modified by volitional set, and 3) to relate these changes to alterations in the M2 component of the EMG response.

Recordings were obtained from six normal human subjects using a torque motor to apply sudden perturbations which stretch the wrist flexors. EMG activity was recorded with surface electrodes over the wrist flexors. Cortical evoked activity was recorded with scalp electrodes over the contralateral sensorimotor cortex. Subjects were instructed to either "let go" (passive mode) or to "oppose" the perturbation by producing a rapid voluntary flexion of the wrist (active mode). Four hundred responses were averaged for each condition. The cortical evoked potential to passive stretch consisted of an initial positive wave beginning 30-35 msec. following activation of the torque motor. This component was often double-peaked. It was followed by a negative wave with a peak at 75-90 msec. and then a late positive deflection. The evoked potential during the active condition had a similar configuration. However, computer subtraction of the "passive" from the "active" evoked potential revealed consistent differences during the 40-50 msec. and 85-110 msec. time periods following activation of the torque motor. The first of these differences could represent activity in cortical neuronal systems associated with the M2 component of the EMC response which began 55-65 msec. following the onset of perturbation. The second period during which the evoked potentials differed could be related to the voluntary EMG response which began beyond 100 msec. These results are compatible with the concept that a transcortical feedback loop contributes to the M2 component of the EMG response to muscle stretch.

Supported by the Medical Research Council of Canada.

187.12 EMG AND MOVEMENT KINEMATIC CHANGES AS A FUNCTION OF LEARNING A MOTOR CONTROL TASK. S. P. Moore\* and R. G. Marteniuk. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Some neural and behavioral theories describe learning as fine-tuning, involving the elimination of unnecessary elements. This results in an efficient movement which, if desired, may be produced with little variability over repeated attempts. Most past studies which have utilized EMG to infer changes which occur at the neural level due to learning have used relatively short acquisition periods (40-100 trials). These short acquisition periods may account for the inconsistent and, at times, contradictory results of this literature. The purpose of the present study was to examine the acquisition of a fast time-constrained aiming movement over an extended period of practice. EMG and movement kinematics were used to assess changes due to practice.

Subjects were required to perform a 45° forearm extension in 200 msec for 100 trials on each of four days. Feedback given to subjects on each trial indicated errors in both the displacement and time domains. Temporal and amplitude measures of EMG activity of both triceps and biceps were derived from digital representations of the normalized rectified signals. Movement kinematics were obtained from a potentiometer mounted to the base of the manipulandum that subjects moved in the execution of their task.

The results indicated systematic changes in both EMC and task kinematics over the 400 trials of practice. The EMC changes noted were: a change from cocontraction early in practice to triphasic activity in late practice which resulted in a systematic decrease of average EMC activity over the 400 trials; and a general decrease in within-subject variability. Kinematic results also showed a consistent reduction in variability. Of interest was the fact that subjects with similar kinematic profiles produced markedly different EMG patterns.

In general, then, the results indicated continuing changes in both neural and behavioral indices of motor control over 400 trials of practice suggesting that previous studies may have been limited in making inferences regarding EMG changes and motor control acquisition. In addition, since no direct link between task kinematics and EMG profiles were found, future investigations must not only use large amounts of practice but also be concerned with individual differences in the acquisition of motor control.

187.13 CHANGES IN ELECTROMYOGRAPHIC PATTERNS DURING ACQUISITION OF A FINE MOTOR SKILL. L.D. Abraham, T. Kinugasa\*, A.M. Baylor, J.C. Blankenship\*, and D.W. Robertson\*. Neuromuscular Lab, Univ. of Texas, Austin, TX 78712.

Texas, Austin, TX 78712. In order to assess neuromuscular characteristics of fine motor skill learning, electromyographic (EMG) recordings were made from muscles controlling ankle movement in normal adult human subjects performing a novel, bipedal task. The subjects were seated comfortably, and each foot was fixed to a pedal which restricted movement to ankle dorsi- and plantar flexion. Subjects were instructed to trace the outline of a geometric figure fixed to an oscilloscope screen with an electron beam controlled in the vertical dimension by the right ankle and in the horizontal dimension by the left ankle. For each subject, EMG recordings were made throughout a single session ( $\leq 2$  hours) during which performance improved to a criterion of excellence which demanded completion in less than 8 seconds with less than 1 degree of instantaneous spatial error.

instantaneous spatial error. Surface electrodes were used with 20 subjects to collect data from 5 muscles (tibialis anterior, peroneus tertius, peroneus longus, lateral gastrocnemius, and soleus) in the right leg. In 6 additional subjects, bipolar intramuscular fine wire electrodes were used to provide clearer records of isolated activity in the tibialis anterior, peroneus longus, lateral gastrocnemius, and soleus muscles. Three conditions of movement were isolated and analyzed separately: dynamic movement of the ipsilateral foot, static positioning during movement of the contralateral foot, and dynamic simultaneous movement of both feet. Analysis of learningrelated changes in EMG patterns revealed that changes were specific to individual subjects. As has been typically found in studies of ballistic tasks, skill acquisition was characterized by a reduction in antagonist EMG activity (control by co-contraction). It was particularly interesting that changes could be observed during static positioning (when one might expect most learning to be evident contralaterally). However skill in this fine motor task was clearly related positively to speed. In some subjects this was evidenced by increases in agonist EMG activity at critical times in the movement, while for other subjects the increases in speed associated with skill acquisition were matched by shifts in activity levels in synergistic muscles.

This project was supported in part by BRSG funding from the University Research Institute, UT Austin.

187.14 CHANGES IN SINGLE MOTOR UNIT ACTIVITY DURING ACQUISITION OF A FINE MOTOR SKILL. A.M. Baylor, T. Kinugasa\*, L.D. Abraham, and J.C. Blankenship\* (SPON: M. Wolf). Neuromuscular Lab, Univ. of Texas, Austin, TX 78712.

Texas, Austin, TX 78712. Investigations of electromyographic (EMG) changes associated with motor skill acquisition have primarily employed ballistic tasks and surface recording techniques. In order to examine the contributions of single motor unit (SMU) recruitment to finelycontrolled motor skills, we used bipolar intramuscular fine wire electrodes to obtain records of SMUs during acquisition of a novel, bipedal task. The subjects (6 normal adult humans) were seated comfortably with each foot fixed to a pedal which restricted movement of the ankle in the sagittal plane. The task required tracing of a triangular shape on an oscilloscope screen, controlling the vertical motion of the cursor with the right ankle angle and the horizontal motion with the left ankle. The task was repeated in blocks of 25 trials until it was

The task required tracing of a triangular shape on an oscilloscope screen, controlling the vertical motion of the cursor with the right ankle angle and the horizontal motion with the left ankle. The task was repeated in blocks of 25 trials until it was completed 3 times consecutively in fewer than 8 seconds with no spatial error greater than 1 degree of joint motion. The number of trials to criterion ranged from 96 to 200. EMG records were obtained, throughout the single session of skill acquisition, from 4 muscles in the right leg: tibialis anterior--a dorsiflexor, and 3 plantar flexors--lateral gastrocnemius, peroneus longus, and soleus.

soleus. Twenty individual SMUs were identified off-line by amplitude and waveform. Although integrated EMG activity is often found to decrease in studies of skill acquisition, in this task we often found increased levels of skill accompanied by recruitment of additional units. These increases were most common just prior to movement and early in each phase of the movement pattern. Since the task required only a small fraction of maximal voluntary activity in these muscles, this result is consistent with the observed increase in movement speed. The increased recruitment was particularly evident in agonist muscle activity; units in antagonist muscles commonly dropped out as skill level increased. These changes support the possibility that acquisition of skill in this fine motor task was accomplished by adopting a more ballistic movement pattern. In several cases, no SMU activity was found after skill acquisition in muscules which exhibited several active units during early trials. This was consistent with previous observations of refinements in synergistic muscle use during motor learning.

This project was supported in part by BRSG funding from the University Research Institute, UT Austin.

- ALTERATIONS IN ELECTROMYOGRAPHIC PARAMETERS ACCOMPANYING 187.15 LEARNING DURING A RAPID WRIST EXTENSOR TASK. Mark W. Cornwall\* and Gary Kamen. Motor Control Laboratory, Indiana University, Department of Physical Education, Bloomington, IN 47405. Individuals who practice responding to a visual stimulus generally improve their reaction time scores during 2-4 days of practice. A preliminary experiment was conducted to determine what electromyographic changes accompany this improvement in response latency using 4 subjects with no prior experience in response latency using 4 subjects with no prior experience in laboratory reaction time tasks. Each subject was tested over four consecutive days. On each day, the subject responded to a visual stimulus with a rapid wrist extension movement of the right hand. Forty trials were given on each day, using from 1.5 to 3.5 msec. Four catch trials were also given on each day. Surface silver-silver chloride electrodes were applied over the belly of the extensor carpi ulnaris. Identical placement of the electrodes over the same site was ensured using an indelible marker. ENC activity was amplified (x 1000), bandwidth limited (10hz-3 khz; -3db) and digitized at 2 khz (10 bit resolution). Results indicated that reaction time (10 bit resolution). Results indicated that reaction time performance did indeed improve (258 msec on day 1 vs 251 msec on day 4), but by a margin somewhat smaller than that reported by previous investigators. Total integrated EMG (IEMG; inte-grated over 60 msec from the onset of electrical activity) varied inconsistently across the four days. However, number of are correspondent during the american ending of zero crossings decreased during the practice period  $(.05 \lt p \lt . 1)$  as did number of turning points  $(p \lt . 05)$ . Thus. these preliminary data indicate that repeated practice of a rapid response task can effect decreases in EMG frequency components without concomitant changes in IEMG.
- 187.16 CO-CONTRACTION OF ANTAGONIST MUSCLES DURING TRAINING OF WRIST MOVEMENTS IN THE MONKEY. J.W. Mink & W.T. Thach. Depts. of Anatomy & Neurobiology and Neurology & Neurosurgery, Washington University School of Medicine, St. Louis, MO 63110.

University School of Medicine, St. Louis, MO 63110. Rhesus monkeys were trained over a 6-month period to insert their hands into a wedge-shaped manipulandum, with fingers extended, and to track a moving visual target by flexing and extended, and to track a moving visual target by flexing and extending at the wrist. Slow 10°/sec trajectories were performed from a midpoint 35° in flexion and extension directions with and without uniform torque loads (0-0.1 Nm). EMG activity was recorded with surface electrodes 2 cm apart over forearm flexors and extensors. Trained rapid alternating movements showed high amplitude EMG activity that was often strictly reciprocal indicating EMG electrode pickup only from the near muscle group and not its opposite. As in previous studies (Schieber & Thach, 1980) extensor EMG was always greater than flexor EMG under equivalent torque loads, presumably due to the greater passive elastic restoring forces of the flexor muscle group. Superimposed on the flexor and extensor activity providing the net wrist torque needed to make the trajectory was a pattern of cocontraction of both muscle groups that varied within and ercoss trials, but was usually much greater than the net activity required for displacement. Co-contraction was present under both no load and load conditions, but was greatest in the first 2 or 3 trials following the introduction of a novel load.

This pattern of co-contraction both contrasts with and resembles that observed in monkeys trained over longer periods (2 years) who limited activity to forearm wrist flexors and extensors in strict reciprocal patterns, yet who demonstrated coactivated flexor and extensor spindle afferents. Is the presence of coactive flexor and extensor spindles produced simply by reducing a co-contracting drive that is common to all motorneurons such as to exclude alphas and retain gammas strictly according to the size principle? Or are gamma motorneurons more selectively controlled by the central nervous system? What are the CNS mechanisms that underlie this adaptive process that preserves precision yet minimizes muscle work? (Supported by NINCDS Grant NS-12777-09.)

# LOCOMOTION II

188.1 INTERPRETING HUMAN LOCOMOTOR REACTION TIMES. L. K. Gorman\*, <u>N. V. Yarbrough\* and M. C. Wetzel</u>. Dept. of Psychology, Univ. of Arizona, Tucson, AZ 85721. Although electromyographic (EMG) segmentation has been report-

Although electromyographic (EMG) segmentation has been reported in selected muscles after mechanical perturbations and in other motor tasks, latency measures, alone, have not revealed the causes. In traditional studies of reaction time (RT) the total effect is largely unknown of a typical "preparatory"-"response" signal sequence. The work summarized here tested a new way to interpret RT, based on the strength of a known causal event: a green light that was established as a discriminative stimulus (Sd) by operant conditioning. One measure of Sd strength was its successful production of a burst by the usually quier rectus femoris (RF) muscle during treadmill walking, when latency was successively reduced across several weeks of training. Sd strength was also measured in relation to other, movementproduced stimulation that caused EMG responses (pre-existing or newly conditioned) during the periodic step cycle.

The Sd (green light) occurred at times randomly determined in relation to heel touchdown. On alternating cycles no light flashed. All 6 subjects met a criterion of 80% correct responses (after 50 or more light flashes) for the first, 400 msec, RT condition. Although the acceptable RT had to be 400 msec or less, a high tone sounded 500 msec after the light only if there was an RF burst (of preset integrated amplitude) that was at least 100 msec in duration. Interspersed randomly with the green light step cycles were cycles in which a red light flashed instead. It was followed by a high tone after 500 msec after the green or red light. Four of the 6 subjects met the next criterion, whose acceptable RT had to be 300 msec or less, and one met criterion at an RT requirement of 200 msec or less.

Evidence was gained for controlling stimuli other than the green light. RF bursts might occur within a few msec after the green light, or even before it, as could be seen when by chance a green light had flashed at about the same time in 2-3 previous steps. While brief or "negative" RTs were more frequent early in training, they were seen occasionally in later days as well. In summary, latency of EMG to the green light was reduced by

In summary, latency of EMG to the green light was reduced by operant conditioning, and there was additional very rapid conditioning to rhythmically recurring events. In most previous RT studies, the delay between "preparatory" and "response" signal has been determined randomly, but within limits spanning only a few sec. Under such traditional semi-periodic conditions, RT to the "response" signal should be interpreted as "minimal" only if all other stimulation sources have been identified or ruled out. 188.2 LOCOMOTOR CONTROL IN SPINAL CORD INJURED HUMANS. M. R. Zomlefer, <u>R. F. Gaines\* and L. G. McCleary\*</u>. Rehabilitation Research and Development Center (153), VA Medical Center, 3801 Miranda Avenue, Palo Alto, CA 94304.

A number of previous studies have shown that many mammals can perform stepping locomotor activity with their hindlimbs after a complete spinal cord transection. The intent of this study was to determine whether spinal cord injured humans were capable of performing some form of patterned locomotor activity. Seventeen male volunteers (age 19-56 and between 10 weeks and 25 years after injury) were used in this study. Clinical exam demonstrated sensorimotor completeness in six of these subjects. The volunteers were suspended in a modified parachute assembly over a motor-driven treadmill; the maximum total time that the subject was held above the treadmill was 20 minutes. The harmess design afforded the subjects an erect posture and subjects were allowed to maintain their stability by holding onto a handrail. A winch could lower the subject until his feet just touched the belt. Speeds were varied from 1.0 to 4.0 mph and, in addition, the treadmill pane. Electromyographic(EMG) activity was bilaterally recorded from selected leg muscles (quadriceps and hamstrings) using surface recording electrodes and a multi-channel telemetry system.

No spontaneous stepping movements were observed in any of the subjects tested so far. Nonetheless, six cases showed EMG patterns characteristic to those found in normal human locomotion when the investigators moved both legs to simulate mechanical locomotor behavior. In several cases, EMG amplitude increased with increasing belt speeds. This EMG activity could be the result of a spinal stepping generator, although other possibilities (e.g., alternating stretch reflexes with strong crossed components) may also be responsible. The presence of these EMC signals may be useful in the the future development and control of external functional stimulation to restore locomotion.

MODULATION OF THE RESPONSE TO NOCICEPTIVE STIMULUS DURING WALKING 188.3 IN HUMANS. A.E. Patla\* & M. Belanger\* (SPON: G. Partlow). Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada The response to nociceptive stimulus in mammals such as cats is found to be dependent upon the phase of the stepcycle when the stimulus is applied (e.g., see Forssberg et al., 1975,77,79). Although the responses of the lower limbs to nociceptive stimulus have been studied in humans (Hagbarth et al., 1963; Shahani et al. 1971; Faganel, 1973), how, if at all, this withdrawal reflex gets

modified during locomotion was not investigated until recently This study, an extension of the work by Patla & Belanger (1983), is designed to explore in detail the modulation of the response to

Notice the stimulus during the complete stepcycle. While the subjects (n=4) were walking at their normal self-paced speed on a treadmill, a 2-3 msec electrical stimulus (3 X Threshold) was applied unexpectedly, via a Cu ring electrode on the second toe and a ground electrode on the dorsum of the foot a few cm apart. This site was most appropriate for eliciting a flexor reflex (Kugelberg, 1960). The delay on the stimulator, which was triggered by a heel strike switch, was varied to apply the stimulus during various phases of the stepcycle. Rectified and filtered (6 Hz) EMG signals from Tib. Ant., Gast., Bic. Fem. & Vas. Lat. were used to study the response.

Typical responses of the Gast. and Tib. Ant. are shown (start-ing from the top) for stimulus applied 100-600, 800 & 900 msec after heel strike (arrows indicate stimulus onset). When the stimulus is applied during the stance phase the following respon-

85 ms. ses were observed: a) innibilion is ses were observed: a) innibilion is the cast. followed by excita-tion. The inhibition is most prominent Evolution (lat.~85 msc) of the Vas. Lat. c) Excitation of the Tib. Ant. (lat.  $\sim$  85 msec) during the early part of the stance was suppressed later. The subsequent flexor activity was slightly enhan-ced. In contrast to this, when the stimulus is applied during the swing phase the following responses were observed: a) Excitation of the Bic. Fem. (lat~85 msec). The latency of the enhanced Tib. Ant. acti-vity was difficult to determine because of background EMG activity. Thus the correc-

tive responses to unexpected perturbations are adapted to ongoing locomotor activity permitting the subjects to maintain stabi-lity and forward progression. Supported by NSERC Grant #A0070.

188.5 RECORDING AND ANALYSIS OF THE GAIT-FORCES USING TELEMETRIC FORCE-RECONDING AND ANALYSIS OF THE GALT-FORCES USING TELEMETRIC PORCE-TRANSDUCERS IN PATIENTS WITH DUCHENDER MUSCULAR DYSTROPHY. E. Toyoshima\*<sup>1</sup>, Y. Mano\*<sup>2</sup>, K. Ando\*<sup>3</sup>, D. Ishihara\*<sup>4</sup>, and S. Miyazaki\*<sup>5</sup>. (SPON: R. F. Mayer<sup>1</sup>). <sup>1</sup>Dept. of Neurol., Univ. of Maryland Sch. of Med. & V.A. Med. Ctr., Baltimore, MD 21201. <sup>2</sup>Dept. of Neurol., Nara Pref. Med. Coll., Nara, JAPAN. <sup>3</sup>National Ctr. for Nerv., Ment. & Musc. Dis., Tokyo, JAPAN. <sup>4</sup>Natl. Sana-Ctr. for Nerv., Ment. & Musc. Dis., Tokyo, JAPAN. <sup>4</sup>Natl. Sana torium Higashi-Saitama Hosp., Dept. of Neurol., Hasuda, JAPAN. <sup>5</sup>Tokyo Med. & Dent. Univ., Inst. for Med. & Dent. Eng., Tokyo, TAPAN.

Gait analysis of patients with progressive muscular dystrophy of the Duchenne type (PMD) was serially studied during a 6-month period. Thirteen male patients, aged 8 to 14 years, were studied initially in the ambulatory phase (stages 1-3 of Swinyard, 1957) of the disease. During the period of observation, the disease progressed so that one patient required braces for walking, and 6 became unable to walk due to increased muscle weakness in lower limbs.

The patients' gait was studied while walking on a flat floor 5 meters in length. Foot-forces during walking were recorded con-tinuously using a simple portable device, which consisted of 2 pairs of force-transducers, amplifier-transmitter units and re-ceiver-processor units. The transducers (6x35-55x65-85 mm in size and 35 g in weight for each) were attached to both soles at the

metatarsal region and the heels of a pair of shoes. In the early stage of PMD, the gait foot-forces showed smaller values at the heel compared with those at the metatarsal region, reflecting pes equinus, which was almost not appreciable in the gait foot-prints and neuro-muscular testing. Variations in the gait gattern of foot-forces and right-left difference were ob-served in patients with similar amounts of muscle weakness and Variations in the gait dysfunction. Gross fluctuations both in amplitude and durasupporting-phase) were easily visualized in the superimposed records of the foot-forces at stationary steps. Serial recordings over 6 months revealed the following: further decrease of amplitude of the foot-forces at the heel, prolongation of the duration

of the supporting plase and large fluctuations in four-forces. Changes in the foot-forces appear to reflect the muscle disa-bility and progression of the disease of patients with PMD. The method and devices used in this study may be helpful in the objective, quantitative and serial assessment of pathological gaits in patients with neuro-muscular disorders. (Supported in part by the Institute for Health and Welfare, Japan, and a grant from the Veterans Administration, U.S.A.).

TOPICAL ANESTHESIA: CHANGES IN GAIT FOLLOWING DESENSITIZATION OF THE SKIN IN NORMAL SUBJECTS. S. Roy, M. Sabbahi and C. J. De Luca (SPON: S. Wolf). NeuroMuscular Research Lab, Dept. do Tribopaedic Surgery, Children's Hospital Medical Center, Harvard 188.4 Medical School, Boston, MA 02115 and Liberty Mutual Research Center, Hopkinton, MA 01748

Evidence for increased alpha-motoneuron excitability has been previously reported following desensitization of the stopical anesthesia (Sabbahi and De Luca, 1981, 1982). the skin by These changes in the discharge characteristics of the motoneuron pool have been associated with alterations in gait and other movement patterns for spastic patients. In the present study, we have investigated the effects of reduction of cutaneous receptor afferent discharge on gait parameters in normal subjects.

Vertical ground reaction forces were measured from a force vertical ground reaction forces were measured from a force plate during gait and while walking in place. Foot switches and infrared detectors recorded the foot contact histories and walking speed respectively. Tests were repeated four times consecutively to measure the movement variability.

Topical anesthesia was sprayed to all skin areas of one lower limb except for the skin overlying the tibialis anterior and the plantar surface of the foot. Measurements were repeated at plantar surface of the foot. intervals post anesthesia.

Vertical ground reaction force peaks corresponding to initial foot contact substantially increased for all subjects during walking in place after anesthesia. Most subjects demonstrated similar increases in ground reaction force at heel-strike during gait post anesthesia. Vertical ground reaction force peaks corresponding to weight shifting ,as single limb support begins, slightly increased after anesthesia. recorded in the contralateral limb. Similar results Were

Our results indicate that the motor control of stereotyped movement patterns, such as those occurring in gait, are modified by the reduction of cutaneous receptor afferent discharges. Other observations made in this laboratory suggest that this observed effect may possibly be the result of increased excitability of the extensor motoneuron pool.

AFFERENT PERTURBATIONS DURING CONTROLLED LOCOMOTION IN THE TURTLE 188.6 P.R. Lennard. Dept. of Biol., Emory Univ., Atlanta, GA 30322. The contribution of cutaneous and muscle afferent information The contribution of cutaneous and muscle afferent information to ongoing locomotor pattern production in the turtle was tested during "controlled swimming of a single hindlimb" elicited by electrical stimulation of the spinal cord. During each 10 sec. swimming sequence the electromyographic pattern of up to 12 hind-limb muscles was utilized as an assay of the locomotor output. Perturbations consisted of a single 0.1 msec., near threshold pulse delivered to a cuffed cutaneous or returnstroke musclenerve. Such transient electrical stimulation of both cutaneous and muscle-nerves was found to have similar phase dependent effects on the perturbed swim cycle but to have dramatically different influences on the long-term locomotor rhythm.

Analysis of phase-response curves indicates a sensitive period early in the swim cycle (measured from the onset of retraction). During this period, cuff stimulation resulted in a statistically significant shortening of the period of the perturbed cycle due to reduced burst duration in powerstroke muscles and reduced inter-burst durations for returnstroke muscles. A second sensi-tive period exists late in the cycle. Stimuli applied at this time resulted in an increase in the period of the perturbed cycle. This increase reflects a prolongation of ongoing activity in returnstroke muscles accompanied by a delay in the onset of activity in powerstroke muscles. Stimuli falling within the sensitive periods have no observable effect on the phase relationships between either synergistic or antagonistic muscles. That is, there is no evidence of disruption in the motor output pattern within the perturbed or subsequent locomotor cycles.

Analysis of post-perturbation effects on the swimming rhythm uncovered a major difference between muscle-nerve and cutaneous stimuli. Muscle-nerve stimuli during both sensitive periods lead to a permanent phase shift in the locomotor rhythm. In contrast, cutaneous-nerve stimuli resulted in a temporary phase shift. These data are not consistent with the modeling of a single central pattern generator for locomotion which combines both clock and intracycle pattern generating functions, but can be explained by either of two alternative models of locomotor production: 1) a coupled system composed of a master pacemaker clock or oscillator which entrains a pattern-generating slave oscillator; or 2) a single clock which controls the swimming rhythm and triggers on a cycle-by-cycle basis a non-oscillating pattern generating network.

(Supported by USPHS grant NS 17732).

LOCOMOTOR ACTIVITY OF LARVAL AND ADULT FROG SPINAL CORD ELICITED 188.7 BY EXCITATORY AMINO ACID AGONISTS. <u>A.D. McClellan and P.B.</u> Farel, Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27514.

The spinal cords of vertebrates contain neural networks, sometimes called central pattern generators (CPG), which produce the basic features of motor patterns underlying rhythmic behaviors. In the tadpole, spinal CPGs produce the motor patterns underlying swimming movements. As the hindlimbs develop, other motor functions, such as jumping, kicking, stepping, and wiping, come under control of spinal motor networks. As an initial step in comparing the operation of larval and adult motor networks, we asked whether similar motor functions could be elicited from the spinal cords of tadpoles and frogs by the same excitatory amino acid agonists, particularly N-methyl-DL-aspartate (NMDA).

In bullfrog tadpoles (Rana catesbiana, st. V-XV) with a spinal cord transection at the level of the third segment, i.p. injection of NMDA (4.0-15.0 mg/kg) resulted in swimming movements which consisted of lateral undulations that propagated towards the tail and effectively propelled the animal forward. EMG activity during these movements alternated from side to side at the same segmental level and showed a rostro-caudal phase lag. Application of NMDA (0.05-0.1 mM) or D-glutamate (0.5-1.0 mM) to a bath containing an <u>in vitro</u> spinal cord preparation activated alternating bursting in ventral roots, but without a rostro-caudal phase lag. These differences in rostro-caudal phase lag are similar to results obtained in studies of spontaneous motor activity in the tadpole (Stehouwer and Farel. 1980).

In frogs (Rana pipiens) with an acute spinal cord transection between the third spinal roots and the obex, i.p. injection of NMDA (4.0-15.0 mg/kg) activated a general sequence of hindlimb NHDA (4.0-15.0 mg/kg) activated a general sequence of hindiam motor functions: spontaneous wiping reflexes, coordinated stepping, and kicking or jumping. The forelimbs, when used during stepping, were coordinated with hindiamb movements. These motor responses were produced by characteristic patterns of EMG activity in hindlimb flexors and extensors. The motor patterns generated by <u>in vitro</u> spinal cords are presently under investigation investigation.

The finding that the same excitatory agents activate swimming in the tadpole as well as rhythmic hindlimb motor activate swimning in the tadpole as well as rhythmic hindlimb motor activities of the adult hindlimb suggests that some overlap exists in neurons comprising the spinal CPG networks in the tadpole and frog. Supported by NIH postdoctoral grant NS06321 (A.D.M.) and by NIH grants NS14899 and NS16030.

A SOLID-STATE CAMERA SYSTEM FOR COMPUTERIZED COLLECTION AND ANALYSIS OF HIGH-SPEED MOVEMENT PATTERNS. <u>Chris M. Wieland</u> \* and <u>Robert C. Eaton.</u> (SPON: Anne C. Bekoff), Dept. Biol., E.P.O., Univ. of Colorado, Boulder, CO 80309 We have developed a system for the automatic collection and analysis of movement in animals. The system is applicable to a vide variety of experimental studies involving quantitative 188.8 А

analysis of movement in animals. The system is applicable to a wide variety of experimental studies involving quantitative analysis of behavior patterns. Body or limb positions are recorded at rates up to 600 frames per sec and a digital representation of the image is stored for computer analysis. The system is based on a solid-state image sensor comprised of 10,000 photodiodes laid out in a 100 by 100 square matrix on a single silicon chip (Reticon Corp., Sunnyvale, CA). This system significantly reduces the time and cost

This system significantly reduces the time and cost associated with the analysis of motion normally encountered when using conventional high-speed photography. Furthermore, its ability to capture data at high frame rates allows fine temporal resolution of fast movement not available when using video-based systems

Our current application involves analysis of the C-type startle response in the goldfish. Simultaneous electro-physiological recordings may be obtained from animals while high-speed movement is recorded with the above system. A variety of measures of motor performance of this stereotyped behavior pattern may be generated using a minicomputer (Hewlett-Packard 9845B) programmed for image analysis techniques. Illustrated below are sequential stages in the computer analysis of a single frame showing the goldfish's position 20 msecs after initiation of the startle response behavior. The computer converts the original figure into a single line representing the midline of the fish. The X,Y coordinates of this line are then used for a descriptive analysis of motor performance and its correlation to underlying neural activity. Our current application involves analysis of the C-type neural activity.

This project was supported in part by BRSG grant RR07013-17 awarded by the Biomedical Research Support Grant Program, Divison of Research Resources, NIH, and by grants from the National Science Foundation (BNS79-005570 and BNS81-12423).

# LEARNING AND MEMORY: ANATOMY II

189.1 EFFECT OF BILATERAL CEREBELLAR LESIONS ON HEART-RATE AND NICTITA-EFFEU OF BLATERAL CERBELLAR LESIONS ON HEARI-RATE AND WILTHY TING MEMBRANE/FYELD CONJITIONING IN THE RABBIT. D.G.Lavond\*, J.S. Lincoln\*, D.A.McCormick\* and R.F. Thompson (SPON: K.H. Pribram). Dept. Psych., Stanford Univ., Stanford, CA 94305. We have reported previously that ipsilateral cerebellar lesions abolish a well-learned nictitating membrane (NM)/eyelid reported without sforting the uncerditioned mergence. There are not without sforting the uncerditioned mergence. There lesions abolish a well-learned nictitating membrane (NM)/eyelid response without affecting the unconditioned response. These same rabbits easily learn with the eye contralateral to the lesion. We proposed that the cerebellum is critically involved in the neural circuit for learned responses. Several lines of evidence suggest that two processes are involved in learning of somatic responses with aversive UCS: the first stage is a tempor-ary emotional or reactive phase (reflected by "conditioned fear", e.g., heart-rate conditioning). The second stage involves learning of the specific adaptive somatic response. which is e.g., heart-rate conditioning). The second stage involves learning of the specific adaptive somatic response, which is abolished by cerebellar lesions. The present study was designed to determine the effect of cerebellar lesions on heart-rate conditioning, to determine the effect of bilateral lesions on M/eyelid conditioning, and to determine the permanency of the abolished NM/eyelid response. Stereotaxic lesions (N=4) and aspiration (N=1) of the cere-bellum were made bilaterally in rabbits who were then allowed 1 week of recovery. Following one day of adaptation to the conditioning chamber the 5 experimental rabbits and 5 control subjects were trained for heart-rate conditioning by pairing

controlling transfer the S experimental rabbits and S control subjects were trained for heart-rate conditioning by pairing a tone (1 KHz, 85 dB SPL, 5 sec duration) offset with a faceshock (2 mA, 500 msec). Both the control rabbits and those with bilat-eral cerebellar lesions learned cardiac deceleration (F(3,30)= 23.2, p<.01 over blocks of training; F<1 between groups and for the interaction).

the interaction). The following day all rabbits began training on the NM/eyelid response, 4 days of training on the left eye followed by 4 days on the right. Control rabbits learned the response in an average of 138 trials to a criterion of 9 correct responses in 10 con-secutive trials. Rabbits with lesions of the cerebellum did not learn on either eye. One rabbit from the experimental group was allowed an additional 5 weeks of recovery and then given 8 more days of training on the NM/eyelid response without learning the habit. An additional rabbit was first trained on the NM/eyelid response on both sides before bilateral aspiration. He did not relearn the response when tested repeatedly over three months. The present study has shown that bilateral lesions of the

The present study has shown that bilateral lesions of the cerebellum have no effect upon heart-rate conditioning. NM/eyelid conditioning is permanently abolished. Furthermore, this abolition is not due to an asymetry of functioning caused by the unilateral lesion because bilateral lesions cause the same abolition of conditioned responding.

EFFECT OF KAINIC ACID LESIONS OF THE CEREBELLAR NUCLEI ON 189.2

EFFECT OF KAINIC ACID LESIONS OF THE CEREBELLAR NUCLEI ON NICITATING MEMBRANE/EYLID CONDITIONING AND AN HRP DEMONSTRATION OF CEREBELLAR AFFERENTS. J.S. Lincoln\*, D.G. Lavond\*, T.L. Hembree\*, J.K. Thompson\* and R.F. Thompson (SPON: M. Stanton). Dept. Psych., Stanford Univ., Stanford (CA 9405. We have demonstrated recently that unilateral electrolytic or aspirative lesions of the lateral deep cerebellar nuclei prevent and abolish ipsilateral learning of the classically conditioned nictitating membrane (NM)/eyelid response in the rabbit. Learn-ing on the eye contralateral to the lesion is not impaired. There is now an abundance of evidence from lesions (effective versus noneffective locations), recordings of neural units, stimulation, and pharmacology that the region including the medial dentate nucleus and the lateral interpositus nuclei are critically involved in the conditioned response circuit. In medial dentate nucleus and the lateral interpositus nuclei are critically involved in the conditioned response circuit. In order to localize the effect better, we injected kainic acid into the deep cerebellar nuclei of well trained rabbits (kainic acid is presumed to cause less damage to fibers of passage). We hoped that kainic acid lesions would partially alleviate the problem of destroying fibers from the dentate nucleus caused by electrolytic lesions of the interpositus. Following 1 week of electrolytic lesions of the interpositus. Following 1 week of recovery, the rabbits were then retrained for 4 days on the ipsilateral eye, 4 days on the contralateral eye, and back 1 day on the eye ipsilateral to the lesion. The animals showed no retention or relearning ipsilateral to the injection but quickly learned on the contralateral eye. Histological analysis of the lesion suggests that the critical site is primarily the inter-positus nucleus. positus nucleus.

Injections of HRP or wheat germ agglutinized HRP were made agree in terms of afferents previously reported for rabbits. The results agree in terms of afferents previously reported for rabbit and/ or for rat, cat and monkey. Retrogradely labeled cells were observed in the spinal and sensory trigential nuclei, the pontine nuclei, the reticular tegmental nucleus, the inferior olive, the red nucleus, the cuneate nucleus, the lateral reticular nucleus, the perihypoglossal nuclei, and neurons located throughout por-tions of the brainstem reticular formation. In our material a tions of the brainstem reficular formation. In our material a few cells were also labeled in the inferior colliculus as were some smaller cells in the superior olive. Interestingly, we also found bilateral labeling of cells in the locus cereleus and many bilaterally labeled cells within the periventricular gray. These data provide information concerning the convergence of subtribute of the uncertained and putative circuitries for projection of the unconditioned and conditioned stimulus information to the deep cerebellar nuclei a necessary condition if that is the locus of plasticity respon-sible for learning.

189.3

LATERAL HYPOTHALAMIC SELF-STIMULATION AFTER LESIONS IN THE ANTERIOR OR LATERAL HYPOTHALAMUS, C. Munoz\*, U. Sprick\* and J.P. Huston. Inst. of Psychology III, University of DUsseldorf, 4000 Düsseldorf, F.R.G. The present experiments were performed as part of the investigation of the neural organization of self-stimulation (SS) in the lateral hypothalamus (LH) of rats. First, we examined LH-SS after destruction of LH neurons, but not fibers of passage, with neuro-toxins. Bilateral injections of either kainic (1  $\mu$ g, n=10) or ibotenic (1  $\mu$ g, n=6) acid destroyed most of the cells in the region of the LH stimulating elec-trodes, but did not significantly influence SS between 12-24 hrs after the injections. Thus, LH neurons may not be essential for LH-SS. Next we examined the effects of radiofrequency lesions in the anterior hypothalamic area (AHA) on LH-SS. Bilateral lesions (n=10), which destroyed AHA and damaged the medial preoptic area, ventromedial hypothalamus and anterior lateral hypothalamus, did not significantly attenuate SS between 5 hrs and 7 days post-surgery. However, more severe unilateral lesions (n=11), which caused additional damage to the lateral preoptic area, the diagonal band of Brocca, the thalamus and the posterior LH, led to lateralized deficits in LH-SS. SS in the hemisphere with the lesion was significantly reduced by 80%, but remained intact in the intact hemisphere. Thus, the AHA seems not to be essential for LH-SS. The lateralized deficits of beserved after the unilateral lesions way have been due to damage to structures which were spared in the bilateral lesion group, such as the lateral pre-optic area.

ACQUISITION AND EXTINCTION OF A CONDITIONED TASTE AVERSION IN 1894 ACQUISITION AND EXTINCTION OF A CONDITIONED TASTE AVERSION IN MICRENCEPHALIC RATS. Joanne Weinberg, Raef Haddad and Ruth Dumas\*. Dept. of Anatomy, Univ. of British Columbia, Vancouver, B. C. VGTIW5, Canada; Dept. of Pathology, New York Med. Coll.-Coler Memorial Hosp., Roosevelt Island, N.Y. 10044; New York State Institute for Basic Research in Developmental Disabilities, Staten Island, N.Y. 10314.

Micrencephaly can be produced in offspring of pregnant rats by giving a single injection of the neurotoxin methylazoxymethanol acetate (MAM Ac) during pregnancy. In a variety of behavioral tasks these offspring appear hyperactive and exhibit learning or performance deficits under both appetitive and aversive conditions. Recently, it has been suggested that altered emotional activity or arousal may contribute to some of these performance deficits. The present study examined acquisition and extinction of a conditioned taste aversion in micrencephalic rats using a paradigm designed to assess arousal, as well as performance.

Pregnant Long-Evans rats were injected intraperitoneally with 25 mg/kg of MAM Ac in saline (or an equivalent volume of saline alone) on day 15 of gestation (vaginal plug = gestation day 1). Male offspring from both MAM Ac and saline injected animals were Male offspring from both MAM Ac and saline injected animals were tested at six months of age. Animals were given five exposures to a novel milk solution and then injected IP with either 0.4 M lithium chloride (LiCl), 7.5 ml/kg, or physiological saline. Following injection, all animals were food deprived for 72 hours and water deprived for the last 24 hours of the period and then re-exposed to the milk solution. Ad lib access to food and water was then restored and mignals were found doily represented to was then restored and animals were given daily re-exposure to milk for nine consecutive days. Mam Ac and control animals ex-hibited similar intake of milk during the five exposures prior to injection, as well as on the first re-exposure to milk follow-ing injection. However LiCL treated MAM Ac animals showed an increased resistance to extinction. In addition, saline treated MAM Ac animals showed less suppression of intake than the saline treated control animals on the first ad lib re-exposure day. These data suggest changes in response inhibition and responsiveness to environmental cues in the micrencephalic animals which may reflect hippocampal as well as cortical dysfunction. (Supported in part by British Columbia Health Care Research Foundation Grant #99).

MEDIAL GENICULATE BUT NOT AUDITORY CORTEX LESIONS BLOCK EMOTIONAL RESPONSES TO AUDITORY STIMULI A. Sakaguchi, J.E. LeDoux, D.J. Reis. Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 We examined whether in rat behavioral and autonomic conditioned 189.5

emotional responses elicited by acoustic stimuli are based on the neocortical processing of the sensory signal or on afferent information

Absorb the processing of the sensory signal of on alterent information diverging from the auditory pathway at subcortical stations. Male Sprague-Dawley rats (300-400g) were subjected to either bilateral subpial aspiration of the auditory cortex (ACX, n=19), as defined by neuroanatomical tracing studies (LeDoux et al, <u>Neurosci</u>. Abs., 1983), sham cortical operation (n=14), bilateral electrolytic lesion Abs., 1983), sham cortical operation (n=14), bilateral electrolytic lesion of the medial geniculate nucleus (MG, n=13), sham lesion of MG (n=7), or lesion of the lateral geniculate nucleus (LG, n=6). Two weeks after surgery, catheters were placed in the carotid artery for computer assisted recording of mean arterial pressure (MAP) and heart rate (HR) and the rats were subjected to aversive classical conditioning (30 trials) and the rats were subjected to average classical conditioning to transpondent involving the pairing of a pure auditory tone (800 Hz, 80 db, 10 sec) conditioned emotional stimulus (CES) with an electric footshock (2.0 mA, 0.5 sec) unconditioned stimulus (US). The next day, conditioned responses were measured. Three days later, unconditioned responses to the US were measured in some animals. The extent of damage was

the US were measured in some animals. The extent of damage was evaluated using standard histological techniques. Bilateral destruction of the auditory cortex had no effect on the rise in MAP (in mmHg: SHAM, 22+2; ACX, 20+3) and HR (in bpm: SHAM, 19+5; ACX, 14+4) or on the duration of immobilization or "freezing" (in sec: SHAM, 88+9; ACX, 74+9) elicited by the CES. In contrast, lesions of MG, but not LG, impaired the establishment of the MAP (SHAM, 22+3; LG, 21+4; MG, 4+1; p<01), HR (SHAM, 19+3; LG, 30+4; MG, 11+3; p 505) and immobilization (SHAM, 97+10; LG, 87+12; MG, 29+8; p<01) responses. MG lesions did not affect unconditioned responses (MAP: SHAM, 36+5; MG, 36+2; HR: SHAM, 132+20; MG, 99+15). These findings demonstrate that MG but not ACX lesions disrupt the establishment of autonomic and behavioral conditioned responses are

responses to an acoustic stimulus. Since unconditioned responses are not affected by such lesions, the results cannot be due to a disruption of the efferent pathways through which the responses are expressed.

We conclude that MG is a crucial afferent station in the pathway through which the emotional significance of an acoustic stimulus is through which the emotional significance of an acoustic stimulus is processed and that the next link in this emotive pathway must involve subcortical structures. Projections of MG to several areas involved in autonomic and somatomotor control (LeDoux et al, <u>Neurosci</u>, Abs., 1983) raises the possibility that these regions constitute subsequent links in the pathway through which autonomic and behavioral responses elicited by acoustic stimuli are regulated. Supported by PHS grant HL 18974.

189.6 A VISUAL PATHWAY THAT MEDIATES FEAR-CONDITIONED ENHANCEMENT OF ACOUSTIC STARTLE. <u>M.D. Tischler<sup>\*</sup> and M. Davis</u> (Spon: M.H. Sheard). Dept. Psychiat., Yale Univ. Sch. <u>Med.</u>, New Haven, CT 06508.

The way in which neural systems mediate associative learning represents an area of increasing interest to physiologists, represents an area of increasing interest to physiologists, pharmacologists and psychologists. Whether working in simple invertebrate systems or in the intact vertebrate, a necessary first step in this endeavor is to isolate the neural circuit where conditioning occurs. One approach to this problem is to work with a simple reflex that can be modified by prior associative learning. Fear enhanced startle in the rat fulfills these requirements. In this paradigm, startle magnitude is increased when the startle-eliciting stimulus is presented in the presence of a light (CS) that has previously been paired with a shock. Hence, conditioning is expressed through some neural circuit activated by the light which ultimately impinges on the startle circuit. Prior work using electrically elicited startle suggests that the light modulates electrically elicited startle suggests that the light modulates startle in the ventral nucleus of the lateral lemnisous (Berg and Davis, 1983). The task of this work was to delineate a pathway that might mediate transmission from the eye to the ventral nucleus of the lateral lemnisous.

80 rats received 10 light-shock pairings on two successive days. 72 hrs after the final training session, subjects received lesions directed at the primary visual areas (deep and superficial layers of the superior colliculus, dorsal lateral geniculate nucleus, pretectal nuclei, visual cortex and geniculate nucleus, pretectal nuclei, visual cortex and thalamic reticular nucleus) or at the nuclei of the lateral lemniscus or reticularis pontis caudalis, proposed components of a primary acoustic startle circuit in the rat. Control animals were sham operated. One day later, all animals were tested for startle by presenting noise bursts in the presence or absence of the light. Potentiated startle (the difference between light-noise vs noise-alone trials) was significantly attenuated or eliminated by lesions directed at the dorsal nucleus of the lateral geniculate, deep layers of the superior colliculus, visual cortex, and the posteroventral region of the nucleus of the lateral lemnisqus. Lesions directed at nucleus of the pretectal nuclei, colliculus, thalan the lateral lemniscus. Lesions directed at of the superior the lateral lemmiscus. I uclei, superficial layers thalamic reticular nucleus, nucleus reticularis pontis caudalis or dorsal nucleus of the lateral lemniscus did not attenuate potentiated startle. The results suggest that the conditioned stimulus pathway that mediates potentiated startle goes from the retina to the dorsal lateral geniculate nucleus to visual cortex to deep layers of superior colliculus and down to the postero-ventral region of the lateral lemniscus where acoustic startle is modulated.

MEMORY FOR STIMULUS-REWARD ASSOCIATIONS IN THE MONKEY IS MORE 189.7 SEVERELY AFFECTED BY AMYGDALECTOMY THAN BY HIPPOCAMPECTOMY. R. R. Phillips\*, B. L. Malamut\* and M. Mishkin (SPON: D. L. Robinson). Lab. Neuropsychol., NIMH, Bethesda, MD 20205. The amygdala appears to participate in stimulus-reward The amygdala appears to participate in stimulus-reward associative memory in two ways: coequally with the hippocampus in stimulus recognition; and alone (i.e. without participation of the hippocampus) in the attachment of affective value to the recognised stimulus. However, a critical piece of evidence in support of this conclusion was derived from an associative memory study in which monkeys had to learn a difficult conditional reaction (Spiegler and Mishkin, <u>Behav. Brain Res.</u>, <u>3</u>:303-317, 1981), a factor that may have contributed substantially to the impairment produced by amygdalectomy (Jones and Mishkin, <u>Exp.</u> <u>Neurol.</u>, <u>36</u>:362-377, 1972). To control for this possibility, we compared the effects of amygdaloid and hippocampal lesions on a nonconditional stimulus-reward association task (Gaffan, Learn. and <u>Motiv.</u>, <u>10</u>:419-444, 1979). Six monkeys were trained preoperatively to choose the positive

object of a trial-unique pair, each object in this pair having just been presented separately in acquisition, one with bait and the other without. Both the order of the positive and negative objects in acquisition and their spatial position in the choice test were determined pseudorandomly. Twenty trials were given daily with 10 second intervals between the successive events within a trial and 20 second intervals between trials. On reaching the criterion of 90 correct responses in 100 trials, three monkeys each were given bllateral amygdallectomy (group A) or hippocampectomy (group H), and after a two-week recovery period they were retrained to criterion. The number of objects presented in acquisition was then increased from the original list length of one pair, to list lengths of two and three pairs each presented to criterion; and, finally, to five and ten pair each given for 300 trials. Group A performed more poorly than group H throughout, requiring more trials to attain criterion pairs. through list lengths of three pairs (881 trials for group A vs 160 trials for group H), and obtaining lower scores on list lengths of five and ten pairs (78% for group A vs 86% for group H).

Because of the nonconditionality of this task, the results provide unambiguous evidence in support of the proposal that the amygdala plays a more important role than the hippocampus in object-reward associative memory, presumably because of the amygdala's special role in the attachment of reward value to a stimulus.

OLFACTORY DISCRIMINATION AND REVERSAL LEARNING IN RATS WITH COM-BINED HIPPOCAMPUS-AMYGDALA LESIONS. A. G. Kat\*, H. Eichenbaum and N. J. Cohen\*. Dept. Biology, Wellesley College, Wellesley, MA 189.8 02181

Humans and monkeys with combined damage to the hippocampus and amygdala (H-A) are normal in the acquisition of procedures des-pite a profound impairment for the outcomes of using procedures. To demonstrate this in rats, animals were trained on discrimination problems and reversals. It was expected that H-A rats and controls would similarly improve on successive discriminations during acqui-sition of the learning set procedure. Normals should take longer to reverse a discrimination, but if H-A rats forget specific material they would perceive the reversed stimuli as novel and might outperform controls.

Five Long-Evans rats with bilateral RF H-A lesions and 6 unoperated controls were trained to 90% correct in a 20 trial block on each of 3 go, no-go odor discrimination problems given on sep-arate days. On the next day the valences of stimuli on the last problem were reversed. Then 3 more discriminations and their reversals were alternated across days.

Both controls and H-A rats rapidly learned the first 3 prob-lems and both groups took many more trials to learn the first relems and both groups took many more trials to learn the first re-versal and the following discrimination and reversal. Thereafter, both groups rapidly acquired all problems. On no individual prob-lem did the control and H-A group scores differ significantly. However, there was a significant group by problem interaction at-tributable to patterns of group performance on the discrimination and reversal which followed the first reversal. On that discrim-ination problem the H-A group performed worse than the control group but improved on reversal. In contrast the controls showed the opposite pattern, i.e. took more trials to reach criterion on the reversal of the problem than on its discrimination. Unlike the famous patient H.M. whose H-A was surgically re-moved, H-A rats can discriminate odors. Also their acquisition rate for odor discrimination and reversal is normal. The differ-ence between H-A rats and normals in pattern of reversal learning provides some support for the prediction that reversal would less affect animals with H-A lesions than normals.

affect animals with H-A lesions than normals.

HIPPOCAMPAL AND NEOCORTICAL CONTRIBUTIONS TO SPATIAL LEARNING AND MEMORY, R. J. Sutherland and R. H. Dyck. Dept. of Psychol., Univ. of Lethbridge, Lethbridge, Alberta, Canada, TlK 3M4. The following series of experiments addresses predictions by

the spatial map, working memory, consolidation and cue salience theories of hippocampal (HPC) behavioural functions and examines the similarity of behavioural deficits resulting from damage to structures closely related to the HPC.

Several experiments were conducted using rats navigating to a hidden platform by means of distal visual or auditory cues in a 1.5 m swimming pool. 1. Rats with bilateral damage induced by intraHPC microinjections of 2µg/.5µl of colchicine could not swim directly to the platform and even though they found the platform on every trial (90 sec max., 8 trials/day), on probe trials when the platform location was changed their behaviour was unaffected rats given several months of prelesion training were similarly impaired. 2. In an attempt to simplify the available navigational cues, the pool was surrounded by black curtains and covered by a one-way glass. Two conspicuous visual beacons were suspended over the water and both the beacons and the initial start point for the rats were in fixed positions relative to the hidden platform. Unrats were in fixed positions relative to the hidden platform. Un-like normal rats, rats with HPC damage could not learn the locat-ion of the platform. In another experiment, auditory beacons were substituted, but again HPC damaged rats were impaired. 3. Bilater-al septal lesions and bilateral aspiration of posterior neocortex (including areas 17, 18, 18a and retrosplenial cortex), but not mammillary body lesions or aspiration of areas 17 and 18 alone, produce a deficit in place navigation that is similar to the HPC deficit. 4. A comparison was made of performance by rats with bilateral amygdala lesions, bilateral HPC lesions or both in the Morris water task and in conditioned taste aversion learning. Only the HPC and both lesion groups were impaired in place navi-gation, whereas, only the amygdala and both lesion groups were impaired in learning to avoid a sucrose solution paired with lithium chloride-induced illness. 5. Daily exploration of a complex environment by normal rats and rats with HPC or medial frontal cortex damage was examined. Despite clear differences among groups in the steady state level ofseveral behavioural measures, both lesion groups demonstrated a normal dishabituation of exploration when the environment was rearranged in various ways, including when the position of proximal objects was rotated 180 degrees relative to the distal objects in the room.

The results are consistent with a view that the hippocampus is essential for solving problems that require knowledge of the posi-tion of a specific object or event in relation to the configurat-ion of cues contained within map-like representations in association zones of the neocortex.

189.10 ON THE ROLE OF HIPPOCAMPAL CONNECTIONS IN THE PERFORMANCE OF PLACE AND CUE TASKS: COMPARISONS WITH DAMAGE TO HIPPOCAMPUS.

Jarrard, H. Okaichi\*, O. Steward and R. Goldschmidt\*. Dept. of Psychol., Washington & Lee Univ., Lexington, VA 24450. A selective impairment on a complex place but not a cue task was recently reported following extensive aspiration lesions of binnocamus and biochiors of biochiors. was recently reported following extensive aspiration lesions of hippocampus and injections of kainic acid into the subiculum and lateral ventricles; following injections of kainic acid into the CA3 cell field performance did not differ from that of controls on either task (Jarrard, <u>Neurosci. Abstr. 8:22</u>, 1982). The present experiment extends this research by employing the same task together with selective damage to structures and/or pathways related to the hippocampus.

Using a within-subjects design, rats were trained before the operations to run on an 8-arm radial maze with a procedure that involves two kinds of learning (place and cue) and two memory involves two kinds of learning (place and cue) and two memory functions [reference memory (RM) and working memory (WM)]. In the place version of the task the same 4 arms were baited from trial to trial and room cues (door, rack of cages, overhead lights) remained in the same spatial location. In the cue task 8 remov-able inserts of different materials were placed in the arms but the location was changed from trial to trial in a random order --4 of the 8 cues were consistently baited.

After learning the two tasks, the rats were divided into two control groups (operated and unoperated) and 4 lesion groups. Colchicine was used to damage cells in the dentate gyrus (DG), while lesions of the fimbria-fornix (FF), entorhinal cortex (EC), and mammillary bodies (MB) were made with radio-frequency. Following recovery, the animals were retrained to approach the last 4 arms (and 4 cues) that had been learned before the operations.

Analysis of the behavioral data indicated that performance of analysis of the Desion was impaired overall, with performance on the place task being especially affected. Further analysis of the types of errors made showed that FF and EC animals made more WM errors than the other groups on both place and cue tasks, but more RM errors only on the place task. Even though rats in the OC Group enforced extension loss of errorule collect there use only DC Group suffered extensive loss of granule cells, there was only a temporary impairment on the place task. Performance of rats

a temporary impairment on the place task. Performance of rats with lesions of the MB was like that of controls. These findings, together with the results of the previous ex-periment, indicate that (1) unlike the WM impairment found follow-ing FF and EC lesions, there is no impairment of memory resulting from direct damage to hippocampus, and (2) cells in the hippocam-pus (DG and CA3) are not necessary for correct performance of the complex place and cue tasks used in these experiments.

189.11 LONG-TERM DEFICITS IN ASSOCIATIVE AND SPATIAL RECOGNITION MEMORY AFTER EARLY HIPPOCAMPAL DAMAGE IN MONKEYS. L. <u>Rehbein and H.</u> <u>Mahut</u> (SPON: A. Skavenski). Dept. of Psychol., Northeastern Univer., Boston, MA 02115.

We reported earlier that 8 rhesus macaque monkeys with hippocampal removals sustained at 2 mos of age were impaired postoperatively, compared to 5 normal infants, on a spatial (L-R) discrimination reversal task and on an object discrimination retention task with 24- and 48-hr intervals between successive retention task with 24- and 48-hr intervals between successive retention tests. The spatial deficit was no longer present, and the retention deficit became attenuated, on a second re-test, two years later. At 5 yrs of age, operated monkeys performed with normal ease on a task in which discriminations between members of 8 pairs of objects had to be learned concurrently and were not impaired, as a group, on the spatial delayed alternation task, though both tasks are sensitive to hippocampal damage in older monkeys. At the same time, however, they were significantly impaired on a trial-unique delayed non-matching to sample (DNMS) recognition memory task (Rehbein <u>et al., Neurosci. Abstr., 6</u>:8, 1980). In view of the unimpaired performance on the two cumulative

In view of the unimpaired performance on the two cumulative learning tasks but a co-existing deficit on a task in which object quality had to be remembered for not more than 2 min after a single presentation, we re-assessed spatial and visual capacities with the use of DNMS tasks. The same monkeys were tested, at 6 yrs of age, on 1. An <u>object-reward association task</u> in which they had to remember which of two equally familiar objects had been associated with food reward 10 to 130 sec earlier (Gaffan, 1979) and 2. A <u>spatial recognition task</u> in which they had to discern, on every trial, an unfamiliar from a familiar location of one of two identical plaques on an 18-well food tray. Operated monkeys were impaired with 70 and 130 sec delays on the first task, and with all delays, on the second. 3. A <u>recognition task with increasing memory loads</u> in which all previously presented items remained on the 18-well tray and food could be obtained by displacing only new, successively added items (identical plaques or different objects). Operated monkeys retained significantly fewer items than did normal monkeys. In 6 of the 8 operated monkeys there was moderate to extensive damage of inferotemporal cortex, but no correspondence could be found between performance and extent of neocortial damage in the present, and one previous (Mahut <u>et al., J. Neurosci.,</u> 2:1214, 1982), experiment.

2:1214, 1962), experiment. Thus, selective deficit on one of two classes of tasks points to the existence of two distinct neural systems: One, mnemonic, which depends on the integrity of the hippocampus, the other, a stimulus-response learning system (Hirsh, <u>Behav. Biol.</u>, <u>12</u>:421, 1974) which remains to be identified anatomically. 189.12 COMPARISON OF MEMORY IN RATS AFTER LESIONS IN MEDIAL SEPTAL AREA AND NUC. BASALIS MACNOCELLULARIS. J. M. Ordy, Pennwalt Corp., Rochester, N.Y. 14623; G. Thomas, U. of Roch., Rochester, N.Y., 14624; W. Dunlap, Tulane U., New Orleans, IA. 70118; and J. Blosser, Pennwalt Corp., Rochester, N.Y. 14623.

Degenerating cholinergic neurons of nucleus basalis of Meynert (nbM) that project to cerebral cortex have been implicated in memory deficits of Alzheimer's disease. Studies with drugs and lesions have indicated an important role for cholinergic septohippocampal (s-h) neurons in short-term memory. In contrast to the compact neurons of discrete nbM in man and other primates, homologous cholinergic neurons in rats appear spatially more dispersed along the ventral pallium medial to the substantia innominata. They have been termed nucleus basalis magnocellularis (nbm). The aim of this study was to compare the effects on memory of discrete septal lesions and small bilateral le-sions of nbm of rats. The short-term memory test was conducted in a T-maze adapted to present a spatial delayed-nonmatching-to-sample problem. The task included trial-specific memory at 10, 90, and 180 sec. delays. Start, choice, and goal laten-cies served as indices of drive and neuromuscular performance. Lesions were made electrolytically through a stereotaxically guided electrode, and they were verified microscopically from Nissl-stained sections cut on a Vibratome. Analysis of Vari-ance evaluated pre- and post-operative differences in trialspecific memory and in motor performance. Operated controls did not differ significantly neither in memory nor performance. Rats with bilateral nbm lesions showed no significant post-Alls with Diractil nom restors showed no experiment pos-operative changes in memory at 10-sec. delays, but they were significantly impaired at 90- and 180-sec. delays (p<0.02). Rats with medial septal lesions were significantly impaired in memory at all three delays (p<0.01). The pre-postoperative differences in motor performance were not significant among the three groups. The results indicated that non lesions in rats produced deficits in trial-specific memory, but they were not as severe as those produced by medial septal lesions. Thus, both cholinergic neurons of nbm and of medial septum appear to be involved in short-term memory. The findings are consistent with the reported correlations between recent memory deficits and degeneration of nbM neurons in Alzheimer's disease. Clar-Clarification of the effects of lesions on transmitter-specific basal forebrain circuits involved in memory in animal models is an important step in the development of therapeutic approaches to Alzheimer's disease.

- 189.13 LESIONS IN NUCLEUS BASALIS OF MEYNERT AND MEDIAL SEPTAL AREA OF RATS PRODUCE SIMILAR MEMORY IMPAIRMENTS IN THREE BEHAVIORAL OF MATS PRODUCE SIMILAR MEMORY IMPAIRMENTS IN THREE BERAFICIAL TASKS. D. Hepler<sup>6</sup>, G. Wenk, and D. Olton. Dept. of Psychology, Johns Hopkins Univ., Baltimore, MD 21218; <u>J. Lehmann</u> and <u>J. Coyle</u>. Dept. of Psychiatry and Behavioral Science, Johns Hopkins School of Medicine, Baltimore, MD. 21205. (SPON: M. Larrabee). The present investigation evaluates the importance of cholinergic activity in cortical brain regions for learning and memory. Rats received lesions in nucleus basalis of Mevnert (nbM), the source of a major cholinergic projection to neocortex, or the medial sectal area (MSA), the source of a major projection to hippocampus. Lesions were made with either radiofrequency current or ibotenic acid. Control rats received sham operations. Three behavioral tasks were used to assess changes in learning and memory: acquisition of a delayed-match-to-sample discrimination on a T-maze, retention of a discrimination learned preoperatively on a radial eight arm maze, and acquisition of active and passive avoidance in a two-way shuttle box. In the performance of all three tasks, rats with nbM and MSA lesions showed qualitatively similar changes, relative to the performance of controls (p < 0.05): performance was impaired in the delayed-match-to-sample task, the radial arm maze discrimination, and passive avoidance, but was facilitated in two-way active avoidance. Thus damage to cholinergic neurons in both MSA and nbM produced behavioral changes similar to those seen with damage to the Lesion size and location was assessed in nisslhippocampus. stained histological material. Choline acetyltransferase (ChAT) assays were performed on samples taken from neocortex and hippocampus following the completion of behavioral testing. ChAT activity was decreased by 20% in the medial frontal cortex of rats with nbM lesions, and by 30% in the hippocampus of rats with MSA lesions. Rats with identical lesions sacrificed seven days after surgery had 50-70\$ ChAT decreases in both brain areas respectively. Thus a considerable recovery of ChAT occured by the end of behavioral testing. These results suggest that cholinergic activity in cortex may have a significant effect on learning and memory in the rat. (Supported by research grant NS18414 from the NINCDS).
- 189.14 PRODUCTION OF AMNESIA FOR REPRESENTATIONAL MEMORY BY SEPTAL AND CORTICAL LESIONS AND ITS RECOVERY IN RATS. <u>G.</u> J. <u>Thomas</u> and P.S. <u>Spafford</u>\* Center for Brain Research, University of Rochester Medical Center, Rochester, New York 14642.

A theoretical distinction was made between dispositional memories and representational memories by supposing, first of all, that memory is a concept (not a datum) that is inferred from discriminative responses. Dispositional memories are indicated when learned discriminations are made between two or more cues that are present to the organism's sensorium at the time of behavioral choice. When successful discriminations are made with the critical cue not present at the time of choice to the animal's sensorium (i.e., the critical cue must be represented by a hypothetical memory trace in the organism's brain from past experience), an instance of representational memory is indicated. A delayed-nonmatching-to-sample task in a T-maze operationalizes this distinction. Considerable preoperative habituation and adaptation are necessary to ensure that the task is yielding relatively "pure" instances of representational memory. After preoperative adaptation and training, all rats displayed

After preoperative adaptation and training, all rats displayed efficient use of the information in sample runs to make correct disciminations on choice runs. The rats were then placed into four matched groups for surgery. Groups consisted of an operated-control group (no brain lesions), a group with posterodorsal septal lesions, a group with prelimbic (area 32) cortical lesions, and a group with both lesions. Lesions were produced electrolytically through a stereotaxically guided electrode. Postoperative testing was precisely the same as preoperative testing. Anatomical characteristics of lesions were determined from Nissl-stained sections cut from celloidinembedded brains.

Septal lesions and lesions in prelimbic cortex resulted in amnesia for representational memories. The amnesia typically ameliorated as a function of continued reinforced postoperative testing. When lesions were placed in both structures in the same animals, amnesia for representational memories also occurred, and with continued testing, it ameliorated as indicated by group data. However, examination of behavioral scores and lesions in individual rats indicated that when both lesions were adequate, choices remained at chance levels. This observation suggests a permanent amnesia for representational memories.

That the lesion-induced amnesia was restricted to representational memories was indicated by the fact that the rats displayed no evidence of amnesia regarding what to do in the maze. They did not act like naive animals, as they should, if they had forgotten dispositional memories regarding maze performance.

It would appear that very nearly complete ablation of critical brain circuits is necessary to preclude recovery.

DIFFERENTIAL ENVIRONMENTS AND RADIAL MAZE PERFORMANCE: 189.15 EFFECTS OF ANTERIOR CINGULATE CORTEX LESIONS. Eric Nisenbaum\*, Janice Juraska, and Constance Henderson\* (SPON: D.M. Schroeder). Dept. of Psychology, Indiana Univ., Bloomington, IN 47405. Rats reared from wearing in a complex environment often are superior in maze learning in comparison to rats in an isolated environment (reviewed by Greenough in <u>Neural Mechanisms of</u> Learning and Memory). In two separate replications, male and female hooded rats raised in either a complex environment (EC) or an isolated environment (IC) were run on a 17-arm radial maze. EC rats made fewer errors in their first 17 arm choices, more correct arm choices until their first error and fewer total errors than IC rats in both replications. There were no sex differences or sex by environment interactions on any of these measures, in contrast to prior reports of male superiority on mazes (reviewed by Beatty, <u>Horm. Beh., 12</u>:117, 1979). The EC rats chose significantly more arms adjacent to their last arm choice than did IC rats; this adjacent arm strategy may have contributed to the superior performance of the EC rats.

In a second experiment, male EC and IC rats were exposed to the differential environments for a month, either lesioned or sham operated in the anterior cingulate cortex and run on a 17-arm radial maze. The EC rats in general made more correct arm choices to the first error, fewer total errors, and more adjacent arm choices. There also was a significant interaction between the environment and lesion conditions in total errors such that sham-operated EC rats made fewer errors than both their lesioned counterparts and lesioned and sham IC groups. The results imply that the anterior cingulate cortex, with its connections to the hippocampal formation, contributes to the superior performance of the EC rats, not in terms of the adjacent arm strategy but rather their working memory. Supported by the MacArthur Foundation and NIH grant HD14949.

189.16 BEHAVIORAL AND HIPPOCAMPAL DEFICITS DUE TO MILD PERINATAL ZINC DEFICIENCY. E.S. Halas, C.D. Hunt\* and H.H. Sandstead\*. Department of Psychology, University of North Dakota, and USDA, ARS, Grand Forks Human Nutrition Research Center, Grand Forks, ND 58202.

A recent study found that adult rats who were severely zinc deficient (ZD) during lactation suffered impaired learning and deficient (2D) during lactation suffered impaired learning and working memory. Rats who were undernourished (PF) during lactation were deficient in learning but not working memory. Reference memory was not impaired. In the present study, a total of 162 adult male rats were used. Every litter was reduced to 9 pups 24 hrs after delivery. Every litter contributed at least 1 male to Groups A, B, and C. There were 13 AL, 11 PF, and 11 ZD litters. Fifty-four adult male rats, who suffered mild zinc deficiency (ZD) during gestation and lactation, were divided equally into three groups. Group A were sacrificed at 100 days equally into three groups. Group A were sacrificed at 100 days of age and their hippocampi, cerebellum, and cortex were histologically examined under light and electron microscopy. Group B, starting at 100 days old, were tested for working Group C, setting at 100 days old, were tested for working memory, reference memory, and learning in a 17-arm radial maze. Group C were individually housed in cages until they were 300 days old. Fifty-four adult male rats, who suffered mild undernutrition (PF) during gestation and lactation, were also divided into Groups A, B, and C and given the same experimental procedures as the ZD rats. A control group of 54 adequately nourished (AL) rats were also divided into Groups A, B, and C. The rats in groups B and C were sacrificed at 300 days of age an age and their hippocampi, cerebellum, and cortex were histologically examined. Because of interactions between age, nutrition, and learning, it was hypothesized that there would be greater anatomical differences between the ZD, PF, and AL rats in Group C than the AL, PF, and ZD rats in Group A and also Group B. Comparing the ZD, PF and AL rats in Group B with their counterparts in Group C will show if learning can compensate for nutritional deficiencies. The anatomical deficits, if any, will be correlated with the behavioral deficits. ZD rats were deficient in both learning and working memory while PF rats suffered only a mild learning deficit. The anatomical data is currently being analyzed. Prior work in our laboratory found both anatomical and behavior deficits due to mild zinc deficiency and/or undernutrition.

189.17 ACCUISITION AND RETENTION OF A RADIAL 8-ARM MAZE TASK BY RATS SUBJECTID TO TRANSIENT FOREBRAIN ISCHEMIA. T. P. Cecere\*, H.J. Davis, W. A. Pulsinelli, and B. T. Volpe\*. Dept. Psychol., S. John's Univ. and Dept. Neurol., Cornell Univ. Med. Coll., NY, St. NY 10021.

Neuropathological and behavioral assessments of a possible animal model of hypoxic ischemic injury in humans following stroke or sudden cardio-pulmonary arrest are reported. The stroke or sudden cardio-oulmonary arrest are reported. The accuisition of the "reference" and "working" memory components of a radial 8-arm maze task were impaired in Wistar rats subjected to 30 min of forebrain ischemia by the method of 1- vessel occlusion (Pulsinelli & Brierley, <u>Stroke</u>, <u>10</u>, 267, 1979) as compared to control rats (p(0.05). While rats made ischemic were slower to learn the "reference" aspect of the task (5 of 8 arms baited), they demonstrated performance identical to that of control mate for <u>00</u> trieds a supersting identical to that of control rats after 60 trials suggesting the importance of repetition in acquisition of this aspect of the importance of repetition in acquisition of this aspect of the task. In contrast, working memory performance by L-vessel occlusion rats during acquisition trials did not approach the level attained by control rats. Rats trained prior to stroke demonstrated normal retention of the reference component during postoperative trials as compared to controls (p>0.20). Postoperative performance by 1-vessel occlusion rats on the working memory aspect of the 8-arm maze task is being assessed and will be reported. Alterations in locomotor activity could not account for performance deficits since control and experimental rats demonstrated equivalent choice time per maze arm. Neuropathologic analysis of 4-vessel occlusion rats showed bilateral destruction of the CA-1 region of hippocampus and bilateral focal infarcts of dorsal caudate nucleus,

189.18 THE EFFECTS OF LOCAL COOLING OF INFEROTEMPORAL CORTEX ON THE PERFORMANCE OF VISUAL TASKS. J.A. Horel, Dept. of Anatomy,

PERFORMANCE OF VISUAL TASKS. J.A. Horel, Dept. of Anatomy, Upstate Medical Center, Syracuse, New York 13210. Three monkeys (<u>Macaca fascicularis</u>) were trained on an auto-mated delayed match to <u>sample</u> (DMS). The animals were restrained in a chair facing three rear projection screens. Seven hundred forty colored photographs of objects were used as stimuli and were rear projected onto the screens. The sample appeared at the center screen and the match and non-match at the two side paraers. Delaye between procentation of the screens and the cent screens. Delays between presentation of the sample and the oc-currence of the match were 0, 15, 30 or 45 sec., presented in random order. Correct performance was rewarded with a squirt of juice to the mouth. Cooling devices were then implanted bi-laterally over the inferotemporal gyri for making localized reversible functional lesions while the animal performed the DMS. These were 10 x 3 mm oblong loops of stainless steel tubing. They were assembled into an array of four, each one 3 mm apart and placed outside the dura over IT so that each one would cool about 1/4 of IT. We call the most anterior #1 and the most posterior #4. Cooled methanol was pumped through the tubing and temperature was monitored by thermocouples placed on the tubes. On experimental trials this was set at  $0^{\circ}$ C. Blocks of 20 trials were run in which one of the four pair of probes was cooled bilaterally or control blocks were run with no cooling. The blocks were randomly intermixed. One hundred twenty trials were blocks were randomly intermixed. One hundred twenty trials were run per day, one block for each of the four probes and two control blocks. The animals were run for 4 days. There was a significant deficit produced by cooling probes 1, 2 and 3 but not 4. There was no significant interaction with delay. In contrast to previous findings of the same cooling in the temporal pole, (Horel et al, Neuroscience Abstracts, 1982) the curves were flat, showing no drop off at the longer delays. At the anterior probes, average performance was between 70-81% correct; on probe 4, performance was 86-96% correct and 80-98% correct on controls. There was improvement in performance over the 4 days of testing. The animals were then trained on a horizontal vertical stripe discrimination and tested for retention during cooling. No deficit was found from any of the probes. However, a deficit was found when the anterior probes were cooled during learning of object discriminations, more from probe 2 than 1 or 3 and not at all from probe 4. Thus, we were able to reproduce some, but not all of the effects of tissue removal lesions with small revers-ible cold lesions. Visual learning was more readily disrupted than was retention.

189.19 EFFECTS OF COOLING ORBITAL AND INFERIOR LATERAL PREFRONTAL CORTEX ON LEARNING AND RETENTION OF VISUAL DISCRIMINATIONS AND THEIR REVERSALS. <u>Mary Lou Voytko</u>. Dept. of Anatomy, Upstate Medical Center, Syracuse, NY 13210.

Cooling the temporal pole disrupts the ability of monkeys to learn visual discriminations (Voytko et al., Neuroscience Abstracts, 1982). The temporal pole has reciprocal connections with the orbital and inferior lateral surface of the frontal lobe. In this study, we explore the ability of monkeys to learn visual discriminations and perform the reversal discriminations while cooling these frontal areas. Implanted loops of stainless steel tubing covered the orbital

and inferior lateral prefrontal cortex. During the experimental trials, the temperature of the loop was set at 0°C. The subjects faced 3 rear projection screens. A white light, projected to the center screen started a trial, and a response to it extinguished the light and exposed the discriminative stimuli on the two side screens. Randomly paired photographs of objects were used as stimuli and the correct stimulus alternated sides randomly.

The ability of the animals to learn a visual discrimination while cooling the orbital and inferior lateral cortex, was severely disrupted. Once the task was learned however, the animals showed excellent retention of the discrimination the next day when the cold was again applied. On the third test day, the animals were trained without the cold on the reversal of the previously learned task. In the first 20 trials, the animals performed below chance levels, but soon thereafter performed at a high level. They showed good retention of the reversal discrim-ination the next day, but on the fourth test day, with the cold applied, the animals' retention of the reversal discrimination was below control levels. This procedure was repeated for 3 more pairs of photographs.

The below chance performance levels in the initial trials of acquiring the reversal discrimination shows that at least some of the task that was learned under cold was retained when tested without the cold. Thus, cooling the orbital and inferior lateral prefrontal cortex severely affects the ability to learn visual discriminations, but does not affect their retention under the cold, if they also are learned under cold. Cooling these frontal areas disrupts the retention of reversal visual discriminations learned before the cold is applied. (Supported by NINCDS NS18291)

COMPARISON OF PERFORMANCE ON A PLAGETIAN OBJECT PERMANENCE TASK 189.20 IN HUMAN INFANTS AND RHESUS MONKEYS: EVIDENCE FOR INVOLVEMENT OF

IN NORAM INFANTS AND KNESDS MONKETS: EFIDENCE FOR INVOLUENCEN OF PREFRONTAL CORTEX. A. Diamond and P. Goldman-Rakic, Sect. of Neuroanatomy, Yale Sch. of Med., New Haven, Conn. 06510. One of the classic tests of cognitive change during the first year of life is Piaget's AB Stage IV Object Permanence Test. AB is very similar to Delayed Response (DR), the task most firmly liked to the performated extern in enhancements. linked to the prefrontal cortex in nonhuman primates. In both tasks the subject watches as a reward is hidden at one of two identical wells, a delay follows, then the subject is allowed to reach. The performance of human infants below 12 months on  $A\overline{B}$  matches that of prefrontally operated monkeys on DR, suggesting that developmental changes in prefrontal cortex may be related to the improvement on  $A\bar{B}$  seen between 7-8 months and one year in children.

To explore the link between the prefrontal cortex and  $A\overline{B}$  more directly, the present study investigated  $A\overline{B}$  in normal infants and, for the first time, in operated and unoperated rhesus monkeys. It is important that the same task was used because  $A\overline{B}$  and DR are not identical. (In DR, side of hiding is varied randomly across trials; in  $A\overline{B}$ , side of hiding remains constant randomly across trials; in AB, side of hiding remains constant until the subject is correct, then it is reversed.) Subjects were 25 full-term infants, tested every 2 weeks throughout the second half of the first year, and 5 rhesus monkeys (Macaca Mulatta, age 2-4 years): 2 with bilateral lesions of dorsolateral prefrontal cortex including the principal sulcus, 2 unoperated, and 1 with a bilateral parietal ablation. Monkeys were tested in the WGTA with care taken to make the procedures as identical to those used with children as possible. Reversal trials were

administered following correct reaches on 2 consecutive trials. When infants began to search for hidden objects at 7-8 months when infants began to search for midden objects at /-o months of age, they made a characteristic set of errors on AB, even with delays of only 1 or 2 seconds. By 12 months they did not err with delays as long as 10 seconds. Like the younger infants, prefrontally operated monkeys failed AB at delays of 2 seconds; while unoperated, and parietally operated, monkeys performed perfectly. Moreover, the pattern of errors displayed by monkeys with prefrontal lesions was identical to that seen in infants. When side of hiding was repeated after a correct reach, both human infants and prefrontally operated monkeys performed correctly. When side of hiding was reversed, however, infants and prefrontal monkeys were impaired and repeated the same error over consecutive trials.

These findings are an important demonstration of a link between the prefrontal cortex and a test sensitive to developmental changes in the cognitive ability of the human infant. (Supported by NSF BNS-8013-447, HD-10094, MH-00298, MH-38456, and grants from the Danforth and Sloan Foundations.)

### LEARNING AND MEMORY: PHYSIOLOGY

190.1 FURTHER STUDIES OF THE INVOLVEMENT OF LOCUS COERULEUS IN PLASTICITY OF AVIAN LATERAL GENICULATE NEURONS DURING LEARNING. C.M. Gibbs, J.L. Broyles\* and D.H. Cohen. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.

We previously reported (Neurosci. Abstr. 7: 752) that during visually conditioned heart rate change in the pigeon a population Visually conditioned near rate change in the pigeon a population of neurons in the avian equivalent of the dorsal lateral geniculate  $(LCN_e)$  shows enhancement of its CS-evoked activity. This population consists of those LGN<sub>e</sub> cells showing decreased (Type II) discharge to foot-shock, the US. In contrast, cells responding with increased (Type I) discharge or which are unresponsive show attenuation, as (1)pe 1) discharge of which are unresponsive show attenuation, as do cells during nonassociative training. More recently, we describ-ed findings suggesting that locus coeruleus (LC) mediates the Type II response and thus may be necessary for plasticity during learn-ing (Neurosci. Abstr. 8: 666). We now describe studies showing that: (a) cells in both LC proper and subcoeruleus (SC) may be antiformically activated by  $LCN_e$  stimulation; (b) stimulation of these structures affects the discharge of most  $LCN_e$  cells; and (c) pairing such stimulation with whole-field illumination (CS) may serve as an

effective US for inducing plastic change in  ${\rm LGN}_{\rm e}$  neurons. Acute electrophysiological experiments demonstrated that  ${\rm LGN}_{\rm e}$ stimulation antidromically activates some cells in both LC and SC, confirming earlier anatomical data. These cells have slowly con-ducting axons (0.5-1.2m/sec), consistent with mammalian findings. Moreover, we extended our earlier findings regarding the US-respon-siveness of LC neurons by showing that 62% of the SC cells respond siveness of the section by showing that 6.2 of the section section respond with increased discharge to foot-shock. Thus, the cells of origin of the coeruleus projection to the LGN<sub>e</sub> appear to be distributed throughout the complex. In another series of studies we found that electrical stimulation of LC and SC affects the discharge of most LGN<sub>e</sub> cells. These stimulation effects are quite similar to those

Long certs. Inset stimulation effects are quite similar to those produced by foot-shock (Neurosci, Abstr. 8:666). Given this, we initiated studies to determine whether coeruleus stimulation may serve as an effective US for inducing changes in the light-evoked activity of LCNg cells. Our preliminary studies involved single cell recordings during a conditioning paradigm in which whole-field illumination is repeatedly paired with corruleus stimulation. The results to date are strikingly consistent with our stimulation. The results to date are strikingly consistent with our earlier findings using foot-shock as a US; the CS-evoked discharge of LCR<sub>e</sub> cells with Type II discharge to LC stimulation showed rapid modification during training, while cells with Type I discharge to stimulation showed response attenuation. Thus, electrical activat-ion of the coeruleus complex constitutes a sufficient US for training-induced modification of  $LCN_e$  cells. This provides an opportunity to develop a thalamic slice as an <u>in vitro</u> "analog model" for associative learning at a vertebrate synapse. 190.2 DISRUPTION OF PERIPHERALLY INDUCED SPINAL FIXATION IN RATS BY A STRONG ELECTRICAL STIMULUS. J. E. Steinmetz\*, D. Molea\*, and M. M. Patterson (SPON: L. Edds). College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

Peripherally induced spinal fixation is a long term persistence of hindlimb flexion that follows appropriate periods of thigh skin stimulation. The present study examined potential similarities between fixation and hypothesized memory consolidation processes underlying information storage in the brains of intact organisms. It was hypothesized that if fixation resembles intact memory consolidation, the fixation process should be susceptible to retrograde disruption by a strong electrical shock in a manner similar to the retrograde disruption of intact memory often seen

with application of electrograde distribution of infact memory often seen Forty-eight anesthetized (pentobarbital, 50 mg/kg, ip) rats received 30 min of thigh skin stimulation (2 mA, 100 pps, 7 msec) after spinal cord section. Flexion present 5 min and 40 min sub-sequent to stimulation offset was recorded by suspending weights Sequence to standardon of set was recorded by suspending weights from the flexed limb. In addition to this common treatment, rats were randomly assigned to six groups (ns = 8) that differed as to when a strong electrical stimulus (10 mA, 500 msec) was applied to the spinal cord at L-1. Spinal shock was given either before stimulation, 15 min after stimulation onset, 10 sec after stimulation offset, 20 min after stimulation offset, for 35 min after stimulation offset, A sixth group served as a control and re-ceived no spinal shock. Results of this study showed a signifi-cant disruption of stimulation induced flexion only when spinal shock was delivered 10 sec after stimulation offset. Furthermore, loss of flexion was apparently permanent since flexion was not observed in this group 40 min after stimulation. Spinal shock applied at other times failed to affect the poststimulation retention of flexion.

The retrograde effect of spinal shock suggests that spinal al-terations are not completely "consolidated" at the offset of stimulation. Moreover, spinal shock seems to disrupt the fixation process in a manner that resembles ECS disruption of intact memory processes. These data support a "consolidation theory" explanation of peripherally induced spinal fixation.

CLASSICAL CONDITIONING OF THE FLEXION REFLEX: ACUTE VS. CHRONIC 190.3 SPINAL CAT. <u>S. Onifer\* and R.G. Durkovic</u>. (Spon: S. Nord) Dept. Physiol., Upstate Med. Ctr., Syracuse, NY 13210 Classical conditioning of the flexion reflex was investigated

in acute, 2 week and 3 month chronic spinal cats. Experimental techniques were the same as those detailed in Physiol. & Behav. techniques were the same as those detailed in Physiol. & Behav. 14:297 (1975). Briefly, the left hind limb of cats with T-10 spinal transections made 3 months, 2 weeks or just before decerebration was anchored with a femur pin and foot clamp. The distal tendon of the tibialis anterior (TA) muscle was cut and connected to a transducer for monitoring reflex tension. The classical conditioning paradigm involved 30 pairings of the CS (10 Hz stimulation of the saphenous nerve for 1.5 sec) with the US (30 Hz stimulation of the cutaneous superficial peroneal n. for 0.5 sec) using a 1.0 sec interstimulus interval. Intertrial intervals were 1 minute in duration. Sensitization control animals received the same number of CS and US presentations over the same time span, but the US was presented 30 sec after each CS presentation (exclusively unpaired).

For all animals the response measured was the maximum tension from the TA muscle during the first second of each CS presen-tation. Reflex responses during acquisition were compared to baseline control values (mean of five CS alone trials) obtained just before acquisition.

In <u>acute</u> spinal animals the conditioning paradigm resulted in a rapid increase in flexion reflex amplitude in response to the CS, while the responses from sensitization control animals remained near baseline levels. A significant difference between conditioning and sensitization 30 trial group means was obtained (p<.01). In <u>2 week chronic</u> spinal animals no facili-tation was observed as the reflex response to the CS declined over trials in both conditioning and sensitization control animals at equal rates. In <u>3 month chronic</u> spinal animals the magnitude of the reflex in conditioning animals remained near baseline levels over trials while that of sensitization control animals declined. Differences between 30 trial means of 3 month chronic conditioning animals were significantly greater than those of the sensitization animals (p<.05). The results show that the ability to demonstrate classically

conditioned responses from the spinal cord can depend upon time after transection. This may help to explain the failure to observe conditioning in chronic spinal animals in earlier studies of other investigators.

Supported by National Science Foundation Grant 80-23943.

RETENTION OF CLASSICALLY CONDITIONED FLEXION REFLEX FACILITATION 190.4

Melianion of classically conditioned Flation Reflex Facilitation IN SPINAL CAT. R.G. Durkovic, Dept. of Physiology, Upstate Medical Ctr., Syracuse, NY 13210. To investigate the retention (duration) of classically conditioned flexion reflex facilitation in acute spinal cat, conditioned stimulus (CS) trials were presented for a 2 1/2 hour period following conditioning or sensitization paradigms. Using decerebrate, T-10 spinal cats, conditioning involved 30 pairings of the CS (10 Hz stimulation of the saphenous nerve for 1.5 sec) with the US (30 Hz stimulation of the same hous never for 1.7.5 sec) with the US (30 Hz stimulation of the cutaneous superficial peroneal n. for 0.5 sec), using a 1 sec interstimulus interval. Random intertrial intervals averaged 3 min. Sensitization animals received the same number of CS and US presentations, over the same time span, but the US was presented in the middle of the interval between CS presentations. Flexion reflex responses to the CS and US were measured by a tension transducer attached to the distal tendon of the tibialis anterior muscle. CS and US cutaneous nerve recordings were monitored to assure consistent inputs to the spinal cord over the course of the experiment. and A& cutaneous fibers of these nerves were activated during stimulation.

For all animals the response measured was the maximum tension from the TA muscle during the first second of each CS presen-tation. Reflex responses during acquisition were compared to baseline control values (mean of three CS alone trials) obtained just before acquisition.

During paired CS-US presentations, the reflex response biring particle CS-OS presentations, the territy response to the CS increased rapidly over trials compared to preacquisition levels. In contrast, the responses to the CS in sensitization animals declined in magnitude. For retention analysis 30 CS alone trials were presented at 5 minute intervals following acquisition. Over the 2 1/2 hour sended deciding at difference between conditioning and sensi-

5 minute intervals following acquisition. Over the 2 1/2 hour period significant differences between conditioning and sensi-tization groups were maintained even to the last trial. The results show that a classical conditioning paradigm applied to the spinal cord induces reflex changes of long duration, a result consistent with the characteristics of a learned response. Supported by National Science Foundation Grant 80-23943.

190.5 EYEBALL RETRACTION LATENCY IN CONSCIOUS RABBIT MEASURED WITH A NEW TECHNIQUE. K.J. Quinn, P.R. Kennedy, C. Weiss and J.F. Disterhoft. Department of Cell Biology and Anatomy, Northwestern

New lechatore. A.J. quinn, r.A. kennedy, c. weiss and J... Disterboft. Department of Cell Biology and Anatomy, Northwestern University Medical School, Chicago, IL 60611. Classical conditioning of rabbit nictitating membrane (NM) extension has been widely used in recent years as a model system for investigations into the neural basis of mammalian associative learning. NM extension is a passive consequence of eyeball retraction (Cegavske, et al, 1976). Thus eye retraction is the primary behavioral event being conditioned. We have been doing single neuron recording and lesion studies of the final output motoneurons in accessory abducens nucleus. For this work it was necessary to have a direct, readily quantifiable measure of the primary behavioral response. We have developed a new, sensitive technique for direct measurement of eye retraction and used it to measure the latency of eye retraction and to demonstrate classical conditioning of the response. The detector circuit is made up of an infrared LED, a photo-diode, and the appropriate amplification components. The inter-face attached to the eyeball consists of a contact lens connected by thin tubing to a film strip. The film strip has a linear light

by thin tubing to a film strip. The film strip has a linear light intensity grating exposed on it. The contact lens is placed on the rabbit's eye and the film strip in a track between the photothe rabbit's eye and the film strip in a track between the photo-diode and LED. Thus, the detection circuit monitors variation in intensity of the LED transmitted light caused by movement of the film strip grating. The detection circuit output voltage is linear with film travel. The device is well tolerated and the baseline is sufficiently stable to reliably record eye retraction movements of .05 mm in the conscious rabbit. Average eye retraction latency to stimulation with .1 ms, 200 Hz nulse trains of the adverage norms (where adment even the stable to retract even the stable to

Hz pulse trains of the abducens nerve (where almost all re-tractor bulbi axons run) in 5 rabbits was 4.8 ms (S.D. = 0.6 tractor bulbi axons run) in 5 rabbits was 4.8 ms (S.D. = 0.0 ms). Average retraction latency to periocular stimulation with .1 ms, 200 Hz, 10 ma pulse trains was 9.5 ms (S.D =2.0 ms). Thus the central conduction time of the response - the time from periocular shock onset to a wave of VI nerve axonal firing - was 4.7 ms, on average. Berthier and Moore (1983) showed accessory abducens unit latencies of 4 ms to periocular shock. We found near antidation is found to be a straight on the state in the shore state of the state state is a straight of the state state. found peak antifromic field potentials in accessory abducens to VI nerve stimulation of .8 ms (Quinn, et al, 1982). The central conduction value of 4.7 ms we measured with our eye retraction transducer matches the 4.8 ms predicted value nicely.

We have successfully used this technique to monitor clas-sical conditioning of eyeball retraction using a white noise CS and an airpuff US aimed at the eyelids. The rabbits acquired eye retraction CRs in one to three 80 trial sessions. Supported by NIMH T32-MH 16097, NIH NS17489, NIH 2 S07 RR05370, and NIH NS14703.

190.6

EVENT-RELATED POTENTIALS REFLECT STIMULUS SIGNIFICANCE DURING DISCRIMINATIVE NM CONDITIONING IN THE RABBIT. <u>D.J. Weisz</u>, <u>G. McCarthy\*, C.C. Wood, and D.T. Thompson\*</u>. Departments of Psychology and Neurology, Yale University, New Haven, CT 06520, and VA Medical Center, West Haven, CT 06516. Studies in both humans and animals have demonstrated that event-related potentials (ERPs) are sensitive to the significance or signal value of a stimulus within a task. Knowledge of the neural generators of task sensitive ERP components may contribute to an understanding of what brain systems and structures are involved in learning and attention. We investigated ERPs elicited during two-tone discriminative conditioning of the nictitating membrane (NM) response in the rabbit. There were two experimental phases: in the initial tones alone phase non-reinforced tones were presented, while in the second phase dis-crimination training occurred. The stimuli in both phases were 1000 Hz and 7000 Hz (85 dB) tones presented in random order. During discrimination training one of the tones served as CS+ and the other as CS-, with tone significance balanced across animals. Tone duration was 850 msec with the CS+ tone co-terminating with a 100 msec air puff to the eye. Intertrial intervals were 20 to 40 seconds. Electrodes were chronically implanted and targeted for cortical, hippocampal, and subcortical sites. Average ERPs for both tones in both experimental phases were sampled at 500 Hz for a 1024 msec epoch beginning 100 msec prior to tone onset. During the tones alone phase, comparable ERPs were evoked by high and low frequency tones. During the first day of

beginning 100 msec prior to tone onset. During the tones alone phase, comparable ERPs were evoked by high and low frequency tones. During the first day of discriminative conditioning marked differences appeared between ERPs elicited by the CS+ and CS- tones with the CS+ eliciting larger potentials than those elicited by the CS-. With further training ERPs to CS- presentation diminished greatly in amplitude. Differences in ERPs elicited by CS+ and CS- trials were most pronounced for potentials with approximate latencies of 80-100 msec from tone onset. Potentials showing such stimulus cincificance offects were recorded from many contical and Sub-room sec from tone onset. Forentials showing such stimulus significance effects were recorded from many cortical and subcortical sites, although steep spatial gradients were only seen in the electrodes targeted for the hippocampus. A later slow potential (latency of 250-300 msec) was less frequently seen, but did appear sensitive to stimulus significance with larger potentials elicited by CS+ tones.

POSSIBLE NEURONAL SUBSTRATE OF CLASSICAL CONDITIONING WITHIN THE MAMMALIAN CNS: DENTATE AND INTERPOSITUS NUCLEI. <u>David A.</u> <u>McCormick† and Richard F. Thompson</u><sup>°</sup> tDept. Neurology, <sup>°</sup>Dept. Psychology, Stanford University, Stanford, CA 94305 190.7

Classical conditioning of the eyeblink response in the rab-bit was achieved by pairing an auditory conditioned stimulus with a corneal airpuff unconditioned stimulus and used as a paradigm a corneal arpurt unconditioned stimulus and used as a paradigm to investigate the neuronal structures underlying this basic form of associative learning in the mammal. Previous investigators have shown that no neural tissue above the level of the thalamus is necessary for the learning and/or retention of this response. We have found that: 1. Lesions of the lateral cerebellum, medial We have found that: 1. Lesions of the lateral cerebellum, medial dentate-lateral interpositus (D-I) nuclei, or the superior cerebellar peduncle (SCP) all permanently abolish the learned eyeblink response without effecting the reflexive eyeblink response or the ability of the animal to learn with the contralateral eyelds; 2. Lesions of any region of the cerebellar cortex (flocculus not tested), lateral dentate nucleus, and fastigial nuclei <u>do not</u> permanently abolish the learned eyeblink response of divergence of the correlater of the correlater of the correlater of the divergence of the cerebellar cortex (flocculus not tested), lateral dentate nucleus, and fastigial nuclei <u>do not</u> permanently abolish the learned eyeblink response; 3. Lesions of permanently abolish the learned eyeblink response; 3. Lesions of the rostromedial inferior olivary complex, which receives a direct projection from the spinal fifth sensory nuclei and projects to the critical region of the D-I nuclei, prevent the maintained performance of the conditioned response; 4. Recordings from the D-I nuclei have revealed increases in neuronal activity which parallels the learning of the eyeblink response (r=.90); 5. Stim-ulation, either before or after learning, of the D-I nuclei can cause an eyeblink response to occur; 6. The D-I nuclei display neuronal responses to additory stimuli and to the somatosensory components of the UCS; 7. Neuronal recordings from throughout the prainster have revealed that the red nucleus pontine nuclei and inferior olive, respond in relation to the performance of the learned eyeblink response. Therefore we propose the following neuronal circuit as a model system by which classically condi-tioned responses may be learned. Motoneurons

We propose that the associational changes in neuronal function we propose that the associational changes in neuronal function encoding this learned response may be localized to the D-I nuclei (star in diagram). Alternatively, the changes may occur afferent to the D-I nuclei with the D-I nuclei forming an essential effer-ent for generation of the response. 190.9 BIDIRECTIONAL ASYMMETRICAL SELECTION FOR BEHAVIORAL AROUSAL TO NOVEL ENVIRONMENT: NAPLES HIGH (NHE) AND LOW EXCITABLE (NLE) RAT STRAINS. A.G.Sadile, A.Cerbone\*, G.Manzi\*, A.Grimal di\*. Inst.Human Physiol., 1st Med.Sch., Univ.Naples, Italy. By continuous genetic pressure, two strains of rats have been obtained from a random-bred Sprague-Dawley population, the Naples High (NSD-HE or NHE) and Low Excitable (NSD-LE or NLE), since 1976 over 15 generations.

The behavioral trait selected hereto was reactive horizon tal and vertical activity (rearings+corner crossings) during two 10min "forced" exposures to a modified Lat's box, at 24hr interval, at the beginning of dark phase of a 12:12LD cycle (Sadile, A.G. et al., <u>Abh.Akad.Wiss.DDR</u>, <u>5</u>:303, 1978). Population's extremes within high and low scoring samples were mated, with great care paid to keep low the inbreeding coefficient a) to increase potentiality of selection; and b) to keep high "fitness" throughout generations.

After six generations, there appeared no population over lap between high (NHE) and low scoring (NLE) rats, with  $\rm NHE$  > NLE by a factor of two. Ever since, the NHE's stabilized at high level ("ceiling effect"), whereas the NLE's have still to reach the "floor". While differing in reactivity to novel environment, the two strains show similar daily and day-night variations in spontaneous activity (Sadile, Tobler

NLE

INCE

MEAN

and Borbely, in preparation). A series of electrophysiolo gical, neurochemical and neu roanatomical correlative stu dies suggest a "dis-integra tion" at the hippocampal den tate area interface in both strains.

The NHE and NLE rats are pro posed as new genetic models to study the role of non-as sociative processes in beha vioral plasticity.

GENERATION OF SELECTION

190.8 EFFECTS OF CONTRALATERAL RED NUCLEAR LESIONS ON RETENTION OF THE CLASSICALLY CONDITIONED NICIEAR LESIONS ON RELEATION OF THE CLASSICALLY CONDITIONED NICITIATING MUBRANE/ EYELID RESPONSE. D. A. Haley\*, D. G. Lavond\* and R. F. Thompson (SPON: Roy King). Department of Psychology, Stanford University, Stanford, CA 94305. Recent studies have shown that lesions of the ipsilateral detector intermediate and the standard for the standard standa

dentate-interpositus nuclear region of the cerebellum abolish the conditioned response of rabbits well-trained in short-delay classical conditioning of the nictitating membrane (NM)/eyelid response (McCormick, D. A., et. al., <u>PNAS</u>, 79:2731, 1982; Clark, G. A., et. al., <u>Neurosci. Abs</u> 8: 22, 1982). The current study investigates the role of Absts. 8: 22, 1922). The current study investigates the role of the red nucleus, a structure receiving major efferent pro-jections from the cerebellar deep nuclei, in retention of the classically conditioned NM/eyelid response. New Zealand white rabbits were implanted with monopolar lesion electrodes and allowed 5 days of postoperative recovery. Animals were then trained on the eye contralateral to the chronically implanted electrodes using standard procedures for classical conditioning of the NM/eyelid recovery (117 chronically implanted electrodes using standard procedures for classical conditioning of the NM/eyelid response (117 trials per day). Animals reaching a criterion of 8 con-ditioned responses on 9 consecutive trials were overtrained for one additional day and then electrolytically lesioned. We here report that lesions of the contralateral red nucleus also abolish the conditioned NM/eyelid response. These re-sults are in agreement with previous reports on the effects of rubral lesions on the conditioned forelimb flexion response in the cat (Smith, A. M., <u>Physiol. Behav.</u>, 5:1121, 1970). In addition, such lesions of the red nucleus produce varying degrees of disruption of the unconditioned response and In addition, such lesions of the red nucleus produce varying degrees of disruption of the unconditioned response and various motor impairments. In at least some animals, the unconditioned response shows recovery over postoperative training, but the conditioned response does not. In contrast, the eye ipsilateral to the rubral lesion can be trained to perform conditioned NM/eyelid responses. These results, along with converging pharmacological evidence (Madden, J. IV, Haley, D. A., Barchas, J. D. and Thompson, R. F., <u>Neurosci. Absts.</u>; 1983), suggest that the contralateral red <u>incleus</u> is necessary for the performance of the conditioned NM/ evelid response. eyelid response.

190.10 THE EFFECT OF CAROTID OCCLUSION ON THE PASSIVE AVOIDANCE RESPONSE IN THE F-344 RAT. <u>G. A. King</u>. Dept. of Pharma-cology, Ayerst Res. Labs., P.O. Box 6115, Montreal, Que., Canada H3C 3J1.

cology, Ayerst Res. Labs., P.O. Box 6115, Montreal, Que., Canada H3C 3J1. Preliminary results obtained in a new rodent model of cerebral ischemia are described. Young male Fisher (F-344) rats were implanted under pentobarbital anesthesia with loose-fitting ligatures around both carotid arteries. Several days post-operatively the ligatures were tightened for varying durations - without the need for anesthesia - in order to block carotid blood flow. The ligatures were removed at the end of the occlusion period. Animals which survived the procedure were trained in a one trial step-through passive avoidance paradigm either 24 or 72 hr post-occlusion. Prior to sacrifice, the carotid arteries were inspected to insure that blood flow has been reestablished post-occlusion Rats were sacrificed by intracardiac per-fusion of fixative, under deep pentobarbital anesthesia and brains processed for histology. In the F-344 rats an increase in the duration of carotid acclusion resulted in an increase in mortality. Within the first 72-hr post-occlusion period, 0, 39 and 66% of rats died after 30, 60 and 90 min of occlusion, respectively. Further-more, rats occluded for > 60 min were significantly impaired in the retention of a passive avoidance response, compared to

in the retention of a passive avoidance response, compared to sham controls, if training was given 24 hr post-occlusion and retention tested 24 hr after training. No impairment was observed if training was given 72 hr post-occlusion or if retention was tested 1 hr after training. Therefore, carotid occlusion may cause a temporary deficit in long-term memory. These experiments demonstrate that bilateral carotid

These experiments demonstrate that bilateral carotid occlusion in the F-344 rat can cause cerebral ischemia which results in increased mortality and failure of memory encoding processes in surviving animals.

190.11 AREA POSTREMA LESIONS ABOLISH LOW-INTENSITY GAMMA RADIATION INDUCED TASTE AVERSIONS IN RATS. K.-P. Ossenkopp and L. Giugno\*. Dept. of Psychology, Univ. of Western Ontario, London, Ontario, Canada, N6A 5C2.

Ionizing radiation is very effective in producing conditioned taste aversions (CTA) when paired with novel taste stimuli in rats. In a recent study Ossenkopp (Behav. Brain Res., 1983, 7, 297) demonstrated that area postrema (AP) lesions in rats attenuate the magnitude of gamma-radiation induced CTA when 200 rad of radiation was paired with a novel saccharin taste stimulus. In the present experiment we examined the possibility that AP lesions might abolish the CTA induced by low levels of gamma radiation. Previous research (Cairnie & Leach, <u>Pharm.</u>, Biochem Behav., 1982, 17, 305) had shown that as little as 20 rad of radiation could produce a CTA if multiple pairings of the CS and US occurred. In the present study six groups of male rats were used. Three groups of rats received lesions of the AP and the used. Three groups of rats received lesions of the AP and the other three groups received sham lesions. Following a recovery period all rats were adapted to a 23.5 hr/day water deprivation schedule. A sodium saccharin solution (0.1) was offered to all rats during the regular drinking period ( $\frac{1}{2}$  hr) on two days per week, with water available on the other days. Presentation of the saccharin was followed by exposure to 0-, 20- or 40-rad of gamma radiation, with one lesioned and one sham lesioned group exposed at each days lesion. at each dose level. Four pairings of saccharm with the respective dose of radiation were then followed by adaptation to a 23 hr/day water deprivation schedule. All animals then received a two-bottle choice test (water vs. saccharin) for 1 hr/day over the next six days. Saccharin intake levels on conditioning days showed that sham lesioned rats given 20- or 40-rad radiation, developed a strong CTA to the saccharin (p<.01) that was dependent on the radiation dose. The sham lesioned rats exposed to 0-rad and all the AP lesioned rats displayed comparable increases in saccharin intake levels over conditioning days. Similarly, the sham lesioned rats receiving 20 and 40 rad radi-ation displayed very low levels of saccharin preference on the two-bottle choice test (p<.01), whereas the 0-rad and all the AP lesioned rats displayed strong comparable preferences for saccharin. Thus, AP lesions completely abolished the CTA normally induced by multiple pairings of saccharin with 20 or 40 rad gamma radiation.

190.12 THE EFFECTS OF KINDLING ON THE ACQUISITION OF CONDITIONED TASTE AVERSIONS (CTA) IN RATS. F. G. Freeman and P. J. Mikulka\*. Dept. of Psychology, Old Dominion Univ., Norfolk, Va. 23508. The amygdala appears to be an important area for the develop-

ment of CTA. This study examined the effects of anygdala kindled seizures on the acquisition of taste and odor aversions and was prompted by the prior work with ECS an CTA. The subjects were Long Evans rats that were kindled in the amygdala until a minimum of 10 stage V seizures had been produced.

In Experiment 1 all subjects were given 15 min. access to a 10% sucrose solution followed 30 min. later by a 2.5 mEq injection of LiCl. Subjects in Group A were kindled 15 min. after the sucrose solution access. Group B subjects were kindled 15 min. after the LiCl injection and the Group C subjects were not kindled. After two days of recovery all subjects were allowed 15 min. access to the sucrose solution. Analysis of these intakes indicated that the Group C subjects drank little sucrose (2.2ml) while the Group A and B subjects drank significantly more (11.1 and 10.8 mls, respectively) F(2,16)=7.5, p < .01). Thus, kindling blocked the acquisition of CTA whether it occurred within the CS-US interval or after the occurrence of the US.

CS-US interval or after the occurrence of the US. Experiment 2 was designed to examine the effects of cue over-shadowing/potentiation of a CTA. All subjects received access to odor cued solution or a taste-odor2 solution paired with a LiCl injection on separate days. After 15 min. access to the solution the subjects were given a LiCl injection 30 min. later. Half of the subjects were kindled 15 min. after access to each solution, while the other half were not kindled. Over a three day test period the subjects were given a "single cue" solution (odor<sub>1</sub>, odor<sub>2</sub> or taste) on each of the three days. The order of testing was counterbalanced. The results indicated that the kindled sub-jects drank significantly more of each cue than the control subjects, F (1,14) = 77.1, p < .01. Again kindling occurring in the CS-US interval disrupted the acquisition/retention of a CTA.

Experiment 3 looked for a time gradient of kindling produced disruption after the US is administered. Using the same design as Experiment 1 the subjects were kindled 15 or 60 min. after the LICI injections. Control subjects were not injected. Tests clearly indicated that only the 15 min. group showed a disruption of the CTA; the 60 min. and control subjects were not different, F (2,13) = 11.6, p < .01.

190.13 POSTTRIAL MICROWAVE EFFECTS ON LEARNING AND MEMORY IN MICE. J. A. Beel\*, L. J. Fisher, R. E. Gerren, and M. W. Luttges. Department of Aerospace Engineering Sciences, University of Colorado, Boulder, CO 80309.

Biological tissue exposed to low-level microwave exposure is biological tissue exposed to low-level microwave exposure is thought to experience overall heating, heating gradients and di-electrically-induced polarization shifts. These effects are be-lieved to be the basis on which a variety of behavioral alterations occur in response to microwave treatments. While the usefulness of microwave irradiation for studies of neural enzymes is reasonably well established, such usefulness as a tool for studying the neural substrates of behavior has not been exploited. In the present studies we have shown that brief, low level microwave treatments delivered posttrail yield significant effects on learning and memory in mice. Following both active and passive avoidance training, irradiated mice received either 15 or 30 min. of continuous exposure to pulsed 3GHz with an average power of 18-22 mW/cm<sup>2</sup>. In half the cases irradiation yielded fixed fields and in the other cases the fields were continuously disrupted and reoriented. Control mice received sham exposures. These exposure levels resulted in  $< 0.5^{\circ}$  C differences in core temperatures. Significant enhancement of learning and memory following 15 min. exposure occurred both with five consecutive days of multiple trial, active avoidance training and with single trial, passive avoidance training. These performance changes were evident in tests given one week after training and microwave exposure. peated daily exposures of 30 min. duration produced enhanced per-formance during the first three days of training and performance deterioration thereafter. Thus, a doubled total irradiation appears to produce detrimental consequences for learning and memory reminiscent of pharmacological dose-response curves. These posttrial effects are not likely to be related to the geometry of microwave fields biasing the polarization of specific neural structures. Heat or heat gradient effects are the more probable causes of the performance changes. This type of non-invasive modification of learning and memory mechanisms deserves further studv.

190.14 DIFFERENTIAL EFFECTS OF CONCUSSIVE HEAD INJURY ON BEHAVIOR IN CATS. <u>C. E. Dixon<sup>\*</sup></u>, <u>G. F. Heath<sup>\*</sup></u>, <u>Y. Katayama<sup>\*</sup></u>, <u>R. J. Hamm<sup>\*</sup></u>, and <u>R. Hayes</u>. Dept. of Psychology and Dept. of Neurosurgery, Virginia Commonwealth Univ., Richmond, VA 23284.

Cerebral concussion is a clinical syndrome characterized by immediate suppression of widespread reflexive functions and loss of consciousness due to mild head injury without gross struc-tural changes and is always followed by post-traumatic am-Recent clinical studies have indicated that disturbnesia. ances in memory functions following concussive head injury in-clude long-term storage and retrieval. It is established that similar reflex suppression and consciousness disturbances can Similar refrex suppression animals by various models of experi-mental concussive head injury. However, virtually no attempt has been made to clarify whether disturbances in memory functions are elicited in these experimental animals. Thus, in contrast to various symptoms of concussion, mechanisms under-lying disturbances in memory functions remain unclear. This study examined the effects of concussive head injury on the retention of a well-consolidated classically conditioned eveblink response in the cat using fluid-percussion head injury (Sullivan et al. <u>J. Neurosurg</u>, 45, 520, 1976), a model with which reflex suppression and loss of consciousness can reliably be elicited.

Prior to conditioning, all animals (N=4) had a stimulating electrode chronically placed in the medial edge of the super ior palpebra. Classical conditioning of the eyeblink consisted of pairing a tone with an electrical shock via the electrode until a criterion of  $\geq 80\%$  correct responses on intermittent tone-alone trials was met. After five days each animal was tested on its pre-injury retention of the eyeblink response. The animals were retrained to criterion, then given a concussive head injury, produced by a single, brief (25 msec), hydraulically-induced pressure transient (1.9-2.1 atmospheres) conducted into the intracranial cavity. This level of injury consistently produced immediate and transient abolition of various reflexive activities (e.g., pinna, blink, and flexion reflexes) and concurrent disturbances in consciousness as inferred by motor indices of arousal and orientation. After five days each animal was tested, retrained, and five days later re-tested again. A comparison of the means of the percent correct for the three retention tests yielded no differences indicating that clinically reported disruptions of memory retrieval are not produced by the same mechanisms for reflex suppression and loss of consciousness. Further work is being done to study the effects of concussive head injury on other memory functions, including consolidation and short-term memory. Supported by N.I.H. NS 12587.

190.15 EFFECT OF PREVIOUS LEARNING UPON UPTAKE OF <sup>14</sup>C 2-DEOXYGLUCOSE EVOKED BY VISUAL STIMULATION. A. Isseroff and Y. Madar\*.Dept. of Isotope Research, Weizmann Institute of Science, Rehovot, Israel. We report that specific training can produce localized changes in cerebral functional activity evoked by a particular stimulus when it is presented outside the training situation. The effects of training are distinct from those of nonspecific stimulation provided by environmental enrichment.

Of thinking are distinct from the lock of interpret trained that is a set of the set

tem (Lancet and Isseroff, <u>Neurosci. Abs.</u> 8:1003, 1982). Uptake of 2-DG was estimated by dividing the optical density of visual structures by that of reference areas. Data were analyzed for laterality (stimulated vs. unstimulated hemisphere) and differences in uptake between groups. As expected, significant ( $\alpha = .05$  2-tailed for all tests) lateralization of uptake was observed in most areas of the visual system in all groups. In the enriched group only, significant laterality was also observed at more anterior points in visual and parietal association cortex. Compared to naive rats, the trained ones, but not the enrichment group, showed significantly increased uptake in the stimulated hemisphere in area l&L near the occiput, at the border of areas 17 and 18L more anteriorly, and in the ventral superior colliculus, and bilateral increases in retrosplenial cingulate cortex. No differences between groups were observed in areas 17 or 18M, auditory or somatosensory cortex, hippocampus or subcortical visual areas save the ventral superior colliculus.

We believe that the differences found in trained rats partially reflect functional activity related to retrieval from memory, recognition and apperception of familiar objects and to attention. Supported by grant 3/83 from the Israel Psychobiology Institute, Charles Smith Family Foundation.

- 190.16 A MATHEMATICAL MODEL FOR MULTIPLE MEMORY DOMAINS-<u>P. A. Anninos and M. Kokkinidis</u>, Dept. of Physics, University of Crete, Iraklion Crete, Greece,
  - University of Crete, Iraklion Crete, Greece. Previous studies with neural nets constructed of discrete populations of formal neurons have assumed that all neurons have the same probability of connection with any other neuron in the net(Anninos et al, J. of Theor. Biol., 26:121, 1970). However, in this new study we incorporate the behavior of the neural systems in which the neural connections can be set up by means of chemical markers carried by the individual cells. A case of such specific chemical markers are the neurotransmitters which effect the intercellular communication in the nervous system. The effects of the chemical and structural nature of neurotransmitters has been studied in a previous work(Gieren, A and Kokkinidia M, Nat, 68:482,1981). However in this present study we do not include the properties of markers, but we consider only neural nets consisting of neurons with different chemical affinities. With this general approach we studied again the dynamics of isolated neural nets as well as the dynamics of isolated neural nets with sustained inputs. Results obtained with this approach show simple and multiple hysteresis phenomena. Such hysteresis loops may be considered to represent the basis for short-term Memory.

# LEARNING AND MEMORY: HIPPOCAMPAL PHYSIOLOGY

191.1 POSTTRIAL RETICULAR FACILITATION OF DENTATE MULTIUNIT CONDITIONING IS FOLLOWED BY AN INCREASED LONG-TERM POTENTIATION. S. Laroche, O. E. Bergis \* and V. Bloch \*. Dépt. de Psychophysiologie, CNRS, 91190 Gif-sur-Yvette, France.

Postrial electrical stimulation of the mesencephalic reticular formation (MRF) is known to facilitate learning in a variety of behavioral tasks. The hippocampal circuitry was used as a model to study the neural basis of this facilitative effect. Previous studies showed that postrial MRF stimulation (1) facilitates the development of associative changes in hippocampal (CA3) and dentate multiunit activity during classical conditioning in rats and (2) results in a long-term enhancement of hippocampal responsiveness to the conditioned stimulus. It was hypothetized that postrial MRF stimulation might facilitate the perseveration of neural processes triggered in those networks by incoming information and that this perseverative process might help long-lasting modifications to occur at the synaptic level. This hypothesis was mainly based on the fact that post-event MRF stimulation (LTP) at the perforant path to dentate granular cells synapses. If a synaptic modification like that associated with LTP is involved in the elaboration or maintenance of associative learning at the cellular level, it might be more easily detected as an exturied there is the more the store the as an enterprocess of the perforant path to the magnetic detected as an enterprocess of the perforant path to dentate for the store of associative learning at the cellular level, it might be more easily detected as an

If a synaptic modification like that associated with LTP is involved in the elaboration or maintenance of associative learning at the cellular level, it might be more easily detected as an actual change in LTP itself rather than as an enhanced single evoked potential. In the present investigation, dentate multiunit activity was recorded in rats submitted to a classical conditioning procedure involving six tone-footshock pairings during six days. One group of animals (MRF group) received a mild (mean intensity 4.5 µA) stimulation of the MRF, 10 sec. after each trial. LTP was induced 2 days after the end of conditioning by 10 highfrequency stimulations (400 Hz, 20 msec.) of perforant path fibers with 5-min. intervals. The analysis of dentate evoked potentials (population spike as well as population EPSP components) elicited after each high-frequency stimulation showed that, in the non MRF group, the amount of LTP was increased after the learning experience. Moreover, this effect was greatly enhanced in the MRF group. Appropriate control groups assured that it was the association of learning experience-MRF and not the total amount of MRF stimulation which had the effect on subsequent LTP.

It is suggested that, during associative learning, a perseverative process is taking place along the neuronal circuits under study which might be enhanced by MRF activation. This perseverative process could initiate long-lasting synaptic modifications revealed by LTP enhancement. 191.2 HIPPOCAMPUS AND TRACE CONDITIONING OF THE RABBIT'S NICTITATING MEMBRANE RESPONSE. <u>P. R. Solomon, E. R. Vander Schaaf\*, A. C.</u> Nobre\*, D. J. Weisz, and R. F. Thompson. Department of Psychology, Williams College, Williamstown, MA 01267. Previous research has shown a substantial neuronal change in

Psychology, Williams College, Williamstown, MA 01267. Previous research has shown a substantial neuronal change in hippocampus during acquisition of the conditioned NMR. Yet the structure's precise role in conditioning remains unclear since hippocampal ablations do not affect acquisition of the conditioned NMR. A number of investigators have suggested that the hippocampus may be essential only when the events to be associated (e.g., the CS and UCS) are separated in time. To test this possibility, we have examined the role of hippocampus in a trace conditioning paradigm during which there is a 250 msec tone CS, followed by a 500 msec trace interval during which no stimuli are present, followed by a 100 msec air puff UCS.

Our first study examined the effects of bilateral hippocampal ablations on acquisition of the trace CR. We found that normal animals acquired the CR in about 500 trials. Hippocampal animals, in contrast, did not acquire the CR over the 900 trials that we conditioned them. When switched to a standard delay paradigm (250 msec ISI), hippocampal animals readily acquired the CR.

A second study examined multiple unit activity in area CAl of hippocampus during conditioned NMR acquisition. Three groups of animals were tested: Animals conditioned in the same trace conditioning paradigm as used in the lesion study (Group T-500), animals that received explicitly unpaired presentations of the CS (tone) and UCS (air puff; Group UP), and animals that underwent conditioning with a 2,000 msec trace interval between CS offset and UCS onset (Group T-2000). Previous work has shown that this trace interval does not support behavioral conditioning. Animals in Group T-500 acquired the behavioral response within an average of 500 trials. Early in training, and well before any CRs occurred, there was a substantial increase in neuronal activity in hippocampus that began during the CS and persisted through the trace interval. There was also an increase in the UCS period. Here, the neuronal activity both preceded the behavioral response and formed a temporal model of its amplitudetime course. Later in conditioning, as CRs emerged, there was no longer neuronal bursting throughout the CS+Trace period. Rather, the activity shifted to later in the trace interval and formed a model of the amplitude-time course of the behavioral CR. Activity in the UCS period was similar to that seen earlier in conditioning. Animals in Groups UP and T-2000 showed no behavioral conditioning and no increased neuronal activity. These findings strongly suggest that the hippocampus is essential for condiguously in time. Supported by NIMH Grant MH36539-01 191.3 FUNCTIONAL RELATIONSHIP BETWEEN HIPPOCAMPAL UNIT ACTIVITY AND RABBIT NM RESPONSE CONDITIONING DURING DISCRIMINATION-REVERSAL LEARNING. W.B. Orr and T.W. Berger. Psychobiology Program, Departments of Psychology and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

This laboratory has previously shown that hippocampal pyramidal cell activity increases significantly during acquisition of a two-tone discrimination-reversal task using the rabbit nictitating membrane (NM) conditioning paradigm (Berger, <u>Soc. Neurosci. Abstr.</u>, 8, 1982). Moreover, latency and amplitude characteristics of poststimulus time-histogram measures of pyramidal cell activity correlate highly with the topography of conditioned responses (CR) to the CS+ during both discrimination and reversal. No significant change in unit activity is recorded on CS- trials when no CR is elicited. In a test of the functional significance of this unit activity, the effects of aspiration lesions of the hippocampus on discrimination-reversal NM response conditioning were measured.

Three groups of subjects were surgically prepared: animals with hippocampal lesions (HLs), with neocortical lesions (CLs), and operated controls (OCS). The effects of hippocampal lesions on the rate of discrimination-reversal acquisition have already been reported (Berger and Orr, <u>Behav. Brain Res.</u>, <u>8</u>, 1983). No difference was found between groups in the number of trials to discrimination criteria. However, during reversal training HLs required significantly more trials to reach criteria than either control group. No difference between OCs and CLs for reversal training was observed. Here we report that conditioned responses made by HLs have a topography which differs significantly from that of OCs and CLs during reversal learning but not during discrimination conditioning. Five different parameters were used to describe response topography: i) latency to onset, ii) latency to response peak, 1ii) peak response amplitude, and iv) integrated MM response in both the CS-UCS interval (CS area) and v) the UCS period (UCS Area). Analyses of each parameter showed that the responding of HLs to the two conditioned stimuli is significantly different from the responding of OCs and CLs. Additionally, when the CS area of responses to both CS+ and CS- trials are plotted as learning functions only the curves for HL animals show a significant cubic component to their shape. In contrast, the CS area curves for OC and CL animals are linear. These results indicate that disruption of hippocampal pathways significantly alters the topography of conditioned NM responses during reversal. These data also suggest that the process(es) by which HL animals eventually acquire reversal is different than control animals. Supported by grants from the McKnight Foundation, NSF (BNS 80-21395) and NIMM (MH 00343).

191.5 MANIPULATIONS OF THE GEOMETRY OF ENVIRONMENTAL ENCLOSURES CONTROL THE SPATIAL FIRING PATTERNS OF RAT HIPPOCAMPAL NEURONS. J.L. Kubie, R.U. Muller\* and J.B. Ranck, Jr., Dept. of Physiology, SUNY, Downstate Medical Center, Brocklyn, N.Y. 11203. Most hippocampal complex-spike cells in freely moving rats fire fastest when the rat is in a particular part of its environment. In the previous abstract, we described a TV system which permits us to generate firing rate maps which clearly show the position, shape, size and contours of such place fields. We reasoned that if these neurons are part of a cognitive mapping system, the significance of their spatial fields would be most clearly revealed by manipulating the geometry of the environment in which the recording is done. Using simply shaped chambers with opaque walls, we obtained spatial firing rate maps for individual neurons when the rat was successively placed into each of four enclosures. Two of these were cylinders (76 cm diam, 61 cm high; 152 cm diam, 122 cm high), while the others were rectangular boxes (46x61 cm, 61 cm high; 92x122 cm, 122 cm

high). The principal finding is that a single complex-spike cell has similarly positioned spatial fields in enclosures of a given shape; the field centers are located at the same relative place, and the field is larger in the larger of the pair of enclosures. By contrast, knowing the field locations in one shape does not predict the field locations in the other shape. Frequently, a cell which had obviously similar spatial fields in, say, the rectangles had no fields in the cylinders. For a minority of cells, we found unrelated fields in a pair of similar enclosures. A second major result is that the shape of a field near the boundary of an enclosure appears to be determined by the shape of the enclosure itself. 'Edge' fields in the rectangles are often linear, while those in cylinders are usually crescent-like. We stress that this effect is not merely due to the impossibility of crossing the boundary; the part of the field facing the inside of the enclosure also runs narallel to the boundary.

of the enclosure itself. 'Edge' fields in the rectangles are often linear, while those in cylinders are usually crescent-like. We stress that this effect is not merely due to the impossibility of crossing the boundary; the part of the field facing the inside of the enclosure also runs parallel to the boundary. These finding show that it is possible to detect meaningful relationships among spatial fields in different environments, and that the shape of the environment is a crucial determinant of the shape and position of the spatial field. They also suggest that the rat's hippocampus may participate in globally representing the current environment.

191.4 HIGH RESOLUTION MAPPING OF THE 'SPATIAL' FIELDS OF HIPPOCAMPAL NEURONS IN THE FREELY MOVING RAT. R.U. Muller\*, J.L. Kubie and J.B. Ranck, Jr. Dept. of Physiology, SUNY, Downstate Med. Ctr., Brooklyn, N.Y. 11203.

O'Keefe and Dostrovsky (Brain Res. V34, 171-175, 1971) first reported that many neurons in the hippocampus of freely moving rats fire fastest when the animal is in a particular region of its environment, and that the firing is largely independent of the rat's behavior within this region, called the "spatial field". Subsequently, many groups have confirmed the existence of spatially firing hippocampal neurons and further described their properties. Nevertheless, because this work has been qualitative, fundamentals such as the size and shape of spatial fields are still not adequately characterized.

We report here that we have developed and used a high resolution, quantitative method for mapping spatial fields. An unrestrained, 20 hour food deprived rat is encouraged to run freely throughout a cylindrical (76 cm diam; 61 cm high) enclosure in search of randomly scattered food pellets, while we record from a well isolated complex-spike cell. We use a video camera 8 feet above the enclosure as the input to a threshold device which tracks the position of a bulb mounted on the rat's head. Every 1/60th of a second (TV frame rate) we send 16 bits (2 bytes) of information to a small computer. 12 bits signal position (6 for X and Y) and 4 bits signal the number of discriminated action potentials during the frame. The TV frame is thus divided into a 64x64 grid of rectangular 'pixels', each 3.4 cm wide by 2.8 cm high. We amalyze the data by creating three 64x64 arrays to repre-

We analyze the data by creating three 64x64 arrays to represent the number of samples the rat spent in each pixel area, the number of spikes (AP) which occurred in each pixel, and the firing rate in each pixel. We use these arrays to print 6-color maps of where the animal spent its time and how fast the cell fired in each position (AP/sec). We have collected a total of about 30 hours of data from 20 cells in 6 rats. Our behavioral method is adequate since the rats visit most every pixel during each recording session, although they tend to spend more time near the wall. Almost all units whose average firing rate is higher than 0.25 AP/sec show one or sometimes two regions of intense firing. The area of such "spatial fields" ranges between about 5 to 30% of the cylinder's area. These fields have obvious firing rate contours, diminishing from 20 AP/sec or more in the hottest parts to virtually zero outside the field. Fields which do not encroach on the boundary tend to be radially symmetrical, while those near the edge are crescent shaped rather than truncations of circles. The fields are stable with time; nearly identical shapes and positions are seen with sessions done several days apart. (Supported by NIH grant NS 14497).

191.6 SINGLE UNIT ACTIVITY IN THE HIPPOCAMPUS OF RATS: BEHAVIORAL CORRELATES IN A NONSPATIAL DELAYED-MATCH-TO-SAMPLE TASK. R. L. Findling<sup>#</sup>, M. Shapiro, and D. S. Olton. Department of Psychology, the Johns Hopkins University, Baltimore, MD 21218. Hippocampal function has been linked to the types

Hippocampal function has been linked to the types of memory processes required for normal performance in delayed conditional discriminations. The present experiment recorded from single units in the hippocampus while rats solved a nonspatial delayed-match-to-sample discrimination. At the beginning of each trial, the rat was presented a distinctive visual stimulus as the sample stimulus to be remembered for that trial. The stimulus was removed for the delay interval of 10 seconds. The rat was then given a choice between this sample stimulus and a second one. Responses to the sample stimulus presented at the begining of the trial were reinforced. A bundle of tungsten microelectrodes was implanted just above the hippocampus and slowly lowered through the CAl pyramidal cell layer. When activity from a unit was electrophysiologically stable and had a sufficient signal-to-noise ratio to be isolated from the background, a series of up to 80 trials was given in the delayed conditional discrimination. Recordings have been obtained from 30 complex spike units. Of these, two-thirds had rates of activity that were strongly associated with the discriminative stimuli. For each of these units, the rate of activity was markedly increased in the presence of one stimulus, and not in the presence of the other. Most of the remaining units had place fields that were associated with the apparatus itself, rather than with the extramaze stimuli surrounding it. These data indicate that when nonspatial stimuli are made salient and relevant as in this discrimination problem, hippocampal units respond to them. The results of this study are interpreted in the context of three other sets of experiments: the effects of hippocampal lesions in rats on performance in conditional discriminations; the activity of single units in other by Research Grant MH24213 from the National Institute of Mental Health.

SPONTANEOUS SYNAPTIC ENHANCEMENT IN HIPPOCAMPI OF RATS EXPOSED TO 191.7 A SPATIALLY COMPLEX ENVIRONMENT. P.E. Sharp, B.L. McNaughton, and C.A. Barnes. Dept. of Psych., Univ. of Colorado, Boulder CO 80309. High frequency electrical stimulation results in a long-term enhancement (LTE) of the perforant path-dentate granule cell syn-aptic connection. Several characteristics make this phenomenon a reasonable candidate for a biological mechanism of learning. This hypothesis requires that LTE should occur during normal acquisi-tion of information, as well as from artificial stimulation. Since the hippocampus is thought to be involved in processing spatial information (O'Keefe and Nadel, 1978), exposure to a spatially complex environment was used in this study in an attempt to generate such natural LTE.

Five albino rats were chronically implanted with stimulating electrodes in the perforant path and recording electrodes in the dentate gyrus. Prior to recording, the animals were housed for at least one month in single cages in a dimly lit room. Since electrically induced LTE decays over several weeks, this spatial im-poverishment was included to permit any naturally present LTE to decay, thus facilitating the detection of any subsequent enrich-ment effect. Daily recording of the granule cell response to single perforant path stimuli was then initiated. During the first ten days of recording the animals remained in the impoverished en-vironment. Three of the animals were then each transferred to individual rooms (150 sq ft approx) filled with boxes, ramps, and other stimulus objects as their permanent living quarters. In the enrichment group, both the population spike and EPSP ex-

hibited a gradual increase over a period of several days following transfer to the new environment, reaching significant peak increases of about 48% and 16% respectively. These effects were not due to behavioral changes during the recording sessions. Further pilot work suggests that prolonged exposure to the spa-

tially complex living quarters results in the eventual decay of the granule cell response back to baseline levels. This fits in well with the notion (e.g., Marr, 1971; Squire, 1983) that the hippocampus serves only as a temporary storage place for memory traces. Subsequent transfer to a second complex environment, however, results in renewed growth of the granule cell response. In addition, preliminary studies indicate that the growth in synaptic efficacy can be generated when animals are given only one-half hour of daily exposure to a complex environment immediately after each daily recording session. Thus, the effect requires relatively little environmental stimulation and can be seen even when mea-sured twenty three hours after each daily treatment.

In conclusion, a change in synaptic efficacy resembling elec-trically induced LTE occurs during a time when animals could be expected to be acquiring a "cognitive map" of a novel environment.

191.8 ELECTROENCEPHALOGRAPHIC CORRELATES OF LONG-TERM POTENTIATION. <u>G. Buzsáki</u>. Dept. of Physiology, Uni-versity Med. Sch. 7643 Pécs, Hungary. LTP has been widely considered as a model for me-

mory storage. The present investigation examined the effect of high frequency stimulation (HFS) delivered to the commissural/associational systems of the hip-pocampus on spontaneous EEG activity. Rats were equip-ped with chronic recording microelectrodes placed in the strata pyramidale and radiatum of CAl and stimulating electrodes positioned in the contralate-ral CA1/CA3 regions. They were trained on a VI-40 ral CA1/CA3 regions. They were trained on a VI-40 sec schedule for water reinforcement. During drink-ing high amplitude (2.0-3.5 mV) sharp-waves (SFW) appeared in the CA1 region reflecting synchronous discharges of a great number of CA3 pyramidal cells and consequent depolarization of the apical dendri-tes of the CA1 pyramidal neurons (Buzsáki, Leung and Vanderwolf, <u>Soc. Neurosci</u>.8:738, 1982). The num-ber of spikes of predetermined amplitude was counted during the initial lo-sec epochs of drinking. The HFS (400 cps 20 meec) invariably induced epilentic during the initial lo-sec epochs of drinking. The HFS (400 cps, 20 msec) invariably induced epileptic discharges followed by LTP of the field postsynap-tic potential and population spike in CA1. The num-ber of SPWs decreased considerably after the HFS up to 4 hrs and then increased significantly up to 4 days. The time course of changes of evoked and spon-taneous activity (SPW) were somewhat different. Following supramaximal single pulses inducing epi-leptic afterdischarges none of the above changes were observed. LTP failed to have an effect on the frequency of lapping or other behavioral parameters. It was not possible to separate whether the poten-tiation effect on SPWs was conveyed through the com-missural or associational systems (Buzsáki and Eidel berg, <u>Br.Res</u>. 237:283, 1982). These findings are the first indication of long-term changes of spontaneous activity within the hippocampal system. The biphasic depression-potentiation effect is explai-ned by the hypothesis that inhibitory interneurons show shorter LTP than principal cells.

191.10 HIPPOCAMPAL UNIT ACTIVITY ALTERED BY LESIONS OF THE FIMBRIA-FORNIX IN RATS. M. L. Shapiro, R. L. Findling\*, and D. S. Olton: Dept. of Psychology, Johns Hopkins University, Baltimore, MD; F. H. Gage, U. Stenevi\*, and A. Bjorklund\*: Dept. of Histology, Lund University, Lund, Sweden.

Neuronal firing patterns in the CA-1 layer of the hippocampus of intact rats were compared to those of rats given lesions of the fimbria-fornix while the rats traversed a radial maze. Single unit recordings were made through a drivable bundle of microelectrodes implanted into the hippocampus at the level of the hippocampal flexure. Both complex-spike and theta unit firing patterns were altered in rats with lesions of the fimbriafornix. Complex-spike units were identified by their waveform, composed of a burst of two or more decrementing spikes, and low firing frequency. Complex-spike units recorded from intact rats had disorete place fields, places on the maze where firing frequency was significantly higher than base rate. The place fields in intact rats were not altered by manipulations of intramaze cues (e.g. covering the maze floor). In contrast, complex-spike units recorded from rats with fimbria-fornix lesions had place fields which were either degraded or abolished. Often the complex-spike units in rats with lesions fired without location specificity. Occasionally place fields were observed in rats with lesions, however these were abolished by manipulations of intramaze cues. These results indicate that the neural locus responsible for establishing place fields may be dissociated from those responsible for maintaining the stability of these fields.

Theta units recorded from intact rats were identified by their waveform (composed of near equivalent positive and negative deflections) and bursting firing pattern, which was phase locked to the theta slow-wave rhythm. These units fired with increased frequency during appetitive behaviors (e.g. walking) and de-creased frequency during consummatory behaviors (e.g. eating Theta units recorded in rats with lesions had or grooming). wave forms identical to those in intact rats. Furthermore, these theta units fired with increased frequency during appetitive behaviors and with decreased frequency during consummatory behaviors. However, the typical bursting pattern of theta units was never observed. These results indicate that the neural locus controlling theta unit firing frequency may be dissociated from that responsible for organizing the pattern of such activity. 191.9 HUMAN HIPPOCAMPAL FIELD-POTENTIALS EVOKED TO WORDS DURING RECENT MEMORY RECOGNITION TASKS. <u>M. E. Smith\*, J. M. Stapleton and</u> <u>E. Halgren</u>. Lab. for Cognitive Neurophysiology, Brain Research Institute, University of California at Los Angeles, and V. A. Southwest Regional Epilepsy Center, Los Angeles, CA. The sensitivity of medial temporal lobe structures to stimulus

familiarity was assessed by recording event-related potentials (ERPs) from chronically implanted depth electrodes during recent memory word recognition. Recordings were obtained bilaterally from amygdala, hippocampus, and parahippocampal gyrus of patients being evaluated for surgical treatment of epilepsy. Stimuli were common nouns, 50% of which were repeats of words presented in previous blocks. Patients performed a forced-choice yes/no recognition task with keypress response. Concurrent ERPs were collected by simultaneous recordings from 23 channels (.1 Hz. -.1 kHz., 7 msec dwell). In associated studies (Stapleton et al., this meeting), ERPs were obtained from the same electrodes during auditory "oddball" tasks.

Visually presented words were observed to elicit large amplitude potentials (50-100  $\mu V$ ), with peak latencies of 250-700 msec and polarity reversals in the area of the hippocampus. Changes observed in response to word familiarity were of two types. One component which appeared similar in morphology and distribution to that observed in oddball tasks decreased in size and latency to repeated words. A second component of earlier latency and different distribution was also noted to decrease amplitude and latency in response to repeats. Keypress response was made 600-850 msec post-stimulus onset. These results suggest that hippocampal activity involved with information processing distinguishes between new words and those stored in Recent Memory. Since the onset of this difference occurs 300-600 msec before response execution, models of memory search operations which specify parallel processes are supported. Supported by USPHS grant #NS18741.

PJACFIDAL RECOVERY FROM HIPPOCAMPAL ANNIC ACID LEBIDAS AND INFERACTIONS WITH SUPERIOR CERVICAL GANGLION. J. P. Kesslar and F. 1. Gage. Chamistry of denavior Program, Dept. of Psychology, Fexas Christian University, Ft. Worth, FX 75129, and Dept. of Histology, University of Lund, Lund, Suddm. 191.11 Jweden.

It has been demonstrated hippocampal KA lesions of the CA3 area can induce performance deficits on learning tasks which recover over time (Handelmann & Olton, 1931). The time-course of recovery from learning tasks which recover over time (dandelmann & Olton, 1931). The time-course of recovery from damage is approximately the same period necessary for sympathetic sprouting after medial september of the study was designed to determine if sympathetic fibers may be contributing to recovery of function following nippocampal &A lesions. Male Sprayue-Dawley rats were pretrained on a forced choice alternation task in a f-maze.

Following learning to criterion animals received either KA (.3nm/.4ul) or pufferel saline injected bilaterally into forsal and ventral nippocampus.

bilaterally into dorsal and ventral nippocampus. Animals were again tested on the forced choice task till reaching criterion. Drirty days after (A or saline injections half the animals in each group received sympathectonies (3C3) and were retested. Analysis of variance and post hoc tests indicated; 1) performance deficits on the forced choice task following (A lesions (p(.JJ1), 2) following ganglion removal only the combined (A-SC3 group showed a significit performance deficit (p(.JJ1). The results of the present study indicate sympathetic fibers may play a role in recovery of function from nippocampal damage. distofluorametric exanination of N2 fibers tentatively indicate an increase in fluorescence; but quantification of differences between groups is necessary before concluding sympathetic fibers significantly contribute to recovery of function.

HIPPOCAMPAL PROTEIN PHOSPHORYLATION AND SPATIAL MEMORY. B. Bank\* 191.12 and D. L. Chute<sup>1</sup>. Div. of Life Sciences, University of Toronto, Scarborough, Ont. Canada MIC 1A4.

The purpose of this experiment was to detect changes in synap-tic proteins as a result of acquisition of an 8-arm spatial maze tic proteins as a result of acquisition of an 8-arm spatial maze task. Twenty-four 400g Charles River male hooded rats were food deprived to a level of 85% of their free feeding weight. Control animals were treated identically to experimental animals, with the exception of actual maze training. Animals were placed daily in an 8-arm radial maze in which each arm was baited with food, and permitted to visit 8 arms in a period of 10 min or less. A cor-rect choice of an arm meant entering an arm which had not been previously chosen. After 2 weeks, only animals performing to a criterion of at least 7 of 8 correct choices were included for blochemical analysis. Twenty-four hours after the last trial, the animals were decanitated, the brains guighly removed and the biobiochemical analysis. Inventy-four nours after the last trial, the animals were decapitated, the brains quickly removed and the hip-pocampus and entorhinal cortex dissected out. The synaptic junc-tional complex was isolated by Triton extraction. The isolated fraction was incubated with  $\{\gamma^{-3} z\}$  ATP and analyzed by 2-dimen-sional polyacrylamide gel electrophoresis. Overall incorporation rates showed a 32% inhibition of protein phosphorylation in the tissue of trained animals compared to controls. This inhibition was reflected in autoradiograms of the 2-dimensional gels as a decrease in phosphorylation of at least three proteins with molecular weights of approximately 50-55, 75-80 and 130K. These changes are consistent with those observed in our lab as a result of other neuroplastic phenomena such as kindling. <sup>1</sup>Supported by an operating grant from the Natural Sciences and Engineering Research Council of Canada.

191.13 CORRELATION BETWEEN WORKING MEMORY AND LEVEL OF HIPPOCAMPAL CHOL-INE ACETYLTRANSFERASE IN RATS. <u>D.J. Hughey\* and E. Friedman\*</u> (SPON: S.H. Ferris). Dept. of Psychology, New York University,

(SrOW: S.H. FEFTIS). Dept. OF FSychology, New fork University, and Dept. of Psychiatry and Pharmacology, N.Y.U. Medical Ctr., New York, N.Y. 10003 & 10016. Short-term memory deficits have often been associated with damage of the hippocampus or its extrinsic connections. Moreover, there is evidence that a central cholinergic dysfunction (partic-ularly in the hippocampus and central may have a more in correularly in the hippocampus and cortex) may play a role in some geriatric memory disturbances. The purpose of this experiment was to examine the relationship between a type of short-term memory and the cholinergic septohippocampal pathway in rats.

And the cholinergic septon/plocampai patiway in late. An 8 arm radial maze was used. The maze consists of an octag-onal center platform from which 8 runways project, like the spokes of a wheel. An abundance of extra-maze stimuli provided spatial orientation cues. A food pellet was placed at the end of each arm. Then a food-deprived rat was placed in the center of the maze and allowed to forage freely. The optimal strategy is to visit each arm only once, thereby collecting all 8 pellets in the first 8 choices. Perfect performance depends on the capacity for short-term retrieval called working memory. All animals were pre-operatively trained on the maze. After

reaching a high criterion of performance, rats were randomly assigned to one of the following groups: unoperated controls, operated controls, or septal lesions. Bilateral septal lesions were produced with cathodal DC current (0.7 mA x 60 seconds). Two post-operative tests were conducted. Each of these consisted of menced 7-10 days after surgery; the second began 50 days after the surgery.

After the completion of post-operative testing, all rats were sacrificed. The hippocampus of each animal was assayed for chol-ine acetyltransferase (CAT), the synthetic enzyme in the formation of acetylcholine.

Behavioral results showed a typical impairment of radial maze performance in the septal lesioned rats. Operated controls were indistinguishable from unoperated controls. Septal vs. control Indistinguishable from imperated controls, beparts, control differences were most pronounced in Test 1. The enzyme assays revealed a significant correlation across groups between maze performance and hippocampal CAT activity (p < .001). Within the septal lesioned group there was also a significant correlation between degree of behavioral impairment and level of CAT depletion (p<.05).

In conclusion, there appears to be a significant linear relationship between working memory, as measured on the radial maze, and hippocampal cholinergic function.

(Supported in part by USPHS RSDA MH 00208 to E. Friedman.)

191.14 THE INFLUENCE OF BEHAVIOR ON (3H)-CHOLINE UPTAKE INTO ACETYL CHOLINERGIC NEURONS OF THE NUCLEUS BASALIS OF MEYNERT AND THE MEDIAL SEPTAL AREA. G. Wenk, D. Hepler\*and D. Olton. Department of Psychology, Johns Hopkins University, Baltimore, MD 21218.

Cholinergic neurons in the basal forebrain, including the nucleus basalis of Meynert and the medial septal area, project topographically to the neocortex and hippocampus, providing a major source of cholinergic input. The present experiments correlated the activity of these cholinergic neurons with behavior by monitoring changes in sodium-dependent high affinity choline uptake in the cortex and hippocampus after the performance of behavioral tasks designed to involved these structures. The tasks included: memory tests on the radial arm maze, active avoidance, and reversal of spatial discrimination on a T-maze. An increase in cortical sodium-dependent high affinity choline uptake following performance in a particular task is taken to indicate increased cholinergic neuronal task is taken to indicate increased cholinergic neuronal activity in the nucleus basalis of Meynert, while an increase in hippocampal sodium-dependent high affinity choline uptake is taken to indicate increased cholinergic neuronal activity in the medial septal area. In each experiment, one group of rats composed an untrained control group, to determine base-line levels of sodium-dependent high affinity choline uptake. A second group performed one of the behavioral tasks designed to activate specific brain regions just prior to sacrificing. The rats were sacrificed by decapitation immediately after The rats were sacrificed by decapitation immediately after testing, and the frontal cortex and hippocampus were isolated. Sodium-dependent high affinity choline uptake was assayed according to the method of Atweh <u>et al.</u>, (Life Sciences, <u>17</u>: 1535, 1975). The results suggest that behavior differentially are interpreted in terms of the influences of basal forebrain cholinergic structures upon behavior. Supported by grant DAMD 17-C-8225.

HIPPOCAMPAL LESIONS: BEHAVIORAL RIGIDITY AFFECTS THE APPRECIATION OF EXPERIMENTAL CONTINGENCIES. N. A. Schmajuk\* and R. L. 191.15

OF EXPERIMENTAL CONTINGENCIES. N. A. Schmajuk\* and R. L. Isaacson. Department of Psychology and Center for Neurobehavioral Sciences, SUNY-Binghamton, Binghamton, NY 13901. Classical conditioning can be described in terms of the contin-gency between the CS and the UCS. Animals with hippocampal lesions did not have any deficit in classical conditioning, when trained with different combinations of P(UCS|CS), the probability of receiving UCS given the occurrence of CS and P(UCS|CS), the probability of receiving the UCS given the non-occurrence of CS. In the first experiment we studied the P(UCS|CS) = P(UCS|CS) = 0.5 combination. When trained animals did not differ in performance

constrained in this condition, hippocampal, contical, and sham lesioned animals did not differ in performance. However, when hippocampal lesioned animals were trained in an instrumental learning situation with  $P(UCS|R) = P(UCS|\overline{R}) = 0.5$ , they responded at a higher frequency, displaying a higher P(R)(Devenport, 1980). This difference between the classical and instrumental results

can be explained in terms of how the animal's behavior defines the degree of contingency between the response R and the consethe degree of contingency between the response R and the consequence S. This contingency can be defined according to the absolute probabilities of receiving S, having produced both R and non-R. These absolute probabilities are the intersection of R and S and can be expressed as  $P(S \cap R) = P(R) \cdot P(S \mid R)$  and  $P(S \cap R) = P(\bar{R}) \cdot P(S \mid \bar{R})$ . Thus, in the instrumental case the degree of contingency is defined by the animal's behavior (Gibbon et al., 1974). The conclusion is that the differences found in instrumental learning could be the result--not of a deficient learning about contingencies in general--but of a different distribution of the responses.

responses.

responses. In a second experiment the distributions of the total time allotted for each behavior and of length of bouts was obtained for hippocampal, cortical, and sham lesioned animals in the open field. These distributions were different for hippocampal lesioned animals when measured in either way. These behavioral differences may account for some of the dif-ferences observed in hippocampectomized animals in instrumental

learning, since the would induce lesioned animals to perceive the experimental contingencies in different ways from normal animals.

WHERE IS THE COGNITIVE MAP? <u>C.A. Barnes and B.L. McNaughton</u>, Dept. of Psych., Univ. of Colorado, Boulder, CO 80309. Several lines of evidence indicate that the hippocampus is cru-191.16

cially involved in spatial information processing. This has led to the theory proposed by O'Keefe and Nadel (1978) that the hippocampus is the locus of a cognitive map. Consistent with this notion is the observation that the principal inputs to the hippocampus are capable of pronounced long-term synaptic enhancement (LTE) following both their electrical activation at high frequency and exposure to a novel environment (Sharp et al., this meeting). Furthermore there is a correlation between the persistence of LTE and an animal's performance on a spatial memory task (Barnes, 1979). If these observations are indeed related, then one would predict that experimental saturation of the LTE mechanism by repeated electrical stimulation should impair cognitive mapping ability.

Ten young (10 mo) and 10 old (25 mo) rats were trained to asymptotic performance on a circular platform maze. This maze requires the animal to find a darkened goal tunnel using extra-maze cues only (odor cues and motor patterns cannot be used to solve the problem). The animals were then prepared for bilateral chronic stimulation of perforant pathway and recording of evoked responses in the fascia dentata. Half of the young and half of the old animals were given 6 high-frequency stimulation sessions distributed over two days. This resulted in a near saturation of LTE. The other half of the animals received the same number of stimulation pulses at a low frequency. No LTE was induced. Twenty-four hours following the last stimulation session, the

animals were retested on the platform. The location of the goal tunnel was, however, rotated 135° away from the original location This permitted an assessment both of the retention of the original location (initial deviation from original goal location) and the acquisition of a new spatial location (number of errors made following three consecutive daily training sessions with the new position).

There was no difference between treatment groups in the retention of the old spatial habit, whereas there was a large and statistically significant difference in the acquisition of the new

statistically significant difference in the acquisition of the new one. While the older animals' performance was poorer overall than the younger animals' on this task, both groups were impaired by the high frequency stimulation only on the acquisition phase. These data suggest that a normally functioning hippocampus is necessary for the formation of a new "cognitive map", but is not necessary for the effective use of a previously established one. Hence it appears that the major input to the hippocampus, while necessary to set up a "map", is not the locus of the map itself.

FUNCTIONAL LATERALITY IN THE MOUSE BRAIN: EVIDENCE DERIVED FROM STUDIES OF PAW PREFERENCE AND ROTATORY BIAS IN SHAKER-1 MUTANT MICE. John M. Cooke, Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605 Mice homozygous for the gene shaker-1 (gene symbol, <u>sh-1</u>) are spontaneously hyperactive and run in circles. The circling activity is lateralized. Individual mice circle in preferred directions, either clockwise or counterclockwise, at rates which average more than 40 rotations per minute. Preliminary neuroanatomical study of the shaker-1 brain has revealed no obvious morphological abnormality. Consequently, the circling behavior may express an inherent functional asymmetry. The present study was undertaken to determine two separate indices of laterality, namely, paw preference and rotatory bias, in the of laterality, namely, paw preference and rotatory bias, in the same individual shaker-1 mice.

Forty-two affected (sh-1/sh-1) and 49 control mice (+/sh-1 or Forty-two affected (sh-1/sh-1) and 49 control mice (+/sh-1 or +/+) of the shaker-1 inbred strain were tested for paw preference using chambers similar to those described by Collins (J. Hered. 59:9, 1968). Paw preference was quantified by scoring the number of right paw entries (RPE's) out of a total of 50 reaches made by a fasted individual to obtain food. Rotatory biases were determined for 34 of the 42 shaker-1 mice by calculating the average percentage of clockwise rotations made by each mouse during a minimum of ten three-minute periods of observation.

of observation. The distribution of paw preferences among the mutant and control populations was similar. There were approximately equal numbers of dextral and sinistral mice within each group; 21 of the 42 shaker-1 mice and 22 of the 49 controls had RPE's greater than 25. Among individuals which expressed stronger degrees of lateralized behavior, seven mutants and six controls had RPE's greater than 40. Of the 34 shaker-1 mice which were also tested for circling

behavior, 13 circled preferentially clockwise, 21 counter-clockwise. Both paw preference and rotatory bias were stable upon repeated testing of the same individual. Paw preference and rotatory bias were not, however, strongly correlated. Individuals which showed similar paw preferences displayed widely varying values for rotatory bias and vice versa. Paw preference and rotatory bias constitute two stable, lateralized behaviors which can be easily determined in shaker-1 mica. Their expression in an inbred genetically uniform

mice. Their expression in an inbred genetically determined in shaker-1 mice. Their expression in an inbred genetically uniform population may offer a distinct advantage for use of this mutant and possibly other circling mutants of the mouse in studies directed toward understanding the neural mechanisms which underlie lateralized function in mammals.

STRUCTURAL ASYMMETRIES AND HIPPOCAMPAL MOSSY FIBER VARIATIONS RE-192.2 LATED TO THE STRENGTH OF HANDEDNESS IN MICE, H.-P. Lipp, R.L. Collins\*, and W.J.H. Nauta. Mass. Inst. of Technology, Dept. Psychology and Brain Science, Cambridge, MA 02139 and Jackson of Laboratories, Bar Harbor, ME 04609.

Laboratories, Bar Harbor, ME 04609. The tenacity of a mouse in using its preferred paw has a strong genetic component as demonstrated by the establishment of two mouse lines selectively bred for differential dexterity in a sim-ple manipulation task. One line (HI) has become strongly late-ralized, using mostly a preferred paw (left or right), the other (LO) is practically ambidextrous. The use of such selectively-bred lines is a convenient tool in attempts to identify a set of bred lines is a convenient tool in attempts to identify a set of brain variables related to a particular behavior, for every trait showing reliable strain differences must be related somehow to the task. Other genetic breeding paradigms can then be applied to iso-late those variables which are critical for the behavior (Schwegler & Lipp, Behav.Brain Res. 7, 1983). The brains of 6 female HI- and 6 LO-mice were processed for Timm-staining and cut horizontally. At a mid-dorsoventral level, when certain allowing

such sections provide an overall view of the mouse brain, allowing easy recognition of left/right asymmetries. In a preliminary morphometric analysis using five sections per mouse brain, we measured cortical thickness at symmetrical locations of the orbito-frontal, somatosensory, and entorhinal cortex; in addition, we determined the volume of the hippocampal formation at the sampling level. These measures were transformed into percentage differ-ences between hemispheres, a difference of more than 10% being

judged as major. Two distinct line differences emerged: 1) 5 HI-mice had a major asymmetry either in the orbitofrontal cortex (OFC) or in hippo-campal (HIP) volumes but never in both locations. One animal had only minor asymmetries but uniformly thicker cortex and hippocampus in one hemisphere. LO-mice showed mainly minor asymmetries, except for the entorhinal cortex. A score based on the combined OFC and HIP-percentages showed a highly significant line difference (p=0.009). 2) In the ambidextrous LO-line, 5 animals had a bilateral peculiarity in their mossy fiber distribution, never described before: the suprapyramidal mossy-fiber layer appeared to described before: the suprapyramidal mossy-tiber layer appeared to be invaded by pyramidal neurons. This trait was qualitative, either present or lacking, and was found in one HI-mouse, too. Yet, there was still a significant line difference (p=0.04, Fisher's Exact). We conclude that a hereditary strong or weak paw prefer-ence is apparently associated with a differential development of several <u>localized</u> hemispheric asymmetries, and with subtle bi-lateral differences in intrahingnoamal circuitry.

lateral differences in intrahipocampal circuitry. Supported by NSF grant BNS80-07905, grant 83.916.0.81 from the Swiss National Science Foundation, and grant GM23618.

THE EFFECTS OF UNILATERAL DECORTICATION ON BEHAVIORAL ASYMMETRIES 192.3 AS A FUNCTION OF GENDER, NEONATAL TAIL POSTURE (NTP), AND EXTRA STIMULATION IN INFANCY. M.J. Hofmann\*, A.S. Berrebi\*, J.S. Gall\*, J. Stockler\*, D.A. Yutzey, & V.H. Denenberg. Depts. of Biobehav-ioral Sciences & Psychology, Univ. of Conn., Storrs, Conn. 06268. Previous research using unilateral cortical lesions demonstra-

revious research using unifateral cortical lesions demonstra-ted that different behavioral responses could be obtained from rats with left (L) or right (R) cortical lesions, suggesting an underlying asymmetrical cerebral organization. Denenberg and his colleagues showed that extra environmental stimulation in infancy (handling) could cause changes in the behavioral organization of

Colleagues showed that extra environmental stimulation in infancy (handling) could cause changes in the behavioral organization of rats, often resulting in the enhancement of the behavioral asymmetry. Recently, neonatal postural asymmetries in rats were related to adult spatial preferences (SPs) on certain tasks. In addition, females and males differ with regard to behavioral and postural asymmetries. This study examined the relationships among gender, NTP, handling, and unilateral cortical lesions, and their effects on SP and activity it the rat. Purdue-Wistar rats of both sexes and NTPs (L or R) were handled (H) or not handled (NH) for 20 days following birth. As adults, they were tested for L-R SP and activity in a water-motivated diamond (D-) maze, a water-motivated rotation apparatus, and an open field. Following this, all animals received unilateral decortication ( $\underline{Y}$  or  $\underline{R}$ ) or a sham lesion. After 30 days recovery, rats were treated again with the presurgical reguimen. Following the experiment, rats were sacrified for histological analyses. Data were treated no significant effect in the D-maze, but shifted their rotational preference uniformly to the side contratateral to the lesion. NH male decorticates shifted their SP to the side contralateral to the lesion. This shift was greater for males with  $\underline{Y}$  than for those with R, indicating a cerebral asymmetry. In the rotation apparatus, H male decorticates shifted their SP contralateral to the lesion, but the shift was greater if the lesion was placed contralateral to the NTP, again indicating a cerebral asymmetry. Finally in the open field, there was a uniform decline in the activity of all groups from pre-to postsurgical tests, except for females with a L-NTP. This group maintained high activity levels. levels.

These results indicate: (1) Male and female behavioral asymme-tries are organized differently; they are more evident for spatial behavior with males and locomotor behavior for females. (2) Handl-ing changes the behavioral organization of males and induces a neural or behavioral asymmetry.

192.5 LATERALIZATION OF ACTIVITY IN APOMORPHINE-INJECTED RATS EXPLORING A NOVEL ENVIRONMENT: PREDOMINANCE OF TURNING IN THE CLOCKWISE DIRECTION. <u>H. Szechtman</u>. Department of Neurosciences, McMaster University, Hamilton, Ontario, Canada, L8N 325. DIRECTION. H. Szechtman. Department of Neurosciences, McMaster University, Hamilton, Ontario, Canada, L&N 3Z5. There is increasing evidence that an asymmetrical brain organization, both functional and structural, is present not only in humans, but also in a variety of animal species, including rats. This presentation reports that apomorphine reveals a striking lateralization in the behaviour of rats exploring a novel environment. In their investigation of an unfamiliar area (a large sheet of glass 183 x 121 cm, suspended 150 cm above the floor) rats (N= 12) injected with apomorphine (1.25 mg/kg s.c.) turned their head, or the head and the body, for a total of 1717 x 45° during a 60 minute test. (The measurements were taken using the Espkol-Wachman Movement Notation, with 1 amount of movement = 45°.) Of this amount, 61% was in the clockwise direction (to the right) and only 39% was in the counterclockwise difference (p < .0001). Uninjected control animals (N= 12) showed no bias during their exploration of the field. Rats which were familiar with the open field also did not show an overall bias in the direction of turning after an injection of apomor-phine, indicating that experience counteracts the revealing effects of the drug. Interestingly, 9 of the 12 apomorphine-injected rats which were unfamiliar with the open field showed a significant bias for turning in the clockwise direction, whereas of the 12 apomorphine-injected animals familiar with the test environment. 4 had a bias for turning in field showed a significant bias for turning in the clockwise direction, whereas of the 12 apomorphine-injected animals familiar with the test environment, 4 had a bias for turning in the clockwise and 5 in the counterclockwise direction. (The re-maining rats showed no significant bias in the direction of their turning.) These data suggest that during exploration of a strange territory, when the animal is presumably forming a "cognitive map" of the area, the left hemisphere is more active than the right one and that this specialized activity of the left side is exaggerated by apomorphine. (NTERHEMISPHERIC REGULATION OF MESOLIMBIC AND NIGROSTRIATAL D2 RECEPTORS. L.H. Schneider<sup>®</sup>, E.E. Coons<sup>#</sup>, and R.B. Murphy<sup>®</sup> <sup>3</sup>Department of Biological Fsychiatry, N.Y.S. Psychiatric Institute vew York NY 10033 and Departments of <sup>#</sup>Psychology and <sup>®</sup>Chemistry, 192.4 New York University, New York, NY 10033

The specific binding of  $[{}^{3}$ H]-spiroperidol (0.6 nM) to the left and right hemisphere terminal zones of the mesolimbic (olfactory and right hemisphere terminal zones of the mesolimbic (olfactory tubercle plus ventral nucleus accumbens: OT+NA) and the nigro-striatal (striatum) dopamine (DA) systems was measured individually in 66 male Sprague-Dawley rats. We have previously reported a nighly significant endogenous left> right asymmetry in striatal D2 receptors, and the strong tendency toward an opposite right>left imbalance in OT+NA (<u>Neuresci Lett. 33</u>: 281-284 (1982). We have also presented evidence that these endogenous lateralizations are odulated by electrode implatting into and elec by electrical Also presented evidence that these endogenous lateralizations are modulated by electrode implantation into and also by electrical self-stimulation (ICSS) of the ventral tegmental area (VTA), site of mesolimbic DA cell bodies (Soc. Neurosci. Abstr. 8: 656 (1982). We now report that the modulation of mesolimbic D2 receptors by unilateral VTA ICSS is found more markedly in the OT+NA contra-lateral to (a COD) arther the interval to (a CO) the

by unilateral VTA ICSS is found more markedly in the OT+NA contra-lateral to  $(p \leq .005)$  rather than ipsilateral to  $(p \leq .09)$  the electrode, although the hemispheric OT+NA asymmetry found after electrode implantation only depends in part on the electrode side in relation to the preoperative D2 receptor imbalance. The magnitude of the contralateral  $\langle$  ipsilateral mesolimbic binding isymmetry found after electrical self-stimulation is significantly related to the depth of the electrode (r=-0.50, p  $\langle$ .006). The interaction of the stimulation with tissue laterality with respect to the VTA electrode was highly significant in the OT+NA  $(p \leq .001)$ , put not in the striatum. out not in the striatum.

These data support the existence and influence of reciprocal inhibitory connections between the left and right hemisphere DA Inhibitory connections between the left and right hemisphere DA /TA cell body groups. That the left and right hemisphere A9 DA 2ell body groups are similarly interrelated is suggested by our evidence that the endogenous striatal D2 asymmetry is abolished by left or right VTA electrode implantation, regardless of subse-quent electrical stimulation treatment. We consider our results imply interhemispheric regulation of mesolimbic and nigrostriatal D2 receptors which could be consistent with the evidence presented for classification of an endogeneous of the subsection of the subsecti from Glewinski's laboratory for interhemispheric control of DA celease in the nigrostriatal system of the cat (Cheramy et al, lature 239: 537-542 (1982).

RIGHT HEMISPHERE DOPAMINERGIC CIRCUITRY IS INVOLVED IN ELECTRO-192.6 DERMAL ACTIVITY CONTROL: EVIDENCE FROM HEMIPARKINSONISM. M. Mintz, R. Tomer\*, <sup>1</sup>Z. Privorkin\*, <sup>2</sup>H. Sroka\* and M.S. Myslobodsky. Psycho biology Research Unit, Tel Aviv University, Ramat Aviv 69978, and Depts. of Neurology, <sup>1</sup>Meir and <sup>2</sup>Beilinson Hospitals, Israel.

Attentional deficit in patients with unilateral Parkinson's syndrome (hemiparkinsonism) may be revealed in abnormalities of the P300 wave of visual evoked potentials (Mintz et al., 1982). The present findings corroborate the above study using the analy-sis of electrodermal activity (EDA). These results also suggest that the right- and left-hemisphere dopaminergic (DA) circuitries have an unequal share in EDA control. A group of 21 patients was screened for analysis: twelve had

strictly unilateral symptomatology (rigidity, tremor and slowing), while in nine there were also initial signs of involvement of the other side. Seventeen patients were on chronic Levodopa medication (125-500 mg/day) and four patients were either drug-free or on anticholinergic medication. Reactive EDA was recorded from the in-dex and ring fingers of both hands, by measuring the resistance changes with 10 µamp constant current. EDA was measured in response to non-signal stroboscopic flashes (baseline session) and during attention task, in which patients were asked to discriminate between, and memorize the number of flashes delivered in two intensities.

Patients were defined as either (a)non-responders (NR), who failed to produce any EDA orienting response or were unresponsive in the first three trials of each session; or (b)responders (R), who produced consistent EDA orienting response, or habituated af-ter at least three trials. Right-sided parkinsonians were largely responders (64.3% during baseline session and 100% during task session), with significantly higher EDA reactivity during the task session (p .02). Conversely, patients with left-sided symptomato-logy were typically NR (85.7% during baseline, and 83.3% during task session). A test for the significance of a difference between proportions revealed that the occurrence of non-responding diffe-red conditionally between the two remers (a for each table). red significantly between the two groups (p.05, two-tailed), in both the baseline and task sessions. Given that unilateral parkin-sonian symptomatology correlates with DA-ergic deficiency in the contralateral hemisphere, our findings suggest that bilateral EDA non-responding is associated with right hemisphere deficit. Three patients with right-sided symptomatology were tested both before and following chronic Levodopa treatment. All three showed slightly enhanced EDA reactivity when on medication. It would therefore appear that DA circuitry in the right hemisphere is responsible for bilateral EDA control. Non-responding, observed in medicated right-hemisphere parkinsonians, indicates irreparable damage to this circuitry.

EVIDENCE FOR LEFT HEMISPHERE DOMINANCE OF VISUAL DIS-CRIMINATION LEARNING IN THE CHICK. <u>Karen E. Gaston</u>\* (SPON: T. J. Mueller). Pitzer College, Claremont, CA 91711. 192.7

Hemispheric specialization of the human brain is well-documented, and there is also accumulating evidence of functional brain asymmetries in nonhuman species, especially birds. In the avian brain, the optic nerve fibers from each eye all cross to the contralateral hemisphere; direct visual input can therefore be lateralized to one hemisphere by occluding the ipsilateral eye. It has been shown that monocularly acquired learning in birds is sometimes stored in the form of a unilateral engram, which may or may not be accessible to the 'untrained' hemisphere by way of interhemispheric fiber connections. Several recent studies have found that chicks trained monocularly on a visual discrimination task learn somewhat faster through the right eye than through the left eye. This observation suggests that the left hemisphere of the chick brain is the functionally superior, or specialized, hemisphere with respect to visual discrimination learning.

While studies of monocular learning can assess the relative com-petence of the two hemispheres for a particular task, they do not by themselves reveal the normal pattern of hemisphere function in birds with both eyes open. When visual information is freely available to both eye/hemisphere systems, it is possible either that both hemispheres acquire and store the information or, on the other hand, that the more competent hemisphere dominates acquisition and retention. The present

experiment examined these alternatives. In an automated operant chamber, 20 chicks were trained with both eyes open on a simultaneous 2-choice pattern discrimination. After on the same discrimination with one eye occluded. Chicks retrained through the right eye (left hemisphere) demonstrated excellent retention of the discrimination. In marked contrast, chicks retrained through the left eye (right hemisphere) showed no retention at all - they behaved as though they had never seen the discrimination before and they required at least as many trials to re-learn the task as they had to learn it the first time.

The pattern of results suggests that both hemispheres have the capacity for this type of visual discrimination learning, but that the left capacity for this type of visual discrimination learning, but that the left hemisphere is dominant when learning occurs with both eyes open. In this situation, it appears that <u>only</u> the left hemisphere learns the pattern discrimination and that memory is stored unilaterally and is not available to the right hemisphere. This failure of interhemispheric transfer is remarkable in light of the good transfer we have previously observed in this trained measurable on the came discrimination task. The chicks trained monocularly on the same discrimination task. The discrepant findings suggest that interhemispheric interactions are quali-tatively different depending on whether or not sensory information is experimentally lateralized.

TRANSCALLOSAL MNEMONIC PROCESSING IS INFERIOR TO INTRAHEMISPHERIC PROCESSING IN <u>MACACA</u> <u>NEMESTRINA</u>. Jeffrey D. Lewine\* and <u>Robert W. Doty</u>, Center for Brain Research, University of Rochester School of Medicine, Rochester, New York 192.9 14642.

Wearing a lightweight mask equipped with shutters which restrict vision to one eye at a time, monkeys with optic chiasm and anterior commissure (AC) cut via a transphenoidal approach sit facing two panels. Photographic images are then serially projected on the upper panel at 10-sec intervals. If it is the first time that a given image is seen on that day, the monkey is rewarded for pressing the upper panel; seen on that day, the monkey is rewarded to pressing the upper panes, if it is the second presentation of that image, the monkey must press the bottom panel for a reward. The mean delay between first and second viewings is 60 sec (range 10-180 sec). Thus, 0-17 images may intervene between first and second presentation. A total of 280 images is presented daily, 5-7 sessions elapsing before any particular image is seen again. For the monkey reported here 5100 presentations have been made, 2800 of which represent first presentations of a given day, and 2300 representing second viewings. Regardless of which eye was being tested, on 20% of the occasions when the monkey viewed an image for the first time, it erroneously responded as though the image were a second presentation. Chance performance for recognition of a repeat presentation is therefore defined by this "false positive" error rate, i.e., 20% not 50% correct. Thus, if the monkey's ability to recognize repetitions is> 20%, it is demonstrating some memory for the first presentation. The monkey's actual performance as a function of 'seconds since initial viewing' (s) is, for the intrahemispheric condition, given by the equation: % accuracy = 90.5 - 0.11(s); and for the interhemispheric condition by: % accuracy = 74.9 - 0.20(s). The intercepts of these two functions differ at p> 99.9% (F 1,64 = 25.034); the slopes also differ at p> 95.0% (F 1,64 = 4.452). These equations apply regardless of which eye was tested (intrahemispheric condition), or the direction of transfer tested (interhemispheric condition). Although we do not have adequate pre-surgical observations on this the first time, it erroneously responded as though the image were a or the direction of transfer tested (interhemispheric condition). Although we do not have adequate pre-surgical observations on this animal, these data clearly demonstrate that despite the presence of the entire callosal system, interhemispheric mnemonic processing is significantly worse than intrahemispheric processing at all tested delays (s). In addition, the findings concerning the slopes of the two functions suggest that the interhemispheric process "decays" faster, or is perturbed more readily. It remains to be determined whether the basis for the observed deficiency of the interhemispheric mnemonic comparison is attributable to the absence of the AC, the weakness of a contralateral engram, inefficiency in accessing a unilateral engram, or more than one of these possibilities. The situation can be delineated by more than one of these possibilities. The situation can be delineated by preserving the AC and/or by selective, reversible blockade of commissural pathways. (Supported by NSF Grant 5-28606.)

LATERALITY IN MONKEYS FOR DISRIMINATING FACIAL EXPRESSION AND 192.8

LATERALITY IN MONKEYS FUR DISRIMINATING FACIAL EXPRESSION AND IDENTITY. B. A. Vermeire, A. L. Erdmann<sup>\*</sup> and C. R. Hamilton. Div. of Biology, Caltech, Pasadena, CA 91125. As part of our search for hemispheric specialization in monkeys we test the ability of each hemisphere to discriminate facial characteristics because this ability is well developed in monkeys, it is lateralized in man, and pilot studies indicate it also may be lateralized in monkeys (Hamilton and Vermeire, <u>Behav. Brain Res.</u>, in press). Expression as well as identity was tested in this experiment because recent work with human subjects has revealed greater lateralization for facial human subjects has revealed greater lateralization for facial numan subjects has revealed greater lateralization for factal expressions than for recognition of individuals. Sixteen split-brain rhesus monkeys, eight male and eight female, learned with each hemisphere to discriminate photographs of the faces of conspecifics. Four discriminations required differentiating one monkey from another with facial expression differentiating one monkey from another with facial expression held constant and four additional problems required differenti-ating one expression from another with the individual held constant. For each discrimination five examples of the positive stimulus and five examples of the negative stimulus were intermixed in a sequence of 80 trials. After the two hemispheres learned the eight discriminations and several months had passed, they were tested separately for retention of the discriminations. Following this, tests were made of expressions or individuals to determine if the desired categories had been learned and to evaluate the specificity of categories had been learned and to evaluate the specificity of

the categories in each hemisphere. The results to date show an overall tendency for the right The results to date show an overall tendency for the right hemisphere to learn more readily than the left, but with 14 monkeys completed this is statistically significant only for the discrimination of expressions by female monkeys. Similarly, there is an advantage for remembering the discrimi-nations with the right hemisphere; with nine monkeys tested this advantage is significant only for the discrimination of expressions. Finally, generalization is also better, although not significant, with the right hemisphere of the seven monkeys which have been tested. In contrast to results from human subjects, no greater hemispheric difference is apparent for discrimination for discrimination individuals. discriminating expressions than for discriminating individuals. In summary, although we have obtained new evidence of hemi-spheric specialization in monkeys for learning and remembering discriminations based on facial characteristics, the lateralization does not seem as robust or consistent as that found with human beings. There is some indication that the degree of lateralization may depend on the task demands and on the sex of the subjects. Supported by USPH grant MH-34770.

192.10 SPECIALIZED HEMISPHERIC RETRIEVAL FROM LONG-TERM SEMANTIC MEMORY: CONVERGENTEVIDENCE FROM NORMAL AND COMMISSUROTOMY SUBJECTS. <u>D. W. Zaidel</u>\* (SPON: D. L. Glanzman). Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The forebrain commissures serve to transmit percep-The forebrain commissures serve to transmit percep-tual and cognitive information from one cerebral hemi-sphere to the other. In normal subjects with intact commissures it is difficult to determine the extent to which experimentally observed hemispheric differences reflect shared, duplicated, or specialized processes. However, convergent data from patients in whom the forebrain commissures had been sectioned completely can help clarify findings obtained with normal subjects. In the present study the performance of patients with sectioned commissures was compared to that of nor-mal subjects on a task designed to measure retrieval of semantic information from long-term storage. The task semantic information from long-term storage. The task consisted of matching tachistoscopically presented pic-torial instances with their natural superordinate torial instances with their natural superordinate categories. Instances were typical or atypical repre-sentations of their categories (E. Rosch, J. of Exp. <u>Psychol</u>., 1975, 104:192-233). The stimuli were later-alized briefly to either the left (LVF) or right (RVF) visual half fields and subjects indicated a match or no-match with a key press. Both accuracy and latency scores were recorded and only correct matches were considered in data analysis. Analysis of the results for latency scores showed (1) a significant interaction between visual half field and the level of typicality in both groups;(2) typical

and the level of typicality in both groups;(2) typical instances were matched faster in the LVF than in the RVF and atypical instances were matched faster in the RVF than in the LVF. There were no visual field differences in accuracy scores.

differences in accuracy scores. In view of the similar pattern of functional later-alization observed in commissurotomy and normal sub-jects these results are interpreted to reflect special ized retrieval from long-term semantic memory in each hemisphere even in the presence of the forebrain comm-issures. This extends previous observations of hemi-spheric specialization by suggesting the functional lateralization of long-term storage of experience as well. well.

192.12

192.11 INTERHEMISPHERIC ASYMMETRIES OF CORTICAL AUDITORY EVOKED POTEN-TIALS USING BRAIN ELECTRICAL ACTIVITY MAPPING. <u>S. Khoshbin\*</u>, L. A. Levin\*, L. M. Milrod\* and M. Hallett. (SPON: S. Wray). Neurology Section, Brigham and Women's Huspital, Harvard Medical School, Boston, MA 02115.

Cortical auditory evoked responses to frequent (90%) 1000 Hz and infrequent (10%) 2000 Hz 50 msec tone bursts were recorded in 14 normal right-handed subjects ranging in age from 18 to 33. Stimuli were presented at 60 dB above hearing threshold to right and left ears separately, with the contralateral ear masked with white noise. The auditory evoked response was recorded over 450 msec from 16 scalp electrodes using the 10-20 international system. Computerized four-point linear interpolation was done to provide a spatial map of the recorded evoked response over a  $48\times64$  matrix. Significance probability mapping using point-bypoint paired two-tailed t-tests was done to demonstrate statistically significant differences in three experimental paradigms. Results were displayed on a television monitor using gray-level coding.

Comparison of the right versus left hemisphere with same ear stimulation showed consistent asymmetries throughout the recording period in all areas except the anterior to mid-temporal. Responses to infrequent stimuli did not show significant interhemispheric asymmetry, as was predicted by visual inspection of the topographic map prior to statistical analysis.

Responses to infrequent stimuli did not show significant interhemispheric asymmetry, as was predicted by visual inspection of the topographic map prior to statistical analysis. Our observations show that the response to frequent stimuli demonstrates a polar pattern (left anterior and right posterior positive, and right anterior and left posterior negative), while the response to infrequent stimuli demonstrates an interhemispheric symmetry, with an anteriorly negative to posteriorly positive gradient. DCMINANCE AND DEVELOPMENT, R. H. Bauer. Dept. Psychol., Middle Tennessee State University, Murfreesboro, TN 37132. A number of processes involved in the rapid searching and naming of visual stimuli and reading were identified, i.e., searching for a match between visual stimuli and visual memory codes, searching for a match between visual stimuli and phonological codes stored in memory, transferring visual stimuli to phonological codes, and the rate of covert responding. On the basis of standardized behavioral tests that measure left and right hemispheric functions, children of 8-, 9-, 10-, 11-, and 12 years of age (N=90) were separated into left-, right-, and neutralhemispheric dominance groups. They were then tested in a number of tasks which measure the rate of each of the processes listed above. The rates of searching for a match between (a) visual stimuli without graphemic and lexical characteristics and visual memory codes, (b) visual stimuli without graphemic and lexical characteristics and phonological codes, and (c) simple motor responses with the dominand hand did not differ as a function of hemispheric dominance but increased with age. The rates of (a) searching for a match between visual stimuli with graphemic and lexical characteristics and phonological codes, and (c) overt vocal responding were faster in children with lefthemispheric dominance and increased with age. In addition, reaction time measures which were faster in children with lefthemispheric dominance were positively correlated with scores on standardized reading tests. Results of the present study indicate that a wide variety of reaction times increase as a function of development. However, only reaction times to graphemic and lexical stimuli and the rate of overt vocal responding differed among hemispheric dominance groups. Reaction times may be a sensitive method for detecting subtle differences in hemispheric functioning in children and, possibly, in adults.

LINGUISTIC PROCESSING SPEEDS AS A FUNCTION OF HEMISPHERIC

192.13 CEREBRAL SYMMETRY OF VISUAL STIMULUS EQUIVALENCES. R.M. Lazar\*, D. Scarisbrick\*, G. Kuslansky\*, and C. Soares\* (SPON: D. Berman). Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367, and Dept. of Psychology and Social Relations, Harvard University. A substantial literature has supported the view that there are functional differences between the two cerebral hemispheres of humans. The data have suggested that the left hemisphere is specialized for symbolic (e.g., language) function, and the right hemisphere is superior for spatial tasks. A question that remains unanswered, however, is the extent to which both hemispheres may share similar cognitive functions. Normal wight backed malee were presented arbitrary matching.

hemispheres may share similar cognitive functions. Normal, right-handed males were presented arbitrary matchingto-sample tasks, using three sets of Greek-letter stimuli designated Sets A, B, and C. Each set consisted of two stimuli. Viewing stimuli through a tachistoscope, subjects were first taught A-B and A-C matching in which a sample stimulus was presented in the center visual field for 150 msec, followed immediately by a comparison stimulus of similar duration in the left or right visual field. Half the subjects used their right hands to activate switches to indicate "match" or "nonmatch"; the other subjects used their left hands to indicate their responses.

After training, every subject was able to perform B-C and C-B matching, even without feedback on test trials. Response accuracy and the corresponding reaction times following comparison stimulus presentation to the left and right visual fields did not differ, suggesting cerebral symmetry with regard to the formation of simple equivalence classes with visual stimuli. The establishment of arbitrary relations among the Greek-letter forms permitted subjects to form equivalences for which there were no previously-learned labels. The data provide support for bilateral, symbolic thought that can be carried out in the absence of language.

COLOR CONSTANCY IN THE ASTIGMATIC EYE WITH 193.1 LONGITUDINAL CHROMATIC ABERRATION: THE NATURAL BASIS FOR THE MCOOLLOUGH EFFECT. Howard C. Howland and Nancy Sayles\*. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

14853. The McCollough Effect is a long-term contingent after-effect wherein a subject who has viewed a field of black stripes alternating with a colored background, sees the complimentary color when subsequently viewing a field of black and white stripes of the same orientation. It is generally thought to be due to the adaptation of a population of neurons which respond to both color and orientation.

We believe that the McCollough effect is due to a normal We believe that the McCollough effect is due to a normal color-constancy mechanism operative in persons with normal amounts of astigmatism. Such persons cannot focus parallel lines in orthogonal meridians simultaneously. Accordingly, when they view sets of black and white orthogonal stripes, one or both sets of such stripes must be defocused. Due to the normal chromatic aberration of the eye, either the red or the blue component of the white light forming the image will be more severely defocused than the other. This will result in a color separation of the two images, yielding colored stripes. The effect is, of course, direction-specific.

The effect is, of course, direction-specific. This hypothesis explains a) why it is a monocular effect (anisometropia), b) why it is a directional effect (astigmatism), c) why we don't ordinarily notice the McCollough effect (color constancy), d) why some persons do not see the effect (no astigmatism), e) why the usual McCollough stimulus presentation "overdrives" the color constancy mechanism (It employs long viewing times of intensly saturated colors), and b) the natural heais of the effect

f) the natural basis of the effect. We are conducting experiments with subjects having varying degrees of astigmatism to test aspects of this hypothesis and will present data to confirm or refute it.

REDISUAL VISION IN HEMISPHERECTOMIZED PATIENTS. A. Ptito\* 193.2 M. Lassonde et M. Ptito. Groupe de neuropsychologie, Université du Québec à Trois-Rivières, Trois-Rivières, Québec, G9A 5H7, Canada.

It has traditionnally been assumed that damage to the occipital cortex will result in permanent blindness in the con-tralateral part of the visual field. These past years, however, an important aspect of research on blindness of cortical origin has been to demonstrate that the patient, even if blind in his subjective experience can respond to visual stimulations presented in his blind field. The present study was thus undertaken to investigate the existence and extent of such residual vision in hemispherectomized patients. Three levels of visual analysis were studied: 1. stimulus detection (SD); 2. movement analysis (MA); 3. pattern discrimination (PD). The experiments analysis (WA); 5. pattern disormination (PD). The experiment were carried out in a light-tight chamber and the Ss were dark adapted for a 30 min. period. Stimulus presentation was compu-ter controlled and ocular movements were constantly monitored. The first experiment (SD) involved the presentation on an oscilloscope of a stationary visual stimulus (2<sup>o</sup>). The oscilloscope position was varied randomly along the horizontal meridian. The S's task consisted in pointing at the location where he (she) believed the stimulus was presented. The second expe-riment (MA) required S to discrimate motion: a) in step 1, S had to indicate whether the stimulus (grating: 2c/deg.) presented in his (her) blind or intact field was stationary or moving; b) in step 2, two gratings were presented in the blind and/or the intact field and S's task consisted in telling whether the stimulus velocity was the same or different; c) in step 3, S had to indicate whether the gratingswere moving in the same or opposite direction. The last experiment (PD) involved two and three-dimensional pattern discrimination (letters, shapes, numbers and familiar objects) presented simul-taneously in the blind and intact fields. Results showed that stimulus detection in the blind field is preserved in all Ss Motion detection and discrimination were also possible in all patients. However, the discrimination of stimulus direction was failed. Concerning pattern discrimination of stimulus direction ject performed the tasks successfully. It therefore seems that some residual vision is present in the blind field of hemispherectomized patients. These residual capacities are sufficient to allow motion detection and velocity comparisons. They are limited however when finer discrimination tasks (di-rection or pattern) are required. The results are discussed in terms of differential involvement of cortical and subcortical mechanisms.

PITCH OF AM-SIGNALS: EVIDENCE FOR A CORRELATION ANALYSIS IN THE HUMAN AUDITORY SYSTEM. G. Langner. Zoologie, TH-Darmstadt, Schnittspahnstr.3, 6100 Darmstadt, FRG. The "residual" pitch P of AM-signals(sinusoidal amplitude modulation) was measured by a matching pro-cedure with a "pure" tone. If the carrier frequency, f<sub>c</sub>, is a harmonic of the modulation frequency, f<sub>m</sub>, (i.e.  $f_c/n_H = f_m$ ,  $n_H$  integral) P corresponds to  $f_m$ . As experiments with nonharmonic AM-signals revealed P is neither defined by the modulation envelope nor by a subharmonic of the carrier since it deviates systema-tically from f<sub>m</sub> as well as from  $f_c/n_H$  (Schouten,J.F. et al., J.Acoust.Soc.Am.34:1418,1962). It is evident that the same discrepancy is found in the time domain since the period  $\tau_D^{=1/P}$  deviates from  $\tau_m^{=1/f_m}$  as well as from  $n_{H} \cdot \tau_c = n_H/f_c$ . Pattern models of an auditory pitch perception could comply with this effect. They are based on the assumption that the audi-tory system analyses the spectral pattern of the AM-signal either on the basilar membrane or central in the auditory system (Goldstein,J.L.,Audiology 17:421, 1978; merbeadt E, ot al. L Acoust Eq. 2016 auditory system (Goldstein, J.L., Audiology 17:421, 1978; Terhardt, E. et al., J.Acoust. Soc. Am. 71:671, 1982; Wightman, F.L.J. Acoust. Soc. Am. 54:407, 1973).

Wightman, F.L.J.Acoust.Soc.Am.54:407,1973). In contrast, the present pitch measurements with 5 human subjects suggest that the auditory system does <u>correlation between the envelope and the carrier</u>. As a <u>result the pitch period</u>  $\tau_p$  may be expressed by:  $\tau_p = n \cdot \tau_c + b$ ( $\tau_c$ , carrier period; n, integer). Furthermore, the results suggest that the values b are multiples of an auditory time constant  $\tau_1 = 0.4$  ms. The same evidence comes from a new interpretation of old pitch measurements (Schouten et al., see above;

old pitch measurements (Schouten et al., see above; Smoorenburg,G.F.,J.Acoust.Soc.Am.48:924,1970). The auditory time constant is also supported by measurements with continuous variations of  $f_{\rm C}$ . The resulting pitch curves revealed steps where  $\tau_{\rm p}$  was a multiple of 0.4 ms.

Adequate neuronal correlation mechanisms were des-cribed for the auditory system of the Guinea fowl. The envelope cycles of AM-signals trigger neuronal oscilla-tions with periods multiple to 0.4 ms. This activity coincide at the midbrain level with neuronal activity phase coupled to the carrier (Langner,G.,Soc.Neurosci. Abstr.43.8,1982;Exp.Brain Res.1983, in press).

193.4 DISORDERS OF TIME PERCEPTION IN BRAIN INJURED PATIENTS, Institute of Medical Psychology, University of Munich, FR Germany.

Institute of Medical Psychology, University of Munich, FR Germany. Human time perception can be described by different categories, each one probably being based on different mechanisms. Using such a classification (Pôppel, Hand-book of Sensory Physiology, Vol. VIII, 1978, p. 713) various aspects of time perception were studied in aphasic patients, control patients with right hemis-phere lesions and control subjects. Observations on fusion and order threshold and on temporal reproduction are reported here. Contrary to previous reports, audi-tory fusion threshold was found to be the same in the two patient groups and in the control subjects. The measurement of order threshold gave a different picture (order threshold marks the interstimulus interval which is needed for a correct identification of the temporal order of successive stimuli). Patients with injuries of the left hemisphere show a significant increase in auditory order threshold is comparable to the control group. Patients with right hemisphere lesions show a significant increase of visual order threshold: their auditory order threshold of the left-hemisphere-patients may be relevant for their aphasia. Voice onset time for instance has a value up to 50 ms; if order threshold is prolonged in patients due to a central lesion beyond this value, difficulties in speech pro-cessing may be expected. It has been suspected for a long time that temporal integration can be tested with experiments on temporal reproduction. Durations of about 2 to 3 sec usually are reproduced correctly; shorter intervals are overestimated, longer intervals underestimated. This observation was confirmed in shorter intervals are overestimated, longer intervals underestimated. This observation was confirmed in control subjects and right-hemisphere-patients. Most of the left-hemisphere-patients showed a deficit in reproduction experiments, usually overestimating also long intervals. If a basic time-keeping mechanism is tapped with this experiment, one has to conclude that aphasic patients in addition to an increased order threshold show a deficit in temporal integration which may be reflected on a linguistic level. (Supported by grant Po 121/3,6,8 of the DFG).

193.5 BIMANUAL PERFORMANCE OF PARKINSON PATIENTS: SIMULTANEOUS VS. CONCURRENT TASKS. L. Z. Podbros.<sup>1</sup> Dept. of Psychology, SUNY at Stony Brook, Stony Brook, NY.

Parkinson patients generally show greater difficulty relative to normals in bimanual than in unimanual activity. The present investigation, which is part of a larger study of Parkinson dysfunction, compared performance on two types of bimanual responding: bimanual execution of the same tasks (simultaneous) and bimanual execution of different tasks (concurrent). An individual research strategy was employed with eight male idiopathic Parkinson out-patients. Patients were administered 37 tasks. In order to compare performance across tasks, standardization data were obtained from comparable normal controls, and raw scores converted to <u>z</u> scores. On the Purdue Pegboard, which involves both conditions, all patients showed greater decrement for simultaneous than for concurrent performance. In order to compare the bimanual skills across tasks, <u>z</u> scores were combined into clusters. Seven patients clearly showed greater decrement for simultaneous than for concurrent performance.

Compare the bimanual shifts across tasks,  $\underline{z}$  scores were comment into clusters. Seven patients clearly showed greater decrement for simultaneous than for concurrent performance. Since bimanual concurrent activity is harder than simultaneous for normals, it is surprising that Parkinson patients show relatively less difficulty with it. An explanation may be found in consideration of patients' performance: in contrast to normals, patients performed the concurrent tasks in consecutive order; however, they could not resort to this strategy for the simultaneous tasks, and hence performed more slowly. Findings are discussed in terms of Parkinson patients' postural instability and increased reliance on visually-directed movement.

<sup>1</sup> Author's current address is Dept. of Neuropsychology, Braintree Hospital, 250 Pond Street, Braintree, MA. 02184. 193.6 COGNITIVE PERFORMANCE IN PATIENTS WITH TEMPORAL LOBE EPILEPSY. J. A. Walker, Cognitive Neuropsychology Laboratory, Good Samaritan Hospital and Medical Center, Portland, OR 97210. Patients undergoing unilateral temporal lobectomy for siezure

Patients undergoing unilateral temporal lobectomy for siezure relief were tested both before and three months after surgery in a battery of tasks designed to measure elementary cognitive operations. The tasks measured the patient's performance in such areas as access to physical, phonological, and semantic features of the test items. The tasks chosen included letter matching, physical or linguistic compatibility/incompatibility, mirror reading, semantic priming, mental rotation, and verbal and nonverbal memory scaning. Several of the visual tasks were presented in both macular and lateralized forms to compare memory skills in the damaged and undamaged hemisphere.

The results indicate that, although there are wide individual differences across patients in these tasks, reflecting different patterns of deficient and normal performance, individuals show an internally consistent pattern. For most patients, there was little or no change in the pre to postoperative period, indicating that surgery, per se, had little influence in determining the patient's pattern of results. In contrast, side of lesion, extent of lesion, and location within the temporal lobe appear to be critical in determining an individual's pattern of elementary cognitive operations.

193.7 INFORMATION PROCESSING AND ENCODING STRATEGIES IN ALCOHOLIC KORSAKOFFS. <u>G.B. Marcil\*</u> (SPON: J. Montplaisir). Dept. de psychologie, Université de Montréal, Montréal, Québec. An information processing deficit is believed to underlie the amnesia associated with Korsakoff's Syndrome. The purpose of the first experiment of this study was to determine if Korsakoff patients are capable of processing verbal information on a semantic level which requires an indepth analysis of the properties of the material. Conversely, they may rely on a more superficial analysis such as attending to the phonetic characteristics of words. It was hypothesized that the less elaborate the encoding strategy, the more prone to decay is the trace. Krasakoffs (n 10), chronic alcoholics (n 10) and normal subjects (n 10) were instructed to memorize lists of words. Exposure rates (2 sec or 8 sec/stimules), types of recall (cued by semantic categories or free recall) and post-acquisition intervals (15 sec or 60 sec) were combined factorally. The results demonstrated that semantic cueing, regardless of temporal factors, was the main determinant in improving recall among Korsakoff subjects. In contrast, free recall resulted in inferior performances. It seems that Korsakoffs, in a free recall condition where they must spontaneously encode the material, adopt a less sophisticated strategy. The consequence is a deficient retrieval of improperly stored information.

The second experiment evaluated the percentage of residual mnemonic traces of the same subjects 30 sec, 15 min, 1 hr and 24 hrs following the original learning of a list of words. Amount of retention was inferred by the number of trials required to relearn the list to criterion. The types of errors on a recognition test were also examined. Results indicated that Korsakoffs did not retain significant amounts of information since they did not demonstrate a decrement in relearning trials as a function of longer learning-relearning time intervals. Qualitatively, errors were similar in the three groups. However, in the Korsakoff group, the quantity of errors did not significantly drop over time. The finding that the Korsakoffs made semantic errors is evidence of limited spontaneous semantic encoding which was not stable enough to allow selective retrieval or recognition of pertinent information.

193.8 NEURAL POPULATION MODELING AND PSYCHOLOGY: A REVIEW. <u>D. S. Levine</u>, Department of Mathematics, University of Houston, Central Campus, Houston, TX 77004. The development of neural modeling as it relates to psychology is traced from the early 1940's to the present. The evolution of the field has been from

to psychology is traced from the early 1940's to the present. The evolution of the field has been from descriptions of randomly connected neurons transmitting all-or-none signals to analyses of structured multilevel networks whose dynamics involve several different spatial and temporal scales.

The cybernetic revolution of the 1940's led to the incorporation into digital neural models of such concepts as linear threshold logic, redundant computation, and information. Each of these concepts has more recently been synthesized with learning to generate a set of adaptive neural models. Concurrently, a variety of data from neurophysiology and from experimental psychology suggested ways to incorporate continuous and nonlinear effects into models.

linear effects into models. Since the late 1960's, there has been much activity in the design of rules for modifiable synapses in models of learning or conditioning. There has also been much activity in the design of lateral inhibitory networks that model sensory pattern storage. The development of models of these effects is outlined, together with that of multi-level networks that combine modifiable synapses and lateral inhibitory anatomies. These multi-level networks model such psychological effects as reinforcement, attention, coding of feature detectors, and interactions between short-term and long-term memory. 194.1 SPATIO-TEMPORAL MAPPING OF DEVELOPMENTAL DIFFERENCES IN EVENT-RELATED POTENTIALS IN YOUNG CHILDREN DURING INFORMATION PROCESSING, J.T. Marsh, R.J. Strandburg, N.S. Brown\*, R.F. Asarnow\* and D. Guthrie\*, Dept. of Psychiatry, UCLA School of Medicine, LA, CA 90024.

INFURMATION PRODESSING. J.I. Marsh, K.J. Strandburg, W.S. Brownx, R.F. Asarnow\* and D. Guthrie\*, Dept. of Psychiatry, UCLA School of Medicine, LA, CA 90024. Event-related potentials (ERPs) were recorded from young (YNG) and older (OLD) children (mean ages 8.5 and 11.5 yrs) during the performance of a complex information processing task to establish developmental norms against which a variety of clinical cohorts being run in our laboratory could be assessed. The task involved the discrimination of a proceeding.

The task involved the discrimination of a randomly placed target letter in 3 or 12 letter arrays which are presented for 50ms, 0.5sec after a 60dB warning tone. ERPs were recorded from a widely distributed array of scalp electrodes and averaged over a 1.5sec interval.

Response to warning tone: YNG subjects produced a longer latency, lower amplitude auditory ERF (PI-NI only) compared to the well defined F1-N1-F2 complex obtained in the OLD group. A midline CNV was apparent at the onset of the ERF. In OLD subjects CNV continued to develop after the warning tone and resolved rapidly after the visual stimulus. Relying less on the auditory warning and visual target stimuli, YNG subjects produced a larger, almost tonic negativity. Though both groups exhibited a lateralized slow negativity at frontal leads, in YNG subjects, a much larger and prolonged hemispheric asymmetry (R>L) was observed.

Response to visual stimulus: In YNG subjects, exogenous components were larger (esp. the F1-N1 wave) and slightly delayed at posterior leads while endogenous components were considerably smaller and later at all leads. This suggests immaturity in perceptual mechanisms and less efficient strategies or neural substrates for higher level information processing and discrimination. A pronounced, lateralized enhancement of P1 and N1 was seen at the right posterior lead in the OLD subjects which was not apparent in thee YNG group suggesting that YNG subjects are not processing information in the same way as OLD subjects. Finally, late positive Slow Wave activity resolves more slowly in YNG subjects, perhaps indicating lack of certainty or closure and continued processing. 194.2 EVENT-RELATED POTENTIAL (ERP) INDICES OF DEVELOPMEN-TAL LAG IN CHILDHOOD SCHIZOPHRENIA. R.J. Strandburg, J.T. Marsh, W.S. Brown\*, R.F. Asarnow\* and D. <u>Guthrie\*</u>, Dept. of Psychiatry, UCLA School of Medicine, LA, CA 90024.

The authors have previously reported a number of ERP concomitants of an information processing impairment observed in schizophrenic (SCH) children. When compared with age-matched (OLD) normals, differences were observed in the magnitude and spatial distribution of the CNV, N1, P3 and Slow Wave components. These suggest deficits in the ability of SCH children to (1) mobilize and direct attention and (2) locate and identify target stimuli.

In this study ERPs from SCH children (age 11.5yrs) were compared with those of children 3 years younger (YNG) to determine if these deficits might represent developmental delays. ERPs were recorded during the performance of a task involving the discrimination of a randomly placed target in multiple letter arrays presented for 50ms, 0.5sec after a warning tone. A widely distributed array of scalp electrodes was used and ERPS were averaged over a 1.5sec interval. The SCH group resembled YNG subjects (while at the same time differing from OLD children) in 4 respects:

The SCH group resembled YNG subjects (while at the same time differing from OLD children) in 4 respects: both exhibit sluggish and poorly stimulus coupled CNV activity; both show a large, prolonged negative shift over right frontal cortex; both fail to produce the lateralized visual N1 enhancement seen in OLD subjects over right temporal cortex; the SCH children demonstrate an even greater degree of amplitude and latency attenuation late positive components (coupled with even more pro-longed late Slow Wave activity) than was seen in the YNG relative to the OLD group. However, SCH subjects do not show the large amplitude, slightly delayed early components (visual P1-

However, SCH subjects do not show the large amplitude, slightly delayed early components (visual P1-N1-P2) seen in YNG subjects nor were they capable of modulating N1 and Slow Wave activity in response to variations in task demand as was the case with both normal groups. Thus, important ERP differences exist between SCH and YNG subjects which suggest that while inefficiencies in (1) the mobilization of general attention and (2) complex information processing may reflect developmental delays in the SCH children, they also exhibit specific attentional deficits not seen in either of the normal groups.

194.3 HUMAN CORTICAL PATTERNS OF "P300" POTENTIALS TO NOVEL VISUAL ITEMS. <u>Merle Primt, George Ojemann, and Ettore Lettich</u>\*. Dept. of Neurological Surgery, Univ. of Wash., Seattle, WA and Dept. of Psychology, Western Wash. Univ., Bellingham, WA.<sup>(+)</sup> The scalp electroencephalographic evoked potential (EP) change associated with novel, attended information is a positive wave peaking at about 300 msec after onset of the attended item, the "P300". The effects of behavioral manipulation on this EP have been extensively investigated, but little is known about the brain mechanisms that generate it. We report here EP's recorded (to a neck reference) directly from human cortex through subdural electrodes placed for the diagnostic evaluation of medicall<sup>v</sup> intractable epilepsy, in 8 cases, during a "visual odd-ball" task, comparing averaged EP's for the 31% counted novel diamonds interspersed among repeated squares (diamonds turned 45<sup>o</sup>), each shown for 100 msec at 4 second intervals. Electrode location varied as determined P300 to novel items was recorded from scalp Cz load of 6 6 encore. In the actor, where where other electrodes placed by the actor where where determined electrodes placed placed starter values and planet dependence.

An augmented P300 to novel items was recorded from scalp Cz leads in 6 of 8 cases. In the case where subdural electrodes overlay a previous anterior temporal resection, EP patterns were of low amplitude, indicating little subdural volume conduction. Large positive-negative-positive complexes for both novel and repeated items were often discretely localized to single subdural electrodes, especially in either temporal lobe. These were only partly reflected in simultaneous recording from overlying scalp in the one case where this was done. Localization of these EP's was unrelated to the site of that patient's epileptic focus. Alterations in the EP's to novel, compared to repeated items include: 1. An augmented "P300" in lateral temporal cortex in 5 of the 6 cases with recording there. The maximum P300 augmentation was localized to anterior-midtemporal cortex in 4. 2. An augmented P300 for lateral cortex, in phase with the scases with recordings there. 3. An augmented P300 from lateral parietal cortex, in phase with an augmented P300 form lateral parietal cortex, in the patient with recordings in that plane. 4. Diminution of EP's to novel items from medial frontocentral sites. These findings indicate phase-reversal of P300 between medial and lateral sides of the posterior balf of cerebral hemisphere, as suggested by earlier studies of P300 localization through medial temporal implanted electrodes (Halgren et al, <u>Science</u> 210:803; Woods et al, Conf. on Cog. Neurosciences, 1982). But contrary to those studies, our data indicate that the generator is much more widespread than just the hippocampus (or even limbic cortex). Similar preliminary data have been obtained using novel auditory items.

194.4 ELECTROCORTICOGRAPHIC (ECoG) CORRELATES OF NAMING, READING AND VERBAL MEMORY. <u>G. Ojemann and E. Lettich\*</u>. Dept. of Neurological Surgery, Univ. of Washington, Seattle, WA 98195.

EcoG correlates of language that have behavioral specificity (present during language tasks and not spatial tasks using the same visual input) and anatomic specificity (present at sites independently related to language functions by electrical stimulation mapping, and not at unrelated sites) were measured in awake patients undergoing craniotomy under local anesthesia for the treatment of medically intractable epilepsy. Such averaged ECoG changes during silent naming (with verbal output delayed to a cue) were previously reported by us (Fried, Ojemann and Fetz, <u>Science</u> 212:353) to include simultaneously recorded slow potentials at frontal, and desynchronization at posterior language sites, suggestive of thalamo-cortical activity in human cortical language mechanisms. We have now studied additional cases, silent reading, and in one unique case, the relation of ECoG changes with silent naming and reading, short-term verbal memory, orofacial motor control, and measures of language understanding (mapping techniques described in Ojemann and Mateer, <u>Science</u> 205:1401). In these new cases, slow potentials lasting up to 1 sec, speci-

In these new cases, slow potentials lasting up to 1 sec, specific to silent naming at naming sites have been identified in both posterior frontal and superior temporal lobes, the former a correlate of effector readiness in a final motor pathway for speech, the latter perhaps a correlate of a system common to sequential orofacial movements and speech sound decoding. Desynchronization at other posterior sites was quantified by spectral density measures, with decreased variance in the 10-11 Hz band 700-1200 msec after onset as an anatomically and behaviorally specific change during silent naming. These patterns are also present in ECoC changes during silent reading, but with a different localization, paralleling the differential localization of maming and reading with stimulation mapping. A unique averaged ECoC potential identified at a site related by stimulation only to short-term verbal memory, and present only during tasks requiring recent memory, is shown in the figure (upper trace: ECoC

shown in the figure (upper trace: ECoG with silent naming, second: spatial task using the same 100 msec visual input (marked in third trace), as recorded from the memory site. Arrow identifies the unique potential). This appears to be an ECoG hallmark of recent memory, perhaps indicating when it is active during language processes.

194.5 BRAINSTEM AUDITORY EVOKED POTENTIALS AND DICHOTIC LISTENING: DO THEIR ASYMMETRIES CORRELATE? <u>R.A. Levine\*</u>, <u>D. Isenberg\*</u>, <u>and P. McGaffigan\*</u> (SPON:E. Keithley). Eaton-Peabody Lab., Mass. Eye and Ear Inf., Boston, MA, 02114

and Ear Inf., Boston, MA, 02114 Significant asymmetries of the brainstem auditory evoked potentials (BAEPs) occur in peaks [-), III(+), and IV(+) when the BAEPs (recorded from a midline pair of electrodes) from right ear stimulation are compared to the BAEPs from left ear stimulation (Levine, R.A., McGaffigan P. Electroencephalogr Clin Neurophysiol, 1983 (in press)). For all three components with significant asymmetries, the peaks from right ear stimulation were larger than for left ear stimulation. The asymmetry is stronger for right-handed than left-handed individuals. The dichotic listening test is a behavioral auditory task that also shows a right-left asymmetry. The asymmetry for dichotic listening also favors the right ear and is stronger in righthanded individuals. Is the asymmetry observed in the BAEPs related to that found in the dichotic listening test? To answer this question, the two tests were done on the same 32 normal subjects (half male, half female; half right-handed, half lefthanded), and their results compared. The Wexler-Halwes dichotic listening test was administered in the standard manner. The BAEPs were obtained by presenting monaural clicks (10/sec, 70dB SL) first to one ear then the other ear. The amplitudes of peaks I(-), III(+), and IV(+) for left ear stimulation were then subtracted from the corresponding amplitudes for right ear stimulation. As expected, significant right-left asymmetries were found for both the dichotic listening test and the BAEPs. The correlation coefficients between these amplitude differences and several measures of asymmetry on the Wexler-Halwes dichotic listening test were then determined. For none of the three peaks was there a strong correlation (p<.05) with any of the measures of asymmetry in dichotic listening. When right-handers and left-handers were considered as separate groups, a weak correlation (pz.05) was found for peak I(-) in right-handers only; otherwise, no significant correlations were found. These results suggest little relationship

194.7 ABDOMINAL EMG ACTIVITY DURING SPEECH, J. Hoit-Dalgaard\* <u>R. Lansing, B. Plassman\* and T. Hixon</u>\*. Depts. of Psychol. and Speech & Hearing Sciences, Univ. of Arizona, Tucson, AZ 85721. EMG activity of the abdominal wall during speech was studied in normal adult subjects. The investigative protocol was designed to determine the effects of electrode placement, body position and

lung volume on speech-related abdominal EMG levels. Ten young adults, five females and five males, served as subjects. Five pairs of electrodes were applied to the right side of the abdomen; one pair each on the upper and lower lateral aspects to monitor the combined activity of the external and internal oblique, and transverse abdominis muscles, and three pairs placed rostrally to caudally along the rectus abdominis. Magnetometers, fixed to the rib cage and abdomen, transduced anterior-posterior diameter changes into linear representations of torso shape and lung volume which were recorded by inkwriters along with the EMG tracings. The protocol consisted of vital capacity maneuvers, isovolume maneuvers, muscle separation maneuvers, and a variety of speech and reading tasks performed in the supine and upright positions.

Data analysis revealed that EMG levels recorded in the supine position were lower overall than the upright EMG amplitudes. In the supine position most subjects showed an increase in lateral EMG levels during speech by the time lung volume fell below FRC. Rectus activity could be seen only when a subject reached very low lung volumes. An increase in lateral EMG levels at utterance onset was exhibited by fewer than half of the subjects when supine, and then only inconsistently. Abdominal EMG levels recorded in the upright body position were

Abdominal EMG levels recorded in the upright body position were higher than those recorded in supine. Unlike the supine data, speech initiation was associated consistently with an immediate rise in lateral EMG amplitudes. Lateral EMG continued to augment and rectus activity rose above resting levels when the subject spoke below FRC. Finally, most subjects in the upright position evidenced brief "shut downs" of active regions to below resting levels when inspiring between spoken breath groups. These shut downs appear to be tied to the speed of inspiration.

Absolute EMG levels and changes in EMG levels were substantially greater in the two lateral EMG signals than in the three rectus EMG signals under both resting and speaking conditions. In contrast, laughter was accompanied by large EMG bursts from all electrode sites. Coughing and throat clearing showed similar patterns.

This study elucidates the regional differences in abdominal EMG activity during speech and shows that EMG levels are position and lung volume dependent. Our data documenting the presence of abdominal activity in speech directly contradict those of Draper, Ladefoged and Whitteridge (1959). 194.6 LATERALIZATION CUE IN THE DETECTION OF SIGNAL IN NOISE. <u>P.W.F. Poon, J.C. Hwang, and K.T. Tam</u>\*, Dept. of Physiology, Faculty of Medicine, University of Hong Kong, Sassoon Road, Hong Kong.

The use of lateralization cue in the detection of brief acoustic signals embedded in background noise was accessed in 4 human subjects using psychophysical procedures that involved headphone presentation of binaural sounds. The acoustic stimulation consisted of a burst of noise (20 to

The acoustic stimulation consisted of a burst of noise (20 to 20 kH white, 100 msec long) that served as the masker, and a simulfaneous train of clicks (derived from 0.1 msec rectangular pulses, repeated at 7 H ) that served as the signal. While the noise masker was centralized throughout the experiment, the click signals could be either centralized or lateralized to various extent by manipulating the interaural time difference. In each trial, the subjects were required to indicate, under a two-alternative force-choice paradigm, the presence of the click signals that had been delivered (at 50% probability of occurrence across trials) along with the noise masker. Their ability to detect the masked signal was determined as a function of interaural time differences of the clicks (0 to 1.0 msec) at fixed click-to-noise intensity ratios.

The results invariably showed that the subjects' ability to detect the presence of the clicks in noise was poorest when both the signal and masker were centralized and improved progressively when the signals became in reasingly lateralized from the centralized masker towards either side. This suggested that lateralization cue was utilized in the detection of the signal in noise delivered in the present manner. (Supported in part by HKU Research Grant #335-034-0002).

194.8 SOURCES OF LATE COMPONENTS OF THE BRAIN MAGNETIC RES-PONSE, <u>F. Richer, R.A. Johnson\* and J. Beatty</u>. Department of Psychology, University of Calif., L.A., Ca. 90024.

The ability to localize tangential current sources in the cortex with neuromagnetic recordings was used to investigate the origin of late components of the brain event-related magnetic fields (ERFs) in perceptual discrimination tasks. We have recorded a set of late components in the ERF which are modality-specific, originating in separate locations in auditory and visual oddball-counting tasks. Attended rare stimuli presented randomly in a sequence of standard stimuli differing in frequency or visual pattern configuration elicited components with latencies as high as 450 msec poststimulus with a rather restricted scalp distribution reversing polarity over a few centimeters. We have shown that emitted and evoked late fields originate in the same location for a particular modality. The late magnetic response is sensitive to the probability of the oddball stimuli and to the complexity of the discrimination performed. The field is best accounted for by sources located in each hemisphere and there are slight inter-individual variations in the location and strength of these sources. In the auditory modality, the late components appear to originate in superior temporal cortex and are oriented in a ventro-dorsal axis about 3 cm below the scalp. Sources in the left hemisphere, which is consistent with the known anatomy of auditory cortices. Late visual ERFs cannot be recorded from the locations in which late auditory ERFs are observed and appear to originate in a more posterior location in both hemispheres. The latency and elicitation parameters of one of the late components appear to correspond to that of the P300 complex of the event-related potential observed at the scalp.

DEXAMETHASONE SUPPRESSION TEST AND MOOD FOLLOWING STROKE 194.9 J:R. Lipsey\*; R.G. Robinson, and G.D. Pearlson Dept. of (SPON: J.R. DePaulo) Dept. of Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205. 46 patients admitted to rehabilitation hospital following thromboembolic stroke or intracerebral hemorrhage were evaluated with standardized depression rating scales (Hamilton, Zung, modified PSE) and were given 1 mg overnight dexamethasone suppression tests (DST). An Overall Depression Score (ODS) (range 0-15) was calculated from the Hamilton, Zung, and PSE scores; and DSM III diagnoses of major depression (MD) were determined from PSE responses. Patients also were categorized as to presence or absence of moderate to severe disturbance of mood, sleep, or appetite (MSA) (at least 1 of the 3). The following tables show DST results for each clinical category.

	DST+	DST-		DST+ DST-			DST+ DST-	
ods≥9	14	5	MD+	11	3	MSA+	21 10	
ods<9	11 (p<	15 •05)	MD-	15 (p<	17 •05)	MSA-	5 10 (p<.05)	

Patients with positive DSTs had significantly higher Hamilton (p<.0125), Zung (p<.025), PSE (p<.0125), and ODS (p<.01) scores than patients with negative DSTs. Patients with positive DSTs were not significantly different in terms of age, race, sex, socioeconomic status, marital status, psychiatric history, time since stroke, or cognitive impairment than patients with negative DSTs. However, positive DSTs were significantly associated with greater functional impairment.

194.10 CAN POST-STROKE DEPRESSION PRODUCE A "PSEUDO-DEMENTIA"?

and T.R. Price. Dept. of Psychiatry, John Hopkins Univ. Sch. Med. and Dept. of Neurology and Psychiatry, Univ. MD. Sch. Med., Baltimore, MD 21205.

Patients (N=30) with a single CT scan verified stroke lesion of either the right or left hemisphere were evaluated for intellectual impairment and depression. Stroke patients with significant intellectual impairment (Mini-Mental Exam score (MME) below 23) (N=17) were not significantly different from patients without impairment (N=13) in their age, sex ratio, years of education, or lesion location along the A-P axis. The volume of the stroke lesion however was significantly larger in patients with MME scores below 23 as compared with those patients with scores above 23 (6.1 + 5.2 SD vs. 2.4 + 4.3 SD). Non-depressed patients with intellectual impairment showed a highly significant correlation between the volume of brain lesion and the degree of intellectual impairment (r =.-94 p < .001). Patients with intellectual impairment and symptoms of major depression (N=7), however, showed no significant correlation between lesion volume and Mini-Mental score (r = -.12 NS). In addition, all patients with major depressive symptoms showed intellectual impairment (7 of 7) while patients without major depression showed intellectual impairment in less than half of the cases (10 of 23) ( $x^2 = 6.8 \text{ p} < .05$ ). Finally, the lesion volume was significantly smaller in

Finally, the lesson volume was significantly amarter in patients with depression and intellectual impairment as compared to those with intellectual impairment and no depression (3.1 + 1.3 SD vs. 8.6 + 5.2 SD p < .05). One patient treated with nortriptyline for depression showed a significant increase in MME score after the depression was improved.

These data suggest that intellectual impairment in non-depressed stroke patients is related to lesion volume. Depressed stroke patients, however, appear to have a different etiology for their intellectual impairment. The depression itself may contribute to the intellectual decline in some patients and may represent another form of treatable dementia.

DIFFERENCES IN RECOGNITION MEMORY AMONG PATIENTS WITH ALZHEIMER'S DISEASE, HUNTINGTON'S DISEASE OR ALCOHOLIC KORSAKOFF SYNDROME M. Moss, M.S. Albert, M. Payne\* and N. Butters. Dept. of Anatomy. Boston Univ. School of Medicine, Depts. of Psychiatry and Neurology, Massachusetts General Hospital and Psychology Service, Boston V.A. Medical Center, Boston, MA.

Memory loss constitutes one of the more striking cognitive im-pairments in various dementing disorders. While emphasis has primarily been placed upon the documentation of such deficits, only recently has attention been paid to the elucidation of their possible disease-specific nature. In order to adequately assess and compare memory function in such groups of patients, particu-larly in those with severe dementia, tasks which are simple to perform, yet sensitive to memory dysfunction, must be used. We have developed such a task by modifying one which was designed to assess spatial recognition memory in non-human primates (Rehbein, 1983) and administered it to patients with Alzheimer's Disease (AD), Huntington's Disease (HD), or alcoholic Korsakoff syndrome as well as to normal control subjects. (KS)

The task requires the subject to identify, in successive trials, a new stimulus among an increasing set of previously presented familiar stimuli displayed on a board with a 5 x 6 matrix. Five different classes of stimulus material; spatial, verbal, color, pattern and faces, were presented for five sets of trials each. In the verbal condition 16 stimuli were presented successively In the verbal condition, 16 stimuli were presented successively regardless of the number of errors committed. In all other condi-

regardless of the number of errors committed. In all other condi-tions, the presentation of the new stimulus was terminated after the first error. In the verbal condition, patients were also asked to recall the stimuli after a 15 sec. and 120 sec. delay. For recognition, results showed that the AD and KS groups were impaired relative to the normal group on each of the five stimulus conditions. However, the group of HD patients, though impaired on four of the conditions, were unimpaired as compared to normals when verbal stimuli were used. There were also significant differ-ences between groups on delayed recall of the verbal stimuli. At when verbal stimuli were used. There were also significant differ-ences between groups on delayed recall of the verbal stimuli. At 15 sec. the AD, HD and KS groups, though not significantly differ-from each other, were impaired relative to the normal group. How-ever, at 120 sec, the KS and HD groups performed significantly better than did the AD group. These results suggest that the rate of forgetting in patients with AD is greater than that in patients with either HD or KS.

The normal performance on verbal recognition by the HD group to-gether with the observed difference in forgetting rate among the groups 1) helps account for recent evidence that memory performance of patients with HD is enhanced with the availability of verbal mediation (Butters et al, 1983) and 2) lends support to the notion that AD, HD and KS patients have qualitatively different memory impairments. 195.1 PUTATIVE NEUROTRANSMITTERS IN NEOSTRIATAL NEURONS: A LIGHT AND ELECTRON MICROSCOPIC STUDY. <u>Ronald H. Bradley, S.T. Kitai and</u> J. Y. Wuk Dept. of Anatomy, Mich. State Univ., E. Lansing, MI 48824-1316, \*Baylor College of Medicine, Houston, TX 77030.

We have previously shown at the light level that rat neostriatal projection neurons contain substance P(SP) and methionine enkephalin(ME). Using a double labeling method with retrogradely transported wheat germ agglutinin(WGA) and GAD immunocytochemistry we found that rat neostriatal neurons also contain GABA(Neurosci. Abs. 48:19, '83). In order to ultrastructually characterize these immunocytochemically identified SP, ME and GABA containing neostriatal neurons we utilized a modified "avidin:biotin" technique. Antisera to SP, ME, and GAD were used and anti-GABA-transaminase (GABA-T) was used to compare GAD and GABA-T staining patterns.

To increase somatic concentrations of neurotransmitters, colchicine was injected into the lateral ventricles. Following 43hrs survival time, rats were perfused according to our previous procedures(Neurosci. Abs. 48:19,'83). The brains were removed and sectioned at 60µm with a Vibratome. Sections were rinsed in MSB buffer, incubated 24 hrs with SP, ME, GAD or GABA-T antiserum and washed with tris buffered saline(TBS). Sections were incubated 2hr with biotinylated IgG, rinsed with TBS, incubated with reagentperoxidase, rinsed with TBS and reacted with DAB. The sections were rinsed with TBS, osmicated, rinsed in TBS, enbloc stained and embedded in Epon-Araldite and viewed unstained in a JEOL 100CX. SP, ME and GAD staining was localized in medium-sized neo-

SP, ME and GAD staining was localized in medium-sized neostriatal neurons(soma size:10-15µm) possessing a smooth, round and unindented nucleus and a thin rim of immunoreative cytoplasm. Immunoreactivity was observed in primary dendrities, dendritic spines and presynaptic terminals. ME and GAD staining was localized primarily in symmetrical boutons while SP staining was localized in medium(10-16µm) and large(25-30µm) sized neostriatal neurons. The medium sized neurons nad either an unindented nucleus or deeply invaginated nucleus and a thin rim of immunoreactive cytoplasm. GABA-T staining was observed in soma, dendrites and dendritic spines.

These results indicate that SP, ME and GAD staining is localized in somata, dendrites and dentritic spines ultrastructually characteristic of medium-spiny neostriatal neurons. GABA-T staining is observed in neostriatal neurons which ultrastructually resemble the large aspiny, medium spiny and aspiny cell types. The lack of GABA-T staining in presynaptic terminals suggests that GAD localization is a better marker for GABA neurons than GABA-T localization. (Supported by NIH Grant RR 05772 to R.H.B. and NS 14866 to S.T.K.). 195.2 MORPHOLOGY AND SYNAPTIC CONNECTIONS OF A GIANT ASPINY INTERNEURON IN THE RAT NEOSTRIATUM. C. J. Wilson, H. T. Chang and S. T. Kitai. Dept. of Anatomy, Mich. State Univ., E. Lansing, MI 48824.

Intracellular recordings were obtained from a sample of giant aspiny neurons identified by their appearance after staining by intracellular injection of horseradish peroxidase and preparation for light and electron microscopic examination. The neurons corresponded to the giant interneuron with radiating dendrites described by Kolliker in 1896, but denied by most subsequent authors. The somata were multipolar or fusiform and could be up to 50 µm in their maximum dimension. They had only a few very stout and straight dendrites that branched and radiated to extend up to 600 µm from the soma. Some dendrites terminated with tufts of fine branched processes that could exhibit varicosities or spine-like appendages. The axons of the cells bifurcated into approximately equal caliber branches that each repeatedly branched in the same way. These formed a dense plexus of very fine varicose fibers extending throughout the dendritic field of the cell and somewhat beyond. There was no main axon that could be identified throughout this plexus and no branch that left the area of the dendritic field. Electron microscopic examination of the axonal field showed it to form numerous synaptic contacts both at the varicosities and along the intervaricose segments. The latter could be as small as 0.1 µm in diameter. The synaptic vesicles were of the smallest diameter class observed in neostriatum and were highly pleomorphic. Most of the postsynaptic elements were shafts of dendrites.

The cells exhibited prominent short latency EPSPs in response to stimulation of thalamus, substantia nigra or cerebral peduncle. The EPSPs were judged to be monosynaptic on the basis of their latency invariance with changes in stimulus intensity. They were similar to those evoked in neostriatal spiny projection neurons by the same stimulation. Only one or two action potentials were evoked by maximal stimulation, and the cells did not exhibit a high rate of spontaneous activity in urethane-anesthetized animals.

195.3 MORPHOLOGY OF SOMATOSTATIN NEURONS IN THE HUMAN PUTAMEN; A CORRELATIVE IMMUNOCYTOCHEMICAL-RAPID GOLGI STUDY. R.S. Williams, P.E. Marshall\* and D.M.D. Landis. Neurology Service, Mass. General Hospital, Boston, Ma. 02114. In the putamens of young adults without neurological dise

In the putamens of young adults without neurological disease, high quality immunocytochemical (ICC) preparations were obtained with antisera to somatostatin-like immunoreactivity (SLI) had a distinctive morphology. Cell somas were small to medium-sized, and oval to fusiform in shape (12-20 um minor axis, 15-30 um major axis). There were 2-4 (50% had 3) stout primary dendrites which often exited from opposite poles. Subordinate dendrites of second to fourth branch order were stained also; they were sparsely branched and many segments were exceptionally long (>150 um). Axon-like processes were tentatively identified on most cells, based upon: 1). A tapering initial segment emerging from the soma or a primary dendrite, 2. A beaded appearance, 3). A meandering course radially outward from the cell soma and 4). Sparse numbers of beaded collaterals emerging at near right angles. We compared the morphology of SLI neurons to the neuron subtypes identified in rapid Golgi impregnations of the same and other human brains. The morphology of SLI neurons is different from that of typical medium spiny, large aspiny or a distinctive ("clewed", "spidery") subclass of small to medium-sized aspiny neurons, as described by others in a variety of species. The dendritic and axonal morphology of SLI neurons corresponds best to a small to medium-sized cell with dendrites that are both relatively aspiny, or invested sparsely in patchy fashion with spines of highly variable morphology. Uur findings in the human striatum contrast with those in the rodent where ICC-electrommicroscopic studies indicate that SLI neurons are aspiny (DiFiglia and Aronin, J. Neurosci. 2:1267, '82), and suggest that the presence or absence of spines is a less reliable criterion for defining the class-characteristic morphology of SLI neurons in the human striatum. (Research supported in part by NIH grants MH 34079 and NS 16367.) 195.4 A GOLGI STUDY OF THE NORMAL HUMAN NEOSTRIATUM. G.A. Graveland, M. DiFiglia, R.S. Williams, (SPON: N.Aronin) Dept. of Neurol., Mass. Gen. Hosp. Boston, MA 02114. As a background for the study of neuropathologic changes

associated with basal ganglia disease, the human neostriatum was examined in Golgi impregnations (Kopsch or rapid methods) of normal tissue obtained within 18 hours postmortem from 28 adult cases (ages 22-99). At least 6 types of neurons were observed. The most frequent was a medium size neuron (15-18µm) with numerous dendritic spines which appeared mostly on secondary and distal branches. The longest dendrites from each of 25 well impregnated cells (N=3 cases) were examined for spine types and their density distribution. The overall density of spines was 7.7/10 m dendrite length. Spines appeared about 25  $\mu m$  from the some and maintained a maximum density (X=9.6/10  $\mu m$ ) 60-200  $\mu m$  from the cell body. Thin, stubby and mushroom shaped spines were present at a frequency of 74, 16 and 10% respectively. The axons of spiny neurons were long with up to 5 collaterals arising and branching within the dendritic field of the cell. A smaller population of medium size neurons with relatively low spine density was observed in the same preparations. Aspiny neurons of density was observed in the same preparations. Aspiny neurons c medium size (14 to 18 µm) were seen frequently. The dendrites were smooth, varicose and in most cases highly branched and curly. The axons within 70 µm of the soma, gave rise to a profuse arborization of fine beaded processes which frequently extended beyond the dendritic field. Large neurons (30 µm in size) with either smooth, highly branched, varicose dendrites and short axons or sparsely branched, long, thick, spiny, dendrites were observed less frequently. A heterogeneous group of small neurons (10-12  $\mu$  m) was relatively numerous in our series. Cells were usually unipolar or bipolar with somatic spines. Dendrites were thin, sparsely branched, and exhibited varicosities and/or spines. Many long dendritic appendages appeared in some neurons. Axons were thin and poorly arborized. Four categories of afferent fibers were also recognized: 1. large diameter fibers (>1.0  $\mu$ m) with numerous smooth branching processes; 2. thick axons with large bulbs (2  $\mu$ m in size); 3. axons (0.5-0.7  $\mu$ m) with short appendages, and 4. thin axons (0.5  $\mu$ m) with fine beaded processes. The present findings confirm and extend recent Golgi processes. The present findings confirm and extend recent Golg observations in the human caudate (Eder et al, Acta Morphol. Acad. Sci. Hung. <u>28</u>, 1980; Braak and Braak, Cell Tissue Res. <u>277</u>, 1982). Although many similarities to the monkey (Fox et al, J. Hirnforsch. <u>13</u> 1971; DiFiglia et al, Brain Res <u>114</u>, 1976) exist, the human neostriatum exhibits overall a greater variation within cell types and quantitative differences in the morphology of spiny neurons. Supported by grants NS 16367 (M.D.), H.D. Foundation (M.D.), and the Stone Fund (G.A.G). 195.5 NEURONAL ORGANIZATION IN THE MONKEY NEOSTRIATUM: A QUANTITATIVE LIGHT MICROSCOPIC STUDY USING SEMI-THICK SERIAL SECTIONS. M. DiFiglia and G.A. Graveland<sup>4</sup> Dept. of Neurology, Massachusetts Gen. Hosp., Boston, Ma. 02114. Golgi studies of the neostriatum in a number of species have

shown that the population of small to medium size neurons visible with Nissl stains is composed of at least 4 cell types, of which spiny neurons are thought to be the most numerous. Aspiny spiny neurons are thought to be the most numerous. Aspiny neurons however are observed relatively frequently in the monkey and human brain (DIFiglia et al., Brain Res. 114 1976; Graveland et al., Neurosci. Abst. 1983). Ultrastructual studies of individually identified neurons using the combined Golgi-electron microscopic method (DIFiglia et al., J. Neurocytol. 8, 1980, DiMova et al, Neurosci. 5, 1980; Somogyi and Smith, Brain Res. <u>178</u>, 1979) and intracellular filling with HRP (Wilson and Groves, J. Comp. Neurol. <u>194</u>, 1980; Bishop et al., Neurosci. <u>7</u>, 1982) have shown that medium size spiny neurons and aspiny neurons can be distinguished by features characteristic of their nuclei and cytoplasm. The nuclei of spiny neurons are unindentee nuclei and cytoplasm. The nuclei of spiny neurons are unindented whereas those of spiny cells exhibit shallow and/or deep enfoldings. In the present study the occurrence and distribution of neurons with nuclear indentations was examined in random samples of monkey (N=3) caudate-putamen. Epon-embedded blocks (1.5 mm<sup>2</sup>) of well-fixed tissue were cut with an ultramicrotome (LKB Nova). Sections,  $0.5 \ \mu$ m thick, were mounted serially (10 to 20 sections) on glass slides, stained with toluidin blue and coverslipped. An area approximately 250 µm from a middle section in each series, An was selected and drawn at 440X with camera lucida. All neurons with nuclei present (approximately 100 cells per sample) were recorded and blood vessels and fiber bundles were included for orientation. With the drawing as a guide, sections preceding and following the drawn section were examined at 100%. Five consecutive sections were usually sufficient to assess nuclear morphology. Results showed that neurons of small to medium size with indented nuclei accounted for 26.4% (X=26.4, SD  $\pm$  7.6, n=10) of the total neuronal population sampled (1065 neurons). indentations were seen in all large neurons ( $\langle 30 \ \mu m \rangle$ ) which Nuclear accounted for an additional 17. The number of small to medium cells with nuclear indentations was significantly greater (p<.02) in the caudate  $(\bar{X}=31.2, \text{ SD } \pm 6.3)$  than in the putamen  $(\bar{X}=21.6, \text{ SD})$  $\pm$  5.9). These findings suggest that a considerable proportion of the small to medium size neurons in the monkey neostriatum may belong to the aspiny category and that they may be more numerous in the caudate than the putamen. Results may be helpful in evaluating the organization of neostriatal neurons in neuropatho-Supported by NIH Grant NS 16367 (MD) and a grant from the Hereditary Disease Foundation (MD).

195.7

 MEDIO-LATERAL TOPOGRAPHY OF CORTICO-STRIATAL TERMINAL FIELDS IN RHESUS MORKEY. L.D. Selemon and P.S. Goldman-Rakic. Sect.
Neuroanat., Yale Univ. Sch. of Med., New Haven, CT 06510.
Kemp and Powell (1970) proposed that in primates corticostriatal projections are topographically arranged along the anteroposterior (A-P) axis of the striatum such that frontal cortex projects to anterior striatum whereas more posterior areas of cortex project to posterior striatum. However, recent studies challenge this model by showing that some areas of cortex project throughout the entire A-P axis of the striatum rather than to one A-P domain (Goldman and Nauta,'77; Yeterian and Van Hoesen,'78). In the present study, the topography of cortico-striatal terminal fields was re-examined. Thirteen rhesus monkeys were injected either with 'H-amino acids or HRP in twelve different cortical sites. Animals were perfused 2-7 days later; the brains were processed either for autoradiography or HRP histochemistry. Distributions of silver grains in the striatum, representing corticostriatal terminal fields, were examined. The major finding of this study is that all cortico-striatal

The major finding of this study is that all cortico-striatal projections are segregated into parasaggital territories that are aligned along the medio-lateral axis of the striatum. Areas projecting to medial regions of both caudate and putamen include orbito-frontal cortex, anterior cingulate gyrus, and superior and inferior temporal gyri. The dorsal bank of the Sylvian fissure projects medially as well but to the putamen only. In contrast, lateral sectors of caudate and putamen receive afferents from the posterior parietal cortex and posterior bank of the superior arcuate sulcus. Cortical projections from pre- and post-central gyri are located laterally but are restricted largely to the putamen. Finally, striatal projections from prefrontal cortex on the dorsal and ventral banks of the principal sulcus, as well as from the dorsolateral convexity of the frontal lobe, are located between lateral and medial zones, in central regions of the caudate and putamen. Likewise, the posterior bank of the inferior arcuate sulcus projects to central regions of the putamen. These findings indicate that the topographic organization of cortico-striatal terminal fields is medio-lateral rather than

These findings indicate that the topographic organization of cortico-striatal terminal fields is medio-lateral rather than antero-posterior and add to the growing body of evidence that there is a "division of labor" between the caudate nucleus and the putamen. While terminal fields from association cortices are distributed to both caudate and putamen, projections from sensori-motor cortices and from premotor cortex are limited almost entirely to the putamen. These findings may prove useful to understanding the biochemical and functional heterogeneity of the neostriatum, as well as the consequences of disease in selected regions of the neostriatum. (Supported by MH00298, MH38546 and a grant from the Hereditary Disease Foundation) 195.6 DEVELOPMENTAL RELATIONSHIPS BETWEEN OPIATE RECEPTORS AND DOPAMINE IN THE FORMATION OF CAUDATE-PUTAMEN PATCHES. <u>D. van</u> <u>der Kooy</u> Neurobiol. Res. Group, Department of Anatomy, University of Toronto. Toronto. Canada M55 1A8

University of Toronto, Toronto, Canada M5S 1A8 "Patchy" distributions of various neurotransmitters, receptors and enzymes are seen in sections through the rat caudate-putamen. Some of these patchy markers change their distribution during development. In particular, the dopamine fibers from the midbrain are distributed in the caudate-putamen in a patchy manner perinatally, before becoming diffusely distributed over the early postnatal weeks. On the other hand opiate receptors are diffusely distributed prenatally but become organized in patches perinatally. We studied the anatomical relationship between opiate receptors and dopamine fibers during the first week after birth when both markers are localized to patches.

Adjacent, fresh frozen sections through the caudate-putamen of a day 5 rat pup were processed to reveal opiate receptors using 3H-etorphine autoratiographic procedures and glyoxylic acid induced endogenous dopamine fluorescence using the SPG procedure. At this age, patches of dopamine fluorescence are seen most clearly in the lateral portion of the caudate-putamen, whereas opiate receptor patches are seen throughout the region. Especially in the dorsal two-thirds of the lateral caudate-putamen the opiate receptor and dopamine patches appear to be continuous. In addition, when the same sections were later Nissl stained, the opiate receptor and dopamine patches appeared to avoid the "islands" seen at this age which contain especially high densities of neuronal cell bodies.

In order to test if dopamine released from the fibers in caudate-putamen patches was important in inducing the formation of opiate receptor clusters, we injected pregnant rats daily with 2.5 mg/kg of haloperidol from 12 days after conception until they gave birth. Prenatal haloperidol treatment has previously been shown to result in a dramatic decrease in pup caudate-putamen dopamine receptors in the post-natal period. However, haloperidol did not seem to block the development of opiate receptor patches in the caudate-putamen as assessed in the pups during the first few postnatal days. Thus, the dopamine patches in the caudate-putamen do not seem to direct the formation of opiate receptor patches, although preliminary knife cut data suggests some influence from caudal brain areas may be necessary for the maintenance of opiate receptor patches.

195.8 AXON COLLATERALS IN THE EFFERENT PROJECTIONS OF THE NEOSTRIATUM IN THE RAT. Louise D. Loopuijt\* and Derek van der Kooy (SPON: V.K. Singh) Department of Anatomy, Faculty of Medicine, University of Toronto, Toronto, Ontario MSS 1A8 Canada It has been well established, that the efferent projections

of the neostriatum have their terminals in the globus pallidus and the substantia nigra (predominantly its pars reticulata). There is circumstantial evidence that the projections to the globus pallidus represent collateral axons, that originate from striatonigral projections.

The present study was undertaken to obtain more direct evidence on the collateralization of these striatal efferents. Therefore, retrogradely transported fluorescent tracers were used: in rats the substantia nigra was stereotactically injected with either nuclear yellow (NY) or propium-iodide (PI) and the globus pallidus with 4-acetamido, 4'-isothio-cyanostilbene -2, 2' disulfonic acid (SITS). Since the striato-nigral fibres run through the globus pallidus, SITS was chosen for injection into this nucleus, because it is not taken up by fibres of passage. The amount of tracer injected into the substantia nigra with either NY or PI was 0.4 ul and into the globus pallidus 0.5 ul. Observations of histological sections of this material in the fluorescent microscope revealed that the whole globus pallidus and the major part of the substantia nigra had been reached by the tracer. Moreover, cell bodies retrogradely labeled with the fluorescent tracer injected in either terminal site were seen throughout the striatum. In part of the nucleus accumbens, cell bodies were only labeled with the tracer that was injected into the substantia nigra. The major portion of the striatum contained cell bodies that were either retrogradely double labeled (with SITS and either PI or NY) or singly labeled with one tracer. These different labeled cell bodies appeared to be intermingled.

Thus, the striatonigral efferents contain axons with collaterals that terminate in the globus pallidus, except for the fibres that originate in the nucleus accumbens. It cannot be excluded, however, that there are fibres that project on either the substantia nigra or globus pallidus without collaterals to the other target nucleus.

INTERHEMISPHERIC INPUTS TO THE NEOSTRIATUM: THE EXISTENCE OF DI-VERGENT CORTICOCAUDATE PROJECTIONS IN THE CAT. <u>C. Shiota\*, R.S.</u> Fisher, M.S. Levine, C.D. Hull and N.A. Buchwald. Mental Retarda-tion Research Center and Brain Research Institute, UCLA, Los An-195 9 geles, CA 90024.

Interhemispheric inputs to the caudate nuclei (Cd) were deter-mined by axonal uptake and retrograde transport of multiple labels.

Interhemispheric inputs to the caudate nuclei (Cd) were deter-mined by axonal uptake and retrograde transport of multiple labels. In six adult cats, wheat germ lectin-bound horseradish peroxidase (MG-HRP) was pressure-injected into the left Cd while a fluores-cent marker (bis-benzamide (Bb) or nuclear yellow (NY)) was in-jected into the right Cd. Four additional cats that served as con-trols received bilateral label injections into the ventricles and/or white matter and neocortex overlying the Cd. 24-72 hrs after injection, cats were sacrificed (aldehyde fixation). Coronal brain sections were processed with peroxidase histochemical me-thods compatible with the retention of Bb and NY. As in our earlier assessments of the Cd inputs using WG-HRP alone, all of the retrograde markers used in this study labelled neuronal somata (WG-HRP) or nuclei (Bb and NY) in the same five brain sites: neocortex (CX), intralaminar thalamus (Th), substan-tia nigra (SN), mesencephalic raphe nuclei (Ra), and globus palli-dus (GP). Such labelling patterns were not evident in control ani-mals. In counterstained material (ethidium bromide), the cytologi-cal characteristics of neurons labelled with Bb and NY were simi-lar, if not identical, with those of neurons labelled with WG-HRP. Leakage of fluorescent labels into glial cells was often evident in the SN and Th (but not in the CX). Three brain regions (Cx, SN, and Ra) projected bilaterally to provide Cd inputs. Only the Cx contained multiply labelled neurons (e.g., WG-HRP in the neuronal cytoplasm and Bb or NY in the nu-cleus). Neurons with divergent corticocaudate axons were found bi-laterally in the precruciate, cingulate, postcruciate, and prorean gyri. The complement of neocortical cells with divergent axonal collaterals was quite small (<1% of labelled Cx neurons) regard-less of the markers used for their demonstration. The double-label-led cells were small-to-medium sized pyramidal neurons interspers-ed randomly in the neocortical laminae providing Cd inputs (layer

cal basis for the functional interhemispheric coupling of the cau-date nuclei shown in numerous biochemical studies. Common input to neurons (as in the Cx, SN, and Ra) projecting exclusively to the ipsi- or contralateral Cd may contribute to such coupling. However, direct inputs from Cx neurons with divergent axonal projections to both Cd could provide a simpler and more synaptically secure coup-ling mechanism. ling mechanism.

Supported by USPHS grant HD 05958.

195.11 PROJECTION NEURONS OF THE NUCLEUS ACCUMBENS: AN INTRACELLULAR HRP PROJECTION NEUKONS OF THE NUCLEOS ACCORDANCE IN INTERSECTION NEUKONS OF THE RAT. H. T. Chang and S. T. Kitai, Dept. of Anatomy, Michigan State University, East Lansing, MI 4824. Neurons of the nucleus accumbens (NAC) project via the medial forebrain bundle (MFB) to ventral pallidum (VP), lateral hypothalamic areas, ventral tegmental area (VTA), substantia nigra (SN), and retrorubral field. Although these projection cells are report ted to be medium in size, their complete soma-dendritic morphology have not been demonstrated. In this study we sought to identify the morphology of NAC projection neurons by the technique of intracellular recording and intracellular labeling with horse-radish peroxidase (HRP) in male Sprague-Dawley rats anaesthetized with Urethane and Ketamine. Bipolar stimulating electrodes were placed in VTA, SN and/or MFB in order to antidromically activate NAC projection neurons. Electrodes were also placed in amygdala and/or thalamus to orthodromically activate NAC neurons. Bevelled glass micropipettes containing 4% HRP in Tris buffer (0.05M, pH=7.6) and 0.5M potassium methylsulfate were used for recording. Both antidromically activated NAC cells and those could only be activated orthodromically were labeled by iontophoretic applica-tion of HRP (3-7nA, 5HZ, 3-10 min 50% duty cycle). The criteria for antidromic activated action potentials include all-or-none at threshold stimulation, constant latency and collision with intra-cellularly evoked spikes. Although some cells could not be antidromically activated, their HRP-labeled axons were traced into VP, and thus were included in the present sample. The somata of NAC projection cells were round or polygonal in shape and medium in projection cells were round or polygonal in shape and medlum in size (10-20µm). The dendrites radiated into a stellate-shaped dendritic field with a radius of 200-250µm. Four to 6 primary den-dritic stems (width, 2-5µm) usually branched within a 50µm radius from the soma into 2° dendrites, some of which terminated without further branching. Frequently, however, 3° and 4° branchings occurred within short distances from the first branch point such that the terminal dendritic branches were 50-150µm in length. The purphene of corner and province (within a 20µm radius surfaces of somata and proximal dendrites (within a 20µm radius from the soma) were generally smooth. More distal dendrites, how-ever, were densely covered with both pedunculated and sessile spines. The axon usually arose from the soma and often took a tortuous course rostrally for up to 200µm before recurving back caudally toward WP. Many fine axon collaterals arose from the initial  $150\mu$ m length of the main axon and arborized extensively within the parent dendritic domain. The main axons, some dividing into two branches within NAC, could be traced into VP in which terminal collaterals were observed. The overall appearance of these NAC projection cells resembled the medium spiny projection neurons of the neostriatum. (Supported by NRSA F32NS06951 to H.T.C. and NIH Grant NS 14866 to S.T.K.).

195.10 POSTNATAL DEVELOPMENT OF GABA NEURONS IN CAT: VENTRAL FOREBRAIN, PERIPALIDAL REGIONS, AND VENTRAL TEGMENTAL AREA. R.S. Fisher, M. S. Levine, A.M. Adinolfi, C.D. Hull and N.A. Buchwald. Mental Re-tardation Research Center and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Angeles, CA 90024. In a series of kittens and adult cats, indirect peroxidase-an-tiperoxidase methods were used to demonstrate neuronal elements containing glutamate decarboxylase (GAD), the synthetic enzyme of the inhibitory neurotransmitter ♂-aminobutyric acid (GABA). This report is a light microscopic analysis of the distribution and postnatal development of GABA neurons in the ventral forebrain (olfactory tubercle-OT, islands of Calleja-IC, and nucleus accum-bens-NA), peripallidal regions (vertical and horizontal limbs of the nucleus of the diagonal band-VL and HL, substantia innominata-SI, and lateral hypothalamic area-LHA), and the ventral tegmental area-VTA). Similar GAD-positive neuronal elements were previously reported in the basal ganglia. Stained punctae were GAD-positive terminals (primarily Gray Type II, axosomatic and axodendritic contacts). Stained cell bodies were GAD-positive neurons. GABA neurons and terminals were evident in each of the examined brain sites in both kittens and adult cats. In contrast to the neostriatum, diffusely distributed GABA terminals were more preva-lent in the neuropil of the OT and AC and formed dense linear ar-rays around cells and dendrites in the IC. Medium-sized GABA neu-ronal somata and dendrites were evident prominently in all of these regions. The large cells of the IC were also stained. As in the pallidal segments, many densely stained medium-to-large fusi-form neurons were evident in all of the peripallidal regions. How-ever, terminal organization varied across these brain sites. In the VL and HL numerous densely stained terminals were found, but linear and circular arravs of terminals were not as prominent as In a series of kittens and adult cats, indirect peroxidase-an-

ever, terminal organization varied across these brain sites. In the VL and HL numerous densely stained terminals were found, but linear and circular arrays of terminals were not as prominent as in pallidum. SI and LHA contained considerably fewer GABA termi-nals than the pallidum. The more diffuse terminal organization of the rostral peripallidal regions was maintained. The VTA was sim-ilar in appearance to the caudal peripallidal regions. It contain-ed fewer, more randomly organized GABA terminals than the substan-tia nigra. As in the basal ganglia, the major developmental trends in all of these brain sites were: 1) terminal addition, 2) termi-nal organization, and 3) terminal elaboration (increasing terminal diameter and staining density). The incidence of stained cell bod-ies also increased with age. Terminal distribution was roughly ma-ture by 30 days of age, but terminals were not elaborated fully by 90 days of age. by 90 days of age.

195.12 CYCLIC NUCLEOTIDE DISTRIBUTION WITHIN THE RAT STRIATOPALLIDAL PRO-JECTION SYSTEM. <u>S.K. Ufkes<sup>\*</sup> & M.A. Ariano</u> (SPON: W.G. Bradley). Anatomy & Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

Previous immunohistochemical studies have documented the medium spiny neuronal localization of cyclic nucleotides within the rat striatum (<u>J. Cell Biol</u>. 91: 287, 1981). Substance P (SP) and met enkephalin (ME) have also been localized within medium spiny cells and implicated as transmitters in the striatopallidal efferent pathway (<u>Neurosci</u>. 6: 1291, 1981). In order to investigate a pos-sible cyclic nucleotide-neurotransmitter relationship within the striatopallidal neurons, these cells were identified through retrograde transport, and characterized using immunohistochemical techniques.

The fluorescent dye Evans blue (EB) was injected stereotaxically into rat brains which were processed for immunohistochemistry (Neurosci., in press). Tissue sections were examined with ultra Violet optics using a 540 mm/590 nm filter set to visualize EB-labeled striatopallidal neurons. The EB-filled cells were oval, 15 µm diameter and displayed unlabeled nuclei. SP- and ME-containing elements were detected with specific rabbit polyclonal anti-bodies (ImmunoTech, Inc.). Cyclic nucleotide immunoreactive cells bodies (immunoiter, inc.). Optic indefeoring immunoiteactive terms were identified with antisera synthesized in our lab. 485 nm/520 nm filter combination was used to detect the fluorescein-labeled immunofluorescent striatal elements. The immunohistochemical staining patterns of the cyclic nucleotides, ME and SP were similar and in agreement with previously published descriptions (J. Cell

and in agreement with previously published descriptions (<u>J. Cell</u> Biol. 91: 287, 1981; <u>Acta Histochem. Suppl</u>. B24: 97, 1981; <u>J</u>. <u>Neurocytol</u>. 12: 325, 1983). Of the cyclic GMP reactive elements, 98.2% were identified as striatopallidal efferent neurons, and 97.4% of the striatopallidal neurons contained cyclic GMP. 99% of the cyclic AMP-reactive cells co-localized with striatopallidal neurons, and 95% of the identi-fied neurons contained cyclic AMP. Of the SP and ME immunoreactive elements, 96% were coincident with striatopallidal neurons, while 87.5% and 83.7% of the striatopallidal neurons contained SP or ME, respectively.

The large proportion of striatopallidal neurons which contain SP, ME, and the cyclic nucleotides supports a link between the primary neurotransmitters and the secondary messengers. Our find-ings demonstrate a 28.9% coincidence of cyclic AMP-staining within striatonigral neurons, in contrast to the 99% coincidence of cyclic AMP present within the striatopallidal system. This variance may reflect a preferential utilization of the cyclic nucleotides in distinct modes of information processing in these different pathways

WEAVER MUTATION HAS DIFFERENTIAL EFFECTS ON THE DOPAMINE INNERVA-195 13 TION OF THE LIMBIC AND NON-LIMBIC STRIATUM. S. Roffler-Tarlov and A.M. Graybiel, Depts. Neurol. & Anat., Tufts Univ. Sch. Med. Boston, MA 02111 & Mass. Inst. Tech., E-25, Cambridge, MA 02139. The dopamine (DA)-containing projection to the striatum con-tains mesolimbic and nigrostriatal components considered to be functionally and anatomically distinct. The mesolimbic DA system projects mainly to the ventral striatum, which includes regions re-lated to limbic forebrain: the nucleus accumbens (NAc), olfactory tubercle (OT), and ventral caudoputamen (CPv). The nigrostriatal DA system projects to the large remainder of the caudoputamen (CP), which is called the dorsal striatum and is interconnected with sensorimotor regions. Here we show that these major DA-containing systems are differentially affected in an inherited disorder and, in particular, that mesolimbic projections to the NAc and associ-ated medial OT are differentially spared whereas the nigrostriatal projection is severely affected. The weaver mouse (ww) carries an autosomal recessive mutation well known for its effects in the certhe bellum and recently shown to produce a severe DA deficiency in the forebrain (Schmidt et al., J. Neurosci, '82). We have measured the DA content of retina, midbrain and the three divisions of the striatum (CP, NAc and OT). Catecholamines were extracted from sam-ples dissected from serial brain slices (or whole retina) and were separated and measured using HPLC followed by electrochemical detection. The 15 weaver (wv/wv) mice and 15 littermate controls (+/wv) examined were on a C57BL6/CBA background and were 1-9 mos. old. Homozygous (+/+) controls have not yet been studied. Values were expressed as pmoles DA/mg protein (mean  $\pm$  SEM). DA in weaver retina was normal  $(7.0\pm.6$  in controls,  $7.9\pm.5$  in weavers). DA depletion was highly nonuniform in the striatum. DA was reduced 68% in the CP, was entirely conserved in the NAc, and was reduced 32% in the OT. The values were: for CP, 245+19 in controls, 78+5 in weavers; for NAc, 239+16 in controls, 234+14 in weavers; and for OT, 228+10 in controls, 156+10 in weavers. Midbrain DA was reduced by 33% (6.9+.5 in controls, 4.6+.4 in weavers). Neither the pattern nor the extent of these DA losses changed from 1-9 mos.

Catecholamine glyoxylic acid fluorescence in the striatum was studied in 11 weavers and 13 controls. All striatal subdivisions fluoresced brightly in controls. The pattern of residual fluores-cence in weavers recalled maps of the limbic striatum: fluorescence was weak in the dorsal CP, gradually increasing ventrally; was very strong in the NAc; and was intermediate in the CPv. There was also a mediolateral gradient in the OT, fluorescence appearing Normal medially but weak laterally. We conclude that DA fiber systems innervating limbic and non-

limbic striatum can be influenced separately in an inherited dis-order. Funded by NIH 2807-RR05598; EY02866; NSF BNS8112125; and by the Wills Foundation.

LIGHT AND ELECTRON MICROSCOPIC IDENTIFICATION OF IMMUNOCYTOCHEM-195.14 ICALLY LABELED SEROTONINERGIC AXONS IN THE SUBSTANTIA NIGRA OF

MONKEYS. <u>G. Holstein<sup>\*</sup>, T. Pasik and P. Pasik</u> (SPON: J. Weinberger). Dept. Neurol., Mount Sinai Sch. Med., New York, N.Y. 10029 Monkeys (<u>M. fascicularis</u>) were perfused briefly with 4% pure formaldehyde and 0.25% purified glutaraldehyde in 0.12M phosphate Some animals received an intracerebral 3 µl injection of buffer. buffer. Some animals received an intracerebral 3 µl injection of 2.5% colchicine solution 16 hr before perfusion. Others were Pargyline (75 mg/kg) and L-tryptophan (100 mg/kg) i.p., three and one hr, respectively, prior to sacrifice. Vibratome 40 µm sections were incubated in a 1:500 or 1:1000 dilution of rabbit antiserum raised against a secotonin-BSA conjugate, and further processed with the PAP technique. No reaction was visible in control sections incubated with the same antiserum preabsorbed with serotonin-BSA conjugate or coprecipitated with this conjugate plus rabbit anti-BSA.

With light microscopy, immunoreactive axons were seen in both regions of substantia nigra, although predminantly in pars reti-cularis. These processes were fine  $(0.5-1.0 \ \mu\text{m})$ , and gave rise to a profusion of thinner branches  $(0.1-0.4 \ \mu\text{m})$ . Varicosities,  $0.7-1.5 \ \mu\text{m}$  in size, were visible along the lengths of all axonal 0.1-1.5 µm in size, were visible along the lengths of all axonal processes, spaced irregularly from 1 to 5 µm apart. Pale reaction was apparent in cells of the pars compacta at the lower, but not the higher serum dilution, contrary to the heavily stained neurons of the raphe nuclei present at both dilutions. Using serial section electron microscopy, labeled profiles of

variable size were observed containing dark particulate reaction product, about 50 nm in diameter. Small dark mitochondria and round vesicles, 50-100 nm in diameter, were scattered throughout the immunoreactive elements. Synaptic contacts between labeled terminals and large dendritic elements were indicated by restricted regions of membrane thickening, enlargement of the cleft and presence of vesicles adherent to the presynaptic membrane. Often the surfaces of these dendrites were completely covered with synaptic membrane specializations, only one of which involved a labeled axon. Most of the synaptic articulations appeared asymmetrical, and occasionally subjunctional dense bodies were visible under the postsynaptic membrane. Somet Sometimes immunostained profiles formed synapses with dark dendrites.

These observations offer positive identification of serotoninergic processes and terminals in monkey substantia nigra. Although the projections from dorsal and median raphe nuclei to this structure have been demonstrated previously, some disagree-ment has persisted about the relative extent of afferent input to the two subdivisions. The present findings support the conten-tion that pars reticularis, not pars compacta, receives the pre-dominant serotoninergic innervation. 195.15 MORPHOLOGY OF NIGROSTRIATAL NEURONS INTRACELLULARLY STAINED WITH HRP. I. Crofova\*, H. Kita and S. T. Kitai (SPON: G. Lew), Dept of Anatomy, Mich. State Univ., E. Lansing, MI 48824 and Dept. of Anatomy, Univ. of Tennessee, Memphis, TN 38163. 48824 and Dept. of

Antidromy, billy, of remeaser, mempils, in Solos. Antidromic responses of rat substantia nigra(SN) neurons to striatal stimulation were intracellularly recorded and the cells were subsequently labeled by iontophoretic injection of HRP. We report here light microscopic data on dendritic arborizations and axons of both physiologically characterized nigrostriatal cells and non-characterized SN projection neurons. The former cells were considered dopaminergic because of their low conduction velocities (antidromic latency from striatum longer than 7 ms). Such criteria were not available for the latter cells, but they were mostly located in the pars compacta (SNC) and the ir axons were traced well beyond the boundaries of the SN.

The majority of nigrostriatal cells were localized within the SNC. They had smooth medium-sized polygonal somata and one or two thick ventrally oriented dendritic stems branching within the pars reticulata(SNR). Several thin and varicose dendrites remained within SNC and made up a large discoid dendritic field. The axons often looped through the SNC before leaving the nucleus, but intrinsic axon collaterals have not been so far seen. A number of non-characterized SNC neurons showed similar morphological features. One slowly-conducting nigrostriatal neuron was local-ized within the SNR. This cell had a thick dorsally oriented dendritic stem ascending into the SNC. Three primary dendrites branched and coursed for long distances within the SNR. The axon coursed rostromedially through the SNC and exhibited prominent varicosities, but did not collateralize. These morphological features were shared with a non-characterized SNR neuron found in the posteromedial region of SNR, an area known to contain dopa-minergic nigrostriatal cells. A few <u>non-characterized cells lying</u> <u>along the dorsal border</u> of SNC had a different soma-dendritic and axonal morphology. Their dendrites radiated into both ventral tegmentum and SNC and their axons emitted recurrent collaterals.

These observations indicate that the SNC contains a rich plexus of varicose dendrites consisting of extensively overlapping den-dritic arbors belonging to slow conducting, possibly dopaminergic nigrostriatal neurons located in both SNC and SNR. The nigro-striatal dopaminergic neurons situated in the SNR are morphologically distinct from the nigrothalamic and nigrotectal SNR cells as well as from the nigrostriatal SNC neurons. Finally, the SNC projection neurons probably consist of at least two different cell types. One with dendrites remaining within the confines of SN and without axon collaterals, and the other with dendrites invading the tegmentum and with recurrent axon collaterals. (Supported by NIH Grant NS 19483 and BRSG Grant 0637).

195.16 ACETYLCHOLINESTERASE-CONTAINING NEURONS IN HUMAN NEOSTRIATUM: A STUDY OF NORMAL AND ALZHEIMER-DISEASED BRAINS. <u>A. Parent, C. Csonka\* and P. Etienne\*</u>. Lab. of Neurobiology, Fac. Med., Laval

<u>Usonka<sup>m</sup> and P. Etlenne<sup>m</sup></u>. Lab. of Neuropiology, Fac. Med., LaVal Univ., Québec and Douglas Hospital Res. Ctr. Montréal, Canada. The cellular localization of acetylcholinesterase (AChE) in human basal forebrain was studied using the Karnovsky and Roots histochemical procedure. Of the 5 brains examined so far, 2 were from patients who had suffered from senile dementia of the Alzheimer type (one case of early and another of late onset), whereas the others served as controls (age ranging from 66 to 84). After an autopsy delay of less than 24 h., a brain slab which included nucleus basalis (substantia innominata) and part of the basal ganglia, was dissected out and keept in 10% buffe-red formalin with DMSO for 60 h. The tissue block was then sectioned on a freezing microtome and the sections (30 um thick, 1 out of 2) were reacted for AChE. The adjacent sections were stained with cresyl violet. In each brain the background AChE staining in neostriatum was

sufficiently low to allow the visualization of large and intensely-stained AChE neurons scattered trhoughout the caudate nucleus and putamen. These AChE neurons vary in shape from fundcleus and putament. These works before before vary in shape from the siform with one thick process emerging from one pole of the cell body, to multipolar with 3 to 6 straight and thinner processes. Measurements made in one control brain reveal that the perikarya had a maximum diameter of  $40.10 \pm 5.93$  um (mean  $\pm$  standard de-viation) and a minimum diameter 27.75  $\pm$  4.03 um. Comparisons with adjacent cresyl violet-stained sections suggest that the AChE neurons do not represent more than 5% of the total striatal AChE neurons do not represent more than 5% of the total striatal cell population. Thus, these highly reactive neurons appear equivalent to similar AChE cells disclosed previously in the neostriatum of rat, cat and monkey after AChE inhibitor (DFP) pretreatment. In these species the striatal AChE neurons were shown to be intrinsic cholinergic elements. On the other hand, in the 2 humain brains examined in which the classical neuropa-thological signs of Alzheimer's disease (abundant neuritic pla-ques neurofibrillary rangelag and accordenced at the constraints) ques, neurofibrillary tangles and granulovacuolar degeneration) were present, the number, morphological characteristics and staining intensity of the large striatal AChE neurons were found to be unaltered, despite a marked loss (most striking in early onset case) of AChE neurons in the adjoining nucleus basalis. These findings suggest that large intrinsic cholinergic

neurons exist in human neostriatum and that these elements, in contrast to those of nucleus basalis, are not affected in Alzheimer's disease.

195.17 THE OUTPUT ORGANIZATION OF THE SUBSTANTIA NIGRA IN PRIMATE. <u>Smith\*, Y., A. Mackey\*, L. De Bellefeuille\* and A. Parent</u> (SPON: M. Filion). Lab. of Neurobiology, Fac. Med., Laval University, Québec, Canada, GIK 7P4.

The exact cellular origin and degree of collateralization of the efferent projections of the substantia nigra (~~) in the squirrel monkey (Saimiri sciureus) were studied using the fluorescence retrograde double labeling method introduced by Kuypers and Van der Kooy. Three combinations of fluorescent tracers were utilized: (1) Evans blue and DAPI-primuline, (2) Fast blue and Nuclear yellow, and (3) True blue and Nuclear yellow. In a first series of experiments (6 monkeys), one tracer was injusted in the sudden subus themes the value and tracer to the tracer of the subus themes the subus themes the sub-

In a first series of experiments (6 monkeys), one tracer was injected in the caudate nucleus whereas the complementary tracer was delivered in the putamen. After these injections numerous clusters of nigrocaudate and nigroputamen cells occur at all rostrocaudal levels in the substantia nigra pars compacta (SNc). These cell clusters were closely interlocked and distributed according to a complex mosaic-like pattern. Although clearly separated from one another in the transverse plane, each of the nigrocaudate and nigroputamen cell clusters appear to run in continuity from section to section when examined along the rostrocaudal axis. This suggests that these clusters may in fact be part of a complex three-dimensional array of tubular neuronal aggregates. Surprisingly, very few SNc neurons were found to project to both caudate nucleus and putamen. In a second series of experiments (10 monkeys), fluorescent tracers were injected in the 3 major target structures of the substantia nigra pars reticulata (SNr): thalamus, superior colliculus and midbrain tegmentum. After these injections numerous double-labeled neurons were observed in SNr. in contrast to what

In a second series of experiments (10 monkeys), fluorescent tracers were injected in the 3 major target structures of the substantia nigra pars reticulata (SNr): thalamus, superior colliculus and midbrain tegmentum. After these injections numerous double-labeled neurons were observed in SNr, in contrast to what has been found in SNc after caudate-putamen injection. Our data reveal that the largest number (about 60%) of SNr branching neurons are those projecting to both the thalamus and the midbrain tegmentum; that a moderate number (20-30%) of SNr neurons send collaterals to the thalamus and the superior colliculus; whereas only a small number (about 10%) of SNr neurons project to both the superior colliculus and the midbrain tegmentum. Such a high degree of axonal branching is a neuronal characteristic that the SNr elements obviously share with those of the internal pallidum in the same species. These findings reveal that, in regard to their efferent projections, the two major subdivisions of SN in primate are organized quite differently. Whereas the SNc cells occur in the form of numerous ligroonutare neuronal subunits

These findings reveal that, in regard to their efferent projections, the two major subdivisions of SN in primate are organized quite differently. Whereas the SNc cells occur in the form of numerous nigrocaudate and nigroputamen neuronal subunits that display a complex mosaic-like arrangement, the SNr neurons appear clearly more multipotential and not compelled to such a rigid topographical organization. (Supported by grant MT-5781 of the Medical Research Council of Canada).

14<sub>C</sub> deoxyglucose studies of the normal rat striatum show 195.19 LUCY L. Brown and Leslie I. Wolfson\*. Dept. Neurol., Albert Einstein College of Medicine, Bronx, NY 10461. Histochemical and autoradiographic receptor binding studies of Histochemical and autoradiographic receptor binding studies of Histochemical and autoradiographic receptor binding studies of the striatum have revealed an organizing principle of "islands" and "mosaic-like compartments" of opiate receptors, cholinester-ase, and afferent systems (e.g. Herkenham, M. & Pert, C., <u>Nature</u>, <u>291</u>:415, 1981). We noted that striatal glucose utilization (GU) measured autoradiographically in rats appeared to be heterogen-eous. Thus we used an image analyser densitometer (Cambridge Instruments) to determine if the heterogeneity in normals showed any consistent pattern. Eight rats were injected with 14C 2-deoxy-D-glucose (CG) with no previous treatment. Saven other rat deoxy-D-glucose (DG) with no previous treatment. Seven other rats were injected with DG 20min following apomorphine (APO), 2.5mg/kg i.p. APO was used as a functional manipulation of the striatum to determine if changes in the normal pattern could be detected. The DG procedures of Sokoloff, et.al. (J. Neurochem., 28:897, 1977) were used. "Islands"of high-normal GU (123+5 umols/100g/min) min) and larger regions of low-normal GU (80+4 umols/100g/min) were observed throughout the striatum of individual animals. This relatively large difference between high and low regions "islands" formed an arc shape in the dorsal striatum. " consistent patterns were seen across animals, forinstance, a low-normal region in the dorsomedial striatum and in a thin strip under the corpus callosum. This thin strip correlated with an area which contains a high level of opiate receptors. The high-normal "islands" were similar to islands of corticostriate afferents (Sharp, F.R., & Evans, K., <u>J. Comp Neurol.</u>, <u>208</u>: 255,1982) and nigrostriatal afferents (Olson, L., et.al., <u>Brain</u> <u>Res.,44</u>:283,1972). APO increased GU in the low-normal regions of ventromedial striatum, but not above high-normal values. The drug decreased GU in the dorsomedial striatum. The results suggest a heterogeneity of striatal organization which can be functionally analysed and further emphasize the importance of Full to the set of specific changes with APO treatment suggest that discrete region-al analysis provides a further analytic tool for DG studies, especially if the topographic organization of afferents is con-sidered. Systemic APO has a complex effect on striatal GU and ay reflect specific afferent system activity as well as a direct effect on dopamine receptors in the striatum.

195.18 6-OHDA LESIONS OF THE MEDIAL FOREBRAIN BUNDLE MODIFY PATTERNS OF GLUCOSE UTILIZATION IN THE BASAL GANGLIA DURING STIMULATION OF THE SUBSTANTIA NIGRA. H. H. Holcomb, H. D. Everist, P. M. Gross, M. Kadekaro, and A. Pert. National Institute of Mental Health Rethesda Md 20205

Stringer 1, P. M. Gross, M. Kadekaro, and A. Pert. National Institute of Mental Health, Bethesda, Md. 20205 Unilateral electrical stimulation of the substantia nigra increases local cerebral glucose utilization in the ipsilateral globus pallidus, entopeduncular and subthalamic nuclei. We have assessed to what extent nigral dopamine neurons contribute to this metabolic activation. Employing the quantitative autoradiographic 2-1°C deoxyglucose method we have measured local rates of glucose utilization in the globus pallidus, entopeduncular and subthalamic nuclei in six groups of animals: ])sham stimulation, 2) unilateral nigral stimulation, 3) nigral stimulation in animals pretreated with haloperidol (0.1 mg/kg i.v., 20 minutes prior to stimulation), 4) unilateral lesion of the medial forebrain bundle with 6-OHDA, 5) 6-OHDA lesion + nigral stimulation, 6) 6-OHDA lesion + nigral stimulation + haloperidol. Stimulation of substantia nigra in animals pretreated with haloperidol increased glucose utilization in the ipsilateral globus pallidus, entopeduncular and subthalamic nuclei as compared to non-treated, stimulated animals. In non-stimulated animals 6-OHDA lesions alone produced a slight increase in metabolic activity of the ipsilateral globus pallidus (20%). Nigral stimulation of 6-OHDA treated animals did not increase glucose utilization in the entopeduncular or subthalamic nuclei. Not further increased by nigral stimulation, pallidal glucose metaboliks memained the same as in 6-OHDA lesioned animals without stimulation. Pretreatment with haloperidol in 6-OHDA lesioned animals. In contrast, the globus pallidus. Nigral stimulated animals. In contrast, the globus pallidus did not require such input. This finding suggests that elevated pallidal glucose metabolic activity is due either to the effects of dopamine denervation or stimulation of non-dopaminergic fibers. In 6-OHDA lesioned animals, haloperidol may suppress metabolics in the globus pallidus by binding to cells rendered hypersensitive to this d

DISTRIBUTION OF AXON COLLATERALS OF IDENTIFIED MEDIAL 196.1 VESTIBULOSPINAL AXONS IN THE UPPER CERVICAL SPINAL CORD OF THE CAT. <u>F. Fleming\* and P. K. Rose</u>. (SPON: F. J. R. Richmond) Dept. of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Dorsal neck muscle motoneurons receive a powerfu Dorsal neck muscle motoneurons receive a powerful monosynaptic inhibitory connection from the vestibular complex. Wilson and Maeda (J. Neurophysiol. 37: 346, 1974) have shown that this connection is mediated by the medial vestibular spinal tract which originates bilaterally from the vestibular nuclei and travels in the ventromedial funiculus. The goal of the present study was to describe the fine structural characteristics of individual medial vestibular axons using

intra-axonal injections of horseradish peroxidase. All of the axons described in the present report travelled in the ventromedial funiculus contralateral to their origin within the vestibular nuclear complex and were monosynaptically excited by stimulation of the vestibular nerve. The distribution of individual collaterals was determined from reconstruction of individual collaterals was determined from reconstruction of collateral branches seen on serial histological sections. Each axon gave rise to more than one collateral, usually spaced 1 to 2 mm apart. All collaterals branched extensively within lamina IX and ventral parts of lamina VIII. There were two distinct regions of termination: 1) the ventromedial nucleus containing dorsal neck muscle motoneuron cell bodies and 2) the spinal accessory nucleus which contains trapezius motoneuron cell bodies. All well-stained collaterals had numerous boutons, usually 250 boutons per collateral. When viewed in the horizontal plane, the distribution of boutons was not uniform, Instead most boutons were concentrated into several small zones. This distribution was accentuated by a special arrangement in which a single terminating branch gave rise to a cluster of five or six boutons. These clusters consisted of a single large central bouton surrounded by a number of smaller boutons.

or six boutons. These clusters consisted of a single large central bouton surrounded by a number of smaller boutons. The results of the present experiments indicate that the medial vestibular spinal tract has a major termination zone within the contralateral ventral horn in a region occupied by the cell bodies of dorsal and lateral neck muscles. Although previous anatomical studies have not reported such a projection, our results are consistent with electrophysiological experiments which describe disynaptic IPSP's in dorsal neck muscle motoneurons following stimulation of the contralateral vestibular nerve. vestibular nerve.

PROJECTIONS OF NECK MUSCLE SPINDLE AFFERENTS INTRA-AXONALLY 196.2

PROJECTIONS OF NECK MUSCLE SPINDLE AFFERENTS INTRA-AXONALLY STAINED WITH HORSERADISH PEROXIDASE IN THE UPPER CERVICAL SPINAL CORD OF THE CAT. S.A. Keirstead\* and P.K. Rose. Dept. of Physiology, Queen's Univ., Kingston, Ontario, Canada K7L 3N6. Electrophysiological studies have shown that stimulation of neck muscle spindle afferents evokes small composite monosynaptic EPSP's (350-3100 uV) in dorsal neck muscle motoneurons (Brink et al., J. Neurophysiol. 46: 496, 1981). Furthermore, no reciprocal or crossed disynaptic IPSP's have been detected in these motoneurons (Banoart 1, Physical 289; been detected in these motoneurons (Rapoport, J. Physiol. 289: 311, 1979). In the present experiments we have examined the intraspinal projections of neck muscle spindle afferents anatomically since electrophysiological studies have provided little positive information about the segmental role of dorsal

neck muscle spindles. Axons of "primary-like" endings of dorsal neck muscle

Axons of "primary-like" endings of dorsal neck muscle spindles were impaled near the dorsal root entry zone of the upper cervical spinal cord, and injected with horseradish peroxidase. The course of the axons and the projections of their collaterals were reconstructed from serial histological sections cut in the sagittal plane. Stained axons gave rise to collaterals at intervals from 0.6 to 5.2 mm (average, 3.4 mm). All collaterals descended along the medial border of the dorsal horn and arborized extensively upon reaching the intermediate horn, in a region which included the central cervical nucleus (CCN). This projection gave rise to a dense termination zone which accounted for 70 to 80% of the boutons from any single collateral. From this intermediate region, the main branch of collaterals from biventer cervicis muscle spindle afferents coursed vertrally and gave rise to boutons along the main branch of collaterals from biventer cervicis muscle spindly afferents coursed ventrally and gave rise to boutons along the medial border of the ventral horn and in the ventromedial nucleus, deep in the ventral horn. In addition to these projections, collaterals from splenius muscle spindle afferents had a lateral branch in the ventral horn, which terminated in the region of the spinal accessory nucleus. The rostrocaudal extent of the diffuse ventral arborizations varied, but usually did at exceed 1000 ur did not exceed 1000 um. The prominent projection of neck muscle spindle afferents to

The prominent projection of neck muscle spindle afferents to the CCN which contains precerebellar neurons could provide a route by which information from neck proprioceptors can be transmitted to the cerebellum. The relatively minor projections from neck muscle spindle afferents to regions containing dendrites and somata of neck muscle motoneurons, combined with the wide intercollateral spacing may, at least in part, explain the small monosyaptic EPSP's which have been observed in dorsal neck muscle motoneurone neck muscle motoneurons.

196.3 TOPOGRAPHIC COMPARISON OF MESENCEPHALIC PROJECTIONS TO THE INFERIOR OLIVE, VESTIBULAR NUCLEI AND UPPER CERVICAL CORD IN THE CAT. S.J. Spence\*, J.A. Saint-Cyr, and M.T. Stechison\*. Playfair Neuroscience Unit and Departments of Anatomy and

Surgery, University of Toronto and Toronto Western Hospital, Toronto, Ontario M5T 258. Mesencephalo-olivary projections have been shown to arise importantly from parvocellular red nucleus (RNp), interstitial importantly from parvocellular red nucleus (RNP), interstitial nucleus of Cajal (INC), nucleus of Darkschewitsch (ND), subpara-fascicular and parafascicular nuclei (sPf and Pf), nucleus of the pre-rubral field (NPRF) and nucleus of the fields of Forel (NFF) (Saint-Cyr and Courville, JCN <u>198</u>, 1981). Some of these regions are also known to send fibres to the vestibular nuclei (VN) and upper cervical cord (C.Sp.). To assess the topograhic distribution of these cells with respect to their efferent projections, retrograde transport experiments were performed using lectin-HRP (WGA-HRP) (0.5- 2.0%; 0.05-0.9  $\mu$ l) and the fluore-scent dyes fast blue and nuclear yellow (1.0-3.0%, 2.6-4.8  $\mu$ l) in a series of 25 cats. The largest injections were confined to the C.Sp. Only those cases wherein injections were restricted to the defined targets (IO, VN, C.Sp.) were used to obtain the following data.

No single mesencephalic region was found to project soley to the IO. the IO. Oculomotor and magnocellular red nuclear neurons were uniquely labeled after VN and C.Sp. injections respectively. Both IO and VN received inputs from certain pretectal nuclei, while common sources of afferents to IO and C.Sp. arose from ND and nucleus of the posterior commissure. The nucleus of Edinger-Westphal projected to both C.Sp and VN. Principal mesodiencephalic cell groups providing inputs to all three targets included RNp, INC, NPRF, SPf, Pf and NFF. The cluvery afferent cell groups formed a compact distribu-

targets included RNP, INC, NPRP, SPT, PT and NPT. The olivary afferent cell groups formed a compact distribu-tion which was densest in the rostral mesencephalon. In con-trast, cells projecting to the VN and C.Sp. were more diffusely distributed, and were found over a greater area both laterally and caudally in the mesencephalon, although they were also more densely concentrated in the rostral mesecephalon. This study suggests that the inferior olive may be in receipt of corpolary information arising from mesencephalic areas also

This study suggests that the interior office may be in recipit of corollary information arising from mesencephalic areas also known to project to vestibular and upper cervical centres. Double labeling studies are in progress to identify such axonal collaterals. In addition, further details with regard to the bilaterality of these projections are under analysis. Supported by grant MT-7209 from MRC of Canada to J.S.C.

POSTSYNAPTIC POTENTIALS OF LUMBAR MOTONEURONS EVOKED BY CUTANEOUS C-FIBER VOLLEYS IN THE CAT. K.Endo\*, Y.Hori\* and W.D.Willis (SPON: J.E. Bottenstein). Marine Biomed. Inst. & Depts. of Physiol. & Biophys. and Anatomy, Univ. TX Med. Branch, Galveston, TX 77550.

Postsynaptic potentials evoked by cutaneous C-fiber volleys (C-PSPs) in lumbar motoneurons were examined in unanesthetized decerebrated cats. The spinal cord was transected at the lower thoracic level. Motoneurons were identified by antidromic spike potentials following stimulation of peripheral muscle nerves. Thesural or tibial nerve was stimulated at strengths sufficient to activate A or A and C afferent fibers with three pulses at The duration of the stimuli was either 100 µs or 1 ms for 33 Hz. activation of A and C fibers, respectively. The afferent A and C volleys were monitored. C-PSPs were obtained by subtracting PSPs

evoked by maximal A volleys from PSPs evoked by A and C volleys. A total of 34 flexor (PBST,DP) and 27 extensor (GS,PL,FDHL) motoneurons were tested. C-EPSPs were evoked in 18 (54%) flexor and 12 (44%) extensor motoneurons, while C-IPSPs were evoked in 8 (24%) flexor and 9 (33%) extensor motoneurons, respectively. The mean latencies of C-EPSPs and C-IPSPs were 292 msec (N = 20, range: 180-630 msec) and 273 msec (N = 11, range: 190-390 msec), respectively, indicating that the fastest C-fiber afferents involved had a mean conduction velocity of 0.8 m/sec. In the early part (400-800 msec after stimulation) of C-PSPs, an increase in membrane conductance was observed. This fact shows that pre-synaptic terminals producing C-PSPs in motoneurons are located on the soma or proximal dendrites.

196.5 FACILITATION AND DEPRESSION OF La-MOTONEURON EPSPS DURING SHORT BURSTS IS DETERMINED BY EPSP AMPLITUDE. W.F. Collins, III, M.G. Honig and L.M. Mendell. Dept. of Neurobiology & Behavior, Stony Brook, NY 11794.

We have examined the frequency dependence of EPSPs at 27 single medial gastrocnemius (MG) Ia-motoneuron connections in intact and acutely transected (T13) cats under Nembutal anesthesia. We elecacutely transected (T13) cats under Nembutal anesthesia. We elec-trically stimulated the Ia fiber impaled in a dorsal rootlet and recorded the resulting EPSPs in the motoneuron (MN) (Honig et al., J. Neurophysiol. 49:). We previously reported (Collins et al., Neurosci. Abstr.  $\underline{8}$ :) that facilitation/depression behavior during long trains (250 stimuli) of intermediate frequency (50-100Hz) is correlated with EPSP amplitude and with MN rheobase (Rh). We have extended these studies by delivering brief, repetitive high freq-uency bursts (32 shocks at 167Hz; 128 bursts; 2-30sec between bursts). We examined changes in EPSP amplitude occurring during th bursts). We examined changes in EPSP amplitude occurring during the bursts by averaging responses in successive bursts. At most connect-ions (90%) the first EPSP in the burst was larger than the average long (90%) the first grow in the burst was larger than the average EPSP in a control low frequency (18Hz) train, due to potentiation from the repeated bursting (Beswich & Conroy, J. Physiol., <u>180</u>;) and/or the presence of a small degree of depression in the 18Hz train. This ambiguity prompted us to measure facilitation/depression relative to both the 18Hz average and the first EPSP in the burst. The results were qualitatively similar and we report only the 18Hz comparison. In control experiments we found the amplitude of later EPSPs in the burst (beyond the first 4 or 5) to be independent of the extent of any initial potentiation. The ratio of the average amplitude of the 30th and 31st EPSPs to the mean amplitude at 18Hz varied from 0.63 (depression) to 1.94 (facilitation) with a highly significant negative correlation between this ratio and EPSP amplitude (18Hz). Plotting these ratios as a function of MN Rh (range 1.7-31nA) revealed a significant positive correlation. Since amplitude and Rh were themselves correlated, it is difficult to decide which is primary in determining facilitation/depression. We have further analyzed these data using the method of partial correlations. This revealed a highly significant contribution of EPSP amplitude to the variability in facilitation/depression be-havior at different connections. However, at present we cannot rule out a small additional contribution to facilitation/depression variability from MN properties as indicated by Rh. We conclude that whatever process regulates EPSP amplitude seems likely to influence facilitation/depression behavior. Our results indicate that these properties are non-uniformly distributed on MNs of different Rh. Thus variability in intrinsic properties of the synapse may be principally responsible for variations in EPSP amp-litude on different groups of MNs. Supported by NIH grants NS06407 (WFC), NS06427 (MGH) and NS16996 and NS14899 (LMM).

DETERMINATION OF SYNAPTIC EFFICACY AT INDIVIDUAL Ia-MOTONEURON 196.6

CONNECTIONS. <u>L.M. Mendell</u> and <u>W.F. Collins, III</u>. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY 11794. Single Ia afferent fibers often discharge in high frequency bursts (Loeb & Duysens, J. Neurophysiol. <u>38</u>) subjecting the EPSPs bursts (Loeb & Duysens, J. Neurophysiol. 35) subjecting the LFSPs they evoke in a-motoneurons to temporal summation. Assuming EPSPs of uniform amplitude, modelling predicts smooth depolarization to a steady DC level with superimposed fluctuations due to each EPSP (Calvin, Brain Res. 39). Increasing the afferent discharge freq-uency should elevate the steady level of depolarization (Harrison & Taylor, J. Physiol. <u>312</u>). We have stimulated single medial gas-trocnemius (MG) Ia fibers using an intrafiber electrode in the dorsal root and recorded the EPSPs produced in a MG motoneuron in anesthetized cats (Honig et al., J. Neurophysiol. <u>49</u>). We observed that the DC level did not always increase monotonically to some that the DC level during the burst (167Hz, 32 shocks). Rather an initial increase was followed by a decline due largely to a decrease in EPSP amplitude during the burst (Collins et al., this volume). At other connections EPSP amplitude increased during the burst pro-ducing a greater level of steady depolarization than anticipated from the amplitude and shape of the initial EPSP. Furthermore, at some connections steady state DC level decreased for bursts of increasing frequency due to greater depression of EPSP amplitude during the burst. To quantitate these effects we have calculated the mean amplitude of the synaptic response by dividing the inte-The mean amplitude of the Symplet response by article EPSP) by its duration. Mean amplitude of EPSPs obtained during low frequency stimulation ( $1\overline{\mathrm{BHz}}$ ) averaged about 1/3 of their peak amplitude. In contrast mean amplitude of the first 15 EPSPs in the burst was only 15% smaller on the average than the <u>peak</u> amplitude of the low frequency run at that connection (n=13). The extent to which the Trequency run at that connection (n=13). The extent to which the mean amplitude of the burst approached or even exceeded the <u>peak</u> amplitude of the low frequency run depended both on EPSP shape (i.e. half width) and the magnitude of depression/facilitation during the burst. We observed that even when <u>peak</u> amplitudes of EPSPs averaged during low frequency stimulation at 2 connections were very similar, the <u>mean</u> amplitudes of the bursts could differ substantially. <u>Mean</u> amplitude may provide a better estimate of synaptic efficacy than peak amplitude because no single connection is sufficiently strong to discharge to motoneuron (see also is sufficiently strong to discharge to motoneuron (see also Barrett & Crill, J. Physiol. <u>293</u>). It follows that estimates of relative synaptic efficacy among connections may differ from those computed from <u>peak</u> amplitudes of EPSPs obtained during low freq-uency stimulation. Such assessments may depend on the specific stimulation conditions (e.g. frequency of stimulation), EPSP shape and facilitation/depression behavior. Supported by NS14899, NS16996 (LMM) and NS06407 (WFC).

IPSP ACTIVITY INDUCED IN LUMBAR MOTONEURONS BY MEDULLARY 196.7 RETICULAR FORMATION STIMULATION DURING ACTIVE SLEEP. P.A. Boxer\*, REFICULAR FORMATION STIMULATION DURING ACTIVE SLEEP. <u>P.A. BOXET</u> F.R. Morales, S.J. Fung and M.H. Chase. Depts. of Physiology and Anatomy and the Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024. Previous experiments performed in the chronically prepared cat have demonstrated that stimulation of the pontomesencephalic

nave demonstrated that stimulation of the pontomesencephalic reticular formation induces a state-dependent hyperpolarizing potential in both brainstem and spinal cord motoneurons exclusively during active sleep (AS) (J. Neurophysiol., 44:372, 1980; <u>Brain Res.</u>, 248:267, 1982). The more caudal area of the reticular formation in the lower medulla has traditionally been implicated in the regulation of sleep and wakefulness, and in descending motor inhibition. The present experiment was designed to examine the contribution of this medullary area to the control of motor functions during sleep and wakefulness. of motor functions during sleep and wakefulness. Accordingly, the effects of electrical stimulation of the nucleus reticularis

of motor functions during sleep and wakefulness. Accordingly, the effects of electrical stimulation of the nucleus reticularis gigantocellularis (NGC) upon the membrane potential of lumbar motoneurons was examined in six cats. Each animal was prepared with a permanent head and spinal cord implant in accord with established procedures for intracellular recording in the chronic cat (<u>Physiol. Behav.</u>, 27:355, 1981). Sleep and waking states were identified on the basis of standard polygraphic criteria. Intracellular recordings were obtained from antidromically identified lumbar motoneurons (n=39) with glass microelectrodes filled with 2M K-citrate or 3M KCl. Various loci within the NGC (P8 to P10, L1 to L2, H-6 to H-8) were stimulated with a monopolar electrode (2 to 4 pulses, 800 Hz) at a low intensity (20-80 uA). A small hyperpolarizing potential with a peak latency of 40 msec arose in some motoneurons following NGC stimulation during quiet sleep and wakefulness; in the remaining cells no corresponding potential was observed. However, during active sleep, <u>in all cells</u>, NGC stimulation produced a larger hyperpolarizing potential with a peak latency of 40 to 45 msec and an amplitude of 2 to 8 mV. The passage of hyperpolarizing current and/or the iontophoretic injection of chloride ions through the recording electrode diminished or reversed this potential, indicating that it was a chloride-dependent inhibitory postsynaptic potential. postsynaptic potential.

These results suggest that the NGC exerts a weak inhibitory These results suggest that the NGC exerts a weak inhibitory influence on lumbar motoneurons during quiet sleep and wakefulness. However, during AS, motoneuron inhibition of NGC origin is omnipresent and considerably more potent. These data indicate that the NGC exerts a function during AS which has not previously been demonstrated electrophysiologically; this function may be related to the atonia of AS and/or the phasic patterns of inhibition which are present during this state. "Compartment Nuclei" of the Cat Medial Gastrocnemius Muscle. O.I. Weeks and A.W. English (Spon: R. McBride). Dept. of Anatomy, Emory University, Atlanta, GA 30322 A "compartment nucleus (CR)" consists of a group of spinal motor neurons which supply individual primary muscle nerve branches of a muscle nerve. Each primary muscle nerve branch (PMNB) innervates a specific subvolume or compartment of a single muscle.

The spatial and size distributions of motor neurons which supply PNMB of the cat medial gastrocnemius (MG) muscle were examined to test the following hypothesis: that the anatomical examined to test the following hypothesis: that the anatomical characteristics of each MG compartment nucleus mirror images a corresponding lateral gastrocnemius (LG) muscle compartment nucleus. The hypothesis predicts a rostrocaudal topographic organization of MG compartment nuclei reversed to those of LG. The more rostral CN of MG would therefore supply more distal muscle compartments and the more caudal CN would supply more

muscle compartments and the more caudal CN would supply more proximal muscle compartments. Individual PMNB of the MG nerve were isolated, microdissected, cut and the proximal stump soaked in a 30-50% horseradish peroxidase (HRP) solution in 1.6 mg % hyaluaronidase. As a control in each case, the entire contralateral MG nerve was similarly cut and soaked in HRP. A 48-72 hour survival period followed. Spinal segments L6-S1 were serially sectioned and processed for HRP using tetramethyl benzidine (TMB). The distribution of retrogradely labeled cells supplying each nerve branch was compared to the distribution of the entire contralateral MG motor nucleus. These data were also compared to data on the spatial and size distribution of motor neurons in the LG motor nucleus.

Preliminary results indicate significant overlap in the distribution of motor neurons in each compartment nucleus. However, a clear rostral to caudal topographic arrangement for each CN exists for proximal to distal muscle compartments. Rather than a reversed topographic organization of each CN of MG, in comparison to corresponding LG compartment nuclei, the arrangement mimics that of LG. However, for each compartment nucleus of MG, relative to the corresponding CN of LG, there is a more lateral, ventral and caudal positional shift. Like LG compartment nuclei, the most rostrally located CN of MG consists of the largest sized motor neurons and the more caudally placed compartment nucleus a larger percentage of the smallest sized motor neurons. Anatomical Organization of Long Ascending Propriospinal Neurons in the Cat Spinal Cord. J. W. Tigges, A. W. English and P. R. Lennard, Yerkes Regional Primate Research Center and Emory University, Atlanta, GA 30322. Long ascending propriospinal neurons (LAPN's) are ascending interneurons which connect the lumbar and cervical regions of the spinal cord. The anatomical organization of the cells of origin of LAPN's were examined using the retrograde transport of wheat germ agglutinin - HRP (WGA-HRP) conjugate. Injections of 1-4% WGA-HRP dissolved in saline were made into the cervical spinal cord in pentobarbital anesthetized cats using a double-barrelled glass micropipette, one barrel of the cervical spinal cord in pertobarbital anesthetized cats using a double-barrelled glass micropipette, one barrel of which was used to inject small quantities  $(0.05\mu l)$  of WGA-HRP and the other to record a field potential elicited by suprathreshold stimulation of the superficial radial nerve. The pipette was advanced obliquely through the dorsal columns until a large negative field potential either disappeared or reversed direction. Analysis of these injection sites indicated that the label use ploced arises injection sites reversed direction. Anal indicated that the label was placed primarily into the [1]. After 48-72 hours survival, intermediate zone (lamina VII). Intermediate zone (lamina VII). After 48-72 hours survival, animals were perfused with 3.5% glutaraldehyde and the lumbar cord sectioned serially and reacted for demonstration of HRP. Two injection paradigms were compared: injections into the cervical enlargement ( $C_5 - T_1$ ) and injections rostral to the enlargement ( $C_{3-4}$ ). Labelled cells were found both ipsilateral enlargement ( $C_{3-4}$ ). Labelled cells were found both ipsilateral and contralateral to the injection site in both the dorsal and ventral horn at all lumbar levels. A large population of moderate-sized, spherical cells were found in the dorsal horn (laminae IV-VI), mainly ipsilateral to the injection site. Injections into the dorsal columns and dorsal column lesions, which were used as controls, indicate that at least some, but not most of these cells are secondary dorsal column neurons injected in the electrode tract. Large multipolar cells were labelled in the ventral part of lamina VII and, in rostral lumbar segment ( $J_{4-2}$ ) a substantial number of labelled cells were enlargement  $(L_{4,-7})$  a substantial number of labelled cells were also noted in lamina VIII. All of these ventral horn cells were found more frequently contralateral to the injection sites and some could be noted to decussate at their segmental level of origin. Controls indicate that these neurons were probably not labelled by damage along the electrode tract. Analysis of the distribution of labelled cells indicates that lower lumbar LAPN's may project more strongly to upper cervical levels where they may interact with short descending propriospinal neurons to exert an effect on cervical motor output. Upper lumbar Upper lumbar LAPN's may project more strongly to the cervical enlargement than the  $C_{3-4}$  region and thus exert their effect more directly. Supported by USPHS NS17531

MUSCLE RECEPTOR INPUT AND INHIBITION IN DSCT. C. E. Osborn and R. Neurophysiol., Univ. of Minnesota, Poppele, Lab. of eapolis, MN 55455. Minneapo

During stimulation of peripheral nerves DSCT units may respond with one of 3 patterns of either inhibition or excitation (Know et al., <u>J. Neurophysiol. 40</u>: 626, 1977). Monosynaptic excitation is the least common (20%), but the only response for which muscle receptor input has been examined (Oscarsson, <u>Physiol. Rev.</u>, receptor input has been examined (Oscarsson, <u>Physiol. Rev.</u>, <u>45</u>;495,1965). We have therefore investigated the receptor input responsible for polysynaptic inhibition or excitation, in DSCT units by recording activity during muscle stretch and contraction. Activity of isolated DSCT units was recorded from the dorsolateral funiculus, and cross-correlated with the Poisson-distributed pulse train (mean rate g(mac) und the dorsolateral functions, and cross-correlated when the Poisson-distributed pulse train (mean rate 8/sec) used in producing stretch, contraction of the gastrocnemius-soleus muscle, or stimulation of the muscle nerve. For most of the 79 units recorded, contraction was the most potent stimulus, and inhibition the most common response. The cross-correlogram illustrated below was typical of the responses of the largest class of DSCT units (40%). These units were inhibited during class of DSCI units (40%). These units were initiated uning contraction, stretch and nerve stimulation, although ususally the response to stretch was weak. Activity in Golgi tendon organs (GTO's) is probably responsible for these responses. The inhibition is due to an activation of afferent fibers as evidenced by the fact that electrical stimulation of the nerve produces the same response as contraction or stretch. The weaker response to stretch would also be expected from an effect due to GTO's. The results suggest that GTO's provide a potent, inhibitory source of input to the DSCT. Supported by NIH grant NS 07147

196.10 INTRINSIC ORGANIZATION OF A MOTONEURON POOL. E. Theriault and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario L&N 325.

The cutaneous trunci muscle (CTM) in the rat is a vast sheet of skeletal muscle that underlies back and flank skin, and is reflexly activated by pinching or heating the overlying skin. Functionally the muscle is compartmentalized, in that a localized nociceptive stimulus to the skin elicits a reflex contraction focussed at the muscle region below the stimulus. This reflex behavior however, does not depend upon a segmentally organized central circuitry; while the sensory input is indeed segmental (T4-L4) all the CTM motoneurons are located in the cervical cord, and the motor nerves originate from the brachial plexus. Coul there be an intrinsic <u>anatomical</u> organization of the CTM moto-Could neuron pool that relates to the functionally compartmentalized nature of its reflex activation? The 3-5 major motor nerves were shown to innervate essentially <u>longitudinal</u> bands of muscle; this is in contrast to the more transversely oriented of most activated areas of the muscle. Retrograde transport of HRP revealed that the CTM motoneurons occupy a crescentic region in the most ventral portion of the ventral horn between segments C6 and T1. The motor nerves supplying the most dorsal muscle band were found to originate from a narrow column of motoneurons located at the medial edge of the crescent, but extending over the entire length of the pool. The more lateral muscle nerves, supplying progressively more lateral bands of the muscle, criginated from similar columns in more lateral regions of the crescent. Thus motoneuron columns within the CTM pool seem to correspond to longitudinally-oriented muscle bands. Small nerve twigs within the muscle were then dissected out, their muscle fields determined, and the twigs soaked in HRP. The labelled motoneurons again were arranged in columns but these occupied only portions of the major motoneuron columns. Injections of HRP directly into the muscle gave results consis-tent with the HRP uptake being into one, or a few, nerve twigs. These findings suggest that the <u>behavioral</u> compartments of the CTM are supplied by sub-groups of motoneurons that are probably short portions of the major columns; the portion length reflects the extent of the muscle compartment in the longitudinal axis, and its medio-lateral location, the location of the muscle compartment in the transverse axis. Perhaps during development this spatial organization of the motoneuron pool facilitates access by sensory information to appropriate sub-populations of motoneurons.

DEVELOPMENTAL PROTEIN MALNUTRITION IN THE RAT: CORTICAL 197.1 DEVELOPMENTAL PROTEIN WALNUTRITION IN THE RAT: CORTICAL SINGLE UNIT ACTIVITY. P.J. Morgane, W.C. Stern, W. Pugh\*, and O. Resnick. Worcester Fndn. Exptl. Biol., Shrewsbury, MA 01545 and Burroughs Wellcome, Research Triangle Park, NC 27709. It was reported previously (Stern et al., Developmental Brain Res., 1983) that adult rats born to dams fed a low protein (8% casein) isocaloric diet starting 5 weeks prior to mating showed the following changes in spontaneous activity of single neurons when compared to 25% casein controls: 25% slower mean discharge rate in frontal cortex and b) 70% fewer fast firing neurons. The present study examined a more severe protein malnutrition condition (6% casein) and evalu-ated the effects of dietary reversals at birth or adulthood on frontal cortex unit activity. Methods consisted of anesthetizing male Sprague-Dawley rats from the malnourished, control and diet reversal groups (total n = 37 rats, 700 neurons) with urethane followed by extracellular recording of frontal cortex units using glass micropipettes. Computer analyses consisted of average discharge rates, mean interspike interval (ISI), variability of the ISI (SD/mean) and percent-age of discharges occurring in bursts or pauses.

The 6% casein group produced effects slightly greater than that previously seen for the 8% casein fed rats, i.e., an approximately 30% decrease in discharge rates, a tripling of the mean ISI, more slow firing cells, and less bursting activ-ity than the 25% casein controls. When the 8% and 25% casein data were analyzed according cortical depth, the most profound differences were noted from 600-1200 microns below brain surface (layers III and IV) where average discharge rates (2-4/sec) were only half that of the 25% control (6-9/sec). The effects of diet reversal at births (8%+25% diet or

vice versa) which were continued until adulthood showed that introduction of the 8% casein diet at birth produced effects on frontal cortex activity comparable in magnitude to when the 8% diets were started prior to gestation. However, resto-ration of a normal diet at birth to an <u>in utero</u> malnourished rat pup failed to reverse the malnutrition effect. Dietary reversals for 2-3 months in adulthood demonstrated that the 25%+8% condition showed no appreciable change from the 25% control group. Similarly, the 88+258 adult reversal did not alter the 88 diet induced changes. Thus, the rat brain is vulnerable to the effects of protein malnutrition starting <u>in</u> <u>utero</u> and at birth, but not starting in adulthood. Dietary restoration introduced as early as a birth following gesta-tional malnutrition is an insufficient means for normalizing cortical neuronal activity in adulthood. (Supported by grant HD06364 and funds from Burroughs Wellcome.)

197.3 GANGLIOSIDES ALTER FUNCTIONAL NEONATAL DEVELOPMENT: INCREASED TURNOVER OF ONS MEMBRANE PROTEIN.

DURIOUER OF UNS MEMBERANE HEILEIN. S.P. Mahadik and Stephen E. Karpiak, Division of Neuroscience, NYS Psychiatric Institute and Depts. of Biochemistry & Psychiatry, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032. Various studies report that exogenously administered gan-tice of the studies of the stud

Various studies report that exogenously administered gangliosides enhance 1) neurite outgrowth in vitro; 2) peripheral nerve regeneration and 3) GNS neuronal regeneration. We have examined the effects of exogenous gangliosides on neonatal rat learning behavior. Rat pups were given injections (daily: sub.cu) of 2.5 mg of total brain ganglioside (average composition: GD1b 16%; GT1 19%; GM1 21%; GD1a 39%). Controls received saline. The neonates were trained and tested for learning on a multi-directional avoidance paradigm on postnatal (PN) days 11,12 & 14. It was found that the rats treated with ganglioside acquired the learned behavior at a significantly faster rate than controls (p<0.01). Further, in testing the rats for retention of the behavior (after skipping a day with no-training) it was found that the rats injected with gangliosides showed 15-20% improved performance, whereas controls showed a 10% loss 15-20% improved performance, whereas controls showed a 10% loss in memory for the task (p<0.01). We have also tested the effectiveness of individual ganglioside species [supplied by Fidia Research Laboratories, Abano Terme Italy]. These include GMI, GDIa, GDIb, and GTIb (sub.cu.:0.5mg/rat/day). Preliminary re-Sults show that GMI and GDIb were as effective as the total gan-glioside injections in enhancing the behavioral performance of the rat pups. GDIa and GTIb were not effective. To study the possible mechanisms by which gangliosides ex-

ert their effect(s), we studied the extent of glucose utiliza-tion in the biosynthesis of cytosolic and membraneous proteins in the CNS. Rat pups (n=16) treated (supra) with total ganglioin the GIS. Ref pups (here) there is a super with total gaugito-sides were given i.p. injections on PN days 10 & 15 of 10 CC [ $\mu$ -14]C-Glucose and killed 3hrs later. Saline treated pups were similarly injected (n=16). Cytosolic and membrane fractions were isolated from brains (minus cerebellum) and [14]C counts incorporated into proteins were determined. At PN days 10 & 15 Incorporated into proteins were determined. At FN days 10 & 15 the levels of [14]C in cytosolic proteins were the same for both groups, whereas levels in membrane proteins were slightly increased at PN day 10, and 30% increased at PN day 15. Total brain wet weight, as well protein levels in cytosolic and mem-brane fractions were similar for all groups. Weight gain for both groups was identical. Our data suggests that ganglioside injections alter membrane protein turnover. This may reflect ac-celerated neuronal maturation and/or an increase in neuronal sy-nantogenesis and dendrogenesis naptogenesis and dendrogenesis.

PRENATAL ASPIRIN: EFFECT ON AMBULATION AND ONE-WAY AVOIDANCE 197.2

PRENAIAL ASPIRIN: EFFELI ON AMBULATION AND UNE-WAY AVOIDANCE IN MICE. C. L. Randall, R. F. Anton\*, G. E. Hoffmeyer\*, and C. J. Wallis. Veterans Adminstration Medical Center and Medical University of S.C., Charleston, S.C. 29403 Aspirin (acetylsalicylic acid, ASA) is one of the most com-mon over-the-counter drugs ingested by pregnant women. Animal studies have shown aspirin to be a potent teratogen. However, in humans, the literature is not clear. Prospective clinical studies are difficult to conduct sicce many composed and provide the studies of the stud in humans, the literature is not clear. Prospective clinical studies are difficult to conduct, since many commercial pre-parations contain ASA. Aspirin use may be denied upon inquiry when, in fact, it was ingested. Given the fact that aspirin is teratogenic in animals and possibly humans, it is of interest to determine whether aspirin use during pregnancy alters behavior in the offspring. We measured spontaneous ambulatory activity and one-way active avoidance behavior in mice exposed to ASA. to ASA in utero.

to ASA in utero. Pregnant C3H mice were injected (s.c.) from Gestation Day 14-parturition with either buffer, 150, or 250 mg/kg ASA. A separate buffer group was run with each aspirin dose because they were not run simultaneously. The data were analyzed accordingly. Litter size, birth weight, sex ratio, and pup viability were recorded at parturition. At 20-25 days of age, 1-2 females/litter were tested for ambulatory behavior in an automated open-field apparatus for 4 consecutive 5 minute periods. Males (1-2/litter) were tested at 35-40 days of age in an automated one-way avoidance chamber for 5 blocks of 10 consecutive trials. consecutive trials.

The results demonstrated a significant increase in gestation length in the 250 mg/kg dose group as compared to buffer but no difference on this measure in the 150 mg/kg group. The acti-vity and avoidance data were analyzed as a 2-factor ANOVA with repeated measures with equal N using each subject as an indivi-dual unit. Individual comparisons were made by Newman Keuls test. Data analysis revealed that ambulatory activity decreased significantly across blocks of time in all groups (p<0.01). There was no effect of 150 mg/kg aspirin on ambula-tory activity, while 250 mg/kg aspirin reduced ambulatory acti-vity in all time blocks (F(1,22)=12.02, p<0.01). There was no significant interaction between time and treatment. The one-way avoidance task failed to reveal a significant difference between the 150 mg/kg and buffer groups in the percent avoidance responses. One way avoidance testing in the 250 avoidance responses. One way avoidance testing in the 250 mg/kg group and their buffer group is in progress as are tera-tologic studies at these doses. These data imply that aspirin may be a behavior teratogen in mice. (Supported by the Veterans Administration and grant #AA04574 from NIAAA.)

PRENATAL EXPOSURE OF GUINEA PIGS TO A 2450-MHz CW MICROWAVE FIELD. 197.4 Mary Ellen O'Connor and David A. Bartsch\*. Bioelectromagnetics Research Laboratory, Department of Psychology, University of Tulsa Tulsa, OK 74104.

This matted female guinea pigs were exposed on gestational days Time mated female guinea pigs were exposed on gestational days 18 through 25 to 2450-MHz CW microwave radiation. The power den-sity of the field averaged 28 mW/cm<sup>2</sup> and was endured for 60 min-utes on each of the 8 days. Ambient temperature was  $20.5^{\circ}$ -21.7°C and relative humidity was maintained at 50%. Pre- and post-expo-sure rectal temperatures were taken. Pre-exposure temperatures are apprendiced at 27 C<sup>o</sup> sure rectal temperatures were taken. Pre-exposure temperatures averaged 37.6°C and post-exposure temperatures averaged 39.5°C. Caeserean sections were performed on day 60. The number of live offspring were noted. Measures of body mass, external skeletal development, and crown rump length were taken. Following the gross skeletal examination the brain was removed and assessed for mass. One fetus per litter was placed in alcohol for further histological examination of skeletal maturity. No abnormalities were observed in either the exposed or the control litters. Anal-ysis revealed no differences in brain mass, body mass, or body length. Commared to data on the teratogenic effects of heat Analysis revealed no differences in brain mass, body mass, or body length. Compared to data on the teratogenic effects of heat stress -- the results are somewhat surprising. It would appear that the temperature change (of nearly 2°) is not the critical factor in inducing abnormalities. Previous reports indicate that guinea pigs are more teratogenically susceptible than other ro-dents and also that some abnormalities should be expected to occur at the temperatures that were used in the present study. The heat that resulted from expected to accurate at the temperatures that were used in the present study. Ine heat that resulted from exposure to microwave radiation apparently is not as stressful as heat induced by other means. Data will be compared to measures taken on guinea pigs exposed under identical conditions but at intensities that will raise the maternal temperature to nearly 42°C.

197.5 DIFTARY DEPRIVATION OF LINOLENIC ACID IN DEVELOPING RHESUS MONKEYS: EFFECT ON VISUAL FUNCTION BUT NOT DISCRIMINATION LEARNING, M. Neuringer\*, C. Van Petten\*, W. E. Connor\*, and L. Barstad\* (SPON: L. Gronke). Oregon Health Sci. Univ., Portland 97201, and Oregon Regional Primate Res. Ctr., Beaverton 97006. Linolenic acid (LA) is the detary precursor of docosahex-aenoic acid (DHA), a major fatty acid in synaptic and photo-receptor membranes. In rats, dietary deprivation of LA produces depletion of DHA from brain and retina, reduction of electroretinogram amplitudes, and impaired learning of a visual discrim-

ination. We are examining the effects of dietary LA deprivation during prenatal and postnatal development in rhesus monkeys. Semipurified diets low in LA (safflower oil as only fat source, LA < 0.3% of total fatty acids) were fed to one group of adult female rhesus monkeys throughout pregnancy and to their infants from birth. A control group of mothers and infants received similar diets supplying ample LA (soy oil as only fat source, LA = 8% of total fatty acids). In the plasma phospholipids of adult females fed the low-LA

diet, the percent composition of LA fell to 5% of the levels in the control group, but DHA was conserved relative to LA and remained at approximately 75% of control values. In the plasma phospholipids of the LA-deprived infants, LA was undetectable and DHA levels were dramatically and progressively depleted, falling from 50% of control values at birth to 15% at 4 weeks, 9% at 8 weeks, and 6% at 12 weeks of age. In other plasma lipid classes, DHA was undetectable by 12 weeks.

In order to assess visual function, we measured the infants' visual acuity at 4 and 8 weeks with the forced-choice preferential looking method. Compared to control infants, the LAdeprived infants' acuity thresholds were reduced by 30% at 4 weeks (p < .05) and by 50% at 8 weeks (p < .0001); their acuity failed to improve significantly between 4 and 8 weeks, whereas control infants demonstrated the expected two-fold improvement.

Starting at 6 weeks of age, the learning ability of LAdeprived infants was tested in a reversal learning task. We used a spatial, rather than visual, discrimination in order to assess learning apart from visual loss. The number of trials and errors required to learn 6 successive reversals did not differ between deprived and control infants. A previous study reported a learning deficit in LA-deprived rats, but used a visual discrimina-tion. If rats and monkeys are affected similarly by LA depriva-tion, then the previous study's results were probably due to the visual nature of the task rather than an inability to learn.

These results suggest that LA may be a dietary essential fatty acid, and that DHA may have a specific function in photoreceptor membranes. (Supported by NIH grant AM-29930.)

197.7 A SELECTIVE ENZYMATIC LESION IN THIAMIN DEFICIENCY.

G.E. Gibson, H.J. Ksiezak-Reding\*, K.-F.R. Sheu,\* V. Mykytyn,\* and J.P.Blass. Cornell University Medical College, The Burke Re-habilitation Center, White Plains, NY 10605.

Thiamin deficiency is a convenient animal model of dementias in man and of selective vulnerability to metabolic insults. Thi-amin deficiency was produced in male Wistar rats (40-50 g) that were fed a thiamin deficient diet and injected daily with the centrally-acting thiamin antagonist pyrithiamin. After thirteen days, the animals developed gross neurological symptoms (tremors, seizures and Wooley-White reflexes). Daily injections of thiamin for seven days reversed the behavioral deficits. The forebrains for seven agy reversed the behavior dentries. The reference the of both symptomatic and reversed rats were used to determine the effects of thiamin deficiency on the <u>in vitro</u> production of  $CO_2$  and acetylcholine from  $[U-^{14}C]$  glucose, and the activities in the brain of thiamin dependent enzymes [pyruvate dehydrogenese complex (PDHC), 2-oxoglutarate dehydrogenese complex and transketolase] as well as other non-thiamin dependent key energy metabotolase] as well as other non-thiamin dependent key energy metabolism enzymes (hexokinase, NAD-glutamate dehydrogenase, phosphofructokinase and PDH-phosphatase). The thiamin dependent enzymes were assayed in the presence of saturating quantities of thiamin pyrophosphate (TPP), so that any reduction should reflect loss of apoenzyme. In symptomatic animals, ACh (106.5  $\pm$  6.0% of control value) and CO<sub>2</sub> (98.5  $\pm$  2.5%) production in low K<sup>+</sup> buffer remained normal. However, the brains from symptomatic animals did not show a K -stimulated increase in ACh or CO<sub>2</sub> production. Values for both variables with low and high K<sup>+</sup> incubation were normal in reversed animals.  $(114.4 \pm 7.9\%)$ , NA The non-thiamin-dependent enzymes hexokinase reversed animals. The non-thiamin-dependent enzymes next inase  $(114.4 \pm 7.9\%)$ , ND-glutamate dehydrogenase  $(97.0 \pm 3.0\%)$ , phosphofructokinase  $(97.4 \pm 6.6\%)$  and PDH-phosphatase  $(105.9 \pm 7.8\%)$  were the same as controls at all stages. PDHC was unchanged in symptomatic  $(96.4 \pm 4.1\%)$  or reversed  $(107.0 \pm 3.0\%)$  animals, whereas the 2-oxoglutarate dehydrogenase complex declined in symptomatic  $(64.4 \pm 4.5\%)$  but not in reversed  $(104.2 \pm 6.6\%)$  animals. Transketolase as assayed in the presence of 11 main-±2.2% of controls in symptomatic animals, and was still dimin-ished to 69.5 ± 1.5% of control after thiamin treatment for seven Agys. A similar decline in transketolase was observed in the ab-sence of TPP. Thus, pyrithiamin-thiamin deficiency caused a se-lective loss of transketolase in reversed animals. Supported by grants NS15125, A04171, Will Rogers Institute, and Brown Williamson Tobacco Company.

EXPOSURE TO ETHANOL IN UTERO ALTERS THE AREAL DISTRIBUTION OF THE INNER MOLECULAR LAYER IN THE DENTATE GYRUS OF ADULT RATS 197.6 FOLLOWING UNILATERAL ENTORHINAL CORTEX ABLATION: A QUANTITATIVE APPROACH USING IMAGE PROCESSING. S.L. Dewey, M.D. Cassell, and J.R. West, Department of Anatomy, University of Iowa, College of Medicine, Iowa City, IA 52422. Characteristic abnormalities of the fetal alcohol syndrome

(FAS) include a host of facial and organ system malformations and central nervous system dysfunction. Previously, we reported that prenatal ethanol exposure permanently altered both the hipthat prenatal ethanol exposure permanently altered both the hip-pocampal mossy fiber teminal field (West et al., <u>Science</u>, <u>211</u>: 856, 1981) and the post-lesion Acetylcholinesterase (AChE) staining pattern in the dentate gyrus of adult rats (Dewey et al., Soc. Neurosci. Abstr., <u>8</u> (1982) 182. Utilizing the Timm's sulfide-silver staining technique, we chose to ivestigate whether the post-lesion staining pattern observed in the dentate gyrus of the hippocampal formation was altered in animals that received 35% ethanol derived calories (EDC) throughout days 1-21 of gestation and unilateral entorhinal lesions as adults. Fol-lowing a survival period of at least 30 days, animals in the lesioned groups were transcardially perfused and processed for Timm's histochemistry. The hippocampi of the selected coronal Timm's histochemistry. The hippocampi of the selected coronal sections were photographed at 4X using Kodak Plus X Pan 35mm Film. The mounted photographic negatives were presented to the camera of the image processing system (EyeCom II/PDP-11/34) by backlighting from a UL700 light table. Following digitization of the mage, the contrast range in the image was expanded such that the differences in the staining pattern were enhanced. By first manually tracing the outline of the molecular layer, the area of the inner molecular layer was determined as a percentage of the total molecular layer. Animals exposed to ethanol in utero showed a significantly (p < 0.01) larger inner molecular layer area as compared to normal lesioned controls. These changes are reminiscent of those observed following unilateral entorhinal cortex ablation in younger (rather than mature) rats. Supported in part by grant AA03884 to J.R.W.

197.8 NEURONAL MIGRATION IN PROTEIN MALNOURISHED RATS. William A. DeBassio\* and Thomas L. Kemper\* (SPON: C. Curcio). Depts. of Neurology and Neuropathology, Boston University School of Medicine, Boston City Hospital, Worcester Foundation for Experimental Biology, (SPON: C. Shrewsbury.

In the mature rat neurogenesis continues in the sub-ependynal layer of the anterior lateral ventricle and the majority of these cells are destined for the 'ntern al granule layer of the main olfactory bulb. This postnatal neurogenesis and migration allows us to study effects of low protein diets on generation and migra-

Rats were fed 8% casein (low protein) or 25% casein (control) isocaloric diets for 5 weeks prior to mating and maintained on these diets until 35 days of age when they were injected intraperitoneally with 5 microcuries per gram body weight of tritiated thymidine as a marker of neurogenesis. The rats were sacrificed at 1, 3 and 6 days and the left anterior forebrain and olfactory bulb was blocked, embedded in epon plastic and se ially sectioned in sagittal plane at a thickness of ser-2 microns. Sections containing the migratory stream were dipped in NTB-2 (Kodak) emulsion and processed according to standard autoradiographic techniques. The migratory stream of each animal was parcellated into sections and counts were made of tagged cells at spec-ific levels along the stream. At 1 day significant differences were seen with control cells showing more heavily tagged cells farther along the stream. However, heavily tagged cells farther along the stream. However at 3 days significantly more tagged cells were seen farther along near the bulb in the experimental group, suggesting that these cells were traveling along more rapidly. At 6 days there were no differences along the stream indicating the rapidly moving cells had arrived at their destination. Calculation of the migratory rates were 600-700 microns/day in the experimental

rates were 600-700 microns/day in the experimental and 450 microns/day in the control group. The early migration lag at 1 day in experimental animals may be related to a longer cell cycle, which occurs in malnourished animals. Our study suggests the brain in the malnourished animals generates cells which migrate more rapidly. This may be an adaptive mechan-ism allowing earlier maturation of neurons. (Supported by NIH Grant 5 PO1 HD 06364).

197.9 DEVELOPMENT IN RAT PUPS ARTIFICIALLY REARED WITH A FORMULA SIMILAR TO RAT'S MILK, J. Diaz, C.R. Stamper, N.S. Auestad and J. Edmond, Dept. of Psych., Univ. of Wash., Seattle, WA,98195 and Dept. of Biol. Chem., UCLA Sch. of Med., Los Angeles, CA,90024. The efficacy of rearing rat pups away from their mother and siblings, and feeding them exclusively via chronic intragastric cannulas, relies on the formula. We have demonstrated that a formula considered an adequate replacement for mother's milk (the "Messer" formula), when used in the artificial rearing procedure yielded pups with significantly lighter brains and heavier livers than their normally reared siblings. These effects were detected within 24 hours of artificial rearing. Closer examination of this formula revealed major differences in its components compared to mother's milk. This experiment examined the effectiveness of a formula which more closely resembles mother's milk. Four day old female Long-Evans rats were assigned by weight to

Four day old female Long-Evans rats were assigned by weight to a normally reared (NR) group or an artificially reared (AR) group. Both groups were subdivided according to the age of sacrifice: day 5,6,8 or 12. AR animals were reared using a formula (RMS-2) developed by J. Edmond and N. Auestad at UCLA. This formula represents a substantial improvement over current rat milk replacements in that the protein/carbohydrate ratio, as well as the osmolarity and the profile of amino acids are all very similar to that of mother's milk. At sacrifice, each animal's brain, liver, kidney and spleen were removed and weighed. The brain was dissected and the cerebellum weighed. The table summings the propert difformers of AH to NE.

The table summarize	es the perce	ent differe	nce of AR	to NR:
Day 5	Day 6	Day 8	Day 12	(* p<.05)
Body Weight3%	-11%*	-16%**	-6%	(** p<.01)
Whole Brain2%	-4%	-12%**	-11%**	
Cerebellum =	-3%	-17%**	-16%**	
Liver3%	-4%	-3%	+33%**	
Kidney3%	-6%	-7%	+16%**	
Spleen25%*	-42%**	-36%**	+60%**	
			· · · ·	

The incidence of gastrointestinal complications in the AR animals, which has been <5% with the Messer formula was 43% in this experiment.

With the Messer formula, brain weights decreased within 24 hours and liver weights increased within 48 hours of artificial rearing. With the RMS-2 formula, there were no differences in these organs at these times. Short term artificial rearing with the RMS-2 formula yielded animals that are not substantially different from their NR siblings. These data indicate that the RMS-2 formula is a significant improvement over the Messer formula in the artificial rearing procedure. However, the data for animals artificially reared for longer than 2 days indicate that relatively long periods of this procedure will require further modifications of the RMS-2 formula.

197.10 EFFECTS OF HIGH AND LOW L-TRYPTOPHAN DIETS IN THE THIRD TRIMES-TER OF MOTHER RATS. <u>M. Sakuma</u>, <u>\*S. Gershon</u>\*, Dept.Psychiat., Wayne State University, <u>951</u> E. Lafayette, Detroit, MI 48207 (Spon:W.P.Clarke, P.D.).

(Spon:W.P.Clarke,Ph.D.) The effects of prenatal exposure to changes in indole and catecholamines were studied in the brains of newborn rats of dams given three different tryptophan diets for a week prior to delivery. It was found that: (1) The mean brain weight of 1-day old pups of the maternal low tryptophan diet group was significantly more elevated than that of controls. The brain weight of pups of the maternal high tryptophan diet (3.0%) group was indistinguishable from that of the controls (0.19%); (2) The concentration of brain tryptophan, 5-HI, 5-HIAA, DOPA, DOPAC, and HVA in low tryptophan and high tryptophan diet groups in 1-day old pups were significantly higher than concentrations of the controls when brain weight of pups was taken into account. Brain levels of indole and catecholamines of the high tryptophan diet groups were significantly higher than those of the controls, whereas 5-HI levels and dopamine metabolites in all diet groups were indistinguishable statistically. Thus, our findings of the low tryptophan diet are consistant with the suggestion of prior studies that the maternal supply during low tryptophan levels provide studies that the put findings of the low tryptophan diet are consistent with pup plasma tryptophan levels provide evidence of a possible difference in metabolites. These findings in pup brain along with pup plasma tryptophan levels provide evidence of a possible difference in metabolits of pups.

NEUROTOXICITY II

198.1

EFFECTS OF PRENATAL LOW LEVEL LEAD EXPOSURE ON MAXIMAL ELECTROSHOCK SEIZURES AND CARBONIC ANHYDRASE ACTIVITY IN NEONATAL RATS. J. C. Coleman\*, J. W. Kemp\* and D. M. Woodbury (SPON: P. Burgess). Dept. of Pharmacology, Univ. of Utah Sch. of Med., Salt Lake City, Utah 84132. Recent studies performed in this laboratory have demonstrated that prenatal, low-level exposure to lead causes alterations in patterns of

Recent studies performed in this laboratory have demonstrated that prenatal, low-level exposure to lead causes alterations in patterns of electrolytes and transport ATPases in the neonatal rat (Coleman, et al., Fed. Proc. 42:1134, 1983). To correlate these changes with possible adverse developmental effects of lead exposure, further studies were performed to analyze seizure activity in neonatal rats by the maximal electroshock seizure (MES) test. Also, carbonic anhydrase (CA) activity was determined in the cerebral cortex and the cerebellum. Female Sprague-Dawley rats were exposed to lead, as lead acetate, via their drinking water. The concentrations of lead used were 0 (control), 40, 80, 160 or 320 mg/l. The females were exposed to the lead for a minimum of eight weeks before mating with normal males. Subsequent offspring were tested on postnatal days 3, 6, 9, 12 or 15. The pups were first subjected to the MES test. The electroshock was given by corneal electrodes with a current of 100 ma for a duration of 0.2 seconds. The degree of seizure response was observed by another member of the laboratory to prevent bias. The intensities of seizure responses were quantified as follows: running seizures were assigned a rating of 1; forelimb clonus was 2; forelimb flexion was 3; hindlimb flexion was 4; and hindlimb extension was assigned a 5. The results of this study show that lead-exposed neonatal rats were more susceptible to the MES test, i.e., lead-exposed rats of the same age as controls had more intense seizures and, hence, were hyperexcitabile. This effect was greatest at earlier ages and was approaching control values at day 15. Others have proposed that the lead-induced hyperexcitability is due to excessive myelination. If this were the case, the activity of the glial enzyme, CA, should be increased. However, in lead-exposed pups the cerebellar CA activity was reduced between days 3 and 9; whereas in the cerebral cortex, CA activity noted in the cereballum of lead-exposed rat upps between 3 and 9 days of age c 198.2 DEVELOPMENT OF LOCOMOTOR ACTIVITY IN RAT PUPS IS ALTERED BY POSTNATAL EXPOSURE TO CADMIUM. Patricia H. Ruppert and Karen F. Dean\*. Neurotoxicology Division, Health Effects Research Laboratory, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Alterations in locomotor activity are a common finding after developmental exposure to toxicants. One type of activity change involves hypoactivity during the neonatal period and hyperactivity during the juvenile or adult period. This biphasic effect on locomotor activity was found in figure-eight mazes following postnatal day (PND) 5 exposure to triethyltin (Reiter et al., Neurobehav. Toxicol. Teratol. 3:285-293, 1981). Exposure of rat pups to 4 mg/kg cadmium on PND 4 was reported recently to produce gross brain damage and juvenile (PND 30) hyperactivity in figure-eight mazes (Wong and Klaassen, Toxicol. Appl. Pharmacol. 63:330-337, 1982). The present study examined the ontogeny of this cadmium-induced alteration in locomotor activity. On PND 5, rat pups (Long Evans; Charles River ) received a single, s.c. injection of saline, 1, 2, or 4 mg/kg cadmium chloride as the base. The volume of injection was 2  $\mu l/g$  . A within-litter design (N=10 litters) was used for dosing; one male and one female from each litter received each dosing; one male and one female from each litter received ea dose and, therefore, each litter contained all treatments. Pups were weighed on PND 5, 10, 15 and 20. Preweaning motor activity was assessed during 30-min sessions in figure-eight mazes from PND 13-21. From PND 13-15, activity of control animals increased both across days and throughout each of the 30-min sessions. A peak in activity occurred in controls on PND 16, after which both within-session and between-session habituation developed. Pups exposed to 4 mg/kg cadmium (which also reduced preweaning growth and produced brain pathology) did not show a peak in activity on PND 16 or subsequent within-session habituation. Initially, high-dose animals were hy-poactive (PND 14-16) but this progressed to hyperactivity on PND 20-21. Preweaning hypoactivity may represent the initial stage in the development of juvenile or adult hyperactivity induced by toxicant exposure. Therefore, age at testing is a critical variable in interpreting alterations in locomotor activity following developmental exposure to toxicants.
CARBON MONOXIDE INDUCED HYPOXIA IN UTERO ALTERS THE POSTNATAL DEVELOPMENT OF ENDOGENOUS NOREPINEPHRINE CONTENT IN THE CERE-198.3 BELLUM OF THE RAT. J.E. Storm and L.D. Fechter. Dept. Envir. HIt Sci., The Johns Hopkins Univ., Baltimore, MD 21205. Previous work has shown that prenatal hypoxia interferes with Dept. Envir. Hlth. Previous work has shown that prenatal hypoxia interferes with the normal development of the central nervous system, leading to changes in susceptible regions that persist into the postnatal and adult periods. One such change is decreased cell number in the cerebellum of 21 day old rats exposed to prenatal carbon mon-oxide (CO) induced hypoxia. We report here that alterations in the progressive postnatal development of norepinephrine (NE) con-tent in the cerebellum also occurs following prenatal hypoxia. Sperm positive female Long Evans hooded rats were placed in one of three chambers supplied with either compressed air or com-pressed air containing 150 or 300ppm CO, and maintained ad libitum until parturition approximately 22 days later. On the day of birth dams and their litters were removed from the chambers and then maintained in a colony room under normal air conditions for the

maintained in a colony room under normal air conditions for the remainder of the experiment. One male pup from each litter was sacrificed on postnatal days 14, 21, 28 and 35. Their cerebelli were rapidly removed, frozen over dry ice and kept at -80°C until assayed for NE content. Unexposed adult male cerebelli were taken assayed for NE content. Unexposed adult male cerebelli were taken for comparative purposes. Final sample sizes were 7 or 8 for each group at each age. Tissue was weighed and homogenized in 10 vols. 0.1N perchloric acid and spun at 3000xg 15 min. NE was extracted from the supernatant and measured using HPLC with electrochemical detection according to a method modified from that of Hefti, et al. (<u>Br. Res.</u>, 195:123, 1980). Prenatal CO induced hypoxia significantly increased mean cerebellar NE content (Two way ANOVA; treatment F(2,80)=4.03, p<.05). These increases were clear at day 14 and persisted at every age through day 35. No differences were evident between the 150 and 300ppm groups so that at each age. mean NE content in both

150 and 300ppm groups so that at each age, mean NE content in both CO exposed groups was 10-20% greater than that of the correspon-ding air exposed group. The general pattern of progressive in-

ding air exposed group. The general pattern of progressive in-creases in NE content during the postnatal period was the same for air and CO exposed groups (Two way ANOVA; day F(3,80)=6.76, p<.01, treatment by day interaction F(6,80)=0.09, N.S.). Gradual postnatal increases of cerebellar NE content are one measure of noradrenergic nerve terminal growth and development in that region. The higher levels of NE observed in CO exposed groups over that of air exposed groups at each age suggests that the de-velopment of normal innervation of the cerebellum by the extrinsic poradrenergic neurons of the locus convolue. or their function noradrenergic neurons of the locus coeruleus, or their function, has been altered by prenatal hypoxia. Supported by EPA grant #R80906101, Health Effects Institute grant #83-1 and NIH grant #ES07094

198.5 SLOW AXONAL TRANSPORT FOLLOWING SINGLE HIGH-DOSE ACRYLAMIDE ADMINISTRATION. B. G. Gold\*, J. W. Griffin and D. L. Price (SPON: A. Pestronk). Neuropathology Lab., The Johns Hopkins

(SPON: A. Pestronk). Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. Acrylamide (AC) produces a distal axonopathy when administered in repeated doses. The mechanism by which AC elicits its neurotoxicity is unknown. Because the axonopathy is associated with distal neurofibrillary pathology, it has been suggested that AC may affect the slowly transported components of the cytoskeleton. A deficit in slow transport is also suggested by our recent observation that a single high dose of AC completely inhibits axonal outgrowth following nerve crush. However, previous studies of slow transport have produced conflicting results. The present study was designed to detect any direct effects of AC on slow transport prior to the development of confounding structural changes.

AC (75 mg/kg, ip) was given to rats 24 hours prior to isotope injection. The lumbar ventral horns of AC-treated and age-matched controls were injected with [<sup>35</sup>S] methionine. Animals were sacrificed six days following labeling and sciatic nerves removed, cut into 3-mm segments, homogenized, aliquots counted, and the proteins separated by gradient SDS-PAGE. Radioactivity in individual proteins was demonstrated by gel fluorography. I In order to determine whether a selective defect exists in the transport of individual slow component polypeptides, the radio-activity of the neurofilament 145 kd protein (NF 145), tubulin, and actin was quantified by cutting, dissolving, and counting their individual bands. Transport velocities were expressed as half velocities (HV); HV for each protein were calculated from plots of cumulative radioactivities by extrapolating to the position along the nerve reached by 50% of the radioactivity.

Inspection of the plots of total radioactivity within nerve segments revealed no apparent abnormality in slow transport peaks. HV, calculated from these data, demonstrated a significant decrease (26%) in slow transport between AC and control groups; HV were reduced from 2.3 to 1.7 mm/day. HV HV of NF 145 protein were significantly decreased from 1.93 to 1.51 mm/day (21%). Tubulin and actin HV were similarly reduced (27% and 25%, respectively) from 2.24 to 1.64 mm/day and 2.22 to 1.67 mm/day, respectively. Morphological studies demonstrated no gross abnormalities (i.e., Wallerian degeneration) during the time of study

These studies demonstrate a modest nonselective defect in the transport of slow component proteins following single high-dose AC intoxication in nerves displaying no evidence of Wallerian degeneration. Future studies will elucidate the possible role of these transport defects in the production of abnormal regenerative properties of nerves from AC-intoxicated animals.

- 5-THIOGLUCOSE PREVENTS GOLD THIOGLUCOSE LESIONS BUT NOT TRIAMINE LESIONS IN THE VENTROMEDIAL HYPOTHALAMUS. D. F. Brown\* (SPON: D. D. Rigamonti). Division of Combat Casualty Care, Letterman Army Institute of Research, Presidio of San Francisco, CA 94129. Recent reports have shown that the triamine, 3,3'-methylimino-bis-(N-methylpropylamine) (MIMPA), produced lesions in the hypothalamus of a variety of rodents, very similar to those produced by gold thioglucose (GTG) in the ventromedial hypothalamus (VMH) of mice (Levine and Sowinski, J Neuropathol Exp Neurol. 41: 54-66. 1982; Fxn Neurol. 70: 462-471 (1983) 198.4 Exp Neurol. 41: 54-66, 1982; Exp Neurol. 79: 462-471, 1983). These authors suggested that MIMPA is a general toxin causing brain necrosis in areas possessing a weak blood-brain barrier. Since MIMPA and GTG are not related chemically but produced hearly identical brain damage, they concluded that GTG causes hypothalamic lesions purely by means of penetrating the hypothalamic lesions purely by means of penetrating the blood-brain barrier. In direct conflict with this idea is the evidence that GTG lesion formation is, 1) not found in the median eminence, 2) sensitive to plasma insulin, glucocorticoid and estrogen levels, hormones involved with carbohydrate metabolism, 3) specific for neural cells and not vascular tissue in the VMH, 4) prevented by glucose transport inhibitors, 5) blocked by abdominal stress, 6) not found in gerbils, 7) increased by a glucose injection, and 8) abolished by mechanical VMH damage. In view of these conflicting ideas, we investigated whether or not 5-thioglucose (5TG), an antimetabolic glucose analog, would prevent the development of GTG and/or MIMPA lesions in the mouse VMH. Female Swiss-Webster mice approximately 3 months of age were used in this study. They were housed at 23 C, on a 12-hour light:12-hour dark photoperiod, fed Purina mouse and rat chow, and given tap water freely. All mice were given 5TG (500 org/kg) intraperitoneally (IP). Thirty minutes later, either GTG (500 or g70 mg/kg, IP) or MIMPA (870 mg/kg, subcutaneously) was administered. The mice were decapitated 24 hours after the GTG or MIMPA was given. The brains were fixed in Bouin's fluid, subjected to routine histology, stained with hemotoxylin and eosin, and examined under the light microscope. Both control groups, GTG only or MIMPA only, developed typical bilateral VMH groups, GTG only of MINTA only, developed typical bilateral VMH lesions. On the other hand, mice challenged with 5TG and GTC did not possess lesions in the VMH, while animals given 5TG and MIMPA displayed typical VMH damage. 5TG is a potent glucoprevic aggent in mice and rats. Presumably, 5TC binds to glucoreceptors in the hindbrain, producing a pronounced hyperphagia. Our results MIMORAIN, producing a pronounced nyperphagia. Our results suggest that 5TC prevented GTG lesion formation by binding to glucoreceptors in the VMH. MIMPA lesions were not inhibited by 5TC, implying that glucoreceptors are not involved with triamine VMH destruction. Moreover, the data demonstrated that although MIMPA and GTC cause similar VMH damage, the mechanism by which each lesion occurs is apparently quite different.
- EFFECTS OF CHRONIC FENFLURAMINE TREATMENT ON THE SEROTONERGIC SYSTEM OF THE YOUNG RAT. P. F. Warren\*, M. A. Peat, C. J. Schmidt\* J. W. Gibb. (SPON: J. A. Madsen) Dept. of Biochem. Pharmacol. & Toxicol., University of Utah, Salt Lake City, UT 84112. Seven day old male Sprague-Dawley rats were housed in a twelve hour light-dark cycle with lactating mothers. At two weeks of age the pups were injected (s.c.) twice daily for 14 days with either 2.5 mg/kg fenfluramine, 7.5 mg/kg fenfluramine, 5 mg/kg d-amphet-amine or saline. Rats were sacrificed by decapitation 24 hours, 3 weeks, 5 weeks or 7 weeks after the last injection and cerebral cortex, neostriatum and hippocampus dissected out. Tissues were frozen at -70°C before analysis. Adult male Sprague-Dawley rats were administered a similar dosage schedule. Tryptophan hydroxy-lase (TPH) activity was measured by a <sup>1+</sup>CO<sub>2</sub> trapping procedure (Life Sci., 25:1373, 1379) and serotonin (5-HT), 5-hydroxyindole-acetic acid (5-HIAA) and tryptophan (TRP) concentrations by HPLC-fluorescence (Anal. Biochem. <u>128:275</u>, 1983). Cortical TPH activity in young rats was still significantly decreased (68% of control) 7 weeks after treatment with 7.5 mg/kg of fenfluramine. However, there was a significant recovery in enzyme activity when compared to that 24 hours after the last in-jection. Although both neostriatal and hippocampal TPH activities were reduced at 24 hours (to 66 and 49% of control respectively) recovery was noted by 7 weeks in the neostriatum and by 5 weeks in the hippocampus. After 14 days of treatment with 2.5 mg/kg fenfluramine TPH activity in the cerebral cortex and neostriatum was decreased 24 hours later to 65 and 68% of control respectively. however, hippocampal TPH activity was not significantly different from control. Seven weeks after treatment ortical and neostria-tal enzyme activities had recovered. Treatment with 5 mg/kg of d-amphetamine only decreased neostriatal TPH activity 24 hours after the last injection. These data show that in young rats there 198.6 EFFECTS OF CHRONIC FENFLURAMINE TREATMENT ON THE SEROTONERGIC

d-amphetamine only decreased neostriatal IPH activity 24 hours after the last injection. These data show that in young rats there is a dose and time dependent recovery of TPH activity in the cerebral cortex, neo-striatum and hippocampus following treatment with fenfluramine. This may be important in view of the recent reports suggesting that fenfluramine is useful in the treatment of autism. Supported by The Thrasher Research Fund.

198.7 PROTEIN I: A BIOCHEMICAL MARKER FOR NEURONAL DAMAGE BY TRIMETHYL-TIN. C. J. Harry\*, J. F. Goodrum\*, M. R. Krigman and P. Morell. Biological Sciences Research Center, University of North Carolina, Chapel Hill, NC 27514.

Protein I is a well characterized nervous system specific phosphoprotein. Immunohistochemical studies have localized Protein I to neurons in all regions of the central and peripheral nervous systems where it appears to be concentrated in presynaptic terminals (Bloom <u>et al.</u>, 1979; DeCamille <u>et al.</u>, 1980). Additional studies have indicated that the developmental appearance of Protein I is a postnatal event (Lohman <u>et al.</u>, 1978) which correlates with the morphological development of synaptic structures in the rat (Crain <u>et al.</u>, 1973). Because of the neuronal localization of Protein I, measurement of its levels may prove to be a useful biochemical marker for neuronal damage following exposure to a neurotoxicant. Examination of the neurotoxic properties of selected compounds by measurement of Protein I in discrete brain regions may reveal alterations or delays in synaptogenesis in developing animals as well as neuronal loss in adults.

To test the possible use of Protein I measurements as an indicator of neuronal damage, we have measured its levels in brain regions of rats treated with trimethyltin (TMT). Adult Long-Evans rats were dosed with either saline or 4 mg/kg TMT for four consecutive days. This dosing regimen resulted in gross manifestations of neuronolgical damage (tremors and seizures) and necrosis of neurons in the hippocampus. Forty-eight hours following the last dose, animals were killed by decapitation and the brains quickly removed. Each brain was dissected into distinct brain regions and stored at -80°C until assayed. Protein I was extracted with citric acid from each distinct brain region sample and phosphorylated in vitro with exogenous protein kinase and gamma  $^{32}P-ATP$  by an adaptation of the method of Goelz et al. (1981). Radiolabelled proteins were separated by SDS gel electrophoresis. Autoradiographs of each gel were scanned for Protein I and areas under the peaks determined. Animals treated with TMT showed a 38% decrease from control animals in the amount of Protein I in the hippocampus.

A similar dosing regimen was used to examine the effects of TMT on the developing animal. Rat pups were dosed orally with either vehicle or 4 mg/kg TMT on postpartum day 10-12. Animals were killed at day 25 by decapitation; brains removed, dissected into distinct brain regions, and stored at  $-80^{\circ}$ C until assayed. The hippocampus of treated animals showed significant decreased level of Protein I compared to control animals While decreases in Protein I appear to be an indicator of neuronal damage, the nature of that damage requires additional specific analysis. Supported by USPHS grants ES07017, ES0104, NS11615.

198.9 INTERACTION OF MERCURIALS WITH MYELIN: COMPARISON OF IN VITRO AND IN VIVO RESULTS. <u>D.A. Kirschner\* and A.L. Ganser</u> (SPON: H.W. Moser). Deparment of Neuroscience, Children's Hospital and Haruard Medical School, Boston, MA 02115.

Moser). Deparament or Neuroscience, Children's hospital and har vard Medical School, Boston, MA 0215. We have previously shown (J. Mol. Biol., 1982, 157: 635) that in vitro exposure of peripheral nerve to mercurials results in either labeling of the phosphatidylethanolamine plasmalogen (with HgCl<sub>2</sub>) or altering of the periodicity and packing of the membranes (with HgCl<sub>2</sub> or CH<sub>3</sub>HgCl). To test whether these in vitro interactions of mercurials with myelin might explain some of their neurotoxic effects, we carried out structural and chemical measurements on myelin from mice intoxicated with these compounds.

on myelin from mice intoxicated with these compounds. Mercurials were administered to groups of mice by four different routes: i.v. injection; i.p. and s.c. injections; inhalation of Hg<sup>O</sup> vapor; and perorally via drinking water. We monitored the mice for signs of neurotoxicity, measured levels of mercury in tissues using atomic absorption spectrophotometry, examined myelin structure using X-ray diffraction, and localized mercury by an electron microscopic histochemical method that uses sulphide to precipitate mercury in fixed tissue. X-ray diffraction is a particularly sensitive way of detecting structural changes and possible chemical labeling in unfixed, intact myelin. Neither i.v. injection (20 & 60 mg/kg) nor i.p. and s.c. injec-

Neither i.v. injection (20 & 60 mg/kg) nor i.p. and s.c. injections of HgCl<sub>2</sub> (1.2 mg/kg/d x 100 d, Mon-Fri) produced neurological symptoms. We found no detectable changes in the X-ray patterns of sciatic and optic nerves, and when these sciatic nerves were treated in vitro with HgCl<sub>2</sub>, the usual changes occurred. Daily exposure (for 40 min) to air saturated with Hg<sup>O</sup> vapor

Daily exposure (for 40 min) to air saturated with Hg° vapor produced a decrease in water consumption and weight after 3-5 d, and neurological symptoms after 6 d. X-ray patterns from the sciatic and optic nerves of severely affected animals were normal.

Even after >400 d of HgCl<sub>2</sub> perorally at 10-20 mg/kg/d, mice did not develop any neurological symptoms. Mercury was not detected in sciatic or optic nerves, but was present in cerebellum (7 ug/g), liver (20 ug/g) and kidney (37 ug/g). X-ray patterns from the nerves were normal, and sciatic nerve was still reactive in vitro with HgCl<sub>2</sub>. No electron dense HgS granules were seen in thin-sections. Mice that received CH<sub>3</sub>HgCl perorally at 10 mg/kg/d lost weight and developed neurological symptoms within two weeks. Tissue levels of mercury ranged from 28 ug/g in cerebellum and 19 ug/g in sciatic nerve to <1 ug/g in optic nerve. However, X-ray patterns from the nerves were normal, and no HgS granules were

We conclude that in vivo intoxication with mercurials does not allow sufficient mercurial to diffuse into and interact with the myelin. This was unexpected in view of the reactive sites in the protein and especially in the lipid of myelin. (Supported by NINCDS #14326).

- 198.8 ALUMINUM LOCALIZATION IN THE RABBIT CENTRAL NERVOUS SYSTEM. G.Y. Wen and H.M. Wisniewski\* NYS Institute for Basic Research in Developmental Disabilities, Staten Island, N.Y. 10314
  - Aluminum is a neurotoxic element. Intoxication of aluminum has been implicated in renal dialysis encephalopathy (Alfrey et al., New Eng J Med 294:184, 1976; McDermott et al., Lancet 1:901, 1978). Aluminum has been known to induce neurofibrillary changes in certain species of animals since 1965 (Wisniewski et al., Klatzo et al., J Neuropath Exp Neurol 24:139, 1965; 24:187, 1965). The nature of neurotoxic action of aluminum is still unknown. This study described the specific association of aluminum with certain cellular components in the CNS of the rabbits.

certain cellular components in the CNS of the rabbits. Rabbits were divided into 3 groups and treated as follows: i) intracisterna-magnum injection of 0.1 ml of 1% AlCl3 or 5 mg of aluminum powders, ii) intravenous injection of 5 ml of 16% aluminum lactate, iii) saline injection as control. Animals were sacrificed by intracardiac perfusion. Silver sulfide EM and fluorescent Morin stain were employed in this study.

Results of this investigation indicate that aluminum in a neuron was associated with the nucleic acids. Aluminum was observed in nucleolus, interchromatin granules, rough ER, free ribosomes, euchromatin and heterochromatin. The consistent association of aluminum with the first four r-RNA containing cellular organelles or components and with the last two DNA containing chromatins suggests that the binding of aluminum to both r-RNA and DNA may be the cause of aluminum neurotoxicity. It may interfere with the normal mechanism of protein synthesis of r-RNA and of the transcription or gene modulation of DNA. Aluminum was not observed in the tangle area. Aluminum was also observed in the astrocytic process and in the nuclei of endothelial cells, pericytes and spinal cord neurons of cerebral cortex and hippocampus and spinal cord neurons. Fluorescent Morin stain also indicate that aluminum was associated with nucleolus, nuclear chromatins and certain cytoplasmic areas, but not associated with fluroescent Morin stain for the same section previously stained with fluroescent Morin stain for the numeron served in the tangle areas of the neurons.

198.10 CLARIFICATION OF APPARENT DESCREPANCIES IN EXPERIMENTAL RESULTS OF LIGHT ENHANCMENT OF THE INHIBITION OF [<sup>3</sup>H]OUABAIN BINDING TO RAT BRAIN MEMBRANES BY ERYTHROSIN B. Sally M. Anderson. Neurotoxicology Section, NINCOS, NIH, Bethesda, MD 20205. Erythrosin B has been demonstated to be a potent in vitro inhibitor of: (1) ATP catalysis by Na,K-ATPase, (2) The efflux of <sup>B</sup>ORb, and (3) the binding of [<sup>3</sup>H]Ouabain to rat brain membrane tissue homogenates (Lafferman, J. and E.K. Silbergeld, Science, 205: 410, 1979; Silbergeld, E.K., Neuropharmacology, 20: 87, 1981). More recently a light-enhanced increase in the potency of the dye's ability to inhibit [<sup>3</sup>H]Ouabain binding to rat brain was reported by Hnatowich and LaBella (Molecular Pharmacology, 22: 687, 1982). However, a significant difference in the effect of this inhibitory action of erythrosin B measured in the light and dark was not observed by Silbergeld et al. (Silbergeld, E.K., et. al., Life Sciences, 31: 957, 1982). The ostensible conflict between the results of these two studies can be explained by differences in the experimental protocols used by these two groups of investigators. Although there are numerous differences in the experimental notocols used by these two research groups the discriminating variable that explains the seeming contradiction between these two studies is time of incubation of tissue with [<sup>3</sup>H]ouabain and erythrosin B

studies is time of incubation of tissue with [>Hjouabain and erythrosin B. The IC50 for erythrosin B inhibition of Type II [3H]ouabain binding (2nM) incubation for 90 min, at 37°C (protected from light) is 2.2  $\mu$ M; the potency of the dye increases when the incubation mixture is exposed to 350 Lux, of light (IC50 = 0.94  $\mu$ M). The amount of inhibition of [3H]ouabain (2 nM) binding by 5 $\mu$ M erythrosin B increases dramatically from 15 to 90 minutes in light-exposed samples, whereas an increase in inhibition in that time period for light-protected samples is not apparent. Similar results were obtained for Type I [3H]-ouabain binding (2M). Therefore, the enhanced potency of inhibition of [3H]ouabain binding to rat brain membrane preparations will be discernible only in results from experimental protocols in which the incubation period is greater than thirty minutes. Studies to elucidate of the differences in the inhibitory processes involved in the light-induced vs. light-protected inhibition of [3H]ouabain by erythrosin B are in progress.

TEMPORAL CHANGES IN DOPAMINERGIC AND SEROTONERGIC FUNCTION 198 11 CAUSED BY ADMINISTRATION OF TRIMETHYLIIN TO ADULT RATS. <u>Diane L.</u> <u>DeHaven, Martin R. Krigman and Richard B. Mailman</u>. Biological Sciences Research Center and Depts. of Psychiatry, Pharmacology and Pathology, Univ. of North Carolina Sch. of Med., Chapel Hill, NC 27514

Trimethyltin (TMT) is known to cause relatively specific lesions of the hippocampus and pyriform cortex (Am. J. Pathol. 104: 237, 1981), and behavioral changes including seizures, hyperactivity, hyperreactivity and memory deficits (Neurobehav. Toxicol. Teratol. 4: 127; 4:177, 1982). Our earlier studies (Soc. Neurosci. Abstr. 8:562, 1982) have shown that a single dose of TMT caused alterations in 5-HT function in several brain regions 7 days post-dosing. The present experiments followed these change at 14, 21 and 28 days post treatment. Male Long-Evans rats (ca. 120 days of age) were administered TMT chloride (7 mg/kg, IG) or The present experiments followed these changes 0.9% saline, and were sacrificed 14, 21 or 28 days later. Striata, olfactory tubercles, nucleus accumbens, frontal cortex, septum, anygdala/pyriform cortex and hippocampus were dissected and DA, 5-HT and their acidic metabolites DOPAC, HVA and 5-HTAA were quantified by HPLC/EC (J. Chromatog.225: 347, 1981), and the ratios of metabolite to parent amine computed. Hippocampal changes were limited to an increase in 5-HIAA at day 28. A similar change in 5-HIAA was seen in septum at day 28, but there was also an increased 5-HIAA/5-HT ratio and decreased DA in this region at days 14 and 21. In amygdala/pyriform cortex, 5-HT levels were decreased at day 14, and DOPAC and 5-HIAA were in-creased at day 28. In striatum, 5-HIAA/5-HT ratios were in-creased at days 14 and 28, whereas DOPAC and HVA were increased only at the latter time. DA concentrations were decreased and 5-HIAA/5-HT ratios were increased at day 21 in olfactory tubercle. In nucleus accumbens, there was a decrease in DA concentration at days 14 and 21, whereas 5-HT was decreased and the 5-HIAA/5-HT ratio increased at day 14. No changes were detected in frontal cortex. From these data, it is clear that a single dose of 7 mg/kg TMT causes profound changes in serotonergic systems that persist, although somewhat attenuated, at least 28 days after treatment. Moreover, there are also less dramatic changes in dopamine systems that appear during the second week post treatment. It is likely that some of these neurochemical perturba-tions, particularly those in the septum and nucleus accumbens, may be related to the known behavioral effects of TMT intoxication.

198.12 EFFECTS OF THIAMIN ON THE NEUROTOXICITY OF LEAD. Ν. D. Woolley-Efigenio\*, D. E. Woolley\*, M. F. Ferrell\* and P. M. Dreyfus\*. Depts. of Nutrition, Animal Physiology and Neurology, Μ.

Univ. of Calif., Davis, CA 95616. Administration of thiamin has been reported to alleviate the neurotoxic symptoms produced by lead exposure in deer, livestock, and rats. The present studies were undertaken to investi-gate further the ability of thiamin to counteract the effects of lead exposure by utilizing the developing, postwearing rat. Neurotoxic effects were evaluated using maximal electroshock sei-zure (MES) patterns. Additional toxic effects evaluated included body growth, food intake, organ weights at autopsy, and tissue levels of lead and certain minerals. Lead exposure was via the drinking water which contained 0.2% lead acetate. In the first study, beginning immediately postweaning at 23 days of age, 3 groups of Sprague-Dawley rats were fed Purina Rodent Chow containing 18 mg thiamin/kg diet. Two groups were exposed to containing 18 mg thiamin/kg diet. Two groups were exposed to lead; animals in one of these groups received daily injections of thiamin sc as follows: 2 mg thiamin/kg body weight from 24-87 days of age, 20 mg/kg from 88-128 days of age, and then 40 mg/kg to 144 days of age. Lead exposure did not alter body growth, but produced an anticonvulsant effect on the MES as shown by increased duration of flexion and decreased durations of full extension and total tonus. Administration of thiamin re-versed most of the effects of lead on the MES. Lead exposure al-so increased kidney weights and treatment with thiamin increased kidney weights even further. Brain levels of lead were not al-tered by the thiamin injections. In the second study, specific So increased kiney weights and treatment with thramin increased kidney weights even further. Brain levels of lead were not al-tered by the thiamin injections. In the second study, specific pathogen free Sprague-Dawley rats were used. Treatment began at 32 days of age and all rats received a semipurfied diet contain-ing either 20 or 0.6 mg thiamin/kg diet. Half of the rats in each group received lead in the drinking water. Body growth rate for the low thiamin plus lead group initially fell behind that of the high thiamin plus lead group. At the end of the study, at 99 days of age, rats in both of the low thiamin groups had the same body weights and weighed significantly less than the two high thiamin groups. The high thiamin plus lead group was the heaviest, weighing even more than the controls (high thi-amin without lead group). Food intake and body weights followed a similar pattern. Kidney:body ratios were increased in the low thiamin group, and even more so in the low thiamin plus lead exposure group. Lead exposure initially had an anticonvulsant effect in the high thiamin group. Low thiamin itself had a con-vulsant effect which was worsened by lead. These preliminary revulsant effect which was worsened by lead. These preliminary re-sults thus indicate that low dietary thiamin levels may exacer-bate the toxicity of lead, and that high thiamin levels may ameliorate it. (Supported by NIH grant ES-01503.)

DIETARY ZINC ALTERS THE NEUROTOXICITY OF LEAD. <u>D. Woolley\*, Z.</u> Hasan\*, L. Zimmer\* and N. Woolley-Efigenio\*. Depts. of Animal Physiol. and Nutrition, Univ. of Calif., Davis, CA 95616. The present study was designed to determine whether or not relatively high levels (100 ppm) of zinc in the diet could coun teract and relatively low levels (2-5 ppm) exacerbate some of the neurotoxic effects of lead exposure. Starting immediately post weaning at 22-24 days of age, Sprague-Dawley rats were fed a conjunction of the diet (Zaiolar Brothers, Carlyners, PA). Lead expos post weaning at 22-24 days of age, Sprague-Dawley rats were fed a semipurified diet (Zeigler Brothers, Gardners, PA). Lead expo-sure was via drinking water which contained 0.2% Pb acetate. To evaluate neurotoxic effects, the duration and phases of the maxi-mal electroshock seizure (MES) pattern were determined at vari-ous time points during the lead exposure. In addition, at 135 days of age animals from each group were implanted with elec-trodes for later study of limbic evoked potentials in unnaes-thetized rate. Lead exposure alowed bedy erouth whether or pot thetized rats. Lead exposure slowed body growth whether or not the diets contained high or low levels of zinc. However, rats on the low zinc diet were affected sooner by the lead exposure, perhaps because lead may increase excretion of zinc which then would increase the growth-retarding effects of a low zinc diet. Animals on low zinc showed much more severe MES seizures than did rats on high zinc, as shown by decreased duration of flexion and increased durations of full extension, total extension and total tonus. Lead exposure had little effect on the MES in rats fed the high zinc diet, whereas lead potentiated the effects of low zinc on the MES, so that rats on low zinc plus lead exposure showed the most severe seizures. Thus, the high zinc diet did

not protect against the growth-retarding effects of lead but did protect against effects of lead on the MES. Plasma zinc levels were significantly decreased in the low zinc group, and were decreased even more by lead administration. High levels of zinc in the diet reduced accumulation of lead in brain when compared with brain levels of lead in animals on low dietary zinc. Levels of zinc in whole brain did not differ in animals on high or low dietary levels of zinc in the absence of lead treatment. Now filetary levers of zhic in the assure of lead treatment. Neither low dietary zinc nor lead exposure altered evoked poten-tials elicited in CA3 of the hippocampus by stimulation of ei-ther the mossy fibers at their origin in the dentate gyrus (DG) or by stimulation of commissural fibers. However, the DG re-sponse to stimulation of the olfactory (prepyriform) cortex was potentiated at high (4/sec) rates of stimulation in the low zinc intake plus lead exposure group, when compared with controls. The latter findings agree with the current observation that the Ine latter rhadings agree with the current observation that the low zinc plus lead exposure group showed the most severe MES seizures and with our previous findings that toxicants which in-crease seizure severity also increase amplitude of the olfactory-evoked DG potential. (Supported by NIH grant ES-01503.)

198.14 BEHAVIOR AND ORGAN WEIGHTS FOLLOWING EARLY CAPSAICIN TREATMENT IN BEHAVIOR AND ORDAN WEIGHTS FOLLWING EARLY CAPSAICIN TREATMENT IN RAT PUPS. E. Murowchick\* and J. Diaz (Spon: I. Bernstein). Dept. of Psychology, Univ. of Wash., Seattle, WA, 98195. Studies in which capsaicin has been given to rat pups have not reported the animals' condition during and immediately after the

treatment. Since the blood brain barrier is not well established in neonatal rats, early capsaicin treatment may be exerting central as well as peripheral effects. This experiment examines the developmental effects of neonatal capsaicin administration.

The developmental effects of monatal capsaltin administration. Long-Evans rat pups were assigned by weight to the capsaltin (CAP) group (n=6) or to the vehicle (VEH) group (n=5). The animals in the CAP group were given daily subcutaneous injections beginning on day 2 and ending on day 6 with the following ascending dose regimen: 25,50,100,100,200 mg/kg. The animals in the UEH group mere injected with the following of the DMSO ascending dose regimen: 25,50,100,100,200 mg/kg. The animals in the VEH group were injected with similar volumes of the DMSO vehicle. Beginning on day 8 both groups were tested daily for negative geotaxis. The occurrence of eye opening and incisor eruption was noted. On day 17, each animal was placed in a plastic tube in a warm incubator (28 C) for five minutes and its core temperature was taken. Immediately following this, the animal was placed in a cool incubator (8-9 C) for an additional five minutes and its core temperature was again recorded. On day 18 each animal was sacrificed; its whole brain, cerebellum, liver, kidney and spleen were removed and weighed.

The initial injections of capsaicin were followed by vocalizations, writhing and in some cases convulsions occurring about five minutes after the injection. Following the injections the capsaicin animals gained less weight than the vehicle animals. There were no significant differences between the groups in the ontogeny of negative geotaxis, the occurrence of developmental milestones, in body, liver, kidney or spleen weights at sacrifice. This table summarizes the remaining means:

BRAIN WT.	CEREB.	WARM TEMP.	COLD TEMP.	DELTA TEMP.
CAP 1.18 g	.116 g *	35.5 C	34.05 C *	-1.48 C **
VEH 1.20 g	.128 g	36.1 C	35.20 C	<b>88</b> C
(* = P<.05; **	= P<.01)			

The decreased growth in the CAP group would suggest a potential problem with nutrition and/or mothering. However, since the groups were not different in negative geotaxis ontogeny, nor in milestone occurrence, frank undernutrition is unlikely. The decreased ability in the CAP group to temperature regulate in response to a mild cold challenge indicates that systems other than pain were effected, perhaps some component of the somatosensory system. The decreased cerebellar weight in the CAP group raises the possibility the capsaicin may effect the central nervous system when given neonatally. Measures more sensitive than gross tissue weights may be necessary to address this issue.

198.15

THE EFFECTS OF POSTNATAL LEAD TOXICITY ON CNS CELL DEATH AND MORPHOLOGICAL DEVELOPMENT OF CEREBELLAR PURKINJE CELLS. D. Lorton and W.J. Anderson. Indiana Univ. Sch. Med., Terre Haute Ctr. for Med. Ed., Terre Haute, IN 47809. Rat pups from pregnant Long-Evans rats were given 600 mg/Kg body weight lead acetate every 24 hrs. beginning one day after birth until cumulative doses of 600, 1200, 1800, 2400, 3000 mg/Kg were administered via stomach intubation. The pups were sacri-ficed every 24 hrs. after administration of the last dose until 10 days of age and also at 21 and 30 days of age. The brains were prepared for histological examination. Pups which received a cumulative dose of 2400 mg/Kg were sacrificed in the same pat-tern as stated above and the brains prepared for Golgi analysis. a cumulative dose of 2400 mg/Kg were sacrificed in the same pat-tern as stated above and the brains prepared for Golgi analysis. Microscopic examination of various brain regions revealed chromo-lytic and pyknotic neurons in many brainstem nuclei, cerebral and cerebellar cortex, and other forebrain structures. These alter-ations had no obvious pattern from one lead exposed brain to the next or with respect to dosage. Examination of camera lucida drawings of Golgi-Cox prepared tissue showed a reduction in the dendritic arborization of Purkinje cells in the cerebellum. In contrast to controls, the dendritic tree frequently did not reach the surface of the molecular layer. There were fewer secondary and tertiary branches on the Purkinje cells. Many of the fine dendritic processes which were present extended from thick den-dritic branches. These results are in agreement with previously obtained data in studies involving dietary lead exposure (Patrick, 1979) which have been criticized due to nutritional deficiency observed in the experimental animals. The effects of malnutri-tion in this study were circumvented by feeding lead acetate directly to the animals by intubation. Thus, the neuronal alter-ations may be attributed directly to lead exposure or may be the result of secondary vascular insults which occur after postnatal lead exposure with rats.

198.16

TOXIC EFFECTS OF MATERNAL EXPOSURE TO TRICHLOROETHYLENE ON BRAIN GROWTH IN RAT PUPS. <u>D. Wines. R. Pfohl" and</u> <u>D. Taylor</u>". Department of Zoology, Miami University, Oxford, Ohio 45056. Trichloroethylene (TCE) is an unsaturated chlorina-ted hydrocarbon widely used in industry. Studies on adult animals have demonstrated that TCE exerts toxic effects on the CNS. Controversy remains regarding the effects of TCE on the developing nervous system. The purpose of this study is to determine if maternal expo-sure to TCE results in anomalous brain growth in pups. Female rats were exposed via drinking water to 2500 ppm TCE from two weeks before breeding until the pups were weaned at 21 days of age. Toxic effects were as-sayed by comparing wet weights and levels of DNA, RNA, and protein in whole brains and cerebella from control and exposed 21-day old pups. In addition, whole brain volume and length and cerebellar width and vermis length were measured in formalin perfused rats. Nucle-ic acids were extracted by a modification of the Schmidt & Thannhauser procedure. DNA was determined by the diperviewing measured by the diperviewing the pup Schmidt & Thannhauser procedure. DNA was determined by the diphenylamine reaction and by a two-wavelength UV absorbance method. RNA and protein were determined by the orcinol and bluret reactions, respectively. No significant differences in the whole brain or

No significant differences in the whole brain or cerebellar volumes, dimensions, or wet weights were noted. Exposure to TCE did, however, result in sig-nificant changes in the levels of nucleic acids and proteins. TCE exposure resulted in a 6% decrease (P<0.01) in the DNA content (or cell number) per gram of whole brain tissue and a 5% increase (P<0.01) in the RNA content per cell. The protein content per gram of cerebellar tissue was 3% less (P<0.05) in TCE-exposed pups than in controls. Decreases in DNA and RNA of 3-4% in cerebella from exposed pups approached signi-ficance (P<0.10). ficance (P<0.10).

ficance (PKO.10). These data suggest that maternal exposure to TCE produces effects in the developing brain. The cerebel-lum may be especially sensitive to TCE exposure as has been reported in adult animals (Haglid et al. 1980. Archs. Toxicol. 43: 187-199). These effects may be due to delayed maturation rather than neural damage. Histological studies are underway to investigate these possibilities. Further experiments are also being conducted to determine if these effects persist into adulthood. adulthood.

#### ACTION POTENTIAL AND ION CHANNELS IV

199.1 MONOCLONAL ANTIBODIES AGAINST THE VOLTAGE-DEPENDENT SODIUM CHANNEL FROM RAT SKELETAL MUSCLE. J. Casadei,\* L. Lampson, E. Bonilla\* and R. Barchi, Depts. of Neurology and Anatomy, Univ. of Penn. Med. Sch., Philadelphia, PA 19104

Penn. Med. Sch., Philadelphia, PA 19104 A panel of monoclonal antibodies that reacts specifically with the saxitoxin (STX)-binding component of the voltage-dependent sodium channel from rat skeletal muscle has been generated. BALB/c mice were hyperimmunized with a partially purified preparation (~1250 pm [<sup>3</sup>H]-STX/mg protein) of the sodium channel protein from rat sarcolemma (Barchi <u>et al</u>. (1980) PNAS 77:1306-1310). A highly purified fraction, (~2500 pm STX/mg) was injected intravenously four days prior to fusion. Hybridomas were generated by fusion of NS-1 cells with spleen cells from hyperimmunized animals. Hybrids were initially screened by a solid-phase radioimmunoassay in which to has one with spin admass were generated by his for the HS-1 terms with spin endpits from hyperimmunized animals. Hybrids were initially screened by a solid-phase radioimmunoassay in which 1251-labelled sheep anti-mouse F(ab')<sub>2</sub> fragments were used to detect antibody bound to the partially purified, immobilized sodium channel protein. Of approximately 2500 hybridoma supernatants tested, 108 gave positive results. A second level of screening was applied to the 57 most reactive cultures by determining the ability of each antibody to specifically immunoprecipitate [9H]-STX binding activity from crude solubilized sarcolemma. Complexes of antibody and sodium channel protein were precipitated by <u>Staphylococcus aureus</u> coated with rabbit anti-mouse immunoglobulins. Of 57 hybridoma supernatants screened, 6 precipitated the sodium channel under these conditions. Of these 6 monoclonal antibodies, 4 are IgG<sub>1</sub> and 2 are IgM. These six hybridomas were subsequently cloned at limiting dilution and grown as ascites tumors. Two of these found and grown as ascites tumors are applied to the solid-phase antibodies were further purified from ascites fluid and covalently coupled to CNB-activated Sepharose 48. These solid-phase antibodies (NRr-activated Sepharose 48. These solid-phase antibodies were shown to precipitate a [<sup>3</sup>H]-STX binding protein from solubilized sarcolemma in a concentration-dependent manner. Specific binding of anti-sodium channel monoclonal antibodies could be detected at the surface of skeletal muscle

antibodies could be detected at the surface of skeletal muscle fibers in frozen section using either fluorescein-or peroxidase-labelled second antibody. Using the indirect peroxidase technique with the electron microscope, specific antibody binding was localized to the plasma membrane at the fiber surface and in caveoli. In addition, specific binding was found in the membranes of the T-tubular system. Specific binding of these monoclonal antibodies was also demonstrated in tissue culture both to L-6 and to primary fetal rat muscle.

199.2 BIOCHEMICAL CLASSIFICATION OF MUTANTS AFFECTING THE VOLTAGE-BIOCHEMICAL CLASSIFICATION OF WORKIS AFFECTING THE VOLTAGES SENSITIVE SODIUM CHANNEL IN DROSOPHILA. L.M. Hall, F.R. Jackson, S.D. Wilson,\* and G.R. Strichartz. Genetics Dept. Albert Einstein Coll. of Med., Bronx, N.Y. 10461 and Dept. Anesthesia Res. Labs., Harvard Med. Sch., Boston, MA 02115. We have found that mutations which cause a reversible, the found that mutations which cause a reversible.

temperature-induced paralysis in the fruitfly <u>Drosophila</u> <u>melanogaster</u> often affect the voltage-sensitive sodium channel <u>melanogaster</u> often affect the voltage-sensitive sodium channel which is involved in the propagation of action potentials. These mutants paralyze at 38°C where wild-type are unaffected. <sup>3</sup>H-saxitoxin binding to membrane extracts prepared from <u>prosophila</u> heads has been used to classify mutants. The <u>seizure<sup>tS-2</sup> (sei<sup>tS-2</sup>)</u> mutant strain shows a temperature-dependent increase in the dissociation constant (K<sub>D</sub>) for saxitoxin binding at 39°C (<u>sei<sup>tS-2</sup> Kp</u>=6.52±0.52nM; wild-type Kp=3.74±0.19nM). The Kp's for mutant and wild-type are the same at 4°C. The total  $K_D$ 's for mutant and wild-type are the same at 4°C. The total number of saturable binding sites (Bmax) was the same in mutant (127± 14.3 fmol/mg protein) and wild-type (135± 7.8 fmol/mg protein) regardless of assay temperature. The seits-2 strain also shows a shift in pH sensitivity of <sup>3</sup>H-saxitoxin binding (seits-2 pKa=6.32, wild-type pKa=5.87). These changes in binding parameters suggest the seits-2 strain has a structural alteration in the saxitoxin receptor. This change appears to be specific for adding abarentryin biding to cholingraphic In the saxitowin receptor. This change appears to be specific for sodium channels because a-bungarotoxin binding to cholinergic receptors in <u>seit<sup>5-2</sup></u> extracts is normal. Another type of mutant-induced change is found in the no-action-potential-temperature-sensitive (nag<sup>15</sup>) mutant strain. This strain shows no effects on KD or on pH sensitivity of toxin binding but does show a dramatic  $\kappa_D$  or on ph sensitivity of toxin binding but does show a durate decrease (30-50%) in the number of saturable binding sites. This reduction is independent of assay temperature. The <u>nap</u> strain appears to affect regulation of saxitoxin receptor number. Although we find no biochemical evidence for structural alterations, we cannot rule out structural alterations such as posttranslational modifications which might affect the efficacy with which channels are incorporated into membranes without affecting the thermal stability or the structure of the saxitoxin-binding site. A third class of mutant binding defect is illustrated by the temperature-induced paralysis-E (tip-E) strain which shows a temperature-induced decrease in saxitoxin binding sites. The suggests a mutant-induced structural alteration that causes enhanced thermal lability. Preliminary studies on the This  $\alpha$ -bungarotoxin binding component suggests that this increased thermal lability may not be restricted to sodium channel components but may also be exhibited by other neuronal membrane components as well. This is different from the nap mutation for which the decrease appears to be restricted to sodium channels. Supported by NIH grants NS 16204 to L.M.H. and NS 18467 to G.R.S.

USE OF GENETIC HETEROZYGOSITY TO DEDUCE THE NATURE OF MUTATIONS 199.3 AFFECTING THE VOLTAGE-SENSITIVE SODIUM CHANNED IN MOTATIONS AFFECTING THE VOLTAGE-SENSITIVE SODIUM CHANNEL IN <u>DROSOPHILA</u>. F.R. Jackson, S.D. Wilson\*, L.M. Hall, and G.R. Strichartz. Genetics Dept., Albert Einstein Coll. Med., Bronx, N.Y. 10461 and Dept. Anesthesia Res. Labs., Harvard Med. Sch., Boston, MA 02115. Mutations which affect the voltage-sensitive sodium channel may

do so by a variety of mechanisms. For example, they might affect channel structure directly by alteration of a gene that encodes a sodium channel polypeptide structural component leading to a change in the primary amino acid sequence of that polypeptide. Alternatively, a structural change could be indirectly induced by mutation of a gene coding for an enzyme involved in the posttrans-lational modification of a sodium channel subunit. Using ligand binding studies alone it would be difficult to distinguish between these two types of alterations, since either could have effects on channel stability or the affinity of the channel for various ligands. The genetic approach of examining the phenotype of heterozygotes (+/m) and comparing them with homozygous wild-type (+/+) and homozygous mutants (m/m) provides one approach to (+/+) and homozygous mutants (m/m) provides one approach to distinguishing different types of structural alterations. For example, a mutation that directly affects a channel structural gene will be <u>codominant</u> because the heterozygotes (+/m) will contain a mixture of normal and mutant channel subunits. The phenotype of these individuals will be intermediate between the two homozygotes (+/+ and m/m). In contrast, a different situation would be predicted for a mutation affecting a channel processing enzyme. Most such enzymes are actually present in excess. Thus, a mutation affecting such an enzyme will be recessing in beterozymotes (+/m) since one normal conv. of the recessive in heterozygotes (+/m) since one normal copy of the gene encoding the enzyme will result in at least 50% of normal enzyme activity. This will generally be sufficient to produce the modification of all channel subunits, and both (+/+) and (+/m) would be wild-type in phenotype. Only mutant homozygotes (m/m)would show the mutant phenotype.

would show the mutant phenotype. Using this genetic approach we have characterized three mutants  $(\underline{sei}^{ts-2}, \underline{nap}^{ts}, and \underline{tip}-E)$  which were described in the previous abstract. Two of the mutants  $(\underline{nap}^{ts} \text{ and } \underline{tip}-E)$  are recessive for both behavioral and saxitoxin-binding phenotypes. The third  $(\underline{sei}^{ts-2})$  is codominant at the behavioral level; heterozygotes  $(\frac{+/sei}{ts-2})$  display paralytic behavior that is intermediate to that seen in wild-type (+/+) and homozygous mutants  $(\underline{sei}^{ts-2})$  heterozygotes. The spectrum of saxitoxin-binding  $\underline{in} + \underline{/sei}^{ts-2}$  heterozygotes. The spectrum of saxitoxin-binding  $\underline{in} + \underline{/sei}^{ts-2}$ with the codominant nature of the mutant effects on behavior makes the seizure strain a likely candidate for one having an alteration in a sodium channel structural gene.

199.4

SODIUM CHANNEL MODIFICATION BY BREVETOXIN B. Virginia Scruggs Luke\* and Toshio Narahashi (SPON: Charles A. Berry). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611. Brevetoxin B (BrTX-B) is one of the toxic components isolated from the dinoflagellate Ptychodiscus brevis which causes "red tide". It consists of eleven ether rings connected in a series in the shape of a ladder with a molecular weight of 894. We hav trudied the effects of BrTX B on the sodium channels of the source We have studied the effects of BrTX-B on the sodium channels of the squid giant axon.

Squid giant axons were internally perfused at  $12^{\circ}$ C with K-free standard internal solution containing 50 mM sodium and 275 mM cesium as replacement for potassium. The external artificial seawater (ASW) contained 100 mM sodium, 360 mM tetramethylammonium, 50 mM calcium and 560 mM chloride. The BrTX-B concentration was 10  $\mu$ M. Sither internal or external annication of BrTX-B depolarized

tetrametry lammonium, so mm calcium and so immicritoride. The BrXAB concentration was 10  $\mu$ M. Either internal or external application of BrXAB depolarized the membrane. The depolarization was reversed by applying 1 mM sodium ASW or tetrodotoxin. The kinetics of the tetrodotoxin sensitive sodium current measured under voltage clamp conditions (holding potential -100 mV) showed that a) BrTX-B had little effect on the time to peak, b) slowed that al BrTX-B had little effect on the time to peak, b) slowed that al ittle effect at more positive potentials, and c) increased the noninactivating steady-state component at all potentials. BrTX-B also had little effect on the sodium tail current following repolarization. The current-voltage relationship in the presence of BrTX-B showed: a) The activation potential was shifted about 25 mV in the hyperpolarizing direction. b) The peak sodium current was only slightly increased at positive potentials, however, as the potential was made more negative, the increase in peak sodium current amplitude became greater. c) The steady-state current was increased at all potentials. d) There was no change in the reversal potential for either the peak or steady-state current.

was increased at all potentials. d) There was no change in the reversal potential for either the peak or steady-state current. In summary, BrTX-B increased both the peak and steady-state sodium current and shifted the sodium conductance voltage dependence in the hyperpolarizing direction. The results are consistent with an interpretation in which BrTX-B at a concentration of 10  $\mu$ M selectively modifies about 20% of the sodium channels by shifting the voltage dependence of activation in the hyperpolarizing direction and preventing inactivation. BrTX-B samples were provided by Dr. Koji Nakanishi of Columbia University, and the present study was supported by NIH grant NS14144. NS14144.

199.5 GATE AND PORE PROPERTIES OF SODIUM CHANNELS IN CRAYFISH AXON MMBBANES TREATED WITH PRONASE AND N-BROMOACETAMIDE. Vincent L. Salgado\*, Jay Z. Yeh\* and Toshio Narahashi (SPON: Donald H. Harter). Dept. of Pharmacol., Northwestern Univ. Med. Sch.,

Chicago, IL 60611. The proteolytic enzyme, pronase, and the protein specific agent, N-bromoacetamide (NBA), both remove the fast sodium inactivation. In the present study, we have found several significant differences between the properties of pronase- and

significant differences between the properties of pronase- and NBA-modified sodium channels. Crayfish giant axons were internally perfused and voltage clamped in a double sucrose-gap chamber. NBA applied internally in K-free solution at 2-5 mM completely removed the sodium inactivation without increasing leakage current. The sodium inactivation in the membrane outside the "node" region, which had been depolarized by K-free internal solution, was not removed as completely as that in the nodal region, which had been held at -100 mV. This residual inactivation could be further removed by NBA provided that the newly established node was held at the hyperpolarized level. Thus, membrane depolarization. the NBA provided that the newly established node was held at the hyperpolarized level. Thus, membrane depolarization, the resultant inactivation, or both protect the h gate from destruction caused by NBA. Pronase treatment at 0.4 mg/ml did not remove sodium inactivation completely. Within 10 min after application at 9°C, 90% of the inactivation was removed, but the remaining 10% was very resistant to further pronase treatment. Any attempts to remove the remaining inactivation such as increasing the concentration of pronase or the duration of treatment resulted in an increase in leakage conductance. After removal of inactivation with pronase, the rising phase of sodium current remained unchanged. With NBA, the rising phase was slowed considerably. With prolonged NBA treatment, the rising phase was slowed even more. This result suggests that NBA modifies more than one site in the channel. The instantaneous current-voltage (I-V) relation was not linear. The current decreased with hyperpolarization beyond -60

The instantaneous current-voltage (I-V) relation was not linear. The current decreased with hyperpolarization beyond -60 mV, and the rectification was intensified by increasing external Ca concentration. This result is interpreted as Ca block of sodium channels. The I-V relation was not modified by pronase or NBA treatment. Impermeant ions applied internally revealed some differences in the pore properties of pronase- and NBA-treated squid axons (Yeh and Narahashi, Biophys. J. 17, 270a, 1977). Such differences were also evident in crayfish axons. When applied internally, 9-aminoacridine blocked the sodium channel. The apparent K<sub>d</sub> values at 0 mV for 9-AA block were 11.3  $\pm$  4.07  $\mu$ M (mean  $\pm$  S.D., n=4) and 19.7  $\pm$  4.96  $\mu$ M (n=6) in NBA-modified and pronase-modified channels, respectively. Supported by NIH grants NS14144 and GM 24866. grants NS14144 and GM 24866.

199.6 A NEUROTOXIC PEPTIDE FROM A MARINE SNAIL THAT PREFERENTIALLY BLOCKS SODIUM CHANNELS IN SKELETAL MUSCLES. <u>Lynne M. Kerr and</u> <u>Doju Yoshikami</u>. Dept. of Biology, University of Utah, Salt Lake

BLUCKS SUDIUM CHANNELS IN SKELETAL MUSCLES. Lynne M. Kerr and Doju Yoshikami. Dept. of Biology, University of Utah, Salt Lake City, Utah 84112. The venom of the marine snail, <u>Conus geographus</u>, contains several neurotoxic peptides with different targets (c.f. Clark, Olivera & Cruz. <u>Toxicon</u> <u>19</u>: 691, 1981). We describe here the effects of one of these peptides, designated as  $\mu$ CgTx, which was obtained in pure form from the laboratories of B. M. Olivera and W. P. Craw in our department.

effects of one of these peptides, designated as  $\mu$ CgTx, which was obtained in pure form from the laboratories of B. M. Olivera and W. R. Gray in our department.  $\mu$ CgTx (~ < 1  $\mu$ M) rapidly, totally, and reversibly blocks action potentials (APs) in muscles of frog and mouse (cutaneous pectoralis and diaphragm, respectively). However, endplate potentials (EPPs) in response to nerve stimulation can still be recorded from muscle fibers after toxin has taken effect. This indicates that  $\mu$ CgTx specifically blocks APs in muscles without blocking AP propagation in nerve.  $\mu$ CgTx appears to be the same as one of the toxins (LIII) characterized briefly by Spence et al. (Life Sci. 21: 1759, 1977). To determine the site of action of  $\mu$ CgTx on muscle, we examined its ability to counteract the effects of the Na<sup>+</sup> channel activator veratridine. Both  $\mu$ CgTx and tetrodotoxin (TTX), a known Na<sup>+</sup> channel blocker, repolarized veratridine-treated frog fibers by about the same amount. This indicates that  $\mu$ CgTx, like TTX, exerts its action by blocking Na<sup>-</sup> channels. Unlike TTX, however,  $\mu$ CgTx does affect Na<sup>+</sup> channels in nerve. Furthermore, the motor nerve terminals in frog are relatively bare and APs therein (which are essential for neuromuscular transmission) are also very susceptible to block by TTX (Katz and Miledi J. <u>Physiol. 199</u>; 729, 1968). usceptible to block by TTX (Katz and Miledi <u>J</u>. <u>Physiol</u>. <u>199</u>: 729, 1968).

In experiments on some, but not all, preparations from frog, the amplitudes of the EPPs were greatly attenuated by  $\mu$ CgTx. This attenuation is not due to postsynaptic effects since miniature EPPs are not affected by  $\mu$ CgTx. It remains to be shown how  $\mu$ CgTx exerts its effect in these instances.

In summary,  $\mu CgTx$  reversibly blocks  $Na^+$  channels in muscles but apparently not in nerve. This suggests that there are differences in the structure or microenvironment of the  $Na^+$  channels in nerve vs. those in muscle.

This research was supported by PHS grants NS15543, NS00465 and an MDA Postdoctoral Fellowship to L. M. K.

EFFECTS OF SLOW INACTIVATION ON PROPERTIES OF SINGLE NA<sup>+</sup> CHANNELS 199.7 MEASURED IN THE ABSENCE OF FAST INACTIVATION. Fred N. Quandt, MEASURED IN THE ABSENCE OF FAST INACTIVATION. Fred N. Quandt, Department of Medical Physiology, University of Calgary, Faculty of Medicine, Calgary, Alberta, Canada T2N 4N1. Voltage-dependent Na<sup>+</sup> channels in nerve membrane appear to have a "slow" inactivation process which reduces the average current across the membrane over a time course 2 to 3 orders of magnitude slower than the kinetics of the activation, or opening, process. Little is known concerning the mechanism by which slow inactivation operates. Single-channel analysis was utilized to study effects of slow inactivation on the properties of single Na<sup>+</sup> channel currents recorded from patches of differentiated NIE-115 neuroblastoma cells. In order to directly study the slow inactivation process, it was useful to eliminate fast inactivation by the brief application of 2-3mM N-bromoacetamide (NBA) to the internal solution perfusing an inside-out patch of membrane. Effects of NBA were consistant with those obtained by Patlak and Horn (J. Gen. Physiol. 79: 334, 1982) in single  $\rm Na^{-1}$  channel studies employing myotubes. Two effects of NBA were obtained: 1) the decline in the probability of the conducting state during a 50 msec depolarization was eliminated; 2) the average lifetime of the conducting state increased, typically by a factor of three (6°C, -20mV). These results confirm the elimination of fast inactivation by NBA for neuroblastoma cells. Following exposure to NBA, Na<sup>+</sup> channels continue to cycle between conducting and non-conducting states during depolarizations over 16 secs. in duration, to potentials ranging from -40 to -10mV, from a holding potential of -90mV. However, the probability of entry into the conducting state declined from initial conditions over a period of 8 - 15 secs.  $(10-12^{\circ}C, -30mV)$  without any change in the amplitude of the conductance of this state. The rate of in the amplitude of the conductance of this state. The rate of decline was faster for greater depolarizations. In the steady-state condition (>2 min.) at any potential, Na<sup>+</sup> channels conduct with only a small probability. In one typical patch which had been exposed to NBA, the total time spent in a conducting state was only 5% of the total observation time (approx. 16 secs.) at 40 min. This proportion decreased with further depolarization (0.5% at -30mV), and openings were not observed at potentials positive to -20mV. These observations are consistant with measurements of Na<sup>+</sup> currents from the whole cell since these potentials lie on the foot of the conductance-voltage curve, yet steady state inactivation (S $^{\infty}$ ) is approaching 0. The slow inactivation process of Na<sup>+</sup> channels in neuroblastoma thus appears to reduce the probability of channel opening relatively independent of fast inactivation, without alterations in conductance of the open state. Supported by the Alberta Heritage Foundation for Medical Research.

 199.9 EFFECT OF SCORPION TOXIN ON THE MEMBRANE POTENTIAL FLUCTUATION OF NEUROBLASTOMA NIE 115 CELLS. K. Iwasa\* and J. Baumgold. (SPON: M. R. Martin). Lab. of Neurobiol., NIMH, Bethesda, MD 20205 Membrane potential fluctuations of neuroblastoma NIE 115 cells

cultured with and without 2% dimethyl sulfoxide (DMSO), were examined. 3 M KCl filled microelectrodes (40-60 M $\Omega$ ) were used for recording the membrane potential and a spectral analyzer (Nicolet 440) was used to obtain power spectra. Buring electrophysiologi-cal recording, the cells were bathed in a medium containing 130 mM NaCl, 5.5 mM KCl, 1.8 mM CaCl<sub>2</sub>, 1.0 mM MgCl<sub>2</sub>, 25 mM glucose and 20 mM HEPES buffer (pH 7.3). Membrane potential fluctuations in-creased in two steps after application of 200 nM scopion toxin (SCTV) curified from Lobuve sciencestricture upper The first (ScTX), purified from <u>Leiurus quinquestriatus</u> venom. The first change took place after about 5 min. and consisted in an enhancean enhancement of fluctuation around 1 Hz which appeared only after 20 min. The first step was less pronounced in cells cul-tured without DMSO. No significant difference in the second phase change was observed in the cells cultured under the two conditions. When  $3\mu$ M tetrodotoxin (TTX) was applied to ScTX-treated cells, the fluctuation around 10 Hz was reduced to control The fluctuation around 1 Hz was unaffected by TTX treatlevels. ment. The resting potential was about -50 mV and -20 mV, respectively, for the cells cultured with and without DMSO. The resting potential was not significantly affected by SCTX or TTX treatment. A peaking of the specta was observed when the fluctuation amplitude around 1 Hz exceeded 1 mV. The peak frequency was 2 Hz in cells cultured in 2% DMSO, and 0.5 Hz in undifferentiated cells cultured without DMSO. The periodic activity of cells cultured in 2% DMSO was suppressed by JuM TTX as well as by 10 mM CoCl<sub>2</sub>. External application of 10 mM CoCl<sub>2</sub>, MnCl<sub>2</sub>, or CaCl<sub>2</sub> were equally effec-tive in reducing the fluctuation around 10 Hz. Although the fluctuation around 1 Hz was not reduced by 10 mM  $CaCl_2$ , it was reduced by 10 mM  $CoCl_2$  or 10 mM  $MnCl_2$ . When 2 mM  $MgCl_2$  and 2 mM EGTA were added to the medium, an enhancement of the 10 Hz component took place together with a reduction of the resting potential. No peaking of the spectra was observed by this treatment. These observations are markedly different from the membrane potential fluctuation of the squid axon [Tasaki & Terakawa, in Cellular Pacemakers, D.O. Carpenter, ed., Wiley, 1982]. We tentatively interpret the fluctuation in the 1 Hz region to be related to a Ca-channel, which seems to be modified by ScTX application. Th spectral change around 10 Hz is attributable to Na-channel and a change in RC-(membrane resistance-capacitance coupling) time con-(Lond.) 278(1978)265, ibid. 292 (1979)297].

199.8 MODIFICATION OF SINGLE SOLUM CHANNELS BY SEA ANEMONE TOXIN ATX-II. S. F. Holloway and C. H. Wu. Dept. of Pharmacology, Northwestern University, Chicago, IL 60611. The kinetics of the Na<sup>+</sup> channel modified by the polypeptide.

The kinetics of the Na<sup>+</sup> channel modified by the polypeptide toxin, ATX-II, from the sea anemone <u>Anemonia sulcata</u> were studied using the patch clamp technique with NIE-II5 neuroblastoma cells. Experiments were performed using the inside-out patch configuration. ATX-II was applied inside the pipette at a concentration of 50-100 nM. The patch potential was stepped to -35 to -25 mV for 180 ms from a holding potential of -85 to -90 mV at 10°C. ATX-II has been found previously to markedly slow sodium inactivation using the voltage clamp technique. Our results at the single channel level indicate that the most dramatic alteration of the channel. The normal Na<sup>+</sup> channel exhibited occasional bursting behavior, but very long bursts were consistently observed

ATX-II has been found previously to markedly slow sodium inactivation using the voltage clamp technique. Our results at the single channel level indicate that the most dramatic alteration caused by ATX-II appears to be a prolongation of burst duration of the channel. The normal Na<sup>+</sup> channel exhibited occasional bursting behavior, but very long bursts were consistently observed for the ATX-II modified channel. In our preliminary experiments, the distribution of burst times in ATX-II showed two exponential components with mean burst times of 3-5 ms and 17-26 ms, as compared to a control which showed only a single exponential time constant of 6-8 ms. The second component seen in ATX-II presumably represents those of the modified channel. The mean open time for the same experiments in ATX-II was 4-10 ms, as compared to a control value of 4-6 ms. The closed time during the burst usually was less than 1 ms. Single channel conductance did not appear to be altered by ATX-II.

When many single channel records were combined to give a pseudomacroscopic current, we observed that ATX-II caused a significant prolongation of the Na<sup>+</sup> current. The time constant of inactivation was lengthened to 80 ms, as compared to a control of 40 ms. When 3-second depolarizing pulses were applied, channel openings with long bursts were observed at the end as well as the beginning of the pulse. Interestingly, we also observed subconductance states in normal and, more frequently, in ATX-II treated membranes. It is very likely that the prolongation of Na<sup>+</sup> current. One possible explanation for this is that ATX-II modifies the channel so that it returns more frequently from a transient closed state

199.10 EFFECT OF VERATRIDINE ON SINGLE SODIUM CHANNEL CURRENTS. Mitsunobu Yoshii\*, Virginia Scruggs Luke\*, and Toshio Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

We have studied the effect of the steroidal alkaloid, veratridine, on the single Na<sup>+</sup> channel currents in a membrane patch excised from the NIE-115 neuroblastoma cell. Veratridine has long been known to depolarize the membrane and cause repetitive firing in nerve and muscle fibers. We have analyzed the veratridine-modified slow component of sodium current in the squid giant axon (Scruggs and Narahashi, unpublished observation) and found that the conductance of the total modified channel population is about 50% of the control. This conductance decrease could be explained by the following hypotheses: 1) the single channel conductance of the modified open state is reduced to 50% of normal; 2) 50% of the modified channels has a normal conductance and 50% is nonconducting; or 3) combination of 1 and 2. The present experiment is designed to distinguish between these hypotheses.

The present experiment is designed to distinguish between these hypotheses. The gigaohm-seal single channel recording technique was used to record currents from isolated membrane patches (inside-out configuration). Extracellular solution contained (in mM): NaCl(125), KC1(5.5), CaCl<sub>2</sub>(1.8), MgCl<sub>2</sub>(0.8), HEPES(20), glucose(25), and sucrose (20). The pH was adjusted to 7.3 by NaOH. Intracellular solution contained (in mM): CsF(150), HEPES(20), and Na-HEPES (1.0). The pH was adjusted to 7.3 by CsOH. Veratridine was added to the external solution contained in the suction pipette at a concentration of 100  $\mu$ M. Veratridine was dissolved in dimethylsulfoxide (DMSO) and the final concentration of DMSO in test solution was 1%. Control experiments showed no effect of 2% DMSO on single channel currents. Temperature was maintained at 12-14°C. Amplitude histograms of the single channel currents showed no significant difference with and without veratridine. Mean amplitudes were between 0.90 to 1.05 pA at the membrane potential of -50 to -40 mV. Probability distribution of the lifetime of the open state revealed a double exponential with time constants of approximately 5 and 20 msec at the membrane potential of -50

Amplitude histograms of the single channel currents showed no significant difference with and without veratridine. Mean amplitudes were between 0.90 to 1.05 pA at the membrane potential of -50 to -40 mV. Probability distribution of the lifetime of the open state revealed a double exponential with time constants of approximately 5 and 20 msec at the membrane potential of -50 to -40 mV under the influence of veratridine in contrast to a single exponential with a time constant of approximately 5 msec in control. The ratio of events which comprise the slower decay to the total number of events was estimated to be 0.4 to 0.5. These results support the hypothesis that the veratridine modified sodium channel is in one of two states, i.e. a state with normal conductance and a prolonged mean open time, or a nonconducting state. Supported by NIH grant NS14144.

TETRODOTOXIN AND SAXITOXIN DISPLACEMENT OF BATRACHO-TOXININ-A BENZOATE BOUND TO VOLTAGE-SENSITIVE SODIUM CHANNELS. George B. Brown and Jack A. Johnston\*. The Neuro-sciences Program and the Dept. of Psychiatry, Univ. of Alabama in Birmingham, University Station, Birmingham, AL, 35294. In one formalism, the voltage-sensitive sodium channel has been characterized as having at least three distinct classes of receptor sites for naturally-occuring neurotoxins. Type I receptors bind saxitoxin (STX) and tetrodotoxin (TTX) which block sodium flux and prevent depolariza-tion. Type II receptors exist for the sodium channel activators batracho-toxin (BTX), veratridine, acconitine and gravanotoxin. The third receptor. tion. Type if receptors exist for the solution channel activators batracho-toxin (BTX), veratridine, acconditione and grayanotoxin. The third receptor, type III, binds the polypeptide neurotoxin from sea anemone and certain toxins from scorpion venom which act by inhibition of sodium channel inactivation (see Catterall, Ann. Rev. Pharmacol. Toxicol. 20:15, 1980, for a review). The binding of toxin at type II and III receptors has been them to be accident. shown to be positively cooperative and an allosteric model describing this interaction has been presented (Catterall, J. Biol. Chem. 252:8669, 1977). Type I and type II receptors, however, have been considered to be 1977). Type I and type II receptors, nowever, have been considered to be distinct and non-interacting (Colquhoun et al., J. Physiol. Lond. 227.95, 1972; Catterall, J. Biol. Chem. 250:4053, 1975). We now present evidence for an interaction between type I and type II receptor sites based uppn the ability of TTX and STX to displace the tritiated BTX analog, H-batrachotoxinin-A benzoate (H-BTX-B), from its sodium analog, <sup>3</sup>H-l

Equilibrium binding of <sup>3</sup>H-BTX-B to sodium channels in rat brain Equilibrium binding of  ${}^{3}$ H-BTX-B to sodium channels in rat brain synaptosomes and microsacs in the presence of scorpion toxin was measured as described previously (Catterall et al., J. Biol. Chem. 256:8922, 1981; Creveling et al., Molec. Pharmacol., in press). At 25<sup>o</sup>C both TTX and STX inhibited the specific binding of H-BTX-B in a concentration-dependent and non-competitive manner. This inhibition was markedly temperature dependent, being negligible at 37<sup>o</sup>C and maximum at 18<sup>o</sup>C, the lowest temperature investigated. H-BTX-B binding in the absence of TTX and STX was, in contrast, temperature insensitive in the range 37<sup>o</sup>C-25<sup>o</sup>C. Scatchard analysis of BTX-B binding isotherms at 25<sup>o</sup>C in the presence and absence of TTX revealed that the iphibition was due to an approx. 3-fold decrease in the affinity of BTX-B inhibition was due to an approx. 3-fold decrease in the affinity of BTX-B binding with no change in the number of receptor sites (Bmax). Com-parison of TTX and STX inhibition of specific H-STX and H-BTX-B parison of 11X and SIX inhibition of specific "H-SIX and "H-SIX-B binding produced superposabale curves, thereby relating inhibition of BTX-B binding to a direct effect of STX or TTX binding at type I receptor sites. Another series of experiments demonstrated that TTX and STX did not alter the binding of scorpion toxin to type II receptors. In agreement with other observations, BTX-B did not have an effect on the binding of "H-STX. We interpret these results to suggest that occupancy of type I receptors by STX or TTX can lead to a conforma-tional meturbation of type I receptors. tional perturbation of type I receptors. CONDUCTION IMPAIRMENT INDUCED BY LOCALIZED COMPRESSION OF IN <u>VITRO RAT TAIL NERVE DETECTED BY TRAINS OF INCREASING FREQUENCY.</u> <u>D.L. Jewett, C. Walden\*, T.C. Chimento\*, and J. Morris\*</u>. Dept. of <u>Orthopaedic Surgery, Special Studies Unit, Univ. Cal. San Fran-</u> cisco, San Francisco, CA. 94143. Acute and chronic nerve compression can be detected from dis-ruption of uniform trains of impulses, well before conduction block occurs. The clinical utility of such a method is limited by the need to record multiple runs to determine the highest conduc-tion frequency. A STIF (stimulus train of increasing frequency)can in a single sweep indicate the highest inter-stimulus frequency which can traverse the compressed region, but analysis of the wave form can be in error when there is summation of potentials at short inter-stimulus intervals. This problem might be expected to interfere with clinical use of the STIF method since surface re-cordings will invole tri-phasic waveforms, some with long lasting slow potentials from the spinal cord. A computerized stimulus and data collection system has been developed which permits reconstruct tion of the individual waveforms despite other interfering waves. The method improves the accuracy so that the compression can be detected when less than 10% of the fibers are affected, and makes the method more appropriate for clinical use. Ventral tail nerves of the rat were studied in vitro before and during compression between segments of plastic tubing, controlled within 0.05 mm. A Nova 3 computer generated SIF patterns of sup-ra-maximal stimuli, automatically averaged 10 repetitions, saved the results on disc, and then repeated the sequence over and over, using one less stimulus in the SIIF pattern than the previous time. During data analysis the differences between successive data files yielded the isolated waveforms were then plotted to show the reconstructed waveform.

STIF, and these isolated waveforms were then plotted to show the reconstructed waveform.

Variability in the heights of the STIF responses are due to summation with later potentials. Use of the reconstruction algor-ithm allows accurate evaluation of the effects of compression as ithm allows accurate evaluation of the effects of compression as compared to before compression. As compression is prolonged or in-creased, there is an increase in the interstimulus interval first showing a decrement of 10% in the height of the wave. This method thus allows detection of the fibers most affected, at minimal im-pairment, when the nerve is still conducting. If the compression is sufficiently great to block some of the fibers(first wave amp-litude decreased compared with the pre-compression recording) then the frequency block is still apparent, so that this method also applies to those cases where only part of the nerve is functioning. The accuracy of the reconstructed waveform allows for the use of a template reconstruction from the first wave in clinical use, which would not require multiple STIF averages, as does the tech-nique described here.

nique described here.

COMPUTER SIMULATION OF PROPAGATING ACTION POTENTIALS IN MAMMALIAN MYELINATED NERVE FIBERS. <u>R.M. Siegel\* and M. Rasminsky</u>. Dept. of Physiology, McGill Univ., and Neurosciences Unit, Montreal General Hospital, Montreal, Quebec, Canada. <u>Propagation of action potentials in mammalian myelinated nerve</u> 199.12

Hospital, Montreal, Quebec, Canada. Propagation of action potentials in mammalian myelinated nerve fibers was simulated using published data. The dynamics of the nodal sodium and leak currents were given by voltage clamp data from rabbit sciatic nerve myelinated fibers obtained at 14°C (Chiu et al., J. Physiol. 292:149, 1979). Nodal capacity was 2 pF. The Crank-Nicolson implicit integration method (for which code was kindly provided by Drs. M. Hines and J.W. Moore) was used to solve the system of differential equations describing the cable proper-ties of the fiber. Axon diameter was 10 µm, internodal length 1000 µm and axoplasmic resistivity 100 Ω-cm. The conductance and capacitance assumed for each myelin lamella was 2 mSieman/cm<sup>2</sup> and 1 µF/cm<sup>2</sup> respectively (Brismar, Acta Physiol. Scand. 113:161, 1981). The model fiber was 30 internodes in length and conduction velocity was measured between nodes 15 and 16. At 14°C the nerve impulse propagated at a velocity of 8.4 m/sec and 5.9 m/sec for fibers with 200 and 100 myelin lamella respectively. Measured maximal conduction velocity of rabbit tibi-al nerve myelinated fibers at 37°C is 59 m/sec (Thomas et al., J.N.N.P. 44:233, 1981) which corresponds to a conduction velocity of about 12 m/sec at 14°C (Paintal, J. Physiol. 180:20, 1965). We examined the effect on conduction velocity of changes in maximal sodium conductance and leak conductance. Doubling maximal sodium conductance increased conduction velocity to 11.2 and 9.2 m/sec for the 200 and 100 lamellae fibers respectively. Increasing maxi-mal sodium conductance beyond this point led first to minor dis-tortions in the repolarizing phase of the action notential and

for the 200 and 100 lamellae fibers respectively. Increasing maxi-mal sodium conductance beyond this point led first to minor dis-tortions in the repolarizing phase of the action potential and ultimately to oscillations or failure to return to resting poten-tial. Both of these effects could be eliminated by increasing leak conductance. For example no distortion was seen if a 10-fold in-crease in maximal sodium conductance was compensated with a 4-fold increase in leak conductance; under these conditions the two model fibers conducted at 12.6 and 12.5 m force proceeding.

The task conductance, under these conditions the two models fibers conducted at 12.6 and 12.5 m/sec respectively. To simulate conduction at  $37^{\circ}$ C we assumed a  $Q_{10}$  of 1.8 (Hodgkin & Huxley, J. Physiol. 117:500, 1952) for sodium activation and inactivation rate constants. Computed conduction velocities for fibers with doubled maximal sodium conductance were 20 and 12.5

where for fibers with 200 and 100 myelin lamellae respectively. We conclude that a reasonable simulation of conduction at  $14^{\circ}$ C can be obtained with minimal manipulation of voltage clamp data but that this data cannot safely be extrapolated to  $37^{\circ}$ C.

SELECTIVE CONDUCTION BLOCKADE AMONG DIFFERENT FIBER TYPES IN MAM-MALIAN NERVES BY LIDDCAINE COMBINED WITH LOW TEMPERATURE. G. Strichartz and M. Zimmermann. II. Physiologisches Institut, Universität Heidelberg, D-6900 Heidelberg, GFR The susceptibility of nerve impulses conducted by myelinated (AB-, AS-) and non-myelinated (C-) fibers to the local anesthetic lidocaine was investigated in the cat sural and tibial nerves, in vivo. Animals were anesthetized with sodium pentobarbital. A Derve was stimulated and the compound action potentials (APs) 199.14

In vivo. An timal's were anescherized with solidin periodarbitat. A nerve was stimulated and the compound action potentials (APs) were recorded by pairs of extracellular bipolar electrodes. An intervening segment of nerve 8 mm in length was desheathed enclosed in a plexiglass chamber. The chamber was irrigated with solutions containing different concentrations of lidocaine. The

solutions containing different concentrations of lidocaine. The temperature of the perfusing solution was varied from 33 to 15°C. Electrodes, nerve, and perfusion chamber were immersed in a bath of paraffin oil contained within skin flaps of the leg. With lidocaine concentrations increasing from 0.1 to 1.0 mM, at 33°C, the A6-fibers are blocked in the steady-state at the lowest anesthetic concentration, followed by the C-fibers and finally by the A6-fibers. The extent of conduction block depended on the frequency at which the nerve was stimulated. The amplitudes of the A8- and A6-components of the APs were reduced at the end of a train of 10 stimuli at frequencies above 20 Hz during partial lidocaine blockade. partial lidocaine blockade, suggesting a use dependent block. In contrast, repetitive stimulation of C-fibers at 5-10 Hz resulted partial Hadcame Blockade, Suggesting a use dependent Diokade. In contrast, repetitive stimulation of C-fibers at 5-10 Hz resulted in an increase in the AP amplitude which might be due to either a better synchrony of impulse conduction or to increased impulse currents in individual fibers, whereas it decreased at higher frequencies. The selectivity of the differential block by lido-caine was enhanced when the perfused nerve section was cooled to 25 or 14°C. Although cooling per se reduced the amplitude of the APs and impaired the frequency-following properties of all fiber types, cooling plus anesthetic were markedly synergistic, parti-cularly in the A6- and C-fibers in the presence of lidocaine during repetitive stimulation at 5-10 Hz did not occur in locally cooled nerves. The AP of C-fibers recovered more slowly than the APs of AB- and A5-fibers both when the anesthetized nerve was warmed, and when the anesthetic was subsequently washed out. These results are of clinical relevance, as a differential block of A5- and C-fibers could eliminate pain while maintaining tactile sensation and motor functions. 199.15 CELL-SPECIFIC ACTIONS OF PROCAIME ON MOCICEPTIVE NEURONS IN THE LEECH. J.Johansen<sup>\*</sup>, J.Yang and A.L.Kleinhaus.Dept. Neurology, Yale U. Sch. of Med., New Haven CT 06510. Last year we showed that the local anesthetic procaine,

exerted opposite actions on the membrane potential of identified neurons in the leech i.e. the Retzius cell and the nociceptive

neurons in the leech i.e. the Retzius cell and the nociceptive (N cell) situated laterally in the ganglion. We now report that procaine can further distinguish among subsets of neurons sharing a sensory modality. The effects of procaine on the electrophysiological properties of the leech neurons responding to nociceptive stimuli (N cells) were examined on isolated segmental ganglia of <u>Macrobdella</u>. In the N cell situated laterally in ganglia 7-19, procaine (1-10 mM) produced a dose-dependent depolarization, while in the N cell situated is caused a dose-dependent hyperplayer N cell situated medially it caused a dose-dependent hyperpolari-zation. In addition, the drug greatly prolonged the action potential of the lateral but not the medial N cell. The proceine induced depolarization was abolished in Na-free Ringer while the hyperpolarization was unaffected by changes in Cl<sup>-</sup>, but was enhanced in low K<sup>+</sup>.

In the specialized ganglia 5,6,20 & 21 only two rather than four N-like cells were found. These cells are nociceptive neu-rons by virtue of their response to noxious stimulation of the rone by virtue of their response to noxious stimulation of the skin, the shape of their action potential, and their morphology as revealed by HRP injections. The two N cells in ganglia 5 & 6 responded to procaine like the medial N cell in ganglia 7-19. In addition, they were sensitive to stimulation of the gut wall, which is a unique feature of the medial N cell (Blackshaw et al. J.Physiol.(326),1982). In contrast, the cells in ganglia 20 & 21 responded to procaine as did the lateral N cella. N cells.

In the leech nervous system, cells responding to nocicep-tive stimuli are subdivided into two subsets: a) cells of the lateral type having peripheral receptive fields only and lateral type having peripheral receptive fields only and b) cells of the medial type which innervate an additional visceral field. These results agree with the findings of other studies (McKay et al. Neurosci. Abst.8, 1982) using monoclonal antibody techniques. The two subsets also con-tain conductance mechanisms which respond differently to pro-caine. The opposite actions exerted by procaine on two sub-sets of mechanosensory neurons in the leech nervous system could be the basis of this drug's dual (convulsant and anti-convulsant) effects on mammalian nervous systems. BARBITURATES EXHIBIT SIMILAR ACTIONS ON MEMBRANE PROPERTIES BUT 199.16 Densitive terfects on FIRING ACTIVITY of CRAVETSH STRETCH RECEPTOR. K.-S. Tan\* and S. H. Roth (SPON: K. E. Cooper), Dept. of Pharmacology & Therapeutics, Faculty of Medicine, University of Calgary, Calgary, Alberta T2N 4NI CANDA. We have observed that pentobarbital and phenobarbital produce

We have observed that pentobarbital and phenobarbital produce opposite effects on the extracellular recorded firing activity of the isolated sensory neuron (crayfish stretch receptor). Pentobarbital produced a depression and phenobarbital an excita-tion of firing frequency. Combination of the two barbiturates at effective concentrations produced an additive effect which could result in firing activity that was similar to control. These results suggest that the sites of action of these two bar-biturates are different. Intracellular techniques were utilized to determine whether these two barbiturates produced opposite actions at the membrane level. In general, the effects of the barbiturates on excitable neuronal membrane properties were similar, however, on a molar basis pentobarbital was more effec-tive than phenobarbital. Both barbiturates depolarized the membrane resting potential and decreased the threshold, ampli-tude and first derivative of the action potential. In addition, the duration of the action potential and membrane resistance were increased. The combination of pentobarbital and phenobar-bital resulted in additive offects on mombrane personation. bital resulted in additive effects on membrane properties. bital resulted in additive effects on membrane properties. We propose pentobarbital to have its major effect on sodium channels, with only a minor effect on potassium channels. This would result in the depression of sodium conductance, a depolar-izing shift of the sodium inactivation curve, and a lengthening of the channel inactivation time. In contrast, phenobarbital may activate potassium channels more effectively than sodium channels, resulting in a depression of both conductances, a hyperpolarizing shift of the sodium inactivation curve, and a lengthening of the inactivation time of both channels. There-fore, a differential effect on these ion channels could account for the opposite effects on firing activity. 199.17 A cAMP ANALOG STIMULATES SINGLE INWARD CHANNEL OPENING FREQUENCY and Rhanor Gillette, Neural and Behavioral Biology Program, Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, Illinois, 61801.

Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, Illinois, 61801. The ventral white cells (VWCs) of the marine mollusc <u>Pleuro-branchaea</u> display minutes-long bursts of progressively broaden-ing action potentials. (Gillette, R., 1982, et al., J. Comp. <u>Physiol.</u> 146: 461-4700. These bursts are stimulated by appeti-tive stimuli applied to the chemosensory apparatus, and drive the rhythmic motor output of feeding. (Gillette, M. et al., J. <u>Neurosci</u>. in press). The driving force for VWC bursting is a slow inward current that can be stimulated in the isolated VWC by cAMP agonists and analogs. (Gillette, R., 1981, <u>Neurosci</u>. <u>Abstr. 7</u>: 113). We examined the effects of the membrane-soluble CAMP analog 8-parachlorophenylthio cAMP (CPT-cAMP) on single channels in the VWCs, using the patch clamp technique. The buccal ganglion was removed and bathed in 0.25% Trypsin for 90 minutes, to provide a clean cell surface for patch clamping. The VWC somata were voltage-clamped with a Dagan single elec-trode apparatus, and successive patches were made until one or more ion channels were identified. CPT-cAMP (10<sup>-4</sup> M) was then perfused through the bath. A population of inward current channels was found that is activated concurrent with slow inward current. Channel conductance was typically 20 pS and had a re-vareal optantial between + MONY and the formy. Channels was found that is activated concurrent with slow inward current. Channel conductance was typically 20 pS and had a re-versal potential between +40mV and +50mV. Bath addition of CPT-CAMP increased channel opening frequency, but did not signifi-cantly affect mean open time or conductance. In a typical ex-periment, the opening frequency increased from a baseline of 1.25±0.19 openings/sec in normal saline, to 2.98±0.32 in CPT-cAMP. Mean open time was 7.21±0.87 msec in normal saline and 8.00±0.68 msec in CPTCAMP. CPT-cAMP had no observable affect on outward channels outward channels.

outward channels. Focal depolarization of the patched membrane did not increase channel frequency, indicating that the channel is not directly voltage dependent. However, depolarization of the whole cell did increase channel opening frequency. This suggests that another factor, such as calcium, may accumulate during depola-rization to further increase channel opening frequency. This hypothetical factor would impart the observed voltage dependence of the inward current. Supported by grants PHS 5T32 GM07143 to D.J.G. and NSF BNS 79-18329 to R.G.

A VOLTAGE SWITCHABLE ION CHANNEL: COLICIN E1, A MODEL FOR 199.18

A VOLTAGE SWITCHABLE ION CHANNEL: COLICIN EI, A MODEL FOR NEURONAL CHANNELS? C. Levinthal, M. Cleveland\*, R. Fine\*, F. Levinthal\*, Q.R. Liu\*, Department of Biological Sciences, Columbia University, New York, N. Y. 10027 The bacterial toxin colicin El kills sensitive cells by forming an ion channel in the plasma membrane. This causes the release of the membrane potential thereby stopping oxi-dative phosphorylation. The activity of this channel can be demonstrated in a Mondal black lipid membrane in which it can be Switched on or off by changing the voltage across the membrane (Schein, et al, 1978. Nature,  $\underline{376}$ : 159-163). We have initiated studies of this protein as a possible model system for neuronal ion channels.

The sequence of the 522 amino acids in colicin El is known from the DNA sequence of the gene which encodes it (Yamada et al. PNAS, <u>79</u>: 2827-2831). We have isolated a C-terminal frag-ment, after cyanogen bromide cleavage, which contains 152 amino acids and which has the same channel forming and voltage switch-ing properties as the intact molecule (Cleveland et al. PNAS, June 1983). The C-terminal fragment contains a hydrophobic region of 35 amino acid residues and 41 of the remaining 117 residues are charged at pH7 (22 positive and 19 negative). When the When the uses are charged at pr/ (22 positive and 19 negative). When the peptide is allowed to contact a planar phospholipid membrane or an oil droplet or a hexane droplet, a strong and irreversible at-tachment takes place by means of a hairpin structure formed of two alpha helices composed of the hydrophobic region plus addi-tional residues which provide salt-bridges to hold the ends of the hairpin together. When only the hairpin is inserted in the the hairpin together. When only the hairpin is inserted in the membrane, the channel is assumed to be in the CLOSED state. The time for the voltage induced transition from OPEN to CLOSED or the reverse is of the order of 10's and 100's of seconds. We The take this to imply that a major conformational change is involved in the transition.

We have generated a molecular model of the structure of the channel OPEN: we assume that six alpha helices span the membrane to form a barrel-like structure with a lumen in the center. All the charged residues can be accounted for as those which have their charged groups: 1) 14 charges are in the lumen; 2) 9 reach to the outside of the lipid region of the membrane; 3) inter-helical salt-bridges and 4) 14 are facing into the lipid and can form intra-helical salt-bridges since they are of opposite sign and 3 or 4 residues apart.

We are altering the amino acid sequence of this peptide by  $\frac{\text{in vitro}}{\text{other molecular models and changing the residues pointing}}$ into the lumen in order to alter the ion selectivity and switch-ing properties of the channel.

VOLTAGE-CLAMP ANALYSIS OF MEMBRANE CURRENTS IN HIPPOCAMPAL CA3 200.1 PYRAMIDAL NEURONS. Kerry L. Zbicz\* and Forrest F. Weight (SPON: G. Cordingley). Lab. of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20952. Membrane currents were studied in hippocampal neurons in vitro.

Thin slices (450  $\mu$ M) of guinea pig hippocampus were held submersed in flowing, oxygenated artificial CSF and the neurons in the CA3 layer were impaled with microelectrodes (15-30 megohms) filled with 3 M KCl. Using the single microelectrode voltage-clamp technique, membrane currents were recorded in response to Clamp technique, memorane currents were recorded in response to step changes in membrane voltage. Depolarizing steps from holding potentials negative to -70 mV activated several outward currents, of which at least three could be identified by their kinetics, voltage activation and inactivation characteristics, and their sensitivity to various substances. A fast, transient outward current developed during depolarizing steps to potentials positive to -60 mV. This current was increasingly inactivated as membrane holding potential was changed from -70 mV to more positive holding potential was changed from -70 mV to more positive volt-ages. The transient outward current was reduced or abolished by 0.5-2.0 mM 4-aminopyridine (4-AP). A second current, observed during steps positive to -50 mV, activated gradually over a period of 200-500 msec and showed no apparent inactivation with maintained depolarization. This persistant current was reduced or blocked by 20 uM muscarine, 0.5-2 mM Ba<sup>2+</sup>, and 2-10 mM tetra-ethylammonium (TEA). A third outward current was activated at potentials positive to -40 mV. This current increased gradually and did not reach a maximum value during depolarizing steps 1 sec in duration. This slow current was reduced by the application of and did not reach a maximum value during depolarizing steps 1 sec in duration. This slow current was reduced by the application of the Ca<sup>2+</sup>-channel blockers  $Mn^{2+}$  (2-5 mM) and Co<sup>2+</sup> (2mM), indicat-ing that it is a Ca<sup>2+</sup>-sensitive outward current. In some experi-ments cesium (Cs<sup>+</sup>) was applied intracellularly by impaling neurons with microelectrodes filled with 3 M CsCl. In Cs<sup>+</sup> filled cells, the transient outward current was not observed. The outward current which remained in Cs<sup>+</sup> filled neurons continued to in-crease during depolarizing steps 1 sec in duration and was only observed at potentials positive to -40 mV. This outward current observed at potentials positive to -40 mV. This outward current was reduced by the application of 2-5 mM  $\rm Mn^{2+}$  or 2 mM  $\rm Co^{2+}$ . The outward currents observed in hippocampal CA3 neurons resemble outward currents previously described in other neurons, with the in molluscan neurons, the persistant outward current first described in molluscan neurons, the persistant outward current resembling the M-current described in frog sympathetic neurons, and the  $Ca^{2+}$ -sensitive outward current being similar to  $Ca^{2+}$ -activated K<sup>+</sup> currents described in both vertebrate and investigation fast transient current resembling the A-current first described

DELAYED EXCITATION IN NEURONS OF THE NUCLEUS TRACTUS SOLITARIUS 200.2

STUDIED IN VITRO. N.S. Dekin and P.A. Getting. Dept. of Physiol. and Biophys., Univ. of Iowa, Iowa City, IA 52242. The ventro-lateral region of the nucleus tractus solitarius (NTS) is thought to be involved in the generation of the respiratory rhythm in mammals. Using extracellular recording techniques in vivo sources (associated provinces have respiratory rhythm in mammals. Using extracellular recording techniques in vivo, several classes of respiratory neurons have been characterized in the NIS. The membrane properties of these neurons, however, have not been studied. Using adult guinea pigs, we have developed an in vitro brainstem slice preparation which allows stable intracellular recordings from NIS neurons. Based on electrophysiological criteria we have found four classes of neurons. The most common class exhibits a long delay in the onset of firing when given depolarizing stimuli. This property of delayed excitation was investigated. NTS neurons with delayed excitation was investigated.

A rong denay in the onset of the first synthesis and the depolarizing stimuli. This property of delayed excitation was investigated. NTS neurons with delayed excitation had an average resting potential of -70 mV and an input resistance ranging from 20 to 30 megohms. The membrane time constant, measured by the injection of short hyperpolarizing current pulses, was less than 8 msec. When a depolarizing stimulus was given from rest, the onset of the first spike was delayed 150 to 200 msec from the stimulus onset. The membrane time constant was too short to account for this long delay. The magnitude of the delay was voltage dependent. When a stimulus was given from a membrane potential of -40 mV the delay decreased to 5 msec, while from -90 mV the delay reached a maximum of 400 msec. The magnitude of the delay was also dependent upon the duration of hyperpolarizing prepulses with maximum delays occurring for prepulses of 100 msec or longer. These effects of time and voltage suggest that the delayed excitation was mediated by a transient, outward K current similar to "A-current" in moll uscan neurons (Connor and Stevens, J. Physiol. 213;21,1971).

213;21,1971). At -40 mV these neurons responded to depolarization with an initial high firing rate which could reach 100 Hz. Following Initial high firing rate which could reach 100 Hz. Following this initial firing, spike frequency declined to a steady-state level below 30 Hz. When the same stimulus was given from more hyperpolarized potentials, the initial high firing rate was diminished but the steady-state firing level remained nearly constant. The voltage dependence of the reduction in the initial firing rate parallelled that of the delayed excitation suggesting that both these phenomena were mediated by a similar mechanism. mechanism. As a consequence of delayed excitation these neurons will not always respond in the same manner to a given depolarization or synaptic input. They will, however, display multiple discharge patterns depending upon the membrane potential preceeding the input. (NS15350 and MH15172).

SYNCHRONOUS BURSTS WITHOUT CHEMICAL TRANSMISSION IN CA2-CA3 AND DENTATE AREAS OF THE HIPPOCAMPUS. R. W. Snow and F. E. Dudek. Dept. of Physiol., Tulane Univ. Sch. of Med., New Orleans, LA 70112. Synchronous bursts have been reported in the CA1 region of hippocampal slices in which chemical synapses were blocked, but other regions of the hippocampus appeared to be resistant to this activity (Taylor and Dudek, Science 218:810, 1982; Jefferys and Haas, Nature 300:448, 1982). We now report that when divalent cat-ions were lowered further than in previous studies, synchronous activity could occur in any area of the hippocampus. Hippocampi were removed from rats (95synchronous activity could occur in any area of the hippocampus. Hippocampi were removed from rats (95-200g), and slices were cut parallel to the alvear fibers. Slices were incubated in flowing saline containing 124 mM NaCl, 26 mM NaHCO<sub>3</sub>, 5 mM KCl, 1.24 mM K $_2$ PO<sub>4</sub>, 1.3 mM MgSO<sub>4</sub>, 2.4 mM CaCl<sub>2</sub>, and 11 mM glucose. After 1 hr, the perfusion medium was replaced with one containing 124 mM NaCl<sub>2</sub>, 26 mM NaHCO<sub>3</sub>, 5-6.2 mM KCl, 0-1.2 mM MgCl<sub>2</sub>, 2 mM MnCl<sub>2</sub>, 0.1-0.5 mM CaCl<sub>2</sub>, and 11 mM glucose. Synaptic potentials evoked by orthodromic stimulation were blocked after 15-30 min in these solutions. After 20-60 min the tissue became hyperext solutions. After 20-60 min the tissue became hyperex-citable, and antidromic stimulation could evoke multiple population spikes in any area of the hippocampus. Simultaneous intracellular and adjacent extracellular recordings revealed spikes in pyramidal and granule cells correlated with the extracellular field poten-tials. Subtraction of the extracellularly recorded potential from the intracellular potential revealed net depolarizations of the neurons during the population spikes. In relatively inexcitable neurons, a subthresh-old current promoted firing during the field poten-tials. Although not each region in each slice generated synchronous bursts, spontaneous synchronous bursts were seen in each area of the hippocampus in some slices. A seen in each area of the hippocampus in some slices. A slow extracellular negativity preceded the spontaneous bursts, suggesting that an increase in extracellular  $K^+$  occurred. Extensive random firing of neurons marked the beginning of spontaneous bursts and led to populative distributed for the provide the set of tion spikes, indicating a recruitment of synchrony. We conclude that each area of the hippocampus can generate synchronous bursts in the absence of chemical transmis-sion, and that electrical field effects contribute to the synchronization. 200.4 INHIBITION OF POSTSYNAPTIC FIRING IN THE HIPPOCAMPUS DURING REPETITIVE STIMULATION BLOCKS LONG-TERM POTENTIATION. H. E. Pharm

Scharfman\* and J. M. Sarvey (SPON: A. Williamson). Dept. Phan Uniformed Services Univ. of Health Sciences, Bethesda, MD 20 Long-term potentiation (LTP) in the hippocampus is a long 20814 Long-term potentiation (LTF) in the nippotampus is a long lasting enhancement of synaptic efficacy following repetitive stimulation of a synaptic input. LTP has been proposed to be a model of synaptic plasticity in the central nervous system. Hebb (1949) has suggested that synaptic efficacy increases when one neuron repeatedly causes an action potential to fire in another. Since LTP is a result of enhanced synaptic efficacy, Hebb's postulate could be interpreted to mean that postsynaptic firing is a consticut during the presentier of the provided to is essential during the repetitive stimulation required to produce LTP. Yet it remains to be proven that presynaptic and postsynaptic activity must be coupled during repetitive stimulation to produce LTP. One approach to this problem is to observe whether LTP occurs if the postsynaptic neuron is inhibited during stimulation which otherwise produces LTP. Extracellular recordings from subfield CAl were taken from

Extracellular recordings from subfield CAI were taken from 375um hippocampal slices of the rat. Electrodes were placed in the cell body layer and apical dendritic layer to record the field potential and EPSP, respectively, in response to Schaffer collateral stimulation. Repetitive stimulation of 100Hz for 2 seconds produces post-tetanic potentiation (PTP), which lasts up to 5 minutes, and ranges from 140-210% (n=11). In other slices is also produced, ranging from 130-210% (n=11). In other slices postsynaptic activity was inhibited by local pressure ejection at the soma of GABA (10mM), pentobarbital (100mM-IM), or tetrodotoxin (luM). Each agent was able to block the population spike reversbly without affecting the EPSP. When the population spike tevers blocked during repetitive stimulation, LTP did not occur (n=18). However PTP was not suppressed (n=17). Since tetrodotoxin inhibits postsynaptic activity by an entirely different mechanism from GABA or pentobarbital, the mechanism of inhibition does not appear to be important.

These experiments suggest that postsynaptic firing during repetitive stimulation is necessary for the induction of LTP. Furthermore, it appears that short lasting changes are dependent on different considerations than longer lasting phenomena.

WEDNESDAY AM

- BLOCKADE OF LONG-TERM POTENTIATION IN RAT HIPPOCAMPAL CAI REGION BY THE PROTEIN SYNTHESIS INHIBITORS EMETINE AND CYCLOHEXIMIDE. P. K. Stanton\* and J. M. Sarvey. Dept. of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814. Hippocampal long-term potentiation (LTP) is characterized by a 200.5 long lasting enhancement in the monosynaptically evoked response following high frequency repetitive (tetanic) stimulation. Because The second synthesis of specific protein fractions following there increased synthesis of specific protein fractions following tetrain stimulation in the hippocampus. However, it is not known terance stimulation in the hippocampus. However, it is not known whether protein synthesis is required for, or merely a by-product of, induction of LTP. Therefore, we examined the effects of protein synthesis inhibitors on the induction of LTP. Extracellular monosynaptic potentials evoked in CAl by stimulation of the Schaffer collateral axons were recorded from transverse slices Schaffer collateral axons were recorded from transverse slices 375µm thick) of freshly dissected rat hippocampus. A protein synthesis inhibitor, emetine or cycloheximide, was applied by bath perfusion to the slices for more than 30 min prior to tetanic stimulation of the Schaffer collaterals (20/s x 10s). The evoked response amplitude was followed for 30 min after tetanic stimulation, and percent change from baseline amplitude of the population action potential (AP) was used as the measure of enhancement of synaptic efficacy. An increase of greater than 35% at 30 min after tetanic stimulation was used to define LTP, since this was two standard deviations from the mean control baseline amplitudes. In the control slices, tetanic stimulation produced an this was two standard deviations from the mean control baseline amplitudes. In the control slices, tetanic stimulation produced an increase >35% (range 40-150%) in AP amplitude in 10 out of 20 slices examined. Emetine at 1.5µM prevented the induction of LTP, with 1 of 16 slices showing LTP ( $\chi^2, p \times 0.5$  compared to controls) while at 15µM, 1 of 12 slices exhibited LTP (p < .05). When applied for periods up to two hours, neither concentration of emetine by itself produced a significant change in AP amplitude or any other measure of neuronal excitability. Intracellular recordings indicated that the drug produces no changes in resting membrane potential, input resistance, action potential amplitude or duration (N=5). A second protein synthesis inhibitor, cycloheximide, was applied at 0.35 and 3.5µM. At the lower concentration, LTP was unaffected, with 4 of 6 slices exhibiting LTP. The higher concentration, however, prevented the induction of LTP, with only 2 of 15 slices exhibiting LTP. Neither concentration of the single scheme is the single scheme is the single scheme is the single scheme is the single scheme in the single scheme is the singl with only 2 of 15 slices exhibiting LTP. Neither concentration of cycloheximide by itself produced a significant alteration in neuronal excitability. The data show that increasing concentration of known protein synthesis inhibitors correlates with decreased probability of LTP following repetitive stimulation. These results suggest the necessity for newly synthesized proteins in the induction of LTP.
- NATURE OF 7-14 HZ RHYTHMIC HYPERPOLARIZATIONS IN THALAMIC RELAY 200.7

NATURE OF 7-14 HZ RHYTHMIC HYPERPOLARIZATIONS IN THALAMIC RELAY NEURONS. M. Deschènes\*, J.-P. Roy\* and M. Steriade (SPON: Y. Lebeux). Lab. Neurophysiol., Dept. Physiol., Laval Univ., School of Med., Québec, Canada, GIK 7P4. The most striking behavior of thalamic neurons is their mem-brane potential oscillations during spontaneous spindle waves. Similar oscillations can be triggered by peripheral or cortical stimulation in barbiturized preparations or during slow-wave sleep in behaving animals. It is believed that spontaneous and stimulus-induced oscillations result from the operation of sleep in behaving animals. It is believed that spontaneous and stimulus-induced oscillations result from the operation of similar mechanisms. Both phenomena are indeed characterized by similar temporal patterns of rhythmic hyperpolarizations interrupted by burst discharges. In order to elucidate synaptic and intrinsic membrane properties underlying these oscillations, intracellular recordings were performed in lateral thalamic nuclei of cats under barbiturate anesthesia. We found that long-lacting shuthmic hyperpolarization defined and for the second state of lasting rhythmic hyperpolarizations were made of three different lasting mythmic hyperpolarizations were made of three difference components: 1) The early component which was reversed by current and Cl injections and which was also sensitive to picrotoxin was identified as a Cl-dependent IPSP. 2) A depolarizing hump was usually present in the depth of the long-lasting hyperpola-rization. This intermediate component was identified as a professe identified or and intermediate of revoltage-dependent dendritic Ca conductance on the basis of re-cordings and ECTA injections performed in relay cell dendrites. 3) The late phase of hyperpolarization was dissociated from the early IPSP by its differential sensitivity to current and Cl injections and to conditioning tetanic stimulation. This late com-ponent was abolished by EGTA and, thus, was interpreted as a Ca-dependent K conductance increase triggered by a dendritic Ca influx.

Activation of intrinsic somatic or dendritic conductances by current pulses never generated rhythmic hyperpolarizations in thalamic relay neurons. Recent observation that thalamocortical cells disconnected from the reticularis thalami nucleus no more constillate within the spindle crange shows that an indicates no more oscillate within the spindle crange shows that oscillations are imposed on relay neurons by synaptic inputs. It is then proposed that other thalamic neurons (intranuclear interneurons or reticu-laris thalami neurons) would have pacemaker properties and/or that oscillations would be produced in thalamic cellular pools by for the product interneuron of the spin of th by feedback interconnections. Supported by MRC Grants MT-5877 and MT-3689.

200.6

The EFFECTS of ORIENTATION of DC or AC EXTRACELLULAR FIELDS on EXCITABILITY in the HIPPOCAMPAL SLICE. <u>A.R. Sheppard, S.M. Bawin,</u> <u>M.D. Mahoney\* and W.R. Adey</u>. VA Medical Center and Loma Linda University, Loma Linda, CA 92357. In previous work we showed short and long-term modulation of the excitability of CAl neurons by 60 Hz sinusoidal electric fields (20-60 mV/cm, p-p) applied in the solution perfusing the slice and oriented perpendicular to the CAl cell layer. It was thought that effects might be caused by either the influence of since and oriented perpendicular to the CAI cell layer. It was thought that effects might be caused by either the influence of small rapid changes in potential along a dendro-somatic axis or by a more constant potential difference developed by rectification of the sinusoidal current that enters the dendritic branches. To test for dependence on axial polarizations that would arise from cure change in dendritic entertials are explicited to the alo

from such changes in dendritic potentials, we applied 60 Hz elec-tric fields (10-140 mV/cm, p-p, 10-30s) oriented perpendicular or parallel to the CA1 layer and measured the population spike evoked by test pulses in the Schaffer pathway (SC). As before, we saw long-term potentiation and short-term depression of the evoked potential, but these changes were clearly independent of current orientation.

To determine if CA1 neurons respond to polarizing currents in a direction-sensitive manner in other circumstances, we applied the test pulse during dc pulses (100-170 mV/cm in the bath, 200-400 ms duration). Currents that made the apical dendrites posi-400 ms duration). Currents that made the apical dendrites posi-tive with respect to the soma increased potentials evoked in the CA1 cell layer by test pulses in SC, while the opposite field polarity caused decreased responses. Similar results previously seen in the granule cells of the dentate using tissue field gra-dients of 50-700 mV/cm (Jefferys, 1980) were confirmed in our study. Currents orthogonal to the cell axis had no effect on responses in either CA1 or dentate regions. These data show that polarization along the cell axis is im-portant for tests during long de pulses.

during and after rapidly varying ac fields are axis-independent and presumably not due to a polarizing effect on CA1 neurons. (Supported by: Department of Energy and Southern California Edison Company)

POLYSYNAPTIC PATHWAYS FROM BRAINSTEM LOCOMOTOR REGIONS TO LUMBAR 200.8 ALPHA MOTONEURONS. <u>S.J. Shefchyk and L.M. Jordan</u>, Dert. of Physiology, University of Manitoba, Winnipeg, Canada R3E 0W3. The fact that electrical stimulation of the mesencephalic

The fact that electrical stimulation of the mesencephalic locomotor region (MLR) can evoke locomotion in the decerebrate cat has been well documented (Shik et. al., Biofizika, <u>11</u>, 1966), as has the spinal cord's intrinsic ability to produce Thythmic alter-nating stepping activity when isolated from higher centers (Grillner, Phys. Rev., <u>55</u>, 1969). Past work done in this labora-tory indicates that lumbar spinal alpha motoneurons receive both excitation and inhibition during MLR evoked locomotion. The purpose of this study is to examine the postsynaptic potentials (PSP) evoked in extensor and flexor motoneurons in the lumbar spinal cord from regions in the brainstem which are effective for evoking locomotion.

Fictive locomotion was produced by stimulation of the MLR in rective focume to was produced by stimulation of the MLM in decerebrate cats paralyzed with Flaxedil. Intracellular records were obtained using 3M potassium acetate-filled microelectrodes, and motoneurons were identified on the basis of their antidromic-activation from peripheral nerves. Both sides of the brainstem were systematically stimulated (40-120  $\mu$ A, 10-50 Hz), and records of the PSPs produced in motoneurons as well as the evoked locomotor activity were obtained.

PSPs that were time-locked to the brainstem stimulation during locomotion were observed in hindlimb flexor and extensor moto-neurons and had latencies of 4-7 msec. Stimulation of either the ipsilateral or contralateral MLR was effective for PSP production. Records from individual motoneurons during locomotor trials in-dicated that stimulation of different mesencephalic locomotor sites could produce different PSPs in the cell. The PSPs dis-played an increase in amplitude with repetitive stimulation, played an increase in amplitude with repetitive stimulation, suggesting that they were polysynaptic. EPSPs, IPSPs, or EPSP/ IPSP complexes could be observed, and often the PSPs were modu-lated in amplitude during the step cycle. In general, EPSPs were maximal during the depolarized phase of the step cycle, and IPSPs were maximal during the hyperpolarized phase. Some EPSPs which were maximal during the depolarized phase. were present during the depolarized phase of the membrane poten-tial oscillations associated with the step cycle disappeared during the hyperpolarized phase, when a longer latency IPSP could be observed. Stimulation of a single brainstem location could produce reciprocal effects, with an excitatory or inhibitory PSP occurring in an extensor (LG) motoneuron and a PSP of the opposite sign in an antagonist flexor (TA) motoneuron.

These experiments indicate the existence of polysynaptic path-ways to lumbar motoneurons from sites in the brainstem where stimulation produces locomotion. Activity in these pathways is modulated during the step cycle in a manner consistent with the involvement of interposed neurons in the generation of locomotion.

VOLTAGE SPREAD IN AN INTERNEURON OF THE BARNACLE'S VISUAL SYSTEM. 200.9 A. E. Stuart, J. H. Hayashi<sup>\*</sup>, and L. A. Oland<sup>\*</sup>, Dept. Physiology, University of North Carolina, Chapel Hill, North Carolina, 27514. The second-order cell of the barnacle's visual system, the I-cell, offers a unique opportunity to study voltage spread in an interneuron. The cell has two distinct arbors separated by a long thin process that connects them across the commissure of the long thin process that connects them across the commissure of the ganglion and extends to the soma. The photoreceptors (PRs) which synapse upon the I-cell are divided among three ocelli, two la-teral and one median, which can be independently stimulated with light or current. Because PRs from each lateral ocellus termi-nate on a single arbor, it is possible to evoke a response in one of the I-cell's arbors and study its subsequent spread to the recording site in the soma. We compared the voltage responses of the I-cell's soma to il-

lumination of the ipsi and contralateral ocelli. Responses eli-cited in the contralateral arbor were consistently slower in rise time and smaller than those elicited in the ipsilateral arbor.

The efficacy of voltage spread to the soma was tested by com-paring the reversal potentials obtained for each lateral input. We illuminated each of the lateral eyes separately while passing hyperpolarizing current into the I-cell's soma. If the cell were isopotential, the ipsi and contralateral responses to light would be expected to reverse at the same potential because the voltage change would be the same in both arbors. However, the ipsilateral response always reversed at a potential substantially less negative than the contralateral response indicating that the cell is not isopotential.

When the ipsilateral ocellus was placed in background light, causing a conductance increase in the ipsilateral arbor thus (Certel and Stuart, 81), contralateral signals were reduced or eliminated. Thus, as the background light increased, the cell's arbors were further isolated from one another.

To ask whether voltage changes spread well within each arbor, we compared the reversal potentials of median and ipsilateral inputs to the I-cell. Median PRs bifurcate and end on both of the I-cell's arbors. To eliminate potential changes spreading from the contralateral arbor, we cut across the commissure. Median and ipsilateral responses had reversal potentials that differed at most by a few mV. This finding suggests that median and la-teral PR synapses are situated at similar electrical distances from the soma, even though anatomical studies show little overlap these inputs on the arbor (Oland and Stuart, these abst.). Thus, voltages may spread quite well within the individual arbors of the I-cell. Oertel and Stuart, <u>J.Physiol.</u> (1981) 311: 127-46. Supported by USPHS grant EY03347.

200.10 THE ABSENCE OF SYNAPTIC INTERACTION AMONG THE MEDIAN AND LATERAL PHOTORECEPTORS OF THE BARNACLE AND A COMPARISON OF THE RESPONSES Stuart. (SPON: J. W. Moore). Dept. Physiology, University of North Carolina, Chapel Hill, NC, 27514.

The absense of synaptic interaction among the PRs of a visual The absense of synaptic interaction among the PRs of a visual system would considerably reduce the complexity of the signals evoked in the second-order cell and permit analysis of the cell's response to input from a single receptor. In the barnacle's visual system, ten photoreceptors (PRs), divided among three ocelli, comprise the barnacle's entire receptor population and converge on the same second-order cell. The PRs within each of the ocelli are electrically independent of each other. That synaptic interaction might occur between receptors of the median and lateral ocelli, was suggested by single cobalt fills of ei-ther median or lateral PRs which showed that they arborized in the same region of the ganglion (Hudspeth and Stuart, 77; Oland, et al, 83). When we simultaneously filled median and lateral PRs with cobalt, we found that overlap of the terminals, in one case et al, 65). When we simultaneously filled median and lateral rms with cobalt, we found that overlap of the terminals, in one case entirely absent, was limited to the outermost fringes of the re-ceptors' arbors. These results suggested that direct interaction was unlikely. We recorded directly from median or lateral terminals and illuminated the opposite ocellus. Stimulation of one ocellus failed to evoke a response in the PR from the other ocellus, even when the receptor terminal was hyperpolarized or

depolarized by 20-30 mV. The absence of interaction among the PRs of different ocelli allowed us to compare the responses of the second-order cell, the l-cell, to median and lateral inputs. Both inputs generate hy-perpolarizing responses that consist of an initial peak that detays to a plateau. The responses are graded with intensity over the same range. However, lateral input always elicits a slower response. Also, following the offset of light over a lateral ocellus, the I-cell simply repolarizes to its dark resting poten-tial or briefly overshoots rest by a few mVs. In contrast, the the offset of light over the median ocellus produces a large depolarization often complicated by an oscillation. This difference is especially intriguing for it is at the offset of light that the third-order cell responds.

Because we can evoke responses in the I-cell with inputs from separate ocelli or from single PRs, we have the opportunity to study signal interaction at an interneuron. Hudspeth and Stuart, J. Physiol. (1977) 272:1-23. Oland, et al, J. Neurophysiol. (1983) 49:516-27. Supported by USPHS grant EY03347.

200.11 CELLULAR PHYSIOLOGY OF THE TURTLE CORTEX. B.W. Connors, A.R. Kriegstein\* and B.R. Ransom (SPON: K.L. Chow) Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305. . The general cortex of reptiles is a favorable preparation for studying principles of cortical organization because it is rela-tively simple, consisting of only three layers. We therefore undertook an investigation of the cellular physiology of the cor-tex of the turtle, <u>Pseudemys scripta</u>. We removed the cortex and placed it ventricular surface upward in a recording chamber where it was bathed in oxygenated saline at 21°C. Intracellular record-ings were made with 3 M K acetate or dye-filled microelectrodes. The cortex contains only two principal cell types, pyramidal

The cortex contains only two principal cell types, pyramidal cells and stellate cells in a ratio of 37:1. We found that cells cells and stellate cells in a ratio of 37:1. We found that cells could be classified into two groups based upon differences in membrane properties. The most frequently encountered cells had long membrane time constants, mean input resistances (R<sub>N</sub>) of 74.5 MΩ, and 5-8 ms action potentials usually with more than one amplitude, possibly indicating more than one spike initiation site. Intracellular staining confirmed these were pyramidal cells. A second cell type was encountered less frequently. These were stellate cells and had mean R<sub>n</sub> = 136 MΩ and faster, unitary, action potentials (1.5-2.5 ms).

Cells and had mean  $\kappa_{\rm M}$  = 130 mM and faster, unitary, action poen-tials (1.5-2.5 ms). Stellate cells have aspiny dendrites and local axon ramifica-tions that form flat, symmetrical synapses onto pyramidal neurons. Smith et al. (<u>J. Comp. Neurol. 190:445, 1980</u>) have hypothesized that these are inhibitory interneurons. Degeneration studies have shown that thalamic afferents form 6 times as many contacts onto each stellate cell as onto each pyramidal cell. Each afferent each stellate cell as onto each pyramidal cell. Each afferent volley should therefore be a powerful activator of inhibitory volley should therefore be a powerful activator of inhibitory interneurons. We studied synaptic responses to local stimulation in the molecular layer of the cortex. Pyramidal cell responses were characterized by inhibitory postsynaptic potentials (IPSPs) lasting from 150-1000 ms. IPSPs were associated with a large conductance increase and had reversal potentials 8 mV negative to the mean resting potential of -63 mV. IPSPs appeared to be Cl<sup>-</sup> dependent since they were inverted by intracellular Cl<sup>-</sup> injection. Focal GABA application produced a hyperpolarizing response with the same reversal potential as the IPSP. Stellate cells, in contrast, responded to local stimulation with excitatory PSPs, sometimes followed by IPSPs. times followed by IPSPs.

times followed by IPSPs. These results suggest that cell form and function are related in this primitive cortex. In addition, they provide physiological support for the role of the aspiny stellate cell as an inhibitory interneuron in cortex and confirm the prediction that afferent stimulation produces profound inhibition of pyramidal neurons. Supported by a Klingenstein Fellowship (ARK) and NIH grants RR 5353 (BWC) and NS 15589 and NS 00473 (BRR) from the NINCDS.

200.12 INTERACTIVE COMPUTER-GRAPHICAL REPRESENTATION OF CALCULATED VOLTAGES OVER THREE-DIMENSIONAL ARBORIZATIONS OF INDIVIDUAL VOLTAGES OVER THREE-DIMENSIONAL ARBORIZATIONS OF INDIVIDUAL NEURONS. <u>S. Senft\*</u> (SPON: S. Rothman). Dept. of Anatomy & Neurobiology and McDonnell Center for Studies of Higher Brain Function, Washington Univ. Sch. Med., St. Louis, MO 63110

A number of procedures exist for quantifying and displaying the three-dimensional structure of single neurons (e.g., Wann et al, 1973). While the function of neurons undoubtedly depends on dynamic ionic, metabolic, and structural components distributed heterogeneously over their processes, there are few direct ways to visualize these spatio-temporal distributions in relation to a cell's form.

However, the expected value of certain electrical quantities at arbitrary locations on dendritic trees may be calculated, based on biophysical assumptions and data collected at point based on biophysical assumptions and data conjected at point locations on the neuronal tree (e.g., Koch et al., 1983).
As a step towards more accurate conceptualization about

subcellular neural physiology <u>in toto</u>, we have constructed an interactive computer-graphic system capable of representing the steady-state distribution of voltages using color and depth cues on complex neuronal dendritic trees.

The standing influence of excitatory and inhibitory synaptic inputs may be assessed over a range of assumed electrical parameters. Examples, showing the effects of inputs at different spatial locations on the three-dimensional dendritic arbors of several different neurons, will be displayed. (Supported by NIH Grant 17763.)

# 200.13 EXTRACELLULAR STIMULATION ANALYZED BY COMPARTMENTAL MODELS

Ian Hentall Department of Neurology, University of California, San Francisco, CA 94143.

An exact theory of extracellular stimulation of neurons is unavailable, except for the simplest axons in restricted situations, and difficult empirical measurements are seldom attempted. But it is fairly simple to compute the potential along variously-shaped cells that are represented by resistively-linked, parallel-RC compartments. For present purposes, compartments were assigned a position in 3-space, and the neurons assumed to be electrically linear below threshold, unmyelinated, internally 1-dimensional, without resistance to external current flow, and surrounded by a homogeneous and isotropic, infinite-volume conductor. Electrodes were modelled as superimposed sinks and sources, always placed further from the cell than any intercompartmental distance; thus a bipolar concentric electrode was a central sink equalled by 100 encircling sources. A battery  $(\Phi_i)$  between each ith compartment's external port and ground represented the stimulus, with  $\Phi = T_0/(485R)$ (R, distance to electrode; S, external conductance;  $I_0$ , stimulus current). The time-dependent, simultaneous, linear, first-order, differential equations thus developed were given anatomically and physiologically realistic parameters and solved by the Runge-Kutta method.

The following are among observations and relationships which may be instructive to the practical user of electrical brain stimulation. First, membrane polarization tends to be larger at constrictions and terminations; this might explain the sometimes greater efficacy of anodal stimulation, for example in the case of pyramidal cells excited from the neocortical surface. Second, especially in thinner processes, charge redistribution can cause the potential to increase after the stimulus is turned off. Third, as suspected intuitively, concentric bipolar compared to monopolar stimulation is preferred for restricting activation to nearby membrane, although comparatively more current is needed. Fourth, the threshold (I<sub>L</sub>) of uniform axons with a monopolar gelectrode  $I_{\rm L} \propto R$ , and with a concentric bipolar electrode  $I_{\rm L} \propto R^{-1}$  (at any constant electrode angle). In monopolar stimulation of spherical somatodendritic regions of volume D and radius A with regular "3/2 power law" branching, assuming a central trigger zone, I<sub>L</sub> is inversely proportional to '/9/R within 10% error; that is, outside the sphere I<sub>L</sub>  $\propto R^{-1}$  ( $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha < R^{-1}$ ,  $\alpha <$  200.14 CURRENT-VOLTAGE RELATIONSHIPS OF PERICRUCIATE CORTICAL NEURONS OF AWAKE CATS USING A COMPUTER ASSISTED METHOD. N. E. Berthier and C. D. Woody. Depts. of Anatomy and Psychiatry, UCLA Med. Ctr., Los Angeles, Ca. 90024. Current pulses ranging from -4nA to +4nA and of 30-500 msec

Current pulses ranging from -4nA to +4nA and of 30-500 msec duration were injected into 17 pericruciate neurons in order to investigate their current-voltage relationships. An active bridge circuit was used to inject the current pulses. It was important that the circuit be accurately balanced so that the measurements would not be distorted by changing electrode resistance. Takeuchi, Kondoh, & Kohno (J. Neurosci. Methods, 4:365-372, 1981) devised an electronic circuit to balance the bridge circuit automatically, but their circuit had the drawback of requiring several synchronizing inputs. We used a similiar algorithm that required only that the electrode time constant be much shorter than the cell time constant, and implemented it on PDP-11/44 computer. Current monitor and intracellular voltage records were A/D converted and analyzed (using a threshold detection method) to determine the time of current pulse onset and offset. The intracellular voltage record was sampled just before pulse onset and just after charging of the electrode (i.e., about 50-100 µ sec after pulse onset), the difference in the two measurements being the magnitude of bridge imbalance. This difference was then subtracted from the voltage trace for the duration of the current step, and the data D/A converted and displayed oscillographically.

The slope of the IV plot in the hyperpolarizing region was taken as the best estimate of R. It averaged 9.1 mR across the 17 neurons. The cells had a mean resting potential of 62 mV, and a mean action potential height of 59.6 mV. A rectification ratio was computed by dividing the average chord resistance of the depolarizing region by the hyperpolarizing resistance. Three patterns emerged: 1) nearly linear, where the ratio of resistances was slightly less than unity (mean ratio = .85, seen in 35% of the cells), 2) "anomalous rectification", where the apparent resistance in the depolarizing region was greater than in the hyperpolarizing region (mean ratio = 1.28, 23% of the cells), and 3) "delayed rectification" where the apparent resistance in the depolarizing region was much less than in the hyperpolarizing region (mean ratio = .55, seen in 41% of the cells). The resting potentials for group 1 averaged 61 mV, group 2 averaged 58 mV, and group 3 averaged 64 mV. Rectification in 94% of the cells. (Supported by AFOSR F49620-83-C-0077 and HD 05958.)

200.15 SYNAPSES BETWEEN HIPPOCAMPAL NEURONS IN CULTURE. Matthew P. Frosch. Deborah M. Barnes and Marc A. Dichter, Dept. of Neuroscience, Children's Hospital, Boston, MA 02115. Neurons were obtained from the hippocampal regions of 20-21

Neurons were obtained from the hippocampal regions of 20-21 day gestation rat embryos and were maintained in primary culture for up to 14 weeks. Cells were dissociated mechanically and plated onto collagen and poly-L-lysine coverslips (500,000 cells per 35 mm dish). Trituration, plating and growth medium (Eagles MEM) was supplemented with 3.5% rat serum, 5% horse serum, 3.75 Go<sub>2</sub>; medium was changed three times weekly. Cytosine arabinoside (10<sup>-</sup>M) was added to inhibit further mitoses in confluent cultures (7-12 days).

Physiological studies of synaptic connections were made at various ages in culture. Spontaneous excitatory and/or inhibitory post-synaptic potentials (psp's) were noted in the majority of neurons sampled in cultures between 1 and 11 weeks in <u>vitro</u>. However, connections between pairs of neurons within one microscopic field (350 um diameter) were not found at times up to 3 weeks but between 3 and 11 weeks, such 'local' connections were uni- or bi-directional with inhibitory synapses predominating. These connections were assumed to be monosynaptic based on their ability to follow at rates up to 50-100 Hz and fixed, short latencies. Few failures of transmission were scaled for synaptic coupling, however, occasional dye coupling was observed in an eight day culture using intracellular 6-carboxyfluorescein injection (a single electrode experiment).

The properties of synaptic transmission under conditions of repetitive stimulation were examined. All connections could be driven at rates up to 50 Hz, with summation of events observed. When inhibitory connections were repeatedly stimulated no diminution in psp size was observed. Tetanization led to a clamping of the resting potential of the post-synaptic cell with little diminution over several seconds. During train stimulation, at interspike intervals sufficient to avoid summation of psp's, it was possible to see early potentialion of some connections, both inhibitory and excitatory. Additionally, post-tetanic potentiation was seen for synaptic connections of both polarity.

both polarity. Davis Center for Behavioral Neurobiology The Salk Institute, P O. Box 85800, San Diego. CA 92138

Cerebellar Purkinje neurons (PNs) in vivo are characterized by a unique firing pattern which is generated by a combination of events including simple spikes, complex spikes and a series of pauses. Recent data from a cerebellar model system, cultured fetal rat cerebellar neurons, suggests that both synaptic and intrinsic components contribute to the pattern of activity characteristic of PNs (Gruol, Brain Res. 263, 1983). In the present studies, three types of electrophysiological recordings were used to investigate further the intrinsic mechanisms which generate the electrical activity of PNs: extracellular unit recording, intracellular voltage recording and single channel recording using the patch clamp technique. PNs were identified on a morphological basis and by immunohistochemical techniques (Franklin and Gruol, this volume). A variety of firing patterns were observed in extracellular recordings from the PNs. Two were observed in extraceilliar recordings from the PNS. Two common patterns correlated well with two types of intrinsically generated, voltage-sensitive activity observed in intracellular recordings: (1) a regular simple spike firing pattern and (2) a regular pattern of large membrane depolarizations which evoked 1 or 2 spikes. The differences in the types of intrinsically or 2 spikes. The differences in the types of intrinsically generated activity of PAs presumably results from differences in the type, location or regulation of the voltage-sensitive ionic mechanisms mediating the activity. As a first step in testing this hypothesis, the technique of single channel recordings was applied to identify the voltage-sensitive ionic mechanisms present in PNs and to characterize the regional distribution (soma vs dendrite) of these mechanisms. Single channel recordings from cell-attached patches revealed a variety of channel activities. Two channel types mediating outward current events were of particular interest because their large size and frequency of detection indicated that they play a major role in the activity of PNs. Both channel types were voltage-sensitive, observed in both the somal and dendritic membranes. One channel type had a single channel conductance of approximately 35 picosiemens (pS) and the second approximately 100 pS. The characteristics of the larger channel suggest it may be a Ca++ The characteristics of the larger claimer suggest it may be a car-activated K+ channel, a possibility that is presently being tested. A major role of K+ currents in generating or regulating the pattern of activity characteristic of PNs was further supported by intracellular studies with K+ channel blockers. 200.17 VOLTAGE CLAMPING OF PURKINJE CELLS IN VITRO: A STUDY IN GUINEA PIG CEREBELLAR SLICES. <u>M. Sugimori and R. Llinás</u>. Dept. of Physiol. & Biophys., New York Univ Med. Ctr., 550 First Ave., New York, NY 10016.

The ionic current activated by depolarization steps applied to somata of Purkinje cells was studied under voltage-clamp conditions. Voltage clamping was obtained with a single patch microelectrode attached to a currentometric amplifier configuration. The electrode was applied directly against the body of the cell after the slice was given a short exposure to trypsin. Following a high resistance seal of the electrode against the surface membrane, negative pressure was utilized to break the membrane in front of the electrode tip which produces a stable intracellular recording paradigm with the input resistance of the electrode being as low as half a megohm. Under these conditions voltage steps as fast as 25-50 µsec can be achieved. In order to simplify the interpretation of the voltage clamp data, the axons and the dendrites of the cells are moved leaving then a spherical isolated somatic Purkinje cell recording. Under these conditions depolarization of the solar generates a fast graded inward current carried by sodium followed by a large outward potassium current. When this later current is blocked by intracellular cesium and tetraethylammonium, the initial sodium current is followed by a slow inward current carried by the non-inactivating sodium conductance (Llinás & Sugimori, J. Physiol. 305; 171, 1980; Sugimori & Llinás, Soc. Neurosci. Abst. 7: 76, 1961). This slow inward current is blocked by tetrodotoxin and absent when sodium is removed from the extracellular bath. When the dendritic tree or part of it is left intact prior to clamp, a sizeable calcium current can be observed which is blocked by cobalt or cadmium. In the case where well isolated somata were voltage clamped, such I<sub>Ca</sub> was not observed. Supported by USPHS grant NSL3742 from NINCOS.

GULFISH MAUTINER CELL Jen-Wei Lin and Donald S. Faber. Div. Neurobiology; Dept. Physiology; SUNYAB, Buffalo, NY 14214. In goldfish, the Mauthner cells (M-cells) mediate the startle response evoked by auditory and visual stimuli. The primary auditory afferents (the saccular nerve) impinge on the M-cell distal lateral dendrite as club endings and endbulbs (Lin, Faber and Wood, <u>Brain Res.</u>, in press). Both gap junctions and chemical synapses are morphologically identified in a single club ending, Previous physiological studies have shown that electrical stimulation of the saccular nerve evokes a strong electrotonic and a weak chemical excitatory postsynaptic potentials (epsp) in the distal lateral dendrite which is consistent with the notion that club endings mediate both modes of transmission. In order to further evaluate this hypothesis and to determine the relative contribution of individual afferents to the M-cell auditory responses, we have employed simultaneous pre- and postsynaptic intracellular recordings. Presynaptically, the large myelinated fibers in the anterior part of the saccular nerve were impaled at the point where they enter the medulla. The postsynaptic recording site was in the M-cell, about 300um lateral to the axon hillock. In 18 experiments, an impulse evoked in an afferent by current injection produced a short latency ((0.1ms) electrotonic psp which was typically about 1 mV (range 0.1-1.5mV) and could

SYNAPTIC TRANSMISSION FROM A SINGLE SACCULAR FIBER ONTO THE

which was typically about 1 mV (range 0.1-1.5mV) and could follow stimulation frequencies up to 100 Hz. If we assume that the presynaptic spike amplitude at the club ending terminal is 80 mV, then the orthodromic coupling coefficient for impulses is about 0.019. When the M-cell axon hillock-initial segment was activated antidromically, the resulting 10 to 15mV spike potential in the lateral dendrite was synchronous with a depolarization of about 1 mV in the saccular fiber. Therefore, the electrotonic coupling between club endings and the M-cell appears to be bidirectional.

Identification of the chemically mediated epsp evoked by single fibers was more difficult because the responses were quite small and exhibited marked fluctuations. Small depolarizations (<150 uV) following the electrotonic psp could be detected at low stimulation frequencies; these responses disappeared with high frequency stimulation.

Generally, the stimulation of the entire saccular nerve fires the M-cell at the peak of a prominent chemical epsp, rather than electrotonic psp. The major source of this chemical epsp is presently being investigated by stimulating discrete areas of the saccular nerve. (Supported by NIH grant NS15335). 200.18 INTRACELLULARLY RECORDED ACTION POTENTIALS IN DORSAL ROOT AFFERENT FIBRES PRODUCED BY ANTIDROMIC ACTIVATION OF MOTONEURONES. <u>F.J. Alvarez-Leefmans and H. Cruzblan-</u> <u>ca\*</u>. Department of Neuroscience, CINVESTAV del IPN. Apartado Postal 14-740, México 07000, D.F. Orthodromic electrical coupling between some afferent fibres and metopuyane dondritor is yell established is

Apartato forsair 1-44, inside of solution, biri-Orthodromic electrical coupling between some afferent fibres and motoneurone dendrites is well established in amphibian spinal cord. Electrical coupling also occurs in the antidromic direction. Shapovalov and Shiriaev (Exp. Brain Res. 33: 299, 1978) showed that ventral root (VR) volleys produce action potentials in sensory fibres. However, this could only be demonstrated in the presence of TEA or 4AP, which might have unwanted direct pharmacological actions, complicating the interpretation of their findings. Here we report preliminary data showing that such an antidromic electrical coupling can be demonstrated lowering the temperature below  $10^{\circ}C$  in the absence of pharmacological agents other than  $Co^{2+}$ . Evening the wave parformed in isolated and hemisec-

Experiments were performed in isolated and hemisected spinal cords of frogs, superfused with Ringer (5-10°C) in which  $Ca^{2+}$  was replaced by 2 mM  $Co^{2+}$ . Suction electrodes were used for stimulating and/or recording from dorsal roots (DR) or VR from segment IX. Intracellular recordings (3 M-KCl microelectrodes 60-90 MΩ), were obtained from sensory fibres at their point of entry into the spinal cord. In 10 out of 13 cases VR stimuli produced the temperature dependent depolarizing DR potential (VR-DRP-II) (Cruzblanca, H. & Alvarez-Leef mans, F.J. <u>Soc. Neurosci. Abst. 8</u>: 912, 1982) which was postulated as resulting from firing of some DR afferent fibres. 2 out of 10 of these fibres fired by VR stimuli, with latencies corresponding to those of the VR-DRP-II (7.4 and 15 ms). The low stimulus strenght used, and the latencies found, rule out any possibility of artefactual spread of the stimulating current to the DR. All the fibres were fired by orthodromic DR stimuli. The mean resting potential was 45.3 mV (S.E. $^{+}$  3.1 mV). The amplitude of the action potential was 63  $^{\pm}$  4.9 mV (mean  $^{\pm}$  S.E.). The shape of these action potentials was similar to that described for the node of Ranvier. The low proportion of fibres fired antidromically is expected since only a small number of axons make monosynaptic contacts with motoneurones. Increasing the temperature to 15-17°C and adding 5mM TEA produced antidromic firing of some sensory fibres (Cf. Shapovalov op.cit). These results resemble those found in the cat spinal cord (Decima, E.E. & Goldberg, L, J. <u>Brain Res</u>. 57: 1, 1973).

ATP-DEPENDENT CALCIUM TRANSPORT INTO NATIVE DISC MEMBRANES 201.1 ISOLATED FROM BOVINE ROD OUTER SEGMENTS. K.L. Puckett\* and S.M. Goldin (SPON: J.R. Glowa) Dept. of Pharmacology, Harvard An ATP-dependent  $Ca^{++}$  transport activity has been found to be Medical

bovine retinal rod outer segments (ROS). Osmotically active disc were isolated from bovine ROS by

solution. Quantitative analysis of the rhodopsin content was performed spectrophotometrically for each sample by bleaching and regeneration of rhodopsin in the presence of 1% digitonin. Ca<sup>++</sup> regeneration of rhouspain in the presence of 1% digitalities transport assays were performed by separation of intradiscal from extradiscal  $4^{5}$ Ca<sup>++</sup> on cation exchange resin both in the presence and absence of 2 mM Mg<sup>++</sup>ATP to determine ATP-dependent Ca<sup>++</sup> uptake. After 5% Ficoll floatation the discs were further purified by separation into two distinct bands on a linear 5-20% Ficoll gradient.

The "rhodopsin" band, containing 90% of total protein in the disc preparation and all the bleachable and regenerable rhodopsin, was further characterized. This band was demonstrated by electron was further characterized. This band was demonstrated by detection microscopy to have morphology characteristic of retinal discs. Also associated with this band was an ATP-dependent Ca<sup>++</sup> uptake activity: ATP stimulated Ca<sup>++</sup> uptake 4 to 8 fold, with a net uptake of 0.1-0.2 nmoles Ca<sup>++</sup>/mg protein/min. In addition 65-80% of the ATP-dependent accumulated  $^{+}Ca^{++}$  was released upon incuba-tion with the Ca<sup>++</sup> ionophore A23187.

To determine whether the association of this Ca++ transport activity with the rhodopsin band was merely coincidental, we exploited the osmotic properties of these sealed disc membranes. The sedimentation properties of the rhodopsin band upon centrifugation on a second 2-15% Ficoll gradient ( $\rho$ =1.007 to 1.052 fugation on a second 2-15% Ficoll gradient  $(p^{21}, 00)$  to 1.052 g/ml) varied with the composition of the gradient solution. In several separate gradient solutions of differing osmotic and ionic strengths, the observed migration position of the thodopsin band varied from  $p^{-1}.02$  to 1.03 g/ml. On each gradient, the Ca<sup>++</sup> uptake activity always precisely co-migrated with the rhodopsin containing membranes. The different sedimentation patterns observed on each gradient were attributed to differences in the osmotic strength between gradient and the resultant ehrinking. osmotic strength between gradients and the resultant shrinking and swelling of the discs.

and swelling of the discs. Therefore, these results strongly suggest that the ATP-dependent Ca<sup>++</sup> transport activity characterized here is associated with intact disc membranes. In addition, the amount of Ca<sup>++</sup> uptake activity was sufficient, in principle, to account for a role of this Ca<sup>++</sup> "pump" in the regulation of cytosolic Ca<sup>++</sup> levels in the rod cells <u>in vivo</u>. Supported by the NIH (NS16475). The McKnight Foundation, and The Searle Scholars Program, to SMG.

PDE AND PDE ACTIVATION: EFFECTS ON ROD MEMBRANE POTENTIAL. 201.3 B. Oakley II<sup>1</sup>, J.W. Clack\*<sup>2</sup>, and P.J. Stein\*<sup>2</sup>. <sup>1</sup>Dept. Elect. Eng. and Bioeng. Program, Univ. of Illinois, Urbana, <sup>1</sup>Dept. of rbana, IL, <sup>2</sup>Dept. of Ophthalmology, Yale Univ. Sch. Med., New Haven, CT In an attempt to determine if the activation of the cGMP phosphodiesterase (PDE) in the rod outer segment (ROS) plays a phosphodiesterase (PDE) in the rod outer segment (ROS) plays a role in the transduction process, we recorded membrane potential,  $V_m$ , intracellularly from red rods in the isolated retina of the toad, <u>Bufo marinus</u>, using double barrel micro-pipettes.  $V_m$  was monitored with one barrel while a protein solution was pressure-injected into the ROS through the other barrel. The injected solution contained 22 mM MOPS (pH 7.2), 4 mM DTT, 15% glycerol, and 1-7  $\mu$ M of various proteins isolated from toad ROS. Injections of pure GTP-binding protein (termed G) that was binding a hydrolysis-resistant analog of GTP, from toad ROS. Injections of pure GTP-binding protein (termed G) that was binding a hydrolysis-resistant analog of GTP, p(NH)ppG, (together termed G) and thus was able to activate PDE, or injections of (partially-purified) active PDE itself, resulted in reversible hyperpolarizations of the ROS membrane as large as 13 mV. A mixture of G<sup>•</sup> and PDE was especially effective and produced prolonged hyperpolarizations. Either of these proteins caused cGMP hydrolysis (as determined by a <sup>3</sup>H-cGMP assay) when added to dark (unbleached) ROS membrane suspensions. Active PDE hydrolyzed cGMP in the absence of membranes a well. Injections of proteins that did not significantly cause hydrolysis of cGMP when assayed did not suspensions. Active PDE hydrolyzed cGMP in the absence of membranes as well. Injections of proteins that did not significantly cause hydrolysis of cGMP when assayed did not significantly (<1 mV) affect V when injected. These proteins included G binding GDP, boiled PDE, and boiled G\*. These results are consistent with the hypothesis that the activation of PDE and the subsequent hydrolysis of cGMP are steps in the

transduction process. The hydrolysis of cGMP yields 5'-GMP and  $H^+$ . Others have suggested that the excitatory signal is not the loss of cGMP but that it is the production of  $H^-$ . To test this idea, we have injected  $H^-$  (acetic acid in 100 mMK<sup>+</sup> acetate<sup>-</sup>) into ROS. Injections of H<sup>+</sup> at pH 4.2 did not significantly affect V, while injections at pH 2.0 caused reversible <u>depolarizations</u> of the ROS membrane. These results argue against <u>simple model</u>, in which the excitatory signal is carried <u>solely</u> by the H that are produced by cGMP hydrolysis. It seems that if protons are involved in the transduction process, other biochemical reactions also are required.

EFFECT OF 2-DEOXY-D-GLUCOSE ON CAROTID BODY (C.B.) CHEMORECEPTORS. <u>A.Obeso' L.Almarazi and C.González</u>.Dpt. of Physiol.Fac.de Med.Valladolid,Spain. The biochemical and/or biophysical steps through which low levels of arterial pO2 promote and increase of chemoreceptors activity are presently unknown.Among the theories of sensory transduction in this receptor perhaps the most commonly accepted is the metabolic the perhaps the most commonly accepted is the metabolic the ory; according to it, hypoxia will promote a decrease in ATP/ADP quotient which ultimately will trigger the release of a transmitter from type I cells leading to increase of sensory impulses in the carotid sinus nerve (c.s.n.). This theory rest on the observations that any metabolic poison which decreases the above quotient ex-cites the arterial chemoreceptors. Nevertheless the the-

netabolic poison which decreases the above quotient ex-cites the arterial chemoreceptors.Nevertheless the the-ory as a whole has been criticized because the metabo-lic poisons so far used have a very wide spectrum of ac-tions. Here we present data in support of the metabolic theory by the use of 2-deoxy-glucose. C.bs were excised from adult cats and prepared to re-cord in vitro. In a first group of experiments the c.bs were superfused with modified Tyrode containing 5 mM glucose or 5 mM Na-pyruvate; the responsiveness of the preparation(activity in the c.s.n.)to different types of stimuli were assessed with either solution. In a se-cond group of experiments the c.bs were superfused with pyruvate containing Tyrode saturated with 100% 02 and do se-response curves for 2-deoxy-glucose on the release of 3H-DA and the activity in the c.s.n. were monitored si multaneously in c.bs. previously incubated with <sup>3</sup>H-Tyro sine. sine.

Our main findings were: The responsiveness of the c.b to hypoxia, acidosis, Ach, Na -cyanide and DA was the same with glucose or pyruvate. The results suggest the inde-pendence of the chemoexcitation from the glycolisis. pendence of the chemoexcitation from the glycolisis. 2-Deoxy-glucose excites the c.b. chemoreceptors; the threshold concentration was 0.25 mM, the maximum effect was obtained with 4 mM and the dose-response curves were hiperbolic in shape. 2-Deoxy-glucose promoted a dose-dependent release of <sup>3</sup>H-DA. The data support the metabolic theory on the basis of the known actions of 2-deoxy-glucose on celular ATP levels. In addition a linkeage between ATP levels and the release of DA seems evident in our data evident in our data.

CAN LOUDNESS GROW NORMALLY IN COCHLEAR-IMPAIRED EARS WITH SLOPING HIGH-FREQUENCY LOSSES? Rhona P. Hellman. Commun. 201.4 SLOPING HIGH-FREQUENCY LOSSES? <u>Rhona P. Hellman</u>. Communication Sciences Laboratory, Boston Univ., Boston, MA 02215. Loudness growth was measured by the psychophysical procedures

of magnitude estimation and production in three listeners with steep bilateral high-frequency losses of cochlear origin. Within the normal-hearing region, two test frequencies, a minimum of one octave apart, were studied. Individual loudness functions were obtained by combining the results of magnitude estimation with those of magnitude production. Results disclose that for each listener the loudness function is steeper at the lower test frequency than at the cutoff frequency, beyond which thresholds decrease by more than 40 dB/octave. On the average, the loudness growth rate decreases by 17% at the cutoff frequency. However, growth rate decreases by 1/% at the cutoff frequency. However, the loudness growth range is the same as in normal hearing. In good agreement with previous loudness measurements in normal ears masked by an adjacent high-pass noise (Hellman, R.P., J. Acoust. Soc. Am., 63:1114, 1978), the loudness of tones as high as 3200 Hz continues to grow, but at a slower rate, over a stimulus range of at least 100 dB. Since very little residual hearing above the cutoff frequency was available, further evidence that the loudness growth range does not require the recruiteent of the loudness growth range does not require the recruitment of neural units at frequencies above the stimulus or test frequency is provided.

G-PROTEIN IN VERTEBRATE PHOTORECEPTORS: BEHAVIOR DURING DARK-201.5 MADAPTATION. N. J. Mangini<sup>\*</sup>, D. R. Pepperberg, W. Baehr<sup>\*</sup> and <u>M. L. Applebury<sup>\*</sup></u>. Department of Biological Sciences, Purdue Univ., West Lafayette, IN 47907.

The light-induced increase in affinity of ROS G-protein (GTP-binding protein, consisting of subunits  $\alpha$ ,  $\beta$ , and  $\gamma$ ) for the disc membranes is reversible in the dark (1,2). To examine the possibility that the state of binding of G-protein influences the photic responsiveness of the receptors during dark-adaptation (3), we analyzed the time course of recovery from the light-induced state of relatively tight binding of G to the discs. The analysis utilized the facts that (i) hypotonic buffer elutes G from darkadapted membranes but not from bleached membranes, and (ii) hypo-tonic buffer containing 40 µM GTP (hypotonic-GTP) elutes G even from bleached membranes (1,2). Isolated retinas of the toad, B. marinus, were subjected to a standard bleach ( $\infty$ 5%; 10-min b. matrices, were subjected to a standard bleach ( $VOS_4$ ; IO=Inth irradiation). After incubation (for T min) in darkness at  $20^{\circ}$  C, retinas were chilled ( $0^{\circ}$  C) and homogenized. The ROS were isolated by sucrose flotation and subjected to initial washing with isotonic buffer. Levels of G eluted by hypotonic and subse-quent hypotonic-GTP washes of the ROS were quantitated by SDS-PAGE and densitometry of identified G bands. Relative binding of G to the membranes was analyzed as the ratio of (G eluting in the hypotonic-GTP wash)  $\ddagger$  (total G eluting in the hypotonic plus hypotonic-GTP washes).

Bleaching induces an immediate increase in the affinity of G for the disc membranes; for freshly bleached (T = 0 min) vs. unilluminated retinas, the fraction of G bound was >80% vs. <15%, respectively. With increasing time of incubation in darkness, the respectively. With increasing time of includation in darkness, the fraction of G eluted in the hypotonic-GTP wash declined gradually and that eluted in the hypotonic wash increased. For T = 90 min, the fraction of G in the hypotonic-GTP wash (=15%) indicated an essentially complete reversal of the bleaching-induced binding to the disc membranes. The period in darkness required for halfcompletion of the recovery was  $\geq 30$  min. Throughout the period of T = 0-90 min, total G eluted in the hypotonic plus hypotonic-GTP washes was roughly constant. These observations will be discussed in relation to the time course of dark-adaptation in toad photoreceptors

THE DIRECT RESPONSE OF THE FROG IRIS TO LIGHT IS INHIBITED BY CAMP. L. Barr and K. Hunsicker\*. Dept. of Physiology and Biophysics. University of Illinois, Urbana, IL 61801. The pupillary sphincter smooth muscle cells of the amphibian

Biophysics. University of Illinois, Urbana, IL 61801. The pupillary sphincter smooth muscle cells of the amphibian iris contain rhodopsin and contract when the rhodopsin is bleached by light. Therefore there is a response sequence in these cells which starts with a sensory response system like that of a retinal rod but ends by triggering smooth muscle cell's contractile apparatus. Preparations of sphincter pupillae were dissected free and cleaned of the iridial stroma. The resulting rings were hung in vitro in order to measure the time course of the tension responses. Responses as small as 0.1 mg were re-corded. We investigated the sequence of events between the ab-sorption of light by the rhodopsin and the generation of active tension. As we surmised from the persistence of the iridial re-sponse to light in Ca<sup>++</sup> free or isotonic K2SOQ bathing solutions, neither TTX nor Verapamil (i.e., blockade of voltage dependent Na<sup>+</sup> channels or Ca<sup>++</sup> channels) prevent the photoresponse of the iris. The photoresponse is unaltered by even 10<sup>-4</sup> M 8-bromo CGMP. On the other hand, as could be surmised from the excitation-coupling sequences seen in other smooth muscles, IBMX and 8BcAMP inhibit tension development in the sphincter pupillae. The calmodulin blocker, TFP, also blocks the iridial photo-response. Our working hypothesis is, therefore, that light acti-vated rhodopsin causes an increase in free intracellular calcium which combines with calmodulin to activate the contractile ap-paratus without the necessity of a transmembrane potential change or an intervening change in cGMP.

ELECTROPHYSIOLOGICAL INVESTIGATION OF DROSOPHILA MUTANTS DEFECTIVE IN PRESUMPTIVE RHODOPSIN STRUCTURAL GENE. E. C. Johnson\* and W. L. Pak (SPON: G. S. Wasserman). Department of Biological Sciences, Purdue University, West Lafayette, IN 47907. Recent work in our laboratory has shown that the <u>ninaE</u> gene on the third chromosome is very likely to be the structural gene for pound eye (Scavarda et al., 1983). Mutations recovered to date from this locus severely reduce the rhodopsin content in R1-6 photoreceptors but not in R7/8 photoreceptor. We have examined several parameters of light-evoked photoreceptor responses of two allelic mutants of <u>ninaE</u>, <u>ninaEP332</u> and <u>ninaEP334</u>, by means of intracellular recording techniques. V-log I curves, which plot the amplitude of the receptor potential against log intensity, are shifted toward the direction of high intensity by about 3 and 6 log units in P332 and P334, respectively, in comparison to those of wild type. The receptor potential of invertebrate photoreceptors consists of small voltage fluctuations, known as "bumps," each of which is thought to be generated by the absorption of a single photon. From the amount of light needed to generate a single bump, we estimate the amount of rhodopsin in R1-6 photoreceptors of P332 and P334 to be approximately 10-3 and 10-6 of the wild-type level respec-tively. Since in flies the receptor threshold is thought to be linearly related to the amount of visual pigment, these estimates are with the threshold measurements hased on V-log L curves tively. Since in flies the receptor threshold is thought to be linearly related to the amount of visual pigment, these estimates linearly related to the amount of visual pigment, these estimates agree with the threshold measurements based on V-log I curves. Power spectra obtained from wild type and P332 display nearly the same shape changes with increasing stimulus intensity, suggesting that both P332 and wild type follow the same course of adaptation. The bump rate varies linearly with stimulus intensity over a wide range of intensities for both wild type and P332 with the P332 curve shifted toward the high intensity direction by a few log units. For a given level of depolarization, the noise amplitude is larger in P332 than in dark adapted wild type and larger still in P334 (>2X), suggesting that the amplitude of individual bumps are substantially larger in the mutants. The increase in bump size in the mutants with a drastically reduced level of rhodopsin is difficult to understand in terms of the existing models of bump production. bump production.

EFFECTS OF CALCIUM ON OUTER SEGMENT MEMBRANE CURRENT OF TOAD 201.8 RODS. G. Matthews. Dept. Neurobiology, SUNY, Stony Brook, NY 11794

External calcium concentration is known to have strong effects on the light response and dark potential of vertebrate photore-ceptors. To examine more directly the effect of calcium on the light-sensitive conductance, the outer segment membrane current of an isolated rod was recorded with a suction electrode (Baylor et al., 1979, <u>J. Physiol.</u>, <u>288</u>, 589) in solutions containing different calcium concentrations. In these experiments, calcium concentration was changed by moving the suction electrode and re-corded cell from one solution to another. The inner segment of the rod was held within the suction electrode and the outer seg-ment was exposed to the bathing fluid. When calcium concentration was lowered from 1.0 to 0.1 mM, the dark current and the flash sensitivity (peak amplitude of a linear flash-response divided by flash photon density) increased 2-3 fold. The timedivided by flash photon density) increased 2-3 fold. The time-to-peak of dim-flash responses increased slightly in low calcium, and the relation between flash sensitivity and time-to-peak was similar to that observed during background desensitization (Bay-lor et al., 1980, J. Physiol., 309, 591). When calcium was de-creased still further, however, this relation did not hold, and in fact at  $10^{-8}$  M calcium the sensitivity declined by as much as 3-4 orders of magnitude, as observed previously in experiments weight thread by the recent of the fact of the physical section using intracellular recording by Bastian & Fain (1982, J. Physiol. 330, 307). Addition of the divalent cation ionophore A23187 to normal saline at 0.2  $\mu$ M reduced the dark current and flash sensi-Normal shifting at 0.2 µm reduced the during carlots and instantial tivity without significant effects on response kinetics. The desensitizing effect of very low external calcium could be coun-teracted by background illumination, as reported earlier by Bastian & Fain. This sensitizing effect of illumination was not associated with an appreciable increase in the dark current and could be produced by backgrounds that themselves produced no de-tectable response. The desensitization in very low calcium and the sensitizing effect of light could be explained at least in part if the outer segment conductance is very high in  $10^{-8}$  M calcium, shunting the dark current. In experiments in which half of the outer segment was drawn inside the suction electrode, some evidence for such a shunt was the observation of a response of evidence for such a shunt was the observation of a response of reversed polarity when light was flashed on the portion of the outer segment inside the electrode. This suggests that current from the base of the outer segment, which would normally flow entirely inside the electrode and thus not be recorded, was di-vided between the inner segment and the abnormally low resistance of the outer segment membrane. (Supported by USPHS Grant EYO3821 and by the Alfred P. Sloan Foundation.)

LINEARITY AND TIME-INVARIANCE OF TURTLE CONE PHOTORECEPTORS. Scott J. Daly\* and Richard A. Normann, Department of Bioengineering, University of Utah, Salt Lake City, Utah 84112. Baylor and Hodgkin (J.Physiol., 234:163, 1973) have shown that turtle cone photoreceptors manifest linearity for dim flashes which evoke low amplitude responses. They also suggested that the turtle cone is time invariant in this linear roution hour door which the intervent of the sum 201.9 region based on their observation that the integral of the cone impulse response was equal in amplitude and kinetics to the cone step response. From these principles of linearity and time invariance, we have modelled the dependence of cone quantal sensitivity on stimulus duration. For short duration pulses, cone sensitivity should be constant; the response is a function only of the purplet of containing and a purplet. pulses, cone sensitivity should be constant; the response is a function only of the number of quanta in the pulse. For long duration pulses, cone sensitivity should be inversely proportional to pulse duration. Plotting log sensitivity versus log pulse duration, the short and long pulse regions approach asymptotes which intersect at a time which characterizes the temporal properties of the cone. The model indicates that this asymptotic intersection time should equal the area under the impulse responded by the response The area under the impulse response divided by the response amplitude (the normalized impulse response). We used standard intracellular recordings from turtle cone

photoreceptors to verify the above predictions. We measured the dependence of cone sensitivity on pulse duration. The experimental data showed the predicted asymptotic behavior. However, the intersection time was three times less than the However, the intersection time was three times less than the normalized impulse response, and consequently, the asymptotic intersection time measured was three times lower than predicted. An additional anomaly appeared in the data. We predicted that the ratio of the area under any linear range response to the number of quanta in the stimulus should be constant. Our measurements indicate that this ratio is only constant for short duration stimuli, and decreases measurements lower than the stimulus of the area under any linear the stimulus of the area under a stimuli, and the stimulus of the area and the stimule of the area and the area and the stimule of the area and the stimule of the area and the stimule of the area and the area and the area and the area and the area and the area and the area and the a monotonically for longer duration stimuli.

These results suggest that the time invariant aspect of the linear range needs more investigation. Moreover, light adaptation may occur even in the "linear range" of the cone.

201.11 INHIBITION OF G-PROTEIN FUNCTION BY MONOCLONAL ANTIBODY IN LIGHT- AND HORMONE-SENSITIVE CELLS. <u>Heidi E. Hamm, Joseph</u> <u>S. Takahashi and M. Deric Bownds</u>. Lab of Molecular Biology

INHIBITION OF G-PROTEIN FUNCTION BY MONOCLONAL ANTIBUDY IN LIGHT- AND HORMONE-SENSITIVE CELLS. <u>Heidi E. Hamm, Joseph</u> <u>S. Takahashi and M. Deric Bownds</u>. Lab of Molecular Biology and Dept. of Zoology, Univ. Wis., Madison, WI 53706, and Lab. of Clinical Science, NIMH, Bethesda, MD 20205. In an effort to find a specific blocker of the light-activated cGMP pathway in frog rod outer segments, a series of monoclonal antibodies to the G-protein were tested for functional effects on the cGMP cascade. One out of the seven purified antibodies tested completely blocked light-induced phosphodiesterase (PDE) activity of permeabilized rod outer segments at low and intermediate light levels; at saturating light levels the antibody caused a significant reduction in PDE activation compared to controls incubated with nonspeci-fic antibody (commercially available IgG or IgG purified from control NSI ascites fluid). The antibody also inhibited light-induced guanyl nucleotide binding, thus it appears to turn off the cGMP pathway by blocking its first step. The antibody inhibition was stoichiometric, i.e., it required only one antibody per G-protein in the mixture for inhibi-tion, and the effect was complete by lo min of incubation. An unexpected second effect of the antibody is to block the phosphorylation of two small proteins, Components I and II, phosphorylation of two small proteins, Components I and II phosphorylation of two small proteins, Components I and II, that have previously been shown to be controlled by light and CGMF; the other six antibodies had no effect on any phosphorylation. Addition of CGMP to the mixture did not reverse antibody inhibition of Components I and II phosphorylation; this indicated that the antibody was not having its effect simply by changing CGMP levels in the outer segment. One possibility is that Components I and II nor-mally control earlier steps of the pathway, such as G-protein or PDE activity.

or PDE activity. In view of the possible homology between G-proteins in light- and hormone-sensitive systems, the effect of the inhi-bitory G-protein antibody on beta-adrenergic stimulated adenylate cyclase was studied. In rat pineal membranes, the antibody inhibited basal, as well as isoproterenol, fluoride- and guanine nucleotide-stimulated adenylate cyclase fluoride- and guanine nucleotide-stimulated adenylate cyclase (approx. 50% inhibition in all cases), while nonspecific anti-body had no effect. Protein blotting (Western) analysis shows a protein band present in rat pineal membranes that binds G-protein antibody at approx. MW 40,000 and another minor band at approx. MW 52,000. These results are further evidence for a structural and functional homology between G-proteins in different tissues.

- BRANCHING OF CENTRAL PROCESSES OF DORSAL ROOT GANGLION CELLS IN 201.10 CATS. K. Chung and R.E. Coggeshall. Departments of Anatomy and Physiology and Biophysics and the Marine Biomedical Institute,
  - University of Texas Medical Branch, Galveston, Texas. Dorsal root ganglion cells are described as pseudounipolar neurons with a single central process that enters the spinal cord via a dorsal root. The major evidence supporting the concept that each dorsal root ganglion cell has a single central process are the counts showing equality of axon and ganglion cell num-bers. Recently, however it has been shown that the axonal counts are inaccurate because of the limited resolution of the light microscope, and when the counts were repeated in the rat, there was a surplus of axons to ganglion cells. The present report extends this work to the cat. Dorsal root ganglion cells were counted in serial light micro-

scopic sections and dorsal root axons from the same segment were counted in the electron microscope. Our preliminary data are shown in tabular form below.

SEGMENT	AXONS	CELLS	SEGMENT	AXONS	CELLS
S1	18,963	8,777	<b>S</b> 2	13,674	8,769
S1	11,858	11,920	S2	13,645	8,881
S1	19,242	12,311	S2	17,128	8,405
S1	22,474	16,982	S2	20,236	12,478
S1	18,148	14,458	S2	16,041	10,508

Note that there is an excess of dorsal root axons as compared to ganglion cells and that the ratio is approximately 1.5/1. interpret these data as indicating that the central processes of some, perhaps many, dorsal root ganglion cells in the cat are branched. It will be important to determine if different branches have different destinations and if certain functional catagories of dorsal root ganglion cells have branched central axons whereas others do not. Partially supported by grants NS10161, 17039, 11255 and 07377 from NIH and an award from the Moody Foundation of Texas.

MEASUREMENT OF ELECTRICAL COUPLING BETWEEN RECEPTORS OF THE 202.1 SALAMANDER RETINA. Martin Wilson, David Attwell\* and Samuel Wu Department of Zoology, University of California, Davis, CA 956 95616, Department of Physiology, University College London and Cullen Eye Institute, Houston, TX 77030.

Electrical coupling between receptors has been measured using pairs of intracellular microelectrodes under visual control These data have been combined with voltage-clamp data obtained These data have been combined with voltage-clamp data obtained previously from isolated rods and cones (Attwell and Wilson, J. <u>Physiol. Lond.</u>, 309:287, 1980; Attwell, Werblin and Wilson, J. <u>Physiol. Lond.</u>, 328:259, 1982) to provide a quantitative model of the receptor network. The use of the model to predict deviations from spectral univariance in retinal receptors is described in another abstract (Wu, Attwell and Wilson, <u>Neurosci</u>. Abst. 1983). Injection of -InA current into a rod elicited a hyperpolariza-tion of beaut 20 Wide mediante when when Wilson

tion of about 20 mV in an adjacent rod and 4 mV in an adjacent cone. More distant receptors showed smaller responses. Injection of -lnA into a cone elicited a hyperpolarization of about 4 mV in a neighboring rod but only 0.5 mV in a neighboring cone. No voltage change was detected in half of a double cone when -lnA was injected into the other half. Assuming that every rod is directly coupled, via ohmic junc-

tions, to 4 neighboring rod is differly coupled, via binning the tions, to 4 neighboring rods and 4 neighboring cones, and that cones are not directly coupled to each other, our results imply a coupling resistance of 300 M $\Omega$  between adjacent rods and 5,000 M $\Omega$ between a rod and an adjacent come. Because of their weak coupling to rods we have omitted comes

from a consideration of signal processing by the rod network. Our model predicts that spatial resolution by the rod network is time-dependent and that the temporal frequency response of the rod network decreases below 5 Hz. Supported by NIH grants EY04112, EY04446, EY00561, an M.R.C. (U.K.) project grant (D.A.) and a grant from the Retina Research Foundation (Houston) (S.W.).

AN ANALYSIS OF SPECTRAL INTERACTIONS BETWEEN RODS AND CONES OF 202.2

AN ANALYSIS OF SPECTRAL INTERACTIONS BETWEEN RODS AND CONES OF THE TIGER SALAMANDER RETINA. <u>Samuel M. Wu</u>, <u>David Attwell\*</u> and <u>Martin Wilson</u>. Cullen Eye Institute, Baylor College of Medicine, Houston, Tx.; Dept. of Physiology, University College London, England; Dept. of Zoology, University of California, Davis, Ca. Photoreceptors are considered to be univariant if their voltage responses depend on the number of photons absorbed, and not on the wavelength (Naka & Rushton, <u>J. Physiol</u>. 185:556,1966). Receptors in the intact retina showed deviations from univariance (or <u>Constants</u> Schwartz & Simon <u>J. Physiol</u> 1973) In (e.g. Fourtes, Schwartz & Simon, <u>J. Physiol</u>. 234:199,1973). In this paper, we report experiments which re-examine these deviations and determine whether they can be explained by photoreceptor coupling. Light responses from rods, single cones and double cones

isolated from the tiger salamander retina were recorded. Stimuli of various wavelength were adjusted in intensity until they produced voltage responses of equal peak amplitudes. Results obtained demonstrated that univariance is obeyed by these isolated photoreceptors.

isolated photoreceptors. Receptors in the intact retina, however, showed significant deviations from univariance: (1) Green-sensitive rods: For low response amplitudes, 700nm light gave a faster response onset than 520nm light. For large response amplitudes, 520nm light gave a faster response onset than 700nm light, and at the termination of a lsec light step 700nm light produced a transient depolarization which 520nm light did not. (2) Single and double cones: For low response amplitudes, 520nm light gave a faster response onset than 700nm light. For all response amplitudes, after a lsec step of 520nm light the response of cones showed a long hyperpolarized tail which was not produced by 700nm light.

after a lsec step of 520nm light the response of cones showed a long hyperpolarized tail which was not produced by 700nm light. Green-sensitive rods have a peak spectral sensitivity around 520nm, single and double cones have theirs around 620nm. Using a quantitative model of the photoreceptor network described in the previous presentation (Wilson, Attwell & Wu, <u>Neurosciences abstract</u> 1983), we found from computation that most of these deviations can be explained by electrical coupling between rods and cones

Supported by a N.I.H. grant EY04446 and a grant from the Retina Research Foundation (Houston) to S.M.W., a M.R.C project grant to D.A. and a N.I.H. grant EY04112 to M.W.

INTER-PHOTORECEPTOR CONTACTS IN THE TURTLE RETINA: COLOR CODING. Jill Jones\* and Helga Kolb. Department of Physiology, University of Utah, Salt Lake City, Utah 84108. Synaptic contacts between photoreceptors in the OPL of the 202.3

Synaptic contacts between photoreceptors in the OPL of the turtle retina have been studied by light and electron microscopy. Neighboring cone pedicles, and rod and cone pedicles make a combination of narrow and wide gap junctions at apposed surfaces (Lasansky, 1971). Photoreceptor telodendria end or give off <u>en passant</u> small projections that become central elements in cone invaginations but the contact may only be with the horizontal cell lateral element (Lasansky, 1971). Telodendria also swell into large vesicle filled profiles that lie in the neuropil of the OPL or enter photoreceptor synaptic complexes, where they engage in wide cleft junctions with photoreceptors and occasionally with bipolar cell dendrites. Light microscopic examination of Golgi stained photoreceptors of the ir

photoreceptors indicate some cone specific connections of their telodendria. Blue single cones go to green single cones, red members of the double cones and red single cones. Both green and red single cones project to neighboring red single cones, green single cones and both members of the double cones but each appears to send more projections to its own color type. Green and red members of the double cone have extensive short projections to each other. The green member also has telodendria to red, green and blue single cones and to both members of other double cones, while the red member goes to a green single cone type. Rods have very long ranging and multibranched telodendria that project to all the cone types but not to other rods. However, their wandering telodendria could be making gap junctions with other rod telodendria in the neuropil of the OPL. Further electron microscopy of the Golgi stained photoreceptors may elucidate the exact nature of these photoreceptor contacts. and red single cones project to neighboring red single cones, photoreceptor contacts.

202.4 GAIN, ABSOLUTE SENSITIVITY AND SIGNAL/NOISE IN BUFO

GAIN, ABSOLUTE SENSITIVITY AND SIGNAL/NOISE IN BUFO MARINUS RETINA. D. R. Copenhagen and T. Reuter\*, University of California, San Francisco, CA 94143 and University of Helsinki, SF-00100, Helsinki 10, Finland. Responses to flashes and steps of light were re-corded intracellularly from rods, horizontal cells and spiking cells and extracellularly from ganglion cells. All recordings were made under identical conditions in dark-adapted eyecups. Maximum flash sensitivities (response amplitude [mV]/photoisomerization per rod [Bb\*]) were found to be 0.9 mV/Bb\* in rods and 6.5 mV/ [Rh\*]) were found to be 0.9 mV/Rh\* in rods and 6.5 mV/Rh\* in horizontal cells. Flash sensitivities in the Rh\* in horizontal cells. Flash sensitivities in the rarely encountered bipolar cells (n = 4) appeared to exceed those of the horizontal cells by 1.5 to 2 times, while spiking cells exhibited flash sensitivities up to 100 mV/Rh\*. Thus, rod signals are amplified as they are transmitted through the retina. The overall amplification exceeds that at the rod to second order neuron synapses, indicating that the gain is distributed sequentially at synapses along the rod pathway. Threshold responses in ganglion cells could be elicited with stimuli producing 0.006 to 0.02 Rh\*. At these flash levels, the average hyperpolarization in each rod ranged from  $_{\sim}$  5 to 20  $\mu V.$  Analysis of signal/noise ratios at absolute threshold, which considered integration times and receptive

field sizes of signal horse factor times and receptive field sizes of each type of neuron, indicated that de-tection of light is limited primarily by spontaneous thermal isomerizations of rhodopsin molecules. Thus, noise processes associated with the random action of synaptic transmitters degrade detection minimally. Furthermore, the enhancement of signal/noise, which enables ganglion cells to reliably detect threshold stimuli, can be accounted for on the basis of simple spatial summation in which the noise generated in rods is summed as vn and light signals as n.

202.5

TEMPORAL TRANSFER PROPERTIES OF INTRARETINAL PATHWAYS IN TURTLE: EFFECTS OF TEMPERATURE, SPOT SIZE, AND INTENSITY. <u>A.R. Adolph.</u> Eye Research Institute, Boston, MA Horizontal cell(HC) response linearity and transfer properties are a function of stimulus diameter and intensity, as well as temperature. At a fixed temperature and stimulus intensity, transfer function low-pass cut-off frequency or low-frequency peak breadth decrease with decreasing spot size. With fixed temp-erature and stimulus size, nonlinearity(the number and amplitudes of second-order distortion products) decreases as a function of light intensity; with fixed temperature and light intensity, non-linearity decreases with stimulus diameter. For light intensities which do not saturate the response dynamic range, nonlinearity is engligible. Dopamine(DA) modifies HC transfer properties and flash responses. Flash response to a large spot, after DA, resembles the pre-DA response of the same HC to a small spot. An HC naving a smooth, broadly peaked low-pass transfer function to HC having a smooth, broadly peaked low-pass transfer function to a 5mm spot, and a monotonic low-pass transfer function to a 500u a 5mm spot, and a monotonic low-pass transfer function to a 500u spot, before DA, has a monotonic low-pass transfer function to the large spot, after DA. Large spot flash response, after DA, re-sembles control small spot response. These effects of DA may be due to its uncoupling action on HC intercellular junctions. Flash response of a hyperpolarizing bipolar cell(HPBC), at a fixed temp-erature to a lmm spot is larger than its response to a 5mm spot (less surround inhibition). There is a slight decrease in trans-fer function low-pass cut-off frequency for the smaller spot compared to the larger spot. For constant spot size, flash response exhibits slower on-and off-set as temperature decreases. Temporal characteristics of the flash response of a sustained amacrine cell are temperature dependent: onset, offset, and amplitude of full-field flash response slow and decrease as amplitude of full-field flash response slow and decrease as temperature decreases. Transfer function is also temperature dependent: The broadly peaked, low-pass shape changes to a monotonic, low-pass shape as temperature is reduced. Generally, cells having relatively sustained flash responses(receptors, horizontals, bipolars, sustained amacrines) differ in their transfer properties from cells like transfert amacrine or ganglion cells. Transfer from cells like transfert amacrine or gangiton cells. Fransfer functions of "sustained-type" cells are narrowly peaked at low frequencies with monotonic, low-pass, high-frequency shapes. In contrast, transfer functions of "transient-type" cells are attenuated at low-frequencies, with broad, mid-range peak and monotonic low-pass, high-frequency shape.

A MODEL OF THE CAT RETINAL AII AMACRINE CELL: ELECTROTONIC RECTIFICATION VIA A LOBULAR APPENDAGE. J.K. Stevens, J.R. Jacobs Playfair Neuroscience Unit, Toronto Western Hospital, University of Toronto, 202.7 Toronto CANADA.

Toronto CANADA. The AII amacrine cell of the cat retina likely conveys rod signals to ganglion cells (Nelson, J. Neurophys.47:928-947 1982). The narrow (40-60 um dia.) dendritic field of the AII arborises in sublamina b of the IPL, and receives synaptic inputs from rod bipolars and makes gap junctions with invaginating cone bipolars. A unique feature of this neuron is a number of babuar emerdance connecting with the some

bipolars and makes gap junctions with invaginating cone bipolars. A unique feature of this neuron is a number of lobular appendages connecting with the soma or proximal dendritic tree through a 1 to 3 micron long neck, as little as 0.2 microns in diameter, and terminating in a swelling 1 to 6 microns in diameter. Lobular appendages are limited to sublamina a of the IPL, receiving inputs from other amacrines and contacting cone bipolars and ganglion cells (Famiglietti and Kolb, Br. Res.84:293-300 1975). Three complete reconstructions of AII amacrine cells were made from series of electron micrographs of ultra-thin, transversely sectioned cat retina, using a computer assisted reconstruction system (Stevens, Br Res Rev2:265-293 1980). Quantitative data of cell morphology obtained from these reconstructions were used to create a steady state electrotonic model of AII amacrine response to synaptic inputs. With sustained synaptic inputs on the lobular appendage, the membrane potential saturates to local maximum; however, the thin neck minimizes the potential change in the soma or the dendritic tree. In contrast, inputs to the dendrites or to the soma create large changes within the soma and dendrites as well as in the lobular appendage. Thus, the lobular appendage neck effectively acts as a rectifer allowing signals to pass from soma to the lobular appendage, but attenuating signals passing from the lobular appendage, but attenuating signals passing from the lobular appendage, but attenuating signals passing from the lobular appendage. to JKS.).

- COMPUTER MODEL OF CONE PATHWAYS IN FROG'S RETINA. Y. Lee\* and 202.6 M. Arbib. COINS Dept. and the Cer Univ. of Mass., Amherst, MA 01003. COINS Dept. and the Center for Systems Neuroscience,
  - There is a rich set of physiological and anatomical data that describes the functions and the underlying structures of the vertebrate retina. But our partial understanding of the neural mechanisms of the retina, together with the differences in the species, levels and methodologies make it almost impossible to integrate essential data into a self-consistent framework. Choosing a species to model cuts down much of the diversities and incompatibilities of the available data. The frog retina is chosen because of the complexity in its response character-

is in the most of the complexity in its response chalacter-istics among other reasons. Cone pathways were chosen to be modelled first to reduce the initial modelling efforts without ignoring the salient features of the output characteristics of the frog's retina. A compute A computer model at the cellular level can provide a coherent and, event-ually, comprehensive conceptual framework to work/think with. The retina is viewed as multiple layers of computing elements which process local visual information in a parallel manner. Overall synaptic organization of the retina follows that of Overall synaptic organization of the retina follows that of Dowling (1976), where a spatial analysis of visual input is initially performed in the outer plexiform layer and a temporal analysis is added in the inner plexiform layer. Major portions of light/dark adaptations are carried out at the photoreceptor level in the model. Cell densities, e.g. 36 single cones per degree<sup>2</sup> at the photoreceptor level, as well as receptive field (RF) sizes are represented following the anatomical data. The center/surround RFs are represented as a 2-dimensional difference of Gaussians. To explain the ethological data quantitatively, the blurring of the retinal image caused by the frog's optical apparatus is included in the model as well as the explicit relationship between the stimulus size, distance and the image size. Initial results show the simulation of the model agrees

qualitatively with the well-known frog's retinal ganglion cell responses.

ON GRATING RESPONSES OF VISUAL CELL SUBUNITS INTERACTING BY MULT-202.8 IPLICATIVE LATERAL INHIBITION. <u>R, B, Pinter</u> Departments of Electric-al Engineering and Zoology, University of Washington, Seattle, 98195.

The shilty of a visual cell to discriminate between marrow and wide field stimuli can be explained on the basis of nonlinear mul-tiplicative lateral inhibition (Pinter, J, theor. Biol. 100, 525; 1983). Further, the numerical values and distribution of this lateral inhibition are not critical to this and other nonlinear response

properties, such as latency shift with mean illumination shift. The nonlinear pathway of Y retinal ganglion cells consists of many nonlinear subunits (Victor and Shapley, 1979, <u>J. Gen. Physiol. 74</u>, 671) of rectifying character, possibly bipolar cells. Koch et al. (1982, <u>Phil, Trans, R. Soc, Lond, B</u> 298, 227) showed the possibility of nearly independent electrical subunits of Y cells. It was suggested that the ganglion cell's activity observed in some potential and spike rate might reflect a linear summation of the electrical subunits' activity.That the nonlinear subunits' activity might be the input to the electrical subunits is a reasonable possibility. This would explain the adding up of subunit activity for the Y cell. The rectifying character of Y cell response arises not necess-arily from a mathematically apecific but cellularly unamerified

arily from a mathematically specific but cellularly unspecified rectifier, but possibly from multiplicative lateral inhibition between subunit cells. This interaction between subunit cells in the Y cell receptive field clearly explains the difference in relative amounts of fundamental and second harmonic response for the temporally modulated stationary bar and peak spatial phase grating versus the null spatial phase grating. This is simply a result of the multiplicative lateral inhibition system's fundamental response polarity dependence on polarity of the input fundamental, and the second harmonic response polarity independence. Thus an array of closely spaced subunits stimulated by a centered null phase stationary grating possesses equal amounts of positive and negative fundamental frequency response, and these add up to zero in the linear summation of subunit activity. The summation of second harmonic and DC component responses is unaffected by polarity of the input fundamental frequency, and therefore remains constant with respect to stationary grating position, or bar versus null grating stimulation. The dependence of second harmonic response on contrast, and the independence of DC response on contrast, are also explained by multiplicative lateral inhibition.

A distinctly different problem is presented by the response of Y cells to drifting gratings. There is not as much second harmonic response as for stationary gratings, but low spatial frequencies and moderate temporal frequencies of the drifting grating cause large second harmonics. This property is also demonstrated by multiplicative lateral inhibition.

- RETINA I
- LINEAR AND NONLINEAR RESPONSES OF BRISK-TRANSIENT (Y) GANGLION 202.9 CELLS OF THE CAT RETING VARY WITH GRAINED (I) GANGLION CELLS OF THE CAT RETING VARY WITH GRAINED ORIGINATION IN DIFFERENT WAYS. L.N. <u>Thibos\* and W.R. Levick</u>. Physiology Dept., J.C.S.M.R., Australian National University, Canberra, AUSTRALIA 2601.

AUSTRALIA 2601. Y-cells display two types of behaviour, linear and nonlinear, which can be isolated for study by a low-frequency drifting grating and by a high-frequency alternating grating, respectively. Previous experiments have revealed that responses of brisk-transient Y-cells to drifting gratings often depend strongly upon stimulus orientation. We asked whether the same might also be true for alternating gratings and, if so, whether the characteristics of such orientation bias are the care or different from these formed for drifting creations.

the same or different from those found for drifting gratings. Data was collected from 5 adult cats anaesthetized for surgical procedures with 1-2% halothane and maintained during surgical procedures with 1-2% halothane and maintained during data collection on 70:28.5:1.5 mixture of nitrous oxide, oxygen and carbon dioxide. The gas mixture was supplemented during inactive stages of the experiment by 30 mg/kg.hr of urethane. Eye movements were controlled by intravenous infusion of neuromuscular blocking agents and the animal was artificially ventilated. Extracellular recordings were made from the cell bodies of cells with tungsten-in-glass microelectrodes. bounds of certis with tungsten-H-grass microelectrodes. Experimental procedure was to collect histograms of nerve action potentials for gratings of fixed contrast (50%), mean luminance ( $82 \text{ cd/m}^2$ ) and temporal frequency of modulation (2 Hz). Grating orientation and spatial frequency were the stimulus variables. Histograms were subjected to Fourier

analysis to determine the magnitude of responses. Some cells were found to have a significant degree of orientation bias for both drifting and alternating gratings. of For these cells the preferred orientations for the two types of grating stimulus tended to be the same but substantial differences were frequently observed. Other cells were biassed for only one or other of these stimuli and still other cells were not biassed for either stimulus.

were not biassed for either stimulus. Orientation bias for drifting gratings has been shown previously to have a radial pattern of symmetry which is centred about the area centralis. A systematic preference for radially-oriented gratings was evident also for alternating gratings in present experiments. Furthermore, there was an additional preference for circumferentially-oriented gratings when the stimulus was alternating. Peoplet in interact that the area of summetry of the recention

Results indicate that the axes of symmetry of the receptive field components responsible for linear and nonlinear behaviour in brisk-transient Y-cells are not necessarily the same.

MODIFIED KELLY'S MODEL FOR HUMAN VISUAL SYSTEM PREDICTS RESPONSES FROM TURTLE HORIZONTAL CELLS. Richard L.Chappell, Masanori Sakuranaga\* and Ken-Ichi Naka. Hunter College of the City University of New SYSTEM 202.10

Richard L.Chappell, Masanori Sakuranaga\* and Ken-Ichi Naka. Hunter College of the City University of New York, New York, NY 10021, USA; Nippon Medical School, Bunkyoku, Tokyo 113, Japan; and National Institute for Basic Biology, Myodaiji, Okazaki 444, Japan. Recordings were made from horizontal cells in the retina of the red-eared turtle, Pseudemys scripta elegans. The stimulus used was a white-noise modulated (white) light whose mean (and the depth of modulation in proportion) was varied by interposing neutral density filters between the light source and the retina. Power spectra were computed from the responses produced by white-noise stimuli of various mean irradiances. Kelly (1971. J. Opt. Soc. Amer. 61:537) described human photopic filicker data in terms of a theoretical model, a diffusion process followed by an inhibition stage. Human photopic filicker data (the incremental threshold function) and turtle horizontal cell response shared the following features: 1) response power spectra or photic filicker threshold function was constant-gain lowpass at low mean but became bandpass at high mean, 2) constituted flicker threshold function was constant-gain lowpass at low mean but became bandpass at high mean, 2) sensitivity decreased roughly in Weber-Fechner fashion, and 3) the power spectra measured at various means had a single asymptote. Kelly's model was modified into a diffusion stage with a negative feedback stage to reflect functional structure of the retina. The modified model predicted the impulse response (first order kernel) from turtle horizontal cells, as well as Kelly's original human data. As the turtle horizontal cells respond linearly over a large range of potential excursion (more than 20 mV), Kelly's diffusion model is an adequate description of the turtle horizontal cell's dynamic

(This work was supproted in part by NIH Grants EY-00777 and EY-01897.)

#### SYNAPTOGENESIS I

203.1 DEVELOPMENT OF ACTIVE ZONES AT NEUROMUSCULAR JUNCTIONS IN THE TAD-POLE. C.-P. Ko. Dept. of Biological Sciences, University of Sout ern California, Los Angeles, CA 90089. The active zone is a unique specialization at the presynaptic -P. Ko. Dept. of Biological Sciences, University of South-

membrane and is believed to be the site of transmitter release. To study the development of this important structure, cutaneous pectoris muscles in the tadpole and adult bullfrog (<u>Rana cates</u>pectoris muscles in the tadpole and adult bullfrog (<u>kana cates</u>-<u>beiana</u>) are freeze-fractured. As seen in <u>Rana pipiens</u>, the active zones in the adult bullfrog have two double rows of large intra-membrane particles, which are located perpendicular to the long axis of the nerve terminal and precisely aligned with junctional folds. During early development in the tadpole, active zone par-ticles are observed before junctional folds can be identified. Most of these particles have not yet organized and are scattered all over the terminal membrane. Some particles are beginning to all over the terminal membrane. Some particles are beginning to show the adult organization of two double rows, but they are often short and randomly oriented and located. This process differs from regenerating terminals in the adult, where even the early clusters of active zone particles are found only opposite to junctional folds. As development progresses in the tadpole, junctional folds are seen and just opposite to them are active zones with normal organization and orientation.

Cross-fracture shows that developing nerve terminals with scat-tered active zone particles already contain synaptic vesicles. When the nerve is stimulated in dilute fixative, dimples, which may represent openings of synaptic vesicles, are seen at develop-ing active zones regardless of their stage of organization.

At the premetamorphic stages, some junctions have two or more nerve endings lying side by side in the same junctional gutter. The orientation and location of developing active zones at these multiple terminals are also associated with the appearance of junctional folds. After metamorphosis, the incidence of multiple innervation decreases but is still observed in young adults. Freeze-fracture of a small bullfrog (body length 2 in.) shows that some junctions still have two terminals in the same gutter. One is large and has mature active zones. The other is small and has short or disorganized active zones. It is possible that this small terminal is in the process of being eliminated. This study suggests that the localization of developing active

zones may relate to the maturation of junctional folds. Also, developing nerve terminals, are already functional before active zone particles organize into the adult pattern. Furthermore, this preparation provides an opportunity to study changes at active zones and other intramembrane structures during synapse elimination.

ULTRASTRUCTURAL SPECIALIZATIONS AT NEWLY FORMED ACETYLCHOLINE 203.2 RECEPTOR AGGREGATES ON CULTURED MYOTUBES. <u>A. Olek\*, A. Ling\*, an</u> M.P. Daniels. Laboratory of Biochemical Genetics, NHLBI, N.I.H., Bethesda, MD. 20205 and

Ultrastructural specializations have been described at regions of high acetylcholine receptor (AChR) site density at the neuro-muscular junction and on cultured myotubes. To help understand the formation and function of these specializations, we have ex-amined the ultrastructure of identified myotube regions in cultures fixed during the initial formation of AChR aggregates. Using video image intensification, the distribution of tetramethyl rhodamine-**G**-bungarotoxin labelled AChR was observed sequentially from 0-6h after the addition of embryonic brain extract (EBX). AChR aggregates at various stages of development were mapped for later examination of thin sections with the electron microscope. In some experiments the precision of mapping was confirmed using horseradish peroxidase-**%**-bungarotoxin as a marker at the ultrastructural level. Distinct specializations were present within mapped AChR aggregate sites by 4-6h after addition of EBX. They were characterized by the enriched presence of basal lamina and a specialized cytoplasmic structure, within 50-100 nm of the plasma membrane, which largely excluded membranous organelles and myo-fibilit. fibrils. The submembrane structure was composed of filamentous (4-10 nm) and particulate material and was most densely packed between 20-50 nm from the sarcolemma, leaving a relatively elec-tron lucent zone immediately under the membrane. The cell surface in these regions was frequently scalloped and sometimes deeply folded.

The proportion of the plasma membrane subtended by this dis tinct cytoplasmic structure was estimated in random sections from control myotubes and myotubes treated 4h with EBX. In treated cells ~7% of the top half of the myotube membrane was subtended by Specialized structure, and the mean length of a specialized region was 0.9  $\mu$ m. In control cells•3% of the top cell membrane was so occupied, and the mean length of a specialized region was 0.2  $\mu$ m. These values agree reasonably well with the increase (from~1-10%) found after 4h exposure to EBX. The results indicate that distinct ultrastructural speciali-

zations are associated with newly formed AChR aggregates and are assembled at least in part during the early formation of the aggregates.

203.3 DIFFERENTIATION OF POSTSYNATPIC SPECIALIZATIONS ON EMBRYONIC MUSCLE CELLS DEVELOPING IN <u>VIVO</u> WITHOUT MOTOR INNERVATION. <u>G.S. Sohal and R.W. Wrenn\*</u>. Department of Anatomy, Medical College of Georgia, Augusta, GA 30912. The postsynaptic specializations at the mature vertebrate

The postsynaptic specializations at the mature vertebrate neuromuscular junction include synaptic folds, postsynaptic densities, basal lamina, clusters of acetylcholine receptors and acetylcholinesterase. The mechanism by which postsynaptic specializations develop during the course of embryonic development is unknown. The present study tested the hypothesis that interaction of developing motor nerve fibers with the muscle cells triggers development of postsynaptic specializations on muscle cells developing in vivo. Superior oblique muscle of the eye in duck embryos was used as a convenient model to determine if postsynaptic specializations characteristic of mature neuromuscular junctions develop in the absence of motor innervation. Superior oblique muscle was made aneural by permanent destruction of trochlear motor neurons in the midbrain. A relatively large area of the dorsal midbrain was cauterized on embryonic day 7 which is three days before the trochlear nerve fibers normally project their axons into the muscle. Absence of innervation was verified with light and electron microscopy of the muscle. Electron microscopy revealed that synaptic folds, postsynaptic densities, basal lamina and associated acetylcholinesterase developed in the absence of motor innervation. Acetylcholinesterase appeared on muscle cells developing without innervation. I<sup>125</sup> $\alpha$ -bungarotoxin autoradiography indicated that clusters of acetylcholine receptors appeared in aneural muscle. These observations indicate that the presence of motor nerve fibers is not necessary for the differentiation of postsynaptic elements of the neuromuscular junction. Thus, the mechanism for the differentiation of the postsynaptic specializations must be preprogrammed in the developing muscle cell. 203.4 SPONTANEOUS RELEASE OF ACETYLCHOLINE FROM GROWTH CONES OF EMBRYONIC NEURITES. <u>S. H. Young and</u> <u>M-m. Poo</u>, Department of Physiology and Biophysics, Univ. of Calif., Irvine, CA 92717. A patch of outside-out embryonic <u>Xenopus</u> muscle membrane formed with gigohm seal at the tip of a micropipette was used as a probe for the presence of channel-inducing substances. Spontaneous single channel events appeared when the probe was positioned near the growth cones of 66% of <u>Xenopus</u> embryonic neurons in culture (total neurites tested 15). No activity was detected along the neurites or near the soma of any of the neurons. Most of the single channel events have the characteristics of acetylcholine (ACh) induced channels in mean open time, single channel conductance, reversal potential, as well as susceptibility to blockage by **G**-bungarotoxin. This suggests that these neurites release ACh from growth cones. The release of ACh occurred in bursts. Some bursts were characterised by rapid rise of multiple channel current followed by slow decline in number of active channels in a "staircase" pattern (see figure). Prolonged release activity was found to be composed of a sequence of staircase bursts. In addition, activation of other as yet un-identified channels were also observed as the membrane patch approached the growth cone. Release of ACh and other substances from growth cone may occur as a by-product of new membrane incorporation during the process of neurite extension; it may also be used by the (NS-1758-01A1) and NSF (BNS 80-12348). S.H.Y. is supported by a fellowship from Muscular Dystrophy Association of America.

203.5 RAPID INDUCTION OF ACETYLCHOLINE RELEASE FROM THE NEURONAL SOMA BY MUSCLE CONTACT. <u>I. Chow and M-m. Poo</u>. Dept. of Physiology and Biophysics, University of California, Irvine, CA 92717.

Spherical muscle cells were manipulated into contact with the soma of neurons in 2-day old Xenopus co-cultures, and changes in the muscle cell membrane potential were monitored by using intracellular microelectrode. Miniature acetylcholine potentials (MAPs) were detected within 10 min of contact in 55% of the soma-muscle cell pairs (N=65). An additional 10% of the cell pairs showed MAPs in the subsequent 20 min of contact. The average MAP amplitude in these cell pairs was  $3.8 \pm 0.2$  mV ( $\pm$  SE) and the average frequency was 0.06 ± 0.02 events/s (± SE), whereas the average miniature end plate potential (MEPP) amplitude at already established neuritemuscle junctions was 6.1  $\pm$ 1.0 mV ( $\pm$  SE) and the frequency was 0.35  $\pm$  0.05 events/s ( $\pm$  SE). The average MAP rise time in the induced soma-muscle cell pairs,  $9.7 \pm 0.6$  ms ( $\pm$  SE), was longer than the MEPP rise time found at the already established junctions, 4.7  $\pm$  0.4 ms ( $\pm$  SE). No MAPs were detected when  $\checkmark$ -bungarotoxin pretreated muscle cells were pushed into contact with identified cholinergic neuronal somas. Interestingly, no MAPs were detected within 30 min of contact between a muscle cell and the soma of a neuron which had already established functional contact with other muscle cells (10 cell pairs tested). These results indicate that neuronal soma can be induced to release acetylcholine by direct contact with a muscle cell. Furthermore, the prior functional contact with other muscle cells apparently led to cellular modulation of the neuron which prevented this muscle cell-induced acetylcholine release from the soma.

This work is supported by grants from NIH (NS-17558-01A1) and NSF (BNS 80-12348).

203.6 NON-QUANTAL RELEASE OF ACETYLCHOLINE AT EMBRYONIC NEUROMUSCULAR SYNAPSES IN CULTURE. Y-a. Sun\* and M-m. Poo. Dept. of Physiology and Biophysics, Uni. of Calif. Irvine, CA. 92717 Local application of tubocurarine (1.5 mM) at neuromuscular synapses in Xenopus embryonic nervemuscle culture resulted in a transient hyperpolarization of muscle membrane potential. Miniature endplate potentials (MEPPs) were abolished during the hyperpolarization and recovered after the return of resting membrane potential. The average peak amplitude of hyperpolarization was 5.8 ± 0.7 mV (N=19, S.E.). The peak amplitude was independent of the frequency of MEPPs, and decreased when curare was applied at regions away from the synapse. Prolonged application of curare led to sustained hyperpolarization of the membrane potential. Ejection of recording medium with similar pressure was without effect. Local ejection of curare on non-innervated muscle cells resulted in a transient depolarization of the membrane potential, consistent with the previous reports of agonist action of curare in embryonic muscle cells. Bi-phasic response (depolarization followed by hyperpolarization) was observed in newly-formed synapses upon local curare application, suggesting a transition of curare aptication, suggesting a transition of curare action on muscle cells from that of an agonist to an antagonist after innervated muscle cell by a steady spontaneous release of acetylcholine (ACh) from the nerve terminal. We estimated that the total amount of ACh released in this non-quantal mode exceeds that of the quantal release underlying the normal spontaneous MEPPs by about 100-fold. This work was supported by a grant from NIH (NS-1758-01A1). 203.7 RELATIONSHIP BETWEEN SYNAPTIC VESICLES AND MINIATURE ENDPLATE POTENTIALS IN ADULT AND NEONATAL MOUSE DIAPHRAGM. <u>R. Hanna\* and</u> <u>M.E. Kriebel</u>\*, (Spon: J. Frank), CESF and Upstate Medical Center, SUNY, Syracuse, NY 13210. Miniature endplate potential (MEPP) amplitude distributions of

adult mouse diaphragm junctions show two classes. The larger MEPPs form a bell-shaped distribution (bell-MEPPs or classical MEPPs) with a variance of 20-30%. The smaller MEPPs form a right-hand skew-distribution composing 1-10% of the MEPPs with a mode 1/10th (s-MEPP class) that of the bell-MEPPs. One day old junctions generate mainly s-MEPPs and the MEPP distribution gradually changes to mainly bell-MEPPs during the first 3 weeks of post-natal development. The purpose of this study was to compare the synaptic vesicles and synaptic clefts of one to three-day-old junctions to those of adults. We found no differences between neonates and adults in regards to synaptic vesicle diameter (52 nm 0.D.) distributions nor in synaptic cleft widths. Synaptic vesicle diameters were similar through the terminal. Day old junctions showed no or shallow postsynaptic folds and fewer synaptic vesicles. Junctions were essentially developed by the 3rd day although one-quarter of the MEPPs were of the skew-class. Therefore, skew-MEPPs must originate from synaptic vesicles of the same size as those generating bell-MEPPs because the diameter of a vesicle required to generate s-MEPPs would only be 30 nm 0.D. (assuming that vesicles are simple containers). We found that distributions of adult synaptic vesicle volumes show a marked right-hand skew. Assuming that vesicles contain free ACh and that there is a simple relationship between ACh released and MEPP amplitude, the distribution of vesicle volumes would not generate skew distribution. Moreover, the wide dispersion of vesicle volumes is much greater than the standard deviation of bell-MEPP amplitudes. Since the distribution of MEPPs does not match distributions of vesicles, we conclude that within the constraints of the vesicle hypothesis of transmitter release that skew- and bell-MEPPs are from the same vesicles and that vesicle volume does not determine the amount of ACh released.

203.8 APPEARANCE OF ACETYLCHOLINE CHEMOSENSITIVITY DURING SYNAPTOGENESIS IN FROG SYMPATHETIC GANGLIA. <u>P.M. Dunn\* and L.M. Marshall\*</u> (SPON: J.D. Greenspan) Dept. of Physiology, University of North Carolina, Chapel Hill,NC 27514.

In the frog, synapse formation in the lumbar sympathetic ganglia occurs during the late metamorphic stages of larval development (Marshall, Soc. Neurosci. Abstr. <u>8</u>:866, 1982). We have now studied the development of nicotinic acetylcholine sensitivity in relation to the functional innervation of the sympathetic ganglia of the bullfrog (<u>Rana catesbiana</u>) <u>in vivo</u>. Intracellular recordings were made from principal

Intracellular recordings were made from principal neurons in the 9th and 10th paravertebral ganglia of adult and larval (stages XV - XXV; Taylor & Kollros, Anat. Rec. <u>94</u>:7, 1946) frogs. Recordings from developing neurons were quite stable, with resting potentials (range -40 to -90 mV) equal to or greater than those of adult neurons. The level of synaptic development was assessed from the response to preganglionic nerve stimulation or the presence of spontaneous miniature potentials. Chemosensitivity was examined by recording the response to iontophoretic application of acetylcholine from a micropipette 10  $\mu$ m above the cell surface (in the presence of 0.5  $\mu$ M

At the earliest stages studied (XV - XVII), about 10% of the neurons showed no response to preganglionic nerve stimulation and were insensitive to applied acetylcholine. By the completion of metamorphosis (stage XXV) all neurons examined were functionally innervated.

innervated. These results suggest that in frog sympathetic ganglia, nicotinic acetylcholine sensitivity is not acquired until the onset of synaptic transmission. Experiments are now in progress using light and electron microscopy to correlate the morphological development of synaptic contacts with the appearance of acetylcholine sensitivity. (Supported by NIH grant NS 17203)

- 203.9 INNERVATION OF MYOFIBERS BY CHICK CILIARY GANGLION NEURONS AND RAT PC12 PHEOCHROMOCYTOMA CELLS IN CULTURE. J.C. Norris, N.R. Ways<sup>5</sup> and B.G. Wallace, Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305. We have compared the interaction of various cholinergic neurons with myofibers in culture with the aim of determining if all cholinergic cells make similar synaptic contacts. Embryonic chick ciliary ganglion neurons and nerve growth factor primed rat PC12 pheochromocytoma cells were dissociated mechanically and plated onto 5 day old cultures of myotubes derived from dissociated embryonic chick skeletal muscles. Intracellular recordings were made from the myotubes after one or two days of coculture and the frequency, amplitude, and time course of synaptic potentials were monitored. Both cell types gave rise to depolarizing synaptic potentials which were abolished by curare or  $\alpha$ -bungarotoxin. The synaptic potentials evoked in the myotubes by ciliary ganglion cells varied in amplitude from 0.15 to 12.4 mV and from 2 to 109 msec in time to peak. Similarly, those arising from PC12 cells ranged from 0.17 to 12.7 mV and 3 to 173 msec rise time. The distribution of amplitude of the synaptic potentials was 1.2 +/- 0.04 mV (N=1058) for ciliary ganglion neurons and 1.4 +/- 0.04 mV (N=1235) for PC12 cells. The distribution of rise times of the synaptic potentials evoked by PC12 cells were slower and had a broader distribution of times to peak. For potentials arising from ciliary ganglion neurons the mode of the distribution was 3.5 msec. Thus, although both PC12 cells and ciliary ganglion neurons the mode of the distribution was 3.5 msec. Thus, although both PC12 cells and ciliary ganglion neurons due to the distribution fries times of the distribution was 3.5 msec. Thus, although both PC12 cells and ciliary ganglion neurons due to the distribution firse time course of acetylcholine release or in the way in which the ir neurites interact with myotubes in culture. This research was fun
- 203.10 DEVELOPMENT OF MUSCARINIC RECEPTOR BINDING IN THE RAT OLFACTORY BULB M.A. Gremillion, T.H. Large and W.L. Klein Dept. of Neurobio. and Physio. Northwestern Univ. Evanston, Ill 60201 Rat olfactory bulb has no intrinsic cholinergic neurons but receives extensive cholinergic innervation from the horizontal nucleus of the diagonal band soon after birth. This system provides us with a simple, isolatable model of cholinergic innervation and synaptogenesis. Appearance of muscarinic receptors (MAChRs) and development of binding properties were studied in three developmental ages of rat; embryonic, neonatal and adult. MAChRs were assayed with 3H-Scopolamine; maximum specific binding in the adult was 1647 fm/mg membrane protein with a dissociation constant of .49 nM. Carbachol competition against 3H-NMS reflected complex binding typical of the MAChR in other

dissociation constant of .49 nM. Carbachol competition against 3H-NMS reflected complex binding typical of the MAChR in other tissues. The IC50 of carbachol blockade was approximately 300 uM and a Hill coefficient of .31. Complex agonist binding may indicate the presence of either separate classes of receptor or could result from receptor coupling to effector proteins. GppNp, an analog of GTP which uncouples the receptor from adenylate cyclase, did not drastically affect the shape or affinity of the carbachol competition curve, primarily reducing the ability of carbachol to bind at low doses. In preliminary experiments, carbachol binding to solubilized receptors had a Hill coefficient of .68. This result suggests that separate classes of receptors may be present in the olfactory bulb or alternatively, the receptor is tightly coupled to effector proteins following solubilization. Binding to solubilized receptors was unchanged by GppNp. MAChR levels in neonate bulb were 237 fm/mg membrane protein. Carbachol competition curve in neonates was essentially identical to adult with a Hill of .38. MAChR were present in the embryonic bulb as early as day 19, well before the onset of cholinergic innervation and synaptogenesis. Specific binding was 192 fm/mg membrane protein, carbachol competition was identical to adult. The results suggest that while MAChR levels develop in parallel with cholinergic innervation and synapse formation, MAChR binding properties develop much earlier.

(Supported by NIH grant NS 15299 to WLK)

203.11 REGULATION OF SYNAPTIC DEVELOPMENT: A ROLE FOR INSULIN. D.G. Puro and E. Agardh\*. LAB. of VISION RESEARCH, NATIONAL EYE INSTITUTE, NIH, BETHESDA, MD 20205.

INSTITUTE, NIH, BETHESDA, MD 20205. Certain regions of the brain, including the retina, contain receptors for insulin (Havrankova et al., 1978). However, the function of these insulin receptors is unclear. One hypothesis is that insulin may have a role in neural development. To help test this hypothesis, we used a cell culture system to examine the effect of insulin on the developmental step in which a presynaptic neuron acquires the ability to transmit excitatory information across a synapse.

Previously, we have shown that cholinergic neurons dissociated from the perinatal rat form functional synapses in culture with rat striated muscle cells. Myotubes are useful as postsynaptic targets since their membranes have areas with a high density of cholinergic receptors and because their response to acetylcholine has been studied both in vivo and in culture. Also, their relatively large size permits prolonged intracellular monitoring of postsynaptic responses.

This retina-muscle cell culture system is well suited for studies of the regulation of specific steps in the development of a synapse. Early in the functional maturation of retina-muscle synapses, there is a period in which the release of acetylcholine occurs spontaneously, but cannot be evoked by excitatory stimulation. This non-transmitting stage is followed by the emergence of transmitter release that can be stimulus-evoked. Here, we report that insulin precociously induced the onset of evocable transmission at retina-muscle synapses. This effect of insulin was dependent on concentration. The half-maximally effective concentration for bovine insulin was 1 nM. A study of the time-course for this insulin-induced effect revealed a 2 to 4 hr interval between the onset of hormonal exposure and the induction of evocable synaptic transmission. The effect of insulin on synaptic transmission was long lasting. Evocable acetylcholine release could be detected for at least 30 hr after a 6 hr pulse of insulin. Experiments have demonstrated that only the retinal cells, not the myotubes, need to be exposed to insulin in order for this precocious induction of synaptic maturation to occur. Other findings suggest that this hormonal induction involves the maturation of mechanisms linking neuronal depolarization with transmitter release.

ation with transmitter release. The results indicate that insulin can regulate the timing of the developmental step in which cholinergic neurons of the rat retina become capable of releasing acetylcholine at synapses in response to excitatory stimulation. 203.12 ENHANCED SURVIVAL OF APPARENT PRESYNAPTIC ELEMENTS BY AN ANTI-MITOTIC DRUG. <u>Richard W. Burry</u>, Department of Anatomy, College of Medicine, The Ohio State University, Columbus, Ohio 43210

In cell cultures of the rat cerebellar cortex neurites grow on polylysine coated beads form apparent presynaptic elements with the beads in the position of the postsynaptic element. The number of apparent presynaptic elements increases to 5 days incubation and then declines. Morphological observations suggest that the non-neuronal cells grow up onto the bead and phagocytose the apparent presynaptic elements (Burry, <u>Brain</u> <u>Research</u>, 247 (1982) 1-16). To test this idea, non-neuronal cell proliferation was inhibited with an antimitotic drug and survival of apparent presynaptic elements was measured.

Dispersed cell cultures of the rat cerebellum were exposed to 5X10<sup>-6</sup>M cytosine arabinoside (Ara-C) from 5 to 7 days in vitro. Polylysine coated sepharose 4B beads were added at 7 days in vitro.

First, cultures were evaluated to determine the antimitotic drug affected the growth of neurites up onto the large sepharose beads. With a procedure using tetanus toxin, anti-tetanis toxin, and rhodamine labeled secondary anti-body, the neurites on the beads with observed in the fluorscence microscope. Quantitation of the neurites on the beads was done on micrographs focused on their largest diameter. It was found that the percent of labeled bead surface was similar in both non-treated and Ara-C treated cultures at incubations to 14 days. Thus the growth of neurites on the beads was not affected by the antimitotic drug.

Next cultures were evaluated to determine if the inhibition of non-neuronal cell proliferation sustained the apparent presynaptic elements. Cultures with or without Ara-C pretreatment were prepared for electron microscopy. The number of apparent presynaptic elements in the cultures with Ara-C declined from a high at 1 day incubation to a low value at 14 days incubation. The cultures treated with Ara-C showed high numbers of apparent presynaptic elements at all times through 14 days incubation. Thus Ara-C enhanced the survival of apparent presynaptic elements in cultures incubated with beads through 14 days.

These results suggest that the antimitotic drug Ara-C can enhance survival of apparent presynaptic elements on polylysine coated beads, but not affect the growth of neurites onto the polylysine coated beads. Thus the phagocytosis of apparent presynaptic elements by non-neuronal cells may be an explaination for the loss of apparent presynaptic elements.

203.13 ULTRASTRUCTURE OF THE POSTSYNAPTIC MEMBRANE AND ASSOCIATED STRUCTURES IN DEVELOPING MOUSE OLFACTORY BULB. R.S. Cohen\* and <u>H.-M. Hwang\*</u> (SPON: L. Benevento). Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, IL 60612. The prenatal development of axodendritic synapses in the

The prenatal development of axodendritic synapses in the glomerulus of mouse olfactory bulb using serial thin sections has been shown. Emphasis was placed on the development of the postsynaptic membrane, the postsynaptic density (PSD) and its associated cytoskeletal network. The fine structure of mouse olfactory bulb seen in the present study is in agreement with previous studies in adult (Pinching and Powell, J. Cell Sci., 9:347, 1971) and developing (Hinds and Hinds, J. Comp. Neurol. 169:41, 1976) animals. Synaptogenesis, in this system, can occur in either of two ways. One involves the formation of a symmetric phase of synapse where there is an equal amount of dense material on the pre- and postsynaptic membranes, followed by a final asymmetric phase, where there is a greater amount of dense material underneath the postsynaptic membrane. The second involves the formation of an unpaired postsynaptic membrane which lacks its presynaptic partner. Also, in agreement, which in the present study, appeared as microfilament bundles. A close association between the cytoskeletal material immediately beneath the postsynaptic density, thereby, representing possible attacthment sites of the microfilament bundle to the membrane and PSD. Based on serial thin section analysis a working model for the formation of spine-like processes, called spine-like branchlets in the postsynaptic density, the microfilament bundles to the membrane and PSD. Based on serial thin section analysis a working model for the formation of spine-like processes, called spine-like branchlets in the plasmaptic density, the microfilament bundles, and the association between them, as well as the association between the microfilament bundles and edjacent dendritic growth cone membrane to involves the irregular microfilament arrays immediately underneath the postsynaptic density, the microfilament bundles on the microfilament bundles and the association between them, as well as the association between the microfilament bundles and edjacent dendritic growth

203.14 FREEZE-FRACTURE ANALYSIS OF THE POSTSYNAPTIC MEMBRANES OF AXODENDRITIC SYNAPSES IN ADULT AND PREMATAL MOUSE OLFACTORY BULB. H.-M. Hwang\* and R.S. Cohen\* (SPON: M. Rezak). Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, IL 60612.

The fine structure of the postsynaptic membranes in adult and developing glomeruli of mouse olfactory bulb was revealed by freeze-fracture of this tissue. Many aggregations of particles, similar to those characterized as postsynaptic sites in other nervous tissues (Sandri et al., <u>Prog. Brain Res.</u>, 46:1, 1977) appeared on fractured faces (IMPs) appeared on the extracellular leaflet (E-face) of the neurites. Aggregations of intramembranous particles (IMPs) appeared on the extracellular leaflet (E-face) of the postsynaptic processes, i.e., dendrites, rather than on the protoplasmic leaflet (P-face). These IMP aggregates have various sizes and shapes and contain different sizes of particles ranging in size from approximately less than 7 nm to larger than 20 nm. Some of the IMP aggregates appeared to have a particle-free area in the middle of the aggregate which may correspond to areas of postsynaptic membrane overlying perforations in postaynaptic densities (PSDs) seen in serial thin sections of these synapses. Prenatal dendritic processes showed small clusters or single rows of various sized particles. With increasing age, these aggregates increased in size and contained different sized particles, the two most prominent being smaller than 7 m and between 7-11 nm. As development proceeded, the aggregates also became irregularly shaped and occasionally, a small perforation was seen; these may correspond to the perforations seen in adult IMP aggregates, but they were not detectable in serial thin sections of prenatal tissue. Computer analysis of the area of IMP aggregates and density of intramembrane particles, revealed that the overall IMP density increased with age. The density of one of the predominent particle sizes, 7-11 nm, remained unchanged throughout prenatal life; a similar density during prenatal life and in the adult, it is thought that this size particle may be involved in stabilization of initial synaptic contacts and of mature synapses, rather than represent receptors or ion channels which would be

PRIMORDIAL SYNAPTIC STRUCTURES IN OLFACTORY CORTEX OF EARLY POST-203.15 NATAL RATS. <u>R.A.E. Bakay, D.D. Kunkel and L.E. Westrum</u> (Spon:R.W. Rodleck). Depts. of Neurological Surgery and Biological Structure, Univ. of Washington, Seattle, WA 98195 and Dept. of Neurosurgery, Emory Univ., Atlanta, GA 30322. Early postnatal synaptogenesis has been examined in many areas

of the rodent brain with emphasis being placed on mature syn-apses. Immature synapses (i.e. with a few vesicles aggregated against membrane specializations of two apposing profiles) and against memory and spectralizations of two appoints profiles) and partial synaptic structures are recognizable and common in post-natal development of rat pyriform cortex. We have studied these primordial synaptic structures and compared them with the emer-gence of mature synapses from postnatal ages 1-30 days. Two major categories of primordial synaptic elements are identifiable and their morphology is based on the presence or absence of pre-and/or postsynaptic membrane specialization(s), presence and position of synaptic vesicles and single versus partial or multi-ple appositions of profiles. The categories are defined as: (1) single apposition - only two completely apposing profiles, variations include: a) pre- and postsynaptic membrane speciali-zations, b) postsynaptic membrane specialization only, c) presynaptic membrane specialization only; the above have a few or no associated vesicles; (2) partial or multiple apposition(s) -present onto a single postsynaptic membrane specialization with present onto a single postsynaptic membrane specialization with a few or without vesicles. Primordial synaptic elements of category 1 are predominant in early postnatal ages. Their fre-quencies (number/100µm<sup>2</sup>) from birth to 7 days doubles to about 2/100µm<sup>2</sup>, remains relatively the same until 14 days and then rapidly declines to less than half by 30 days. Category 2 develops slower with the highest level reached by 21 days, after which a slow decline is observed. A shift in frequency from single apposing profiles to partial or multiple synaptic appo-sitions is observed. The numbers of primordial synaptic elements parallels our counts of mature synapses between 1 and elements parallels our counts of mature synapses between 1 and elements parallels our counts or mature synapses between 1 and 21 days after which mature synapses increase and primordials decrease. At 30 days, the frequency of primordial synaptic structures returns to a level near that seen at birth. The presence of primordial elements of immature synapses at 30 days of age suggests the probability of synapse formation and possible competitive synaptogenesis as late as 30 days. Hospital and Department of Pharmacology, University of Missouri, Columbia, Missouri 65212. 203.17

> Previously we demonstrated that during development there is a decrease in synaptic membrane fluidity as monitored by changes in the steady-state flourescence polarization of 1,6-diphenyl-1,3,5-hexatriene (DPH) (Hitzemann and Johnson, No-diphenyl-1,,,-hexarriene (DPH) (hitzemann and Jonnson, Neurochem, Res. 8:121, 1983). The DPH polarization increased 15% from day 7 to the adult. This change compares to the 7% decrease in DPH polarization caused by a high (200 mM) con-centration of ethanol (Harris and Schroeder, Mol. Pharmacol. 20: 128, 1981). The developmental changes in DPH polar-ization persisted in bilayers prepared from lipid extracts of the sumaric membranes extracting that the changes in the the synaptic membranes, suggesting that the changes in the intact membranes are in part related to developmental changes in lipid composition. In the present study we have compared three flourescent probes to assess the changes in membrane order that occur during development. DPH was used as a probe order that occur during development. DPH was used as a probe of the hydrophobic core of the membrane (Blitterswijk et al., Biochem Biophys. Acta 644:323, 1981). 1-(4-trimethyl-ammoniumphenyl)-6-phenyl-1,3,5-hexatriene (TMA-DPH) was used as a probe of the outer portion of the membrane (Prendergast et al., Biochem. 20:733, 1981). Cis-parinarate (CP) was used as a probe of the middle region of the acyl chains (Schroeder, Eur. J. Biochem. 112:293, 1980). Synaptic membranes were prepared from 7 day, 14 day and adult rat cortex as described elsewhere (Hitzemann, Neurochem. Res. 6:935, 1981). Confirming our previous observation DPH polarization showed a significant developmental increase from .187 (day 7) to .198 (14 day) to .243 (adult). In contrast TMA-DPH showed no developmental changes. Polarization values .187 (day 7) to .198 (14 day) to .243 (adult). In contrast TMA-DPH showed no developmental changes. Polarization values were .301 (day 7), .300 (day 14) and .309 (adult). CP gave an intermediate developmental response. The polarization values were .215 (day 7), .215 (day 14) and .250 (adult). Overall these results show that it is the hydrophobic core rather than the membrane surface which shows the greatest developmental regulation of membrane order. Data will be presented documenting the polarization changes over a more extended time course (days 3 to 35 and adult) and the results from a flourescence lifetime study of DPH in these membranes. Supported in part by grants MH-37377, DA 02855 and the Veterans Administration.

DEVELOPMENT OF SYNAPTIC TRANSMISSION IN A MODEL CULTURE SYSTEM: 203.16

DEVELOPMENT OF SYNAPTIC TRANSMISSION IN A MODEL CULTURE SYSTEM: REGULATION BY DOPAMINE. H.H. Yeh, B-A. Battelle and D.G. Puro. Lab. Vision Res., National Eye Institute, NIH, Bethesda, MD 20205. We have been using a culture system consisting of retinal and muscle cells to study the maturation of synaptic function. In our experimental model, cholinergic neurons dissociated from perinatal rat retinas form, in time, functional synapses with rat striated muscles cells. In the initial stages of synaptic development, neurotransmitter release occurs spontaneously at the retina-muscle synapses but campat be evolved by avriatory ctimulation. This synapses but cannot be evoked by excitatory stimulation. This non-transmitting phase then progresses to a transmitting phase in which excitation of the presynaptic cholinergic retinal neurons with iontophoretically applied glutamate evokes neuronal release of acetylcholine onto the postsynaptic muscle cells.

acetylcholine onto the postsynaptic muscle cells. We have previously shown that the induction of this stimulus-dependent cholinergic transmission in our culture system is a regulated step. Specifically, we have found that the cAMP analogs, 8-bromo-cAMP or dibutyryl cAMP, precociously induced stimulus-evoked release of acetylcholine from embryonic cholinergic neurons of the rat retina. In this study, we considered the possibility that agents which stimulate cAMP generation may influence the maturation of cholinergic transmission. Here, we present dopamine as a candidate for regulating the development of synaptic function. The results of our electrophysiological experiments indicate that, within 2 hr after changing from control medium

that, within 2 hr after changing from control medium to medium containing 1mM 8-bromo-cAMP or 0.25-0.5µM dopamine, stimulus-evoked acetylcholine release could be induced at synapses newly formed by acetylcholine release could be induced at synapses newly formed by embryonic cholinergic retinal neurons. In the presence of 8-bromo-CAMP, glutamate-evoked synaptic activity could be detected in 44% of the innervated muscle cells which had no evocable synaptic input prior to exposure to the cAMP analog. Similarly, dopamine induced evocable cholinergic transmission in 47% of the cases tested. Pre-incubation of cultures with 1.0µM haloperidol, a dopamine receptor antagonist, blocked the inductive effect of dopamine but not that of 8-bromo-cAMP. Using techniques of local microperfusion, the inductive effects of 8-bromo-cAMP or dopamine could be detected within minutes. Preliminary biochemical studies indicate an ele-vation of cAMP levels following stimulation of retinal cell cultures with 0.25µM dopamine. Additional experiments have detected dopamine synthetic activity. Chronic exposure of cultures to 0.5µM haloperidol delayed the time course for the development of cholinergic transmission. cholinergic transmission.

In summary, dopamine everts a marked inductive effect on the emergence of cholinergic transmission in our cell culture system. Electrophysiological data are correlated with biochemical measures of dopamine-stimulated cAMP levels and dopamine synthetic activity to suggest that the catecholamine, by activating cAMP, may play a role in the maturation of synaptic function.

CAMP-DEPENDENT CHANGES IN GLYCOPROTEINS OF NG108-15 CELLS 203.18 ASSOCIATED WITH SYNAPTOCENESIS. Karl E. Krueger\*, Mark J. Millert\*, and Marshall Nirenberg. Laboratory of Biochemical Genetics, NHLBI, and †Laboratory of Carcinogen Metabolism, NCI, NH, Bethesda, MD 20205.

Treatment of NG108-15 neuroblastoma-glioma hybrid cells with  ${\rm PGE}_1$  activates adenylate cyclase and gradually shifts the cells to a more differentiated state which enables them to form certs to a more differentiated state which enables them to try synapses with cultured striated myotubes. Since many of the newly expressed neuronal properties may be dependent on intrinsic membrane glycoproteins, the effects of  $PGE_1$  on the glycoproteins of NG108-15 cells were investigated.

Logarithmically dividing, control NG108-15 cells or cells treated with 10  $\mu$ M PGE<sub>1</sub> for 7 days were incubated for 18 hours with  $^{35}$ S-methionine.  $^{35}$ S-Protein soluble in 1% Triton with <sup>35</sup>S-methionine. <sup>35</sup>S-Protein soluble in 1% Triton X-100 was fractionated by chromatography on wheat germ agglutinin-, <u>Lens culinaris agglutinin-</u>, and <u>Ricinus communis</u> agglutinin<sub>II</sub>-agarose columns. <sup>35</sup>S-Glycoproteins were eluted with 0.5 M N-acetylglucosamine, 0.2 M &-methylmannoside, or 0.2 M lactose, respectively, and subjected to two-dimensional polyacrylamide gel electrophoresis and autoradiography. Autoradiograms were analyzed and compared with a computerized event weight of that described by We et al. (Apal. Biochem system similar to that described by Vo et al, (Anal. Biochem.

112; 258-271, 1981). In most cases, different species of <sup>35</sup>S-glycoproteins were eluted from each lectin column. Most <sup>35</sup>S-glycoproteins were eluted from each lectin column. Most  $^{3}S$ -glycoprotei were expressed by both control and PGE<sub>1</sub>-treated cells. However, some  $^{3}S$ -glycoproteins were expressed by PGE<sub>1</sub> treated cells, but not by control cells. Other species of  $^{3}S$ -glycoproteins were found that were expressed only by control cells. Apparent shifts in the isoelectric points of some species of glycoproteins also were found. In addition, large quantitative changes in the radioactivities of some species of  $^{35}\mathrm{S-glycoproteins}$  resulted from treatment of spectres of  $3_{5}$  grycoproteins restrict the total  $^{35}$ -glycoproteins detected were altered in cells treated with  $PGE_1$  for 7 days. These effects were not detected when cells were incubated with 10  $\mu$ M  $PGE_1$  for 20 minutes. These results show that prolonged treatment of NG108-15 cells

with  $PGE_1$  affects many glycoproteins, and suggest that elevation of cAMP levels of cells results in changes in the post-translational modifications of glycoproteins and/or changes in gene expression.

- MONOCLONAL ANTIBODIES WITH REGIONAL SPECIFICITY IN THE NERVOUS SYSTEM. Gerald B. Grunwald, David Trisler\*, and Marshall Nirenberg. Laboratory of Biochemical Genetics, MHLBI, National Instituties of Health, Bethesda, MD 2025. Our objective is to use monoclonal antibodies to identify molecules involved in synaptogenesis or synaptic function. Monoclonal antibodies directed against 14 day embryo chick peural fettina were assayed by indirect immunofluorescence for binding to molecules recognized by antiped the synaptic function. Monoclonal antibodies directed against 14 day embryo chick peural fettina were assayed by indirect immunofluorescence for binding to forms, or all, retina cells at each age examined. The antibody markedly agglutinated cells. Retina proteins were solubilized and separated by SDS-PAGE; the antibody B0000 to a single band of protein with an Mr of approximately 180,000. The antigen was not detected elsewhere in the nervous system (cerebral lobe, optic lobe, cerebellum, spinal cord, dorsal root ganglia and peripheral merve), or in kidney, or striated, smooth, or cardiac muscle. Antibody 007M11 bond the tot of 7 or 10 day retina. Antibody also bound to some cells in the optic tectum, but not to other neural and non-neural tissues tested. Antibodies 1888, 6661 and 92A2 recognize punctate antigens in the outer synaptic layer of 19 day embryo retina which were not found in adult retina. In adult retina, antigen 1888 was not detected; antigen 66El was localized in punctate structures in some cell soma in the inner nuclear layer; and antigen 92A2 was found in structures which resemble ellipsoids of photoreceptor inner segments. IBB8 bound the ascending spino-cereellar tray, maid cow, probaby associated with plasma membranes. In neither case was binding detected in other tissues tested. Antigen 11501 was first detected in the day embryo retina associated with fibers datified the outer synaptic layer. The antigen response antibody 93A7 bound to a punctate antigen restricted to the inner antibody 93A7 bou

203.21 SYNAPTIC CONNECTIONS BETWEEN EMBRYONIC AMPHIBIAN SPINAL NEURONS IN CELL CULTURE. Leslie P. Henderson & <u>Micholas C. Spitzer</u>. Biology Department, UCSD, La Jolla, CA 92093.

The development of several membrane properties of Rohon-Beard (RB) neurons in vivo has been described, and the development of the action potential and neurotransmitter sensitivity in spinal the action potential and neurotransmitter sensitivity in spinal cord neurons grown in dissociated cell culture is similar to that occurring in the animal. The population of cultured neurons appears to include primarily motoneurons (MNs) and RB cells: the former are hyperpolarized by GABA and glycine and depolarized by glutamate; the latter are depolarized by GABA or by GABA and gly-cine (Spitzer & Bixby, 1982). Although these cells do not respond to a variety of other classical neurotransmitters, a small number of MNs or depolarized by GABA and plot in vity here also of MNs are depolarized by aspartate. RB cells in vivo have also been shown to be electrically coupled to one another in a voltage-dependent, non-rectifying manner until the early tailbud stage of the embryo. We wanted to determine if coupling and stage-dependent uncoupling occur in culture as they do in the spinal cord. Further, if chemical synapses were formed by RB cells, application of pharmacological blockers might provide clues as to the identity of their neurotransmitter(s).

The neural plate region was dissected from embryos of <u>Xenopus</u> <u>laevis</u> and dissociated cells were plated in a manner that increased the probability of neuroneuronal contacts. Cultures were main-tained for periods up to 48 hrs, and intracellular recordings were made from pairs of cells during continuous perfusion with physio-locical collar. logical saline. Neurotransmitters were bath applied at concentrations of 100  $\mu M$  to identify neurons.

Electrical junctions were formed by both RB cells and MNs in tro. Coupling was observed as early as 8 hrs after plating. vitro. some, but not all cases, coupling exhibited rectification. No voltage-dependent uncoupling has been observed. Coupling was not found between all pairs of cells in apparent contact with one another.

With a lower frequency, neurons were also seen to make chemi-cal connections and joint electrical and chemical contacts with cal connections and joint electrical and chemical contacts with other neurons. Action potentials in one cell could elicit long duration psp's (up to 0.5 sec) in other cells. These potentials were abolished reversibly by 10 mM Mg/1.8 mM Ca saline. In most cases, psp's were depolarizing in sign. Since MNs are believed to be purely cholinergic, and no cells in these cultures show sensi-tivity to ACh at the times studied, we believe that the presynaptic neurons are not MNs and are likely to be RB neurons. In some cases, the postsynaptic cell was identified as a MN. To determine the putative neurotransmitter(s) of RB cells, experiments were made in which the effects on synaptic potentials of picrotoxin and in which the effects on synaptic potentials of picrotoxin and strychnine, which block GABA and glycine responses respectively, were examined. Supported by the Giannini Foundation and the NIH.

IMMUNOHISTOCHEMICAL LOCALIZATION OF SYNAPTIC VESICLE ANTIGENS IN 203.20 DEVELOPING CAT CORTEX. J.J.M. Coun and C.J. Shatz. Department of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305. As part of ongoing studies of synaptogenesis during mammalian

CNS development, we have begun to use 3 separate antibodies (Ab's) that recognize synaptic vesicle antigens. These are: sera 30 and 48 from Reichardt and Matthew (J. Cell Biol., <u>91</u>:257, 1981) and Protein I antibody from Greengard and De Camilli (PNAS 76:5977, 1979). In adult tissue prepared for immunohistochemistry, these 1979). In adult tissue prepared for immunohistochemistry, these Ab's selectively label synaptic regions. We therefore studied the distribution of these Ab's during pre- and postnatal development of the cat's brain. Tissue from 17 animals aged adult, postnatal day 65 (P65), P21, P14, P7, P1, embryonic day 61 (E61), E50, and E48 was prepared and reacted using HRP-DAB immunohistochemistry. In adult cats, stinging patterns and intensities for all 3 Ab's In adult cats, staining patterns and intensities for all 3 Ab's are indistinguishable. Highest density staining is always localare thatstinguismatter ingress density statistics to damage the state of the state matter (WM) is virtually unstained. In embryonic material (E48-Pl), regional staining is distinctly different. For example, there is almost no staining within the cortex itself but rather intense stain is present immediately below in the incipient WM, and also above in future layer 1. Within the basal ganglia, ir-regularly shaped islands of staining are seen. Within the lateral geniculate nucleus, most stain is located within and adjacent to the optic tract. These staining patterns were again seen with all three Ab's.

The intensity of cortical staining gradually increases, and WM staining decreases, during the immediate postnatal period (P1-P21)  $\,$ until by P65, the pattern of staining becomes adult-like. Layer 1 staining intensity remains relatively constant during this period. Preliminary microdensitometric scans of cortex and WM from E48 to adult have confirmed quantitatively this shift in the pattern of cortical staining during development. Thus the ratio of staining density in WM to that in cortex declines from E48 until adult values are reached. In contrast, control sections of adult cere-bellum reacted at each age varied in density by only about 10%. These findings show that some components of mature synaptic regions are present in embryonic cat brain as early as E48. This could reflect the accumulation of synaptic machinery within the growing axons for later use. However, in many mammals both layer l and the region directly below the cortex are known to contain synapses during development, suggesting that the staining seen here indeed signals the presence of synapses. We wish to thank Drs. L. Reichardt and P. De Camilli for the Ab's

203.22 SYNAPTOGENESIS IN THE PRIMARY VISUAL CORTEX: QUANTITATIVE

SYNAPTOGENESIS IN THE PRIMARY VISUAL CORTEX: QUANTITATIVE ANALYSIS IN PRE- AND POSTNATAL RHESUS MONKEYS. J.P. Bourgeois\* and P. Rakic, Sec. Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510 The upper bank of the calcarine fissure of primary visual cortex (area 17) was analyzed by electron microscopy (EM) in 17 rhesus monkeys, ranging in age from the 65th embryonic day (E65) to 17 years of age. Two EM probes spanning the cortical thickness were made for each age. The number of synapses/100un<sup>2</sup> of neuronile was determined in each probe on photomostages of neuropile was determined in each probe on photomontages of neuropile was determined in each prove on proclamination consisting of consecutive overlapping micrographs. On E65, immature synaptic contacts were observed within the marginal zone (prospective layer I) and in the subplate and intermediate zones below the developing cortical plate, which at this age contains only prospective layers V and VI. By Ell2, when all visual cortical neurons have been generated and attained their final positions, synapses are present throughout the full span of the cortex with high density in layers I,IV and V and only occasional cortex with high density in layers 1,1V and V and only occasional synapses recorded in layers II and upper III. Synaptic density increases exponentially during the second half of gestation and by the time of birth (E165) the mean density of synaptic contacts is equivalent to that found in the adult visual cortex. The density of synapses nevertheless continues to increase until the third postnatal month (P96), forms a "plateau" until the seventh month (P222) and then decreases slowly towards puberty where it reaches adult level. The time-dependent changes in synaptic densities for symmetric and assymetric synaptic contacts situated on cell soma, dendritic shafts and spines will be described for each cortical layer. For example, two successive peaks were observed in synaptic density (around P20 and around P96) in layer I, which is known to receive multiple afferent inputs; and only one peak was observed in layer IVC (around P96) which receives its input mainly from one source, the lateral geniculate body. The highest rate of increase in synaptic density in layer IVC is observed between Ell2 and P61. The rapid accretion of synapses in this layer coincides with the highest rate of neuritic degeneration, as revealed by the frequency of myelin-like degeneration, as revealed by the frequency of myethicated membrane whorls, and darkened vesicular, autophagic-like profiles in the neuropile. Moreover, the observed increase in synaptic density in layer IVC and the peak of neuropile degeneration coincide with the time of segregation of ocular dominance columns (Rakic, 1976; Hubel and Wiesel, 1977), but it may be significant that the fastest increase in the synaptic density in this layer precedes rather than follows segregation of terminals subserving the two eyes. [Supported by grant EY02593]

ULTRASTRUCTURAL CHANGES IN THE RAT SUPERIOR COLLICULUS ATTRIBUTED 203.23 TO DEPRIVATION. M.R. Gurski\* and N.M. Kettlewell. Dept. of Physiology & Biophysics and The Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294 and Dept. of Psychology, University of Montana, Missoula, MT 59801.

Normal ultrastructural development of the superior colliculus in the albino rat occurs in three distinct stages. In stage l there is an initial proliferation of optic synapses followed by the proliferation of intrinsic synapses. Stage 2 is characterized by continued optic synapse development, as well as by multiple and serial synaptic formation. The third stage is typified by another increase in the formation of intrinsic collicular synapses (Lund, R.D. and Lund, J.S., Brain Research, <u>42</u>:1-20, 1972)

The purpose of this study was to assess neuronal plasticity in the superior colliculus during third stage development. This was accomplished by evaluating ultrastructural changes in the superior colliculus as a function of various environmental conditions: dark conticulus as a function of various environmental conditions; dar rearing (Group SD), low and high intensity light homogeneous environments (Groups LH and HH), and low and high intensity light patterned environments (Groups LP and HP). With the exception of the SD group, all groups were on a 12 hour light/dark cycle. The data analysis consisted of planned comparisons between the darkreared group and the four other groups and a 2 X 2 factorial design between light and pattern. The functional organization of the superior colliculus was assessed by the following dependent measurements: percentage of spheroid vesicled type terminals, percentage of flat vesicled type terminals and density of the synaptic junctions. Length of the synaptic junction and the number of vesicles per terminal were used to assess terminal integrity.

With respect to Groups SD, LH, and LP, results indicate that light in and of itself produces an intermediate level of development in the superior colliculus; however, for normal development to occur, a patterned environment is needed. The groups that developed in an intense light field were in most ways similar to the SD group. Indications are that as the light level increases, this has an adverse effect on collicular development and possibly collicular function. A light microscopy analysis of the retinas revealed the retinas to be normal under the experimental conditions utilized.

MUSCARINIC RESPONSES IN THE AVIAN RETINA DEVELOP PRIOR TO SYNAPTO-203.24 T.H. Large, N.J. Cho\*and W.L. Klein Dept. of Neurobio. GENESIS

and Physiology, Northwestern University, Evanston, Ill. 60201 Muscarinic responses are produced through coupling of the activated receptor with separate effector proteins. To determine if the muscarinic system develops prior to synapse formation, we have investigated changes in receptor binding and identified a muscarinic mediated phosphatidylinositol response (PI) in the developing avian retina.

Reproducible differences were observed between the agonist binding curves of membranes from retinas prior to synapse formation (9 days in ovo) and following synapse formation (4 weeks post hatching). Carbachol competition against 3H-Scopolamine binding in adult membranes displayed a Hill coefficient of .32, indicative of heterogeneous binding properties. In comparison, carbachol competition in embryonic membranes was steeper, Hill = .58, but still complex. In contrast, the Hill coefficient of atropine competition was equal to 1, consistent with the notion that agonists, but not antagonists, induce complex binding through receptor-effector coupling. To determine if heterogeneous agonist binding was due to protein interactions or separate classes of receptors, retina membranes were solubilized with 2% digitonin. Solubilization converted receptors from both age groups into a homogeneous population with low affinity. However, the possibility remains that only one class of receptor was solubilized from the membrane.

The early appearance of receptor coupling was further investigated by assaying cultured retina cells for a muscarinic mediated PI response. In monolayer cultures, at a developmental age just prior to synapse formation, PI turnover was stimulated 416% by 1 mM carbachol. Receptor coupling to adenylate cyclase (AC) was investigated with GppNp, an analog of GTP which uncouples AC. GppNp (100 uM) decreased the agonist affinity of both embry-AC. onic and adult receptors but increased the Hill coefficient to a greater extent in embryo (Hill = .82) than adult (Hill = .47) Solubilized receptors were unaffected by GppNp.

The results suggest that prior to synapse formation, the MAChR is coupled to two different effector systems, AC and PI This is consistent with the heterogeneous agonist response. binding in embryonic membranes and suggests why GppNp fails to produce a completely homogeneous receptor population. Differences in agonist binding between adult and embryo may result from changes in receptor environment during synapse formation, changes in coupling or modification of the receptor protein. The role of the PI response and diacyglycerol stimulated protein kinase C activity in synaptogenesis is currently being investigated. (Supported by NIH grant NS 15299 to WLK)

**REGENERATION: CENTRAL I** 

GLIAL CELLS SECRETE SPECIFIC PROTEINS DURING REGENERATION OF 204.1 THE GOLDFISH OPTIC NERVE WHICH MAY PLAY A ROLE IN AXON GROWTH. Michael A. Deaton\* and John A. Freeman. Department of Anatomy, Vanderbilt University, Nashville, Tennessee 37232.

Molecular interactions between neurons and their surrounding glial cells following axonal injury are likely to play a significant role in neuronal regeneration. In order to determine whether glial cells synthesize selective proteins which are secreted following axonal injury, we examined changes in protein synthesis by glial cells in the goldfish optic nerve using one- and two-dimensional gel electrophoresis coupled with fluorography. To study glial proteins, we either crushed one nerve intraorbitally or enucleated one eye, waited crushed one nerve intraorbitally or enucleated one eye, waited ten days, and then incubated the glial cell-containing nerve sheath in 355-methionine for 2.5 hours. We found 3 newly synthesized proteins (MW 16, 30 and 42K daltons) that are released into the medium, and thus appear to be secreted by glial cells. All three proteins are acidic (pI  $\leq 5.5$  pH) and display charge microheterogeneity on IEF gels, typical of glycoproteins. These proteins are not secreted by tectal following these manipulations, or by normal optic nerve cells glial cells; they can, however, be detected at very low levels in nerves that have been lesioned as short a time as 3 hours prior to incubation. Thus, there appears to be a rapid inducution of their synthetic mechanism following axonal injury. The signal that triggers the synthesis of these glial proteins is unknown, but since they are synthesized in the proteins is unknown, but since they are synthesized in the absence of nerve fibers, it is possible that the latter might absence of nerve fibers, it is possible that the latter might normally release a suppressive factor. The 30K protein exhibits the greatest synthesis, and binds to the membrane fraction obtained from regenerating optic nerve. Binding occurs in the presence of a four-fold excess of unlabeled glial-secreted protein, indicating that a specific 30K glial-secreted protein, indicating that a specific receptor may be present on the regenerating axon membranes. specific glial protein/axon receptor binding would suggest that glial protein/axon receptor binding would suggest that glial proteins whose synthesis is triggered after nerve injury might interact with and influence the subsequent behavior of the injured axons. It is possible that glial cell proteins released during nerve regeration play a role in the induction or in the guidance of axon growth. Supported by NIH Grants # E201117 and NS18103 to J.A.F.

204.2 REGENERATION OF TRANSECTED AXONS ACROSS A SPINAL GAP IN LAMPREYS. John W. Pendleton\* and Melvin J. Cohen, Dept. of Biology, Yale University, New Haven CT 06511.

Regeneration of central neurons can be studied in larva of the lamprey, <u>Petromyzon marinus</u>, a primitive vertebrate in which identified neurons, including the giant Muller and Mauthner cells, regenerate across a spinal transection. In this study In this study, we describe a lamprey preparation in which axons and their growth cones from regenerating giant neurons are exposed as they cross a gap in the central nervous system made by removing a section of spinal cord.

Larval lampreys were anesthetized and 1 to 4 mm of spinal cord was removed through a dorsal incision. After ten to 200 day postoperative intervals, the animals were re-anesthetized, as and a postoperative intervals, the animals were re-anesthetized, and a few ul of 5-10% horseradish peroxidase (HRP) in lamprey saline was extracellularly injected into a new transection site either in or close to the gap. Twelve hours to five days after the HRP injection, the preparations were processed with standard histochemical methods, and examined as cleared whole mounts under a light microscope.

HRP injections placed 5-10 mm anterior to the gap selectively stained the regenerating giant axons within the gap. Ten to 30 days after the initial surgery, some Muller and Mauthner axons approached the proximal margin of the cut cord and then sent one or more processes into the gap. Regenerating axons exposed in the gap have have swollen "growth cone"-like endings. At later stages, axons crossed the gap and entered the distal spinal segment; SEM observations show that the growing axons follow a base of presumably mesenchymal tissue across the surface of the notochord. The cellular elements in the gap are directly exposed to the extracelluar environment of the spinal canal. Using Nomarski optics, regenerating axons and their growth cones can be clearly observed within the gap in the living animal. Fibers in the gap showed a strong tendency to fasciculate; this fasciculation tends to disappear once the distal edge of the gap is reached by the growing fibers. Injection of HRP directly into the gap selectively labels

cells that have regenerated into the gap. Cells and axons labeled by intra-gap HRP injections include descending giant reticulospinal axons, lateral interneurons, giant interneurons, and edge cells located close to the gap. Thus it is possible to identify which cells contribute to regeneration and the recovery of function in the larval lamprey. The spinal gap preparation provides a system for spinal trauma study with ready access to relatively exposed regenerating vertebrate central neurons and their growth cones. (Supported by NIH Spinal Trauma Grant NS 10174).

THREE FACTORS AFFECTING THE GROWTH OF BRAIN STEM AND NEOCORTICAL 204.3

THREE FACTORS AFFECTING THE GROWTH OF BRAIN STEM AND NEOCORFICAL TRANSPLANTS. <u>C.M. Chanaud\* and G.D. Das\*</u>. (SPON: J. Altman). Dept. of Biological Sciences, Purdue University, West Lafayette, IN 47907. It is well established that embryonic neural tissues, when transplanted in the brain of neonatal or adult rat hosts, sur-vive, grow and become integrated with the host brain parenchyma. This study examines the affect of several factors on the growth of both brain stem and neocortical transplants. These factors are: 1) initial volume of transplanted tissue, 2) freezing of the embryonic tissue, and 3) embryonic age of the neural tissue (16-day versus 21-day tissue) (16-day versus 21-day tissue). Donor embryos were obtained from pregnant Wistar-Albino rats

on day 16 and 21 of gestation. Brain stem or neocortical tissue was dissected from these embryos and tissues with initial volumes of 3.5, 7.0, 10.5 and 14.0  $\rm mm^3$  were transplanted as fresh tissues into the vermis of the 21-day-old host animals. Frozen neural tissues were frozen in advance for 2-3 months in lactated Ringer's solution containing 10% DMSO. Prior to transplantation, the frozen tissue was washed, rapidly thawed, and transplanted. Thirty days after transplantation, host animals were sacrificed. Brain sections were stained with cresyl violet and Bodian stains. Volumetric analysis of each transplant was performed.

With brain stem tissue, there was an optimal initial volume of tissue that resulted in a maximum final volume of the transplant. With neocortical transplant grew large. Transplants of the initial vol-ume, the neocortical transplant grew large. Transplants of frozen 16-day and 21-day neocortical and 16-day brain stem tissues survived, whereas, frozen 21-day brain stem tissue did not. All fresh tissues survived and yielded larger, more highly integrated transplants than frozen tissues. Transplants of 16-day neocortical or brain stem tissue yielded larger, more

16-day neccortical or brain stem tissue yielded larger, more integrated transplants than did the 21-day tissue. The transplants composed of neuroepithelial cells, e.g. neo-cortical transplants of 16-day embryonic tissue, grew large, became integrated with the host brain and contained well-dif-ferentiated neurons. In contrast, transplants composed of partially differentiated neuroblasts, e.g. brain stem transplants of 21-day embryonic tissue, did not grow well, became extraparen-burght and continued structure human transplants of an extraparen-burght. chymal, and contained atrophying and hyperchromatic neurons Under identical conditions, neocortical transplants achieved a greater final volume than brain stem transplants.

OPTIC TRACT REGENERATION IN ADULT RAT: ANATOMY J. Diamond, A. Foerster and B. Visheau\*. Dept. of Neurosciences, McMaster 204.5 University, Hamilton, Ontario L8N 325.

Lesions were made in the postchiasmatic optic tract (OT) of anesthetized adult male Long-Evans rats, with cutting devices each consisting of 1-4 mm portion of razor blade, or 90 µm dia-meter wire, supported between two vertical (also 90 µm) wires, never wire, supported between two vertical (also 90 µm) wires, lowered by a micromanipulator until it reached the floor of the skull; the two protruding support wires were cemented to the cal-varium, and the excess lengths cut off. The animals, some of which were used in the experiments described in the accompanying Poster (Poerster, Holmes and Diamond), were sacrificed immediately roster (roerster, homes and Diamond), were sacrificed immediately or at times up to 5 months; after fixation of the brains the im-planted device was removed via the ventral surface. In horizontal sections the two support wire channels appeared as two holes which marked the limits of the original cut. Such devices make pre-cisely predictable lesions around which severed tracts appear to regenerate (Foerster, 1982; J. Comp. Neurol. 210: 335). As in the earlier studies, silver-stained brains revealed (unless the lesion had been too extensive) a progressive reorganization of severed optic axons to form a "detour" that curved around the lesion and back into the distal tract. The retinal origin of these axons was confirmed by TMB-staining after intracular injection of HRP. Two days after the lesion, HRP-filled axon stumps faced the reti-nal side of the cut, but at later times HRP-filled optic axons were observed to have extended around the cut, and into the distal tract and SC. (We are further examining the SC and the OT at various times following OT lesion for degenerating boutons, immature boutons, growth cones, etc.). In a typical animal whose OT was almost totally cut, the third electrophysiological mapping, done after 3 weeks, revealed a recovery of visual responsiveness within the initially blinded region of the SC (see accompanying Poster); following intraocular HRP the recovered region of the SC was shown by TEM examination to contain, among the numerous normal non-retinal nerve endings and synapses of the stratum griseum superficiale, less frequent endings that contained HRP reaction product, generally had characteristically pale mitochordring and in many instances made synaptic contacts with dend-ritic profiles. These endings sometimes had fine structural appearances suggestive of immaturity. Often degenerating myelin-ated axons were seen in the same regions. We suggest that the endings containing the HRP reaction product were those of optic axons that had regenerated after the initial cut, and that they were responsible for the observed recovery of visual function in were responsible for the observed recovery of visual function in the SC.

204.4

OPTIC TRACT REGENERATION IN THE ADULT RAT: PHYSIOLOGY. A. FOErster, M. Holmes\* and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario L8N 325. The location of the superior colliculus (SC), of pentobarbital-anesthetized adult male Long Evans rats, with respect to a permanent landmark, a graphite-filled crossline on the skull, was de-termined by transcortical penetrations, 0.5 mm apart (except for the most medial 0.5 mm underlying the sagittal sinus), with tung-sten-in-glass microelectrodes which recorded multiunit receptive fields (MRFs); these were evoked usually with a black edge moving just outside a transparent hemisphere, r=34 cm, centered upon the eye. Eye movements were monitored by retesting of sites. The optic disc location was projected on the hemisphere with a rever-sible ophthalmoscope. A lesion was made with a cutting device sible ophthalmoscope. A lesion was made with a cutting device aimed at the optic tract (see accompanying Poster by Diamond, Foerster and Visheau). Immediate remapping revealed either (1) absence of visual response, (2) a well-defined scotoma or (3) no change, indicating respectively a (1) complete, (2) partial or (3) "control" lesion of the tract. The animals were allowed to recover for periods of 1-10 wk when a third mapping was done, and on occasion a fourth. So far 8/9 rats have shown a return of visual function in the silenced SC, evidenced by responses from rections of the retina which were ineffective immediately after regions of the retina which were ineffective immediately after the lesion. Although somewhat bizarre, an approximately topo-graphic retinal projection was present by 3 wk. In the same SC "recovered" MRFs varied in vigor, excitability and fatiguability; they ranged from nearly normal size (about 10°) to ones responding user the artire visual field. The large MBFs often bed encored over the entire visual field. The large MRFs often had one or more foci; single foci, not always in the MRF centers, could be near the correct retinal projection site. The orderliness of maps, and the restriction of field sizes, appeared to "improve" with time after the lesion. Interestingly, after a partial cut, the spared normally-responsive portions of the SC later might acquire new sizes and foci of their MRFs. None of these changes

occurred in control SC remappings. The observed topography of "recovered" maps is not explained by collateral sprouting of a discrete portion of a topographically organized tract that might have escaped lesion. Perhaps spared, grossly aberrant, "silent" optic fibers sprout to become effective. Conceivably, the recovered MRFs might be driven by normally undetectable but now strengthened SC inputs from brain regions served by the portion of the tract proximal to the lesion. However, in the light of the anatomical findings (see accompanying Poster) we suggest that the observed return of visual function is mediated by regenerated fibers which tended to select their normal region of the SC and compete for it, with progressively increasing success

(Supported in part by the John A. Bauer Memorial Fund).

TARGET REGULATION OF THE CELL BODY REACTION DURING REGENERATION OF 204.6 GOLDFISH RETINAL GANGLION CELLS. D.W. Burmeister\*, G.W. Perry\*, and B. Grafstein, Dept. Physiology, Cornell University Medical College, New York, N.Y. 10021

Axonal regeneration of retinal ganglion cells in the goldfish is accompanied by increases in the size of the cell body and in the synthesis and axonal transport of proteins. In order to investigate the role of the target tissue in regulating these changes we have examined the effect of removing the major axonal target, the contralateral optic tectum.

During regeneration following intraorbital optic nerve crush, the cell body reaction was more prolonged in tectum-ablated fish than in tectum-jintact (sham operated) fish. Under both conditions cell size and H-proline incorporation showed the same initial rise. In the tectum-intact animals both values gradually returned to near normal levels after 10 to 12 weeks, whilst in the tectum-ablated animals both values remained elevated. The presence of the contralateral optic tectum affected the survival of the re-generating cells. Regeneration with an intact tectum resulted in small decrease in the overall incidence of ganglion cells across the retina. In the absence of a target tectum there was a further decrease in cell incidence although over 80% of the ganglion cells still remained after 12 weeks. By 12 weeks at least some of the axons had innervated the ipsilateral tectum. However, when both tecta were ablated the cell body changes were the same as when only the contralateral tectum was removed.

When rapidly transported proteins, labeled by intraocular in-jection of H-proline, were separated by two-dimensional gel electrophoresis, the analysis of 20 of these proteins showed increases in labeling during regeneration, but two of them changed more than the others. One, which constituted the largest fraction of rapidly transported protein in normal nerves, had a molecular of rapidly transported protein in normal nerves, had a molecular weight of about 150 kD and was spread across a pI range of 4.9 to 5.3, a pattern characteristic of many glycoproteins. The second, with a molecular weight of about 45 kD and pI about 4.6, increased more than 50-fold over normal to become the most prevalent trans-ported protein in regenerating nerves. Labeling of the 20 rapid-ly transported proteins was the same in tectum-ablated and tectum-intact fish at 3 weeks. At 5,8, and 12 weeks, however, when re-orth blocks of comporting the comparison in recomposition. establishment of connections is occuring in normally regenerating nerves, differences were seen, particularly in the two proteins mentioned above.

204.7 REGENERATION OF SENSORY AND MOTOR AXONS INTO THE SPINAL CORD OF THE ADULT FROG. A STUDY USING DORSAL TO DORSAL AND VENTRAL TO DORSAL ROOT ANASTOMOSES. F.J. Liuzzi and R.J. Lasek, Dept. of Anatomy, Case Western Reserve Univ., Cleveland, OH 44106. Anterograde injury-filling with HRP was used to demonstrate the extent and distribution of central (dorsal root axons) or peripheral (motoneuron axons) when dorsal or ventral roots were grafted into the proximal stumps of cut lumbar dorsal roots in

Rana pipiens. Contrary to the results reported in the cat (Messenger and Kingsley, 1982), cut dorsal root axons do regenerate into the cord with large myelinated axons entering the dorsal funiculus and small diameter unmyelinated axons entering a small discrete bundle in the dorsolateral funiculus, which is homologous to Lissauer's tract in mammals. Not only do the regenerating dorsal root axons travel in the spinal white, they also send collaterals into the spinal gray where at the light microscopic level they appear to reproduce the normal segmental distribution as has previously been shown with HRP (Liuzzi, Beattie, and Bresnahan, 1982).

Motoneuron axons within ventral roots grafted to cut dorsal roots, will also regenerate into the frog lumbar cord as has been previously demonstrated in the cat (Messenger and Kingsley, 1982). Many of these axons form a discrete bundle in the DLF suggesting, as Katz and Lasek (1981) have proposed, that this region is a substrate pathway which, in the case of the <u>Rana</u> <u>pipien</u>, persists in the adult, thereby allowing axons to grow and fasciculate. Other large diameter motoneuron axons are seen within the dorsal funiculus. A few of these axons give rise to collaterals, which, with long-term survival, are observed to enter the dorsal gray. Here, at the gray-white interface, they immediately bifurcate and subsequently arborize within the dorsal horn having numerous varicosities in close apposition to dorsal horn having numerous varies the gray-matcher the dorsal substate of synaptic terminals.

On occasion, sensory, and more often, motor axons are observed with quite large swellings along their lengths as well as at their apparent ends. Some of these swellings are up to 12.5 um in diameter and may represent instances where the axon's growth has been slowed or halted by mechanical or other barriers. These swellings might, therefore, represent single-axoned neuromas. In light of the regenerative capacity of dorsal root axons in the frog, an in vivo model is now available for comparing the regeneration of two very different, yet well characterized, populations of axons introduced into the same CNS environment. This model is being used in continuing studies in this laboratory to investigate basic mechanisms of axonal growth and guidance. 204.8 OLFACTORY MUCOSA AND EMBRYONIC BRAIN TISSUE TRANSPLANTATION IN THE ANTERIOR CHAMBER OF THE EYE OF RAT. J. A. Heckroth\* and P. P. C. Graziadei. Dept. Biol. Science, Florida State University, Tallahassee, FL 32306

Previous experiments have shown that the olfactory neurogenetic matrix of postnatal rats transplanted into the anterior chamber of the eye of adult rats maintains its capacity to produce mature olfactory neurons (Heckroth et al. Int. J. Devel. Neuroscience, 1983).

Offactory neurons (neuron court and the court network end of a court of the eye of a court of the eye together with fragments of different regions of embryonic rat brain to study the possible interaction of the regrowing olfactory axons with a variety of targets. Donor tissue from embryonic rat brain to study the possible interaction of the regrowing olfactory axons with a variety of targets. Donor tissue from embryonic rat brains was transplanted into the anterior chamber of the eye of adult rat hosts. Following a 7 day recovery period olfactory mucosa from postnatal rat donors was introduced into the anterior cye chamber and positioned close to the brain tissue. Animals were sacrificed after 60 and 90 days and the tissue processed for light microscopy. A total of 63 transplants involving the olfactory bub, frontal and occipital cortex, cerebellum, tectum and medulla were performed, 53 of which were successful. Apposition of the brain and the mucosa transplants resulted in the penetration of the regenerating olfactory axons of the reconstituted olfactory axons invaded the adjacent brain transplants or the ris without selective differences. The degree of interaction between brain and mucosa transplants varied between preparations but showed no relation to the type of brain tissue available to the regenerating olfactory axons command between the olfactory axon terminals. Only exceptionally have we observed the olfactory axon turning the glomeruli characteristic of the olfactory axon terminals. Only exceptionally have we observed the olfactory axon terminals to there in circumscribed areas of the brain tissue where structures resembling glomeruli were seen. However, this rare finding deserves further confirmation.

Continuation. Olfactory neural elements were observed migrating from the epithelium and at instances penetrating into the transplanted brain tissue. Further experiments at ultrastructural level are in progress to determine the detailed nature of interneuronal contacts of the olfactory axons with the brain parenchyma in the <u>in oculo</u> environment, as well as the long term survival and behavior of the olfactory neurons and their matrix. (Supported by NIH Grant number NSI6421)

204.9 IMMUNOCYTOCHEMICAL AND MORPHOLOGICAL OBSERVATIONS OF OLFACTORY NEUROEPITHELIUM TRANSPLANTS IN RAT BRAIN. <u>E. E. Morrison\*</u> and <u>G. A. Monti Graziadei\*</u> (Spon. L. Beidler). Dept. of Biological Sciences, Florida State University, Tallahassee, FL 32306

The olfactory neurons are replaced normally and when injured, by the olfactory neurogenetic matrix (basal cells) present at the base of the neuroepithelium. The mature olfactory neuron produces a specific low molecular weight acidic protein, olfactory marker protein (OMP), that is found in the perikaryon, axons and axon terminals. In the present study we have transplanted neonatal olfactory mucosa (P4-P10) into the cerebral ventricles of neonatal and adult rats, to examine the neurogenesis and maturation of the olfactory neuron and to determine the presence of OMP within a foreign environment. The OMP was visualized by the peroxidase-antiperoxidase immunohistochemical method. The post operative examination period was 10-100 days. The transplant was promptly vascularized and formed a series of inter-connecting vesicles lined by a respiratory and sensory epithelium. The transplant was in contact with the cerebrum, cerebellum and medulla. At early survival times (10-20 days), few OMP positive neurons are observed. Between 20-35 days survival the number and intensity of OMP positive neurons and sensory axons has increased. All transplants examined up to 100 days survival demonstrate varying amounts of OMP positive sensory neurons and axonal fascicles. Silver preparations and OMP visualization demonstrated mature olfactory neurons characterized by their dendrites and their axons. OMP positive axonal fascicles are observed to originate from the neuroepithelium and penetrate the host brain, however, no characteristic glomerular structures are present. Mature OMP positive olfactory neurons are observed, migrating away from the neuroepithelium, within the lamina propria and in the host brain. We conclude that the transplanted neurogenetic matrix produces mature OMP positive olfactory neurons in the absence of its normal target tissue. Ultrastructure examination of host transplant connectivity is currently being conducted. (Supported by NIH grant NS 16421). 204.10 AUTORADIOGRAPHIC TRACING OF CROSSED CORTICO-THALAMIC PROJECTIONS IN CATS WITH NEONATAL ABLATION OF ONE CEREBRAL HEMISPHERE. <u>B.J.</u> <u>Sonnier, J.R. Villablanca, C. Olmstead, F. Gómez, J.P. MacAllister</u> Ment. Ret. Res. Ctr., Depts. Anat. & Psychiatry, UCLA Sch. Med. Los Angeles, California 90024

Los Angeles, California 90024 In a continuing investigation of brain reorganization and func-tional recovery, the left half of the telencephalon was removed (hemispherectomy) in 6 kittens (X age 12.3  $\pm$  7.6 days) which were followed into adulthood (companion Abstract) and then used for this study. Six intact adult cats served as controls. All cats received injections of 50:50 mixture of tritiated leucine-proline into the right pericruciate cortex. Starting at about 4 mm from the midline, 5 to 6 injections were made (0.2 to 0.6  $\mu$ l at 50 $\mu$  Ci/  $\mu$ l) 1.0 to 1.5 mm in front and behind the cruciate sulcus at a depth of 3 mm. Five daws later the cats were perfused intracardepth of 3 mm. Five days later the cats were perfused intracardially, frozen coronal serial sections were cut at 50  $\mu m$  and processed for autoradiography. Sections were developed after a 6 week exposure and injections sites and terminal field areas were recon-structed by serial drawings under both light and dark field illumination (atlases of Jasper & Ajmone-Marsan and of Reinoso-Suárez) In intacts cats, there were cortical projections along the entire A-P extent of the thalamus in the following main nuclei: ventralis anterior, reticularis, ventralis lateralis, central lateralis-parafascicularis, centralis medialis (NCM), lateral portions of medialis dorsalis, ventralis medialis (NcH), fateral portions of alis, and centrum medianum. All projections were strictly ipsilateral except for a few which continued 1 to 3 mm into the left side dor-sally at the level of NCM, and more posteroventrally at the level of the nucleus subparafascicularis and dorsal aspects of zona incerta. In all hemispherectomized cats the outstanding, apparently only difference was the presence of fibers crossing the midline and terminating in most of the hemi-thalamus ipsilateral to the and terminating in most of the nemi-thatamus ipsilateral to the ablation. The crossing also was at the two dorso-ventral levels seen in intacts but both portions were more extensive and dense. The dorsal portion terminated along the entire extent of the in-tralaminary nuclei, while the ventral one filled most of the re-maining atrophic left ventral thalamus. These crossed projections were relatively sparse and diffuse, never reaching the high density seen for terminal field areas in the intact side. We are now using computer-assisted densitometry to quantify the extent of this novel crossed terminal distribution. This finding, with additional changes reported elsewhere, indicate that after hemispherectomy there is an extensive anatomical reorganization in subcortical structures which parallels the functional recovery seen. (Supported by USPHS Grants HD-05958 and HD-04612)

- IMMUNOCYTOCHEMICAL DEMONSTRATION OF SUBSTANTIA GELATINOSA-LIKE 204.11 REGIONS AND SEROTONERGIC AXONS IN EMBRYONIC SPINAL CORD TRANSPLANTS IN THE RAT. <u>Paul J. Reier and Barbara S. Bregman</u> Dept. Anatomy, Univ. Maryland School of Medicine, Baltimore, P Recent studies in this laboratory have demonstrated survival and differentiation of embryonic rat spinal cord transplants introduced into intracerebral and spinal could transpirate and natal rats. Currently, we are using immunchistochemical tech-niques to investigate the development and distribution of chemically-defined neuronal elements within these transplants and their innervation by identified neuronal populations of the host CNS. In the study reported here, we have examined whether any topographical differentiation occurs in spinal cord transplants and whether they become innervated by serotonergic fibers from the recipient CNS. Donor tissue was obtained from 14- and 15-day-old fetal rats and placed into either the choroidal fissure or subtotal lesions (i.e., dorsal funiculotomics or hemisections) of the spinal cords of 250 gm. rats. After 1-4 month survival periods, the recipients were sacrificed and tissues were prepared for either indirect immunofluorescence or peroxidase-antiperoxidase visualization of neuronal processes exhibiting immunoreactivity for antisera (Immunonuclear Corp.) to Met-enkephalin, neurotensin or serotonin. The distribution of myelinated axons was also demonstrated with anti-MBP (myelin basic protein). In some experiments, tissues were prepared for electron microscopy. Sections stained with anti-MBP and plastic 2µm sections revealed numerous unmyelinated regions in these transplants containing small neurons (20-30µm in diameter). Sections stained with Met-enkephalin antiserum showed many immunoreactive fibers in the transplants whether the grafts were integrated with the host CNS or not. In many cases, intense staining was observed in regions corresponding to the myelin-free Neurotensin-positive fibers were also seen with many being areas. concentrated in the unmyelinated zones of the implants. Examination of transplants in lesions of the spinal cord showed that some of the implants which were partially confluent with the host neural parenchyma contained a sparse population of serotonin-positive fibers, whereas transplants which were completely isolated from the host spinal cord, as well as cerebral cortex, failed to exhibit any immunoreactive elements. These initial findings suggest that the distinct, unmyelinated regions which develop in embryonic spinal cord transplants share some morphological and immunohistochemical characteristics of the molphological and immunoristochemical characteristics of the substantia gelatinosa. In addition, the presence of serotonin-like immunoreactive fibers indicates innervation of these transplants by at least one population of chemically-defined neurons in the host CNS. (Supported by NIH Grant NS-13836)
- ADRENAL MEDULLA IMPLANTS IN THE ADULT RAT SPINAL CORD. C. L 204.13

AMENAL MEDILLA IMPLANIS IN THE ADULT KAT SPINAL CORD. C. L. Jones\*, J. T. Buchanan\*, and H. O. Nornes. Department of Anatomy, Col. State Univ., Ft. Collins, CO. 80523. Neural grafting is an experimental technique for replacing specific missing neural input after lesioning the central nervous Since spinal catecholaminergic systems may be involved system. systems. Since spinal catecholaminergic systems may be involved in the descending control of the stepping generator (Grillner, 1975, **Physiol. Rev. 55**: 247-304), attempts are being made to reinnervate the transected spinal cord with transplants of catecholamine-containing cells. The purpose of this study was to determine if chromaffin cells from the adrenal medulla (AM) survive implantation in the adult rat spinal cord. The AM from 10 to 12 day old Sprague-Dawley rats were placed

into surgically prepared cavities made in the upper lumbar spinal cord of Sprague-Dawley adult rats. In 12 host animals, the cavity was made subpially in the dorsolateral portion of the spinal cord (dorsolateral cavity) with a special pipette and gentle suction. In 15 animals, the cavity was made in the gray matter, leaving the dorsal white matter largely intact (central cavity). Survival times ranged from 7 to 121 days before the tissue was processed for Falck-Hillarp catecholamine histofluorescence.

Eleven of 12 dorsolateral cavity implants, and 13 of 15 Eleven of 12 dorsolateral cavity implants, and 13 of 15 central cavity implants had surviving fluorescent chromaffin cells. The number of cells per implant ranged from 30 to 3,000. Few chromaffin cells formed processes. The few processes that formed were 25 to 30 microns in length. Regeneration of host CA fibers into the implant was rarely observed. There was good tissue continuity between the host spinal cord and the implant, however, the interface contained a layer of collagenous tissue. (Supported by grapts formed to Parcelured Matterage Aministration (Supported by grants from the Paralyzed Veterans Administration, no. OBR-156, and Spinal Cord Society).

204.12 SYNTHESIS AND TRANSPORT OF TWO RELATED PROTEIN MARKERS OF THE REGENERATING GOLDFISH VISUAL SYSTEM. T. S. Ford-Holevinski\* and B. W. Agranoff. Neuroscience Laboratory, University of Michi-Ann Arbor, MI 48109. gan,

The goldfish retina responds to intraorbital axotomy by al-tered patterns of protein synthesis which can be studied by comparing rates of incorporation of labeled amino acids into proreturns rates of incorporation of labeled amino acids into pro-tein in in vitro incubations of control (normal, N) and post-crush (PC) retinas. Alternatively, one can inject labeled pre-cursor intraocularly and measure the subsequent arrival of axonally transported labeled proteins in the newly regenerated nerve tract and terminal field in the optic tectum (OT). The in vitro procedure has the advantage that early events following axotomy can be observed, and the drawback that the ganglion cells support only a fraction of total measured retinal protein synthesis. Once new nerve has been formed, the in vitro approach permits us to see only those proteins that are synthesized in the ganglion cells and then transported. The two apsized in the ganglion cells and then transported. The two approaches are complementary, as indicated in the present study. By autoradiography of 2D PAGE gels, we previously detected the presence of a closely-associated pair of axonally transported labeled proteins ( $M_{\rm T}$  68-70K; IEP=4.8-4.9) in the tectum of the PC, but not the N side. Like tubulin and actin, the two proteins are slowly transported and are found in the  $10^5$  x g supernatant of OT homogenates. In incubations with <sup>3</sup>H-leucine or <sup>35</sup>S-methionine, we now find that the 68-70K proteins are not labeled in N rations. not labeled in N retinas, but appear within 4 days of crush, become more intensely labeled for the next few weeks, and dis-appear by 35 days PC. In mixing experiments, Coomassie Bluestained spots identified in 2D gels of fish brain soluble pro-teins comigrated with the labeled retinal 68-70K proteins. By means of a sensitive silver stain, we have visualized the 68-70K proteins which give rise to the autoradiographic spots. However, N and PC retinas contain similar amounts of 68-70K proteins on the basis of their silver stain intensities. In contrast, silver-stained 2D gels of supernatants from regene-rating optic nerve indicates prominence of the 68-70K proteins and their absence in the N nerve. Thus in the nerve, the silver stain for the presence of chemical amounts of the 2 pro-teins parallels autoradiographic findings, while in retina it does not. We are pursuing the identity and possible function of these regeneration-linked proteins. We also find evidence for enhanced synthesis of additional retinal proteins in regeneration, including one at 33K, possibly analogous to the "soluble" 33K growth-associated protein described in the re-generating toad optic nerve by Skene and Willard (J. Cell Biol. 89:86, 1981). (Supported by NIH Grant NS 13743.)

204.14 PROPERTIES OF PROTEINS ASSOCIATED WITH OPTIC NERVE REGENERATION IN THE GOLDFISH. Larry I. Benowitz and Ellen R. Lewis. Dept. of Psychiatry, Harvard Medical School, McLean Hopsital, Belmont, MA Belmont, MA 02178.

Unlike mammals, the goldfish optic nerve will regenerate within 1-2 months of being damaged, to re-establish central visual connections and restore visually-guided behaviors. During the course of regeneration, marked changes occur in the complement of proteins transported intra-axonally in the optic nerve. In the rapid phase of transport, the group which includes membraneous components destined for the nerve terminals, the most membraneous components destined for the nerve terminals, the most marked increases that occur are for proteins with apparent molecular weights of 24-27K, 44-49K and 210K early in the regenerative process, and 110-140K at later stages (Benowitz, Shashoua and Yoon, J. Neuroscience <u>1</u>:301, 1981). In the regenerating toad visual pathway, specific increases for membrane-bound, rapidly-transported proteins with apparent MW's of 24K, 43K and 50K have been described (Skene and Willard, J. Cell Biol. <u>89</u>:86, 1981). Studies using 2-dimensional gel electrophoreais indicate that the greatest chance occurring among electrophoresis indicate that the greatest change occurring among the rapidly-transported proteins in the regenerating goldfish optic nerve actually involves a group of at least 3 proteins optic nerve actually involves a group of at least 3 proteins having molecular weights between 44-49,000 and highly acidic isoelectric points. These proteins are abundant in proline relative to methionine, are found in both the soluble and plasma membrane fractions of the optic tectum, and are associated with neuronal processes but not glia (Benowitz and Lewis, J. Neuroscience, in press). The 44-49X acidic proteins become turned on at least 50-100 fold in retinal ganglion cells undergoing axonal regeneration. This increase occurs regardless of whether or not the optic tectum is present (Benowitz, Yoon and Lewis, in prep.; Yoon et al., these <u>Abstracts</u>). The presence of the appropriate target field, the optic tectum, does, however, regulate the abundance of other rapidly-transported components, in particular proteins of 120-160,000 daltons (pI 5.2-5.4) (Yoon et al., these Abstracts). We are currently investigating additional properties of these various proteins associated with et the regenerative process, and examining their relationships to identified protein species. Supported by NINCDS Grant ROl NS16943.

205.1 ATTEMPTS TO MAINTAIN ABERRANT RETINO-RETINAL AXONS AFTER OPTIC NERVE REGENERATION IN THE FROG. D.J. Stelener and J.A. Strauss\*. Dept. of Anatomy, Upstate Medical Center, Syracuse, N.Y. 13210 After optic nerve crush (NC) in adult <u>Rana pipiens</u>, optic axons are misrouted out the opposite (opp.) optic nerve and into the ganglion cell fiber layer (GCFL) of that retina. These retino-retinal (ret-ret) axons are in greatest number 4-6 wks. after NC and most have disappeared 3 mo. p.o. (J. Comp. Neurol. 196; 605-643). Two expts. were done attempting to maintain this projection. Autoradiography was used to assess regeneration killing frogs at various p.o. periods 24 hrs. after intravitreal H-proline injection (40 µCl/4 µl saline) ipsilateral to NC. In the 1st expt., kainic acid (KA, 5 ng/4 µl saline) was in-

In the 1st expt., kainic acid (KA, 5 ng/4  $\mu$ 1 saline) was injected intravitreally to denervate ganglion cells in the eye opp. NC. Pilot work showed that 4d after KA injection, many inner nuclear layer cells had degenerated and heavy degeneration filled the collapsed inner plexiform layer. Most ganglion cells survived. In 18 frogs, NC was performed and KA injected into the opp. eye at the same time (N=8, NC-KA) or 4-6 wks. later when ret-ret axons are maximal (N=10, NC-dKA). Controls showed that axons filled the opp. nerve and ret-ret axons were present 5-6 wks. after NC-KA(N=5). In all frogs studied 3 mo. after NC-KA (N=3), and in most frogs studied 4-6 mo. after NC-KA(N=7), no evidence was found that KA induced denervation of ganglion cells maintained ret-ret axons were, in 3 frogs 4(N=1) and 6(N=2) mo. after NC-KA some labeled axons remained within the nerve and within the GCFL for up to 1 mm around the optic disc. The ganglion cells in this region were disorganized and silver grains distributed among them suggested that actual connections may have formed. Thus, denervating ganglion cells can maintain ret-ret axons but the effect is small and timing may be critical. In the 2nd. expt. right NC and bilateral optic tectum and posterior thalamic lesions were made to remove the targets of the

In the 2nd. expt. right NC and bilateral optic tectum and posterior thalamic lesions were made to remove the targets of the majority of regenerating optic axons. Right optic axons were studied 6 wks.(N=5), 3 mo.(N=6) and 6 mo.(N=2) later. Ret-ret axons were found at 6 wks. p.o. but the number was less than that seen with NC or NC-KA. Most label in the opp. nerve was along its edge. Three mo. p.o. fav labeled actions remained in the opp. nerve. Even though bilateral tectal ablation did not maintain ret-ret axons, projections were formed bilaterally in the middle thalamic neuropil and istmal nuclei, normally targets of tectal efferent axons and, particularly at 3 mo. p.o., within the telencephalon and brainstem.

Thus, most ret-ret axons remain transient even when normal optic targets are missing or when ganglion cells in the opposite retina are denervated. (Supported by NS 14096)

205.3 EFFECT OF MULTIPLE LESIONS ON REGENERATION OF GOLDFISH OPTIC AXONS. Janet R. Sparrow and Bernice Grafstein. Dept. Physiology, Cornell Univ. Med. College, New York, N.Y. 10021 Axonal regeneration may be accelerated in neurons subjected to a previous "conditioning" lesion. This effect is particularly

Axonal regeneration may be accelerated in neurons subjected to a previous "conditioning" lesion. This effect is particularly marked in the goldfish optic nerve: the rate of regeneration is doubled if a conditioning lesion precedes the second lesion (testing lesion) by 2 weeks (McQuarrie and Grafstein, <u>Brain Res.</u> 216:253, 1981) and less pronounced increases are observed with shorter intervals (Edwards et al, <u>Exp. Neurol</u>, 72:672, 1981). Since a single conditioning lesion has <u>such</u> a dramatic effect we sought to determine whether the effects of a series of lesions can be cumulative and what the maximum change in the rate of axonal outgrowth might be. Goldfish were subjected to optic tract transection and/or

Coldfish were subjected to optic tract transection and/or nerve crushing made at varying intervals. Either single (testing lesion alone), double (conditioning lesion and testing lesion) or triple (2 conditioning lesions and a testing lesion) lesions were made. During regeneration following the testing lesion, we measured 1) the outgrowth distance of the optic axons from the distribution of radioactively labeled axonally transported protein after <sup>3H</sup>-proline injection into the eye, 2) the amount of fast transported protein in the nerve, and 3) the accompanying changes in the size of the retinal ganglion cells (RGC).

In nerves receiving one conditioning lesion 14 days before the testing lesion, the rate of outgrowth following the testing lesion was doubled, but not further enhancement of outgrowth was evinced by a third lesion given 7 or 14 days before the conditioning lesion: perhaps with one conditioning lesion given 14 days before a testing lesion the axons elongate at the maximum rate attainable. When the interval between the conditioning and testing lesions was shortened (i.e. to 7 or 14 days) so that the conditioning lesion caused a submaximal increase in the rate of outgrowth, another lesion given either 3 days after or 3 days before the original conditioning lesion produced a further acceleration of outgrowth. In the latter experiment the increase in RGC area was also greater with a triple lesion than with a double lesion, but the amount of fast transported protein was the same in both the triple- and double-lesioned nerve.

It is concluded that regenerating goldfish optic neurons can respond to more than one conditioning lesion when the individual lesions produce a submaximal enhancement of axonal outgrowth.

### 205.2 EFFECTS OF DOUBLE TRANSECTION ON REGENERATION OF LAMPREY SPINAL AXONS. H.S. Yin and M.E. Selzer, Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Following transection, the spinal axons of sea lamprey larvae (Petromyzon marinus) regenerate for short distances past the scar, but then stop. This might be explained if the zone of injury exerted a trophic effect on the growing axon tip. To test this hypothesis, double simultaneous transections, 4-17 mm apart were made and animals allowed to recover 59-88 days. Using intra-axonal injection of HRP, the distance of regeneration was determined for giant reticulospinal axons. When these axons are singly cut high in the cord (i.e. close to their cell bodies), they ordinarily regenerate vigorously (up to 5 mm). Double transections in the rostral cord did not significantly affect the distance of regeneration. However, in the caudal cord where single transection was followed by meager regeneration, double transection was followed by an increased distance of regenerated past the scar after initial die-back. In contrast, of eight neurites in double caudal transected animals, four regenerated past the scar, the longest reaching 1.3 mm below the transection.

We also stained dorsal cells and giant interneurons located between the two transection sites. Both cell types ordinarily project, and also regenerate, rostralward. This pattern was unaffected by the presence of a second lesion caudal to the axotomized cells. In 16 injected dorsal cells, the distal end of the regenerating neurite was oriented rostralward, and only one neurite looped caudalward as it approached the scar. Of eight injected giant interneurons, seven had rostrally projecting regenerating neurites and one had no stained axon. Even when retrograde axonal degeneration was complete and axon-like neurites grew from posteriorly oriented dendrites, these neurites looped and regenerated rostralward.

These results are consistent with the hypothesis that, in some circumstances, the zone of injury may exert a trophic effect on the magnitude of axonal regeneration, but probably does not determine the directional specificity of growth.

NIH Grant NS14837.

205.4 REGULATORY ROLE OF THE SYNAPTIC TARGET TISSUE DURING REGENERATION OF THE GOLDFISH VISUAL SYSTEM. <u>Dana Giulian</u> (SPON: H. Epstein) Department of Neurology, Baylor College of Medicine, Houston, Texas 77030

Transection of goldfish retinal ganglion cell axons initiates a regenerative process that leads to the regrowth of axons, new synapse formation within specific regions of the optic tectum, and the recovery of sight. During this regeneration, ganglion cells of the retina and glia of the optic tract have dramatic increases in new protein biosynthesis. Removal of the optic tectum decreases glial biosynthetic activity during an early phase of regeneration and alters production of a high molecular weight ganglion cell protein during the late phase. Such data suggest that the early phase, or that time prior to axonal regrowth into the target tissue, may be mediated by the release of tectal humoral factors acting upon optic tract glia. In contrast, ganglion cells are influenced by the target at a later regenerative phase, perhaps through cell-to-cell contact mechanisms. In support of this model, further study shows that a trypsin sensitive peptide of less than 20,000 daltons stimulates protein biosynthesis of optic tract glia. 205.5 INCREASED FIBROUS COLLAGEN AND REDUCTION OF AXONAL GROWTH INHIB-ITORS ARE ASSOCIATED WITH ENHANCED REGENERATION, M. Schwartz,

NONS ARE ASSOCIATED WITH EMPARED REDERRATION, M. SCHWATCZ, V. Lavie\* and I. Rachailovich\*, Dept. of Neurobiology, the Weizmann Institute of Science, Rehovot 76100, Israel. We have recently established conditions to study the contrib-ution of non-neuronal cells to the process of goldfish optic nerve regeneration. We adapted the use of X-irradiation to restrict the division of non-neuronal cells consciented with the injured regeneration. We adapted the use of X-irradiation to restrict the division of non-neuronal cells associated with the injured nerve. Regenerative capacity was determined subsequent to X-irr adiation. At an early period post injury X-irradiation resulted in increased capacity of the corresponding retinae to sprout, <u>in</u> <u>vitro</u>. In this work, we present analysis of events associated with the enhanced regenerative capacity.

Observations at the electron microscopic level of an injured nerve following X-irradiation revealed a striking enlargement of the endoneurial extracellular space which was filled with fibrous collagen.

The observed increase in collagen at the EM level was supported by our finding of a 3-fold increase in <sup>3</sup>H-proline incorporation by the non-neuronal cells associated with a segment of X-irradia-ted injured nerve. The direct association between the appearance of fibrous collagen and the increased ability to regenerate was shown by treating the fish whose optic nerve had been injured with β-aminopropionitrile (BAPN), an inhibitor of the enzyme lysyl oxidase. This leads to disrupted formation of collagenous fibers. Treatment with BAPN was started when X-irradiation was performed. We found that such treatment resulted in a marked decrease in the in viro. The inhibitory effect on X-irradiated regenerating ret-inae was 3-fold higher than on regenerating retina. It should be noted that the BAPN treatment had no effect on the incorporation of <sup>3</sup>H-proline. These results further emphasize the importance of collagenous matrix for regeneration collagenous matrix for regeneration.

The increase in collagen was accompanied by changes in the pro-file of substances released by the surrounding non-neuronal cells. This included a drastic decrease in the level of axonal growth inhibitors as shown by the bioassay on regenerating retinal ganglia cells, in vitro.

The reduction in the level of axonal growth inhibitors and the increase in collagen at the same time may open a new perspective relating to the capacity of neurons to regenerate. Whether these two events are directly or indirectly related remains to be seen.

NEUROCHEMICAL AND BEHAVIORAL EFFECTS OF GANGLIOSIDES IN RATS WITH A UNILATERAL LESION OF THE MAGNOCELLULAR FOREBRAIN NUCLEI (MFN). G. Pepeu, L. Bracco\*,G. Lo Conte\*,L. Bartolini\* and F. Casamenti\*. Departments of Pharmacol. and Neurol. Florence Univ. 50100 Florence, 205.6

Italy. Italy. It has been shown (Wojcic, M. et al., <u>Neurosci., 7</u>: 495, 1982) that i.m. administration of <u>gangliosides</u> stimulates the recovery of choline acetyltransferase Ayy, 1982) that is a administration of gangitosides stimulates the recovery of choline acetyltransferase (CAT) and acetylcholinesterase in the hippocampus of rats after a septal lesion. In order to demonstrate whether ganglioside-stimulated CAT recovery was associ-ated with functional recovery, 30 mg/Kg ism. of CM, ganglioside (Fidia Res. Lab.) were administered dafly for 22 days to adult rats with a unilateral electrolyt-ic lesion of the MFN. This lesion was followed by a de-crease in the ipsilateral cortical CAT activity and an impairment of passive and active conditioned avoidance responses (Lo Conte, G. et al., Pharmac. Biochem. Behav., 17:93, 1982). The rats received daily sessions in a shuttle box from day 10 to day 22 after the lesion. On day 22 they were also trained in a one-trial passive avoidance task. The rats were then killed by decapita-tion and brain samples were removed for CAT activity and noradrenaline (NA) level determination. Histologi-carried out. carried out

The ipsilateral decrease in CAT activity induced by the lesion was significantly reduced by ganglioside treatment. Instead of a 39 and 20% decrease found in the ipsilateral frontal and parietal cortex of saline the ipsilateral frontal and parietal cortex of saline treated rats, in the ganglioside treated rats a signi-ficant decrease was detected only in the ipsilateral frontal cortex. Conversely, a significant increase was found in the ipsilateral parietal (+16%) and controlat-eral frontal (+36%) and parietal (+35%) cortices. The lesion brought about an increase in controlateral NA level. The ganglioside only induced a further small in-crease in the controlateral frontal cortex. The impair-ment of the passive conditioned avoidance response was not modified by GM, treatment. Conversely, the lesioned rats treated with GM, always performed significantly more active avoidance responses than the controls. In conclusion, repeated GM, administrations appear

In conclusion, repeated GM, administrations appear to stimulate the recovery of lesioned cholinergic path-ways associated with a partial functional restoration. Partly supported by C.N.R. grant nº 82.02266.56

205.7 EFFECT OF PERIPHERAL NERVE INJURY ON REGENERATION OF EFFECT OF PERIPHERAL NERVE INJURY ON REGENERATION OF AXONS IN THE DORSAL COLUMN OF THE SPINAL CORD. <u>P.M. Richardson</u>. Division of Neurosurgery, Montreal General Hospital and McGill Univ., Montreal, Canada. To investigate the regeneration of spinal axons ascending from lumbar dorsal root ganglia (DRG), a dorsal incision was made in the rat spinal cord at high cervical level. As a favorable substratum for axonal growth (Soc. Neurosci. Abstr. <u>8</u>:869, 1982), one end of a peripheral nerve segment was grafted in the midline to the cut spinal cord. Each graft was taken from the right sciatic nerve of the same rat and the left sciatic nerve was not injured. Two months after grafting, horseradish peroxidase (HRP) was injected one rafting, horseradish peroxidase (HRP) was injected into the grafts as a retrograde tracer for neurons with regenerating axons. Particular attention was paid to neurons in the L4 and L5 DRG some of which have peripheral axons in the sciatic nerve and central axons reaching the spinal cord. HRP-containing neurons were consistently present in the right L4 and L5 DRG but rarely on the left. These observations suggest that peripheral axotomy of DRG neurons enhances regeneration of their simultaneously injured spinal axons. (Supported by the Medical Research Council of Canada and Multiple Sclerosis Society of Canada.)

205.8 PHYSIOLOGIC PROPERTIES OF RAT BRAINSTEM NEURONS REGENERATING AXONS INTO PERIPHERAL NERVE GRAFTS. <u>M. Munz, M. Rasminsky & A.J. Aguayo</u>. Neurosciences Unit, Montreal General Hospital, Montreal, Quebec.

The regenerative potential of CNS neurons becomes apparent when peripheral nerve grafts are inserted into various areas in the neuraxis (Aguayo et al, Adv. Cell. Neurobiol. 3,215:1982). We

heuraxis (Aguayo et al, Adv. Cell. Neurobiol. <u>1</u>,213:1962). we have now made physiological recordings from axons regenerating from CNS cells into peripheral nerve grafts. Autologous grafts of 4 cm lengths of the left peroneal nerve were inserted into the right lower lateral medulla of adult rats, the distal end of the graft ending blindly. After 10 to 24 weeks the distal end of the graft ending blindly. After 10 to 24 weeks had elapsed to allow graft reinnervation from brainstem neurons (David & Aguayo, Science 214,931:1981; Munz & Aguayo, Soc. Neurosci. Abstr. <u>8</u>,869:1982), grafts were reexposed and biphasic extracellular recordings were made from the desheathed grafts. 1) Spontaneous activity: in most preparations little spontaneous efferent activity was recorded from the grafts. The enhancement of spontaneous activity by systemic administration of

picrotoxin suggested that brainstem neurons regenerating axons into the grafts are tonically inhibited by GABA mediated input. Some spontaneously active units fired in bursts immediately preceding respiratory muscle activity. Such units presumably reflect activity in respiratory modulated brainstem neurons.

 Physiologically evoked activity: stimulation of mystacial vibrissae and facial skin elicited responses from putative trigeminal nucleus neurons projecting into the grafts. After adminstration of picrotoxin, responses were elicited by touching the skin in various areas of the body, the stimuli presumably

the skin in various areas of the body, the stimuli presumably exciting dorsal column nucleus neurons projecting into the grafts. 3) Electrically evoked activity: electrical stimulation of limb nerves evoked unitary responses. Two criteria suggested that such responses were synaptically mediated: i) the latency usually showed appreciable jitter; ii) a collision test in which the responding unit was stimulated in both the periphery and on the graft itself indicated interposition of at least one synapse between the periphery and the graft. Electrical stimulation of limb nerves also caused inhibition of firing of some spontaneously active units for periods of up to 400 msec. Both excitation and inhibition showed somatotonic specificity, being elicited by inhibition showed somatotopic specificity, being elicited by electrical stimulation of single limbs or nerves in limbs. Presumed reticular units were observed to respond with an increase in spontaneous firing rate to electrical stimulation in the periphery.

We conclude that brainstem neurons regenerating axons into peripheral nerve grafts retain many of the physiological properties of normally functioning neurons in intact animals.

RAT VISUAL SYSTEM NEURONS GROW AXONS ALONG PNS GRAFTS. U. BUnger\* 205.9 and A.J. Aguayo (SPON: A. Peterson). Neurosciences Unit, The Montreal General Hospital and McGill University, Montreal, Canada. Axons from neurons in different regions of the adult rat brain have been shown to elongate extensively along PNS grafts (Nature 296: 150, 1982). In this study we examined the regrowth from neurons in the rat visual system. In adult Sprague-Dawley rats a 2 to 3.5 cm long segment of

autologous sciatic nerve was taken and implanted either into the visual cortex, the superior colliculus, or the thalamus in the vicinity of the lateral geniculate nucleus. The other end of the graft was sutured to nearby muscles. From 7 to 15 weeks after grafting, the extracranial portion of the graft was re-exposed, transected and HRP applied to its tip to retrogradely label cells whose axons had grown along the graft.

Labelled nerve cells were found in all three regions of the visual system as well as nearby areas such as other thalamic nuclei and hippocampus. The population of labelled cells in the nuclei and hippocampus. The population of labelled cells in the visual cortex was distributed over layers II to VI with the greatest proportion of cells found in layers IV and V, the diameter of the cells ranging between 12 and 37  $\mu$ m. In the superior colliculus labelled cells have been found in deep and superficial strata. The yield of labelled cells in the lateral geniculate nucleus is very low, only a few cells have been found. In all cases the labelled neurons were in close proximity to the graft. the position of the graft apparently influencing the location of labelled cells. The total length of the newly grown axons from these labelled neurons is approximately 2 cm.

These results indicate that there are nerve cells in several areas of the adult rat visual system that have the capacity for axonal growth under the conditions provided in these experiments. This potential for growth appears to be expressed when these neurons intrinsic to the brain interact with nonneuronal components of the PNS.

HISTOPATHOLOGICAL CHANGES IN DEVELOPING NEURAL TRANSPLANTS. 205.10 J. Brasko\* and G.D. Das\* (SPON: R.P. Maickel). Dept. of Biological Sciences, Purdue University, West Lafayette, IN 47907.

It is well established that embryonic neural tissues may be successfully transplanted into the brains of neonatal and adult host animals. Following transplantation, both the donor and host tissues undergo a series of histopathological and developmental changes which ultimately result in the achievement of fully grown, integrated transplants. The exact nature, magnitude, and time course of these changes are not known. In this study, we

time course of these changes are not known. In this study, we report qualitative and quantitative findings on these histolog-ical phenomena of developing neural transplants. Neocortical tissue, 3.5 mm<sup>3</sup> in volume, from 17-day rat embryos was transplanted into the cerebellum of 30-day and 3-month old hosts (Das, '74, '79). Hosts were sacrificed 1, 3, 5, 7, 9, 12, 15, 20, 25, and 30 days following surgery, and their brains were processed for cresyl-violet, hematoxylin and eosin, and Fink-Heimer histology.

The results demonstrated the presence of areas of viable transplant, necrotic transplant, blood, and CSF filled space in the host cerebellum on day 1 after transplantation. C-V and H & E material showed that the portion of viable transplant underwent sequential phases of regression, recovery, and growth, with an initial decrease in volume on days 1 and 3, followed by a steady increase which plateaued by day 20. The volumes of a steady increase which placedue by day 20. The volumes of necrotic transplant and blood increased from days 1-3, but rapidly declined to 0 between days 5-7. The volume of CSF filled space increased to 0.5 mm<sup>3</sup> by day 3, a volume which was maintained through day 9 before falling to 0 by days 12-15. The viable portion of the transplants grew initially by proliferation of the surviving neuroepithelial cells, and subsequently by dispersion and differentiation of neuroblasts.

An additional assessment of the host brain reaction to the developing transplant was obtained from Fink-Heimer processed brains. While there was no degeneration argyrophilia present within the transplants at any time, a significant amount of degeneration persisted in laminae of the crebellum apposed to the transplant, as well as in the deep cerebellum nuclei, up to day 30. Argyrophilic staining was also observed in folia not directly in contact with the transplant throughout the develop-mental period studied, though the nature of this staining differed qualitatively between the short and long survival times. These observations indicate that transplantation of neural tissues causes trauma to both the transplant and the host brain.

With the proper techniques of transplantation these histopatho-logical changes can be kept to a minimum. Supported by N.I.H. Grant No. NS-08817.

NEURAL REGENERATION AND FUNCTIONAL RECONNECTION FOLLOWING OLFAC-TORY NERVE TRANSECTION IN HAMSTER. R.M. Costanzo, Department of Physiology & Biophysics, Medical College of Virginia, Richmond, VA 23298

The olfactory sensory neurons in the vertebrate nervous system are unique in that they undergo continuous neurogenesis and replacement. Anatomical studies have shown that transection of the olfactory nerves leads to a degeneration of sensory neurons followed by a neurogenesis and replacement with newly formed cells. Replacement neurons grow axonal processes that are capable of re establishing morphological connections with cells in the olfactory bulb.

To determine the functional capacity of these anatomical reconnections, single unit responses to odor stimuli were recorded from the olfactory bulb following recovery from unilateral olfacfrom hamsters with recovery times of 4, 35, 60, 90, 120, 180 and 270 days. At day 4, although there was spontaneous activity recorded from bulb units on the experimental side (N=10), they did not respond to stimulation of the olfactory epithelium with odors. not respond to stimulation of the offactory epithelium with dots. Control units (N=9) from the unoperated side of the same animals showed normal odor responses. By day 35 some of the units tested responded to odor stimulation, indicating that connections had been reestablished with sensory neurons. With longer recovery times an increasing percentage of units responded to odor stimuli. In addition, concentration response functions showed that units were capable of signaling differences in stimulus intensity. T response of units to four odors (amyl acetate, 1-butanol, ethyl The vity, suggesting their ability to discriminate among odors. Histological verification of the extent of nerve transection was

made possible by use of teflon markers. Nerve connections ob-served above these markers were assumed to come from newly reconnected receptors and presumably provided the pathway for stimulus information to reach bulb units.

These results demonstrate that following nerve transection olfactory neurons are capable of reestablishing nerve transcriptions with the olfactory bulb and, furthermore, that these connections with functional synapses that transmit sensory information to second order cells. These findings in the olfactory system suggest that regeneration and repair of neural pathways within the central

nervous system are possible. This work was supported by NIH grant NS-16741.

CM1 GANGLIOSIDE FACILITATES FUNCTIONAL RECOVERY AFTER AN ENTOR-205.12

CM1 GANGLIOSIDE FACILITATES FUNCTIONAL RECOVERY AFTER AN ENTOR-HINAL LESION; INCREASE IN ACETYLCHOLINESTERASE IN DENTATE GRRUS S.E. Karpiak, F. Vilim & S.P. Mahadik. Division of Neurosci-ence, NYS Psychiat. Inst. & Depts. of Psychiatry & Biochemistry, Coll. of Physicians & Surgeons, Columbia U., N.Y., N.Y. 10032. Exogenous gangliosides have been reported to enhance both neurite outgrowth and regeneration (in vitro & in vivo). We had examined the effects of total brain ganglioside on the course of recovery of alternation behavior after an entorhinal cortical lesion in rat (1). It was found that the injection of ganglio-sides (I.M.:50mg/kg) facilitates recovery of the alternation belesion in rat (1). It was found that the injection of ganglio-sides (I.M.:50mg/kg) facilitates recovery of the alternation be-havior as seen in: 1) reduction in the initial behavioral loss after lesioning; 2) return to pre-lesion performance levels soon-er than controls and 3) long-term improved behavioral perfor-mance. Using the same model system, we have now examined the ef-fects of CMI ganglioside on functional recovery. Male Sprague-Dawley rats (180gr), after 4 days of training on a conditioned alternation behavior, received a unilateral entorhinal cortical lesion. On day 3 of training rats began receiving daily injec-tions (I.M.: 10mg/kg) of GMI ganglioside. Controls were injected with saline. Results show that GMI administration significantly limits the magnitude (34% fewer errors than controls) of behav-ioral deficit seen 24hrs (day 5) after the entorhinal lesion. Re-turn to pre-lesion performance levels was achieved by day 8 for GMI rats and day 11 for controls. At 2 wks post-lesion the GMI treated rats made less than 1 error daily, while controls made 2-3 errors daily. Recovery of the alternation behavior has been reported to be dependent upon collateral sprouting of glutaminerreported to be dependent upon collateral sprouting of glutaminerreported to be dependent upon collateral sprouting of glutaminer-gic afferents into the denervated dentate. We are presently meas-uring changes in levels of glutamate (HPLC) in the dentate. How-ever, we have examined the cholinergic input, which also reinner-vates the denervated molecular zone of the dentate. To assess whether gangliosides affect the course of this cholinergic rein-nervation, AChE was assayed in the dentate gyrus of rats 7 days after a unilateral entorhinal lesion. Rats were injected daily with CML (10mg/Krat M) and controls results of controls controls. with QMI (10mg/kgiI.M.) and controls received saline. Controls showed AChE levels of 4.8 0.19<sup>s</sup> µmoles/hr/mg protein and QMI rats had levels of 5.9<sup>s</sup>0.22 µmoles/hr/mg protein, representing a 25% increases above control levels. In summary, we have found that treatment of rats with GMI ganglioside, like total ganglioside, facilitates functional recovery after an entorhinal lesion and accelerates cholinergic reinnervation of the dentate gyrus. It is hypothesized that gangliosides accelerate functional recovery after an entorhinal lesion by facilitating sprouting.

206.1 DISORGANIZATION OF OPTIC NERVE PROJECTIONS MEASURED WITH THE THE VEP: IS IT DUE TO HYPOPIGMENTATION? R.L. Klingaman<sup>\*</sup>and G. Fishman<sup>\*</sup> (SPON: D.I. Tepas). Dept. of Physiology, Life College, Marietta, GA 30060 and Dept. of Ophthalmology, University of Illinois Medical Center, 1855 W. Taylor St., Chicago, IL 60612.

It has been consistently reported that the optic nerve (ON) fibers do not cross-over in a normal manner in mammals with albinotic fundi (hypopigmentation). It has been found that pattern VEPs recorded from human albinos support the view that there exist abnormal routing of ON projection at the optic chiasm. The authors of these reports have postulated that this developmental disorganization of ON fiber projections was associated with the hypopigmentation of the retina. We have recently tested an individual who, although

We have recently tested an individual who, although exhibiting some clinical signs of ocular albinism, such as pendicular nystagmus, low visual acuity and a poorly developed fovea (hypoplasia), did not display any sign of ocular or skin hypopigmentation. We conclude that he should be classified as an example of "isolated foveal hypoplasia".

The fact that this individual, like albinos, demonstrated a marked asymmetry in the amplitude of the monocular pattern VEP recorded from the right and left occipital hemispheres leads us to conclude that abnormal foveal development rather than a mellanin defect, may be the variable responsible for the misrouting of ON projections at the chiasm. 206.2 DENDRITIC AND SYNAPTIC CHANGES IN THE DORSAL LATERAL GENICULATE NUCLEUS AFTER CUTTING ONE OPTIC NERVE IN KITTENS. J.A. Robson. Dept. of Anatomy. SUNY Unstate Medical Center. Syracuse. WY 13210

NUCLEUS AFTEK CUTTING ONE OFTIC NERVE IN RITENS. J.A. KODSON. Dept. of Anatomy, SUMY Upstate Medical Center, Syracuse, NY 1321C In the dorsal lateral geniculate nucleus of cats each lamina is innervated by only one eye and previous studies have shown that removal of an eye in newborn kittens results in severe transneuronal atrophy in the denervated laminae. However, some neurons in the denervated laminae do not atrophy and it has been hypothesized that these "surviving large cells" escape the atrophic effects of deafferentation because they are innervated by axons from the intact eye (Guillery, J. Comp. Neurol., 146:407, 1972).

To test this hypothesis kittens had one eye removed in the first two weeks after birth. Nine to 12 months later neurons in the dorsal lateral geniculate nucleus were filled with horseradish peroxidase (HRP) via injections into the optic radiations. In some animals retinal projections from the intact eye were also demonstrated autoradiographically. To permit combined light and electron microscopic analysis of the HRP-filled neurons, diaminobenzidine was used as a chromogen and every third section was embedded in plastic. The other reacted sections were mounted on glass slides and, in the appropriate animals, processed for autoradiography.

Surviving large cells were densely filled with HRP in several animals. Most of these cells are located near a normally innervated lamina and resemble Guillery's class l cells (J. Comp. Neurol., 128:21, 1966). They have large somata and radiate dendrites which give rise to few appendages. In all cases these neurons contribute a large portion of their dendritic tree to regions innervated by the intact eye either by growing dendrites into a normally innervated lamina or by growing them into a region demonstrated autoradiographically to contain translaminar axonal sprouts from the intact eye (Guillery, J. Comp. Neurol. 146:407, 1972; Robson, J. Comp. Neurol., 195:403, 1981). Electron microscopic studies of

Electron microscopic studies of the labeled dendrites of surviving large cells provide direct evidence that they are innervated by the intact eye. These dendrites are postsynaptic to axonal profiles that have the cytological characteristics of the terminals of retino-geniculate axons - these profiles have round synaptic vesicles and pale-appearing mitochondria and they are always presynaptic, forming asymmetric contacts. As in normal cats some of these terminals are large and contact the proximal dendrites of labeled cells, often in glomerular complexes, while others are smaller and contact more peripheral dendritic segments. (Supported by EY-03940 and the Alfred P. Sloan Foundation.)

206.3 SEQUENCE OF SYNAPTIC FORMATION IN THE PERIFOVEAL REGION OF THE RHESUS MONKEY RETINA: QUANTITATIVE AND SERIAL SECTION ELECTRON MICROSCOPIC ANALYSES. Y. Nishimuta\* and P. Rakic (SPON: P. S. Goldman-Rakic), Sec. of Neuroanatomy, Yale University School of Medicine, New Haven CT 06510

The perifoveal region of the retina was analysed by electron The perifoveal region of the retina was analysed by electron microscopy in 19 rhesus monkeys ranging in age between the 45th embryonic day (E45) and 3rd postnatal year. Two EM probes (photomontages) consisting of overlapping electromicrographs were made across the full thickness of the retina for each age. The appearance and density of synaptic contacts were determined in the inner (IPL) and outer (OPL) plexiform layers. In addition, in younger embryos, where the type of synapse was difficult to classify, up to 40 serial ultrathin sections were made to trace the origin and nature of procession is elements. The IPL the origin and nature of pre- and postsynaptic elements. The IPL becomes recognized at E65 and the OPL appeared one month later (E99) as a thin acellular zone composed of immature neurites. Also, synaptogenesis begins earlier in the IPL than in the OPL. In the IPL, the first conventional synapses (paired membrane specializations accompanied with synapses (parted memorale specializations accompanied with synaptic vesicles) are recog-nized in the E78 specimen. Three dimensional reconstructions revealed that at this age all the synapses in the IPL, except for those whose origin could not be identified, occurred between amacrine and ganglion cells. Synapses between pairs of amacrine cells and between amacrine and bipolar cells were observed at E91. The first immature ribbon synapses (complexes between E91. The first immature flobon synapses (complexes between bipolar, amacrine and ganglion cells) were recognized in the IPL of the E105 specimen. Initially, prospective ribbons have the form of dense spherical aggregates and only assume their bar shape by E114. In the OPL, the first synaptic junctions associated with vesicles were observed in the E105 specimen. Although synaptic vesicles were observed in the terminals of photorecep-tors cells, they were not as yet associated with the ribbon bar. The typical ribbon synapses consisting of a bar surrounded by synaptic vesicles were first seen at El30. Thus, from this and earlier studies on synaptogenesis in the lateral geniculate (Cooper and Rakic, 1981) it appears that synaptic conliculus (Cooper and Rakic, 1981) it appears that synaptic connectivity of the primate visual system is initiated in central structures, followed two to three weeks later by formation of contacts between ganglion and bipolar cells in the IPL, and still almost one month later between bipolar and photoreceptor cells. Th central to peripheral sequence of synaptogenesis is somewhat This unexpected in view of presumed peripheral control of sensory connectivity. Furthermore, local circuits between amacrine and ganglion cells may occur before true line projections from eceptors via bipolar cells to ganglion cells. Supported by EY 02593.

206.4 DISTRIBUTION OF CELLS PROJECTING TO THE SUPRAGENICULATE NUCLEUS OF CATS, T. P. Hicks, Wm. Fletcher\*, and C.A. Smith\* Depts of Medical Physiology and Anatomy, The University of Calgary Faculty of Medicine, Calgary, Alberta, Canada. Single neurones in the suprageniculate nucleus (SGn) of cats

Single neurones in the suprageniculate nucleus (SGn) of cats can be activated by visual stimuli. These visually responsive cells have identifiable receptive fields and each responds preferentially to particular light stimuli. Since there is no evidence that the SGn receives direct input from the retina, it was considered important to attempt to determine by neuroanatomical methods the sites of cell bodies sending projections to this nucleus.

sidered important to attempt to determine by neuroanatomical methods the sites of cell bodies sending projections to this nucleus. Unit activity was recorded with glass micropipettes filled with a 20% buffered solution of HRP in 0.2 M NaCl. When a visually -responsive neurone was located below 15 mm depth from the cortical surface, its receptive field was plotted and the ocularity determined. Ejecting currents of between 0.5 and 2.0 µA were used to expel HRP for about one hour. Animals were perfused and the entire brain removed for cutting in 60 µm-thick sections. All sections were reacted according to the TMB method, were mounted on slides and counterstained with neutral red. Neurones labelled with HRP reaction product were found in a variety of cortical and subcortical sites. Some of these sites included the intermediate division of the superior colliculus and the medial zone of the pretectum, as well as other pretectal sites less easily identified but associated closely with the medial pretectum. Relatively intense labeling could also be observed in

Neurones labelled with HRP reaction product were found in a variety of cortical and subcortical sites. Some of these sites included the intermediate division of the superior colliculus and the medial zone of the pretectum, as well as other pretectal sites less easily identified but associated closely with the medial pretectum. Relatively intense labelling could also be observed in the substantia nigra (reticulata) and in and around the periaqueductal grey (dorsal aspect). Cells were detected in the anterior ectosylvian gyrus and within both banks of the anterior ectosylvian sulcus, with greater labelling being observed in the lateral than in the medial bank. It appears from these data that cortical and tectal inputs are likely to provide at least a major component of the visual information giving rise to the physiological properties of SGn neurones.

(This work was supported by the Alberta Heritage Foundation for Medical Research and the MRC of Canada) 206.5 THE LONG TERM BENEFITS OF REVERSE OCCLUSION IN PROMOTING RECOVERY FROM MONOCULAR DEPRIVATION IN KITTENS. K. Murphy\*, D.E. Mitchell and M. Kaye\*. Dept. of Psychology, Dalhousie University, Halifax, N.S., Canada.

While the behavioral, anatomical and physiological consequences of monocular deprivation can be extremely severe, considerable recovery can occur if at the time that patterned visual input is recovery can occur if at the time that patterned visual input is restored to the deprived eye, the other eye is occluded (reverse occlusion). Recovery is substantial if this procedure is initiated in kittens at 4 or 5 weeks of age. We have examined the permanence of this recovery in kittens that were monocularly deprived from near birth until either 4, 5, or 6 weeks of age and reverse occluded for periods of from 9 to 84 days. Daily measurements of the grating aculty of each eye made upon recovering of hisoroglar wined force the revealed of and d restoration of binocular visual input revealed a rapid and reciprocal change in the visual acuity of the two eyes. In the majority of cases the acuity of the initially deprived eye fell dramatically within 2 weeks of termination of reverse occlusion, erasing much of the gains in vision made during this period. At At the same time the aculty of the other eye improved to approach normal levels. However, in some cases the aculty of this eye remained substantially below normal. Morphological recovery in the LGNs of these animals as revealed by measurements of cell cross sectional area made on completion of behavioral testing, was significantly less than that observed in other animals on whom measurements were made immediately upon termination of reverse occlusion. Similarly, physiological recordings from the visual cortex (area 17) of selected animals revealed a substantial bias of ocular dominance toward the eye that was open during the initial period of monocular deprivation rather than the deprived eye as would be observed immediately following the period of reverse occlusion. Thus, neither the morphological recovery observed in the LGN or the substantial shifts of ocular dominance towards the initially deprived eye that occur during the period of reverse occlusion appear to be permanent. These various findings suggest that the neural connections formed during the initial period of occlusion are different in a fundamental way from those functional connections established with the deprived eye during the period of reverse occlusion.

206.7 FUNCTIONAL AND MORPHOLOGICAL REORGANIZATION OF AREA 17 AND LATERAL GENICULATE NUCLEUS FOLLOWING MONOCULAR DEPRIVATION IN GM<sub>1</sub> TREATED CATS. G. Carmignoto\*, R. Canella\*, C. Comelli\* A. Gorio, <u>S. Bisti\*</u><sup>o</sup> (SPON: A. Cangiano). Dept. of Cytopharmacology, Fidia Research Laboratories, Via Ponte della Fabbrica 3/A, 35031 Abano Terme (PD) Italy. <sup>o</sup> Institute of Neurophysiology, C.N.R., Via S. Zeno 51, Pisa, Italy.

In the peripheral nervous system gangliosides (GA) have been suggested to be involved in developmental processes, in cellular differentiation, axonal growth and sprouting. The functional reorganization of the cat visual cortex following various forms of visual deprivation could be considered one of the most striking model to investigate neuronal plasticity in the Central Nervous System of the mammalian brain and the possible involvement of GA in this complex process. Monocular deprivation (MD) during the early months of life leads to profound cells atrophy at the level of the Lateral Geniculate Nucleus (LCN) and to large modifications in the development of connections at the level of the striate cortex, where probably inhibitory and excitatory terminals relating to the two eyes input, are redistributed. Sprouting and formation of new synaptic contacts could be involved in the mechanisms underlying the synaptic reorganization of LGN and striate cortex. Experiments were performed on 16 kittens divided in two groups: 9 cats for the untreated group and 7 cats for the CM<sub>1</sub> treated group. All the animals were monocularly deprived at 35th day from birth. Monosialoganglioside (CM<sub>1</sub>) treatment at alternate days (30 mg/Kg i.p.), starts at the time of deprivation and continues till the day of recording at about 4 months of age. Ocular dominance distribution was assessed by recording from single unit in area centralis of area 17. Results suggest a modification of cortical reorganization following visual deprived eye, a higher percentage of cells maintain a binocular response, on the contrary in the hemisphere ipsilateral to the deprived eye increase the possibility for the deprived eye is reover. Experiments are in progress trying to verify if GM<sub>1</sub> treatment could enhance the recovery when the deprived eye is reopened and the original undeprived eye is closed, even after the critical period is going to end. At the level of LGN experiments are unantical reduced to the detert possible modifications of the dendritic tree

206.6 EXPANDED RETINOGENICULATE PROJECTIONS IN THE CAT FOLLOWING PRENATAL UNILATERAL ENUCLEATION: FUNCTIONAL AND ANATOMICAL ANALYSES OF AN ANOMOLOUS INPUT. R. WILLIAMS and L. M. Chalupa California, Davis, CA.

In the adult cat, crossed and uncrossed retinal projections to the lateral geniculate nucleus (DLGn) are segregated within separate cell layers; crossed fibers are limited to laminas A, C and C2, uncrossed fibers to A1 and C1. In contrast to the mature pattern, early in development the retinal input is widespread and fibers from the eyes are intermixed.

The removal of an eye 2-3 weeks before birth (between embryonic days E-42 and E-51) disrupts the formation of the normal lamination pattern: the DLGn is composed of a single thick magnocellular layer (which may correspond to a composite A/A1 layer), and a ventral parvocellular layer. The ipsilateral nucleus is at least 20% smaller than its contralateral mate. Intraccular injections of HRP demonstrate that the retinal influx from the spared eye of cats enucleated on E-42 and E-49 arborizes diffuse input is though to result primarily from a failure of fibers to withdraw to their normal domain-the fetal pattern of input is maintained into maturity-and secondarily, from the compensatory sprouting of the remaining optic axos into sparejons.

innervated regions. is this extensive and aberrant retinal projection fully functional? Does the DLGn have a normal visual field organization? In order to answer these questions, extracellular single cell recordings were made in the DLGn of 4 adult a nimals from which an eye had been removed between E-45 and E-51. For comparison we also studied 8 normal cats and 2 cats from which an eye was removed on the sixth postnatal day. All regions of the DLGn of the prenatally enculeated animals appear to receive functional innervation. In 44 electrode penetrations through the DLGn of visually 'silent' regions corresponding to denervated remnants of layers A or Al (or to the far lateral monocular segment of the pisliateral nucleus) were noted. However, in postnatally enucleated animals denervated regions were consistently documented. The topographic order of the expanded projection was, given the limits of the technique, normal. Receptive fields were limited to the contralateral beinfield, and extended 86° peripheral in the contralateral DLGn; 36° in the ipsilateral DLGn. The representation of the zero vertical meridian could not be distinguished from normal. Neurons isolated within the upper magnocellular A/Al layer had smaller receptive fields than those within the parvocellular C layer.

Unliateral injections of HRP were made into the DLGn of two experimental cats--enucleated E-45 and E-51--to determine whether the decusation of ganglion cell axons conformed to the normal pattern. There appeared to be no significant difference in the origins of crossed and uncrossed retinal projections to the DLGn in the one-eyed cats.

The results demonstrate that the anomalous retinal influx to the DLGn is functional, and that the topography of the aberrant projection, as shown both anatomically and physiologically, is congruent with that of the normal retinal projection.

206.8 RETINO-THALAMIC PROJECTIONS IN THE RABBIT FOLLOWING NEONATAL MONOCULAR ENUCLEATION. A. M. Grigonis\*, E. H. Murphy and H. E. Pearson. (SPON: L. Botticelli). Dept. Anatomy, The Med. Coll. of Pennsylvania, Philadelphia, PA 19129.

Tearson. Control of the rabbit optic tract is distributed to 3 Pennsylvania, Philadelphia, PA 19129. The projection of the rabbit optic tract is distributed to 3 divisions of the lateral geniculate complex of the thalamus: the dorsal lateral geniculate nucleus (LGNd), the ventral lateral geniculate nucleus (LGNv), and the intergeniculate leaflet (IGL). All three receive a large crossed and small (10%) uncrossed input from the retinae. Monocular enucleation on the day of birth was performed in order to determine the organization of the remaining visual input to these thalamic targets. Tritiated proline and leucine were injected into the remaining eye after survival  $\geq 70$ days, and planimetric measurements were made to assess the size of the labeled terminal regions in both normal and enucleated animals.

The normal ipsilateral projection to LGNd consists of a band of label at the medial edge of the nucleus. In addition, there is a distinct reduction of label density in this medial region of the LGNd contralateral to the injected eye. In rabbits with one eye removed at birth, the ipsilateral projection from the surviving eye appears normal, despite shrinkage of the nucleus. The contralateral projection from the remaining eye, however, does not appear normal. The area of reduced label density in the ipsilateral projection from the intact eye had invaded this area. In contrast to the LGNd in which the contralateral projection was changed but the ipsilateral projection from the remaining eye. The ipsilateral projection from the sincreased in size in enucleated rabbits compared with normals, although no changes were observed in the LGNv or IGL contralateral to the intact eye.

The mechanisms responsible for changes in the nucleus either ipsilateral or contralateral to the remaining eye could include an expansion of an existing projection or a failure of retraction of an 'exuberant' projection, or both. The results suggest that following partial deafferentation of a target nucleus which normally receives bilateral innervation, different factors may determine whether the ipsilateral or contralateral projection is altered for different thalamic nuclei.

TRANSNEURONAL DEGENERATION OF BETA GANGLION CELLS IN CAT RETINA. 206.9 B. R. Payne, H. E. Pearson and P. Cornwell.\* Dept. of Anatomy, The Med. Coll. of Pennsylvania, Phila., PA 19129; Dept. Psychol. Pennsylvania State Univ., Univ. Park, PA 16802. Following neonatal visual cortex ablation in the cat, there is rapid retrograde degeneration of cells in the dorsal lateral geniculate nucleus (dLGN). Removal of this principal target

nucleus produces transneuronal retrograde degeneration of retinal anglion cells, in particular cells with medium-sized somata (Pearson <u>et al</u>. '81). In order to determine whether this trans-neuronal degeneration is restricted to a particular morphological class of retinal ganglion cells, we used the technique of retro-grade labeling of ganglion cells following injection of horse-radish peroxidase (HRP) into the dLCN. This allowed us to study ganglion cells which we knew projected to the remaining dLGN and also to classify the cells into  $\alpha,\ \beta$  and  $\gamma$  types on the basis of soma size and dendritic morphology.

Kittens received bilateral ablation of visual cortex at 5 days of age. The ablation involved principally areas 17 and 18, with some involvement of area 19. Following a survival time of 34-48 months, multiple injections of HRP were made in both dLCNs of these cats, and also of a group of normal adult cats. Whole mounts of the retinae were made following reaction with benzidine dihydrochloride and hydrogen peroxide. In all cats, HRP injections into both dLGNs results in labeling throughout the retina of ganglion cell bodies and much of their dendritic arbors. We selec-ted a 1200x1200µm<sup>2</sup> sample area in nasal retina centered at a distance of 9mm from area centralis. Ganglion cells were classified as  $\alpha$ ,  $\beta$  or  $\gamma$  types on the basis of dendritic morphology. In noras  $\alpha$ ,  $\beta$  of  $\gamma$  types on the basis of denarratic morphology. In normal cats,  $\alpha$  cells comprised 8-10% of the total population in the sample area,  $\beta$  cells comprised 64-67% and  $\gamma$  cells comprised 23-27%. In the retinae of visual cortex-ablated cats, there were normal numbers of  $\alpha$  and  $\gamma$  cells present, but the  $\beta$  cell population was severely depleted by 90% of the normal number.

Therefore, morphological analysis and density determination of cat retinal ganglion cells show that, in peripheral retina, neonatal visual cortex ablation spares  $\alpha$  and  $\gamma$  cells but results in almost complete loss of  $\beta$  cells. Survival of some ganglion cell populations and the death of others may be explained in terms of the pattern of projections of the different cell types. We conclude that  $\beta$  cells degenerate following visual cortex ablation because of removal of their sole target cells in the dLGN, whereas  $\alpha$  and  $\beta$  cells survive because they have collateral projections to other targets.

206.10 RELATIONSHIP OF LATERAL GENICULATE NEURON MIGRATION TO STAGES

RELATIONSHIP OF LATERAL GENERAL REMAINS IN AVAILABLE OF STATES OF OPTIC TRACT GROWTH IN THE HAMSTER. S. <u>Jhaverity M. Edwards</u> <u>& G.E. Schneider</u>. Research Lab of Electronics and Psychology Department, Mass. Inst. of Technology, Cambridge, MA 02139. As a prerequisite to understanding the critical cellular events involved in the establishment of CNS connectivity, precise information on the relative timing of arrival of afferent axons and their target cells in a given structure is necessary. We are gathering such information in Syrian hamsters, focussing on the lateral geniculate nucleus and its afferents from the eye. The of optic-tract development has been determined with the sequence aid of HRP transport, and Golgi and Cajal-DeCastro methods (Jhaveri et al., Anat. Rec., <u>205</u>: 225A,'83): ganglion cell axons emerge from the eyeball and traverse the optic stalk on embryonic day 11 (E11; mating=E0), cross at the chiasm and course over the surface of the dorsal thalamus (E13) and reach the caudal end of the SC (E13.5). During this period, axons grow rapidly (60-80  $\mu m/hr),$  are fasciculated and unbranched -- characteristics of an elongation mode of growth. It is only after another 2 days at E15.5-P0 (PO=day of birth) that at least some of the axons begin second mode of growth -- the arborization mode -- in which individual retinofugal axons extend multiple collateral branches among their target cells. These collaterals are non-fasciculated

and have a slower apparent growth rate. Neurons of the hamster's LGd become postmitotic from E10.5 to E12.5 (Crossland & Uchwat, Dev.Brain Res., 5: 99, '82). In order to study the migration of LGd neurons we labelled hamster embryos with  ${}^{3}\text{H}$ -thymidine at ages varying from ElO to El3.5, and pro-cessed the brains for autoradiography following survival times of  ${}^{1}_{2}$  to 4 days. Cells heavily labelled by injections on El0.5 to El1 migrate away from the ventricular zone, and some have reached the dorsal thalamic surface by El2.5, at which time a presumptive LGd nuclear mass can be identified lateral to a primitive external medullary lamina. Thus, the pioneering retinofugal axons grow past the earliest-born LGd neurons in their course over the dorsal thalamic surface on El3. Many neurons labelled on El1.5 (peak of LGd histogenesis) accumulate in the immature LGd from El3.5 to El4, mixing with cells generated earlier. The optic tract increases in thickness during this period but extensive invasion of the LGd by collaterals of retinofugal axons does not begin until El5.5, when most, if not all, LGd neurons are already in their final target positions.

Since the LGd neurons are present prior to the onset of the 2nd axonal growth stage, a hypothesis worth considering is that of their maturation provides the stimulus for the some aspect onset of collateral growth and arborization by optic afferents. Support: NIH grants 5R01-EY00126 & 5P30-EY02621 & Ortho Labs.

206.11 EARLY DEVELOPMENT OF RETINAL SPECIALIZATION: THE DISTRIBUTION AND DECUSSATION PATTERNS OF GANGLION CELLS IN THE PRENATAL CAT DEMONSTRATED BY RETROGRADE PEROXIDASE LABELING. B. Lia, R. W. Williams, and L. M. Chalupa Department of Psychology and The Physiology Graduate Group, University of California, Davis, CA. 95616

In cat, as in most other mammals, the adult retina shows features of regional specialization, including a high cell density area centralis region and a sharp decussation pattern. In the present study we sought to determine whether these characteristics of retinal topography are evident during fetal development or whether they arise subsequent to axon-target interactions and differential cell death.

Interactions and ditterential cell death. Horseradish peroxidase (HRP) was injected into the major retino-recipient regions of the fetal brain in order to differentiate unequivocally ganglion cells with centrally projecting axons from other profiles within the immature ganglion cell layer. Bilateral injections were made into the thalamus and midbrain on embryonic days E-34, 37, 41, 44, 49, and 56 (gestation: 65 days). In additional cases unliateral injections of HRP were made into the thalamus. Following a 12-24 hour survival the fetuses were removed and perfused with EM grade fixative. Retinae were dissected and reacted with the chromagen phenylenediamine. To minimize shrinkage the retinae were not counterstained. Labeled and unlabeled cells could be readily distinguished in wholemounts using Nomarski interference contrast optics with a 100x oil immersion objective.

In the youngest retinae, at E-34, a primordial area centralis was already apparent: within this region the density of labeled cells is 38,000/mm<sup>2</sup> while in peripheral regions the packing density fails to 17,500 mm<sup>2</sup>. In addition to packing density, central and peripheral regions of the retinae differ strikingly in morphology, even in the E-34 retinae. Peripheral neurons typically had elongated cell bodies and prominent dendrites, whereas those in the central region were round with few labeled dendrites. By E-56 a number of large ganglion cells, presumably the a-cell precursors, could be easily distinguished.

The distribution of labeled ganglion cells following a unliateral injection into an E-44 fetus was similar to that san after comparable injections in adults. The ipsliateral nasan hemiretina was devoid of labeled cells, and the demarcation between labeled and unlabeled hemiretinae was sharp.

The majority of ganglion cells are generated by about E-32 (Kliot & Shatz, 1982; Walsh et al., 1983) and our findings indicate that shortly thereafter an incipient retinal specialization is already apparent. At this stage ganglion cell axons have just reached the major retino-recipient targets (Williams & Chalupa, 1982; Shatz, 1983). While axon-target interactions may well play a role in sculpting out the mature pattern of retinal topography, our findings indicate that the basic features of retinal specialization are organized very early in development. basic features of in development.

## 206.12 PHYSIOLOGICAL DEVELOPMENT OF SECOND ORDER NEURONS AND THEIR CONNECTIONS IN THE RETINA OF KITTENS. D.I. <u>Hemasaki</u>\*, <u>Gregory W. Maguire, Janie Rudolph and Gail S. Tucker</u> (SPON: S.H. Gruber). Bascom Palmer Eye Institute, Univ. Miami, FL.

Earlier studies have shown that the anatomical and physiological properties of the photoreceptors of kittens are adult-like by 3 weeks of age. For this study, the bewave and oscillatory potentials of the ERG were used to follow the development of the potentials of the ERG were used to follow the development of the second order neurons and their connections in the IPL. At 3 weeks of age, the threshold and amplitude of the b-waves were significantly different from that of adult cats. The b-waves were smooth with no signs of oscillatory potentials. There was a rapid increase in the sensitivity and in the amplitude of the b-wave during the next several weeks. The oscillatory potentials were first observed during this period but they were is incluse the amplitude and the thet of adults. Pu 728 significantly smaller and slower than that of adults. By 7-8 weeks, the amplitude of the b-wave was comparable to that of the adult but the threshold was still elevated. The oscillatory potentials at this age were still smaller and slower than those of the adult. Experiments are continuing to determine when the oscillatory potentials are completely adult-like.

In dark-reared kittens, the threshold and amplitude of the b-waves were not affected but the oscillatory potentials appeared smaller and slower than those of light-reared kittens of comparable age.

These results show that the b-wave and oscillatory potentials of the ERG not only have different origins but also that their course of development is different. In addition, these findings demonstrate that kittens enter and pass through the critical developmental period with a physiologically immature retina.

NEONATAL CANNABINOID EXPOSURE AFFECTS BIOGENIC AMINES 207.1 AND PITUITARY FUNCTION IN ADULT MICE. <u>S. Dalterio\*, R.</u>. <u>Steger\* and D. Mayfield\*</u> (SPON: N. Hagino). Departs. Pharm. & Ob/Gyn., Univ. Tex. Hith. Sci. Ctr., San Antonio, TX 78284. Ob/Gyn., Univ. Tex. Hith. Sci. Ctr., San Antonio, TX 7824. In previous experiments we have demonstrated that maternal ex-posure to either the major psychoactive component of marihuana,  $\Delta^{9}$ -tetrahydrocannabinol (THC), or the relatively non-psychoactive cannabinol (CBN), or cannabidol (CBD) during late pregnancy resulted in long-term alterations in biogenic amines and endocrine resulted in long-term alterations in biogenic amines and endocrine functions. The present experiments examined the effects of post-natal cannabinoid exposure on later neuroendocrine function. Postcastration, the turnover of norepinephrine (NE) in hypotha-lamus (H) after  $\alpha$ -methylparatyrosine ( $\alpha$ -MPT) was significantly less in THC- and CBN-exposed males, 18% and 14%, respectively, compared to 27% in controls. In contrast, dopamine (DA) turnover in brain of THC- and CBN-exposed males was increased 24% and 18%, compared to 6% in controls, while, in CBN-exposed castrates, HDA levels were lower than control [997  $\pm$  96 (8) vs 1652  $\pm$  196 (8) ng/a). Turnover of HDA in CBD-exposed castrates was increased 24%. HDA levels were lower than control [99/1 96 (8) VS 1652 195 (8) ng/2]. Turnover of HDA in CBD-exposed castrates was in-creased 45% vs 15% in controls. Postnatal THC exposure signifi-cantly increased brain 5-HT [1212 ±101 (7) vs 851 ± 117 (6) ng/2] and 5-HIAA [423 ± 455 (7) vs 251 ± 28 (6) ng/2] post-castration. Ovariectomized female mice postnatally-exposed to cannabinoids also explicited alterations in biogenic prices. D CBN exposed for

Ovariectomized remain mice postnatally-exposed to cannability also exhibited alterations in biogenic amines. In CBN-exposed fe-males, HNE levels were reduced [2286 ± 194 vs 3430 ± 366 ng/g]. The % reduction after  $\alpha$ -MPT for HNE levels was lower [12% vs 37%] in CBD-exposed, as it was for brain NE [0% vs 32%] in the THC-exposed females. In contrast, THC and CBD-exposed females showed a greater reduction, 18% and 16%, in brain DA levels com-pared to 2% in controls.

Postnatal cannabinoid exposure reduced plasma LH levels in both intact and castrated animals, while intact FSH levels were reduced only in THC-exposed males [ $987 \pm 33$  (I6) vs I22I  $\pm 47$  (I5) ng/ml]. Administration of  $\alpha$ -MPT did not influence plasma hormone levels in male castrates, but ovariectomized females postnatally-exposed to cannabinoids had lower levels of LH and FSH after  $\alpha$ -MPT. to cannabinoids had lower levels of LH and FSH after unit . Pituitary weights were significantly increased in males postnat-ally-exposed to THC and CBN, and in vitro pituitary LH produc-tion was also significanly increased [ $3383 \pm 298$  (9) in THC, and 4030  $\pm$  1036 (6) in CBN] compared to 1956  $\pm$  339 (5) ng/mg/hr in controls. Pituitaries from cannabinoid-exposed males were less responsive to in vitro stimulation by LHRH, with increases in LH production of 195% in THC, 218% in CBN, and 247% in CBD, com-

pared to 425% in controls. The present findings indicate that postnatal exposure to cannabinoids, whether psychoactive or non-psychoactive, alters biogenic amines and pituitary function in adulthood.

207.2 CHANGES IN ANTERIOR PITUITARY HORMONE SECRETION AND HYPOTHALAMIC CATECHOLAMINE METABOLISM DURING MORPHINE WITHDRAWAL IN THE RAT. S.M. Gabriel<sup>\*</sup>, J.W. Simpkins<sup>\*</sup> and W.J. Millard (Spon: A.J. Dunn) University of Florida, Gainesville, Florida, 32610 and Harvard Medical School, Boston, Massachusetts, 02114.

Studies were undertaken to simultaneously assess changes in an-erior pituitary hormone secretion and hypothalamic catecholamine (CA) metabolism during naloxone (NAL) precipitated withdrawal in morphine (MOR) dependent female rats. MOR dependency was induced by multiple s.c. implantation of pellets containing 75 mg MOR freebase. Rats were ovariectomized and immediately received 1 MOR pellet followed by 2 additional pellets 2 days later. After 4days of morphine exposure, rats received NAL (1 mg/kg, s.c.) and were sacrificed 0, 5, 15, 30 and 60 min later. Trunk blood was collected for serum hormone analysis by RIA and the medial basal hypothalamus (MBH) and preoptic area (POA) were isolated for later determining of CMLa be provided in a retrained and the medial basal determination of CA's by amperiometric methods. Concentrations of norepinephrine (NE), normetanephrine (NME), dopamine (DA), dihydroxyphenylacetic acid (DOPAC), and homovanillic acid (HVA) Within 5 min after NAL injection to MOR-dependent rats, serum

luteinizing hormone levels were increased 8-fold and remained moderately elevated through 60 min. Serum  $\beta$ -endorphin-like-immunoreactivity increased 6- to 8-fold from 5 to 60 min after NAL administration, while serum prolactin levels were increased sig-nificantly only at 15 min. In contrast, both growth hormone (GH) and thyroid-stimulating hormone (TSH) secretion decreased during MOR withdrawal. GH levels were significantly decreased by 15 min and were undetectable (<2.5 ng/ml) by 60 min after NAL. Serum TSH

levels fell progressively from 5 to 60 min after NAL treatment. In both the MBH and POA, NME concentrations were increased by 166 to 237% within 15 min of NAL administration and remained elevated through 60 min. This increase in NME levels was followed at 30 and 60 min by a 25 to 40% reduction in NE concentration in both SU and CO min by a 25 to 40% reduction in NE concentration in both tissues. Thus, a marked increase in NE turnover appears to accom-pany precipitated MOR withdrawal. In the MBH concentrations of HVA and the ratio of HVA to DA increased significantly by 5 min and remained elevated through 60 min after NAL administration while no alteration in HVA levels were observed in the FOA at any of the sampling times. In contrast in both MBH and POA, DOPAC levels were significantly elevated at 30 and 60 min and these increases were coincident with significant increases in DA concentrations. Thus, while DA metabolism is enhanced during MOR with-drawal, this does not appear to represent increased release of DA from nerve terminals. These alterations in CA metabolism and hormone secretion may mediate, in part, the dramatic alterations in physiological processes associated with MOR withdrawal. (Supported in part by NIH AGO2021 to JWS).

207 3

EPINEPHRINE, 5-HYDROXYTRYPTAMINE, 5-HYDROXYINDOLE-3-ACETIC ACID AND DOPAMINE IN HYPOPHYSIAL PORTAL AND PERIPHERAL PLASMA OF INTACT AND ADRENALECTOMIZED RATS. C.A. Johnston, D.M. Gibbs<sup>a</sup> and A. Negro-Vilar. Dept. of Physiology, Univ of Texas Health Science Center, Dallas, Texas 75235; and <sup>a</sup>Department of Reproductive Medicine, School of Medicine (T-002), University of California, San Diego, La Jolla, California 92093. Hypophysial portal blood was collected from urethane anesthetized male rats by stalk cannulation (Porter method) or by periodic aspiration of portal blood (Worthington and Fink method). Portal and peripheral plasma epinephrine (EPI), 5-hydroxytrypta-mine (5-HT), dopamine (DA) and 5-hydroxyindole-3-acetic acid (S-HLAA) were concurrently measured using high performance liquid chromatography with electrochemical detection (LCEC). Hypophysial portal plasma samples consistently demonstrated chromatography with electrochemical detection (LCE). Hypophysial portal plasma samples consistently demonstrated significantly higher concentrations of EPI, 5-HIAA and DA but not of 5-HT independent of the collection method. Adrenalectomy (ADX) abolished peripheral plasma EPI whereas hypophysial portal plasma EPI was only slightly attenuated. The presence of EPI in hypophysial portal plasma following ADX strongly suggests that a significant fraction of the amine is derived from a central (neural) source and that the amine may have a direct physiological role in the regulation of anterior pituitary function. ADX did not alter the concentrations of 5-HT, 5-HIAA function. ADX did not alter the concentrations of 5-HT, 5-HTAA or DA in either hypophysial portal or peripheral samples. Although 5-HT concentrations in both portal and peripheral plasma were not different, 5-HTAA levels were 3-fold higher in portal plasma. The high concentration of 5-HTAA in portal plasma was not due to conversion of 5-HT to 5-HTAA by monoamine oxidase in plasma. Although the possible physiological significance of this finding, if any, is yet to be determined, the possibility that a compound thought of as an end product metabolite in the CNS may have a role in the function of another tissue must be considered. As previously reported, DA was 10-15 fold higher in portal plasma. These data demonstrate for the first time a concentration gradient for EPI (derived from a central source) and 5-HTAA in hypophysial portal versus peripheral plasma. 5-HIAA in hypophysial portal versus peripheral plasma. hermore, they demonstrate the utility of LCEC for the and and S-HIAA in hypophysial portal versus peripheral plasma. Furthermore, they demonstrate the utility of LCEC for the concurrent determination of several monomines and metabolites in hypophysial portal plasma. Finally, they suggest that the portal aspiration method may be particularly well-suited for measuring potentially labile substances because appropriate preservatives/ enzyme inhibitors can be added to the samples within seconds. SEROTONERGIC MODULATION OF CORTICOTROPIN RELEASING FACTOR AND VASOPRESSIN SECRETION INTO HYPOPHYSIAL PORTAL BLOOD. D.M. Gi 207.4 and W. Vale. Dept. Repro. Med., UCSD, La Jolla, CA 92093 and The Salk Institute, La Jolla, CA 92138.

Among the several hypothalamic hormones which can stimulate Among the several hypothalamic hormones which can stimulate ACTH secretion in vitro, the recently described 41 amino acid corticotropin releasing factor (CRF) and arginine vasopressin (AVP) are both thought to be involved in the physiological regula-tion of ACTH secretion, but their exact roles are unknown. Since central serotonin pathways appear to be involved in the release of ACTH, we studied the effect of fluoxetine, a serotonin reuptake inhibitor, on the release of CRF and AVP into hypo-physial portal blood as well as the release of ACTH and AVP into the peripheral circulation. To define the effects of fluoxetine on nituitary serverion of ACTH and AVP, pentobarbital anestheon pituitary secretion of ACTH and AVP, pentobarbital anestheon pituitary secretion of ACTH and AVP, pentobarbital anesthe-tized male rats with atrial cannulae were injected ip with fluoxetine 10 mg/kg or saline and blood samples were obtained at 20, 40, 60 and 80 minutes. ACTH levels in fluoxetine treated rats rose from a basal value of  $121.7 \pm 38.5$  pg/ml to a peak value of 20 min of  $1192 \pm 180$  pg/ml. AVP levels continued to rise throughout the 80 min collection period from a baseline of  $22.8 \pm 1.8$  pg/ml to  $93.0 \pm 15.3$  pg/ml at 20 min to  $136 \pm 33.2$ pg/ml at 80 min. Neither ACTH nor AVP concentrations changed significantly in rats injected with saline. In a separate ex-periment, hypophysial portal blood was collected for 30 min from significantly in rats injected with saline. In a separate experiment, hypophysial portal blood was collected for 30 min from 7 pentobarbital anesthetized rats injected with fluoxetine 10 mg/kg ip and 7 rats injected with saline. CRF levels in portal plasma from fluoxetine treated rats were  $1.37 \pm 0.09$  ng/ml vs  $0.85 \pm 0.10$  ng/ml in controls (p < 0.01). AVP levels in portal plasma from fluoxetine treated rats were  $1.54 \pm 0.16$  ng/ml vs  $1.03 \pm 0.16$  ng/ml in controls (p < 0.05). These concentrations of CRF and AVP in portal plasma are in the range which can stimulate ACTH secretion in  $\frac{vitro}{vs}$ . The data suggest that modulation of ACTH secretion into hypophysial portal blood. Supported in part by NIH grant HD 13527 and a grant from the Mellon Foundation.

207.5 SEROTONIN-CONTAINING CELLS AND FIBERS IN THE PITUITARY OF AN ELASMOBRANCH FISH. R.B. Leonard, T.C. Ritchie, M.G. Hughes\* and D.J. McAdoo. Departments of the Marine Biomedical Institute, Physiology and Biophysics and Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, Texas. Serotonin (5-HT) has been implicated in influencing endocrine

Serotonin (5-HT) has been implicated in influencing endorrine functions, including the release of several pituitary hormones. However, it has proved difficult to determine the site(s) of 5-HT's action in the brain-pituitary axis. Despite reports of significant quantities of 5-HT in the pituitaries of several vertebrates, histological demonstration of the cellular localization of pituitary 5-HT has been elusive. Recently, 5-HT fibers and cells have been reported in the pituitaries of frogs and rats with immunocytochemistry although other reports have been negative.

5-HT was localized in the pituitary of the Atlantic stingray, <u>Dasyatis sabina</u>, with immunocytochemistry using the PAP method. Preabsorption controls indicated high specificity for 5-HT. There was no cross-reactivity to bovine serum albumin, or norepinephrine while dopamine, 5-methoxytryptamine and tryptamine caused some reduction in staining intensity.

Caused some reduction in staining intensity. Cells and fibers exhibiting 5-HT-like immunoreactivity were observed in the stingray pituitary without any seasonal variation. The elasmobranch pituitary is an elongated structure, consisting of a large caudally placed neuro-intermediate lobe (NIL) and a rostrally placed pars distalis with rostral (RPD) and proximal (PPD) subdivisions. The ventral lobe, a subdivision of the PPD peculiar to elasmobranchs, was not included in this study. The 5-HT cells are located ventromedially in the PPD. They were oval ( $6x12 \ \mu m$ ) or round (8  $\mu m$ ) or occasionally polygonal in shape. Short processes were often evident, which occasionally appeared to end on a blood vessel. Thin varicose fibers traversed the median eminence and infundibular stalk to reach and ramify in the NIL. Patches of fibers were variously located surrounding blood vessels or intermedia cell cords. In preliminary HPLC measurements we have detected 5-HT in the PPD and the NIL.

Both the immunocytochemistry and the HPLC results indicate that the stained cells contain 5-HT. However, it is possible that the cells take up 5-HT from blood or CSF, instead of synthesizing it. The demonstration of 5-HT cells and fibers in the stingray pituitary suggests that this situation arose early in phylogeny. Supported by NIH grants NS07185, NS11255 and NS16093. 207.6 LOCALIZATION OF MONOAMINE OXIDASE-B IMMUNOREACTIVITY IN THE NEO-NATE AND ADULT RAT PITUITARY GLAND. <u>V. Cooperš J. E. Pintar and P. Levitt</u> (SPON: T. J. Cunningham). Div. Endorcinology, Mt. Sinai Sch. of Med., New York, NY 10029 and Dept. Anatomy, The Med. Coll. of Pennsylvania, Philadelphia, PA 19129. Monoamine oxidase (E.C. 1.4.3.4) is the primary enzyme in-

Monoamine oxidase (E.C. 1.4.3.4) is the primary enzyme involved in the degradation of biogenic amines such as norepinephrine, dopamine, and serotonin. These and other amines function as primary regulators of specific pituitary cells. One way in which levels of these amines can be regulated is by the action of degradative enzymes such as MAO. Two kinds of MAO activity (MAO-A and MAO-B) have previously been characterized by pharmacological criteria and are mediated by structurally different proteins. We have produced multiple antisera to purified MAO-B that do not cross-react with MAO-A and have previously used these antisera to localize MAO-B immunoreactivity in astrocytes and serotonergic neurons of the adult rat brain (Levitt <u>et al</u>. PNAS 79:6385). We have here used these antisera to localize MAO-B immunoreactivity in the neonate and adult rat pituitary gland and have made the following observations. First, MAO-B immunoreactivity is found in the major cell class of the posterior lobe, the pituicytes. This is consistent with other recent observations that these cells express many astrocyte-like properties and indicates that these cells may inactivate transmitters that are released from hypothalamic nerve endings in the posterior lobe. Second, MAO-B immunoreactivity is found in a boundary layer of cells between the anterior and intermediate lobes; this is the first biochemical characteristic expressed in these previously morphologically defined cells and indicates that they may insulate one lobe from hypotologic effectors in the adjacent lobe. Third, about 15% of anterior lobe cells exhibited MAO-B immunoreactivity; we are currently determining whether MAO-B cells correspond to specific peptide-containing cell types. Finally, initial experiments with l4-day neonates have demonstrated a different pattern of MAO-B localization with many anterior lobe cells and fewer pituicytes stained. Together, these results suggest that MAO activity may contribute to regulation of pituitary function.

6-HYDROXYDOPAMINE-INDUCED ALTERATIONS IN NEURITES OF THE PITUITARY PARS INTERMEDIA. L.C. Saland and E. Ortiz\*. Department of Anatomy, University of New Mexico School of Medicine, Albuquerque, New Mexico 87131.

Pro-opiomelanocortin cells of the rat pituitary pars intermedia receive direct synaptic connections from the hypothalamus. Neurites have been demonstrated to contain catecholamines by fluorescent histochemistry and may be a source of inhibitory neuroregulation for the secretory cells. Previous studies introducing 6-hydroxydopamine (6-OHDA) intravenously have led to variable effects on catecholamine innervation to intermediate lobe. Here, we demonstrate ultrastructural evidence for degenerative changes in neurites after peripheral 6-OHDA injections. Adult male Sprague-Dawley rats received two intravenous injections (150mg/kg) 6-OHDA in ascorbic acid and saline on consecutive days. Controls received vehicle only. At times ranging from 24 hours to one week after injections animals were ether anesthetized and perfused intracardially with buffered aldehydes. Pituitary glands were prepared for transmission EM. Micrographs of glands from 6-OHDA-treated rats revealed swollen neurites containing myelin figures as well as some normal-appearing neurovesicles. Endocrine cells exhibited extensive, granule containing folgi zones and areas of expanded rough endoplasmic reticulum. Injection of the false transmitter 5-hydroxydopamine to several animals revealed electron-dense "dots" in neurovesicles, confirming uptake ability for the terminals. Results with peripheral 6-OHDA injections suggest that the neuroxing ains access to pituitary neurites to cause degenerative changes. The drug also appears to induce a cellular activation or "disinhibition" indicative of peptide release and new synthesis. Supported in part by DA-02269 and RR-08139. 207.8 VASOPRESSIN AND NORADRENERGIC NEURONS IN DISPERSED HYPOTHALAMIC AND BRAIN STEM CULTURES. C.D. Sladek, M. Gallagher\*, M.F.D. Notter, G. Hoffman, and J.R. Sladek, Jr. Depts. Neurol. and Anatomy, Univ. Rochester Med. School, Rochester, N.Y. 14642.

<sup>16622.</sup> We have developed a protocol for preparing and maintaining monolayers of dispersed fetal or neonatal brain cells which is compatible for maintenance of the vasopressin (VP) neurons of the supraoptic nucleus (SON) and brainstem catecholamine neurons (A1). To prepare the cultures, the appropriate fragments of brain tissue are dissected and dispersed by trituration following a 10 min incubation with 0.1% trypsin. Whole cells are pelleted by centrifugation and subsequently resuspended in culture medium (Eagles minimum essential medium fortified with 10% fetal calf serum, 0.1% glutamine, 0.6% glucose, 100 uU/ml penicillin, 100 ug/ml streptomycin, and 2.5 ug/ml fungizone). Cells are plated onto poly-D-lysine coated culture slides or cover slips. The hypothalamic region dissociated is the area surrounding the optic chiasm which includes the SON. With approx. 10<sup>6</sup> cells plated/35 mm dish, we routinely detect VP in the culture medium during the 1st 72 hours. When fetal donors are used (19 or 20 days post-coiturs of pc) VP commonly is then undetectable in the culture medium during the next 10-20 days. However, in three different preparations VP reached detectable levels after 1.5 to 2.5 weeks of culture. This correlates with the developmental sequence in the VP neuron in vivo in which VP and neurophysin content of the SON neurons increases progressively from 17 dpc to 21 dpn. Following fixation with acrolein , VP, neurophysin (NP), and oxytocin (OX) positive cells were visualized in the hypothalamic cultures by immunocytochemistry. In one preparation of fetal neurons examined after 3 weeks in culture, there were 90  $\pm$  4 VP positive cells were large bipolar neurons.

In dispersed cultures from the ventrolateral medulla which includes the AI neurons, neurons were identified by the presence of neuron specific enolase (NSE) immunoreactivity and the noradrenergic phenotype was identified by the presence of glyoxylic acid induced catecholamine fluorescence or the presence of dopamine- $\beta$ -hydroxylase (DBH) immunoreactivity (antiserum by S. Watson). The A1 neurons were complex multipolar cells with shapes characteristic of reticular formation neurons. In one preparation the DBH positive cells represented 47% of the population of NSE positive neurons. The ability to maintain VP and NE neurons under the same culture conditions under thest and culture these neurons.

The ability to maintain VP and NE neurons under the same culture conditions suggests that we will be able to co-culture these neurons. This would provide the opportunity to study the regulation of the VP neuron by the NE neurons which innervate them in vivo. Supported by NIH grant R01-AM-19761.
LACK OF EVIDENCE FOR AUTOINHIBITION OF VASOPRESSIN (VP) RELEASE 207.9 IN VIVO AND IN VITRO. <u>Christine M. Gregg</u>\* (Spon: E. Hibbard) Dept. of Biology, Penn. State Univ., Univ. Park, PA 16802. Many authors have reported recurrent inhibition of vasopres E. Hibbard). sinergic neurons, but the neurotransmitter involved is not known. Nicoll and Barker (Brain Res. 35:501, 1971) proposed VP itself may play some role since application of VP to supraoptic neurons was followed by electrical inhibition. Both <u>in vivo</u> and in vitro studies have been used to test this hypothesis.

For the in vivo study Alzet minipumps were used to infuse either artificial CSF or VP (0.25 to 50 ng/hr) into lateral ventricles of male SD rats (266±24g, n=36). Metabolic data were collected both before (7 days) and during (10 days) central infusion. Water and food intake, urine volume and osmolality, and fractional water, Na, and K excretion were measured. Comparison of pre and post infusion data provided no evidence that central VP infusion inhibited VP release. In fact, at infusion rates of 2.5 ng/hr and above, urine volume decreased, osmolality increased, and there was net water retention. 24 hours of dehydration + CSF VP infusion also failed to blunt the expected rise in plasma VP concentration. At the highest the expected rise in plasma VP concentration. At the highest infusion rate (50 ng/hr) plasma VP was elevated 10-fold compared to controls (>130 pg/ml vs. 13±3 pg/ml). These data indicated that VP was probably leaking from CSF into plasma. To circumvent this problem hypothalamus (HT) and neural lobe (PP) were organ-cultured in separate compartments. The intact

infundibular stalk passed through a hole in the fluid-tight barrier which separated the 2 sides (Neurosc. Abs. 8:65, 1982) PP VP release was measured during a control and test hour and  $\frac{r_F}{dat}$  expressed as % of control. During the test HT VP concentration was increased to 40 ng/ml alone or in combination with an osmotic stimulus of +15 mOSm. Since a leak of 1% or less cannot be detected, VP alone was used as the control for VP+  $\uparrow$ OSm.  $\Delta$  = (VP+ $\uparrow$ OSm)-(VP alone).

Stimulus:	none	VP	VP+	Δ	↑Osm
		alone	†Osm		alone
PP VP Release	93±9	177±23 <sup>a</sup>	487±114 <sup>a</sup>	311±123 <sup>a</sup> ,b	236±56 <sup>a</sup>
% of control	(13)	(9)	(9)	(9)	(10)

p<0.05: control hour vs. test hour, paired t-test; n.s. compared to †Osm alone, ANOVA.

These data provide no support for the hypothesis that VP inhibits its own release. The increase when VP alone was added is most likely due to a small leak in the barrier (<1%/hr). Supported by NINCDS 17300, McNeil Pharmaceutical and PSU RIG.

(HNMT), the major Hm inactivating enzyme in brain, have been found in the hypothalamus and posterior pituitary. Current evidence indicates that Hm may regulate the secretion of vasopressin (AVP) not only in the hypothalamus, but also in the neurohypophysis since Hm levels in this lobe are selectively decreased in AVP de-Since nm levels in this loop are selectively decreased in AV de-ficient Brattleboro rats (Soc. Neurosci. Abstr. 8:55). To investi-gate this possibility, we evaluated the effect of 1) chronic oral saline administration or 2) stalk sectioning on Hm, HNMT and AVP levels in the rat posterior pituitary. Both Hm and HNMT were assayed by recently developed radiometric methods that have im-proved constitutive and encodified by (Bod Proc 41, 1709, Frd proved sensitivity and specificity (Fed. Proc. 41, 1709; Fed. Proc. 42, 907). AVP was quantified by radioimmunoassay.

## POSTERIOR PITUITARY

2% Hype	rtonic	Hm	HNMI		AVP			
saline	(days)	(ng/mg prot	ein) (units*/mg	protein) (1	ig/mg pro	otein)		
	0	18.8 + 2.	7 0.175 + .	.02 1	14.5 +	0.9		
	2	12.9 + 1.9	9a 0.235 + .	.02b	4.86 +	1.3 <sup>c</sup>		
	5	15.7 + 1.3	3 0.229 + .	.03b	0.612 +	0.22 <sup>c</sup>

*unit =	nmoles	of T methylhistamine formed/hr						

Following hypertonic saline administration, AVP and Hm levels in the posterior pituitary decreased while HNMT activity creased thusly suggesting an increase in Hm turnover. No changes were observed in adenohypophyseal Hm or HNMT.

Were observed in ademonypophyseal tim of indif. Im levels increased 100% in chronic stalk-sectioned rats ver-sus sham operated controls in both the posterior  $(30.1 \pm 5.07 \text{ vs.})$   $15.6 \pm 2.37 \text{ ng/mg}$  protein) and anterior  $(3.62 \pm 0.68 \text{ vs.})$   $1.85 \pm 0.13 \text{ ng/mg}$  protein) lobes. HNMT levels remained unchanged and no differences were observed in hypothalmic Hm or HNMT levels.

The current studies confirm that high levels of Hm and HNMT are present in the rat posterior pituitary. Interruption of de-scending fibers to the neurohypophysis did not decrease but instead substantially increased Hm levels. This result indicates that Hm is non-neuronal in origin and is possibly located in mast cells that may be regulated by descending input. The changes in the levels of Hm and HNMT in the posterior lobe induced by a physiological stimulus for AVP release support a possible link between the two systems.

207.10 RELEASE OF VASOPRESSIN IN VITRO FROM THE ARTERIALLY PERFUSED HYPOTHALAMO-MEUROHYPOPHYSIAL COMPLEX DURING OSMOTIC, CHOLINERGIC OR ELECTRICAL STIMULATION OF THE SUPRADPTIC NUCLEUS. R.B. Meeker\*, R.S. Greenwood and J.N. Hayward. Dept. Neurology and Neurobiology Program, Univ. North Carolina, Chapel Hill, N.C.,

27514.

A hypothalamo-neurohypophysial complex (HNC) containing the intact supraoptic nuclei, the supraoptico-hypophysial tract and neurointermediate lobe was rapidly isolated from the rat brain (Sladek & Knigge, Endocrinol. 101:1977) and placed in a plexiglas chamber support system. The internal carotid was cannulated with a glass micropipette and the HNC was perfused with medium at a rate of 1-2 ml/min (Llinas et.al., Fed. Proc. 40:1981; Bourque & Renaud, J. Neurosci. Meth. 7:1983). Perfusate was collected continuously with temporal discriminations of 1-10 min. Vasopress-Continuously with temporal discriminations of 1-10 min. Vasopress-in, measured by radioimmunoassay (Hayward et.al., Endocrinol. 98: 1976) was released at basal levels (5-15 pg/min) for up to 6-8 hrs Intracarotid infusions of hypertonic medium (20-40 m0sm/kg above controls) over 10-60 min resulted in immediate or delayed eleva-tions in vasopressin output of up to 150 pg/min. Nicotine sulfate (5 n moles/ 50 nL) was directly microinjected into the supraoptic nucleus by means of a glass micropipette (tip diam. 30-40 um) and a budenulic microfative system. Micropipette output of a production of the supraoptic nucleus by means of a glass micropipette (tip diam. 30-40 um) and nucleus by means of a glass micropipette (tip diam. 30-40 um) and a hydraulic microdrive system. Microinjections over 10 min result-ed in elevations of vasopressin output to 13-20 pg/min (200-400% of baseline). Bipolar electrical stimulation (0.5-1 mA, 0.5 msec, 15 Hz) of the supraoptic nucleus with tungsten microelectrodes resulted in immediate elevations in vasopressin output of up to 150 pg/min. These results can be compared to bipolar electrical stimulation (0.05- 0.2 mA, 0.5 msec, 15 Hz) of the pituitary otalk with ploting microwing upper broutbed in empired stalk with platinum-iridium microwires which resulted in maximal elevations of 400-600 pg/min of vasopressin output.

These results demonstrate that the arterially perfused HNC is capable of releasing vasopressin in vitro in response to intracarotid osmotic stimuli, locally microinjected chemicals and electrical stimulation of the supraoptic nucleus. The responsive-ness of the supraoptic nuclei to osmotic, cholinergic and electri-cal stimulation was apparently less than the maximal secretory capacity of the HNC as demonstrated by electrical stimulation of the stalk. We expect that this arterially perfused HNC, used previously for electrophysical studies of the supraoptic nucleus (Bourque & Renaud, Neuroendocrinology <u>36</u>:1983), will prove useful for parallel studies of the central neural regulation of vasopressin secretion by supraoptic neurons. Supported, in part, by NIH Grant NS-13411.

SUPRAOPTIC NUCLEI AND NEURAL LOBES IN RATS WITH CORONAL CUTS 207.12 SUPRADFIL NOLLEI AND NEURAL LUBES IN RAIS WITH CURUNAL CUIS CAUDAL TO THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) REGION. J. R. Carithers, S. L. Bealer and A. K. Johnson. Dept. of Veterinary Anatomy, Iowa State Univ., Ames, IA 50011, Dept. of Physiology and Biophysics, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163 and Dept. of Psychology, Univ. of Iowa, Iowa City, IA 52242. Electrolytic lesions of tissue surrounding the preoptic recess (AV2V) merian another survey loce of stimulatory input to the (AV3V) region appear to cause loss of stimulatory input to the supraoptic nuclei from angiotensin receptors and osmoreceptors. To investigate the pathways affected by these AV3V lesions, we compared the ultrastructure of supraoptic nuclei and neural lobes in ten rats which had received coronal cuts in a plane just caudal to the AV3V region with that of nine control rats which had undergone a sham procedure.

Seven days after cuts were placed, degenerating axons were present in supraoptic nuclei, and degenerating terminals occurred in axodendritic and axosomatic synapses on neurosecretory cells. However, in contrast to their appearance in rats with AV3V lesions, neuronal somas showed no decrease in size of cells or their nuclei. her indications, neuronal sumas showed no deviate the size of certains of their nuclei. The percentages of multiple and marginated nucleoli were unchanged, and cytoplasmic organelles evinced no changes indicative of depressed secretory activity. In neural lobes of rats with cuts, terminals tended to be depleted of neurosecretory granulated vesicles.

	Sham Group (%)	Cut Group (%)
empty terminals	2.2 + 2.1	12.4 + 4.0*
full terminals	62.6 + 8.8	36.1 7 8.1*
volume density of terminals	37.6 + 6.8	26.5 + 3.7*
perivascular glial processes	42.8 7.9	31.3 + 6.9*

perivascular gilal processes 42.8 ± 7.9 51.5 ± 0.9<sup>\*</sup> The percentage of terminals which contained no neurosecretory vesicles was significantly increased while the percentage of full terminals was decreased after cuts. Depletion of hormone stores from axon terminals also caused a significant decrease in the volume density of terminals in the neuropil. Furthermore, withdrawal of glial processes after cuts were placed permitted axon terminals to occupy a greater proportion of the secretory interface along the basal lamina surrounding fenestrated capillaries. These changes in the neural lobe are associated with enhancement of hormone release and are the opposite of changes seen after electrolytic AV3 lesions.

with enhancement of hormone release and are the opposite of changes seen after electrolytic AV3V lesions. The presence of degenerating axons and terminals in supraoptic nuclei indicates that afferent fibers were destroyed by the cuts. However, normal morphology of neuronal somas in supraoptic nuclei and evidence of enhanced release of hormone from neural lobes make it clear that stimulatory input remains adequate to induce a robust response. Supported in part by Farm Bill of 1977 (P.L. 14388) Section 1433 and USPHS HL-25877.

207.13 SUBFORNICAL ORGAN CONNECTIONS WITH THE HYPOTHALAMIC PARAVENTRICU-LAR NUCLEUS: AN ELECTROPHYSIOLOGICAL STUDY IN THE RAT. A.V. Ferguson & L.P. Renaud. Neurosciences Unit, Montreal General Hospi-

The subformical versity, Montreal, Quebec, Canada H3G 1A4. The subformical organ (SFO) has been implicated in the physiological control of water balance and sexual behaviour, the former possibly through an associated release of vasopressin from the posterior pituitary. In view of recent anatomical studies describing a pathway from the SFO to the paraventricular nucleus (PVN), whose projections include brainstem and spinal autonomic centres as well as the neurohypophysis, we have examined the effects of electrical stimulation in SFO on the excitability of neurosecretory and other unidentified PVN neurons. In the course of these experiments we have observed also that discrete electrical stimulation in the SFO (100-400µA, 0.1msec, 5-20Hz) produces a short latency 4-16mm Hg rise in arterial pressure, a response which may be mediated in part by the PVN.

Experiments were conducted on pentobarbital or urethane anaesthetized male Sprague-Dawley rats. Electrical stimulation (0.1 msec,0.2-0.8mA) in the SFO was delivered through 30 gauge concentric bipolar electrodes which were implanted stereotaxically. A ventral exposure permitted access to the hypothalamus for extracellular unit recording, and stimulation of posterior pituitary axon terminals of PVN neurosecretory neurons.

A total of 136 neurons in the region of the PVN were tested. Of these cells 44 were identified by antidromic activation as neurosecretory neurons. In response to single SFO stimuli 32 neurosecretory neurons displayed an enhanced activity(latency 10-50 msec) lasting up to 500msec, 10 cells showed no response, and 2 cells showed an initial depression(15-60msec) followed by a longer latency increase in excitability similar to that observed in the neurons which displayed only an excitation. This enhancement in excitability was observed in both putative vasopressinergic(phasic, blood pressure-sensitive), and oxytocinergic(continuous, nonblood pressure-sensitive) neurons.

Among the remaining 92 non-neurosecretory cells, 58 showed orthodromic activation following stimulation of the SFO, with a latency range of 15-40msec, and a duration of 8-30msec. An initial decrease in activity was observed in 20 neurons, and 14 showed no obvious response.

These observations indicate that SFO stimulation exerts a predominantly facilitatory effect on the excitability of PVN vasopressinergic and oxytocinergic neurons. Our data also suggest that SFO stimulation influences a separate population of PVN neurons that may mediate other functions(e.g the increase in blood pressure) associated with the SFO.

207.15 EFFECT OF INTRAVENTRICULAR (IVT) INFUSION OF ANGIOTENSIN II (AII) ON PULSATILE LH SECRETION IN OVARIECTOMIZED RATS. <u>M.K. Steele</u>, <u>R.V. Gallo and W.F. Ganong</u>, Department of Physiology, University of California, San Francisco, CA 94143. In ovariectomized rats treated with estrogen, IVT AII in-

In ovariectomized rats treated with estrogen, IVT AII increased plasma LH levels; while in untreated ovariectomized rats, LH concentrations were not modified when discrete blood samples were taken 10, 15 and 30 min after IVT AII (Steele et al., Endocrin. 111:722, 1982). However, LH release in ovariectomized animals is pulsatile, with wide fluctuations in blood levels over 15 to 30 minutes. Therefore, we further investigated the effect of IVT AII on LH secretion in ovariectomized rats by employing a blood sampling protocol where the pulsatile nature of LH secretion could be fully characterized. Rats were implanted with chronic IVT cannulae, ovariectomized,

Rats were implanted with chronic IVT cannulae, ovariectomized, and tested 8 days later. A jugular cannula was inserted 24 hr prior to testing. Rats were bled continuously via a peristaltic pump at 50 µl whole blood/7-8 minutes for 3.5 to 4.0 hrs. Blood samples were analyzed by RIA and values expressed as ngLH/ml whole blood. Following a control bleeding period of 1.5 to 2.0 hrs, artificial CSF or AII (in CSF at a dose of 15, 150, or 600 ng/25 µl/hr) was infused for 1.5 to 2.0 hrs. Mean LH levels during infusion of AII at 15 ng/hr were not significantly different from preinfusion values, nor from levels during infusion of 250 m for 600 ng/25 µl/hr) was in the decreases in mean LH concentrations compared to preinfusion levels and to those during CSF administration. Pulse frequency and pulse amplitude were also depressed by the two highest doses of AII.

Using an identical protocol, infusions of the AII receptor blocker saralasin at doses of 1.5  $\mu$ g or 15.0  $\mu$ g/25  $\mu$ l CSF/hr produced small increases in mean LH levels, significantly different from values during infusion of CSF, but not different from their respective preinfusion levels. Therefore, under these conditions, saralasin did not exhibit any agonistic AII activity. Co-infusion of saralasin (1.5  $\mu$ g) plus AII (150 ng) abolished the depressive effects of AII upon mean LH levels, pulse amplitude and pulse frequency.

These results demonstrate that infusion of AII into the cerebral ventricles of ovariectomized rats suppresses, in a doserelated fashion, pulsatile LH secretion. The abolition of these effects by saralasin suggests a specific action of AII at its receptor. Furthermore, when taken together with the data from experiments from estrogen-pretreated rats, these data suggest that the steroid millieu of the animal determine the direction of the LH response to IVT AII. (Supported by USPHS Grants AM06704, HD18020, HD05577 and Kroc Foundation). 207.14 EVIDENCE THAT INTRAVENTRICULAR RENIN INCREASES DOPAMINE SYNTHESIS AND TURNOVER IN THE MEDIAN EMINENCE. R.H. Alper and W.F. Ganong, Dept. of Physiology, Univ. of Calif., San Francisco, CA 94143. We have shown previously that intraventricularly (ivt) infused angiotensin II (AII) caused a small, brief increase in catecholamine (CA) synthesis in the median eminence (Alper et al., Neurosci. Abst. 1982). The present studies were undertaken to provide a quantitative analysis of the effect of ivt renin on the CA innervation of the median eminence.

Male rats were implanted unilaterally with chronic lateral ventricular cannulas. Approximately 1 week later rats were administered either artificial cerebrospinal fluid (ACSF; 10  $\mu$ 1) or hog renin (Sigma) over a 4-5 min period. Renin is dipsogenic so water was removed from the cages after the infusion to eliminate differences in water intake in the 2 groups. CA synthesis was estimated <u>in vivo</u> by measuring the rate of DOPA accumulation 30 min after the injection of m-dihydroxybenzylhydrazine (NSD 1015; 100 mg/kg, ip). Dopamine (DA) and norepinephrine (NE) turnover rates were estimated by measuring the decline of both amines in the median eminence following the inhibition of their synthesis with  $\alpha$ -methyl-p-tyrosine ( $\alpha$ MT; 250 mg free base/kg, ip). In 2 separate experiments, renin (0.05 or 0.1 U/rat) had no effect on DOPA accumulation in the median eminence at 30 min and

If 2 separate experiments, refin (0.00 of 0.1 0.1 0.1 1.1 and non effect on DOPA accumulation in the median eminence at 30 min and 2 hr, but increased DOPA accumulation at 4 hr; the concentration of DA in the anterior pituitary was unaltered from 30 min-4 hr. In another experiment, renin (0.1 U/rat, ivt) increased DOPA accumulation at 4 and 8 hr, but not at 12 hr as compared to 4 hr ACSF-infused or 12 hr water-deprived controls. The concentration of DA in the anterior pituitary was increased at 8 hr, but was not different from controls at other times. When the  $\alpha$ MT-induced decline of DA and NE was examined 6 hr after renin (0.1 U/rat, ivt), the turnover of DA was found to be increased and the turnover of NE was unaltered. Also, the DA concentration of the anterior pituitary was doubled and the serum prolactin concentration was decreased 6 hr following ivt renin. Other rats that received renin (0.1 U/rat, ivt) drank 15±1 ml water in 30 min and 29±2 ml in 8 hr, compared to an intake of 3±1 ml in 8 hr controls. Total daily water intake was increased for 3 days following the single ivt infusion of renin.

single ivt infusion of renin. These data provide evidence that ivt renin, probably through the generation of AII in the CSF or brain, stimulates the release of DA, but not NE, in the median eminence of male rats. This, in turn, may cause the increased anterior pituitary concentration of DA and the decreased secretion of prolactin. The effects of renin on DA in the median eminence develops more slowly than the effects on water intake. (Supported by USPHS Grants AM06704 and AM07265).

207.16 FOLLICULAR DEVELOPMENT AND ENDOCRINE LEVELS: EFFECT OF A NEW MATE ON PREOVULATORY CHANGES E. Sims\*, A. Johnson<sup>1</sup> \*, & M. -F. Cheng (SPON: J. Cohen). Inst. of Animal Béhavior, Rutgers Univ., Newark, N.J. 07102; <sup>1</sup> Dept. Animal Science, Cook College, Rutgers Univ., New Brunswick, N.J. 08903
When a male and female ring dove are paired, their behavior

When a male and female ring dove are paired, their behavior patterns change in a complex and predictable sequence. The endocrine changes that culminate in ovulation after 7-10 days of pair interaction presumably also follow a predictable pattern. In the present study we examined the pattern of ovarian development and endocrine levels associated with each day of pairing until egglaying. We found that follicular development proceeds slowly until two days prior to ovulation at which time it proceeds in an exponential growth pattern and dramatic increases occur in levels of luteinizing hormone and progesterone. .To determine if this sequence of physiological events can be

To determine if this sequence of physiological events can be altered by external factors, we introduced new males to previously paired females. In a previous study we found that a two or three day delay in ovulation can occur if a female previously paired for four days is then paired with a new male. Therefore, we compared the physiological changes of females re-paired with new males to those of females remaining with original mates. We found that the phase of rapid follicular growth appears to be a critical period with respect to the new male's effect on the female's ongoing physiological processes. If the new male is introduced prior to the critical period, ovarian development and the corresponding changes in LH and progesterone levels are delayed. If the male is introduced during the critical period, it appears that it is too late for a delay in the physiological processes leading to ovulation. This delay in ovulation may allow time for the male and female to coordinate their respective reproductive changes and activities. Reproductive synchrony between pair members is presumably important for the successful completion of the breeding cycle in monogamous species, such as ring doves. Hence, the delay in the physiological events leading to ovulation may have significance in terms of the reproductive success of the female and the new male. 207.17 ANTISERA GENERATED AGAINST HAPTEN-CONJUGATES CAN YIELD FALSE-POSITIVE STAINING WHEN USED FOR IMMUNOCYTOCHEMISTRY. Gerald P. Kozlowski and W. Les Dees\*. (SPON: N.H. McArthur). Department of Physiology, U.T.H.S.C.D., Dallas, TX 75235. When raising antiserum to peptides, it is a common practice to couple the hapten to a high-molecular weight carrier molecule in order to enhance immunogenicity. Such is the case for several antisera generated against luteinizing hormone releasing hormone-bovine serum albumin (LHRH-BSA) conjugates: Arnel #104, White-Porter #1 (WP-1), Kelch #12 and Nett-Niswender #42. These antisers avere used in the unlabeled-enzyme immunocytochemical (ICC) procedure for staining LHRH in the medial basal hypothalamus of the rat. For the first reactant, tissue sections were incubated 24 hrs with a 1:700 dilution of untreated antiserum or antiserum to which was added either: LHRH, BSA or both LHRH and BSA. Following washes between steps, the sections were then incubated in: sheep anti-rabbit 1g6, peroxidase-antiperoxidase complex and developed in diaminobenzidine-H,O. When untreated antiserum was used, there was staining of fibers in the zona externa of the median eminence near the intermediolateral sulcus as well as staining of neuronal cell bodies in the median eminence and arcuate nucleus area. When 120 µg of LHRH was added to 1 ml of a 1:100 dilution of the primary antiserum 24 hrs before use, the staining of fibers persisted, whereas the staining of cell bodies disappeared. Adding as much as 1 mg of BSA was added to 1 ml of a 1:100 dilution of the median eminence-staine antiserum, all staining was abolished. Therefore, these antiserum, all staining was abolished. Therefore, these antiserum, all staining the median eminence-arcuate nucleus area but also cells of the median eminence-arcuate nucleus area but also cells and fibers of the magnocellular neurosecretory system. It is likely that neurosecretory cells in contact with fenestrated blood vessels are able to take up serum albumin, or

208.1 CHANGES IN DOPAC/DA RATIOS IN THE MEDIAL (MEm) AND LATERAL (MEI) MEDIAN EMINENCE IN RESPONSE TO HYPERPROLACTINEMIA AND SUCKLING. Jeffrey I. Mechanick\*, Ilene R. Cohen-Becker\*, Karen A. Gregerson\* and Michael Selmanoff. Department of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201. We have established a radioenzymatic-thin layer chromatographic assay which simultaneously determines dopamine (DA), norepinephrine (NE) and epinephrine with a sensitivity of 1-10pg and 3,4-dihydroxyphenylacetic acid (DOPAC) and 3,4-dihydroxyphenyl-glycol (DOPEG) with a sensitivity of 80-120pg. We have used this assay in three experiments. In each experiment microdissected tissue from 5 rats was pooled for a single assay determination such that experimental groups of 8 comprised tissue from 40 rats. We first completed a localization study in adult male rats in 20 brain structures and the anterior (AP) and posterior (PP) pituitary glands. This is the first such study for DOPEG and the most thorough one to date for DOPAC. DOPAC was detectable in 13 of 22 structures with DOPAC/DA ratios ranging from 8% (caudate nucleus, structures with DOPAC/DA ratios ranging from 8% (caudate nucleus, CN) to 25% (ME1). DOPEG was detectable in 6 of 22 structures with DOPEG/NE ratios ranging from 8% (interstitial nucleus of the stria terminalis, ventral aspect) to 32% (MEm). The second and third experiments attempted to see if the DOPAC/DA ratio in the MEm and ME1 would change under circumstances in which we expected to observe the tuberoinfundibular dopamine (TIDA) neurons to increase (in response to elevated prolactin) or decrease (in response to extern weblies estimilies) their activity. Wale rate were made (in response to elevated prolactin) or decrease (in response to an acute suckling stimulus) their activity. Male rats were made hyperprolactinemic with 7 injections (Amg/kg sc) of ovine prolac-tin (oPRL) spaced 8 hours apart. In such rats the DOPAC/DA ratio was increased in the MEm (2.2-fold) and the ME1 (1.9-fold) but not in the CN nor the PP gland and there was a 2.6-fold increase in the concentration of DA in the AP gland. DOPEG/NE ratios remained unchanged in the MEm and the ME1. In 10 day postpartum mother rats, 10 but not 20 minutes of suckling produced a de-crease in the concentration of DDAC in the MEm compared with 0 mother tars, to but not 20 minutes of sucking produced a de-crease in the concentration of DOPAC in the MEm compared with 0 time controls. However, there was no change in the DOPAC/DA ratio in the MEm or the ME1 nor were any DOPEC/NE changes observed. The results suggest that elevated PRL increases the TIDA neuronal activity which is reflected in increased DOPAC/DA ratios in the MEm and the ME1 and the increased DA exponentration ratios in the MEm and the MEl and the increased DA concentration in the AP gland. The suckling stimulus either produces a small decrease in TIDA neuronal activity which is not detected by this metabolic index or suckling does not affect the activity of these neurons. 208.2 MILK EJECTION AND EEG STATE IN URETHANE-XYLAZINE ANAESTHETIZED RATS. D.W. MCKay\* and K. Brown-Grant\*. (SPON: P. Redfern)., Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, A1B 3V6.

Isherwood and Cross (J. Endocr., 87, 437, 1980) reported that the frequency of milk ejection (ME) was twice as high in suckled rats anaesthetized with urethane (U) plus xylazine (X) as compared with rats given U alone. Because Lincoln et al. (Exp. Brain Res., 38, 151, 1980) had shown that ME in U treated rats occurs only when the EEG is synchronized, we determined ME frequency while recording the EEG pattern, synchronized (SS) or desynchronized (DS), in rats given U or U + X.

Episodic release of oxytocin was monitored by the stretch reactions of the 10 suckling pups in Long-Evans rats on Day 14 of lactation anaesthetized with either 1.2 g/kg U i.p. or 0.8 g/kg U i.p. plus 3 mg (0.15 ml) X i.m. The EEG was recorded from stainless steel screw electrodes implanted on day 15 of pregnancy and blood samples were taken through an intracardiac catheter implanted on day 8 of lactation.

With U alone the EEG alternated between SS and DS. Three hours after induction of anaesthesia, if pups were applied, the  $\star$  time in SS increased from about 35 to more than 90 for up to 1 hr, and then gradually decreased again over the next 1.5 hr of suckling to about 60%. In agreement with Lincoln et al., oxytocin release occurred only when the rat was in SS. In rats given U + X the initial EEG pattern was continual SS and when pups were applied at 30 min after the induction of anaesthesia the EEG pattern remained in SS for the subsequent 2.5 hr period of suckling. The mean number of ME per rat was 21.4  $\pm$  3.4 (8) for the U + X rats but only 9.5  $\pm$  2.1 (11) for U rats (p < 0.02). However, it does not appear that this difference can be explained wholly by the greater amount of time spent in SS by U + X rats. When the ME number of U rats is multiplied by the ratio of total suckling time to time in SS, the mean ME number is increased only to 13.1  $\pm$  2.5.

A second neuroendocrine response to the suckling stimulus also differs between the two groups. In the U rats the mean plasma prolactin (PRL) concentration was initially low, but began to increase steadily after about 45 min of suckling and reached a mean value of 120  $\pm$  31 ng RP2/ml after 2.5 hr of suckling. In contrast, PRL was initially high in the U + X rats (176  $\pm$  52) but fell rapidly, despite suckling and frequent milk ejections, to a final value of 8  $\pm$  3.

208.3

INFLUENCE OF PROGESTERONE AND ESTRADIOL ON ACUTE, OVARIECTOMY-INDUCED CHANGES IN PULSATILE LH RELEASE IN THE RAT. R.E. Leipheimer\*, A. Bona Gallo\*, and R.V. Gallo. Physiology Section, Biological Sci. Group, and Department of Biobehavior-al Sciences, University of Connecticut, Storrs, CT 06268 The object of this study was to determine whether the rapid increases in LH pulse amplitude and frequency which occurred within 24 h after ovariectory (oxy) on diestrus 1 (D1; Leipheimer and Gallo, Neurosci. Abst. 8:63, 1982) were due to the removal of progesterone (P) and/or estradiol (E). Initial studies demonstrated that plasma levels of E and P were 18.2  $\pm$ 1.2 pg/ml and 34.1  $\pm$  3.2 ng/ml, respectively, between the evening of D1 and the morning of D2 in our colony of intact rats. Immediately following oxx and jugular vein cannulation Scutters bemonstrated that plasma levels of L and P were 18.2  $\pm$ 1.2 pg/ml and 34.1  $\pm$  3.2 mg/ml, respectively, between the evening of D1 and the morning of D2 in our colony of intact rats. Immediately following ovx and jugular vein cannulation on the morning of D1, rats were implanted either with empty silastic capsules or capsules capable of restoring physiolo-gical levels of E and P comparable to control values reported above. These rats were continuously bled (75u1/6 min) for 3 h one day after ovx for analysis of pulsatile LH release, and then decapitated for determination of plasma E and P levels. Rats with empty capsules had decreased levels of E and P, and increases in mean blood LH levels, LH pulse amplitude and frequency. Animals with E capsules had physiological levels of E, decreased levels of P, but no suppression of pulsatile LH release. In contrast, animals with P capsules had physiologi-cal plasma levels of P, decreased levels of E, and a marked reduction in the acute LH response to ovx. This suppression was due entirely to a decrease in LH pulse amplitude, as pulse frequency was not altered. Rats with E and P capsules had physiological levels of these hormones which resulted in an even greater reduction in the acute LH response to ovx. This suppression was due to decreases in both LH pulse amplitude was centrally mediated since the in vitro response to LHRH of anterior pituitary (AP) fragments from P-implanted rats was the same as that of AP fragments from P-implanted rats was in LH pulse amplitude that occurs within 24 h after ovx on D1 is due to the absence of a central inhibitory effect of ovarian P, while the rapid increase in LH pulse frequency is due to the loss of both ovarian E and P. Thus during the rat estrous cycle (Gallo, Biol. Reprod. 24:771, 1981) the decrease in LH pulse amplitude occurring from D1 to D2 may well be due to the central inhibitory effect of P, while the stable LH pulse frequency between D1 and D2 may bedue to the braking effect of E and P combined upon the firi

LESIONS OF THE PARAVENTRICULAR NUCLEAR REGION SUPPRESS PULSATILE FSH BUT NOT LH RELEASE. M.D. Lumpkin<sup>\*</sup>, W.K. Samson<sup>\*</sup>, J.K. McDonald and S.M. McCann. Department of Physiology, University of Texas Health Science Center, Dallas, TX 75235. Previously we reported that bilateral lesions of the para-ventricular nucleus-dorsal anterior hypothalamic area (PVN-DAHA) would reduce the post-castration blood levels of FSH but not those of LH in male and female rats (Fed Proc 38:1107, 1970) and would also attenuate the processerance science and scien 208.5 1979) and would also attenuate the progesterone stimulation of FSH but not LH in the estrogen-primed ovariectomized (OVX) rat (Fed Proc 41:984, 1982). However, the pulsatile nature of gonadotropin release was not examined in the above experiments. gonadotropin release was not examined in the above experiments. In addition, we first characterized the ultradian release of FSH in the OVX rat in a previous communication (Endo Soc, Abst. 574, 1981). In the present report, we sought to confirm the presence of pulsatile FSH release in the OVX rat and to examine the role of the PVN-DAHA in selective periodic FSH secretion. This task was accomplished by generating radio-frequency lesions in the PVN-DAHA of female rats ovariectomized for 3 weeks. Control animals consisted of the restored attrifrequency lesions in the PVN-DAHA of female rats ovariectomized for 3 weeks. Control animals consisted of sham-operated rats in which the lesion electrode was lowered to the level of the corpus callosum but was not fired. One week post-lesion, all rats were fitted with jugular cannulae. Blood samples (250 µ] were withdrawn from conscious, undisturbed animals at 10 min intervals for 3 hours and the blood volume replaced. Control animals displayed secretory peaks of FSH in plasma with a frequency of 4.0t0.44 per 3 h (or 1 peak/40-50 min) while LH, as expected, pulsed at a frequency of  $5.8\pm0.49$  per 3 h (or 1 peak/20-30 min). The mean peak value was 2401±104 ng FSH/ml (RP-1 ref. prep.) and 43.3±1.32 ng LH/ml (S-1 ref. prep.) in controls. PVN-DAHA destruction reduced FSH peak frequency to 1.2±0.37 per 3 h while the number of LH oscillations remained unchanged at  $5.6\pm0.25$  per 3 h. The mean peak value for FSH was reduced to  $1477\pm243$  mg/ml but the average for LH peaks did not change significantly (40.6±1.25 ng/ml). Immediately after the 3 h sampling period, synthetic LHRH (200 ng) was infused i.v. into rats and blood samples withdrawn 10 and 40 min later. for weeks. Control animals consisted of sham-operated rats into rats and blood samples withdrawn 10 and 40 min later. PVN-DAHA ablation did not alter pituitary gland sensitivity to the LHRM challenge since LH and FSH were released at similar levels in the 2 groups of animals. Since little or no radio-immunoassayable LHRH is present in the PVN-DAHA and because obliteration of the PVN-DAHA does not reduce median eminence levels of LHRH (Fed Proc 38:1107, 1979), we conclude that the PVN-DAHA drives pulsatile FSH release but exerts no control over episodic LH secretion and that the putative FSH-releasing factor and not LHRH is probably responsible for the periodic FSH profile. (Supported by NIH HD-09988 and HD-07062).

CHANGES IN LH PULSE AMPLITUDE AND FREQUENCY AS A FUNCTION OF TIME 208.4 FOLLOWING CASTRATION OF MALE FERRETS. Cheryl L. Sisk and Claude Desjardins\*. Dept. Zoology, Univ. Texas, Austin, TX 78712 Plasma LH patterns in intact adult male ferrets are characterized by the occurrence of LH pulses. Peak LH levels range from 3-7 ng/ml, while plasma LH is typically undetectable in the interpulse interval. On average, LH pulse frequency is 0.5 pulse/hr. However, pulses do not occur at regular intervals and may appear in groups of 2-4 spaced within 2 hours' time. In contrast, the In groups of LH pulses in long-term (>60 days) castrated ferrets is a consistent 2 pulses/hr. Post-castration basal LH concentra-tions are  $\geq 4$  ng/ml and peak LH levels are 8-12 ng/ml. In this study we followed the development of this castration response by examining the pattern of pulsatile LH release as a function of time after castration. Male ferrets (age >6 mos; wt >1.5 kg) were fitted with an in-

Male ferrets (age >0 mos; wt >1.5 kg) were fitted with an in-dwelling atrial cannula and loosely tethered to a value mounted outside the cage. Blood was obtained from each ferret during 3 separate sampling periods. Two days after cannulation, blood sam-ples (0.4 ml) were withdrawn every 5 min for 8 hr. Withdrawn blood was replaced by a mixture containing 48% ferret red blood blood was replaced by a mixture containing 48% ferrer red blood cells and 2.5% human plasma proteins in Krebs-Ringer solution. Five days after this initial sampling period, ferrets were castra-ted. Twenty-two hr later, a second set of blood samples was with-drawn every 2.5 min for 4 hr. The third set of blood samples was obtained in a similar fashion on day 6 post-castration. Plasma LH

obtained in a similar fashion on day 6 post-castration. Plasma Li concentrations were measured by a heterologous ovine-ovine RIA. In intact ferrets, LH pulse frequency was 0.3-0.6 pulse/hr. The characteristics of these pulses were similar to those de-scribed above for intact ferrets. Within 22 hr after castration, LH pulse frequency increased to 1.5-2 pulses/hr. Basal LH levels rose to 2-4 ng/ml. The amplitude of LH pulses was small, with peak LH levels reaching only 4-6 ng/ml. At 6 days post-castra-tion, LH pulse frequency was 2 pulses/hr. Basal LH levels were ~5.5 ng/ml and peak LH levels were ~11 ng/ml. ~5.5 ng/ml and peak LH levels were ~11 ng/ml.

The frequency of LH episodes increases and becomes maximal within the first 22 hr following castration. In contrast, in-creases in basal LH levels and in the amplitude of LH pulses continue through at least 6 days following castration. These results suggest that the testes normally inhibit an inherent  $\approx 30$  min periodicity underlying pulsatile LH release, and that this inhibition is quickly unmasked following castration. The more gradual post-castration increase in basal LH levels and in pulse amplitude may reflect a change in pituitary responsiveness to LHRH and/or increased LHRH stimulation following castration. Supported by NIH HD-13470 and HD-05909.

- 208.6 ALTERATIONS OF THE RAT ESTROUS CYCLE WITH KAINIC ACID OR ELECTROLYTIC LESION OF THE ROSTRAL HYPOTHALAMUS. O. K. Rønnekleiv and M. J. Kelly. Oregon Regional Primate Research Center, Beaverton, and Depts. of Anatomy and Physiology, Oregon Health Science Univ., Portland, Oregon 97201.

Previous experiments, using electrolytic lesions and knife cuts, have demonstrated that the suprachiasmatic/medial preoptic (SCN/MPN) region of the hypothalamus is essential for the occurrence of the proestrus surge of prolactin (PRL) and luteinizing hormone (LH) in the female rat. In order to further elucidate the role or the SCN/MPN region in the regulation of proestrus LH and PRL surges two lesion procedures were used: 1. The neuro toxin, kainic acid, at 20-800  $\mu Mol$  doses was pressure-pulse injected bilaterally through a glass pipette (20  $\mu$ m tip diameter) into the SCN to lesion the cells, leaving fibers of passing 2. Electrolytic lesions were made using Wood's metal intact. electrodes of 20  $\mu m$  tip diameter and 0.35 mA current for 3 min to destroy cells and fibers.

Young, adult, female rats were treated with kainic acid (n = 25) or received bilateral electrolytic lesions (n = 6). (n = 25) or received bilateral electrolytic lesions (n = 6). Control animals (n = 5) had the micropipette lowered into the SCN but no lesion was made. Vaginal smears were monitored before lesion and 6-8 weeks afterwards. Serial blood samples (0.4 ml) were obtained every 20 min for 4 hr in the afternoon at various stages post lesion. The plasma was retained for hormone determi-nation the blood calls were recommended to a support of the statement of the stateme nation, the blood cells were resuspended in a plasma protein solution and reinjected. The majority of animals treated with kainic acid showed some disruption of their estrous cycle. We placed injections into the SCN caused increased incidence of estrous-type smears, but preliminary data indicate that these animals had normal afternoon surges of LH and PRL. Histological examination of the tissue with nissl and immunocytochemical staining revealed that some cells were still present in the SCN.

Large electrolytic lesions including the MPN and the rostral SCN, but leaving the organum vasculosum (OVLT) intact caused con-stant estrous animals. These animals had no LH surge, but did show a 1-hr delayed PRL surge. Immunocytochemical staining for luteinizing hormone releasing hormone (LHRH) revealed fiber and cell stain in the OVLT region. LHR fibers and cells were also present in the mediobasal hypothalamus. These data indicate that lesion of the SCN neurons are effective in altering the estrous cyclicity of female rats. Experiments are in progress using increased doses of kainic acid in the SCN or the MPN to elucidate which neurons control the estrous cycle of the female rat.

208.7 THE POSTPARTUM PREOVULATORY SURGE OF GONADOTROPIN SECRETION MAY BE INITIATED BY THE LABOR PROCESS. <u>Susan R. Fox\* and M. Susan</u> <u>Smith\* (spon: D.M. Koester). Dept. of Physiol., University of</u> Pittsburgh, Pittsburgh, PA 15261.

The rat has a preovulatory surge of gonadotropins postpartum (PPsurge). The signal that initiates this PPsurge could be 1) a time of day signal similar to that occurring on the afternoon of proestrus during the rat estrous cycle, or 2) a time of parturition signal created by either the removal of a placental factor or the addition of a signal from the labor process. To examine what signal initiates the PPsurge blood samples were taken after delivery of the last pup, 2,4,6 and 8 hrs later, and on the following day at 1300,1500,1700 and 1900 hrs. Plasma was assayed for LH and FSH. In 11 rats delivering between 0700 and 2000 hrs the peak gonadotropin concentrations occurred between 1320 and 2325 hrs. Rats delivering in the afternoon had PPsurges in the evening. Thus, the PPsurge is apparently a function of both the time of day (as it occurs only in the PM) and the time of parturition. If the time of day signal is the primary signal for the PPsurge then administration of an ensethetic dose of pentobarbital to rats delivering before 1400 hrs should block the PPsurge. Pentobarbital blocked the PPsurge in only 5 of 11 animals on the day of parturition. Suprisingly, these 5 rats had a LH surge the following afternoon despite the presence of 8 suckling pups. The refractoriness of the PPsurge to pentobarbital blockade and to an inhibitory suckling stimulus suggests that although a time of day signal may be necessary for the expression of the PPsurge, it is not the primary signal. Rather the process of parturition has been completed. Furthermore, when the labor process dig not seem to be served on the day of parturition are sufficient to initiate an LH surge, a surge occurs only after parturition has been completed. Furthermore, when the labor process dig not seem to be present following examples in the expression of the PPsurge in LH was not observed on the day of parturition are sufficient to initiate an LH surge, a surge occurs only after parturition has been completed. Furthermore, when the labor process dig not seem

208.9

Evidence for serotonergic-catecholaminergic coupling in the central control of LH secretion in normal and androgenized female rats. R.J.Handa ,T.P.Condon and R.A.Gorski (SPON: C.H.Sawyer). Lab. of Neuroendocrinology, BRI and Dept. of Anatomy. UCLA, Los Angeles, CA 90024

We have reported that the timed administration of serotonin (5-HT) induces ovulation in lightly androgenized female rats exhibiting the delayed anovulatory syndrome (DAS; Anat.Rec.202:74a). In this study we examined the role of 5-HT and catecholamines in the estrogen-promoted circadian discharge of LH in both normal and androgenized female rats. To induce the DAS, 10ug of testosterone propionate (TP) was injected on day 5 of life. Controls received oil. Ovariectomy (ovx) was performed 3 weeks after the onset of oil. ovariectomy (ovx) was performed 5 weeks after the onset of persistent vaginal estrus in the TP-treated group or in age matched controls. A 5mm silastic capsule filled with crystalline 17B-estradiol (E) was implanted SC 15-18 days following ovx. Blood was sampled by intra-atrial cannulae throughout the following 3 days (day 1-3). This E treatment resulted in a daily afternoon re-lease of LH in control but not in androgenized females. Pretreat-ment of controls with parachlorammheramine (PCA.10me/ke BW a dement of controls with parachloroamphetamine (PCA, 10mg/kg BW; a depletor of 5-HT) 1 day prior to E administration abolished the LH surge. Vehicle injections on day 1 had no effect on LH release in PCA,E-pretreated rats, but 5-hydroxytryptophan (5-HTF; 10,20,50 mg /kg BW IP, given at 1000 h) on days 2 and 3, reinstated the after-noon surge of LH. This effect of 5-HTP was characterized by an noon surge of LH. This effect of 5-HTP was characterized by an acute dose-dependent rise in plasma LH within 15 minutes on injection, followed several hrs later by an afternoon increase in LH similar to that seen in the E-only treated female. Whereas increasing doses of 5-HTP prolonged the acute response of plasma LH, the highest dose resulted in an attenuation of the afternoon rise in LH. In vitro incubation of hemipituitaries from PCA\_E-pre-treated control females in medium containing 5-HTP (10 M) failed treated control remains in medium containing J-mir (16 m) finite to increase basal LH levels, suggesting a central site of 5-HTP action. All androgenized females pretreated with PCA and E responded to 5-HTP given at 1000 h on days 2 and 3 with an acute rise in LH. In addition, 60% of these animals also showed after-noon rises on day 2. This afternoon response was much smaller than that of control females but is comparable in amplitude to the pro-estrous rise in plasma LH seen in lightly androgenized females which are still cycling (Endo.Soc.Abst. #421,1983). Vehicle had no effect. The administration of AMPT (200mg,kg BW; a catecholamine synthesis inhibitor) to PCA.E-pretreated normal and androgenized females on the evening prior to 5-HTP administration, abolished remarks on the evening prior to 5-mir auministration, abolished the afternoon LH response while leaving the acute response to 5-HTP intact. These data suggest that a stimulatory afternoon catecholaminergic neural signal which drives LH secretion is tem-porally coupled to previous serotonergic activity. In the andro-genized female this coupling may be lost. HD01182, GM07191

208.8 LONGTERM PULSATILE LHRH INFUSION CAUSES PSEUDO-PRECOCIOUS PUBERTY AND PERSISTENT ESTRUS IN THE PREPUBERTAL FEMALE GUINEA PIG. M.D. LOOSE<sup>4</sup>& E. Terasawa, Neurosciences Training Program & Wisconsin Reg. Primate Res. Ctr., University of WI, Madison, WI 53715-1299. Employed union price upon chuided the investigate the effective to be officient.

Female guinea pigs were studied to investigate the effects of pulsatile LHRH infusion on the onset of puberty. Prepubertal female guinea pigs  $(19.6 \pm 1.7 \text{ days of age; n=13})$  received jugular catheters through which a two minute pulse of LHRH  $(0.05 \mu \text{g or } 0.1 \mu \text{g})$  was infused once an hour for 14 to 39 days. Animals were placed in a canvas jacket with a flexible tether which lead to a swivel allowing free movement. The swivel was connected to an in-fusion pump and automatic timer apparatus. The vagina was exami-ned daily and, if open, vaginal smears were taken. Laparotomies were performed shortly before or after the termination of the infusion to determine the presence or absence of corpora lutea and to measure ovarian and uterine dimensions. In control females which received no infusion (n=10), the day of the first vaginal opening (VO) and ovulation were similarly determined. To examine ovarian histology five animals which received the LHRH infusion and 4 prepubertal control animals which releaved the lark initial solution and 4 prepubertal control animals were ovariectomized at 32-40 days of age. In the control females VO occurred at 47.4  $\pm$  11.3 days of age and the mean age at the first ovulation was 54.1  $\pm$ 14.4 days. The age at VO of the LHRH infused animals was 24.5  $\pm$ 1.9 days, 5.0  $\pm$  0.8 days after the infusion was begun and was significantly earlier ( $\wp$  0.001) than the controls. After vaginal opening all 13 animals that received LHRH showed characteristics of persistent estrus; 1) the vagina in 11 of 13 animals remained open until the infusion was stopped, the remaining 2 animals had prolonged vaginal opening; 2) cornified cells were predominant in the vaginal smear; 3) the histological appearance of the ovaries polyfollicular and 4) the uterus was significantly enlarged, 4.4 ± 0.3mm in diameter, as compared to the prepubertal controls, 2.6 ± 0.8mm, (p<0.001). The effects of LHRH infusion on the day of ovulation were not consistent: Four animals ovulated at 38.8 + 3.3 days of age during the infusion period, while the remaining four animals ovulated at  $58.9 \pm 9.1$  days of age, 5 or more days after the infusion was terminated. None of the histologically examined ovaries had corpora lutea. We interpret these results to indicate that the exogenous LHRH stimulated gonadotropin secretion which in turn stimulated folliculogenesis and steroid synthesis causing premature and prolonged vaginal opening and cornification, as well as increased uterine size, but not precocious ovulation. There-fore, we conclude that the doses and frequency of LHRH infusion Thereemployed in this study caused pseudo-precocious puberty followed by persistent estrus in the female guinea pig. Furthermore, the present experiment also suggests that increased release of pulsa-tile LHRH may be one of the causes of the persistent estrus syn-drome. 208.10 OVARIAN STEROIDS REVERSE THE INHIBITORY EFFECTS OF NOREPINEPHRINE (NE) ON LH SECRETION IN CASTRATE MALE RATS. T.P. Condon\*, R.J. Handa\*, C.H. Sawyer and D.I. Whitmoyer. Dept. of Anatomy and Lab. of Neuroendocrinology, BRI, UCLA, Los Angeles, CA 90024.

It has been reported previously that intracerebroventricular (ICV) infusion of NE into ovariectomized (OVX) rats inhibits pulsatile LH secretion whereas similar NE infusion into estrogenprogesterone (EP)-primed OVX rats facilitates secretion of LH. We now report an analogous reversal of the inhibitory effects of NE on LH secretion by EP priming in adult male rats. Adult long-term (4 wks) castrated male Sprague-Dawley rats

bearing chronic 3V-ICV cannulae were maintained under standard-ized lighting and temperature conditions. Unanesthetized, freely-moving rats were bled via intra-atrial cannulae at 5-min (unprimed) or 15-min (primed) intervals for 4-5 h. Plasma LH and FSR secretory patterns were determined by radioimmunoassay using NIADDK reagents. After each sample (0.25 ml) was drawn, an equal volume of blood substitute was infused. Steroid priming was volume of block substitute was influeed. Sterior priming was accomplished by SC injection of 50 µg estradiol benzoate + 25 mg progesterone two days before the bleeding session. After a 2-3 h control bleeding period, animals received an ICV infusion (2 µl over 2 min) of either 0.3 µmoles NE or vehicle (acid saline, pH 5.5-6.0) and were bled for an additional 2 h. Gonadotropin sec-After a 2-3 h retory patterns during control periods were similar to those we have reported in OVX rats (Neuroscience 1982 Abst. #18.46). In unprimed rats distinct pulses of LH were observed while FSH excursions were less well defined. The apparent LH pulse periodi-city of 15-25 min in castrate male rats was somewhat shorter than that observed in long-term OVX rats (approx. 30 min). NE infusion into unprimed castrate male rats caused a rapid and potent inhibition of pulsatile LH secretion while FSH levels wer affected to a much lesser extent. Vehicle infusion had little or no effect on LH or FSH levels. LH secretory patterns in primed animals during control periods remained low and non-pulsatile. However, ICV infusion of NE caused a distinct and immediate However, ICV infusion of NE caused a distinct and immediate increase in LH in 7 of 8 rats, lasting 30-60 min. This facilita-tion of LH secretion was similar in magnitude and duration to that reported in OVX, EP rats. Again, FSH levels did not appear to be affected. Vehicle infusion was without effect. From these data we conclude that, in the absence of gonadal hormones, NE has a marked inhibitory effect on LH secretion in male rate as in female rate. However costrate male rates primed This facilita-

From these data we conclude that, in the absence of gonadal hormones, NE has a marked inhibitory effect on LH secretion in male rats as in female rats. However, castrate male rats primed with ovarian steroids can respond to an NE stimulus with a facilitation of LH secretion. We suggest that the central mechanisms by which ovarian steroids modulate noradrenergic effects on LH secretion in adult female rats are also present in the adult male (Supported by NIH grants NSO1162, HD06332-01, and HD01182.)

ALTERATIONS IN THE PATTERN OF PULSATILE SECRETION OF LH FOLLOWING 208.11 OVINE PROLACTIN (oPRL)-INDUCED HYPERPROLACTINEMIA IN SHORT-TERM OVARIECTOMIZED RATS. <u>Ilene R. Cohen-Becker\*</u>, <u>Michael Selmanoff</u> <u>and Phyllis M. Wise</u> (SPON: N. Pilotte). Department of Physiology, <u>University of Maryland</u>, School of Medicine, Baltimore, MD 21201.

Previous investigators have demonstrated that chronic hyperprolactinemia suppresses the elevated levels of LH found following ovariectomy (Grandison et al., Neuroendo. 23:312, 1977; Smith, Biol. Reprod. 19:177, 1978; Login et al., Neuroendo. 35:327, 1982). In these studies hyperprolactinemia was induced by multiple pituitary grafts under the kidney capsule, lactation or prolactin secreting tumors. Each method used produced high prolactin levels, however, in every case additional hormones were secreted. To obviate this problem, we induced a state of hyperprolactinemia by exogenous treatment with oPRL. The purpose of this experiment was to examine the effect of prolactin on the pattern of pulsatile was to examine the effect of prolactin on the pattern of pulsatile secretion of LH in the ovariectomized rat, as may be evident by a change in the frequency and/or amplitude of the pulses. Female Sprague-Dawley rats (200-225 gms) were bilaterally ovariectomized under ether anesthesia on Day O. Animals were given subcutaneous injections of oPRL (4 mg/kg body weight) every eight hours begin-ning at 0900h two days after ovariectomy (Day 2). Control animals reconjund on conjulater recipience of which on Pland correlation (0 mm) received an equivalent regimen of vehicle. Blood samples (0.1 ml) were withdrawn and replaced with an equivalent volume of saline, from 1400h to 1700h at ten minute intervals. LH concentrations were determined by radioimmunoassay in serum using the RP-2 Control animals exhibited a mean of  $1.90 \pm 0.16$  pulses standard. of LH per hour. Hyperprolactinemic animals showed a decreased frequency of LH pulses with a mean of only 1.29  $\pm$  0.23 pulses per Irequency of LA pulses with a mean of only 1.29  $\pm$  0.29 pulses per hour. Differences in the peak amplitude were observed between control and hyperprolactinemic animals. The amplitude of the pulses in the control rats averaged 4.58  $\pm$  0.50 mg/ml of LH. To contrast, the amplitude of the pulses in hyperprolactinemic rats was significantly lower, averaging only 2.30  $\pm$  0.15 ng/ml of LH. was significantly lower, averaging only 2.30  $\pm$  0.15 ng/ml of LH. In conclusion, oPRL-induced hyperprolactinemia in short-term ovariectomized rats resulted in an alteration in the pattern of pulsatile secretion of LH. This change involved both a decrease in the frequency and the amplitude of the pulses of LH. Since LH pulse frequency is thought to be dependent upon a Gn-RH pulse generator, our data may be due to a direct effect of oPRL on the frequency of Gn-RH pulses. Studies are in progress to determine if the decreased amplitude resulted from an alteration in pitui-tary sensitivity to Gn-RH. Supported by NIH grant HD-15955.

208.12 FURTHER EVIDENCE FOR THE INVOLVEMENT OF SEROTONIN IN STEROID FURTHER EVIDENCE FOR THE INVOLVEMENT OF SELECTIONIZED ATS. S. Iyengar\* and J. INDUCED LH RELEASE IN OVARIECTOMIZED RATS. S. Iyengar\* and J. Rabii. (SPON: A.K. Sinha). Dept. of Biological Sciences,

Rabii. (SPON: A.K. Sinha). Dept. of Biological Sciences, Rutgers University, Piscataway, NJ 08854. We have continued our investigation of the role of serotonin in the hypothalamic regulation of luteinizing hormone (LH) in the hypothalamic regulation of luteinizing hormone (LH) secretion. In our earlier experiments (Neuroscience Abst. 18:48, 1982), using a neuropharmacologic approach, we reached the conclusion that brain serotonin plays a stimulatory role in the control of LH secretion. This abstract presents the results of our recent work in which a direct approach to the brain serotonergic system was used in an attempt to further elucidate the involvement of this amine with LH release. The experimental model is the ovariectomized rat primed with estrogen (5ug) and treated with progesterone (1.5 mg) 48 hours later. This treatment leads to a well defined LH peak about six hours following the administration of progesterone. In the six hours following the administration of progesterone. In the six nours following the administration of progesterone. In the first study, the dorsal raphe nucleus, site of origin of hypothalamic serotonergic input, was destroyed by electrochemical lesioning. A current (anodal-direct) of 2mA was applied via a monopolar stainless steel electrode for 15 seconds. Sham lesioned animals were used as controls. Surgery was performed one week before steroid treatment. Destruction of the dorsal raphe nucleus led to a marked reduction in the of the dorsal raphe nucleus led to a marked reduction in the steroid induced LH release. In the second study the serotonergic neurons were destroyed by the intraventricular injection of the neurotoxin 5,7-dihydroxytryptamine ( $150_{\rm ug}$ ), while the catecholaminergic system was protected with desipramine. Sham controls were infused with the ascorbic-saline vehicle. This treatment, a week before steroid administration, also led to a marked reduction in progesterone-induced LH release in the estrogen-primed castrated rats. Finally using a Halasz-type knife (a 1.5 mm blade) the serotonergic pathway to the hypothalamus was transected. A sham group, in which the blade was lowered to the superior aspect of the tract, was used as control. Here again a marked reduction in LH release was observed in transected rats, when treated with estrogen and progesterone a week later. These data are in agreement with those using a week later. These data are in agreement with those using a pharamacologic approach and strongly suggest a stimulatory role for serotonin in the hypothalamic control of LH secretion. Supported by the Bureau of Biological Research, Rutgers University, and a BRSG grant from the Office of Research and Sponsored Programs (RU).

208.13 LHRH RELEASE IN VITRO IS INCREASED IN ESTROGEN-TREATED CYNOMOLGUS MACAQUES. J.E. Levine and H.G. Spies. Div. of Reproductive Biology and Behavior, Oregon Regional Primate Center, Beaverton, OR 97006. It has been proposed that gonadotropin secretion in the primate the has been proposed that gonadottopin secretion in the binate occurs under the permissive influence of tonic hypothalamic input. This view has been challenged by a recent study which demonstrated that a neural signal is required in the generation of a preovula-tory luteinizing hormone (LH) surge (Norman et al., <u>Endo</u> 111: 1874). We sought to determine if this hypothalamic signal is composed of an estrogen-dependent change in the hypothalamic secre-tion of luteinizing hormone-releasing hormone (LHRH).

Diencephalic tissue blocks were obtained at autopsy from indi-vidual cynomolgus macaques and placed in ice-cold, oxygenated Krebs-Kinger-Phosphate (KRP) medium. Mediobasal hypothalamic (MBH) and preoptic-anterior hypothalamic (POA/AH) tissue fragments were Alton in spectral the probability of the set of the se determined by Leydig cell bioassay.

LHRH release was typically greater from MBH compared to POA/AH fragments, and both tissues responded to treatment with 60mM K<sup>+</sup>-KRP with increased LHRH secretion. Average release rates during 3h of superfusion and subsequent tissue concentrations are summarized below:

	LHRH Release	e (pg/min)	LHRH content	t (pg/mg)
Group	MBH	POA/AH	MBH	POA/AH
CTL	.331+.062	.128+.012	34.1+4.3	6.4+2.1
12h	.731+.204*	.609+.096***	38.0+1.9	15.8+5.1
36h	.239+.088	.141+.022	42.1+7.7	6.4+2.1
42h	.867+.247**	.661+.104***	62.7+11.4**	21.1+2.6***
48h	.118+.018	.106+.003	25.2+20.8	6.2+2.1
*~~ 05	**~~ 025 ***	n 01, compared	to CTT	_

LHRH release was maximal at 42h, when serum LH levels were also LHRH release was maximal at 4.0, when serum in revers were also highest. Paradoxically LHRH release was also higher at 12h post- $E_2$ , during the period of LH inhibition. These results confirm our concurrent <u>in vivo</u> studies (Soc. for the Study of Rep. Abst. #37) which also demonstrate that LHRH release is increased in  $E_2$ -treated monkeys. On the basis of both studies we contend that the primate hypothalamus actively participates in the generation of the  $E_2$ -induced gonadotropin surge through the increased secretion of LHRH. Supported by NIH grants HD-16631 and HD-07133.

208.14 SUPRESSION OF LH BY ESTRADIOL IS BLOCKED BY LY117018 IN FEMALE

SUPRESSION OF LH BY ESTRADIOL IS BLOCKED BY LY11/018 IN FEALE C57BL/6J MICE. C. Mobb\*, N. Telford\*, N.N. Gordon\*, and C.E. Finch (SPON: Z. Wenzel). Dept. of Biology, Andrus Gerontology Center, USC, Los Angeles, CA, 90089-0191. Selective antagonists to estradiol (E\_2) would aid examination of LH secretion and loss of estrous cycles, which are both sensitive to low physiological levels of plasma E\_. However, most known antagonists possess significant agonistic activity, and so are of limited utility in studying such sensitive neuroendocrine phenomena. In contrast, LY117018 is reportedly a selective E antagonist cybibiting little agonistic activity. selective  $E_2$  antagonist exhibiting little agonistic activity, as shown by effects of the drug and  $E_2$  on uterine weight. The drug's mechanism of action in the uterus involves competition at drug's mechanism of action in the uterus involves competition at the estradiol receptor. However, little is known about its effects on neuroendocrine functions. Therefore, we examined whether LY117018 could block the supression of LH by E<sub>2</sub>, and if by itself the drug would supress LH secretion. Female, 3-month-old virgin C57BL/6J mice were ovariectomized for one week, then given either E<sub>2</sub> or sham implants; the E<sub>2</sub> implants gave stable plasma E<sub>2</sub> levels of about 10 pg/ml, a low physiological value in intact mice. Three days after implantation, half of the mice in each implant group were given daily subcutaneous injections of LY117018 (50 ug in 100 ul oil) or oil only. After 2 weeks of daily injection, all mice were sacrificed between 1400 and 1600 h by decapitation. LH levels and uterine weights are shown in the table. The drug blocked the effect of the E2 implant on both uterine weight and LH levels (p<.05, ANOVA), and by itself slightly increased uterine levels (p<.05, ANO/A), and by itself slightly increased uterine weight (p<.05, Newman-Keuls), but did not by itself affect LH levels.

Group	Ut. Wt. (mg)	LH (ng/ml)
Sham+oil	21+3	230 <u>+</u> 50
E_+oil	72+3	80 <del>+</del> 60
Sham+drug	32+3	340+50
E2+drug	36-3	310 - 50

These results indicate that LY117018 can antagonize the effect These results indicate that LY11/018 can antagonize the effect of a physiological level of E2 on LH secretion without, by itself, affecting LH secretion. Since the antagonist showed some agonistic activity on uterine weight, LY117018 may be even more selective as an E2 antagonist at neuroendocrine loci than at peripheral loci.

These studies were supported by NIA grants AG-00117, AG-00443, and 5T32 AG00037-05. LY117018 was generously supplied by Lilly Research Laboratories.

ELECTROPHYSIOLOGICAL ACTIONS OF 17 B-ESTRADIOL ON MEDIAL BASAL 208.15 HYPOTHALAMIC LUTEINIING HORMONE-RELEASING HORMONE NEURONS IN THE FEMALE GUINEA PIG. M.J. Kelly, O.K. Ronnekleiv and J.E. Levine\*. Depts. of Physiology, Anatomy, and Oregon Regional Primate Center, Oregon Health Sciences University, Portland, OR 97229

A central issue in neuroendocrinology today is the role of medial basal hypothalmic (MBH) luteinizing hormone-releasing hormone (LHRH) neurons in the control of the female reproductive cycle and feedback regulation of gonadal steroids on these neurons. We have utilized the <u>in vitro</u> hypothalamic slice preparation to identify estrogen-responsive, luteinizing hormone-releasing (LHRH) neurons in the arcuate (ARC) and cell-poor zone (CPZ) of cycling female guinea pigs. Sagittal cell-poor zone (CPZ) of cycling female guinea pigs. Sagittal hypothalamic slices were prepared as previously described [Kelly et al., Exp. Brain Res. 40:440-447 (1980)]. Intracellular recordings were made in eighty-four ARC-CPZ neurons using procion yellow and KC1/KCitrate-filled electrodes. Resting membrane potentials ranged from -35 to -75mV. Similar to <u>in vivo</u> findings, ARC-CPZ neurons exhibited slow, irregular spontaneous activity, and fourteen percent of the ARC-CPZ neurons were antidromically identified as projecting to the median eminence (ME). Also, orthodromic activation was possible via stria terminalis and ME stimulation and spontaneous postsynaptic potentials were activation was possible via stria terminalis and ME stimulation, and spontaneous postspinaptic potentials were observed. Concentrations of  $10^{-9}$  to  $10^{-8}$  M 17*B*-estradiol (E<sub>2</sub>) in the slice medium hyperpolarized and/or inhibited the spontaneous activity of 29 of the 84 neurons. Inhibition of spontaneous activity of sports at similar concentrations in spontaneous EPSPs was observed at similar concentrations in other neurons. Most of these cells were identified through intracellular labeling with procion-yellow. The estrogen-responsive neurons tended to be small (l0um) bipolar, fusiform neurons, and four of these were found to contain immuno-reactive LHRH [for immunocytochemical staining of slices see Kelly et al., Exp. Brain Res. 48:97-106 (1982)]. Furthermore, preliminary evidence indicates that we can measure LHRH release from the slices during the recording and correlate the rate of release of the peptide with the electrophysiological effects of estrogen on LHRH neurons. In conclusion, we have physiological and morphological evidence that E<sub>2</sub> acts directly on MBH LHRH neurons to inhibit spontaneous activity and alter the neurosecretory release of the peptide. We hypothesize that these rapid membrane effects are involved in the negative feedback actions of E<sub>2</sub> on the mammalian hypothalamus. mammalian hypothalamus. (Supported by NIH Grant NS 18989)

EFFECTS OF FLUROTHYL- AND ELECTRO-CONVULSIVE SHOCK ON LH AND 208.16

EFFECTS OF FLUROTHYL- AND ELECTRO-CONVULSIVE SHOCK ON LH AND PROLACTIN SECRETION. R. Bhanot and M. Wilkinson. Depts. of Physiol. Biophys. and of Obstet. Gynecol., Dalhousie Univ., Halifax, N.S., Canada, B3H <sup>4</sup>H7. We have previously reported that repeated convulsions exert adverse effects on the hypothalamic-pituitary-gonadal system of the rat (J. Endocr. 95:37; 95:43, 1982). We now report the effects of flurothyl- and electro-convulsive shock (ECS) on the onset of sexual maturation and on LH and prolactin secretion. Repeated flurothyl convulsions and ECS (one convulsion per day from age 24 days) significantly delay sexual maturation: convulsed rats reached vaginal opening at 37t1 (flurothyl) and 40t1 (ECS) days compared with 34t1 days (control). Moreover, almost all control rats at first estrus showed ova in the ovi-ducts whereas only 20% of the convulsed group ovulated. In an

ducts whereas only 20% of the convulsed group ovulated. In an effort to clarify the mechanism of action of convulsions on pub-erty onset, we examined acute changes in gonadotropin and probety onset, we examine actue changes in gonauotropin and pro-lactin secretion and the positive feedback response of LH to EB/P priming. Serum LH levels (ng/ml  $\pm$  sem) in immature female rats (48 h post-OVX) 15 min following a single flurothyl convul-sion were 86±17 (1.H, p<0.025) and 6±1 (prolactin, p<0.005) com-pared with 288±78 (LH) and 19±3 (prolactin) in controls. Thus, pared with 288+78 (LH) and 1943 (prolactin) in controls. Thus, flurothyl convulsions potently <u>inhibit</u> prolactin secretion. In contrast, a single ECS <u>stimulates</u> prolactin secretion in immature females (48 h post-OVX). Serum LH and prolactin levels were  $175\pm42$  and  $55\pm10$  (p<0.005) in convulsed female rats vs. 200±25 and  $10\pm44$  ng/ml in the control group. However, both flurothyl convulsions and ECS attenuate EB/P-induced LH surges in OVX immature rats. Repeated flurothyl seizures (one per day x 10 days) reduced LH surge levels to  $423\pm171$  from  $1040\pm202$  ng/ml (controls). Similarly, peak LH levels were 663±202 following ECS (one per day x 10 days) vs 2310±480 ng/ml (controls). These results show that convulsive seizures do not significantly alter tonic gonadotropin secretion whereas prolactin output is potently and selectively modified. We have also observed a remarkable difference between the effects of flurothyl and ECS on prolactin. This result has important implications toward the understanding of dopamine-mediation of the antidepressant effects of convulsive treatment. Our results show that flurothyl and ECS convulsions selectively block the neural mechanisms underlying preovulatorytype LH secretion and sexual cyclicity. The disruption of the positive feedback mechanism is apparently not mediated by dopamine/prolacting since thronic broncerptine treatment delays sexual maturation without blocking ovulation at first estrus. Similarly bromocriptine does not disrupt EB/P-induced LH surges in immature OVX rats (Supported by MRC grant to MW).

208.17 MAITOTOXIN, A CALCIUM CHANNEL ACTIVATOR CANDIDATE, STIMULATES MAITOTOXIN, A CALCIUM CHANNEL ACTIVATOR CANDIDATE, STRUCANES THE RELEASE OF FROLACTIN IN VITRO. K. Koike, K. S. Schettini,\* A.M. Judd,\* M.J. Cronin, I.S. Login\* and R.M. MacLeod. (SPON: N. Lenn). Depts. of Med., Physiol. and Neurol., University of Virginia School of Medicine, Charlottesville, Virginia 22908. Maitotoxin (MTX) (kind gift from T. Yasumoto, Tohoku Univ.,

Virginia School of Medicine, Charlottesville, Virginia 22908. Maitotoxin (MTX) (kind gift from T. Yasumoto, Tohoku Univ., Sendai, Japan), a dinoflagellate (Gandierdiscus toxcus) marine toxin, is a potent calcium (Ca<sup>2+</sup>) channel activator in pheo-chromocytoma cell lines (Takahashi et al., J. Biol. Chem., 257: 7287, 1982) and stimulates  $^{45}Ca^{2+}$  influx and norepinephrine release. We studied the effect of MTX on pituitary prolactin (PRL) release, which is a  $Ca^{2+}$ -dependent process. In primary cultures of anterior pituitary cells, MTX stimulated FRL release in a dose-dependent manner ( $10^{-9}$  to  $10^{-7}$  g/ml); the stimulation was 10-fold at the highest concentration used (p 0.01). MTX (5 x  $10^{-8}$  g/ml) significantly (p 0.01) enhanced PRL release after 1.5 min of exposure (4-fold increase) and stimulation was maximal after 1 h (10-fold increase, p 0.01). We studied the effect of manganese ( $Mn^{2+}$ ), a  $Ca^{2+}$  channel blocker, on the MTX-mediated increase in PRL release: 300 uM Mn<sup>2+</sup> partially blocked (67%; p 0.01), whereas 3 mM abolished the stimulation of PRL release by MTX (p 0.01). The effect of MTX was also studied in perifused pituitary cells. A 10-min exposure to 5 x  $10^{-9}$  g/ml MTX acutely stimulated PRL release (5-fold) which remained elevated for 1-2 hr. After PRL levels returned to baseline, the cells responded to 100 nM TRH by increasing PRL release. Pre-liminary experiments on  $^{45}Ca^{2+}$  uptake using dispersed anterior pituitary cells is howed that 5 x  $10^{-8}$  g/ml MTX rapidly stimulated the net uptake of  $^{45}Ca^{2+}$  uptake, suzgestime that at least one component of PRL and  $^{45}Ca^{2+}$  uptake, suzgestime that at least one component of

the net uptake of  $\sqrt[-2]{Ca^{2+}}$ . These results indicate that MTX induces a marked release of PRL and  $45Ca^{2+}$  uptake, suggesting that at least one component of the stimulatory action of MTX may be ascribed to activation of Ca<sup>2+</sup> channels. We suggest that MTX may be a useful tool to investigate the involvement of Ca<sup>2+</sup> in hormone secretory processes.

TRANSIENT OUTWARD CURRENTS IN CLONAL PITUITARY CELLS ARE REGULATED 208.18 BY PEPTIDE HORMONES. B. Dufy and J.L. Barker, Laboratory of Neurophysiology, Univ. Bordeaux II, France and Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD. 20205 The prolactin-secreting pituitary clone GH3/6 is electrically excitable and individual cells respond to a variety of peptide hormones. Since hormonally-induced changes in excitability coincide temporally with alterations in prolactin secretion, it is evident that changes in one or more ion conductance mechanism may regulate secretory activity. We have applied single- and two-electrode voltage clamp techniques to study the electrically excitable membrane properties resident in GH3/6 cells and the effects of peptide hormones on these properties. Using these techniques we have observed several types of transient and delayed outward cur-rents in addition to inward spike-related currents. Inactivation and activation curves and the rapid kinetics of the transient out-ward currents (TOCs) indicated that these currents are superfiwald contents (nots) indicated that these contents are soperin-cially similar to several types of TOC previously reported in a variety of invertebrate and vertebrate cell types. As in other cells these K<sup>+</sup> -dependent TOCs are blocked by either 4-amino-pyridine or Co<sup>2+</sup>, but are relatively insensitive to tetraethyl-ammonium ions. In other cells the TOCs function to control either rate. The TOCs recorded in GH3/6 cells appear to play similar roles in regulating excitability.

Toles in regulating excitability. Previous work has shown that thyrotropin releasing hormone (TRH) rapidly stimulates prolactin secretion and increases action poten-tial discharge rate, while somatostatin (SS) has inhibitory actions on both hormone release and cell excitability. We have examined the effects of TRH and SS on TOCS evoked in GH3/6 cells. TRH consistently depresses (Fig. 1A), and SS consistently potenti-ates TOCs in these cells (Fig. 1B). These effects may help to explain the facilitatory and inhibitory effects of these peptides on action potential discharge rate and prolactin secretion. on action potential discharge rate and prolactin secretion.

EVIDENCE FOR THE INVOLVEMENT OF ARACHIDONIC ACID METABOLISM IN 208.19 THE MECHANISM OF PROLACTIN RELEASE IN VITRO. P.L. Canonico\* and R.M. MacLeod (SPON: S. Vandenberg). Dept. of Med., Univ. of Va. School of Med., Charlottesville, VA 22908. Recent evidence suggests the involvement of phospholipid and arachidonic acid metabolism in the secretory mechanisms of

several anterior pluitary hormones. We attempted to delineate the role of the fatty acid and its metabolites in the mechanism of prolactin (PRL) release. Arachidonic acid added <u>in vitro</u> to rat pluitary glands significantly stimulated (dose-related) the release of RIA and newly synthesized PRL. Arachidonic acid meta-bolism occurs primarily through the cyclooxygenase and lipoxy-genase pathways. Indomethacin (1-100 uM), a cyclooxygenase genase pathways. Indomethacin (1-100 km), a cyclooxygenase inhibitor, did not affect basal PRL release or PRL release stimu-lated by TRH, phospholipase A<sub>2</sub> or phorbol myristate acetate (PMA). These findings seem to exclude this metabolic pathway as a regula-tor of PRL secretion. Indomethacin (50 kM) did, however, enhance the stimulatory effect of 100 kM arachidonic acid on PRL release. We have reported that northydrogualaretic acid (NDCA), a rather selective lipoxygenase inhibitor, inhibited basal and TRH-stimulated PRL release in vitro. We now report that 50 uM NDG significantly inhibited the stimulation of PRL release by phospho-lipase A<sub>2</sub> or PMA. To further determine lipoxygenase involvement in arachidonic acid metabolism in the mammotroph, we used BW755c, another inhibitor of this pathway. At a concentration of 250 uM, this compound inhibits lipoxygenation of arachidonic acid in pancreatic beta cells and markedly inhibits basal and TRHstimulated PRL release by hemipituitary glands incubated in vitro and by pituitary cells perifused in columns. In both systems, BW755c also inhibited PRL release induced by 50 mM K<sup>+</sup>. Phosphatidylinositol (PI) turnover involvement has been suggested in the mechanism of basal and TRH-stimulated PRL release. PI and other mechanism of basal and IMH-stimulated PKL felease. Pl and other intermediates of the PI cycle (1,2-diacylglycerol, phosphatidic acid) are the cellular sources of arachidonic acid, through the activity of specific lipases, in many cellular systems. We investigated the possible involvement of diglyceride lipase, the enzyme that cleaves the fatty acid from 1,2-diacylglycerol, in enzyme that cleaves the faity acid from 1,2-diacy[g]ycerol, the the mediation of PRL release by using a selective inhibitor of the enzyme's activity, RHC 80267. At 70 uM RHC 80267 markedly inhibited both basal and TRH- or K<sup>+</sup>-stimulated PRL release from hemipfluitary glands <u>in vitro</u>. The specificity of this effect is indicated by the finding that neither basal nor stimulated thyrotropin release was affected by the drug. Our findings suggest that pituitary arachidonic acid derived from membranal phospholipids, i.e. 1,2-diacylglycerol, is stimulatory to PRL release presumably through its metabolism via the lipoxygenase pathway.

208.21 THE EFFECT OF GRADED "PHYSICAL" AND "PSYCHOLOGICAL" STRESS ON RolACTIN RELEASE IN RATS. <u>G. K. Weiss\*</u>, D. Yelvington\*, <u>A. Ratner\*</u>. (Spon: D. Savage). Dept. Physiol., University of <u>New Mexico</u>, School of Medicine, Albuquerque, New Mexico 87131. Although there have been a number of parametric studies inves-tigating the adrenal response to graded stress it is not clear if the pituitary hormone, prolactin, shows a similar type of corre-lation. We studied two types of graded stress in rats. One that is considered to be primarily "physical" was produced by various magnitudes of unavoidable footshock and a second, considered to be "psychological", produced by exposing rats to different degrees of novelty. All rats were habituated to handling and blood samples were obtained via right atrial cannulas and analysis for prolactin done using RIA. Footshock was delivered through a metal grid floor of the rat's cage at values between 0.3-10 MA for a duration of 30 sec. Blood was drawn at 5, 10, 15, 25 and 45 min after the shock ended. The magnitude of the pro-lactin response at 5-10 min was shown to be a function of footshock strength and no habituation of the prolactin response occurred over 15 days. Observation of behavior also showed accentuated "stress related behavior" as the intensity of the footshock increased. Variability of the prolactin response between animals to a given footshock was also correlated to the variability of the behavioral responses.

A second group of rats was exposed either to cages similar to their home cage (low level of stress) were placed on platforms above water (high level of stress). The high levels of stress produced a much greater increase in prolactin than did the low level of stress. Rapid habituation occurred under these conditions. These data indicate that the magnitude of the prolactin response to either a predominantly physical or psychological stress is directly correlated to the intensity of the stress.

CHARACTERIZATION OF ARACHIDONIC ACID INDUCED PROLACTIN RELEASE. 208.20 L. Grandison and A.M. Camoratto<sup>\*</sup>. Department of Physiology and Biophysics, Rutgers Medical School UMDNJ, Piscataway, N.J. 08854.

We have recently provided indirect evidence that arachidonic acid or its metabolites participate in regulating both basal and secretagogue induced prolactin secretion. Pharmacological and secretagogue induced prolactin secretion. Pharmacological agents which inhibit arachidonic acid release from membrane phospholipids block basal, and K, TRH or VIP induced prolactin release (Camoratto and Grandison, <u>Fed. Proc.</u> 42:868, 1983) and conversely agents which stimulate arachidonic acid release induce prolactin secretion. To confirm and extend these earlier studies we have characterized the effect of arachidonic acid itself on prolactin release. For this purpose we used  $GH_3$  cells, a clonal cell line producing both prolactin and growth hormone, maintained in <u>vitro</u>. Addition arachidonic acid to the media was associated with a dose related increase in prolactin release. The lowest effective . Addition of related increase in prolactin release. The lowest effective dose was 10 nM which produced a 50% increase in secretion. Maximal stimulation occurred at 1 to 10µM and was 300% of control. Further increases in the doses of arachidonic acid were associated with inhibition of secretion. The stimulatory effect of arachidonic acid on prolactin release was dependent on extracellular Ca<sup>+</sup>. Addition of EGTA to a low calcium media blocked the arachidonic acid response. Replenishment of Ca<sup>+</sup> was associated with a responsement of Ca<sup>+</sup> to a second the second term of term of the second term of term of term of term of the second term of t was associated with a reappearance of arachidonic acid stimulation of prolactin release. These data provide further evidence that arachidonic acid or its metabolites are involved in regulating prolactin secretion.

208.22 VARIATIONS IN LEVELS OF OXYTOCIN AND VASOPRESSIN IN THE PARAVEN-VARIATIONS IN LEVELS OF OXTIOCIA AND VASORESSIN IN THE PARAVEN-TRICULAR NUCLEUS OF THE HYDTHALAMUS DAURING STAGES OF THE ESTROUS CYCLE IN RATS. <u>E.R. Greer\*, C.A. Pedersen\*, M.F. Johnson\*, and A.J. Prange, Jr.</u> (SPON: M.C. Diamond). Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514 Oxytocin (OT) and Arginine-8-vasopressin (AVP) were measured by radiodmmunoassay in micropunched hypothalamic neurosecretory valed of wirdin female Sprayee Dawley rats during four stages of

nuclei of virgin female Sprague Dawley rats during four stages of the estrous cycle.

In the paraventricular nucleus: 1) OT concentration (pg/ $\!\mu g$ protein) was highest during diestrus, was reduced during proestrus by 45% (p < 0.001), during estrus by 48% (p < 0.001), and during metestrus by 23% (p < 0.025; the OT concentration during metestrus differed from that in proestrus (p < 0.01), in estrus (p < 0.005), and in diestrus (p < 0.025). 2) The concentration of AVP was lowest during estrus, and was 79% higher during proestrus  $(p<0.001),\;38\%$  higher during metestrus  $(p<0.05),\;and\;66\%$  higher during diestrus  $(p<0.05).\;and\;66\%$ tions of AVP to OT (AVP/OT) was elevated during proestrus relative to the other three stages: estrus (p < 0.001), metestrus (p < 0.001), and diestrus (p < 0.001). In the supraoptic nucleus a similar trend occurred; the concentration of OT was elevated during diestrus as compared to estrus

(NS); AVP was reduced during estrus relative to proestrus (NS); and AVP/OT was higher in proestrus than in metestrus (p < 0.05) and diestrus (p < 0.005), while estrus exceeded diestrus (p < 0.05).

The variations in concentrations of OT and AVP during the stages of the estrous cycle in the paraventricular nucleus were distinctly cyclic, and may reflect an influence of plasma ovarian steroids on synthesis, axonal transport, and/or release of these peptides.

N: proestrus = 12; estrus = 18; metestrus = 18; diestrus = 10. [Supported by NICHHD HD-16159, NIMH MH-32316, and MH-22536 (AJP)]

REGULATION OF <sup>3</sup>H-IMIPRAMINE BINDING SITES IN BRAIN BY NORADREN-ERGIC AXONS. <u>K.J. Kellar and C.S. Cascio\*</u>. Dept. of Pharmacol-ogy, Georgetown Univ. Sch. of Medicine, Washington, DC 20007 209.1 ogy, Georgetown Univ. Sch. of Medicine, Washington, DC 2000 Repeated administration of most tricyclic antidepressant drugs to rats down-regulates beta-adrenergic and 5-HT-2 receptors in brain. In addition, repeated administration of desipramine or imipramine decreases the number of 3H-imipramine (3H-I) binding sites which are associated with presynaptic 5-HT nerve terminals. (Raisman et al., Eur. J. Pharmacol. 61, 1980; Kinnier et al., Eur. J. Pharmacol. 67, 1980). Recently, the possible influence of serotonergic systems on beta-adrenergic receptor regulation following chronic antidepressant drug treatment has been investi-gated (Brunello et al., Neuropharmacology 21, 1982; Janowsky et al., Science 218, 1982). In these studies, Tesions of 5-HT axons were found to prevent the down-regulation of beta-adrenergic receptor binding sites following chronic desipramine treatment. We have investigated the effects of noradrenergic axons on the response of serotonergic receptors (5-HT-2) and imipramine bind-ing sites to repeated administration of amitriptyline or electroing sites to repeated administration of amitriptyline or electro-convulsive shock (ECS).

convulsive shock (ECS). Noradrenergic systems in brain were lesioned with 6-hydroxy-dopamine (200 ug intraventricular) or received vehicle injections only. Beginning 8 or 19 days later rats received daily injections of saline, anitriptyline (10 mg/kg, 23 days) or ECS (1/day, 12 days). All rats were sacrificed 1 day after last treatment. The lesion resulted in reductions of 3H-NE uptake in cerebral cortex and hypothalamus of 65% and 79%, respectively. In non-lesioned rats the chronic amitriptyline treatment de-creased 3H-spiperone binding to 5-HT-2 receptors in the cortex by 25% and repeated ECS increased binding to 5-HT-2 receptors sy more than 40%, as expected. In the 6-OHDA lesioned rats these treatments produced very similar effects on 5-HT-2 receptors: amitriptyline reduced the binding by 24% and ECS increased it by 30%. Thus, noradrenergic systems do not appear to be necessary 30%. Thus, noradrenergic systems do not appear to be necessary for 5-HT-2 receptor regulation to occur.

In non-lesioned rats chronic amitriptyline treatment decreased In non-lesioned rats chronic amitripuine creatment decreased 3H-I binding sites in the cortex (46%), hippocampus (12%) and in the hypothalamus (22%). (ECS did not affect <sup>3</sup>H-I sites in cortex or hippocampus.) In contrast to the lack of effect of noradrener-gic lesions on 5-HT-2 receptor regulation, the 6-OHDA lesion appeared to completely prevent the down-regulation of <sup>3</sup>H-I bind-ing sites in the cortex binnocampus and hypothalamus following

ing sites in the cortex, hippocampus and hypothalamus following chronic amitriptyline treatment. These results indicate that noradrenergic and serotonergic systems in the brain can interact in complex ways to regulate either postsynpatic adrenergic receptor regulation or presynaptic sites related to reuptake of 5-HT.

209.2 STIMULATION OF BETA ADRENERGIC RECEPTORS DECREASES BETA RECEPTOR DENSITY AND INCREASES SEROTONIN2 RECEPTOR DENSITY IN RAT CEREBRAL CORTEX SLICES. JAMES A. SCOTT\* AND FULTON T. CREWS. Dept. of Pharmacology, University of Florida Medical School, Gainesville, FL 32610.

Recent studies have indicated that administration of beta adrenergic agonists enhanced behavior responses to 5-hydroxytryptamine (Cowen et al., 1982). Since these behavioral responses may be mediated by serotonin<sub>2</sub> (5HT<sub>2</sub>) receptors in the brain (Peroutka et al., 1980), we studied the effects of  $\beta$ -adrenergic stimulation on 5HT<sub>2</sub> receptor binding sites in rat cerebral cortical slices. Cortical slices were incubated with 100  $\mu$ M (-)isoproterenol for various periods of time and  $\beta\text{-}adrenergic$  and 5HT<sub>2</sub> receptor binding determined using <sup>3</sup>H-dihydroalprenolol (DHA) and  $^{3}H$ -spiperone, respectively. After 90 min of incubation with 100  $\mu$ M (-)isoproterenol, <sup>3</sup>H-DHA specific binding decreased from  $95 \pm 1$  fmol <sup>3</sup>H-DHA bound/mg protein to 61 ± 2 fmol <sup>3</sup>H-DHA bound/mg protein (p<0.001). In contrast, <sup>3</sup>H-spiperone specific binding was <u>increased</u>  $17 \pm 3\%$  (p<0.001) from a control value of 241  $\pm$  11 fmoles/mg protein to 282  $\pm$  7 fmoles <sup>3</sup>H-spiperone binding/mg protein. Time course studies indicated that these changes require several minutes of incubation, reach a maximum around 30-60 min and are maintained for at least 120 min. Scatchard analysis indicated that there was an increased 5HT2 receptor density. Isoproterenol treatment increased <sup>3</sup>H-spiperone maximum binding  $(B_{max})$  from a control value of 414 ± 34 fmol/mg protein to 573 ± 46 fmol/mg protein (p<0.025). There was no change in apparent Kd. In contrast to the increase in 5HT2  $B_{max}$ , isoproterenol treatment decreased the  $B_{max}$  for <sup>3</sup>H-DHA binding. These post-synaptic changes in serotonergic and noradrenergic receptors could represent an important site of interaction between these two central biogenic amine systems. Possible mechanisms of these receptor interactions will be discussed.

SEROTONIN INNERVATION OF DOPAMINE NEURONS IN RAT VENTRAL TEGMENTAL 209.3 AREA. D. Hervé\*, T.H. Joh, V.M. Pickel and A. Beaudet, Montreal Neurological Inst., McGill Univ., Montreal, Quebec H3A 2B4 and Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, N.Y. 10021

Biochemical studies have suggested that ascending serotonin (S-HT) neurons might be implicated in the regulation of dopamine metabolism in dopaminergic neurons of the ventral tegmental area (VTA). In an attempt to identify the morphological substrate for such interactions, cellular relationships between 5-HT nerve term-inals and tyrosine hydroxylase (TH) immunoreactive neurons were investigated in the VTA by combined radioautographic and immuno-cytochemical methods. Adult rats were pretreated with a monoamine oxidase inhibitor and submitted to 3h intracerebroventricular in-fusion of  $10^{-4}$ M tritiated serotonin (<sup>3</sup>H-5-HT) to which  $10^{-3}$ M nonradioactive noradrenaline was added to prevent uptake of  $(^{3}\text{H})5\text{-HT}$ by catecholamine elements. Brains were fixed by intraaortic per-fusion of 0.5-1% glutaraldehyde and 4% paraformaldehyde. Serial  $20~\mu\text{m}\text{-thick}$  vibratome sections were taken across the VTA, immunocytochemically reacted against TH according to the PAP method of Sternberger and processed for light and electron microscope radio-autography. In light microscope immuno-radioautographs, (<sup>3</sup>H)5-HT-labeled varicosities appeared as small and dense clusters of silver grains intermingled with, and often adjacent to, TH-im-munoreactive perikarya and proximal dendrites. Labeled varicosi ties were mainly detected within the ventral third of the VTA (to which the tracer had better access) and predominated in the inter-fascicular nucleus. Double-labeled structures were never observed, confirming the specificity of the radioautographic reaction. At electron microscopic level, 5-HT varicosities corresponded to small axonal enlargements (0,6 µm in mean diameter) containing a mixed population of small, pleomorphic electrolucent vesicles and a variable number of large granular vesicles. Some characteris-tically showed an array of minute "microvesicles" associated with microcanaliculi and embedded in a dense cytoplasmic matrix. Twenty percent of 5-HT varicosities detected in the VTA were directly apposed to large TH-immunoreactive dendritic shafts. A number of these exhibited well differentiated, symmetrical junctional complexes in single thin sections. Relationships between 5-HT terminals and immunoreactive perikarya were less frequent by far (<1%). These proportions are likely to be underestimated, however, the method tending to favor detection of either type of labeling over the other. In any event, the results provide solid morpho-logical evidence for direct functional interactions between sero-tonin and dopamine containing neurons in the VTA. Supported by the Medical Research Council and the Edith and Richard Strauss foundation of Canada.

RELATIONSHIP OF THE NUCLEUS TRACTUS SOLITARIUS AFFERENTS, MONOAMINES AND PEPTIDES IN THE PARABRACHIAL NUCLEUS OF THE RAT. T.A. Milner, T.H. Joh, R.J. Miller, and V.M. Pickel. Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021. 209.4 RELATIONSHIP OF THE NUCLEUS TRACTUS SOLITARIUS

Anatomical and physiological studies have revealed that a major output of the nucleus tractus solitarius (NTS) is to the parabrachial nucleus (PBN) and that both the NTS and the PBN contain monoaminergic and peptidergic neurons. We sought to determine the distribution and ultrastructural relationship of the NTS afferents to that of the monoamines and peptides within the PBN by combining autoradiography with immunocytochemistry. One to three days autoradiography with immunocytochemistry. One to three days following a unilateral injection of 10 to 30 nl of 100uCi/ul mixed  $^{3}H^{-}$ aldehyde perfusion then TTS of adult rats, the brains were fixed by aldehyde perfusion then the PBN was processed for immunocytochemistry. The antisera included tyrosine hydroxylase (TH), an enzymatic marker for catecholamines, 5-hydroxytryptamine, substance P (SP) and met 5 enkephalin.

Light microscopy. Both the anterograde labeling of the NTS afferents and the immunocytochemical labeling of 5-HT, SP and enkephalin were more extensively distributed in the lateral PBN than in emerginalin were more extensively distributed in the lateral FBN than in the medial. However, within the lateral PBN, anterograde labeling was predominantly in the ventral region, while immunoreactivity for 5-HT. SP and enkephalin were primarily in the dorsal. Both 5-HT and SP were localized to varicose processes whereas enkephalin was found in a few perikarya as well as varicosities. TH localization differed in that perikarya and processes were heaviest in the medial PBN with fewer perkarya and processes were nearbest in the medial PBN with lewer processes and scattered neurons found laterally. Within the lateral PBN electron microscopy revealed that enkephalin, SP, 5-HT and TH were localized in terminals having similar morphology. The labeled terminals were .4 to 1.2 um in diameter, contained large dense core and many clear vesicles and formed primarily axodendritic synapses. In addition to terminals, TH immunoreactivity was detected in perikarya, dendrites and preterminal axons. The perikarya were 12-15 um in diameter and exhibited vesicle filled evaginations. Axosomatic synapses between TH exhibited vesicle filled evaginations. Axosoniatic synapses between fill labeled terminals and perikarya were occasionally detected, however, most of the terminals forming synapses with catecholaminergic soma or dendrites were unlabeled. Terminals showing autoradiographic labeling following injections of 3H-amino acids were found rarely in the immediate vicinity of immunocytochemically labeled profiles. These studies suggest that the NTS probably contributes a minor component, if any, to either the peptidergic or monoaminergic terminals within the PBN.

EVIDENCE FOR A GABAERGIC INHIBITORY INFLUENCE ON CENTRAL SEROTONERGIC NEURONS EXERTED IN THE DORSAL AND MEDIAN RAPHE. B. Scatton 209.5 Nishikawa\*. Synthélabo-LERS, 92220 Bagneux, France and and T. Nishikawa\*. Synthelabo-LEKS, 92220 Bagneux, France. GBAB exerts an overall inhibitory influence on serotonergic transmission in the rat brain. Thus, systemic administration of the GABA receptor agonist progabide (50-1200 mg/kg ip) as well as of the indirectly acting GABA mimetics  $\gamma$ -acetylenic-GABA (200 mg/ kg ip), dipropylacetamide (150 mg/kg ip) and aminoxyacetic acid (50 mg/kg ip) diminish (by 20-30%) 5-hydroxytryptophan (5-HTP) ac-cumulation (after aromatic L-aminoacid decarboxylase inhibition), minimum af herein and the second an index of servicion neuronal activity, in a variety of brain areas receiving a service innervation from either the dorsal areas receiving a serotomergic innervation from either the dorsal (striatum, substantia nigra, olfactory tubercle) or median (hippo-campus, frontal cortex) or both (hypothalamus, septum) raphé nuclei. Progabide (400 mg/kg ip), given subacutely, also reduces the re-lease of extracellular 5-hydroxyindoleacetic acid (5-HIAA) (as

measured by in vivo electrochemical detection) in the rat striatum. The GABAergic influence on serotonergic neurons is not exerted at the level of nerve terminals as: 1) the progabide-induced re-duction in striatal and hippocampal 5-HTP accumulation is abolished after cerebral hemitransection and 2) intrastriatal infusion of  $\gamma$ -vinyl-GABA (100 µg) or SL 75102, the active and soluble metabolite of progabide (100 µg), fails to alter 5-HTP accumulation

in the striatum. The GABAergic control of central serotonergic transmission is The GABACTERIC control of central seriornergic transmission is more likely exerted at the level of cell body. Thus, local injec-tion of GABA (10-100  $\mu$ g), SL 75 102 (10-100  $\mu$ g) or  $\gamma$ -vinyl-GABA (100  $\mu$ g) into the dorsal raphe diminishes 5-HTP accumulation in the striatum but not in the hippocampus, whereas intra-median ra-phe injection of these compounds reduces 5-HTP accumulation in the hippocampus but not in the striatum. In addition, intra-dorsal ra-phé infusion of these drugs reduces the release of extracellular 5-HIAA from the striatum, the latter effect being antagonized by a local infusion of 20  $\mu$ g of R 5135, a novel steroid derivative possessing potent GABA receptor antagonist properties.

In conclusion, the present data indicate that GABA exerts an In conclusion, the present data indicate that GABA exerts an inhibitory influence on central serotonergic transmission which is mediated via stimulation of GABA receptors located in the dorsal and median raphé nuclei. Preliminary studies indicating that progabide (1200 mg/kg ip) reduces 5-HTP accumulation in the spinal cord, the serotonergic innervation of which is originating from the raphe magnus, suggest that GABA might also exert an inhibitory influence on this raphe nucleus.

ELECTROPHYSIOLOGICAL EVIDENCE SUGGESTING MULTIPLE SEROTONERGIC EFFECTS ON CEREBELLAR PURKINDE CELLS: CORRELATION WITH BASELINE FIRING RATE. <u>Munhyang Lee\*</u>, Jean C. Strahlendorf, and Howard K. <u>Strahlendorf</u> (Spon: Richard D. Nathan). Physiology and Medical and Surgical Neurology, Texas Tech Univ. Hlth. Sci. Ctr., Lubbock TX 70430 209.6

and Surgical Neurology, lexas recent controlled Lubbock, TX 79430. Purkinje (P) cells represent once class of target neurons receiving serotonergic afferents in the cerebellum. This study was designed to reevaluate the effects of iontophoretically applied serotonin (5-HT) on P cells. 5-HT elicited one of three effects measured during the ejection period: 61% of neurons were suppressed; 27% of the cells responded biphasically (i.e., a brief period of inhibition preceded a dominant period of excitation), and 11% of the P cells displayed an excitation (N=99). 5-HT-mediated inhibition had shorter onsets and durations than 5-HT-mediated excitatory and biphasic responses durations than 5-HT-mediated excitatory and biphasic responses A correlation between the spontaneous rate of P cells and the A correlation between the spontaneous rate of P cells and the action of 5-HT was evident. P cells excited by 5-HT had a significantly lower pre-drug firing rate (37 Hz) than those inhibited by 5-HT (51 Hz). On several occasions, the direction of the P cell response to serotonin reversed after a shift in the baseline firing rate (i.e., a rapidly firing neuron that was depressed initially by serotonin responded subsequently with an increase in rate as the continuous rate clowed). When the Pdepressed initially by serotonin responded subsequently with an increase in rate as the spontaneous rate slowed). When the P-cell firing rate was increased or decreased arbitrarily by glutamate or glycine, respectively, the 5-HT response changed in a rate-dependent fashion. Methysergide appeared to have a differential action on excitation and inhibition: inhibition was augmented, whereas excitation was attenuated. Spiperone attenuated the serotonin-mediated inhibition. These studies suggest that P cells may contain two 5-HT receptor subtypes: inhibitory and excitatory. The response to 5-HT may reflect a functional balance between the two subtypes that is determined in part by the spontaneous rate of the cell. The overall qualitative effect of 5-HT may be to set P cells at a preferred rate. Currently, we are examining the possible presynaptic mechanisms underlying these observations. (Supported by Tarbox Parkinson's Disease Institute, TTU.)

209.7 TRYPTOPHAN HYDROXYLASE INHIBITION BY P-CHLOROPHENYLALANINE (PCPA): EFFECT ON DMI INDUCED CHANGES OF THE NOREPINEPHRINE (NE) RECEPTOR COUPLED ADENYLATE CYCLASE IN RAT CORTEX. D.D. Gillespie\*, D.H. Manier\*, L.R. Steranka<sup>1</sup> & F. Sulser. Tennessee Neuropsychiatric Institute, Vanderbilt University School of Medicine, Nashville, TN 37232 and Indiana University, Gary, IN 46408.

Previous studies have shown that specific lesions of serotonergic neurons with 5,7-dihydroxytryptamine (5,7-DHT) abolish the git incurons with 3,7-a hydroxytypiamine (3,7-bhl) abolish thedesipramine (DMI) induced down-regulation of*B*-adrenoceptors inbrain (Brunello <u>et al</u>. Neuropharmacology <u>21</u>, 1145, 1982; Janow-sky <u>et al</u>. Science <u>218</u>, 900, 1982) and decrease the agonist affin-ity for isoproterenol (Manier <u>et al</u>. Europ. J. Pharmacol. <u>86</u>,137, 1983). Since the neurotoxin 5,7-bHT reduces not only sero-Torin (SRT) but also affects the concentration of neuropeptides (substance P and TRH), the lack of down-regulation of  $\beta$ -adreno-ceptors by tricyclics following 5,7-DHT could be the consequence of the lack of SHT or the neuropeptides or both. To determine whether the alteration in NE receptor density and function are the consequence of the loss of 5HT per se, we studied the effect of PCPA on the DMI induced down-regulation of cortical  $\beta$ -adrenoof PCPA on the DMI induced down-regulation of cortical  $\beta$ -adreno-ceptors and the concomitant attenuation of the NE sensitive adenylate cyclase. DMI (10 mg/kg b.i.d.) caused within 4 days a significant attenuation of the NE sensitive adenylate cyclase (re-sponse to 100 µM NE in pmol/mg protein  $\pm$  SEM; controls 72.5  $\pm$ 5.2; DMI 42.3  $\pm$  3.6; p < 0.001) and a reduction in the  $B_{max}$ value of  $[^{3}H]$  -dihydroalprenolo1 (DHA) binding from 135.0  $\pm$  8.9 to 95.6  $\pm$  5.4 fmol/mg protein  $\pm$  SEM (p < 0.005). Within 2 days, PCPA (400 mg/kg i.p.) "reversed" the down-regulated  $\beta$ -adrenocep-tor population despite continuous DMI administration ( $B_{max}$  values: 183  $\pm$  9.6 [DMI + PCPA] vs. 88.5  $\pm$  3.9 [DMI] fmol/mg protein  $\pm$ SEM). Simificantly, the DMI induced attenuation of the NE sensi-SEM). Significantly, the DMI induced attenuation of the NE sensitive adenylate cyclase remained unchanged following PCPA (cyclic AMP response to 100  $\mu$ M NE: 37.4 ± 4.4 [DMI] vs. 39.9 ± 6.0 (PCPA + DMI) pmol/mg protein ± SEM). The agonist affinity of  $\beta$ -adrenceceptors as determined from the inhibition of  $[{}^{3}H]$ -DHA binding by (-)-isoproterenol, was significantly decreased following PCPA in normal animals and further reduced in DMI treated rats ( $IC_{50}$ values in  $\mu$ M ± SEM; controls, 0.38 ± 0.02; DMI, 0.44 ± 0.05; PCPA, 2.4 ± 0.04; DMI + PCPA, 10.1 ± 1.4). Conclusions: 1) SHT per se is co-required with NE for DMI induced down-regulation of e-democentors. 2) 6-democentors following PCPA divide the period.  $\beta$ -adrenoceptors. 2)  $\beta$ -Adrenoceptors following PCPA display char-acteristics of "uncoupled" receptors. 3) The DMI induced down-regulation of  $\beta$ -adrenoceptors is "reversible" by inhibition of tryptophan hydroxylase with PCPA. SEROTONERGIC-OPIATE INTERACTIONS IN DISTRESS VOCALISATIONS OF JUVENILE GUINEA-PIGS. Berend Olivier\* and L.DiAnne Bradford. Dept. Pharmacology, DUPHAR b.v., P.O.Box 2, 1380 AA Weesp, The 209.8 Netherlands.

In an animal model of social affiliation behavior, separa-

In an animal model of social affiliation behavior, separa-tion-induced distress vocalisation (DV) in juvenile guinea-pigs, the involvement of serotonergic and opiate compounds and their interactions was assessed. Fluvoxamine, a specific 5-HT reuptake blocker and new anti-depressant drug, decreased DV in a dose-dependent way (5-20 mg/kg, i.p.). Methysergide enhanced DV's and antagonized the decrease in DV's induced by fluvoxamine. Methysergide (5 mg/kg, i.p.) antagonized the decrease in DV caused by morphine (2 mg/kg, i.p.), whereas naloxone (10 or 25 mg/kg, i.p.) also antagonized the decrease in DV caused by fluvoxamine (10 mg/kg, i.p.). Fluvoxamine (10 and 20 mg/kg, i.p.) when combined with morphine (0.5 mg/kg, i.p.) potentiated the decrease of the DV's in a dose-dependent way. These results show that serotonin and opiate systems in the CNS influence social affiliation behavior in guinea-pigs, and that these systems interact in a modulatory manner.

that these systems interact in a modulatory manner.

- MEDIATION BY NORADRENALINE OF THE GABAERGIC INFLUENCE OF MUSCIMOL 209.9
  - MEDIATION BY NORADRENALINE OF THE GABAERGIC INFLUENCE OF MUSCIMOL ON RAT STRIATAL CHOLINERGIC ACTIVITY. A. Vezzani\*, S. Consolo\*, <u>M. Sieklucka\*, J-X. Wang</u> and H. Ladinsky<sup>\*</sup> (SPON. L. Valzelli). Laboratory of Cholinergic Neuropharmacology, Mario Negri Institute for Pharmacological Research, Milan, Italy I-20157. Muscimol, a rigid analog of GABA and a potent GABA-mimetic drug, increased the content of ACh in rat striatum by about 55% at the optimal dose and time of 10 mg/kg, i.p., 30 min without affecting choline content. The increase in ACh was mediated by the GABAErgic system as pretreatment with picrotoxin completely blockactivities or NE content. The increase in ACh was mediated by the GABAergic system as pretreatment with picrotoxin completelyblock-ed the effect while atropine, pimozide, metergoline and PCPA pre-treatments were ineffective against muscimol. Unilateral degenera-tion of the corticostriatal input by undercutting of the frontal cortex prevented completely the increase in ipsilateral ACh content induced by muscimol after two postoperative weeks. In addition, the action of muscimol was strongly prevented when  $\alpha_1$ -ad-renoceptors were blocked by prazosin and when NE synthesis was inhibited by  $\alpha$ -MpT. Furthermore, the increase in striatal ACh induced by a supramaximal dose of oxotremorine, an action proposed to be mediated by the noradrenergic system, did not summate with the increase induced by a supramaximal dose of muscimol, suggesting a common neuronal target in the mechanism of the drugs. The drug's cholinergic effect was not influenced by reserpine pretreatment. The results indicate that in addition to suggested glutamatergic mediation, there coexists noradrenergic mediation of the GABA effect of muscimol which relies upon newly-synthesiz-ed NE. Conceivably, the activation of a -adrenergic receptors by muscimol produces inhibition of glutamate release which in turn muscimol produces inhibition of glutamafe release which in turn leads to suppression of ACh output and to the ensuing buildup of intraneuronal ACh. Consistently, it was found that at least 15% of the specific binding sites for (<sup>3</sup>H)prazosin were lost in the striatum ipsilateral to the lesioned corticostriatal glutamate-rgic pathway after two postoperative days. If GABA and NE acted in series, i.e. GABA(-)/NE(-)/GLU(+)/ACh, then muscimol would be expected to decrease the level of ACh. It is proposed instead that GABA and NE act in conjunction at the level of the glutamatergic neuron to regulate glutamate release and then glutamatergic neuron to regulate glutamate release and then cholinergic activity.
- 209.10 BIOCHEMICAL EVIDENCE FOR AN INHIBITORY CONTROL OF THE LC BY THE C2 ADRENALINE NEURONS. B. Astier\*, B. Renaud. Laborato Neuropharmacologie. Faculté de Pharmacie. Université Laboratoire de Claude Bernard. LYON, France.

Since the discovery of the existence of adrenaline (A) in mammalian brain and the localization of both A cell bodies and A nerve terminals in the rat medulla oblongata, several physiolo-gical and pharmacological experiments have suggested for these neurons a role in the central regulation of blood pressure which may be different from the possible role of the noradrenaline (NA) neurons. It thus seems important to study the possible (na) neurons, it thus seems important to study the possible interactions between these neurons. An anatomical basis for such interactions, is provided by immunohistochemical observations, showing the existence of A terminals derived from Cl and C2 groups, innervating the NA cell bodies of the locus coeruleus (LC) (Hökfelt et al., Brain Res., 1974, <u>66</u>, 235-251). Therefore, in this study, we sought to compare the biochemical response of the LC (which innervates almost the entire central nervous system) after the lesion of another catecholaminergic neuronal group of the rat medulla oblongata : either one group of NA neurons : the A2 group (nucleus commissuralis, NCO) or one group of A neurons, the C2 group. The electrolytic lesions were produ-ced on rats previously anesthetized with halothame, by passage ced on rats previously anesthetized with halothane, by passage of a 3 mA cathodal current for 5 seconds, medially for A2, and bilaterally for C2. The response of NA neurons of the LC was followed after the lesion of the A2 or C2 group, by using as markers the "in vitro" activity of the two catecholamine-synthe-sizing enzymes tyrosine hydroxylase (TH) and dopamine- $\beta$ -hydroxy-lase (DBH). The activity of the adrenaline-synthesizing enzyme phenylethanolamine-N-methyltransferase (PNMT) was used as a specific marker of the A terminals within the LC. In order to measure the changes occuring in an area rich in NA and A termi-nals, the enzymatic activities were also determined in the trac-

nais, the enzymatic activities were also determined in the trac-tus intermediolateralis (TIML) of the spinal cord. No change was observed in the TH and DBH activities within the NA cell bodies of the LC, 5 days <u>after lesion of the A2</u> group (NCO). The PNMT activity of the LC was not changed either. Within the NA and A terminals of the TIML, these three enzymatic activities were not modified.

On the other hand, the TH activity within the LC was significantly increased ( $\pm 104\%$ , p < 0.001) 5 days <u>after bilateral lesion</u> of the C2 group. Modifications occured neither in the DBH and PNMT activities of the LC, nor in the TH, DBH and PNMT activities of the LC activities of the PNMT ties within the NA and A terminals of the TIML.

This increase in TH activity occuring in the LC after lesion-ing of the C2 A neurons favors the hypothesis of an inhibitory control of the LC by the A nerve terminals derived from the C2 A cell bodies.

209.11 NOREPINEPHRINE (NE) POTENTIATES THE VIP-INDUCED ACCUMU-LATION OF CAMP IN MOUSE CEREBRAL CORTICAL SLICES : EVIDENCE FOR AN ALPHA-ADRENERGIC MEDIATION. P.J. Magistretti and M. Schorderet\*. Dept. of Pharmaco-logy,CMU,University of Geneva,1211 Geneva,Switzerland. VIP and NE are two cortical neurotransmitters con-

tained in neuronal systems organized in striking con-trast:VIP is localized to bipolar, radially oriented, intracortical neurons and NE to tangentially organized cortical afferents which originate in the locus coeruleus. In cerebral cortex, these two neurotransmitters share two sequentially related cellular actions : stimulation of cAMP formation and the subsequent activation of glycogenolysis.

In a series of experiments we have investigated the interactions between VIP and NE on cAMP formation in mouse cerebral cortical slices. We have found that VIP and NE, when tested at supramaximally effective concentrations display overadditive effects on cAMP formation (pmoles cAMP/mg prot.±SEM) : Control (C)=6.65±1.6; VIP 1  $\mu$ M=210±25; NE 50  $\mu$ M=31.8±6.6; VIP 1  $\mu$ M + NE 50  $\mu$ M= 475±27<sup>+</sup> (n=6). Furthermore the stimulating effects of VIP on cAMP formation are potentiated by phenylephrine (PE) but not by isoproterenol (ISO) : C=13.6±0.21; VIP 1  $\mu$ M=192±20.4; VIP 1  $\mu$ M + PE 50  $\mu$ M=356±16.7<sup>++</sup>; PE 50  $\mu$ M=14.7±0.79; VIP 1  $\mu$ M + ISO 50  $\mu$ M=182.4±18.2; ISO 50  $\mu$ M=19.1±3.5 (n=5). In addition phentolamine but not propranolol antagonizes the NE-induced potentiation of the VIP-mediated CAMP formation.

These results therefore demonstrate that NE potentiates the stimulatory effects of VIP on cAMP formation and that this potentiation is mediated by alpha-adrenergic receptors. They also suggest that VIP and NE neurons may act, at least in part, upon the same target cells in cerebral cortex. Furthermore, these results, demonstrating a functional synergism between VIP and NE, would suggest that the two neurotransmitters could act physiologically in concert in a given region of cortex delineated by the intersection of the tangential trajectory of noradernergic fibers and a radial cortical volume(s) defined by the arborization pattern of activated VIP-containing neurons.  $^{\dagger}$  p<0.005 when compared to the effects of VIP and NE.

p<0.01 when compared to the effects of VIP and PE. ++

209.12 BETA-ADRENERGIC RECEPTORS IN ASTROCYTES: CHARACTERIZATION AND INTERACTION WITH PEPTIDES. D.L. Niehoff and A.W. Mudge\*. MRC Neuroimmunology Res. Prog., Dept. Zoology, University College, Gower St., London, WC1E 6BT, England.

Rat cortical astrocytes in culture have been demonstrated to respond to the addition of norepinephrine by an increase in the production of cAMP (Rougon <u>et al</u>, Soc. Neurosci. Abst. **8:** 239, 1982). This response is potentiated by substance P, somatostatin, and VIP, and inhibited by met-enkephalin, all of which have little or no effect on basal cAMP levels. These results suggested the presence of interacting  $\beta$ -adrenergic and peptide receptors on astrocytes in culture. We have now demonstrated and the effects of neuropeptides on this binding.

Astrocytes were prepared by a modification of the method of McCarthy and de Vellis (J. Cell Biol. 85: 890, 1980) and plated at a density of 2 x  $10^5$  cells/well in multiwell plates. Only cultures which were 95-98% positive for glial fibrillary acidic protein were used in binding assays. 3-8 days after plating cells were washed in a Hepes-buffered balanced salt solution and incubated with ICYP and various drugs or peptides at 37° for 1 Included with for and various arous of perturbs at 3, for 1 hr. Non specific binding was determined in the presence of 2.5 x  $10^{-7}$  M (±) propranolol.

10 ' M (±) propranolol. The binding of 10-200 pM ICYP was saturable; Scatchard analysis revealed a KD of 55 pM and Bmax of 1.4 fmol/10<sup>6</sup> cells. Displacement of ICYP by the  $\beta_1$ -selective antagonist, atenolol (IC<sub>50</sub>=120nM) or the  $\beta_2$ -selective antagonist ICI 118,551 (IC<sub>50</sub>= 300nM) yielded shallow plots indicative of receptor multiplicity, with about 65% of the total receptor population composed of the B1 subtype. Displacement by the agonist isoproteronol was also shallow ( $IC_{50}$ =0.9 µM), and the high affinity component was selec-tively shifted to the right by 10<sup>-5</sup> M GTP. VIP, met-enkephalin, and somatostatin ( $10^{-8}$ - $10^{-6}$  M) had no effect on ICYP binding. Preliminary experiments indicate that somatostatin may reverse the GTP-induced alteration in agonist displacement of ICYP.

These results indicate that astrocytes possess 8-adrenergic These results indicate that astrocytes possess A-adrenergic receptors which are similar to those previously described in rat cortex and demonstrate the efficacy of the <u>in situ</u> assay as a technique for the study of adrenergic and peptidergic receptors on astrocytes. In addition, these data suggest that peptidergic modulation of catecholamine action does not proceed via a direct effect on 8-receptors, but may instead occur by altering receptor interaction with another component of the receptor-cyclase complex, e.g. the nucleotide regulatory subunit. 209.13 EFFECTS OF NEUROTENSIN ON DOPAMINERGIC ACTIVITY FOLLOWING INTRANIGRAL OR INTRASTRIATAL INJECTIONS. H.D. Everist, C.C. Chieuh and A. Pert. Biological Psychiatry Branch and Laboratory of Clinical Science, NIMH, Bethesda, MD 20205 Neurotensin (0, 1.0 or 10.0 nmoles in 1 ul saline) was adminis-tered unilaterally into the substantia nigra or caudate nucleus of male Sprague-Dawley rats. Rotational behavior was automatically recorded for 30-45 min. following neurotensin administration. The rats were then immediately decapitated and the ipsilateral and contralateral substantia nigra and caudate nuclei were microdissected. The fresh frozen brain samples were assayed within 24 hr. by an HPLC procedure for the simultaneous determi-nation of L-DOPA, dopamine, serotonin and their metabolites. While the administration of neurotensin failed to elicit consistent rotational behavior, significant dose-dependent increases in the acidic metabolites of dopamine ipsilateral to the side of injection were found. Nigral administration of neurotensin (10.0 nmoles) produced 30 to 80% increases in the nigral contents of DOPAC and HVA with concomitant 100 to 190% increases in these metabolites in the ipsilateral caudate nucleus. The striatal content of dopamine was increased about 60% ipsilaterally after injections of the high dose of neurotensin into either the substantia nigra or caudate nucleus. Neurotensin increased the NSD-1015-induced accumulation of L-DOPA in the caudate nucleus from 1.8  $\pm$  0.2 to 2.9  $\pm$  0.3 ng/mg. Similar effects on dopamine and dopamine metabolism were observed in the nucleus accumbens following intranigral injections. Serotonin and 5-HIAA contents in the nigrostriatal system were not altered significantly by treatment with neurotensin. These behavioral and neurochemical observations indicate that neurotensin increases the synthesis of dopamine and the intraneuronal metabolism by MOA, whereas it decreases the neuronal activity or shuts off the release of dopa-mine. This notion is consistent with the results of the following experiment with <u>d</u>-amphetamine. Unilateral intramigral administration of neurotensin resulted in no significant rota-tional behavior. However, when <u>d</u>-amphetamine (2.5 mg/kg, i.p.) was administered 15 min. later, significant turning contralateral to the injection side was observed in 10 of 14 rats. AMPT pretreatment significantly attenuated this amphetamine-induced rotational behavior. In conclusion, neurotensin could turn off the dopaminergic activity in the nigrostriatal system in a manner similar to axonal transsection or treatment with gammabutyrolactone.

209.14 ELECTROPHYSIOLOGICAL EVIDENCE FOR MODULATION OF DOPAMINE NEURONS BY 8-HYDROXY-2(DI-N-PROPYLAMINO)TETRALIN. S.L. Fallon\*, H.S. Kim\* and J.J. Welch. Res. Dept., Pharm. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

Summit, NS 07901. Serotonin (5-HT) neurons originating in the dorsal raphe nucleus are known to have a modulating influence on the impulse activity of dopamine (DA) neurons in the substantia nigra. This connection is thought to be responsible for the enhanced DA transmission caused by the 5-HT agonist, 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) (Christoph <u>et al., Life Sci., 21</u>:1585, 1977). By interacting with 5-HT autoreceptors to reduce raphe activity, 5-MeODMT presumably disinhibits postsynaptic DA neurons. Hjorth <u>et</u> <u>al.</u> (J. Neural Trans., 55:169, 1982) have described a new potent 5-HT agonist, 8-hydroxy-2(di-n-propylamino)tetralin (8-OH-DPAT) which also is believed to activate 5-HT autoreceptors. Their biochemical and behavioral investigations have indicated that 8-OH-DPAT lacks appreciable effects on DA neurons. Using electrophysiological techniques we have investigated the 5-HT and DA properties of 8-OH-DPAT. For comparison, 5-MeODMT and quipazine were also tested.

Extracellular activity was recorded from single neurons in either the dorsal raphe nucleus or the substantia nigra zona compacta of chloral hydrate anesthetized rats. Small intravenous doese of 8-OH-DPAT, from 2 to 10  $\mu$ g/kg, inhibited completely the firing rate of 5-HT neurons located in the dorsal raphe. In contrast, the predominant effects of 8-OH-DPAT on DA neurons in the substantia nigra were clearly excitatory. In 70% of the DA neurons tested, 8-OH-DPAT at doses up to 1 mg/kg caused a marked and long-lasting firing rate increase. The average increase was approximately 30% of baseline regardless of the dose tested. The activity of the remaining neurons was either depressed or not affected. At doses above 1 mg/kg, 8-OH-DPAT caused a dosedependent firing rate inhibition of DA neurons. Haloperidol treatment (0.1 mg/kg) antagonized the inhibitory effects of the higher doses of 8-OH-DPAT on DA activity but enhanced its low dose excitatory effects. 5-MeODMT (30-80  $\mu$ g/kg) and quipazine (0.5-1 mg/kg) inhibited 5-HT neurons completely and caused excitation of DA neurons equal in magnitude to the 8-OH-DPAT-induced increase.

These results are consistent with other studies showing that 8-0H-DPAT is a potent 5-HT agonist. Additionally, our electrophysiological findings suggest that low doses of 8-0H-DPAT may, by virtue of its ability to enhance DA neuronal transmission, cause an indirect activation of DA receptors. However, at high doses, 8-0H-DPAT appears to be a direct acting agonist at DA receptors, sharing a property common to most 2-aminotetralin derivatives.

209.15 CHOLECYSTOKININ MODULATES THE IN VIVO RELEASE OF DOPAMINE IN THE NUCLEUS ACCUMBENS OF THE RAT. M. Voigt\* and R. Y. Wang. Dept. of Pharmacology, St. Louis Univ. Sch. Med., St. Louis, MO 63104. CholecystoKinin (CCK) and dopamine (DA) have been shown to coexist within a subset of AlO neurons located in the ventral tegmental area. These CCK/DA neurons project primarily to the medial nucleus accumbens (NAC). Previous studies in this lab (White and Wang, in preparation) have demonstrated that ionto-phoretically applied CCK increases, whereas DA suppresses, the firing rate of neurons in the medial NAC. This suggests that CCK and DA are functional antagonists in this structure with regards to postsynaptic effects. In the present study, we have attempted to examine the effects of CCK on a presynaptic event, the release of endogenous DA, within the NAC. This was done through the use of push-pull cannula perfusion. Concentric cannulae were implanted stereotaxically into the

Concentric cannulae were implanted stereotaxically into the medial NAc of chloral-hydrate anesthetized rats. Perfusion of a previously described artificial cerebrospinal fluid was begun and maintained at a constant rate of 15  $\mu$ L/min. Perfusate was collected in ten minute fractions and endogenous DA was measured using HPLC coupled with electrochemical detection. Cannula placement was verified for each experiment using standard histological procedures, and only those experiments where the lesion was confined to the tip of the cannula were used for data analysis.

procedures, and only chose experiments where the festion was confined to the tip of the cannula were used for data analysis. During perfusion with normal buffer, basal DA levels were below the limits of detection. d-Amphetamine at 10 µM elevated DA levels to 40 pg/min. Buffer containing 55 mM K<sup>+</sup> (hi-K), when perfused for 10 min, increased DA levels to 61.848 pg/min (K+SF, n=5). This stimulated release was demonstrated to be Ca<sup>++</sup> dependent. In experiments (n=3) where the cannula was placed lateral to the NAc proper, no DA was detected during stimulation by hi-K. The effects of various concentrations of CCK on hi-K induced DA release were then tested. At 20 nM, CCK-8SO<sub>4</sub> had no effect (62.3  $\pm 5 pg/min, n=4$ ). At 200 nM, CCK-8SO<sub>4</sub> decreased hi-K stimulated release by 63% (23.0+6 pg/min, n=5, p<0.0005 vs. control). Interestingly, CCK-8SO<sub>4</sub> at 2 µM only decreased release by 47% (33.2+5, n=4, p<0.025 vs. control). In marked contrast to CCK-8SO<sub>4</sub>, unsulfated CCK at 200 nM had no effect on K<sup>+</sup>-induced DA

In conclusion, our results showed that: 1)  $K^+$  increases DA release in the NAC in vivo in a Ca<sup>++</sup> dependent manner, and 2) only the sulfated form of CCK-8 suppressed  $K^+$ -induced DA release. This latter finding supports the concept that CCK may functionally antagonize the action of DA in the NAC. (Supported by USPHS Grants MH34424 and MH00378.)

209.16 EFFECTS OF THYROTROPIN-RELEASING HORMONE ON GLUTAMATE EXCITATION OF RAT SPINAL MOTONEURONS. <u>S.R. White</u>, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland AlB 3V6.

Thyrotropin-releasing hormone (TRH) and serotonin (5HT) appear to coexist in some bulbospinal neurons which send terminals to the lumbar ventral horn of the rat spinal cord (Johansson, et al, Neurosci. 6, 1981, 1557). 5HT facilitates glutamate excitation of rat spinal motoneurons (White & Neuman, Brain Res. <u>188</u>, 1980, 119), but TRH has been found to selectively depress glutamate excitation of rat cerebral cortical neurons (Renaud, et al, Science <u>205</u>, 1979, 1275). The present study was undertaken to determine the relationship between the effects of TRH and 5HT on glutamate excitation of rat spinal motoneurons.

The center, Nacl-containing barrel of a multibarrel micropipette was used to record extracellular action potentials from physiologically identified motoneurons in the lumbar spinal cord of urethane-anesthetized rats. Other barrels contained 4 M NaCl for automatic current balance or control current ejection, and 1 M monosodium-L-glutamate (GLU), 0.16 M serotonin bimaleate (5HT) and 0.01 M TRH for iontophoresis. Stable baseline responsés to GLU were established by manipulating GLU ejection currents and cycle durations. The effects of TRH or 5HT on the baseline activity evoked by GLU were then examined. TRH (20-30 nA, 60-90 sec) had a prolonged facilitatory effect on GLU excitation without affecting spike amplitude in 16 out of 19 motoneurons tested from five different rats. A brief

TRH (20-30 nA, 60-90 sec) had a prolonged facilitatory effect on GLU excitation without affecting spike amplitude in 16 out of 19 motoneurons tested from five different rats. A brief decrease in GLU-evoked activity often accompanied the onset of current to the TRH barrel, but facilitation of firing usually began well before current offset and lasted two to four minutes after offset. This effect of TRH was very similar to that produced by SHT (15-20 nA, 60 sec). However, unlike for SHT, a marked tachyphylaxis developed for the facilitatory effects of TRH. This tachyphylaxis hampers investigation of interactions between effects of TRH and 5HT, but preliminary results suggest that the facilitation of spinal motoneuron excitability produced by SHT may be enhanced by prior application of TRH.

The finding that TRH ehanced glutamate excitation of rat spinal motoneurons corresponds to previous reports that systemically administered TRH increased EMG activity in hindlimb muscles, depolarized ventral roots and increased MSR amplitude in spinal rats (Barbeau & Bedard, Neuropharm. 20, 1981, 477; Ono & Fukuda, Neuropharm. 21, 1982, 739) and that bath application of TRH depolarized motoneurons in frog isolated spinal cords (Nicoll, J. Pharm. Exp. Ther. 207, 1978, 817).

209.19

CHANGES IN OVARIECTOMIZED RAT BRAIN MONOAMINE AND PEPTIDE NEURO-209 17 TRANSMITTER CONCENTRATIONS FOLLOWING ESTRADIOL ADMINISTRATION. <u>N.</u> Barden, V. Picard\* and T. Di Paolo, Dept. of Molecular Endocrino-logy, Le Centre Hospitalier de l'Université Laval, Ste-Foy, Quebec GIV 4G2.

We have previously reported effects of chronic estradiol ( $E_2$ ) administration on the nigro-striatal dopaminergic system. In order to extend these studies to possible interactions of E2 with neurotransmitter systems other than dopamine, we have investigated the effects of  $E_2$  on rat brain serotonin (5-HT) and certain neuropeptides including TRH and substance P (SP). Ovariectomized rats were treated with 178 restradio1 (1 µg bi.d.) for 3 weeks or with one dose (50 µg) 12 h or 24 h before sacrifice. Individual with one dose (30  $\mu$ g) 12 h or 24 h before sacrifice. Individual brain nuclei were removed from frozen brain sections by a micro-punch technique and the 5-HT content measured using HPLC with electrochemical detection or peptide concentrations determined by specific radioimmunoassay. Whilst the appearance of anti-dopaminergic actions necessitate chronic  $E_2$  administration, effect on brain SUT une produced by case. dopaminergic actions necessitate chronic  $E_2$  administration, effects on brain 5-HT were produced by acute, but not chronic, treatment and were restricted to increased concentrations in the substantia nigra and dorsal raphe nucleus. Similarly, acute, but not chronic  $E_2$ , reduced the SP content of substantia nigra. This reduction in SP may be secondary to effects on 5-HT in view of reciprocal changes in SP and 5-HT concentrations of several brain nuclei following inhibition or stimulation of 5-HT synthesis. Concentrations of TRH in anterior hypothalamus and arcuate nucleus were significantly increased by acute  $E_2$  administration, whilst chronic treatment was without effect. In contrast, chronic whilst chronic treatment was without effect. In contrast, chronic E2 administration prevented the d-amphetamine-induced decrease in sriatal SP concentrations, suggesting mediation via an anti-dopaminergic mechanism. These results indicate that E2 effects on the CNS are not restricted to dopamine-containing neurons but are also exerted on at least one other monoaminergic system and also exerced on at least one other monomannergit system and either directly or as a secondary effect can influence peptidergic neurotransmission. These actions of  $E_2$  on monoamines and peptides in both the nigro-striatal system and hypothalamus may be of significance in relation to movement disorders and control of pituitary hormone secretion.

209.18 CHOLECYSTOKININ OCTAPEPTIDE (CCK-8) DOES NOT INTERACT IN VITRO WITH RAT HYPOTHALAMIC ADRENERGIC RECEPTORS. R.L. Kochman, T. Greyš and J.D. Hirsch. Dept. of Biological Research, G.D. Searle & Co., Skokie, IL 60077.

Adrenergic receptors are involved in appetite regulation in Adrenergic receptors are involved in appetite regulation in the rat:  $\alpha$ -agonists such as clonidine can elicit feeding, while  $\beta$ -agonists such as isoproterenol suppress feeding. Cholecysto-kinin (CCK), a peptide found in both brain and gut, may be an important endogenous modulator of appetite. Both CCK and the adrenergic agonists may produce their appetitive effects via the hypothalamus, which has been proposed as the central locus for constitue rescubicion. In order to determine a encodible direct appetite regulation. In order to determine a possible direct action of CCK on adrenergic receptors, we studied the effects of sulfated CCK octapeptide (CCK-8) on agonist and antagonist binding to the  $\alpha-$  and  $\beta-adrenergic receptors in the rat hypothalamus.$ Ing to the  $\alpha$ - and  $\beta$ -adrenergic receptors in the rat hypothalamic. Crude  $P_2$  hypothalamic homogenates were incubated at  $37^{\circ}$ C for 30 minutes with 0.3-30nM <sup>3</sup>H-p-aminoclonidine (<sup>3</sup>H-PAC)± 10µM phen-tolamine to assess  $\alpha$ -agonist binding; 1nM <sup>3</sup>H-PAC ± 1-30nM phen-tolamine to assess  $\alpha$ -antagonist binding; 0.3-30nM <sup>3</sup>H-1-dihydro-alprenolol (<sup>3</sup>H-DHA)± 30µM propranolol for  $\beta$ -antagonist binding; 1nM <sup>3</sup>H-DHA ± 1-30µM d,1-isoproterenol for  $\beta$ -agonist binding. In come acces, the methynness were pre-denolarized with 500m KCl ± some cases, the membranes were pre-depolarized with 50mM KC1 + 2.5mM CaCl<sub>2</sub> to release endogenous CCK. Since guanine nucleotides are known to modulate both CCK and adrenergic binding, the effects of 10nM CCK-8 on 0.1mM 5'-guanylylimidodiphosphate (Gpp(NH)p)modulated adrenergic binding were determined.

 $\alpha$ - and  $\beta$ -Agonist and antagonist binding were unaffected by 1.  $\alpha$  - and B-Agonist and antagonist binding were unaffected by 1, 10,or 1000M CCK-8. In depolarized membranes, these concentrations of CCK-8 had no effect on <sup>3</sup>H-PAC or phentolamine binding. Simi-larly, the effects of 0.1mM Gpp(NH)p on binding were not affected by 10mM CCK-8. The results of these studies do not support the hypothesis that CCK-8 produces satiety via a direct action on hypothalamic adrenergic receptors.

	K <sub>D</sub> (nM)	B <sub>max</sub> (fmol/mg protein)

TRANSMITTER INTERACTIONS IN THE HYPOTHALAMUS OF THE RAT. R.S. Flint and W.J. McBride. Depts. Psychiatry and Biochemistry, In stitute of Psychiatric Research, Indiana University School of 209.20 Īn-Medicine, Indianapolis, IN 46223.

The interactions of amino acid, monoamine and cholinergic transmitter systems were studied in minislices of rat hypothala-mus by measuring release of endogenous neurotransmitters. The hypothalami from three adult male Wistar rats were sliced into  $300\ x\ 300\ \mu m$  sections oriented perpendicular to the horizontal plane. The slices were combined and aliquots of the tissue suspraise. The strices were combined and arriquets of the trisse sus-pension were transferred to polypropylene columns containing G-50 Sephadex. The tissue slices were dispersed in the Sephadex and superfused with physiological media in equilibrium with 95%  $0_2/5^{\circ}$  CO<sub>2</sub> at 37°C and pH 7.4. A submaximal Ca<sup>+2</sup>-dependent re-lease of norepinephrine (NE), dopamine (DA), serotonin (5-HT), CABA eluterate (Club and compartice (ArD) was obtained with 35 lease of norepinephrine (NE), dopamine (DA), serotonin (5-HT), GABA, glutamate (Glu) and aspartate (Asp) was obtained with 35 mM K<sup>+</sup>. The effects of 100  $\mu$ M (a) carbachol on the release of  $\leftarrow$ NE, 5-HT, Glu and Asp; (b) DA, NE and 5-HT (individually added) on the release of Glu and Asp; and (c) GABA and Glu (indivi-dually added) on the release of endogenous NE, DA, 5-HT, Glu and Asp were determined in the presence of 35 mM K<sup>+</sup> first in the ab-sence of Ca<sup>+2</sup> and then in the presence of 2.5 mM Ca<sup>+2</sup>. The cholinergic agonist, carbachol, had little effect on the 35 mM K<sup>+</sup>-stimulated, Ca<sup>+2</sup>-dependent release of NE, 5-HT, Asp and Glu (N=3). NE potentiated the release of Glu in 2 of 3 cases and had little effect on the release of Asp. In addition. both 5-HT and (N=3). NE potentiated the release of Glu in 2 of 3 cases and had little effect on the release of Asp. In addition, both 5-HT and DA significantly enhanced the release of Glu by 40 and 70%, re-spectively. Neither amine appeared to alter the stimulated re-lease of Asp. GABA had little effect on the release of NE, DA and 5-HT but did produce a 5 and 2-fold increase in the release of Asp and Glu, respectively. Glu had little affect on the re-lease of NE and DA and appeared to reduce the K<sup>+</sup>-stimulated, Ca<sup>+2</sup>-dependent release of 5-HT by 35% (N=3). On the other hand, Glu potentiated its own release as well as the release of Asp. All the observed changes upon release appeared to be dependent on the presence of  $Ca^{+2}$ . Overall, the data indicate that (a) the monoamine systems in the rat hypothalamus are not regulated by cholinergic or amino acid transmitter systems; (b) the mono-amines, but not the cholinergic system, are capable of acting upon glutamatergic neurons; and (c) the amino acid transmitter systems are capable of interacting with one another transmitter any of the interactions are direct pre- or post-synaptic actions or are indirectly mediated cannot be determined with the present data. (Supported in part by NS19286, MH00203 and AA03243).

EFFECT OF &-PHENYLETHYLAMINE ON REGIONAL BRAIN CATECHOL-O-METHYL-TRANSFERASE ACTIVITY. <u>Charles J. Hannan, Jr.</u> and <u>William F.</u> <u>Shivers, Jr.</u> Clinical Investigation and Psychiatry Departments, DD Eisenhower Army Medical Center, Ft Gordon, GA 30905.

30905. This preliminary study examined the change in regional brain catechol-O-methyltransferase (COMT) activity in gerbils after 10 daily i.p. injections of  $\beta$ -phenylethylamine (PEA, 50 mg/kg). Brains were divided into the 6 parts indicated in the Table below. COMT was estimated by incubating tissue supernatants with an excess of dopamine (2.3 mM) and S-adenosylmethionine (0.5mM). Phosphate buffer (pH 7.8), magnesium chloride (0.5mM) and adeno-sine deaminase (3U) were also added to a final volume of 0.55 ml. The reaction was stopped after 100 min incubation with 4M MCL containing methoyybergylamine internal standard and HCl containing methoxyhydroxybenzylamine internal standard and the pH adjusted to 6.5 with borate buffer. This was passed through CG-50 cation exchange resin and then injected onto a reversed phase HPLC column equipped with an electrochemical detector. The amount of 3-methoxytyramine (3-MT) and 4-O-methyldopamine (4-MT) produced was calculated and results are given as ng product/min/mg wet weight of tissue.

Retired breeder male gerbils treated with PEA were found to have generally lower COMT activity than PEA treated or saline control young males. There was also a general increase in mean COMT activity of young animals treated with PEA over those not treated. PEA has been proposed to exert its behavioral effects by release of catecholamines or by direct stimulation of neurons. Using COMT activity to reflect the prolonged activity of cate-cholamine systems, it appears that PEA stimulates catecholamines sufficiently to induce an increase in COMT.

- WHOLE BLOOD SEROTONIN AND PLATELET IMIPRAMINE BINDING IN AUTISTIC AND NORMAL SUBJECTS. <u>G.M. Anderson, 1\* E.L. Hoder, 2\* P.P.G. van</u> <u>Benthem, 3\* F.R. Volkmar, 4\* C.R. Hansen, Jr. 5\* R.B. Minderaab<sup>\*</sup></u> <u>B.A. Shaywitz, 7 D.J. Cohem<sup>3\*</sup></u>. Departments of Laboratory Medicine<sup>1</sup> Pediatrics, 2\*, 8° and Neurology 7 and the Child Study Center, 1-8 Yale University School of Medicine, P.O.B. 3333, New Haven, CT 06510. A number of researchers have reported that group means of plasma or whole blood serotonin (5-HT) are elevated in autistic children compared to normal subjects. The cause of this hyper-serotonemia and its relationship to central serotonergic function 210.1 serotonemia and its relationship to central serotonergic functionserotonemia and its relationship to central serotonergic function-ing remain unclear. We have examined 5-HT levels in large groups of normal, autistic, and mentally retarded subjects in order to better characterize this basic finding. We have also measured platelet imipramine (IMI) binding in a group of autistics and nor-mals because of the known association of the IMI binding site with brain and platelet 5-HT uptake systems. Whole blood serotonin (5-HT) and tryptophan (TRP) were measured using an HPLC method in (5-HT) and tryptophan (TRP) were measured using an HPLC method in a group (N=87) of normal children and young adults and in an autistic population (n=40) having a similar age distribution. Whole blood 5-HT was significantly elevated in the drug-free (N=21 autistic group (205±16 ng/ml, 776±87 ng/109 platelets) compared to normal subjects (136±54 ng/ml, 552±26 ng/109 platelets). Platelet counts were similar in drug-free autistic and normal subjects. Autistic subjects on anticonvulsants and neuroleptics had signifi-lower 5-HT levels (117±12 ng/ml) than drug-free autistic subjects that autistic and rotarded gubicste ba taken off medication when testad This drug induced lowering of 5-HT levels makes it imperative that autistic and retarded subjects be taken off medication when tested for the presence of hyperserotonemia. A sex difference was observed in the normal group with young males (1-6 years old) hav-ing significantly higher levels than young females (181H15 vs  $113\pm15$  ng/ml). The significant negative correlation (-.48, p.001) observed in the normal group between 5-HT concentration when expressed as ng/109 platelets and the platelet count suggests that the concentration is best expressed as ng/ml. It is also an indi-cation that the increase in 5-HT is due to increased production cation that the increase in 5-HT is due to increased production rather than a literation in platelet function. Additional corre-lations of 5-HT (ng/ml and  $ng/10^9$  platelets), TRP, platelet count, and the ontogeny of the measures in the normal, autistic, and retarded groups will be presented along with group means and correlations observed for platelet IMI binding.
- 210.2 CHRONIC ELECTROCONVULSIVE SHOCK DIFFERENTIALLY AFFECTS BRAIN AND PLATELET <sup>3</sup>H-IMIPRAMINE RECOGNITION SITES, M.S.Abel\*, L.R.Meyerson, D.E.Clody\* and L.P.Wennogle\*. (SPON:B.Beer). Dept.CNS Res., Med. Res.Div. of American Cyanamid Co., Lederle Labs, Pearl River, NY 199556 10965. NY

NY 10965. The density of  $^{3}$ H-imipramine (IMI) receptors on the human blood platelet has been used as a marker for certain psychopathological states, including depression. For example, in a number of studies a decreased density of IMI sites is found in platelets derived from depressed individuals as compared to normal controls. It is tempting to speculate that these altered peripheral IMI sites may reflect a similar state in the central nervous system. The pre-sent study was designed to assess the effects of various chronic antidepressive treatments on the regulation of IMI binding in cortical and platelet membrane preparations from the same animal. The well-established effects of these treatments on the cortical a-adrenergic system were also monitored as verification of the The well-established effects of these treatments on the cortain g-adrenergic system were also monitored as verification of the efficacy of the chronic regimens. Rats were treated chronically (14 days) with either distilled water, desipramine (DMI, 10mg/Kg i.p., b.i.d.), electroconvulsive shock (ECS, 75 mA 0.5 sec dura-tion, once per day, corneal electrodes), ECS plus DMI, or diazepam (5 mg/Kg i.p., once per day). After a 24 hour washout period, Scatchard analyses were performed from saturation isotherms using 3H-IMI to identify the serotonergic transporter/allosteric regu-lator complex. <sup>3</sup>H-Dihydroalprenolol (DHA) was used as a marker for  $\beta$ -adrenergic recognition sites. Previously reported altera-tions in DHA binding were replicated in our laboratory, thereby verifying the proper administration of the chronic treatments; ECS. DMI and the combination of ECS plus DMI all produced a down-regulation in the cortical  $\beta$ -adrenergic receptor with no changes in affinity(Kg). However, regarding <sup>3</sup>H-IMI binding, after ECS or ECS plus DMI a markedly elevated Bmax was observed in platelets whereas no significant change was seen in the brain. We found no significant change in <sup>3</sup>H-IMI binding parameters in platelet or cortex after DMI administration. Therefore, the supersensitivity  $\beta$ -adrenergic system were also monitored as verification of the significant change in <sup>3</sup>H-IMĬ binding parameters in platelet or cortex after DMI administration. Therefore, the supersensitivity observed in the ECS treatment groups can be attributed to the effects of ECS <u>per se</u>. No statistically significant changes in <sup>3</sup>H-IMI affinity were observed after any experimental regimen. The mechanism underlying elevations in IMI binding to platelets after ECS is unclear. It is, however, interesting that a treatment localized to the CNS (i.e. ECS) produced a large change in the periphery. These results are indicative of independent regulation of recognition sites in platelets and CNS tissue by antidepressive therapy and suggest that the platelet may not be an entirely adequate model for the CNS component of the biochemistry of psychopathologies. psychopathologies.

# 210.3 PLATELET ALPHA-2 ADRENERGIC RECEPTOR SENSITIVITY IN MAJOR DEPRESSIVE DISORDER. <u>S.M. Stahl, P.M. Lemoine,\* R.D.</u> <u>Ciaranello, and P.A. Berger\*</u>. Stanford University, Stanford, CA 94305.

CA 94305. Recent investigations suggest that antidepressant medica-tions can decrease (i.e. "down regulate") the number of recep-tors for a variety of neurotransmitters. Specifically, central nervous system beta adrenergic,  $\alpha$ -2 adrenergic and serotonin-2 receptors may all be down regulated by antidepressants over a two to three week time course comparable to the onset of clin-ical antidepressant effects. Accordingly, numerous investiga-tear have hypethecized that doepnecing may be linked to super Tors have hypothesized that depression may be linked to super-sensitive neurotransmitter receptors, and that antidepressant medications may exert their clinical effects by down-regulating these receptors. Platelets contain  $\alpha$ -2 adrenergic receptors which have the same kinetic and pharmacolocic properties as central nervous system a-2 adrenergic receptors, and, thus, may provide an acceptable receptor functioning in depressed paprovide an accept an electron functioning in operased par-tients. We have investigated the functioning of  $\alpha$ -2 adrenergic receptors in patients with major depressive disorder by measur-ing the specific binding of <sup>3</sup>H-yohimbine, an  $\alpha$ -2 adrenergic receptor antagonist, to platelet membranes. Patients with the diagnosis of major depressive disorder (unipolar or bipolar, Research Diagnostic Criteria) hospitalized on a clinical re-search ward, and who had been medication free for at least four weeks, consented to venepuncture for collection of platelets. Bmax and K<sub>D</sub> values for platelet <sup>3</sup>H-yohimbine binding were normal in unmedicated patients with major depressive disorder, and did not correlate with scores on the Hamilton rating scale for depression. Platelet  $\alpha$ -2 adrenergic antagonist sites were also unchanged in number or affinity in depressed patients after long term treatment with a variety of antidepressant medications. Thus, our results with <sup>3</sup>H-yohimbine fail to demonstrate supersensitive platelet  $\alpha$ -2 adrenergic antagonist sites in ummedicated patients with major depressive disorder. Also, platelet  $\alpha$ -2 adrenergic antagonist sites are apparently not down regulated by chronic antidepressant treatment. We have investigated the functioning of  $\alpha-2$  adrenergic not down regulated by chronic antidepressant treatment.

210.4 DOWN REGULATION OF BRAIN &-ADRENERGIC RECEPTOR BY IPRINDOLE. O. Gandolfi\*, M. L. Barbaccia\*, D. M. Chuang\* and E. Casta (SPON: B.T. Ho) Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032. In rats receiving two daily doses of iprindole (5 or 10 mg/kg i.p.) repeated for 21 days, the number but not the affinity of &-adrenergic receptor recognition sites in the frontal cortex is decreased. In rats receiving such a dose regimen of iprindole the Vmax of NE (100 µM) stimulated adenylate cyclase activity in minces of frontal cortex is attenuated. In addition.this long term administration of iprindole de-

stimulated adenylate cyclase activity in minces of frontal cortex is attenuated. In addition this long term administration of iprindole decreases the Bmax of [<sup>3</sup>H]-mianserin and [<sup>3</sup>H]-ketanserin binding to crude synaptic plasma membranes prepared from rot frontal cortex and hippocampus, whereas the characteristic of [<sup>3</sup>H]-ketanserin binding displaced by LSD (1 M) is unchanged. The decrease in [<sup>3</sup>H]-mianserin and [<sup>3</sup>H]-ketanserin binding is due to a reduction in their densities but not their affinities with bigding sites. Protracted iprindole injections modify neither the uptake of [<sup>3</sup>H]-SHT by minces of frontal cortex nor the number of imipramine binding sites. An acute injection of iprindole does not modify the binding of [<sup>3</sup>H]-mianserin, [<sup>3</sup>H]-SHT to crude synaptic membranes of rat brain. While the lesion of SHT axon terminals with 5,7-dihydroxytryptamine prevents the down regulation of  $\beta$ -adrenergic receptors (decrease in recognition sites and attenuation of the NE stimulation of receptor-coupled adenylate cyclase) elicited by long term stimulation of receptor-coupled adenylate cyclase) elicited by long term imipramine or desipramine treatment, this specific lesion with the neurotoxin fails to modify the down regulation of  $\beta$ -adrenergic receptor

and of cAMP accumulation induced by repeated iprindole administration. Our results suggest that iprindole may act on a specific recognition site(s) located on neuronal membranes postsynaptic to 5HT terminals, resulting in a decrease of  $\beta$ -adrenergic receptor function and perhaps an appearance of its therapeutic effect upon long term treatment. In conclusion iprindole acts on a site that bears some similiarities to that of mianserin, though it is not identical because mianserin does not down regulate its non binding while iprindole down regulates the Bmax of mianser in binding.

210.5 INCREASED β ADRENERGIC RECEPTOR BINDING IN HUMAN FRONTAL CORTEX. <u>M. T. Zanko\* and Anat Biegon</u>, Department of Pharmacology, Hoffmann-La Roche Inc., Nutley, NJ 07110 (Sponsored by R. A. O'Brien)

β Ådrenergic receptors in rat brain are decreased in number following chronic treatment with tricyclics, MAO inhibitors and electroconvulsive therapy. suggesting involvement of these receptors in the therapeutic action of these treatments. Therefore, we have undertaken a study of β adrenergic receptors in postmortem brain tissue from drug-free suicide victims and matched controls. Since changes in receptors may be highly localized, we have chosen a quantitative autoradiographic approach to screen for differences in discrete brain regions. Coronal sections (50 μ) were cut through the frontal cortical level of the right hemisphere of 6 suicide victims and 6 age and sex matched controls (5 men and 1 woman per group). The sections were incubated with 150 pM iodopindolol, 2200 Ci/mmole (nonspecific binding was assessed by co-incubation with 0.5 μM progranolol) and apposed against tritum sensitive sheet film (LKB H-ultrofilm) alongside tissue-iodine standards. After 4.5 or 24 hours exposure the autoradiograms were subjected to computerized densitometry and converted to fm/mg protein using the tissue standards. We find significant elevations in β adrenergic binding in the frontal inferior, cingulate and orbital gyri of the cortex. Samples of these regions from the same subjects were homogenezed and saturation binding studies were carried out to determine whether the change is due to increase affinity or Bmax. Using "H-DHA (NEN 90 Ci/mmole) we find and increase in Bmax in the suicides and identical Kd's. Thus using two different techniques we were able to show an elevation in β adrenergic binding in suicides, which may be relevant to the biochemical changes underlying depression and suicide.

210.6 MUSCARINIC CHOLINERGIC BINDING SITES ON FIBROBLASTS: A TOOL FOR INVESTIGATING AFFECTIVE DISORDERS. E.S. Gershon and N.S. NADI\*, Sect. on Psychogenetics, NIMH, Bethesda, MD 20205

Using <sup>3</sup>[H]-quinuclidinyl benzilate (QNB) as ligand, we have demonstrated saturable and specific binding with a single binding site (Kd =  $10^{-10}$  H,  $B_{max} = 200$  fmol/mg protein). A series of 8 pharmacologic agents at  $10^{-8}$ M showed similar displacement of QNB binding from rat brain homogenate and fibroblasts in vitro (r = 0.97). A physiologic role of this binding site as a receptor is suggested by demonstration that  $10^{-5}$ M arecoline, or xotremorine, or  $10^{-6}$ M acetylcholine inhibits norepinephrine sensitive adenylate cyclase in the fibroblasts by an average of 51%.

The number of binding sites increases by 25% after exposure to 10uM atropine for 24 hours, with return to previous values one passage after removal. 10uM lithium carbonate produces a 16% decrease in number of binding sites.

These cells also have some choline acetyltransferase activity (150 fmols/mg protein/15 minutes). High affinity choline uptake similar to brain has been demonstrated in human fibroblasts by others (Riker et al., J. Neurochem. 36, 746, 1981) and confirmed by us.

No, 1901) and confirmed by us. Differences in  $B_{max}$  among cell lines from different individuals are stable over several cell passages, suggesting genetic variation controlling  $B_{max}$ . The percentage increase in  $B_{max}$  in the presence of atropine is also a stable individual characteristic.

Twelve patients with major affective disorder have higher  $B_{max}$  (329.0 + 63.9 fmol/mg protein) than 12 normal controls (277.8 ± 47.3 fmol/mg protein). Nine relatives of these patients who also have had a major affective diagnosis also have significant  $B_{max}$  elevation (294.8 ± 47.3 fmol/mg protein). No significant differences in Kd are observed. This suggests that increased muscarinic receptor density in fibroblasts may be associated with genetic vulnerability to major affective disorder.

In addition, cells from 7 of these patients had greater decrease in  $B_{max}$  after Li<sup>+</sup> incubation (46.6 fmol/mg protein) than did cells from 6 controls (9.5 fmol/mg protein). This observation may offer several interesting investigational leads for the study of the mechanism of lithium action in relation to the pathophysiology of affective disorders. These findings suggest that fibroblasts may be useful in the studies of affective disorders.

210.7 EFFECTS OF CHRONIC L-DOPA AND BROMOCRIPTINE TREATMENT ON DOPAMINE RECEPTORS IN AN ANIMAL MODEL OF PARRINSON'S DISEASE. <u>M.B. Schneider\*, L.C. Murrig and R.F. Pfeiffer\*</u>, Depts. of Pharmacology and Neurology, Univ. of Nebraska Medical Center, Omaha, NE 68105. (Spon: F.M. Skultety)

Parkinson's Disease is characterized by degeneration of the nigrestriatal pathway resulting in a loss of striatal dopamine (DA) and development of denervation supersensitivity in striatal dopamine (DA) and development of denervation supersensitivity in striatal dopamine (DA) and development of denervation supersensitivity in striatal dopaminergic receptors. The 6-hydroxydopamine (6-OHDA) lesion of DA neurons in the striatum has provided an animal model for this disease. The objective of the present study was to evaluate dopaminergic markers in this model following chronic treatment with either 1-dops or bromocriptine. DA receptors were measured using standard membrane binding techniques. <sup>3</sup>H-Spiroperidol (spiperone, <sup>3</sup>H-SP) was used as the ligand in concentrations from 0.1 nM to 10 nM in saturation gtudies. Specific binding represented the difference between <sup>3</sup>H-SP binding in the presence and absence of 1  $\mu$ M d-butaclamol. Data were anlyzed by Scatchard plot and by computer-assisted fitting using LIGAND. DA and dihydrate anesthesia received lesions of the right striatum by stereotraic injection of 8  $\mu$ g of 6-OHDA in 4  $\mu$ l of 0.02% ascorbate. Two weeks postoperatively animals were tested for contralateral rotational behavior with apomorphine (0.5 mg/kg i.p.), bromocriptine (2 mg/kg i.p.) or polyethylene glycol (vehicle) every 12 hrs for 30 days. Twenty-four hours after the last drug administration the animals were sacrificed and striata were dissected. Lesion with 6-OHDA produced a supersensitivity in dopamine receptors as indicated by an increase in Bmax of binding. This supersensitivity was reversed by either 1-dopa or bromocriptine treatment. Neither drug treatment affected DA or DOPAC levels were results suggest chronic administration of bromecriptine or 1-dopa reverses the denervation supersensitivity seen following -M-SP. Drug treatment affected DA or DOPAC levels compared to controls. These results suggest chronic administration and Sandoz, Inc. and BNS-7921105.

210.8 Neurochemical effects of L-dihydroxyphenylalanine (L-DOPA) on N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine-induced parkinsonian monkey. C.C. Chiueh, R.S. Burns\*, S.P. Markey\* and I.J. Kopin. Lab. of Clinical Science, NIMH, Bethesda, MD 20205. N-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine(NMPTP) produces a chronic and persistent extrapyramidal motor dysfunction in Rhesus monkeys (Burns et al., Proc. Nat. Acad. Sci. in press, 1983) which resembles the parkinsonian syndrome in drug abusers after i.v. administration of illicit synthetic batches of N-methyl-4phonyl A programma and the contaminant NMPTP (Dayis

monkeys (Burns et al., Proc. Nat. Acad. Sci. in press, 1983) which resembles the parkinsonian syndrome in drug abusers after i.v. administration of illicit synthetic batches of N-methyl-4 phenyl-4-propionoxypiperidine and the contaminant, NMPTP (Davis et al., Psych. Res. 1: 249-254, 1979; Drug Enforcement Agency Microgram 15: 165, 1982; Langston et. al., Science, 219: 979-980, 1983). However, NMPTP does not produce severe Parkinson's syndrome in animals other than primates (Chiueh et al., Proc. 5th Int. Catecholamine Symp. in press, 1983). The antiparkinsonian drug, L-DOPA, reversed the NMPTP induced extrapyramidal motor syndrome (flexed posture, rigidity, tremor, immobility, akinesea, freezing syndrome) in man and monkey. In the present experiment, we investigated the effects of L-DOPA on the metabolites of monoamines in the CSF of the monkey model of Parkinson's disease. The ventricular CSF was collected through a chronic implanted catheter in the lateral ventricle of

In the present experiment, we investigated the effects of L-DOPA on the metabolites of monoamines in the CSF of the monkey model of Parkinson's disease. The ventricular CSF was collected through a chronic implanted catheter in the lateral ventricle of monkey treated chronically with NMPTP. After the monkey developed extrapyramidal syndrome, L-DOPA(100-200 mg) and MK-486 (10-20 mg) were suspended in 50 ml of Tang orange drink and administered orally. The CSF was collected during 30 min intervals and assayed for L-DOPA, dopamine, serotonin and their metabolites by high performance liquid chromatograph. The basal levels of HVA, 5HIAA, and MHPG in CSF were decreased. As had been shown previously, L-DOPA effectively reversed the NMPTP-induced extrapyramidal syndrome. The behavioral effects of L-DOPA peaked at one hr and lasted for 3 hrs. This coincided with increased levels of domaine and L-DOPA. The CSF. The increase in HVA occurred much later and peaked at 3-4 hrs after administration of L-DOPA. The CSF levels of 0-methyl-DOPA, 5HIAA and MHPG also increased, but like HVA, did not correlate with the time-course of behavioral improvement.

Improvement. Despite dramatic decrease in striatal dopamine (5-10% of control) in the chronically treated monkey surviving dopaminergic terminals still appear to synthesize dopamine from L-DOPA and meet the demand of supply of dopamine in the nigrostriatal system. It is also possible that dopamine could be synthesized in the intact serotonergic neurons and reached the postsynaptic dopaminergic receptors in the striatum as a "false transmitter" (Mg et al., Science 170:76-77, 1970). Thus L-DOPA can be converted to dopamine even in dopamine deficient parkinsonian brain and reverses the extrapyramidal motor dysfunction following the chronic administration of NMPTP in primates.

210.9 CLINICAL RESPONSE TO L-DOPA DEPENDS UPON ITS ENTRY INTO BRAIN BY CLINICAL RESPONSE TO LODA DEPANS DION ITS ENTRY INTO BALLY BY LARCE NEUTRAL AMINO ACID TRANSPORT SYSTEM. J.G. Nutt, W.R. Woodward, and J.P. Hammerstad. Department of Neurology, Oregon Health Sciences University, Portland, Oregon 97201. L-DOPA crosses the blood-brain barrier by a saturable large neutral amino acid (LNAA) transport system. This potentially rate limiting step in the clinical response to L-DOPA has been investigated in 6 parkinsonian patients with a rapid fluctuating response to L-DOPA ("on-off" phenomenon). Patients received continuous intravenous infusions of L-DOPA producing constant plasma L-DOPA concentrations and therapeutic effects for 12 to 36 hours. During the infusion, the patients received various amino acids (100 mg/kg) administered orally in solution. The large neutral amino acids, L-phenylalanine, L-leucine, and L-isoleucine pro-duced a rapid and marked deterioration in the clinical response of the patients beginning 45 minutes after the administration of the amino acids and persisting for 2 to 6 hours with a gradual return to the optimal clinical state. The plasma L-DOPA concentrations were not altered by the amino acid administration. Glycine and lysine, both transported by other amino acid transport systems, had no effect on the therapeutic response or plasma L-DOPA level. High protein meals also abolished the clinical response to intravenously administered L-DOPA. The rise in plasma concentration of total LNAA's was similar after the high protein meal or phenylalanine administration.

These results suggest that transport of L-DOPA across the blood-brain barrier by the LNAA transport system can be a rate limiting step in the clinical response to L-DOPA and that the ratio of plasma L-DOPA concentration to total plasma LNAA concentration may correlate better with therapeutic effects than the plasma L-DOPA concentration alone.

THE EFFECT OF CHRONIC DOPAMINE AGONIST TREATMENT ON TYROSINE HYDROXYLASE ACTIVITY AND DOPAMINE-B-HYDROXYLASE ACTIVITY AND ON D-1 AND D-2 POST-SYNAPTIC DOPAMINE RECEPTORS. K.D. Wilner, I.J. Butler and Y.C. Clement-Cormier. Depts. of Pharmacology, Neuro-biology and Neurology, University of Texas Medical School, Houston, Texas 77025. 210.10

The effect of chronic levodopa or bromocriptine treatment was tested on D-1 and D-2 post-synaptic receptors in the striatum; and on tyrosine hydroxylase and dopamine- $\beta$ -hydroxylase activitested on D-1 and D-2 post-synaptic receptors in the striatum; and on tyrosine hydroxylase and dopamine-B-hydroxylase activi-ties as enzymatic markers of pre-synaptic neuronal activity in selected rat brain regions. Levodopa (1000 mg/kg) in combina-tion with carbidopa (100 mg/kg) was administered by the oral route whereas bromocriptine (10 mg/kg) was administered by the intraperitoneal route. Each study lasted for 28 days. At in-tervals, rats were sacrificed and (1) dopamine-sensitive adeny-late cyclase (D-1 receptor activity), (2) (<sup>3</sup>H)spiroperidol binding (D-2 binding sites), (3) tyrosine hydroxylase (TH) and (4) dopamine-B-hydroxylase (DBH) activities were evaluated after drug treatment. The data from these studies demonstrated D-1 receptor function after 1 day treatment as shown by a signifi-cant reduction in the Vmax for adenylate cyclase. However, af-ter 12 days of levodopa, there was no longer a change in maximal enzyme activity but there was a two-fold increase in the EC50 for dopamine. In contrast, bromocriptine treatment had no ap-parent effect on dopaming-sensitive adenylate cyclase activity. Binding studies using (<sup>3</sup>H)spiroperidol revealed a significant increase in D-2 binding sites after 5, 12 and 21 days of levodo-pa treatment. Yet bromocriptine produced no change in D-2 bind-ing studies using (<sup>3</sup>H)spiroperidol revealed a significant increase in D-2 binding sites after 5, 12 and 21 days of levodo-pa treatment. Yet bromocriptine produced no change in D-2 bind-ing studies using the mediate the studies of the discretion. pa treatment. Yet bromocriptine produced no change in D-2 bind-ing sites but did produce a three-fold increase in the dissocia-In sites but did produce a three-told increase in the dissola-tion constant compared to control after 12 days of treatment. Finally, both drug regimens differentially affected the enzyme markers of pre-synaptic neuronal activity. Levodopa, following 5 to 21 days, significantly increased the Ymax for the phospho-rylated and non-phosphorylated forms of tyrosine hydroxylase in rylated and non-phosphorylated forms of tyrosine hydroxylase in striatum and cortex whereas bromocriptine decreased the activity of both forms of the enzyme but only in the striatum. Levodopa dramatically reduced DBH activity in serum and brain regions after 12 to 21 days of treatment. In contrast, bromocriptine increased DBH activity. Possible causes for the alterations in enzyme activity after levodopa and bromocriptine treatment will be discussed. Still these results suggest that levodopa induces Increased DBH activity. Possible causes for the alterations in enzyme activity after levodopa and bromocriptine treatment will be discussed. Still these results suggest that levodopa induces excess dopaminergic activity whereas bromocriptine decreases this activity and thus, these two apparently opposing effects on the dopamine system may explain a possible biochemical mechanism for the success of combination levodopa and bromocriptine ther-apping the treatment of Parkinson's disease apy in the treatment of Parkinson's disease.

210.12 CHRONIC FLUPHENAZINE AND CLOZAPINE ELICIT OPPOSITE CHANGES IN BRAIN MUSCARINIC RECEPTOR BINDING. IMPLICATIONS FOR UNDERSTAND-ING TARDIVE DYSKINESIA. E. Friedman,\* G. Gianutsos, J. Kuster\*. Depts. of Psychiatry & Pharmacology, N.Y.U. School of Medicine, New York, NY 10016 and Section Pharmacology & Toxicology, UCoun, Storrs, CT 06268.

The effects of long-term treatment with the antipsychotic drugs haloperidol (HL), fluphenazine (F) and clozapine on brain dopaminergic and muscarinic receptor binding sites was examined. Mice were treated with HL and F in their drinking water (0.005 and  $0.001\%^W/v)$  or with clozapine-containing diet (0.075\%  $^W/w)$ for up to  $12_3$  weeks. The 3 neuroleptic drugs elicited increases in striatal H-spiroperidol binding. Muscarinic binding of H-QNB was decreased only in striatum of animals treated with HL on fluphenazine for 12 but not for 3 weeks. This reduction in binding density was not accompanied by alteration in K, nor was the relative distribution of high to low affinity agonist sites affected. Tolerance to fluphenazine-induced catalepsy was afterced. loterance to fluphenazine-induced catalepsy was obtained after 14 days, while catalepsy to a challenge dose of pilocarpine was observed after 42 days of fluphenazine treatment Twelve weeks of clozapine administration elicited increases in H-QNB binding densities in the striatum, cortex and hippocampus. No alteration in striatal muscarinic agonist sites was obtained in clozapine treated mice. Furthermore, no alteration in fluphenazine- or pilocarpine-elicited catalepsy was detected in clozapine-treated animals. Choline acetyltransferase activity was not affected by long-term fluphenazine treatment; however, clozapine administration induced an increase in striatal enzyme activity. These data indicate that while HL, fluphenazine and clozapine elicit increases in striatal dopamine receptor sensi-tivities, they differ with regard to their effects on brain muscarinic cholinergic receptors. This differential response may be attributed to the high antidopaminergic/low anticholinergic potency of HL and fluphenazine and the potent direct antimus-carinic efficacy of clozapine. These data suggest that the incidence of tardive dyskinesia during long-term treatment with antipsychotic drugs may be related to the ratio of dopamine supersensitivity/muscarinic subsensitivity induced by the drugs. 210.11 DOPAMINERGIC ACTIVITY IS REDUCED IN DIABETIC RATS. C. F. Saller\*

 DOPAMINERGIC ACTIVITY IS REDUCED IN DIABETIC RATS. C. F. Saller\*
 (Spon: M. E. Goldberg). Laboratory of Clinical Science, National
 Institute of Mental Health, Bethesda, MD 20205.
 Acute injections of D-glucose suppress the firing of
 nigrostriatal dopamine (DA)-containing neurons in chloral hydrate
 anesthetized rats [Saller and Chiodo, Science 210, 1269 (1980)]
 and reduce striatal DA release in conscious rats [McCaleb and
 Myers, Brain Res. Bull. 4, 651 (1979)]. Moreover, the number of
 striatal DA receptors, as evidenced by increased [\*H]spiperone
 binding to striatal membranes, appear to be increased at six and
 ten weeks after rats are made chronically hyperglycemic using
 either alloxan or streptozotocin to destroy insulin-secreting

 either alloxan or streptozotocin to destroy insulin-secreting cells [Lozovsky, Saller, and Kopin, <u>Science</u> <u>214</u>, 1031 (1981)]. These findings suggest that the increased number of DA receptors in diabetic rats might be a compensatory response to a reduction in the activity of striatal DA-containing neurons. To evaluate this hypothesis, rats were given either alloxan (185 mg/kg, s.c.) or saline (1 ml/kg, s.c.), and six weeks later dopaminergic activity hypothesis, rats were given either alloxan (185 mg/kg, s.c.) or saline (1 ml/kg, s.c.), and six weeks later dopaminergic activity was assessed by measuring the striatal levels of DA and its two major metabolites, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). Neither DA nor DOPAC concentrations in the diabetic rats were significantly different from control values. However, striatal HVA levels were 30% lower (p<0.05) in the diabetic rats (592 + 66 ng/g, mean + S.E.M.) than in controls (848 + 34 ng/g), suggesting that DA release may be reduced in diabetic rats. In addition, the biosynthetic capacity of DA-containing nerve terminals in the striatum of diabetic rats appears to be reduced. This was evidenced by a 27% decrease (g<0.05) in the V of synaptosomal ['H]DA synthesis from ['H]tyrosine in the diabetic rats (18.12 + 1.61 and 24.70 + 1.40 pmole/mg protein/min in diabetic and control animals, respectively). The K for tyrosine of the diabetic rats (0.61 + 0.05 µM) was also reduced (p<0.05) by 33% (controls, 0.91 + 0.07 µM). Thus, it appears that DA synthesis and release may be reduced in diabetic rats. Whether or not these effects are due to chronic hyperglycemia or hypoinsulinemia remains to be determined. Nonetheless, it is clear that dopaminergic transmission in the striatum is markedly affected by changes in carbohydrate metabolism, and it seems likely that the apparent increase in the number of striatal DA receptors in diabetic rats may be a consequence of a reduction in the activity of nigrostriatal DA-containing neurons. 210.13 MOLINDONE COMPARED TO HALOPERIDOL IN ANIMAL MODELS OF TARDIVE DYSKINESIA. W.C. Koller<sup>+</sup>, J.C. Curtin<sup>+</sup> and J.Z. Fields<sup>2</sup>. Neurology Research Lab., Loyola Univ. Coll. Med., Chicago<sup>+</sup> and Dept. Pharmacology, Chicago Med. Sch., North Chicago, IL<sup>2</sup>.

logy Research Lab., 1901a off. Net., Coll. Net., Chilago and Deft. Pharmacology, Chicago Med. Sch., North Chicago, IL. Tardive dyskinesia (TD) is a hyperkinetic movement disorder resulting from long term neuroleptic usage. Since TD may be irreversible and unresponsive to treatment, prevention of TD has become a major concern. The ability of various neuroleptic drugs to induce TD may differ. It is claimed that the newer neuroleptic, molindone, is less likely to induce TD. We have therefore compared molindone to the standard neuroleptic haloperidol in an animal model of TD. Both behavioral supersensitivity to dopamine agonists and alteration of striatal dopamine receptor binding were measured. Groups of 10 guinea pigs were initially challenged with apomorphine (0.4 mg/kg) and the behavioral response of each group recorded (pre-test). Animals were then treated for 12 days with saline or molindone (1,3, or 6 mg/kg) or haloperidol (0.1, 0.5 or 5.0 mg/kg). Six days after cessation of treatment, animals were re-challenged with apomorphine and stereotypy was measured (post-test). Two days after that, animals were sacrificed, the striatum removed, and binding of (3H) spiroperidol to striatal dopamine receptors was determined (Control Kd-29 MM, Bmax=13.9 fmol/mg tissue). Molindone at 1 mg/kg produced no change in stereotypy as compared to chronic saline. Molindone at 3 mg/kg produced a slight (+21%) but statistically significant increase in stereotypy. At 6 mg/kg, molindone produced an even greater behavioral increase (+55%). Behavioral supersensitivity was also seen with all haloperidol groups (+37% to 50%). In the haloperidol treated group, the maximu number of D-2 dopamine receptors labelled by high affinity (3H) spiroperidol binding was increased (+63 to +77%). At the same time, the affinity for these two groups simultaneously increased (+37%, +56%). These changes are consistent with the molindone-induced increases in stereotypy. Haloperidol is thought to be c 210.14 CHANGES IN MUSCARINIC CHOLINERGIC BINDING SITES FOLLOWING SPINAL CORD TRANSECTION. S.M. Lasley, J.K. Wamsleyt, J.E. Smitht and J. D. Lane. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107; † Department of Psychiatry, University of Utah Medical Center, Salt Lake City, UT 84132; and ‡ Department of Psychiatry, LSU Medical Center, Shreveport, LA 71130.

I Department of respendery, soo meaned to tenter, sincereport, and Irreversible spinal cord injury results in a flaccid paralysis (spinal shock) followed by the progressive evolution of hyperreflexia (spasticity). The neural mechanisms responsible for these events are hypothesized but only tentatively understood. To investigate potential effectors, adult cats were transected at the T5-7 level and maintained for periods of up to three months. Neurological signs were monitored. At selected time points, the animals were sacrificed and the lumbar cords removed. Frozen sections were processed for in vitro gutoradiography. After mounting, tissue was incubated with [<sup>3</sup>H]-N-methylscopolamine (lnM) in the absence or presence of carbachol or atropine, then affixed to LKB Ultrofilm. Compared to sham-operated controls, total binding was increased 10-11% during spinal shock, had returned to normal by 7 days, afterwhich it decreased slightly but not signfitcantly over the remaining time course. High affinity sites (sensitive to carbachol displacement) and low affinity sites were monitored, and differences were observed beginning circa 14 days which persisted up to 3 months. In the dorsal horn, there was a 38% increase in high affinity and concomitant decrease in low affinity binding. Based on the concept that high affinity sites are transported from the cell body to the terminals, and low affinity sites are those inserted into the membrane, i.e., "functional", the changes in the ventral horn could be due to loss of suprasegmental cholinergic input onto motorneurons, resulting in a denervation-like supresensitivity, i.e., increase in "functional" receptors. The change in the dorsal horn could be a down regulation of sites resulting from excess agonist assault due to hyper-reflexic arcs at the segmental level. It appears that two elements of plasticity are active in the dorsal and ventral horns. These changes could be a consequence of and/or result in spasticity. GABA, glycine and opioid binding in the same tissue w

210.15 ELECTROPHYSIOLOGICAL AND BIOCHEMICAL ANALYSIS OF CEREBELLAR SEROTONERGIC MECHANISMS IN THIAMINE DEFICIENCY. <u>Howard K.</u> Strahlendorf, Jean C. Strahlendorf, Rong-Sheng Lee\* and Kim Light<sup>+</sup>. Medical and Surgical Neurology and Physiology, Texas Tech Univ. Hlth. Sci. Ctr., Lubbock, TX 79430, †Univ. of Arkansas for Med. Sci. Little Rock, AR. Wernicke's encephalopathy is a neurologic disorder in which patients display gross motor abnormalities as a result of thiamine (Vitamin B<sub>1</sub>) deficiency (TD). A selective impairment of the high affinity neuronal uptake system for serotonin (S-HT) in rat cerebellar synaptosomes occurs as a result of thiamine deficiency.

Wenticke's encephalopathy is a neurologic disorder in which patients display gross motor abnormalities as a result of thiamine (Vitamin B<sub>1</sub>) deficiency (TD). A selective impairment of the high affinity neuronal uptake system for serotonin (5-HT) in rat cerebellar synaptosomes occurs as a result of thiamine deficiency. Recent ultrastructural and autoradiographic studies in rats have demonstrated a selective loss of labeling of cerebellar serotonergic nerve terminals in hypovitaminosis B<sub>1</sub>. A functional impairment of cerebellar 5-HT neurons should alter the responsiveness of target cells to 5-HT. These changes in cerebellar serotonin systems probably account for some of the neurologic signs of thiamine deficiency. The electrophysiological changes in the cerebellum induced by the lack of thiamine have not been studied: neither have the serotonin receptor binding properties been examined. Rats were fed a thiamine free diet for 5 weeks. Sensitivity of Purkinje cells (PC) to iontophoretic 5-HT was determined in urethane anesthetized animals. In controls 5-HT elicited three effects: 61% of the neurons were depressed; 27% of the cells responded biphasically, inhibition followed by excitation; and 11% of the neurons were excited. PC from TD rats responded solely with inhibition to 5-HT. Comparisons of threshold currents to elicit a just noticeable slowing of firing rate revealed a significant difference between control (8NA) and TD rats (2NA). The entire dose response curve from TD rats is qualitatively and significantly to the left. These data suggest that the response of cerebellar PC to 5-HT. Receptor binding assays are currently in progress utilizing <sup>3</sup>H-LSD as the ligand for 5-HT<sub>1</sub> and 5-HT<sub>2</sub> receptors. Preliminary results reveal no difference in binding properties of LSD between TD rats and controls (Kd and Bmax). However, analysis of the slopes from Hill plots reveal a Hill number greater than one in both TD rats and controls which suggests the existence of more than one serotonin receptor ( 210.16 EVIDENCE SUGGESTING ALTERATIONS IN CEREBELLAR HISTAMINERGIC MECHANISMS IN THIAMINE DEFICIENCY. Jean C. Strahlendorf, Howard K. Strahlendorf, Kim Light<sup>+</sup> and Munhyang Lee<sup>\*</sup>. Departments of Physiology and Medical and Surgical Neurology, Texas Tech Univ. Hith. Sci. Ctr., Lubbock, TX 79430, <sup>+</sup>Univ. of Arkansas for Med. Scis., Little Rock, AR 72201. Thiamine deficiency is believed to cause a relatively selective impairment of cerebellar serotonergic mechanisms. Other putative neurotransmitters in the cerebellum are, for the most, unaffected or only slightly compromised by thiamine deficiency, e. o. prepingenbrie GARA. Quitamate and aspartate. Histamine

Thiamine deficiency is believed to cause a relatively selective impairment of cerebellar serotonergic mechanisms. Other putative neurotransmitters in the cerebellum are, for the most, unaffected or only slightly compromised by thiamine deficiency, e.g. norepinephrine, GABA, glutamate and aspartate. Histamine however, has not been studied. The cerebellum has both histamine-l (H<sub>1</sub>) and histamine-2 (H<sub>2</sub>) receptors. It has been shown by others that Purkinje cells are primarily inhibited by iontophoretically applied histamine and this response is mediated by both H<sub>1</sub> and H<sub>2</sub> receptor subtypes. As part of our investigation of serotonergic mechanisms in thiamine deficiency (TD) we have uncovered large changes in cerebellar histamine receptor binding and apparent concomitant electrophysiologic changes. Utilizing "H-pyrilamine as H<sub>1</sub> receptor langd, a significant decrease in receptor number (gmax: Control - 0.1639; TD - 0.4043). These effects are intriguing in light of the apparent specificity of thiamine depletion for cerebellar neurotransmitter systems. Parallel assays done on cortical tissue from the same groups of animals showed no difference between controls and TD rats. Electrophysiological experiments examining the effect of histamine applied directly to Purkinje cells are underway. Preliminary results indicate Purkinje neurons may be more profoundly inhibited by histamine in TD rats. These data present a new finding that thiamine deficiency affects cerebellar histaminergic systems as well as serotonergic systems. Additional experiments are underway to confirm and expand these results. (Supported by the Institute for Nutritional Sciences, TTU).

GABAERGIC SYSTEM IN SCRAPIE INFECTED HAMSTERS. C. Masullo\*, M. Pocchiari\*, W.D. Lustt, C.J. Gibbs, Jr.\* and D.C. <u>Gajdusek</u>. Lab. of CNS Studies and tLab. of Neurochemistry, <u>NINCDS</u>, N.I.H., Bethesda, Md 20205. Golden Syrian hamsters inoculated with the 263K strain of 210.17

scrapie virus show an abnormal aggressive behaviour suggesting an alteration in the GABAergic system. Isonicotinic hydrazide, a drug that decreases the level of GABA, injected subcutaneously in control and scrapie infected hamsters induces tonic-clonic seizures in scrapie hamsters significantly earlier (P(t)<0.0000) than in control animals. These data indicate a derangement in the GABAergic GABAergic system we studied the concentration of GABA, glutamate, cyclic GMP and cyclic AMP in the brains of

control and scrapic infected hamsters. To minimize fixation artefact, 8 control and 8 scrapie infected hamsters were sacrified 56 days after inoculation during clinical disease by freezing in liquid nitrogen. Brains were removed and dissected at -20°C into three areas: cerebral cortex, cerebellum and brain stem. GABA and glutamate were determined by fluorometric methods and the cyclic nucleotides by radioimmunoassay. No significant alteration was detected in the

No significant alteration was detected in the concentration of GABA, glutamate, cGMP and cAMP in the brain regions tested in scrapie infected hamsters. This suggests that the GABAergic neurons might be spared by the scrapie virus and that the defect might be in the post-synaptic GABA receptor or dependent on other neurotransmitter systems which are closely related.

Further studies are in progress to evaluate the activity of the glutamic acid decarboxylase and GABA transaminase and to test the functionality of the GABA-benzodiazepinechloride receptor complex.

EFFECTS OF SOMAN ON ENERGY STATE AND SELECTED METABOLITES IN MOUSE BRAIN. <u>G.B. Viana and F.C. Kauffman</u> Department of Pharmacology and Experimental Therapeutics, University of 210.19 Maryland School of Medicine, Baltimore, Md., 21201.

The effects of soman (methylphosphonofiluoridic acid 1,2,2-trimethylpropyl ester) on various metabolites in mouse brain were examined 30 min after a single administration of either 175  $\mu g$  or 330  $\mu g/kg$  body weight of soman. The drug was administered subcutaneously and animals were killed by immersion in distribution (100) advised to the source of the source administered subcutaneously and animals were killed by immersion in liquid nitrogen. ATP, phosphocreatine (PCr), alanine, glutamate, GABA and citrate were measured by coupled enzymatic procedures. A dose-dependent increase in PCr was noted in the cerebral cortex and basal frontal part of the brain, however, concentrations of this intermediate remained constant in the brain stem and cerebellum. Increases in PCr occurred in the absence of any change in ATP. Administration of soman resulted in significant increases in glutamate and decreases in alanine in several brain regions. Patterns of change in the alanine:glutamate ratio were opposite to that noted after alanine:glutamate ratio were opposite to that noted after ischemic injury in which alanine:glutamate ratios increase (Conger<u>etal.</u>, J. Histochem. Cytochem. <u>26</u>: 423, 1978). These results suggest that the metabolic changes produced by soman cannot be ascribed to alterations secondary to ischemia. The possibility that soman stimulated oxidative metabolism in mouse brain is suggested by the finding that steady state concentrations of citrate were elevated in the cerebral cortex and brain stom of citrate or some and brain stem of mice exposed to soman. Increases in both PCr and ATP were observed when animals were

treated with 70-90  $\mu$ g/kg of soman 3 times over a 24 h period. The increase in high energy phosphate content does not appear to be sex related since ATP and PCr were elevated in various brain regions of both male and female mice. Animals that had received the low doses of soman over a 24 h period did not show alteration in steady state concentrations of glutamate, alanine or GABA.

The results indicate that exposure to sublethal amounts of soman produce a significant increase in high energy phosphate content in mouse brain. Changes in steady state concentrations of alanine, citrate and glutamate support the hypothesis that increases in high energy phosphate content after soman treatment may result from stimulation of metabolism via the citric acid cycle. It is not known whether these metabolic changes represent a primary action or occur secondary to stimulation of cholinergic systems. DIABETES IN RATS: ALTERED CENTRAL AND PERIPHERAL CATECHOLAMINE FUNCTION, AND EFFECTS OF MANIPULATING DIETARY FAT AND PROTEIN INTAKE. N.Rowland, J.N.Joyce, L.L.Bellush and M.J.Fregly\*. Depts Psychology and Physiology, Univ. Florida, Gainesville FL 32611. Mildly diabetic (D) rats showed a preference for dietary fat compared with nondiabetics (ND), but severely D rats self-select-ed a high protein regimen (Bartness & Rowland, Soc.Neurosci. 82). We now examine whether different diet selections have functional consequences. Rats were made D with streptozotocin (35 or 70 mg/ kg) and received chow for 1 mo. They and ND groups then received either high protein (50%P,40%C,10%F), high fat-protein (50%P,15%C 35%F), or normal (25%P,65%C,10%F) purified diets for 4-6 wk. Food intake, body weight, and metabolic data are presented at this meeting by Bellush & Rowland. The rats were then tested for amphetamine (AM, 3 mg/kg)-induced stereotypy in their home cage. All D rats showed decreased maximum intensity of stereotyped shiffing relative to ND, but the duration of activation was the same in both groups. No effect of diet type was evident. We subsequently found no difference in the amount of 3H-AM in the striatum of D and ND rats I hr after injection. These data agree with previous findings of decreased AM stereotypy (Marshall, 78), but do not confirm a partial restoration with high fat/protein. The decreased intensity does not simply reflect a behavioral ceiling effect in either group: 5 mg/kg AM produced stronger stereotypy in both D and ND, and the behavioral ratings of the D rats were now comparable to those observed in the ND after 3 mg/kg AM. We also examined the behavioral response to the dopamine (DA) receptor agonist apomorphine (APO, 1 mg/kg). The maximum stereo-typy rating was not different between the D and ND rats; the duration of the behavioral activation was much reduced in D. Again, no dietary effects were noted. A presynaptic dose of APO (.05 mg/kg) produced comparable decreases in open field activity of D severity of diabetes.

severity of diabetes. Peripheral B-adrenergic function was assessed using isoproterenol (ISO). ISO (5  $\mu$ g/kg) produced larger maximal increases in heart rate in D (125 bm) than ND (70 bpm). However, tail skin temperature rise with ISO (25  $\mu$ g/kg) was less in D (basal 32.5°C, max 33.2°) than in ND (basal 28.4°, max 33.8°). There were no differences in colonic temperature. We are currently assessing whether the difference in basal tail skin temperature reflects altered BMR. We shall present data on  $\beta$ -receptor binding to heart and cerebral cortex; parallel data from saturated vs. unsaturated high fat diets for ISO and AM responses are being collected.

210.20 PHARMACOLOGICAL AND NEUROCHEMICAL CHANGES FOLLOWING CHRONIC Y-BUTYROLACTONE: A POSSIBLE GABAERGIC ROLE IN A MODEL OF DEPRES-SION. <u>P.D. Suzdak and G. Gianutsos</u>. Section of Pharmacology and Toxicology, University of Connecticut, Storrs, CT 06268

Numerous investigations into the mechanism of action of antidepressant drugs have focused on the change in amine receptor function induced by long-term drug administration, with a decrease in  $\beta$ -adrenergic receptors gaining favor as a possible model (Sulser, Pharmakopsychiat. Neuropsychopharm.  $\underline{11}$ :43, 1978) We have been interested in the pharmacological effects of We have been interested in the pharmacological effects of y-butyrolactone (GBL), an analog of GABA which produces a down-regulation of GABA receptors following long-term treatment (Suz-dak & Gianutsos, Fed. Proc. <u>42</u>:878, 1983). Long-term oral admini-stration of GBL (0.75% v/v in fruit punch) to mice also resulted in a 23% decrease in maximal specific binding of H-DHA, a ligand which labels  $\beta$ -adrenergic receptors, in the "frontal" cortex without affecting binding in the hippocampus. These results suggest that a) GBL may be an effective antidepressant drug; b) GABA may be involved in depression; and/or c) GABA neurons participate in the regulatin of eta-adrenergic function in the cortex. In order to test the first hypothesis, GBL (5-100 mg/kg) was tested for activity in the Porsolt behavioral despair test (Arch. Int. Pharmacodyn. 229:327, 1977). GBL was at best only weakly active after acute administration. However, after chronic GBL administration, the dose-response curve for the tricyclic antidepressant, imipramine, was shifted to the left. Furthermore, small doses (10-20 mg/kg) of the GABA-T inhibitor aminooxyacetic acid (AOAA) were found to be active in this test for potential antidepressant activity. These results may suggest a possible role for GABA in depression.

PROPHYLACTIC AND REVERSAL EFFECTS OF PROLYL-LEUCYL-GLYCINAMIDE 210.21 (PLC)(NDOPAMINE RECEPTOR SUPERSENSITIVITY. P. Chiu+G.Rajakumar\* and R.K. Mishra\*(SPON: M. Steiner). Dept. of Psychiatry and and R.K. Mishra\*(SPON: M. Steiner). Dept. of Psychiatry and Neurosciences, McMaster Univ., Hamilton, Ontario Canada. Tardive dyskinesia, a major adverse effect associated with chronic neuroleptic therapy reflects the presence of hyper-sensitive postsynaptic dopamine receptors in the basal ganglig. PLC has been found to preferentially enhance the affinity of apomorphine binding to dopamine receptors in human and rat brains, and reverse the morphine- and haloperidol-induced catalepsy in rats. This suggests that PLG binding sites are catalepsy in rats. Inis suggests that ris binding sites are capable of differentially modulating dopaminergic neuro-transmission. In the present study, the possible desensitizing effect of PLG on dopamine receptor supersensitivity was examined. Four groups of six rats per group received various drug treatment: Groups 1 and 3 A,B,C were given isotonic saline (1 m1/kg, ip) daily for 28 days; Groups 2, 4 A,B,C received haloperidol treatment (3 mg/kg, ip) daily for 28 days. Groups 3 A,B,C and 4 A,B,C were treated with PLC (20 mg/kg sc) daily, for A, b, c and 4 A, b, c were treated with FLS (20 mg/kg sc) daily, for 5 days prior to, and 5, 10 days after saline or HAL treatment respectively. Animals were sacrificed 5 days after the last drug session and dopamine receptor binding eas carried out on striata of each rat with ('H) spiroperidol as radioligand and 1 um butaclamal as displacing agent. Binding data were analyzed by Scatchard plot.

Our data indicate that chronic haloperidol treatment induced supersensitivity of dopamine receptors as evidenced by an enhancement of  $\binom{1}{H}$  spiroperidol binding sites in the striatum of the treated group. Administration of PLG prior to and after chronic HAL administration inhibited the supersensitivity of dopamine receptors as shown by a statistically significant decrease in B max (the number of maximal binding sites). Th longer treatment group exhibited a more dramatic reversal effect of PLG. In all drug treatment groups no statistically (K<sub>p</sub>). Administration of PLG alone to saline treated rats did not modify specific (<sup>4</sup>H) spiroperidol binding.

Our findings suggest that PLG can effectively prevent or reverse the fully developed dopamine receptor supersensitivity, and that this PLG mediated biochemical antagonism of altered receptor sensitivity in the striatum is reflected primarily in the relative density of the ligand binding sites. Clinically, PLG should be considered as a potential prophylactic and therapeutic antidyskinetic agent in the management of tardive dyskinesia.

### REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS II

IDENTIFICATION OF PICROTOXIN/BARBITURATE BINDING SITES IN RAT BRAIN BY LICHT MICROSCOPIC AUTORADIOGRAPHY WITH  $[3^{5}S]$ -t-BUTYL-BICYCLOPHOSPHOTHIONATE. K.W.Gee, J.K.Wamsley<sup>+</sup> and H.I.Yamamura. Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724 and <sup>+</sup>Department of Psychiatry, University of Utah Medical Center, Salt Lake City, Utah 84132. t-Butyl-Dicyclophosphothionate(TBT) is a potent convulsant cent of hor horo churp to inbhit CAMA constructed and an in 211.1

agent and has been shown to inhibit GABA neurotransmission in electrophysiological studies. Its ability to displace  ${}^{3}\text{H}$ -dihydro-picrotoxin binding suggests that TBT produces its convulsant ef-fect through the picrotoxin/barbiturate(P/B) site. The specific binding of  ${}^{35}\text{S}$ -TBT in rat brain has been recently demonstrated by a filtration binding assay(Squires et al.,1983).  ${}^{35}\text{S}$ -TBT binds biliding of  $3^{-1}$  bills in the offen into the state of  $3^{-1}$  bills in a filtration binding assay(Squires et al., 1983).  $3^{-1}$  S-TBT binds to P/B sensitive sites with high affinity(K<sub>d</sub>=17 nM) and with relatively low non-specific binding. In the present study we deto 1/2 sensitive sites with high altituty  $(a_1, a_2)$  and  $(a_2, a_3)$  to be a study we describe the distribution of  $^{35}$ S-TBT binding sites in the rat brain by light microscopic autoradiography.

By light microscopic autoradiography. Freshly removed whole rat brains from male Sprague-Dawley rats were prepared for microtome sectioning by coating in plastic em-bedding medium and freezing onto microtome chucks+liquid nitrogen. Coronal sections of brain(10  $\mu$ m) were cut and thaw mounted onto microscope slides. Slide mounted sections were preincubated in 5 mM Tris buffer, pH 7.4(+200 mM KCl & 1 mM EDTA) at 25°C for 90 min. Incubations were terminated by rinsing in Tris buffer and distilled Ho. distilled H2O. Sections were air dryed and autoradiographs pre pared by exposing the sections to tritium-sensitive film for 10 days at 4<sup>0</sup>C.

Under the conditions used, specific binding accounted for approximately 60% of the total  $^{35}$ S-TBT bound. Most brain regions were uniformly labelled with a significant amount of specific binding. A high degree of specific labelling was observed in the granule cell layer of the cerebellum; lamina I & IV of the cerebral cortex; the zona incerta; subthalamic nucleus and the para-fascicular nucleus. Moderate binding was observed in the caudate/ putamen; molecular layer of the cerebellum; stratum oriens(CAl) of the hippocampus and the inferior olivary nucleus. Binding in white matter areas was slightly above background. The regional White matter areas was slightly above background. The regional distribution is somewhat similar to the observations made in corresponding brain regions using a filtration binding assay. In conclusion, <sup>35</sup>S-TBT appears to be a suitable radioligand for light microscopic visualization of the P/B binding site in the rat brain. (Supported by PHS grants MH-27257 and MH-30626, KWG is a recipient of a RSDA type II(MH-00095))

NON-CORRESPONDENCE OF <sup>3</sup>H-GABA UPTAKE AND GAD LOCALIZATION: 211.2 TWO POTENTIAL MARKERS OF GABAergic AMACRINE CELLS IN GOLDFISH RETINA.

POTENTIAL MARKERS OF GABAergic AMACKINE CELLS IN GOLDFISH RETINA. C.L. Zucker & S. Yazulla, Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY, and J-Y. Wu, Dept. of Cell Biology, Baylor College of Medicine, Houston, TX. In retina, as well as many other regions of the CNS, GABA is a strong candidate as an inhibitory transmitter. Uptake of  ${}^{3}\text{H-GABA}$ or the presence of the GABA biosynthetic enzyme glutamic acid de-carboxylase (GAD) have both been used as markers for GABAergic function. The accumption has how mode that either one is a good function. The assumption has been made that either one is a good probe to identify a cell population which uses GABA as its transmitter. In the inner plexiform layer (IPL) of the goldfish retina, GAD immunoreactivity (GAD-IR) and <sup>3</sup>H-GABA uptake have been local-ized to amacrine cell processes in a similar but not identical labeling pattern. Unistatified pyriform amacrine cells which ram-ify in the proximal 20% of the IPL and make many synaptic contacts with Mb bipolar cell terminals take up  $^3H-GABA$ . Uptake by this cell type accounts for the very dense autoradiographic labeling seen in the proximal IPL relative to more distal laminae. In contrast to this, GAD-IR is found throughout the IPL with strong bands at the 20%, 50% and 80% levels. Although coexistense of  ${}^{3}\text{H-GABA}$ uptake and GAD has generally been assumed, it has not been demon-strated. We have used a double labeling technique (EM immunocytochemistry/autoradiography) to study the correlation between these two markers in goldfish amacrine cells. GAD-IR is found in ama-crine cell processes which make synapses onto the processes of other amacrine cells (which may or may not contain GAD-IR), bi-polar cells, and possibly ganglion cells. In most cases, GAD con-taining processes do not take up <sup>3</sup>H-GABA. Processes that accumu-late <sup>3</sup>H-GABA are found adjacent to and occasionally postsynaptic but never presynaptic to GAD-IR processes. Many processes taking  $^{3}$ H-GABA are not associated with GAD containing processes. The only examples of coexistence of  $^{3}$ H-GABA uptake and GAD-IR are when two or more GAD-IR processes are adjacent to or in a synaptic re-lationship with each other. The speciousness of <sup>3</sup>H-GABA uptake is seen further in synapses involving bipolar cell terminals where is seen further in synapses involving bipolar cell terminals where neither presynaptic GAD-IR processes nor the postsynaptic terminals take up  ${}^{3}\text{H}$ -GABA, unless two or more presynaptic GAD-IR terminals are adjacent to each other. These relationships are consistent throughout the IPL. This study suggests that in goldfish IPL, GAD-IR is a marker for GABA releasing neurons, whereas  ${}^{3}\text{H}$ -GABA uptake is not.  ${}^{3}\text{H}$ -GABA uptake may be involved in the inactivation of GABA after release, however, its localization provides equiv-ocal results regarding the actual location of GABAergic synapses. AUTORADIOGRAPHIC DISTRIBUTION OF GLUTAMATE RECEPTOR SUBCLASSES 211.3 AllocableGaphic Distribution of GLUTAMAIE RECEPTOR SUBCLASSES IN RAT BRAIN. D.T. Monaghan<sup>\*</sup>, V.R. Holets, D.W. Toy<sup>\*</sup> and C.W. Cotman. Psychobiology Dept., Univ. of Cal., Irvine, CA 92717. The action of glutamate in the CNS is mediated by multiple receptors. Four acidic amino acid receptors have been charactretrief physiologically by their selective sensitivity to N-methyl-D-aspartate (NMDA), kainic acid (KA), quisqualate, and 2-amino-4-phosphonobutyric acid (APB). We now report that receptor subtypes can be localized autoradiographically using  $^{3}H^{-1}$ Leglutamate. Rat brain tissue sections were incubated at 30°C for 30 min. with 100 nM <sup>3</sup>H-L-glutamate. After rinsing and drying, the sections were placed against LKB <sup>3</sup>H-Ultrofilm for 10-30 days, then analyzed by quantitative densitometry. Our results indicate that there are at least 4 distinct <sup>3</sup>H-L-

Glutamate binding sites. The differing sites exhibit a similar affinity for L-glutamate ( $k_D = 0.7$  uM), yet have distinctly different distributions and pharmacologies. The major population appears to represent the NMDA receptor. The affinity of both NMDA and D-2-amino-5-phosphonovaleric acid (D-APV) is approxi-Much and D-2-amino-3-phosphonovalence acts (D-ArV) is approxi-mately 2 uM whereas L-APV, APB, KA, and quisqualate are con-siderably less potent. The distribution of these sites is quite anatomically specific. In the hippocampus the greatest density of these sites is found in the CAI stratum radiatum. In general, the distribution is appropriate for a corticofugal and allocort-

the distribution is appropriate for a corticotugal and allocat-ical neurotransmitter. Differing subdivisions within the cere-bral cortex, basal ganglia, thalamus, hypothalamus, amygdala, septum, brain stem and other regions are readily differentiated. A second site is NMDA-insensitive  $(k_i > 100 \text{ uM})$  but easily displaced by quisqualate and KA (KA  $k_i = 70 \text{ mM}$ ). The most dense localization of these sites is within the stratum lucidum of the hippocampus. The distribution of these sites and their affinity for both glutamate and kainate suggest that these sites are the previously described <sup>3</sup>H-KA binding sites. A third population of glutamate binding sites are those which

A third population of glutamate binding sites are those which are not displaced by either NMDA or KA. In the hippocampal formation these sites are found enriched in the stratum oriens and subiculum. A fourth population is found when  $Ca^{++}$  and  $Cl^{-}$ ions are added. These sites are also NMDA and KA insensitive but within the hippocampus these sites are found within the stratum lacunosum-moleculare and in the molecular layer of the dentate gyrus. None of the glutamate binding sites observed in this budy memory to expresent to make a layer for a layer of in this study appears to correspond to major class of glutamate binding sites that have been extensively characterized in membrane preparations.

These data demonstrate that there are multiple populations of glutamate binding sites and that at least two of these may represent acidic amino acid receptors which have been shown to be involved in neurotransmission.

211.5 TO WHAT EXTENT DOES [H-3]SPIPERONE LABEL, SEROTONIN RECEPTORS IN VIVO? D.C. Chugani, J.R. Barrio and M.E. Phelps. Departments of Pharmacology and Radiological Sciences, Division of Biophysics, UCLA School of Medicine, Los Angeles, CA 90024.

To define the requirements for imaging human neuroreceptors vivo with [F-18]spiperone and positron computed tomography, To define the requirements for imaging human neuroreceptors in vivo with [F-18]spiperone and positron computed tomography, it is important to fully characterize spiperone's (SP) in vivo binding properties. In particular, the resolution of its serotonergic and dopaminergic components is critical. In order to correlate the in vivo localization of SP with the large body of in vitro SP binding data, we compared the anatomical localization of [H-3]SP using contact autoradiography (LKB tritium sensitive film) with rat brain sections labeled by intravenous administration (1000  $\mu$ Ci/kg, 17 Ci/mmol, sacrifice at 2 hr) (in vivo) to sections labeled by incubation in buffer containing [H-3]SP (1 nM, 17 Ci/mmol, 30 min incubation, two 5 min washes) (in vitro). Visual examination of the autoradiographs revealed several striking differences between the in vivo and in vitro sections: a. the choroid plexus was heavily labeled in vitro, but not in vitro; b. the hippocampus was heavily labeled in vitro, but not in vivo; and c. the cortex, especially lamina IV, was more heavily in vitro than in vivo. Microdensitometry was used to quantify this cortical difference in sections matched for similar optical density in striatum after 4 weeks of film exposure. The mean ratio of optical density in striatum to lamina IV was 4.8 in vivo and 1.3 in vitro. Labeling in the choroid plexus in vivo inght be attributed to a high rate of delivery of SP to this tissue coupled with nonspecific bind-ing. The significance of the hippocampal binding in vitro is not clear because it has been reported that it is not delivery of SP to this tissue coupled with nonspecific bind-ing. The significance of the hippocampal binding in vitro is not clear because it has been reported that it is not displaceable by either dopaminergic or serotonergic drugs. The fact that SP binding in cortical lamina IV was considerably less in vivo than in vitro, however, is very important as these sites have been reported to be solely serotonergic in nature (Palacios, J.M., et al, <u>Brain Research</u>, <u>213</u>:277, 1981). This finding suggests that SP may be more selective for dopamine receptors in vivo than in vitro. The selective retention of SP at dopaminergic sites 2 hours after intravenous injection may be a reflection of the 3-4 fold higher <u>in vitro</u> dissociation rate constant for SP at seroton-ergic sites as compared to dopaminergic sites. ergic sites as compared to dopaminergic sites.

AUTORADIOGRAPHIC LOCALIZATION OF BENZODIAZEPINE RECEPTOR 211.4 SUBTYPES IN <u>SPASTIC</u> AND CONTROL MICE USING A COMPUTERIZED SINGLE BIT PLANE IMAGE ANALYSIS SYSTEM. L.J. Regan<sup>#</sup> AND W.F. White (SPON: T.O. Fox). Department of Neuroscience, Children's Hospital, and Neuropathology, Harvard Medical School, Boston, MA, 02115.

Behavioral and electromyographic abnormalities observed in the mutant mouse <u>spastic</u> suggest a decrease in inhibitory neurotransmitter function. Pharmacolgic and receptor binding neurotransmitter function. rnarmacolgic and receptor binding studies suggest that there is a decrease in inhibitory neurotransmission mediated by glycine; there is an 80-90%decrease in binding to the postsynaptic glycine receptor in the spinal cord, brainstem, and midbrain of <u>spatic</u> compared with littermate control mice. In addition there is an increase in the binding of ligands for both the GABA and benzodiazepine receptors and this increase appears dependent on the relative receptors and this increase appears dependent on the relative density of glycine to GABA or benzodiazepine receptors. These data suggest the possibility of interregulation between inhibitory neurotransmitters in the affected regions. In order to further localize and characterize the nature of the increase in benzodiazepine receptor binding observed in the mutant mouse <u>spastic</u> autoradiographic analyses of benzodiazepine binding were performed on "H-flunitrazepam binding to cryostat sections of <u>spastic</u> and control lumbar, thoracic, and cervical spinal cord, brainstem, and midbrain using diffusable substance <u>spasiin</u> and control lumbar, thoracic, and cervical spinal cord, brainstem, and midbrain using diffusable substance autoradiographic techniques. Benzodiazepine receptor subtypes were investigated using 1 uM clonazepam, 1 uM Ro5-4864, 200 nM CL 218,872, 10 uM GABA, and 10 uM diazepam to define nonneuronal, neuronal, type 1 and 2, GABA potentiated, and nonspecific binding. The procedures described in "Quantification of microautoradiograms by single bit plane image analysis (this meeting) were used to analyse the autoradiogram and quantitate the binding in fmoles bound per mg dry weight. Two dimensional maps of receptor density were used to localize benzodiazepine receptor subtype density and to compare densities between homologous regions in the <u>spastic</u> and control animals. Supported by N.I.H. Grants NS18584, NS16278, and HD06276.

211.6 <sup>3</sup>H-SPIPERONE BINDING TO DOPAMINE-2 RECEPTORS IN AREA POSTREMA AND OTHER BRAINSTEM AREAS REGULATING EMESIS. N. W. Pedigo and K. R. Brizzee. Dept. Pharmacology, Louisiana State Univ. Med. Ctr., New Orleans, LA.

POSIREMA AND OTHER BRAINSTEM AREAS REGULATING EMESTS. N. W. Pedigo and K. R. Brizzee. Dept. Pharmacology, Louisiana State Univ. Med. Ctr., New Orleans, LA. 70112 and Neurobiology Lab, Delta Regional Primate Ctr., Covington, LA. 70433. Dopamine receptor antagonists may exert their anti-emetic effects via peripheral dopamine receptors, dop-amine type-2(D2) receptors in the area postrema (AP) or D2 receptors in other brainstem areas regulating emesis. The purpose of these studies was to character-ize D2 receptors in bovine AP, vagal nuclear complex (VNC), including nucleus tractus solatarius and dorsal motor nucleus of the vagus, reticular formation (RF), and vestibular<sub>3</sub> complex (VC). Specific binding of H-spiperone (H-S) to D2 receptors in brainstem tissue was defined at equilibrium (30 min at 37°C) using 10µM (+)butaclamol or chlorpromazine. The AP is rich in 'H-S binding sites, measured at a saturating concentration of ligand (2.7nM), as is bovine VNC (572 ± 84 and 335 ± 37 fmol/mg protein, respectively). In comparison, bovine caudate nucleus has only 50% more binding (about 800 fmol/mg protein), while RF and VC have considerably fewer 'H-S binding sites (167 ± 17 and 150 ± 26 fmol/mg protein, respectively. In-terestingly, CPZ and THI are each very effective in preventing motion-induced emesis in squirrel monkeys, whereas DOM is only partially effective. This indi-cates that CPZ and THI may exert additional antiemetic attivity at D2 receptors in other brainstem areas, such as VNC, or through other neurotransmitter systems. For example, CPZ has significant anticholinergic activity, but THI and DOM are much weaker muscarinic blockers. Muscarinic cholinergic receptors are heterogeneously distributed in bovine brainstem (VC), and are indefinition of the reception and the state of the set of the state of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set of the set o

but IH1 and DUM are much weaker muscarinic blockers. Muscarinic cholinergic receptors are heterogeneously distributed in bovine brainstem (VNC>RF>VC), and are also found in AP. Hence, it is likely that the anti-emetic activity of these drugs is due to a combination of antidopaminergic, antimuscarinic and, possibly, antihistaminergic effects mediated via specific brain-stem nuclei and the area postrema. (Supported in part by the E. G. Schleider Foundation, NASA-Ames NAC-2-101 and NIH RR00164).

211.8 AUTORADIOGRAPHIC LOCALIZATION OF MUSCARINIC RECEPTOR AGONIST BINDING SITES USING [<sup>3</sup>H]-CIS METHYLDIOXOLANE. J. K. Wamsley, W. R. Roeske\* and H. I. Yamamura. Dept. of Psychiatry, University of Utah, Salt Lake City, UT 84132 and Dept. of Pharmacology, University of Arizona, Tucson, AZ 85724.

Displacement of radiolabeled muscarinic antagonists using muscarinic agonists, has been used to indirectly demonstrate muscarinic receptor heterogeneity (Birdsall <u>et al.</u>, Mol. Pharmacol. 14:723-736, 1978). Microscopic localization of the high affinity vs. low affinity agonist sites has been accomplished using carbachol displacement of  $[^3H]$ -N methyl scopolamine binding. This study indicated the high affinity sites exist independently in many distinct brain regions (Wamsley <u>et al.</u>, <u>Brain Res. 200</u>:1-12, 1980). Direct labeling of muscarinic receptors with a tritiated form of the agonist cis methyldioxolane ( $[^3H]$ -CD) had been attained in membrane homogenate preparations and demonstrate the specificity of this ligand for the muscarinic receptor (Ehlert <u>et al.</u>, <u>Life Sci. 26</u>:961-967, 1980). We have labeled slide mounted tissue sections with [ $^{3}H$ ]-CD in order to microscopically localize the binding sites for this compound using receptor autoradio-graphic techniques.

Slide mounted sections of rat brain were pre-incubated 20 minutes in ice cold 10mM sodium potassium phosphate buffer containing 200MM sucrose. This was followed by a 120 minute incubation period in the same buffer containing  $5^{\rm M}$  [<sup>3</sup>H]-CD with a subsequent momentary rinse in fresh buffer. Nonspecific binding was represented on adjacent sections labeled using the same parameters with the added presence of 1 micromolar atropine. Labeled sections were rapidly dried, apposed to a sheet of LKB Ultrofilm in an X-ray cassette and allowed to expose the emulsion for several weeks. After development of the film, the receptor autoradiograms were analyzed by computer assisted microdensitometry. Muscarlnic agonists characteristically show only small amounts of specific binding and this study was no exception. However, examination of the receptor autoradiograms showed the presence of highly specific labeling concentrated in many discrete regions of the brain. These include several lamina of Broca, anterior thalamic nuclei, olfactory tubercle, lateral posterior nucleus of the thalamus, facial nerve nucleus, nucleus tractus solitarius and the nucleus of the hypoglossal nerve. Thus, these regions represent the subpopulation of muscarinic receptors preferentially labeled by agonist (high affinity sites) as evidenced by direct labeling with [<sup>3</sup>H]-CD.

211.9 IN VIVO MUSCARINIC RECEPTOR BINDING. K. A. Frey, R. L. Ehrenkaufer\* and B. W. Agranoff. Neuroscience Lab and Division of Nuclear Medicine, University of Michigan, Ann Arbor, MI 48109. The recent advent of <u>in vitro</u> autoradiographic methods for regional visualization of neurotransmitter receptors in animals has encouraged clinical neuroscientists to seek analogous receptor images in humans using emission computed tomography. We report here progress towards quantitative <u>in vivo</u> imaging of muscarinic receptors using [<sup>3</sup>H]scopolamine in rats. [Methyl-<sup>3</sup>H]scopolamine was synthesized by heating (-)norscopolamine with [<sup>3</sup>H]methyl iodide. The product was purified by thin layer chromatography using tetrahydrofuran-diisopropylethylamine (95: 5) as solvent. [<sup>3</sup>H]Scopolamine was administered intravenously to rats using an infusion protocol calculated to yield constant arterial plasma concentrations. At various times following initiation of the infusion, animals were killed and samples of discrete brain regions were extracted with ethanol. Scopolamine concentration was quantitated following chromatography. Regional scopolamine uptake was greatest in the striatum, with lower values in cerebral cortex and hippocampus. Cerebellar uptake was still lower (cortex/cerebellum = 7:1 after 240 min of infusion). Binding was displaced by carrier scopolamine and by atropine, but not by methyl scopolamine. A model is presented which describes regional tracer uptake in terms of muscarinic receptor density, cerebral blood flow and capillary permeability, and endogenous neurotransmitter levels. Potential clinical applications of the method will be discussed. (Supported by NIH Grant NS 15655.)

211.10 LOCALIZATION OF MUSCARINIC ACETYLCHOLINE RECEPTORS IN CINGULATE CORTEX. <u>Brent A. Vogt</u>. Dept. of Anatomy, Boston University School of Medicine, Boston, MA 02118.

Cingulate cortex is considered to be a major component in the cholinergic limbic system because of its extensive acetylcholinesterase (AChE) activity. However, very little is known of the distribution of muscarinic acetylcholine receptors (AChR) in this cortex and nothing is known about their association with specific afferents and AChE-positive axons.

The distribution of AChR was assessed by determining the specific binding of <sup>3</sup>H-propylbenzilylcholine mustard (PrBCM; 2.4 nM) to cryostat sections of rat brains using standard autoradiographic techniques. Specific binding was defined as the total number of autoradiographic grains/2500  $\mu m^2$  minus the number of grains in control sections incubated in atropine (10<sup>-6</sup> M) and PrBCM.

Binding of PrBCM throughout all layers of anterior area 24 was relatively even (67.7 $\pm$ 8.7 grains/2500  $\mu$ m<sup>2</sup>). In contrast, area 29c of posterior cingulate cortex had particularly high levels of binding in layers Ia and IV (116 $\pm$ 18.1 and 75 $\pm$ 7.8, respectively), while the mean for all other layers was 54.9 $\pm$ 9.4. Since these two layers of the rat area 29c receive most afferents from the anterior thalamic nuclei (ATN), the hypothesis was explored that these receptors are localized to the axons of this afferent.

Ablations of the ATN were made and PrBCM binding and ACùE (Koelle method) assayed 2 days to 2 weeks postoperatively in serial sections. PrBCM binding was reduced 41% in layer Ia and 27% in layer IV, while no changes were apparent in other layers. Microdensitometric measurements indicated a loss of AChE activity also in layers Ia and IV. Since these losses appeared very soon after lesion placement (2-3 days) at a time when axons have begun to undergo morphologically distinct degeneration but are not yet pinched from the postsynaptic element, it is presumed that these changes are associated with axonal changes and possibly reduced transport of receptors from the ATN to area 29c.

Since undercut lesions also only reduce binding in layers Ia and IV, it is concluded that the heterogeneity of AChR binding in area 29c is due almost entirely to the ATN axonal receptors. All other binding, therefore, is intrinsic to cingulate cortex, i.e. nonsynaptic dendritic, postsynaptic and/or presynaptic to intrinsic neurons. Finally, the same axons that have AChR are also AChEpositive. Since lesions of the ATN do not alter activity of the synthetic enzyme choline acetyltransferase, it is proposed that these afferents may not be cholinergic. Rather, the release of an unknown transmitter from ATN afferents may be presynaptically modified by acetylcholine.Supported by grants NS 18745 and 16841. 211.11 EVIDENCE FOR A CHOLINERGIC INNERVATION TO FACIAL MOTONEURONS OF THE RAT. D. B. Hoover and J. C. Hancock. Dept. of Pharmacology, Quillen-Dishner College of Med., East Tenn. State Univ., Johnson City, TN 37614. The facial nucleus (FN) is one of several cranial nerve

The facial nucleus (FN) is one of several cranial nerve nuclei reported to contain a high density of muscarinic receptors (Brain Res. Rev. <u>1</u>: 167-183, 1979; J. Neurosci. <u>1</u>: 176-191, 1981). Although it is recognized that efferent cholinergic neurons in the FN supply skeletal muscles of the face, the cellular localization and function of muscarinic receptors in this region are unknown. The aim of the present study was to determine whether these muscarinic receptors are associated with the motoneurons. Previous studies have demonstrated that cholinergic efferent neurons in the hypoglossal nucleus and dorsal motor nucleus of the vagus (J. Anat. <u>107</u>: 197-208, 1970) lose acetylcholinesterase (AChE) in response to axotomy. This change presumably reflects a generalized deficiency in protein synthesis by the damaged neurons. Therefore, receptors normally synthesized by the efferent neurons should likewise be depleted after axotomy. Making this assumption, we examined the effect of facial nerve transection on the localization of AChE and [<sup>3</sup>H]quinuclidinyl benzilate ([<sup>3</sup>H]QNB) binding in rat FN. Male Sprague Dawley rats were anesthetized with pentobarbi-

Ache and L'Hiquinucliainyl benzilate (L'HiQNB) binding in rat FN. Male Sprague Dawley rats were anesthetized with pentobarbital, and an incision was made candal to the external auditory meatus. The right facial nerve was isolated and cut in experimental animals. Fourteen days after surgery, animals were decapitated and their brains removed for analysis. Brain stems were frozen on specimen plates and transverse sections were cut for thionin staining, QBN autoradiography, and AChE histochemistry. Sections for autoradiography were incubated in 1 nM [<sup>3</sup>HJQNB or 1 nM [<sup>3</sup>HJQNB plus 1  $\mu$ M aropine for 2 hr at room temperature. After 3 washes in cold PBS, the sections were dried and placed in x ray cassettes with LKB Ultrofilm. After a 4 week exposure period, the autoradiograms were developed and photographic prints made for analysis.

After sectioning the right factal nerve, there was a marked depletion of AChE from most cholinergic efferent neurons located in the ipsilateral FN. Although AChE staining was also decreased in the neuropil, numerous AChE-containing nerve fibers were still present. Specific binding of  $[\frac{2}{H}IQNB$  was decreased substantially in the ipsilateral FN after axotomy. These data indicate that the bulk of the muscarinic receptors in the FN are associated with the motoneurons. The persistence of AChE-containing nerve fibers in the neuropil of the ipsilateral FN is consistent with the motoneurons receiving a cholinergic innervation.

EFFECT OF CERVICAL VAGOTOMY ON [<sup>3</sup>H]QUINUCLIDINYL BENZILATE 211.12 BINDING, CHOLINE ACETYLTRANSFERASE AND ACETYCHOLINESTERASE IN VAGAL NUCLEI. J. C. Hancock and D. R. Hoover. Dept. of Pharma-cology, Quillen-Dishner College of Med., East Tenn. State Univ., Johnson City, TN 37614

The dorsal motor nucleus of the vagus (DNV) and the nucleus ambiguus (NA) contribute to the parasympathetic innervation of the heart and other viscera. Cholinergic neurons and neuropil in these regions stain intensely for cholinesterases (ChEs). Recent autoradiographic studies have shown a high density of muscarinic receptors in NA and low to moderate density in DNV suggesting the presence of cholinergic synapses. In the present study, we examined the effect of cervical vagotomy on muscarinic receptors and choline acetyltransferase (ChAT) in vagal nuclei. An earlier study demonstrated that ChEs are depleted from ipsilateral DNV and NA by unilateral cervical vagotomy (J. Anat. <u>107</u>: 197-208, 1970). Based on this finding, we expected muscarinic receptors and ChAT associated with vagal efferent neurons would decrease in response to axotomy.

Male Sprague Dawley rats were anesthetized with pentobarbital for right cervical vagotomy or control surgery (neck incision). ChAT activity and autoradiographic localization of  $[^{3}H]$ quinuclidinyl benzilate ( $[^{3}H]$ QNB) binding were examined at 14 days after surgery. To label muscarinic receptors, transverse sections of medulla oblongata were incubated in 1 nM  $[^3H]_{0NB}$  in PBS for 2 hr at room termperature. After several washes in cold PBS, sections were dried, and the localization of label was determined with LKB Ultrofilm. Photographic prints were made from autoradiograms and evaluated in a single prints were made from autoratiograms and evaluated in a single blind fashion by two persons. Another series of brains were used for analysis of ChAT activity. Alternate 50  $\mu$ m and 300  $\mu$ m sections were cut through the medulla. The 50  $\mu$ m sections were stained for acetylcholinesterase (AChE) and used to aid in

micropunching 300 µm sections for subsequent ChAT determination. Right vagotomy caused a 52% decrease in ChAT in the ipsilateral DNV/n. tractus solitarius complex and a 42% decrease in the rostral pole of NA. No significant changes in ChAT occured at other levels of NA or in the hypoglossal nucleus. In adjacent sections. AChE was depleted in ipsilateral DNV and rostral pole of ipsilateral NA. Therefore, both enzymes made by vagal efferent neurons are decreased after vagotomy. In contrast, no difference in localization of QNB binding was seen in vagal nuclei of experimental vs control brains. This data suggests muscarinic receptors in these medullary nuclei are not located on efferent cholinergic neurons.

211.13 TOPOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN MOUSE

TOPOCHEMICAL LOCALIZATION OF GHOLINE ACETYLITRANSFERASE IN MOUSE BRAIN, M.N. Gordon\* and C.E. Finch (SPON: P.S. Got). Andrus Gerontology Center and Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA 90089-0191. The specific activity of choline acetyltransferase (CAT) was measured at neuroanatomically defined loci using the Palkovits punch technique. Young female C57BL/6J mice were ovariectomized 4-7 d before sacrifice. Unfixed frozen brains were sectioned (200 μm) in a cryostat and 1 mm diameter punches were collected from nuclei in the basal forebrain and hypothalamus. Highest activity was seen in the corpus striatum  $(161\pm12, n=9)$ , followed activity was seen in the corpus striatum ( $161\pm12$ , n=9), followed by rostral areas of the diagonal band of Broca ( $88.9\pm16.4$ , n=5), the magnocellularis area of the preoptic area ( $65.6\pm4.9$ , n=23) and the n. accumbens ( $45.8\pm6.4$ , n=3). Moderate activities were seen in the medial septal n. ( $21.7\pm3.2$ , n=13) and the bed n. of the stria terminalis ( $15.7\pm1.8$ , n=15). Hypothalamic regions had the lowest CAT specific activity of the areas examined (suprachiasmatic n.,  $12.4\pm1.8$ , n=16; median eminence-arcuate n.,  $10.0\pm1.8$ , n=15; n=623, 63.2, n=23; 10.9±1.8, n=15; medial preoptic area, 4.53±0.63, n=23;

ventromedial n, 4.47±0.27, n=6). The areas of high specific activity were quite circumscribed. For example, at the level of the proptic area, lateral punches (magnocellularis area) have high activity (63.6±4.9, n=23), while (magnocellularis area) nave ingn activity (0.04.7, in-25), will medial punches less than 1 mm away have 14-fold lower specific activity (4.53±0.63, n=23). In addition, the diagonal band showed a profound rostro-caudal gradient of CAT specific activity. Rostral diagonal band (1.0 mm anterior to bregma) showed highest specific activity (88.9±16.4, n=5). CAT activity showed highest specific activity (88.9210.4, n=3). Cal activity then decreased approximately linearly in more caudal sections, decreasing to 22% of anterior values by 0.5 mm anterior to bregma (specific activity = 19.9 $\pm$ 3.5, n=5). However, there was no evidence for a rostro-caudal gradient of CAT specific activity in the corpus striatum as has been reported for the rat (Strong et al, J. Neurochem 39:831, 1982). Since all areas of the basal forebrain examined here have

CAT-containing cell bodies, differences in CAT specific activity may reflect the relative density of cholinergic cells in these nuclei.

Subcutaneous injections of  $17\beta$ -estradiol (at doses up to 0.1 ug/g body weight/day for 7 days) had no effect on CAT specific activity in any nucleus examined here.

211.14 ANTIBODIES THAT DISTINGUISH BETWEEN MOLECULAR FORMS OF ACHE

ANTIBODIES THAT DISTINGUISH BETWEEN MOLECULAR FORMS OF ACHE LOCALIZE DIFFERENTIALLY ON TORPEDO ELECTROCYTES. L. B. How-land\*, M. H. Ellisman, P. Taylor\*, T.J. Deerinck\*, B.P. Doctor\* and S.J. Camp\* (SPON: J.H. Brown). Department of Neurosci-ences, Laboratory for Neurocytology and Department of Neurosci-ences, Laboratory for Neurocytology and Department of Medicine, University of California, San Diego, La Jolla, CA 92093. Distinct molecular forms of AChE have been isolated from Torpedo electric organs and characterized biochemically. These include an asymmetric "tailed" species (17S+13S) and a dimeric hydrophobic species (5.6S). Monoclonal antibodies (MCAb) were raised against Torpedo AChE and have been characterized for antigenic specificity. Most antibodies show a high degree of cross reactivity between the different molecular forms of AChE, but two demonstrate selectivity for only one form. MCAb 4F3 is cross reactivity between the different molecular forms of AChE, but two demonstrate selectivity for only one form. MCAb 4F3 is specific for the asymmetric species (and is unreactive towards this form of the enzyme following collagenase or trypsin remo-val of the tail section). MCAb 4E7 exhibits 100-fold selec-tivity for the catalytic subunit of the 5.6S hydrophobic dimeric form of AChE. Using these MCAbs as probes, we were able to examine the distribution of the different forms of AChE in <u>Torpedo</u> electric organ by immunofluorescence and immunoelec-trop microscopy. MCAb 4E7 shows a diffuse distribution, stain in <u>lorpedo</u> electric organ by immunofluorescence and immunoelec-tron microscopy. MCAb 4E7 shows a diffuse distribution, stain-ing within the synapse giving the appearance of labeling both the innervated and non-innervated surfaces with approximately equal density. These patterns were confirmed using immunoelec-tron microscopy. In contrast, polyclonal antibodies raised against the asymmetric form bind both asymmetric and hydropho-bic forms with equal avidity in vitro. Although these poly-clonal antibodies do not appear to distinguish between molecu-lar forms in vitro. the antigenic sites they localize in situ ar loss in vitro, the antigent to distinguish between molecu-lar forms in vitro, the antigenic sites they localize in situ are less uniformly distributed than those localized by the monoclonal antibody directed against the hydrophobic dimer only. Localization by both light microscopy and electron microscopy reveal the same pattern of staining. (Supported by research grants from the NIH #NS14718 to M.H.E., #GM1860 to P.T.; NMSS to M.H.E.; MDA to M.H.E. and P.T. and predoctoral fellowship support for L.B.H. from USPHS GM07752).

## LAMINAR DISTRIBUTION OF NEUROTRANSMITTERS IN THE RAT VISUAL 211.15 CORTEX. S. G. Speciale, J. K. McDonald, and J. G. Parnavelas. Depts. of Psychiatry and Physiology, UTHSCD, Dallas, TX 75235, USA and Dept. of Anatomy, Univ. College, London, England. The mammalian visual cortex (VC) contains a variety of putative neurotransmitters, such as the monoamines (norepinephrine (NE) and neurotransmitters, such as the monoamines (norepinephrine (NE) and serotonin (SHT)), GABA, acetylcholine, asparate, glutamate, and a number of peptides (Parnavelas and McDonald, 1983). With the exception of some established functional properties for NE and GABA, little is known about the function of other putative neuro-transmitters in the VC. In the present study, we have examined the laminar localization of NE, SHT, and choline acetyltransferase (ChAT) and glutamic acid decarboxylase (GAD), synthetic enzymes and marker for acetylcholine and (CMA) excentionally in the VC. and markers for acetylcholine and GABA, respectively, in rat VC. It has been speculated that cortical lamination might have functional significance.

Albino rats were decapitated, the brains rapidly removed, and VC blocked out by razor cuts and frozen on dry ice. The limits of each layer were established from stained coronal sections of VC from animals of the same age. Monoamines were analyzed by HPLC-EC, while ChAT and GAD were measured by radiometric assays (Fonnum, 1975). Tissue concentrations of enzyme activities were calculated on the basis of protein content.

(Foldman, 193). Thisble concentrations of enzyme activities were calculated on the basis of protein content. NE concentrations were higher in layers I, II&III, and IV, and lowest in layer V (differing significantly from layers IV and VI, P<0.05). 5HT concentrations were highest in layer I and exhibited a gradient, being lowest in layers V and VI (almost 50% that in layers II&III). The 5HT metabolite, 5-hydroxyindole-acetic acid, an index of 5HT neuronal activity, was found in similar concentrations in layers I-V, but was elevated in layer VI, about 50% over the upper layers. Dopamine or its metabolite, 6HT activity was maximal in layer V, followed closely by layers I, II&III, IV and VI. GAD activity was highest in layer IV, where the GAD immunocytochemically reactive non-pyramidal neurons are concentrated, and tapers off slightly in the layers above and below. In a related study, we examined the development of the laminar enzymatic activity, which was clearly detectable in 8 day and older animals. Both enzymes showed a rapid phase of increased activity between days 8 and 16. GAD activity reached adult-like levels by da 24 in all layers, except layer IV, which showed a continued increase to adult</p> except layer IV, which showed a continued increase to adult levels. As for ChAT activity, it demonstrated a steady increase in all layers to the adult activity from day 16 onward. The functional role of the differences in the laminar distribution of these neurotransmitters remains for further study.

LOCALIZATION OF ALPHA, -ADRENERGIC RECEPTORS IN HUMAN CEREBRAL CORTEX. R. T. McCabe\*, S. S. Stensaas and J. K. Wamsley. Depts. of Psychiatry, Anatomy, Pharmacology, and Pathology, 211.16 Univ. of Utah, Salt Lake City, Utah 84132. Alpha,-adrenergic receptors have been autoradiographically

localized in rat cerebral cortex using (<sup>3</sup>H)-WB4101 as a ligand (Young and Kuhar, Proc. Natl. Acad. Sci. 77:1696, 1980). A fairly unremarkable distribution of these sites was shown within fairly unremarkable distribution of these sites was shown within the laminae of individual cortical regions.  $(\exists H)$ -previous in (New England Nuclear; Boston, MA), a more selective ligand for alpha<sub>1</sub>adrenergic receptors, has been used for labeling membrane homogenate preparations (Miach et al., N.S. Arch. Pharmacol. 312:23, 1980). Unnerstall and Kuhar (personal communication) have autoradiographically localized alpha<sub>1</sub>-adrenergic receptors in particu-lar areas of rat brain. Their procedures have been used to label alpha<sub>1</sub>-adrenergic receptors with (<sup>3</sup>H)-prazosin in sections of postmortem human cerebral cortex in order to determine their existence and laminar distribution in different cortical areas

Several cortical regions were obtained at autopsy from 7 adult male patients. The tissue was rapidly frozen on dry ice and individual sections were cut in a cryostat and placed on micro-Individual sections were cut in a cryostat and placed on micro-scope slides. Tissue sections were labeled by incubating them at room temp. for 60 min. in 0.17M Tris-HCl buffer, pi 7.4, containing lnM ( $^{3}$ H)-prazosin followed by a l min. rinse in fresh buffer (4°C). Areas of nonspecific binding were localized by incubating adjacent sections in media containing 10<sup>-5</sup>M phentolamine to inhibit the specific binding of the radiolabeled ligand. All tissue sections were rapidly dried and apposed to sheets of LKB Ultrofilm for 5½ months. After this exposure period, the film was developed and examined using computer assisted microdensitometry.

Alpha1-adrenergic receptors were unevenly distributed in each Alpha-adrenergic receptors were uneventy distributed in each cortical region examined. The highest density of receptors was observed in lamina I of the striate cortex and pre- and post-central gyri, with a 10% decrease of receptor density in lamina VI when compared with lamina I. Intermediate levels of receptor density were found in laminae II-V of these areas. Superior temporal gyrus, in comparison, had slightly lower specific binding in laminae I and VI, with a marked lack of labeling in laminae IV and V. Cingulate and parahippocampal cortex differ from these areas by having homogeneous labeling throughout all layers.

Thus, alpha<sub>1</sub>-adrenergic receptors are differentially distribu-ted in regions of the human cortex. Coupling these observations with those of alpha<sub>2</sub> and beta-adrenergic receptors should provide insight into the complicated sites of adrenergic action in the cortex.

211.18 AN IMMUNOCYTOCHEMICAL STUDY OF THE SEROTONERGIC INNERVATION OF THE TRIGEMINAL NUCLEAR COMPLEX IN THE RAT. E. C. Cropper\*, J. S. Eisenman, and E. Azmitia. Depts. of Physiology and Anatomy, Mount Sinai School of Medicine, New York, NY 10029. Serotonin has been implicated in the modulation of informa-tion of the second se tion through various motor and sensory nuclei, particularly in those sensory nuclei which receive inputs from small diameter afferents. This study describes the distribution of serotonin innunoreactive fibers in the trigeminal nuclear complex, which includes the motor nucleus and sensory nuclei that receive in-puts from both large and small diameter afferents.

Animals were pretreated with pargyline (200 mg/kg, IP) and tryptophan (200 mg/kg, IP)and perfused intracardially with a 0.1 M phosphate buffer solution containing 4% paraformaldehyde, 3% sucrose, and 0.05% magnesium sulfate. Brains were post-fixed overnight and sections cut in both the coronal and hori-contal large. zontal planes. Tissue was processed for immunocytochemical staining using a modification of Sternberger's peroxidase-antiperoxidase (PAP) technique. The serotonin antiserum was a gen-erous gift of Dr. J. Lauder.

marginal and gelatinosa layers of the spinal subnucleus caudalis were found to be densely innervated while the magno-cellular portion of caudalis contained few immunoreactive fibers. Innervation of most of the subnuclei oralis and inter-polaris was sparse although occasional patches of dense innerpolaris was sparse although occasional patches of dense inher-vation were present in both nuclei; oralis appeared to contain more labeled fibers than interpolaris. Little immunoreactiv-ity was observed in the main sensory nucleus. The motor nu-cleus was as densely innervated as the marginal and gelatinosa layers of caudalis, and when compared to the caudalis innervation, the fibers in the motor nucleus appeared thicker and less varicose.

In conclusion, labeling within the sensory nuclei of the trigeminal complex is dense only in the spinal subnucleus caudalis, i.e., only in an area which receives small diameter afferents and projects to the posterior thalamus. The main sensory nu-cleus, which receives large diameter afferents and projects to the VB complex of the thalamus, contains few labeled fibers. This suggests that serotonergic modulation of somatosensory transmission in the trigeminal nuclear complex occurs primarily on activity related to small diameter afferent input. The mo tor nucleus is densely innervated as are other motor nuclei of the brain stem and the ventral horn of the spinal cord.

211.17 DIFFERENTIAL DEVELOPMENT IN THE RAT OF MU1 AND MU2 BINDING SITES AS MEASURED BY QUANTITATIVE AUTORADIOGRAPHY. J. Kent\*, L. Recht\*, E. Hiesiger\* and G.W. Pasternak. Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021. Previous studies have shown that the high affinity (mu1) opioid Variance and the state of the state of the state of the state of the state. binding sites had a different developmental appearance than the lower affinity binding sites of  $^{3}H$ -dihydromorphine (DHM; mu<sub>2</sub>) or  $^{3}H$ -D-ala-D-leu-enkephalin (DADL; delta; Zhang and Pasternak, Eur J Pharmacol 73: 29, 1981) as well as a different regional distibu-tion (Zhang and Pasternak, Eur J Pharmacol 67: 323, 1980). In an effort to examine the regional development of mul and mu2 sites, effort to examine the regional development of mu<sub>1</sub> and mu<sub>2</sub> sites, we utilized quantitative autoradiography (QAR) to measure the density of opiate receptors in rats 2 days old and adults using a fixed concentration of <sup>3</sup>H-DHM (1 nM). Previous studies have shown that <sup>3</sup>H-DHM alone bound to both mu<sub>1</sub> and mu<sub>2</sub> sites and unlabeled DADL at 1 nM displaced the binding to the mu<sub>1</sub> sites selectively (Wolozin and Pasternak, PNAS 78: 6181, 1981). There-fore, sections (10 microns) were incubated with <sup>3</sup>H-dihydromor-phine alone or with <sup>3</sup>H-DMM and 1 nM DADL. Nonspecific binding was determined using levallorphan (1000 nM). Tissue sections were exposed to LKB Ultrafilm for 3 months. The images were then developed and distirged on a PDP11/23 computer. Ontical then developed and digitized on a PDP11/23 computer. Optical densities were determined from the computerized images. In b In brief. mul binding appeared to develop later and differently from mul binding. This is best illustrated in the medial thalamus. In binding. This is best illustrated in the medial thalamus. In 2 day old rats, 1 nM DADL displaced only approximately 4-5 % of the specific <sup>3</sup>H-DHM binding. By contrast, in adult rats, the same concentration of DADL displaced <sup>3</sup>H-DHM binding by approximately 80 %. These studies support the concept of differences in the developmental appearance of mu<sub>1</sub> and mu<sub>2</sub> binding sites.

211.19 QUANTIFICATION OF MICROAUTORADIOGRAMS BY SINGLE BIT PLANE IMAGE

QUANTIFICATION OF MICROAUTORADIOGRAMS BY SINCLE BIT PLANE IMAGE ANALYSIS. R. A. Pearlstein<sup>®</sup>, J. E. Simons<sup>®</sup>, W. F. White, S. <u>O'Gorman<sup>®</sup></u>, L. J. Regan<sup>®</sup> and R. L. Sidman. Image Graphics Laboratory, Dept. of Neuroscience, Children's Hospital and Dept. of Neuropathology, Harvard Medical School, Boston, MA 02115. Autoradiographic techniques are applicable to problems rang-ing from measurement of metabolic activity, to fiber tract and synaptic field tracing, cell birthday determinations, and neuro-transmitter receptor or other ligand binding site localization. A general solution is proposed for the rapid, accurate quanti-fication of autoradiograms using an automated computer analysis system. The components of the system consist of a three-axis computer-controlled brightfield light microscope, 100X neofluar objective, Chalnicon instrumentation video camera, a single computer-controlled orightifield light microssope, four heat har objective, Chalnicon instrumentation video camera, a single bitplane image analyzer and analog thresholding front end (Omnicon 3000, Bausch & Lomb, Rochester, N.Y.). Stage motion in the X,Y plane, focus, image acquisition and analysis are all under operator-independent computer control. Grain and tissue layers are separated by optical sectioning and counterstain-matching wavelength filters. An analog video thresholding algo-rithm mediates uniform grain detection by sensing peak height of the video waveform; the binary image of grain features is deter-mined by a constant threshold below this peak height. Small but mined by a constant threshold below this peak height. Summarian out critical changes in grain layer focal plane are compensated by an autofocus technique which operates to maximize the number of features in the binary image, a condition coincident with true focus. Grain number is derived from measurements of the total area occupied by detected features in the binary image. We have verified repeatedly that a linear relationship exists between grain number and detectable feature area at the constant thresh-Specific activity of radionuclide label is determined by old. preparation of a stepwedge standard: analysis of grain number in the stepwedge is used to convert feature area directly to disinthe stepwedge is used to convert feature area discrete specific activities are written to a pen plotter as hidden-line supressed three axis maps in which modulation of the Z-axis expresses count/activity level. A version of this autoradiography program now in preparation will allow quantitative radioactivity levels in a given set of serial histological sections to be spatially represented in arbitrary colors superimposed directly onto reconstructed three-dimensional images of the same sections. Supported by N.I.H. Grants NS16278, NS18584, and HD06276.

211.20 AUTORADIOGRAPHIC LOCALIZATION OF GLYCINE RECEPTORS IN <u>SPASTIC</u> AND CONTROL MICE USING A COMPUTERIZED SINGLE BIT PLANE IMAGE ANALYSIS SYSTEM. <u>W.F. White</u> and <u>L.J. Regan</u>. Dept. of Neuroscience, Children's Hospital, and Neuropathology, Harvard Medical School, Boston, MA, 02115.

The mutant mouse <u>spasic</u> has behavioral and electromyographic abnormalities which suggest a decrease in inhibitory neurotransmitter function. On the basis of both pharmacologic and receptor binding studies this decrease appears to involve inhibition mediated by glycine. Previous studies using receptor binding techniques have demonstrated an 80-90% decrease in the specific binding of <sup>3</sup>H-strychnine, a ligand for the postsynaptic glycine receptor, to the spinal cord, brainstem, and midbrain of <u>spasic</u> compared with littermate control mice. This decrease could result from a highly localized decrease in <sup>3</sup>H-strychnine binding sites with other areas ungffected, or it could result from a more generalized decrease <sup>3</sup>H-strychnine binding sites with all areas affected. In an effort to test these two possibilities, autoradiograms of <sup>3</sup>H-strychnine binding sites were prepared from <u>spasic</u> and control lumbar, thoracic, and cervical spinal cord, brainstem, and midbrain using diffusable substance autoradiographic techniques. Background binding was defined in adjacent sections using either 10 mM glycine or 100 uM strychnine to displace specific binding. Analyses of these autoradiograms were performed using the procedures described in "Quantification of microautoradiograms by single bit plane image analysis" (this meeting). Receptor localization in fmoles bound per mg dry weight was determined from two dimensional plots of area occupied by silver grains. High receptor densities were seen in the gray matter of spinal cord and specific brainstem and midbrain nuclei. Receptor densities were significantly lower in all regions of <u>spasic</u> spinal cord, brainstem, and midbrain suggesting that the decrease in glycine receptors is not specifically localized.

Supported by N.I.H. Grants NS18584, NS16278, and HD06276.

### PINEAL GLAND

212.1 DECREASE IN PINEAL MELATONIN CONTENT DURING HIDERNATION IN THE GROUND SQUIRREL, <u>CITELLUS LATERALIS.</u> T. L. Stanton, C. M. Craft and R.J. Reiter. A. I. duPont Inst., Wilmington, DE 19899 and Dept. Anat., Univ. Texas Health Sci. Ctr., San Antonio, TX 78248. Investigations of the effects of pinealectomy or melatonin administration on the incidence and duration of torpor in hibernating mammals have produced inconclusive results. In this study, the role of the pineal gland in modulating the obligatory hibernation bouts of the golden-mantled ground squirrel was explored by comparing pineal melatonin content in hibernating animals with that of euthermic (not hibernating) animals at the same time of year (early February).

Euthermic animals were housed individually in a colony room under natural light conditions. Hibernating animals were housed at  $4^{\circ}$ C in dim light (.02-.35 fc) on a 12:12 light:dark schedule. Hibernating animals were divided into two groups in order to look for differences between animals who were in the first day of their respective bouts (early bout = EB) and animals who were near the end of their respective bouts just prior to expected spontaneous arousal (late bout = LB). Individual bout periods, averaging 5-15 days across animals but relatively constant within each animal, were separated by short intervals (less than 24 hrs.) of spontaneous euthermia. All animals were ascrificed between 1400-1600 h. Melatonin was measured in duplicate aliquots by radioimmunoassay in a single assay. The data were analyzed by one-way analysis of variance and Duncan's multiple comparison. The results showed that pineal melatonin decreased significant-

The results showed that pineal melatonin decreased significantly during hibernation. Mean melatonin content (pg./pineal ± SEM) was 560.7 ± 95.7 for euthermic animals (n=5), 351.7 ± 51.3 for EB hibernators (n=6), and 167.0 ± 34.0 for LB hibernators (n=6). Pineal melatonin was significantly higher in euthermic animals compared to EB hibernators (p < .05) and LB hibernators (p < .01). The decrease in pineal melatonin from the EB to LB period of hibernation was also significant (p < .05). Of particular interest was the relationship between individual bout length and pineal melatonin content, wherein animals who exhibited longer bout lengths had higher melatonin values. An examination of this relationship revealed a correlation coefficient of .89 for EB hibernators and .96 for LB hibernators. When bout length was introduced as a covariate, the significant difference between EB and LB hibernation groups became even greater (F=39.5; p<.000001).

The demonstration that melatonin content of the pineal changes as a function of hibernation provides evidence that the pineal gland may play a role in the cyclic hibernatory behavior of this species. The strong correlation between bout length and melatonin content further suggests that pineal melatonin may be important in determining the duration of individual hibernation bouts. (Supported by NSF grant PCM-8003441 to R.J.R. and A.I. duPont Inst.) 212.2 THE EFFECTS OF INSULIN INJECTIONS ON THE PINEAL MELATONIN SYNTHETIC PATHWAY IN EXPERIMENTALLY-INDUCED DIABETIC AND NON-DIABETIC MALE SYRIAN HAMSTERS. <u>T. H. Champney, A. P. Holtorf\*</u> and R. J. Reiter. Dept. Anatomy, Univ. of Texas Health Sci. Ctr., San Antonio, TX 78284. Decreases in nocturnal pineal melatonin content have been shown

Decreases in nocturnal pineal melatonin content nave been snown previously in Syrian hamsters rendered diabetic by injection of streptozotocin or alloxan. This study examined the effect of insulin injections on pineal serotonin (SHT), N-acetylserotonin (NAS) and melatonin content in diabetic and control hamsters. Pineal serotonin N-acetyltransferase (NAT) activity and hydroxyindole-0-methyltransferase (HIOMT) activity were also determined. Male, Syrian hansters were maintained under a 141:10D photoperiod (lights on at 0600h) with food and water available ad photoperiod (lights on at 0600h) with food and water available ad libitum. They were injected with either alloxan monohydrate (65 mg/kg in saline, i.v.) or streptozotocin (65 mg/kg in 0.05M citrate buffer, pH 4.5, i.p.). Eleven alloxan-injected animals and 11 non-diabetic animals were injected daily at 1600h for 3 days with insulin (2 IU/kg in saline, s.c.). Ten control hamsters were injected with citrate buffer (i.p.) on the first day and with saline (s.c.) for 3 days. On the fourth day, the hamsters were killed at 0400h. Fineals and trunk blood samples were collected. Flood clucose lavels were determined by a colorimetric enzymatic Blood glucose levels were determined by a colorimetric, enzymatic method (Sigma kit #510). Hamsters with blood glucose values over 300 mg/100 ml were considered diabetic as compared to control values of 100 mg/100 ml. Pineal levels of 5HT and NAS were measured by high performance liquid chromatography. Melatonin content was measured by radioimmunoassay. NAT activity and HIOMT activity were measured by radioenzymatic microassay. All of the above parameters were measured within the same pineal gland. Pineal NAS was not detectable in any of the groups. Pineal melatonin content was significantly decreased (p<0.05) in both the l streptozotocin-induced diabetic groups. Insulin in alloxan-diabetic animals had normal melatonin alloxan and streptozotocin-induced diabetic injections values, while insulin injections in control animals had an apparent, but not significant, increase in pineal melatonin content. Pineal 5HT content was significantly depressed (p<0.05)content. Pineal 5HT content was significantly depressed (p<0.05) in the alloxan and streptozotocin-diabetic groups and in the group injected with insulin alone. Alloxan-diabetic hamsters injected insulin had normal pineal 5HT levels. Neither NAT activity nor HIOMT activity were significantly altered by experimentally-induced diabetes or insulin injections. This study confirmed that experimentally-induced diabetes reduces pineal 5HT and melatonin content and that insulin injections restored those values to normal. It appears that diabetes alters substrate availability in melatonin synthesis and not enzyme activity. Further studies are planned to examine this effect in detail. (Supported by NSF Grant No. PCM 8003441.)

AGING DIFFERENCES IN ALPHA-ADRENOCEPTOR MEDIATED EFFECTS ON RAT 212.3 AGING DIFFERENCES IN ALPHA-ADRENOCEPTOR MEDIATED EFFECTS ON RAT PINEAL GLAND N-ACETYLTRANSFERASE ACTIVITY. Robert L. Terry\*, David M. Bronstein\*, Thomas Motroni\*, and Loy D. Lytle (SPON: H.J. Carlisle). Laboratory of Psychopharmacology, Department of Psychology, University of California, Santa Barbara, CA 93106. The activity of the pineal gland enzyme, N-acetyltransferase (NAT), is controlled at least in part by the action of sympathetic nerve terminal release of norepinephrine (NE) onto pinealocyte beta-adrenoceptors. Recent evidence suggests that postsynaptic obbedding chapters in the part of the second chapters in the second sympathetic for the second sympathetic of the second sympathetic for the second sympathetic of the second sympathetic of the second sympathetic for the second sympathetic of the second sympathetic for the second sympathetic of the second sy

alpha-adrenoceptors may also be involved in NE-induced changes in NAT activity in pineal gland organ cultures (Klein <u>et al</u>., <u>Proc.</u> Nat. Acad. Sci. 80:599, 1983) and in pineal cell cultures (Rowe, V. and Parr, J., J. Pharmacol. Exp. Ther. 218:97, 1981). To assess possible age-related differences in alpha-adrenoceptor

mediated effects on pineal gland NAT activity, we includated pineal glands taken from rats at different developmental time periods (fetal, neonatal, adolescent, or adulthood) in <u>vitro</u> with diff-erent concentrations of the alpha-adrenoceptor agonist drug phenylephrine or with the alpha-adrenoceptor antagonist drug

Brent concentrations of the alpha-adrenoceptor antagonist drug phenylephrine or with the alpha-adrenoceptor antagonist drug prazosin. Following a 4 hr incubation period, the glands were removed and assayed for NAT activity by a modification of the radiometric assay of Deguchi and Axelrod (J. Analyt. Biochem. 50:174, 1972) utilizing the accumulation of N-(3H-acetyl)-trypt-amine as a measure of enzyme activity. Incubation of fetal (19 days post-conception) or adult (50 days old) pineal glands with phenylephrine increased NAT activity in a concentration-dependent manner. Fetal glands required approxi-mately 10-fold greater concentrations of the agonist compared to adult glands in order to achieve significant elevations above basal levels of NAT activity. Phenylephrine also significantly increased NAT activity in pineal glands obtained from neonatal (2, 5, or 10 days postnatal) or adolescent (25 days postnatal) animals. The concentrations of agonist necessary to elevate NAT activity in pineal glands at all ages were between 1-10 µM, doses which may be in excess of those required for selective alpha-adrenoceptor activation. However, we also found that NAT activities in pineal glands taken from neonatal animals are dacreased by approximately 70% following their incubations with activities in pineal glands taken from neonatal animals are decreased by approximately 70% following their incubations with 10  $\mu M$  of the highly selective alpha-adrenoceptor antagonist drug prazosin. These and other data suggest that alpha-adrenoceptors may be functionally important in pineal glands throughout development, and also support the notion that these receptors may normally mediate some of the effects of NE and/or other catecholamines involved in the control of pineal gland hormone synthesis. (Supported in part by NIMH grant MH-31134). 212.4 MELATONIN BINDING IN BRAIN MEMBRANES AND EFFECTS ON ADENYLATE CYCLASE, L.P. Niles. Department of Neurosciences, Faculty of Health Sciences, McMaster University, Hamilton, Ontario L&N 325 Canada.

Considerable evidence indicates that the pineal hormone, melatonin, influences brain and endocrine function, however, melatonin, influences brain and endocrine function, however, the underlying mechanisms remain obscure. Binding studies with (<sup>4</sup>H) melatonin have shown the presence of high affinity binding sites in membrane (Vacas and Cardinali, Neurosci. Lett. 15: 259, 1979) and cytosol (Niles et al., Eur. J. Pharmacol. 55: 219, 1979) fractions from rat brain. Nonetheless, a detailed characteri-zation of binding has been hampered by the instability and poor quality of the radioligand.

Recently, high levels of (<sup>3</sup>H) melatonin binding have been detected in rat brain membranes subjected to multiple washings. While the binding affinity (K\_=15-20 nM) is comparable to that previously reported, the binding site concentration (B\_=1200 1400 fmol/mg protein) significantly exceeds that previously ob-served in either particulate or soluble brain fractions. Regio Regional studies indicate that binding occurs in membranes from diverse CNS areas with the hypothalamus being particularly enriched in binding sites. The pharmacologic features of binding indicate that the 5-methoxy substituent is necessary for high affinity binding.

Preliminary studies of melatonin's effects on adenylate cyc-lase activity in rat brain and endocrine organ homogenates indicate that it produces a GTP-dependent inhibition of enzyme activ-ity in the rat hypothalamus and pineal gland. These findings suggest that the hypothalamus is a primary target for melatonin suggest that the hypothalamus is a primary target for melatonin whose neuroendocrine effects may involve modulation of cyclic-AMP-dependent mechanisms in this brain region. Moreover, mela-tonin's inhibitory effect on pineal adenylate cyclase activity suggests that this indoleamine plays a role in regulating pineal function and supports the hypothesis (Niles et al., Int. J. Immunopharmacol. 1: 213, 1979) that melatonin may inhibit its own synthesis via a negative feedback system.

## THE EFFECTS OF MELATONIN ADMINISTRATON ON HUMAN MOOD AND

THE EFFECTS OF MELATONIN ADMINISTRATON ON HUMAN MOOD AND PERFORMANCE. Harris R. Lieberman, Franz Waldhauser\* Gail S. Garfield\* and Richard J. Wurtman. Dept. of Psychology, MIT, Cambridge, MA O2139. It has been suggested that the hormone melatonin, which is released at night by the human pineal gland, has hypotic properties. Also it has recently been established that the normal nocturnal secretion of this hormone in man can be suppressed by presentation of sufficiently bright light. In spite of these unique properties few investigations of the effects of this hormone on human mood and behavior have been conducted. We therefore investigated the acute effects of oral administration of melatonin on human mood, performance, visual sensitivity and memory. Fourteen healthy male subjects participated in this double-blind placebo controlled study. The subjects received a total of 240 mg, of melatonin, a pharmacological dose, in three 80 mg. capsules over a 2 hour period (12:00 noon to 2:00 p.m.). For 2 hours (10:00 a.m. to 12:00 noon) immediately preceding the initial ingestion of melatonin the subjects were given a battery of psychological tests. Performance was assessed with a simple auditory reaction time (RT) task, four-choice visual RT, a test of sustained motor performance using a grooved pegboard, and the Digit Symbol Substitution Test. Certain aspects of memory and visual sensitivity were also evaluated. All of these tests were then repeated in the same order after melatonin administration (2:00 p.m. to 4:00 p.m. Two self-report mood questionnaries, the Profile of Mood States (POMS) and the Stanford Sleepiness Scale (SSS) were administered every hour. Melatonin had significant effects on mood and performance but did not alter memory or visual sensitivity. Subjects reported significantly more Fatigue on this scale of the POMS at 3:00 PM after melatonin administration compared to placebo. The Vigor scale of the POMS and the SSS also detected significant hypnotic-like effects of me

administered.

It is concluded that melatonin, administerd orally, has definite hypnotic properties affecting both human self-reported mood and performance. The duration of melatonin's effects were brief even though it was administered over a two hour period of time. (Supported by NIH grant 2R01-HD11722-04 and NASA grant Naca 122) NAG2-132)

DEVELOPMENTAL CHANGES IN SYMPATHETIC NERVOUS SYSTEM MECHANISMS FOR 212.6 THE CONTROL OF RAT PINEAL GLAND N-ACETYLTRANSFERASE ACTIVITY. Loy D. Lytle, Robert Terry\*, David Bronstein\*, and Anthony Altar\*. University of California, Department of Psychology, Laboratory of Psychopharmacology, Santa Barbara, CA 93106. Manipulations increasing norepinephrine (NE) neurotransmitter release from the postganglionic sympathetic neurons innervating the prioral cloud only man the overtheoric and release of the ningal

the pineal gland enhance the synthesis and release of the pineal gland hormone, melatonin, by increasing the activity of N-acetyl transferase (NAT), the enzyme which apparently rate-limits overall synthesis of the hormone. The enzyme increases are mediated by release of NE from sympathetic nerve terminals onto pinealocyte  $\beta$ -adrenoceptors, which activates a receptor-linked adenylate cyclase system, causing increases in cyclic AMP concentrations leading to the synthesis of new enzyme protein or to an activation of existing enzyme material (Minneman and Wurtman, 1976). The present experiments were undertaken to characterize the approximate time during development when drugs known to alter pre- or post-synaptic noradrenergic neurotransmission, adrenoceptor, or cyclic

synaptic noradrenergic neurotransmission, adrenoceptor, or cyclic AMP mechanisms might reach functional maturation. Fetal (19 or 20 days post-conception), neonatal (0, 2, 5, or 10 days old), adolescent (25 days old), or adult (50 days old) male or female albino rats were killed during the light portion of the day:night cycle. Their pineal glands were incubated in vitro for a 4 hr period in the presence of the  $10^{-3}$  N HCl vehicle or with a single dose of a drug known to enhance noradrenergic neurotrans-mission by acting presynaptically (1-dopa, amphetamine, veratridine, pargyline, or desmethylimipramine), by acting as an agonist at the pinealocyte postsynaptic S-adrenoceptor (epinephrine, norepine-phrine, isoporterenol, terbutaline, dobutamine), or by acting to pinealocyte postsynaptic B-adrenoceptor (epinephrine, norepine-phrine, isoproterenol, terbutaline, dobutamine), or by acting to increase intracellular pinealocyte concentrations of cyclic AMP (isobutylmethylxanthine or dibutyryl cyclic AMP). In vitro pineal gland NAT activity was quite low in fetal rats, increased dramatic-ally between birth and the 10th postnatal day, and then declined to adult values by 25 days of age. None of the presynaptically acting drugs tested produced any changes in pineal gland NAT activity in fetal animals but each did so in all postnatal animals tested, with maximal drug enhancement of enzyme activity observed between 5-10 maximal drug enhancement of enzyme activity observed between 5-10 days of age. In contrast, the postsynaptic receptor agonist drugs and those which increased cyclic AMP caused significant elevations in pineal gland NAT activity in fetal as well as in all postnatal animals examined. Taken together, these results indicate that presynaptic mechanisms important for the control of pineal gland NAT activity may not become functionally mature until the time of birth. In contrast, postsynaptic receptors or the receptor-linked adenylate cyclase system appear to function at a time during devel-opment when presynaptic mechanisms are still immature. (Supported in part by NIMH grant MH-31134)

A NEURAL SITE OF ACTION FOR PINEAL DEPENDENT PHOTOPERIODIC 212.7 CONADAL SITE OF ACTION FOR PINEAL DEPENDENT PHOTOPERIUDIC CONADAL RESPONSES IN THE GOLDEN HAMSTER, A. Roberts, M. Hastings and J. Herbert\*(SPON: European Neuroscience Association). Department of Anatomy, University of Cambridge, Cambridge, UK. This study reports the identification of a site in the anterior hypothalamus (AHA), destruction of which prevents the photo-periodic response to short photoperiods although such

lesions do not interrupt normal circadian or estrous functions. In the first experiment, adult female golden hamsters main-tained in long photoperiod (LD 16:8) received bilateral infusions into the anterior hypothalamus of the selective neurotoxin neethyl aspartate (MMA, 15  $\mu$ g in 1  $\mu$ L) or control vehicle. Histological analysis identified areas of neuronal destruction within the anterior hypothalamic area although the paraventricular, supraoptic and suprachiasmatic nuclei and fibers of passage were spared. Following transfer to short daylengths (LD 8:16), unlesioned vehicle-infused animals showed the expected gonadal regression after 6 - 8 weeks. In contrast, lesioned animals failed to show a photoperiodic response and maintained gonadal activity during long-term exposure to LD 8:16. Integrity of the circadian system in lesioned animals was confirmed directly by recordings of locomotor activity patterns in continuous dim red light (DD) or 24-hr LD cycles, and an intact estrus generating system inferred by the maintenance of regular estrous cycles in females.

A second experiment has utilised the counter-antigonadotrophic effect of continuous melatonin application in the golden hamster with melatonin, melatonin suspended in beeswax or solely beeswax were implanted bilaterally into the anterior hypothalamus or adjacent areas. (Release rates of melatonin into saline at 37°C were previously determined by HPLC/EOD measurements). Adult male hamsters, following surgery were transferred from LD 16:8 to LD 8:16 and gonadal condition monitored for 8 weeks. Preliminary findions suggest that particular that we have the subject of the findings suggest that continuous administration of melatonin to a site within the anterior hypothalamic area prevents the normal gonadal regression response to short photoperiods shown by control animals.

The findings from these two experiments, taken together, indicate that a site within the AHA may be a target for the pineal control of the photoperiodic response to LD 8:16 in the golden hamster, separate from neural centers concerned with circadian or estrous rhythms.

ELEVATED PINEAL ARGININE VASOTOCIN (AVT)-ACTIVITY IN 212.8

ELEVATED PINEAL ARGININE VASOTOGIN (AVT)-AGTIVITY IN RATS AND HAMSTERS DURING AUGUST. M.M. Prechel\*, T.K. Audhya\* and W.H. Simmons\* (SPON: G.L. Humphrey). Department of Biochemistry and Biophysics, Loyola University Medical Center, Maywood, IL 60153. A 14-month study of pineal glands from inmature rats has shown that AVT-immunoactivity varied from barely detectable picogram levels most of the year, to levels exceeding one nanogram per gland each August (Prechel, et al., <u>Endocrinology</u> 112:1474,1983). We now report that the dramatic August increase in pineal AVT-activity also occurs in adult rats, and in hamsters. Male and female rats and hamsters were housed with food and water ad libitum for 2-10 days prior to sacrifice. Rats (60-95 days) were maintained in a 12:12 light:dark cycle. Hamsters (55-90 days) were housed in LD 14:10. Animals were removed, pooled, homogenized in 0.1 N acetic acid with 10-6M pepstatin (an acid protease inhibitor), and then heat denatured to precipitate large proteins. Supernatants were studied by AVT radioimmunoassay (Fernstrom, et al., <u>Endocrinology</u> 106:243, 1930). Each pineal extract consisted of 3 pooled glands, and 3 replicate pools were prepared at each sampling. Male and female animals were studied separately; each of the four groups was sampled once or twice per week from July until early September, 1932. Results showed that for all four groups the mean pineal AVT-immunoactivity was uniformly low (410 pg/ gland) until mid-July, then increased significantly by mid-August. For hamsters, maximum values of 1272  $\pm 49$  (mean  $\pm 58$ : m=3) and 1055  $\pm 62$  pg/ gland were recorded for males and females, respectively. For rats, peak values were 940  $\pm 12$  pg/gland for males and 1040  $\pm 34$  for females. For the rats and male hamsters AVT-activity exceeded 1000 pg/pineal from 3/9 through 3/21. The present results closely resemble those of the earlier study with prepubertal rats, which showed peax levels (>1000 pg/gland) of AVT-activity on 3/16/30 and 3/10/31. Thus it now appears tha the year

212.9 DIURNAL VARIATION IN GLUCOSE UTILIZATION IN THE PINEAL BODY OF THE MONKEY. <u>M. Ito, R. Nakamura, C. Kennedy, L. Sokoloff</u>, Laboratory of Cerebral Metabolism and Laboratory of Psychology

and Psychopathology, NIMH, Bethesda, MD 20205. The concentration of melatonin in blood and CSF of the monkey varies during the twenty-four hour day. The concentrations at night are consistently higher than those during the day (Reppert night are consistently nigher than those during the day (keppel et al., 1979; Perlow et al., 1979). Whereas light deprivation during the day does not result in a rise in the normally low melatonin levels in the CSF, exposure to light at night suppresses the normally high nocturnal level (Reppert et al., 1981). These diurnal variations in melatonin levels are the

1981). These diurnal variations in melatonin levels are the result of corresponding changes in the rate of production and elaboration of melatonin in the pineal gland. In order to determine if the diurnal variations in melatonin levels and pineal function are reflected in corresponding changes in energy metabolism of the pineal gland, we employed the quanti-tative [<sup>4</sup>C]deoxyglucose method to measure glucose utilization in the pineal gland of pubescent monkeys housed in an environment in which lighting was automatically controlled to produce a 12-hour day and 12-hour night. Glucose utilization was measured under four conditions: A) in daytime with both eyes open (n=7); B) in four conditions: A) in daytime with obtained each open (n=2), b) in daytime daytime after 3 hrs of light deprivation (n=3); C) at night, awake, in total darkness (n=4); and D) at night during slow-wave sleep in total darkness (n=4). Arterial pH, pCO<sub>2</sub>, pO<sub>2</sub>, mean arterial blood pressure, and hematocrit were monitored. Glucose utilization in the pineal was 80-111% higher in the nocturnal, awake animals compared to the rate of both groups studied during the day (Bonferron's t test, p<0.05). During slow-wave sleep the mean rate was also above the rates of daytime animals, but the differences were not statistically significant. Short term visual deprivation during the day was without effect on pineal glucose utilization.

These results indicate that there is an elevation of pineal metabolic rate at a time when blood and CSF levels of melatonin are elevated. The metabolic increase probably reflects increased activity in sympathetic nerve terminals distributed throughout the gland which stimulate its increase in hormone production.

212.10 EFFECTS OF DIET, PHOTOPERIOD AND MELATONIN ON BODY WEIGHT AND ENERGY BALANCE IN SYRIAN HAMSTERS. T.J. Bartness\* and George N. Wade. Department of Psychology, Univ. of Massachusetts, Amherst, 01003. MA

Both endogenous (short-day-induced) and exogenous (afternoon injections) increases in melatonin (MEL) cause a collapse of the reproductive tract in Syrian hamsters. We report the effect of these manipulations and of diet on body weight and energy balance. In Experiment 1, male and female Syrian hamsters housed in long (16:8) or short (8:16) light:dark cycles were fed either Purina #5001 chow pellets (Chow) or a high-fat diet (2:1 chow: shortening). Half the long-day-housed animals received daily shortening). Haif the long-day-noused animals received dariy afternoon (3 hrs prior to lights-off) s.c. injections of MEL (25 µg) or the ethanolic saline vehicle. Despite roughly equivalent caloric intakes across the 12 wk period, body weight gain (Fig. 1 & 2), carcass lipid (Fig. 3), carcase energy and % calories stored (Fig. 4), interscapular brown adipose tissue (The product of the same and NE of the same ad NE of the same strengt and NE of the (IBAT) wet weight, protein and DNA (Fig. 5) and NE-stimulated thermogenesis (Fig. 6 & 7) were increased in fat-fed hamsters vs chow-fed controls. These effects were enhanced by short days and MEL. Females showed greater diet and photoperiod/MEL effects than males.

Because the effect of short days and MEL on these measures could be due to a functional gonadectomy, in Experiment 2 the protocol of Experiment 1 was repeated using ovariectomized hamsters. As before fat-feeding resulted in increased body weight gain, feed efficiency, and IBAT and parametrial white adipose tissue (PWAT) wet weight. These effects were again en-hanced by short days and MEL to an extent of about 80% that seen in intact females (Fig. 8). To determine the role of the pineal/MEL in the effects of

To determine the role of the pineal/MEL in the effects of short days seen above, pinealectomized (PINX) and sham-PINX (Sham) female hamsters fed the high-fat diet were housed in long and short days. Fourteen wks later, the short-day-housed PINX group had body weight gains, feed efficiencies, and IBAT and PWAT wet weights equal to that of their sham counterparts. Uterine weight was reduced in sham, but not PINX, animals housed in short days. Both short-day-housed groups exhibited the en-hanced effects of this photoperiod on body weight and related measures us the long day controls (Fig. 9). measures vs the long day controls (Fig. 9).

Therefore, it appears that short photoperiods exert pineal/ MEL- and gonad-independent and dependent effects on body weight and energy balance in Syrian hamsters, effects which were ex-aggerated by high-fat diets.

212.11 CIRCADIAN CHANGES IN CATECHOLAMINE SYNTHESIS IN THE HAMSTER PINEAL GLAND AFTER SUPERIOR CERVICAL DECENTRALIZATION OR GANGLIONECTOMY OR CONTINUOUS LIGHT. <u>C. M. Craft, W. W. Morgan and R. J. Reiter</u>. Dept. of Anatomy, Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

The purpose of this study was to examine the effect of superior cervical decentralization (SCDC) or ganglionectomy (SCGX) or continuous light (LL) on the circadian changes in catecholamine (CA) synthesis in the hamster pineal gland. Earlier experiments (Endocr. Abst. #385, 1983) demonstrated for the first time diurnal changes in CA synthesis in the pineal two hours after the onset of darkness. Fluctuations in CA synthesis provide a measure of sympathetic neuronal activity which is believed to elicit the well established diurnal rhythm in indoleamines in the pineal gland. With SCDC, SCGX or LL, the circadian fluctuations do not occur in pineal indoleamine production. Therefore, we examined catecholamine synthesis in the pineal under these conditions to determine if CA changes occurred to explain the disappearance of pineal indoleamine rhythms. Male Syrian hamsters were maintained in 24:0 LD cycle (lights on at 0600 h) for one week prior to and during the experiments except the group in LL which was maintained in 24:0 LD for 10 days after the first week. In the first experiment, animals were SCDC, SCGX or sham (S) operated ten days prior to the experiment. All animals were injected with NSD-1015 (100 mg/kg, i.p.), a dihydroxyphenylalanine (DPA) decarboxylase in-hibitor, 30 min prior to killing. CA synthesis was measured by the accumulation of DOPA. Norepinephrine (NE), DOPA and dopamine (DA) were estimated by high performance liquid chromatography and expressed in ng/pineal. In SCDC and SCCX, DOPA accumulation was measured at 2200 h, (1.19  $\pm$  .33, S; .32±.15, SCCC; .17  $\pm$  .04, SCGX; p<.005) and 2400 h (1.29  $\pm$  .19, S; .44  $\pm$  .14, SCDC; .66  $\pm$  .46, SCGX; p<.001). NE content was lower at 2400 h in SCCX than S (1.63  $\pm$  .17, S; .91  $\pm$  .1, SCCX; p<.001. Ne content/s at 2400 h (.22  $\pm$  .03 vs .78  $\pm$  .17 ng/pineal; p<.025) and 2400 h (.24  $\pm$  .03 ng/pineal; p<.025) and 2400 h (.24  $\pm$  .03 ng/pineal; p<.025) and 2400 h (.24  $\pm$  .03 ng/pineal; p<.025) and 2400 h (.24  $\pm$  .03 ng/pineal; p<.025) and 2400 h (.24  $\pm$ 

- 212.13 DESTRUCTION OF THE DEEP PINEAL FAILS TO PREVENT SHORT-DAY-INDUCED TESTICULAR REGRESSION IN THE GOLDEN HAMSTER. Keith D. Anderson\* and Fred W. Turek. Dept. Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60201. The pineal gland of the golden hamster consists of two parts, the superficial pineal (SP), located just beneath the confluence sinuum, and the deep pineal (DP), located in direct contact with the third ventricle between the habenular commissure and the posterior commissure. The pineal gland is innervated by sympa-thetic nerve fibers that originate in the superior cervical ganglion, many of which terminate in the SP, but some of which pass through the SP and the pineal stalk to terminate in the DP. Bilateral superior cervical ganglionectomy prevents short-day-induced testicular regression that normally occurs in male hamsters transfered from a long day of 14 hrs light, 10 hrs darkness (14L:10D) to a short day (6L:18D). Superficial pineal-ectomy (SPx) also eliminates the short-day testicular response, indicating that the SP mediates the effect of photoperiod on testicular function. However, since SPx also interrupts sympa-thetic input to the DP, this result does not rule out the possibility that the DP mediates, at least in part, the effect of short days on reproductive function. To determine if the DP is required for short-day-induced testicular regression, we monitored testis size in hamsters with an electrolytic lesion of the DP. 37 adult male hamsters were placed under 14L:10D for 8 weeks prior to surgery. 24 of these animals were lesioned by passing 2 mA of current through a stereotaxically placed electpassing 2 ma of current through a stereotaricarly placed electronic rode for 15 sec. The remaining 13 hamsters were sham operated (SH). One week later, 12 of the lesioned and 6 of the SH hamsters were transfered to 6L:18D. Testis widths were measured at 2-3 week intervals for 9 weeks. All animals were then sacrificed, testes were weighed, and lesion placements were historicary for heart measured and for heart measured at 2-3 were the sacrificed. logically verified. As expected, the testes of SH hamsters exposed to 14L:10D were large, while the testes of SH hamsters exposed to 6L:18D had completely regressed. No significant exposed to of:10D had completely regressed. No significant difference existed between the mean testes weight of SH hamsters (2843 mg  $\pm$  224; N=7) and hamsters with confirmed DP lesions (3189 mg  $\pm$  561; N=7) exposed to 14L:10D for 9 weeks, nor between SH hamsters (346 mg  $\pm$  54; N=6) and hamsters with confirmed DP lesions (491  $\pm$  129; N=5) exposed to 6L:18D for 9 weeks. Testis width measurements revealed no difference in the rate of testicular regression between SH hamsters and DP-lesioned hamsters exposed to 6L:180. These results demonstrate that the deep pineal is not required for normal short-day-induced testicular regression in the golden hamster.

212.12 PREVENTION BY TRH OF SHORT PHOTOPERIOD-INDUCED TESTICULAR ATROPHY IN GOLDEN HAMSTER: POSSIBLE PARTICIPATION OF BETA-ENDORPHIN. H.J. Chen, J. Targovnik\*, L. McMillan\*, and S. Randall\*. Barrow Neurological Institute, St. Joseph's Hospital & Medical Center, Phoenix, AZ 85013 and Maricopa Medical Center, Phoenix, AZ 85008. Daily injection of luteinizing hormone-releasing hormone (LHRH) prevents short photoperiod (SP)-induced testicular atrophy in golden hamsters (H.J. Chen, J. Endocrinology <u>96</u>: 147-154, 1983). The purpose of the present study was aimed at investi-gating if TRH, another hypothalamic hormone, could prevent testicular regression in the male golden hamster exposed to SP. 48 male golden hamsters were divided into 8 groups of 6 animals each and given treatments as follows: Group 1, long photoperiod each and given treatments as follows: Group 1, long photoperiod (LP) controls were given vehicles (the remaining groups were in SP of 6L:18D); Group 2, SP controls were given vehicle at lights on (LO) and lights off (LX); Group 3 animals were injected with 1 ug LHRH at L0; Group 4 animals were given 1 ug TRH at L0; Group 5 animals were given 1 ug LHRH and 1 ug TRH at L0; Group 6 animals were given 1 ug LHRH at LX; Group 7 animals received 1 ug TRH at LX; and Group 8 animals were given 1 ug LHRH and 1 ug TRH at LX. The animals were terminated after 8 weeks of treatment and 15 min after last injection of LHRH ad(or TRH Both LHRH and 15 min after last injection of LHRH and/or TRH. Both LHRH and TRH prevented testicular regression if they were injected LO (p<0.01 when compared with vehicle injected controls). LHRH, but not TRH, partially prevented testicular regression if injected at LX. Synergistic effects of LHRH and TRH to prevent testicular regression were observed only when given at LX. LHRH stimulated about a 15-fold increase in LH  $36\pm$  vs  $554\pm$  ng/ml) and 2 to 3-fold increase in FSH, but no increase in PRL in response to TRH was observed at this bleeding schedule. Plasma beta-endorphin concentrations in LP controls were 286±49 pg/ml vs 380±31 pg/ml in the SP controls (p<0.01), others tending to be higher in groups with atrophic testes and lower without atrophic testes. These results indicate that TRH like LHRH can prevent SP-induced testicular regression in hamsters by some unknown mechanism and that beta-endorphin may be involved in the control of testicular function in hamsters.

212.14 EVIDENCE FOR MEDIATION OF PHOTOPERIODIC RESPONSES IN THE DJUNGA-RIAN HAMSTER BY CHANGES IN DURATION OF THE CIRCADIAN PULSE OF PINEAL MELATONIN SECRETION. B.D. GOLDMAN<sup>\*</sup>, Worcester Foundation for Experimental Biology, 222 Maple Ave., Shrewsbury, MA 01545

The Djungarian hamster is a species in which the pineal is known to be capable of exerting both stimulatory and inhibitory effects on reproduction, depending on photoperiodic conditions. To study the role of pineal melatonin in reproductive regulation, juvenile males were pinealectomized (pinx) and given timed daily infusions of melatonin. In the first experiments, the animals were raised from birth in a stimulatory (i.e., long day) photoperiod and were pinx at 18 days of age. When 10 ng melatonin was inhibited after 12 days of treatment (testes wts. = 63  $\pm$  7 and 54  $\pm$  9 mg for 8h and 10h melatonin groups, vs. 412  $\pm$  26 mg in saline-infused controls). When the same amount of melatonin was given over a 4h or 6h period each day, testis growth was not impaired (testes wts. = 430  $\pm$  33 and 501  $\pm$  30 mg for 4h and 6h melatonin groups). The time of day at which the infusions were administered did not affect the response. Thus, the duration of the daily melatonin pulses, but not its circadian phase, appears to be the most important parameter. Hamsters must be exposed to daily melatonin us to produce the inhibitory effect, since hamsters which received two 5h infusions each day, separated by a 2h period with no treatment (i.e., 5h on-2h off-5h on) did not show inhibition (testes wts. = 532  $\frac{1}{2}$  30 mg).

In a second set of experiments, juvenile males were raised in an inhibitory (i.e., short day) photoperiod and were pinx at 23 days of age. Daily melatonin infusions were given for 12 days. Animals which received melatonin (0.83 ng/h) for 4h or 6h each day showed testicular stimulation, while those which received melatonin for 8h or 12h daily showed inhibition (testes wts. =  $196 \pm 16$  and  $180 \pm 21$  mg for 4h and 6h melatonin groups vs.  $38 \pm 6$  mg in saline-infused controls; testes wts. =  $47 \pm 15$  and  $22 \pm 1$  mg for 8h and 12h melatonin groups). Thus, in summarizing the results from both studies, exposure to daily melatonin pulses of 4-6h duration was stimulatory to testis growth, while exposure to melatonin pulses of 8-10h duration was inhibitory. In conjunction with other data from this laboratory, these results suggest that the effects of photoperiod on testis growth in the Djungarian hamster are mediated by changes in the duration of the circadian peak of pineal melatonin secretion.

PINEAL MELATONIN IN TURKISH HAMSTERS EXPOSED TO DIFFERENT PHOTO-PERIODS AND DURING HIBERNATION. J.M. Darrow\*, D.S. Carter\*, M.J Duncan\*, B.D. Goldman\* and L. Tamarkin\*. (SPON: R.D. Hall) Worcester Foundation for Experimental Biology, Shrewsbury, MA 212.15 01545.

The rhythmic daily production of melatonin by the pineal gland is known to be regulated by the circadian pacemaker system and to be important in the photoperiodic control of annual breeding cycles in several mammalian species. In order to characterize be important in the photoper locate control of animal breating cycles in several mammalian species. In order to characterize the 24-hour pattern of melatonin production in long-day breeding Turkish hamsters (Mesocricetus brandti) during different phases of the annual cycle, we measured pineal melatonin content (by (RIA) in adult female hamsters exposed to long days (LD 16:8), short days (LD 10:14) and during hibernation. Both long and short day females show a nocturnal elevation of melatonin beginning several hours after lights-off and ending shortly before the lights-on transition. No significant differences in amplitude of the peaks was detected (mean values ranged from <100 pg/gland during the day to >600 pg at night), but the two groups did differ in the duration of their melatonin peaks (mean values were elevated above 200 pg/gland for 4 hours on long days; 6 hours on short days). This finding may have functional significance, since in the Djungarian hamster (Phodopus sungorus), a similar extension of the pineal melatonin peak occurs in animals exposed to short days and is largely responsible for mediating the effects of photoperiod on reproduction. effects of photoperiod on reproduction. When Turkish hamsters are induced to hibernate by exposure to

When lurkish hamsters are induced to hibernate by exposure to LD 10:14 at 6°C, they undergo alternating bouts of torpor (lasting 5-8 days) and arousal (lasting 1-3 days) over a period of 4-5 months. The torpid state is characterized by a dramatic decrease in core body temperature (by more than 20°C). Most females sacrificed during torpor showed baseline melatonin values (<50 pg/gland), regardless of time of day, suggesting an attenuation of pineal melatonin production during torpor. In contrast, hamsters sampled during the first day after arousal displayed a nocturnal pagk of pineal melatonin similar in phase Contrast, namsters sampled during the first day after arousal displayed a nocturnal peak of pineal melatonin similar in phase, amplitude and duration to that seen in short day females main-tained at room temperature (21°C). These results indicate that during the hibernation season, the Turkish hamster continues to receive a nocturnal pineal melatonin signal on days of arousal. The data also suggest that the circadian clock, which governs the phase of the melatonin peak expressed during arousal, is not contend by affected by the degraced bedy temperature accuration. seriously affected by the decreased body temperature occurring during torpor.

## POSTSYNAPTIC MECHANISMS II

ACTION OF SUBSTANCE P AND TELEOST LHRH ON BULLFROG SYMPATHETIC 2131 ACTION OF SUBSTANCE P AND TELEOST LHRH ON BULLFROG SYMPATHETIC NEURONS. Stephen W. Jones and Paul R. Adams. Dept. of Neuro-biology and Behavior, SUNY Stony Brook, Stony Brook, NY 11794. Jan et al. (PNAS 76:1501-1505, 1979) have shown that M-LHRH [mammalian luteinizing hormone- (or gonadotropin-) releasing hormone] mimicks the late, slow EPSP of bullfrog ganglia, and than an M-LHRH-like peptide is present in these ganglia. How-ever, the endogenous peptide is not identical to M-LHRH, and may be the LHRH of teleost fish (T-LHRH: [Trp<sup>7</sup>, Leu<sup>8</sup>]M-LHRH; Sherwood et al. PNAS in prese). We have found that T-LHRH is at least et al., PNAS, in press). We have found that T-LHRH is at least 10x more potent than M-LHRH on the bullfrog ganglion. As for We have been club that in bard of the set of the gauge state of the large dependent with the set of the set o K current that is activated by depolarization below -60 mV. The EC50 for M-current inhibition by T-LHR is approximately 0.35 µM, with a Hill coefficient near 1. In some cells, T-LHR H also induces an additional inward current associated with an increased conductance, which (like M-current inhibition) would depolarize an unclamped cell.

an unclamped cell. Chicken LHRH ([Gln<sup>8</sup>]M-LHRH), in contrast, is less active than M-LHRH, as is [Gln<sup>7</sup>,Leu<sup>8</sup>]M-LHRH. [Trp<sup>8</sup>]M-LHRH is less potent than T-LHRH, but more potent than M-LHRH. These results support the hypothesis that T-LHRH is the actual transmitter for the late, slow EPSP of bullfrog sympathetic ganglia.

Substance P (SP) and muscarinic agonists also depolarize bullfrog ganglion cells, and inhibit the M-current. As for T-LRRR, these agents occasionally induce an additional inward current. This effect was typically seen at higher concentra-tions, and was slower in onset and offset than the M-current this inhibition. Cells varied widely in their response to SP, with some cells unresponsive to 10  $\mu$ M, and others with EC50's of 10 nM or lower. The effect on a given cell was clearly concentra-tion-dependent. Hill coefficients for inhibition of the M-current by SP were consistently less than 1, which was also observed for muscle consistential, tess than 1, when way table to observe for muscle and oxotremorine. The M-current inhibi-tion produced by SP occasionally desensitized during a 1 min application, which has not been observed for other M-current inhibitors. The SP effects are minicked by other tachykinins inhibitors. The SP effects are mimicked by other tachykinins (eledoisin, eledoisin-related peptide, and physalaemin). Two proposed SP antagonists, [D-Pro<sup>2</sup>, D-Trp<sup>7</sup>, 9]SP and [D-Arg<sup>1</sup>, D-Pro<sup>2</sup>, D-Trp<sup>7</sup>, 9, Leu<sup>11</sup>]SP, showed weak agonist activity and no clear antagonism of SP on these cells. The muscarinic effect is responsible for the slow EPSP of bullfrog ganglia; it is not yet known whether SP mediates a synaptic potential there. CHOLINERGIC STIMULATION OF SINGLE VERTEBRATE SMOOTH MUSCLE CELLS IS ASSOCIATED WITH A CONDUCTANCE DECREASE. <u>Stephen M. Sims</u>,\* Joshua J. Singer and John V. Walsh. Dept. Physiology, Univ. Massachusetts Med. School. Worcester, Mass. 01605. Single electrode voltage clamp and current clamp techniques were used to study acetylcholine (ACh) induced responses in freshly isolated gastric smooth muscle cells from the toad <u>Bufo</u> <u>marinus</u>. Application of ACh (50 µM to 1 mM) by pressure <u>ejection from a micropipette caused slow depolarization</u>, sometimes divinor rise to action potentials and contractions. ejection from a micropipette caused slow depolarization, sometimes giving rise to action potentials and contractions. ACh-induced depolarization was accompanied by a conductance decrease, although the cells exhibit outward-going rectification in the absence of ACh. ACh application to voltage clamped cells confirmed the conductance decrease and revealed the suppression of an outward current, as illustrated in the inset. Under conditions of elevated  $[K^+]_{out}$ , the ACh-suppressed current reversed in direction when the potential was more negative than  $E_{V}$ . These observations are consistent with ACh- suppression  $E_{K}$  . These observations are consistent with ACh- suppression of a  $K^{+}$  current.

of a K<sup>+</sup> current. Further results suggest that the K<sup>+</sup>current suppressed by ACh has some characteristics similar to the M-current of sympathetic neurons. Slow current relaxations to steady-state levels, reflecting the closing of ionic channels, occurred in response to hyperpolarizing voltage commands. The reversal potential for the current relaxations was -94 mV, and shifted 51 mV positive per tenfold increase in  $[K^+]_{out}$ , indicating that K<sup>+</sup> ions carry most of the charge for the current relaxations. The slow relaxations were abolished by ACh, suggesting that ACh acts on the same ionic channel responsible for the relaxations. Cholinergic agents appear to reversibly depress this voltage-Cholinergic agents appear to reversibly depress this voltage-sensitive  $K^+$  current. These results can explain the AChinduced conductance decrease and depolarization observed in the isolated muscle cells. The existence of a cholinergic conductance decrease is of interest because it runs counter to the generally accepted view of cholinergic excitation in vertebrate smooth muscle. ROLE OF EPHAPTIC INTERACTIONS IN PAIRED PULSE AND FREQUENCY POTENTIATION OF HIPPOCAMPAL FIELD POTENTIALS. R.W. Turner, T.L. Richardson and J.J. Miller. Department of Physiology, University 213.3 of British Columbia, Vancouver, B.C. V6T 1W5 Recent studies have suggested that extracellular field

potentials in the hippocampal formation elicit an ephaptic depolarization capable of discharging pyramidal neurons. Si both paired-pulse (PP) and frequency stimulation of certain Since afferent inputs to the hippocampus are known to result in an augmentation of field potential amplitudes, it was of interest to determine the extent to which ephaptic interactions may contribute to these short-term potentiation phenomena. Orthdromic ground referenced intracellular responses, evoked

by stratum radiatum (SR) stimulation, were recorded from CAl pyramidal neurons in the 'in virco' slice preparation. The electrode was withdrawn from the cell and the evoked extracellular field potential subtracted from the intracellular response to obtain a measure of the transmembrane potential (TMP). Action potential generation on intracellular ground referenced recordings occurred from the peak of a graded negative-going "notch" on the rising edge of the EPSP at a latency equivalent to the extracellular population spike. Subtraction of field potentials revealed a sharp depolarizing wave on the TMP with an amplitude and latency that varied directly with that of the population spike. With a subthreshold stimulus intensity for intracellular spike generation, PP or frequency stimulation of SR evoked a potentiation of the population spike, a corresponding increase in the amplitude of the TMP depolarizing wave and an increase in the probability of action potential discharge. Action potentials elicited by either a test stimulus or during a frequency train arose from the peak of the TMP depolarizing wave in virtually all cells examined.

It is proposed that ephaptic interactions contribute to potentiation of the CAI extracellular population spike through recruitment of neighboring cells during repetitive afferent stimulation.

POSTSYNAPTIC-CELL MEMBRANE EVENTS ACCOMPANYING HABITUATION. с. 213.4 Larry Keenan and Harold Koopowitz, Developmental and Cell Biology, Univ. of California, Irvine.

Habituation of intracellularly measured vibration evoked responses from polymodal neurons in the brain of Notoplana acticola involves at least three postsynaptic phenomena. Changes that occur concurrently with habituation include decreases in postsynaptic membrane resistances, increased thresholds for firing action potentials, and decreases in cell membrane time constants. Membrane input resistances decreased on the average 11% from a mean of 33.8 Ma  $\pm$  8.9 (n=6). Thresholds for firing as measured by injecting depolarizing current into the cells increased up to threefold in some cases. This increase was further demonstrated by interspersing suprathresh-old depolarizing pulses between vibration stimuli (1 stimulus/ Under these conditions both the number of action 2 sec). potentials evoked by the pulses decreased as habituation pro-ceeded and the latency to the first spike evoked by each pulse Current injections of the same magnitude and freincreased. quency but without the vibration stimuli showed no significant decrease in number of spikes evoked. From this we concluded that neither accommodation nor fatigue were contributing factors. When prehabituation resting potentials were compared factors. When prehabituation resting potentials were compared to posthabituation resting potentials, the posthabituation potentials were 4.4 mV  $\pm$  2.1 (mean  $\pm$  S.D.) more negative than prehabituation resting levels (n=13). Decreases in time constants calculated from aRall analysis were obtained from all types of vibration-sensitive neurons studied. The results suggest that both cell resistivity and capacitance may be altered significantly in postsynaptic membrane as a consequence of synaptic events accompanying habituation. - STRUCTURE-DEPENDENT MODIFICATION OF END-PLATE CURRENT KINETICS BY ALKYL-BIS-GUANIDINES. Stephen M. Vogel\*, Jay Z. Yeh\* and Toshio Narahashi (SPON: Richard A. Berenberg). Dept. of Pharmacol., 213.5 SINUCIUME-DEPENDENT MODIFICATION OF END-PLATE CURRENT KINETICS BY ALKYL-BIS-GUANIDINES. Stephen M. Vogel\*, Jay Z. Yeh\* and Toshio Narahashi (SPON: Richard A. Berenberg]. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611. The alkyl-bis-guanidines contain two guanidinium groups, which are positively charged at physiological pH, separated by a linear alkyl chain of 4 to 10 carbons (bis-G-C<sub>4</sub> to bis-G-C<sub>10</sub>). We examined the influence of several compounds of this series on the end-plate current (EPC). The neuromuscular junction of the frog cutaneous pectoris muscle was voltage-clamped by the two-microelectrode method at 22°C. Clamp steps of 2 sec were made from a holding potential of -40 mV. The EPC was elicited by nerve stimulation 1 sec following the beginning of a clamp step. The clamp potential was varied between -140 and +60 mV in 20-mV increments. All of the derivatives reversibly suppressed the peak EPC in a manner dependent on the concentration. Bis-G-C<sub>4</sub> (10 mM) depressed the EPC in a voltage-independent manner. In contrast, bis-G-C<sub>6</sub> (0.3 mM), bis-G-C<sub>8</sub> (0.003 mM to 0.03 mM), and bis-G-C<sub>10</sub> (0.02 mM) caused a voltage-idependent block, i.e., the block was intensified with hyperpolarization of the EPC decay phase. Bis-G-C<sub>4</sub> and bis-G-C<sub>6</sub> lengthened the decay time constant of the EPC. With bis-G-C<sub>8</sub> (nduced a double exponential decay, as reported earlier (Vogel et al., Fed. Proc., 42, 1144, 1983). Bis-G-C<sub>10</sub> drastically shortened the decay time constant, which remained a single exponential. For bis-G-C<sub>8</sub>, kinetic analysis of the EPC using a sequential model gave a forward blocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at 0 mV and an unblocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at 0 mV and an unblocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at 0 mV and an unblocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at 0 mV and an unblocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at 0 mV and an unblocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at 0 mV and an unblocking rate of 0.61 x 10<sup>8</sup> M<sup>-1</sup> sec<sup>-1</sup> at
- MEPROADIFEN ENHANCES ACTIVATION AND DESENSITIZATION OF THE ACETYLCHOLINE RECEPTOR IONIC CHANNEL COMPLEX (AChR): SINGLE CHANNEL STUDIES. <u>Y. Aracava\*, S.R. Ikeda,\* and E.X.</u> 213.6 Albuquerque. Dept. Pharmacol. & Exp. Ther., University Maryland Sch. Med., Baltimore, MD 21201. The quaternary local anesthetic meproadifen is a noncompetitive

antagonist of the AChR which increases the affinity of acetyl-choline (ACh) for its binding site in <u>Torpedo</u> electric organ membranes (Mb1. Pharmacol. <u>15:294</u>, 1979). At the frog neuromuscular junction, meproadifen causes a voltage- and time dependent decrease in the peak amplitude of endplate currents and miniature endplate currents and accelerates ACh-induced desensitization. All the effects of meproadifen on these macroscopic events occurred without significant change in channel macroscopic events occurred without significant change in channel lifetime or conductance (bb1. Pharmacol. <u>22</u>:636, 1982). In the present study, we used patch clamp technique on myoballs cultured from neonatal rat muscles to assess directly the effects of meproadifen on ACh-induced single channel currents. The presence of meproadifen the low concentrations (10-50 nM) and ACh (20-300 nM) in the patch pipette resulted in an initial increase in the frequency of channel openings which subsequently decreased. For example, with ACh (250 nM) and meproadifen (10 nM) in the pipette, the frequency increased to 300-400% of control values and after 20-30 min it declined gradually. At a higher concentration of meproadifen (> 200 nM), the duration of increased channel activation was shorter and occasionally not seen. Indeed, at 500mephoaliten (v ) for any, the unarteen of intreased channel activation was shorter and occasionally not seen. Indeed, at 500 nM, meproadifen produced such a rapid decrease in the frequency of channel opening that the initial period of increased activation was not observed. However, at all concentrations of meproadifen (up to 2.5  $\mu$ M) applied with ACh in the pipette, no significant change in the channel lifetime or conductance was seen. In addition, during channel openings in the presence of meproadifen, a marked increase in the thickness of the baseline with fast 'flickers' occurred. These events happened simultaneously with 'bursting' activity which appeared between long silent periods, finally culminating in almost complete absence of channel opening. In contrast to other quaternary agents such as pyridostigmine (Akaike <u>et al.</u>, unpublished) meproadifen, even at high concentrations (10  $\mu$ M), did not affect the frequency, life-time or conductance of ACh channels when applied in the bath to cell-attached or inside-out patches. Thus, in agreement with our previous observations, it is suggested that meproadifen interacts primarily with AChR site located in the extracellular face of the cell membrane. Further, this study indicates that ant angints cell membrane. Further, this study indicates that late gonists such as meproadifen can facilitate activation and desensitization without affecting channel lifetime or conductance. (Supported by USPHS Grant NS-12063, U.S. Army Medical Research and Development Command Contract DAMD 17-81-C-1279 and FAPESP, Brazil.)

EFFECT OF GEPHYROTOXIN (GyTX) ON THE ACETYLCHOLINE (ACh) RECEPTOR IONIC CHANNEL COMPLEX: OPEN CHANNEL BLOCKADE AND ENHANCEMENT OF DESENSITIZATION. C. Souccar<sup>41</sup>, W. Varanda<sup>41</sup>, Y. Aracava<sup>41</sup>, J. Daly<sup>2</sup> and E. X. Albuquerque<sup>4</sup> (SPON: R.G. Grenell). Dept. Pharmacol. and Exp. Ther., University of Maryland Sch. of Med., Baltimore, MD 212016 6 Lab. Bioorganic Chemistry, NIADDKD, NIH, Bethesda, MD 20205. 213.7

GyTX is a tricyclic alkaloid, identified as [18,3a8,5a8,68(Z),-9aR,10R]dodecahydro-6-(2-penten-4-y1)pyrrolo[1,2-a]quinoline-1-ethanol, found in skin secretions of the Colombian poison arrow frog <u>Dendrobates histricoicus</u>. As previously reported by our laboratory (Fed. Proc. 41:1299, 1982), the action of GyTX on the frog neuromuscular junction is characterized by a combined effect both as an open channel blocker and as a desensitization-enhancing both as an open channel blocker and as a desensitization-enhancing agent. We have found that the toxin decreases the peak amplitude of the endplate current (epc) as well as the epc decay time constant ( $\tau_{epc}$ ). These effects were concentration dependent but only slightly voltage or time-dependent. The plot of  $1/\tau_{epc}$  versus concentration of GyTX was linear in accordance with the sequential model for open channel blockade. Noise analysis data showed that GyTX shortens the channel lifetime without affecting its conductance. its conductance. To assess more directly the effects of GyTX at the microscopic level, we used patch clamp technique in tissuecultured myoballs obtained from meonatal rat muscles. This allowed us to measure both lifetime and conductance of ACh-activated ionic channels. GyTX was either superfused into the bath solution or present in the patch pipette together with ACh. Recordings were obtained both from cell-attached and inside-out patches. GyTX (1-50  $\mu$ M) decreased the channel lifetime in a concentration-dependent manner, but single channel conductance patches. concentration-dependent manner, but single channel conductance remained unchanged at all concentrations studied. Quantitatively similar effects were seen by adding the drug to the bath in both cell-attached and inside-out patches. However, when GyTX was present in the pipette, the onset of the drug effect was faster and its potency higher. For example, at 20  $\mu$ M, GyTX decreased channel lifetime by about 35% of control values and this effect appeared 20-30 minutes after the toxin superfusion. On the other hand, at the same concentration, GyTX present inside the pipette shortened channel lifetime by about 75% almost immediately after the gigaseal was achieved. In addition to blocking the ACh ionic channel in its open conformation, GyTX also seemed to induce an increase in affinity of ACh for its receptor. This was seen as an enhancement of the desensitization rate as indicated by studies using double-barrelled pipette technique and also by an increase in the binding of agonists to the ACh recognition site in Torpedo electroplax membranes. (Supported by USPHS Grant NS-12063, U.S. Army Research Office Grant DAAG 29-81-K-0161 and FAPESP and CNPq, Brazil.)

213.9 DENDRITIC SPINE EPSPS IN CAT PYRAMIDAL CELLS - ACTIVE OR PASSIVE DENDRIIC SPINE EPSPS IN CAI PYRAMIDAL CELLS - ACTIVE OR PASSIVE TRANSFER FROM SPINE TO SOMA? D.A. Turner. Inst. of Neurophysio-logy, Oslo, Norway and VAMC, Univ. Minn., Minneapolis, MN. 55417 Andersen et al (J. Physiol. <u>307</u>:273, 1980) observed that prox-imal and distal synapses onto CAT hippocampal pyramidal cells are equipotent and similar in time course. Their explanations for this anomalous finding include the effect of dendritic spines and 'active' enhancement of dendritic EPSPs. Passive electrotonic active' enhancement of dendritic EPSPs. Passive electrotonic spread of EPSPs may be analyzed by computing EPSP shapes and mag-nitudes for varying input regions of a dendritic tree. Differences between modeling predictions and observations may indicate either net enhancement or rectification, implying 'active' EPSP trans-fer from a spine to the soma.

fer from a spine to the soma. To predict passive EPSP characteristics in CA1 pyramidal cells I have used a segmental cable model derived from HRP anatomy (Neurosci. Abstr. 8:945, 1982). Spine EPSPs were simulated with a transient conductance change ( $\alpha$  =50 and integrated magnitude of 12\*10<sup>-10</sup> S-msec). This input was applied to anatomically chosen proximal (PX) and distal (DS) sites on CA1 pyramids. The resulting soma waveforms were computed and compared (n=36 sites each):

	Xin Rspine		Spine	Soma	Rise	Half- Width	Charge	Charge
	( <sub>λ</sub> )	(10 <sup>8</sup> Ω)	(mV)	(µV)	(τ)	(τ)	(%)	(%)
ΡX	0.32	12.8	21.3	82.1	0.10	0.59	30.4	57.1
DS	1.00	17.4	23.2	16.1	0.40	1.45	33.5	22.5

The PX and DS parameters varied significantly, except the spine peak and the charge loss due to the reduced driving potential. These values are also close to those observed by Andersen et al: rise time of  $0.25\tau$  and halfwidth of  $1.0\tau$ . Thus, this passive cable model suggests the proximal and distal inputs to be differ-ent in terms of both synaptic efficacy (soma peak and charge trans-fer) and waveform parameters (rise time and halfwidth). In this model, dendritic spines did not significantly delay or attenuate the simulated EPSPs. The spine neck contributed less than 100 M $_{\Omega}$  of longditudinal resistance, compared to the rela-tively high input resistances into the dendrites. Other possible

than 100 M $_{\rm NC}$  of longditudinal resistance, compared to the relatively high input resistances into the dendrites. Other possible explanations for Andersen et al's observations include a diffuse spread of inputs and an 'active' enhancement of the EPSPs. Preliminary physiological evidence suggests that small EPSPs from proximal and distal sources (less than 1 mV) display a difference in rise time. Thus, the larger EPSPs recorded by Andersen et al (5-10 mV) may be above threshold for some active process, such as a slow inward current. Clearly, though, the model predictions differ from the observations on larger EPSPs, suggesting 'active' EPSP transfer in these neurons. NIH Grant #NS 06792

ALTERATION OF GANGLIONIC FAST EXCITATORY POSTSYNAPTIC CURRENTS 213.8 BY BARIUM. <u>E.A. Connor and R.L. Parsons</u>. Dept. of Neurobiology, Stanford Univ., Stanford, CA 94305 and Dept. of Anatomy & Neurobiology, Univ. of Vermont, Burl., VT 05405.

Barium is used as a pharmacological tool in many studies of membrane ion channels. It is a potent blocker of most voltage-dependent potassium channels and often has been used as a calcium substitute to investigate the kinetics of voltage-gated calcium channels. We have found that barium also has a direct postsynaptic action on the nicotinic fast excitatory postsynaptic current (EPSC) recorded from amphibian postganglionic sympathetic current (EPSC) recorded from amphibian postganglionic sympathet, neurons. In the present study, barium-induced alterations in fast EPSCs have been studied in voltage-clamped bullfrog sympathetic ganglion B cells (22-23°C). In the presence of barium (2-8 mM) EPSC decay was prolonged and in many cells, the EPSC decay phase deviated from a single exponential function. The decay phase in these cases was more accurately described as the sum of two exponential functions. The prolongation and frequency of occurrence of a complex decay increased both with increasing barium concentration and hyperpolarization. For 8 control cells voltage-clamped to -SOmV, the EPSC decay  $\tau$  was 4.7  $\pm$  0.1ms (mean  $\pm$  SEM) whereas for 11 other cells voltage-clamped to -SOmV and exposed to 8mM barium, the decay time course, clamped to -50mV and exposed to 8mM barium, the decay time course, fitted as the sum of two exponential components, had time constants of 5.1 ± 0.2 and 17.9 ± 1.0ms. The decay time course of spontaneous miniature excitatory postsynaptic currents (MEPSCs) was prolonged to an extent very similar to that of evoked EPSCs recorded in the same barium-treated cells. In control cells, the EPSC decay  $\tau$  increased with hyperpolarization; the coefficient of voltage dependence being -0.0027 ± 0.0003mV^{-1}. Both decay components in 8mM barium-treated cells increased with hyperpolarization; the coefficient of voltage-dependence being -0.0049 ± 0.001mV^{-1} for the initial component and -0.0086 ± 0.0022mV^{-1} for the second, slower component. At -50mV, EPSC amplitude was not markedly influenced by barium (2-8mM) whereas at -90mV there was a progressive increase in peak size with increasing barium concentration. As a consequence, although the EPSC-voltage concentration. As a consequence, although the EPSC-voltage relationship was linear between -20 and -100mV in control co cells, relationship was linear between -20 and -100mV in control cells, in barium-treated cells this relationship became progressively non-linear with membrane hyperpolarization. The EPSC reversal potential was shifted from -6.3  $\pm$  1.6mV to -11.4  $\pm$  2.1mV in the presence of 8mM barium. There was a voltage-dependent increase in charge movement during the EPSC in barium-treated cells which was not present in control cells. We conclude that barium alters the kinetics of recentor-channel certing in cert the kinetics of receptor-channel gating in amphibian postganglionic sympathetic neurons. Supported by NSF Grants BNS82-06452, BNS81-10974 and a MDA Grant.

213.10 DIFFERENT SYNAPTIC CHANNEL KINETICS IN FAST AND SLOW CONDUCTING SYMPATHETIC NEURONS OF THE FROG. L.M. Marshall\* (SPON: J.N. Weakly). Dept. of Physiol. University of North Carolina, Chapel Hill, NC 27514. Lumbar sympathetic ganglia of the frog have two populations of principal neurons that are innervated by two distinct classes of cholinergic preganglionic nerve fibers. The rapidly conducting B-neurons are innervated by rapidly conducting D-neurons receive synaptic input from the slowly conducting C-fibers (Nishi <u>et al.</u>, J. Cell. Comp. Physiol. <u>66</u>:19, 1965). This study examined and compared the properties of nicotinic acetylcholine channels that produce fast excitatory postsynaptic urrents (EPSCs) in these two types of sympathetic neurons.

types of sympathetic neurons. Neurons in the 9th and 10th paravertebral ganglia of adult bullfrog (<u>Rana catesbiana</u>) were identified or adult bullfrog (<u>Rana catesbiana</u>) were identified according to preganglionic conduction velocity and voltaged-clamped at -50 mV (22 deg. C). The EPSC, evoked by preganglionic stimulation, decayed as a single exponential for both cell types, but the decay time constants differed considerably;  $5.5 \pm 1.1$  msec (mean  $\pm$  s.d.) for B-neurons and  $10.2 \pm 2.3$  msec for C-neurons.

C-neurons. Spectral analysis was performed on membrane current fluctuations produced by the steady application of acetylcholine, in the presence of 0.5  $\mu$ M atropine (Anderson & Stevens, J. Physiol. 235:655, 1973). Power density spectra fitted single Lorentzian relations and gave estimates of the mean channel open-time of 5.2  $\pm$  0.9 msec (mean  $\pm$  s.d.) for B-neurons and 9.8  $\pm$  2.0 msec for C-neurons.

This close agreement between the EPSC decay time This close agreement between the EPSC decay time constant and the mean channel open-time supports the idea that, in frog sympathetic neurons, the decay of synaptic current is controlled by the closure of membrane channels, as proposed for the frog end-plate (Katz & Miledi, J. Physiol. <u>231</u>:549, 1973). Further, the clear differences in EPSC decay rate for B- and C-neurons is most likely due to the differences in the mean open-time of their synaptic channels. (Supported by NIH grant NS 17203). 213.11

CALCIUM CHANNEL ANTAGONISTS DISPLACE [<sup>3</sup>H]PHENCYCLIDINE BINDING TO TORPEDO ELECTRIC ORGAN MEMBRANE. P.M. Epstein\*, J.J. Lambert\*, S. Moraski Jr.\*, and E.G. Henderson. Dept. of Pharmacology, Univ. of Connecticut Health Center, Farmington, CT 06032. (SPON: S. Pfeiffer) The specific binding of 2nM [<sup>3</sup>H]phencyclidine ([<sup>3</sup>H]PCP) to electric organ membrane isolated from Torpedo californica, measured in the presence of 10µK carbachol, was displaced by CaCl<sub>2</sub> and several structurally different classes of calcium channel antagonists, including verapamil, diphenylmethylalkyl-amines, and the 1.4-dihydropyridines. The LGo's for displace-ment of [<sup>3</sup>H]PCP binding by these compounds was: CaCl<sub>2</sub> - 2.3mM, verapamil - 4.8µM, flunarazine - 2.7µM, cinnarazine - 1.5µM, nicardipine - 1.4µM, nimodipine - 2.5µM, and nifedipine - 9.8µM. At the concentrations at which they produced 50% inhibition of [<sup>3</sup>H]PCP binding, none of these antagonists inhibited the initial rate of [1<sup>25</sup>I]- $\alpha$ -bungarotoxin binding to these membranes. These results suggest an association between the [<sup>3</sup>H]PCP binding site and an ion channel that can conduct calcium in Torpedo mem-branes. PCP has been shown to interact with the ion channel associated with the nicotinic acetylcholine receptor (AchR) in Torpedo membranes (Eldefrawi et al., Proc. Natl. Acad. Sci. USA 77:7458, 1980). Since this channel is not ion specific and can conduct Ca<sup>2+</sup> in addition to Na<sup>+</sup> and K<sup>+</sup> (Lambert et al., Ann. Rev. Pharmacol. Toxicol. 23:505, 1983), it is possible that Ca<sup>2+</sup> antagonists may interact with this channel lifetime were, how-ever, not evident. Verapamil (25µM) and nicardipine (10µM) pro-duced no change in channel lifetime (τ) in voltage-clamped, transected frog cutaneous pectoris muscle when end-plate curduced not change in channel lifetime (t) in voltage-clamped, transected frog cutaneous pectoris muscle when end-plate curtransected frog cutaneous pectors muscle when end-plate cur-rents were elicited 500 mscc after jumps to potentialis ranging from -130 to +50mV. Hence, if these antagonists interact with the ionic channel associated with the AchR, they may interact with an agonist activated, but nonconducting state of the channel. (Supported in part by Miles Laboratories, a Wellcome Research Travel Grant to J.J.L., and U.S. Army contract DAAG29-81-K-0165.)

WAVEFORM ANALYSIS OF DISCRETE INHIBITORY SYNAPTIC POTENTIALS IMPINGING ON MOTONEURONS DURING THE ATONIA OF ACTIVE SLEEP. F.R. Morales, P.A. Boxer\* and M.H. Chase. Depts. of Physiology and Anatomy and the Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024. We have reported, in the chronically prepared cat, the presence of spontaneous discrete IPSPs in high gain intracellular recordings of alpha motoneurons during the atonia of active sleep (<u>Exp. Neurol</u>. 78:471, 1982). In the present study we performed a quantitative analysis of the waveform parameters of these notentials in order to understand the wide variability in IPSP quantitative analysis of the waveform parameters of these potentials in order to understand the wide variability in IPSP amplitudes observed within given motoneurons. These inhibitory potentials were found to exhibit large variations in amplitude, not only within a given cell, but also across cells. Their amplitudes ranged from 0.2mV (resolution limit) to 3.5mV; 10-90% rise-times ranged from 0.3 to 1.6 msec and half-widths from 0.5 to 6 msec. The relationships among these waveform parameters were then evaluated within the conceptual framework developed by Rall based on a mathematical neuronal model (<u>J. Neurophysiol</u>. 30:1138, 1967).

Rall based on a mathematical neuronal model (<u>J. Neurophysiol</u>. <u>30:1138, 1967</u>). For all cells (n=31) a statistically significant correlation was found between the rise-time and potential amplitude. Correlation coefficients (r) ranged from 0.48 to 0.73. The slopes of these correlations were all positive and extended from 0.2 to 0.65. For theoretical synaptic potentials that differ only in their location, Rall has shown that a negative correlation should be expected between rise-time and amplitude. Consequently, the differences in amplitude in the IPSPs cannot be explained purely on the basis of different synaptic locations. A positive correlation also existed between the rise-time and

A positive correlation also existed between the rise-time and half-width of these potentials; however, the importance of this correlation, vis-a-vis their synaptic location, is reduced due to an unexpected positive correlation between the potential's amplitude and its half-width. A statistically significant negative correlation was found between the rate-of-rise negative correlation was found between the rate-of-rise normalized by the amplitude and the amplitude of the IPSPs (r: from -0.49 to -0.65; slopes from -0.25 to -0.8), indicating that the rising phases of large IPSPs are relatively slower than those of the small IPSPs.

These data can be tentatively explained by postulating that the presynaptic inhibitory neurons which are responsible for the large IPSPs provide relatively greater numbers of synaptic boutons to alpha motoneurons compared with the presynaptic neurons generating small IPSPs. The variability in IPSP size may reflect a need for a highly tuned pattern of inhibition to accord with the fluctuating levels of neuronal activity during active sleep.

ACTIVATION OF AN ELECTROGENIC SODIUM PUMP IN HIPPOCAMPAL PYRAMIDAL 213.13 ACTIVATION OF AN ELECTROGENIC SODIUM PUMP IN HIPPOCAMPAL PYRAMID NEURONS. <u>Scott M. Thompson\* and David A. Prince</u>. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305. Application of glutamate to CAI hippocampal pyramidal cells produces a brief depolarization which is followed by a prolonged hyperpolarization. The mechanisms by which this post-glutamate hyperpolarization (PGH) is produced were examined. Transverse hyperpolarization (PGH) is produced were examined. Transverse slices of guinea pig hippocampus were prepared and maintained in vitro in the usual manner at  $37^{\circ}$ C. Applications of glutamate (5-25 mM in normal bathing medium) were made from broken pipettes (5-10 µm tips) placed in stratum radiatum or stratum pyramidale with in 200 µm of the recording electrode. Neuronal responses consis-ted of a depolarization of up to 30 mV, followed by a rapid repo-larization and a prolonged hyperpolarization which gradually returned to resting levels. The amplitude and duration of the PGH were proportional to the size of the depolarization evoked by the glutamate application. The PGH could be as large as 15 mV and last as long as 25 min. Experiments were performed to distinlast as long as 2.5 min. Experiments were performed to distin-guish between two possible explanations for this post-glutamate hyperpolarization: 1) stimulation of an electrogenic sodium pump

hyperpolarization: 1) stimulation of an electrogenic sodium pump by sodium accumulation during the depolarization, or 2) a pro-longed increase in calcium-activated potassium conductance. The PGH was found to be unaffected by perfusion with media con-taining manganese (4-5 mM) and low concentrations of calcium (0-1 mM) which effectively blocked vol tage-sensitive calcium channels and synaptic events. Furthermore, the PGH did not reverse polar-ity when the cells were polarized beyond the potassium equilibrium potential with direct current injection. However, the amplitude and duration of the PGH were reduced by lowering the temperature as little as 5°C. In addition, local application of strophanthi-din (0.1 mM) completely abolished the PGH. This evidence there-fore supports the hypothesis that the post-glutamate hyperpolari-zation is produced by the activity of an electrogenic sodium pump which is stimulated by sodium accumulation during the depolariza-Zation is produced by the activity of an electrogenic sodium pump which is stimulated by sodium accumulation during the depolariza-tion. Preliminary data suggest that the electrogenic sodium pump is also activated by prolonged stimuli, such as direct depolari-zing current injection, which evoke a steady train of action potentials. These data make it likely that the pump would be strongly activated during sustained epileptiform discharges. Steady state pump activity may also directly contribute to the resting potential. Post-glutamate hyperpolarization provides a useful providencial measure of sodium num activity in binpouseful physiological measure of sodium pump activity in hippo-campal neurons.

DIRECT EFFECTS OF NEOSTIGMINE ON THE END-PLATE RECEPTOR CHANNEL 213.14 COMPLEX. J. F. Fiekers. Dept. of Anatomy and Neurobiology, Univ. of Vermont College of Medicine, Burlington, VT 05405. Most effects of the anticholinesterase agents at cholinergic

synapses are considered primarily indirect as a result of the inhibition of the acetylcholinesterase enzyme (esterase). However, additional direct actions of many of the anticholinesterase agents have also been reported. In the present study the effects of a carbamate antiesterase agent, neostigmine, (Neo) on the MEPC amplitude and decay kinetics and agonist induced end-plate current fluctuations were studied in voltage-clamped snake costo-cutaneous neuromuscular junctions. Neo, in concentrations up to 10-5M, produced a concentration-dependent increase in both the amplitude and the time constant of MEPC decay ( $\tau_{MEPC}$ ) without altering the voltage dependence of  $\tau_{MEPC}$ . Power density spectra obtained with either acetylcholine (ACh) or carbachol (CCh) were well fitted by a single Lorentzian with a characteristic frequency unchanged by neostigmine. Concentrations of Neo greater than  $10^{-5}M$  produced a concentration dependent decrease in MEPC Liam 10  $^{\text{M}}$  produced a concentration dependent decrease in the BPC amplitude and a corresponding increase in t<sub>MEPC</sub>. In addition, the spectra of fluctuations produced by ACh could only be fitted with two Lorentzian components. Two component spectra were also obtained with CCh-induced current fluctuations indicating that the effects were not a result of esterase inhibition. Additional experiments were performed on muscles pretreated with collagenase (2 hours, 0.2%) to inactivate the esterase. Power density spectra obtained with either ACh or CCh-induced fluctuations also exhibited multiple time constants. In each case, the second, slower time constant was increased with either membrane hyperpolarization or increasing concentrations of Neo. The effects of Neo were reversible with washing. These results indicate that Neo produces direct effects on the receptor-channel complex which are unrelated to inhibition of esterase. Further, the voltage and concentration dependencies of each spectral component do not appear to support an open channel blocking mechanism. It is sug-gested that Neo, in addition to its actions on the esterase, has direct actions to (1) block the cholinergic receptor and (2) to It is sugproduce drug-induced alterations in the gating kinetics of the receptor-channel complex at the neuromuscular junction. EFFECTS OF SOMAN ON ACETYLCHOLINE MEDIATED CONDUCTANCES IN <u>APLYSIA CALIFORNICA</u> NEURONS. <u>Margaret G. Filbert\*</u> (SPON: J.F. Glenn) Neurotoxicology Branch, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, ND 21010. 213.15 Institute of Chemical Defense, Aberdeen Proving Ground, MD 2000. Acute intoxication by organophosphorus anticholinestrase compounds produces cholinergic crises resulting in convulsions, ataxia, respiratory paralysis, coma and death. Treatment for exposure to these compounds is based on the premise that the toxic properties of the inhibitors are due to the persistence and toxic properties of the infinitions are due to the persistence and accumulation of acetylcholine. Classical acetylcholine antagon-ists, however, such as atropine, d-tubocurarine and mecamylamine do not entirely reverse the effects nor significantly increase the LDSO. A number of investigators have suggested that while the primary effects of the organophosphorus compounds can be

the primary effects of the organophosphorus compounds can be attributed to the inhibition of cholinesterase, an additional action on effector organs may also be present. Using current- and voltage clamp techniques, the effects of soman were examined on neurons of <u>Aplysia californica</u>. Acetyl-choline and carbachol were applied by iontophoresis from double barrel micropipettes. Soman was dissolved in artificial sea water and applied by superfusion into a recording chamber which were continually perfused with artificial sea water membrane water and applied by superfusion into a recording chamber which was continually perfused with artificial sea water. Membrane potential, input resistance and current-voltage relationship were monitored before and after application of soman. At 10<sup>-5</sup>M and higher concentrations of soman, a marked increase in input resist-ance was observed. The response to acetylcholine usually showed an initial increase in amplitude and in duration while the response to carbachol was decreased in spite of the increased imput resistance represented to a source subsequently. decreased in amplitude. When the response subsequently decreased in amplitude. When the responses to acetylcholine and carbachol were normalized to constant input resistance a dose dependent inhibition by soman on response amplitude was apparent. Upon washout of soman by perfusion with soman-free sea water, recovery to control amplitude of both acetylcholine and carbachol responses was seen but the prolonged duration of the acetylcholresponses was seen but the probaged duration of the acetylcholinesterase, remained unchanged. These results suggest that a direct effect of soman on passive properties of the membrane and a blocking action at the receptor-channel complex may occur in addition to the inhibition of acetylcholinesterase.

213.16 ROLE OF CYCLIC AMP IN ADENOSINE-INDUCED POTENTIATION OF

RULE OF CYCLIC AMP IN ADENDSINE-INDUCED POIENIATION OF MUSCARING HYPERPOLARIZATION IN NEUROBLASTOMA CELLS. <u>Akinobu</u> <u>Tsunoo<sup>\*</sup> and Toshio Narahashi</u> (SPON: S.-C. Cheng). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611. We have previously reported that adenosine, 2-chloroadenosine, and prostaglandin E1 (PGE1) potentiate the muscarinic hyperpolarization but not dopamine depolarization in neuroblastoma cells, and proposed that this effect is produced by the receptor-mediated increase in cyclic AMP (Tsunoo, A. and T. Narahashi, Biophys. J. 41, 66a, 1983). The present study was carried out to substantTate the notion that adenosine and PGE1 activate adenyl cyclase which in turn increases cyclic AMP

activate adenyi cyclase which in turn increases cyclic AMP producing its physiological effect. Intracellular recordings were made from cultured cells of neuroblastoma NIE-115 line. Acetycholine and dopamine were iontophoretically applied. Other drugs were given by bath application or intracellular pressure injection through a second micropipette

Injection of 10 mM cyclic AMP for 0.2-0.4 sec potentiated the uscarinic hyperpolarization to 173 \* 19% of the control (mean \* SEM, n=4) without changing the resting membrane potential, nicotinic depolarization and dopamine depolarization. nicotinic depolarization and dopamine depolarization. Three-second injection caused a further potentiation up to 287  $\pm$ 59% of the control (n=4). However, injection of the carrier solution containing 150 mM KCl and 5 mM HEPES (pH 7.4), or 10 mM adenosine 5'-monophosphate did not affect the muscarinic hyperpolarization. It has been shown that activation of various receptor-related adenyl cyclase is GTP-dependent. Therefore, 3 mM GTP-y-S, a GTP analog resistant to hydrolysis, was injected. This potentiated the muscarinic hyperpolarization to 162  $\pm$  17% of the control (n=5) without application of adenosine and PGE<sub>1</sub>. Morphine, which is known to inhibit adenyl cyclase, was examined whether it depressed the 2-chloroadenosine-induced potentiation of the muscarinic hyperpolarization. Bath application of 75 µM whether it depressed the 2-chloroadenosine-induced potentiation of the muscarinic hyperpolarization. Bath application of 75  $_{\rm M}$  2-chloroadenosine increased the amplitude of the muscarinic hyperpolarization to 273 \* 32% of the control, and 2  $_{\rm M}$  morphine decreased the 2-chloroadenosine-induced potentiation to 170 \* 16% of the control (n-4). Naloxone antagonized the inhibition by morphine. Potentiations by 75  $_{\rm M}$  2-chloroadenosine in the absence and presence of 2  $_{\rm M}$  morphine and 8  $_{\rm M}$  naloxone were 260 \* 38% and 252 \* 32% of the contral (n-4), respectively. The present results provide further evidence that cyclic AMP mediates the adenosine- and PGE1-induced enhancement of the muscarinic hyperpolarization and that morphine inhibits such potentiation by depressing adenyl cyclase through activation of specific opiate receptors. Supported by NIMH grant MH36183.

213.17 MODELLING OF GLUTAMATE RECEPTORS IN THE DISTAL RETINA OF THE MUDPUPPY. M.M. Slaughter; B. Kalman\*, and R.F. Miller. (SPON:
P. Simmons). Dept. of Ophthalmology, Physiology, and Biophysics,
Washington University School of Medicine, St. Louis, Mo. 63110
Photoreceptors in the vertebrate retina are believed to use an excitatory amino acid neurotransmitter. Biochemical release measurements using HPLC techniques and pharmacological experiments surgements using HPLC techniques and pharmacological experiments using an electrophysiological approach indicate that glutamate is the cone transmitter in the mudpuppy retina. Although ultrastruc-tural data indicates that these cone photoreceptors synapse onto three classes of neurons, our experiments have shown that each class of these second-order neurons contains a different type of glutamate receptor. We were interested in characterizing these three distinct glutamate receptors by comparing the molecular structures of compounds that selectively interacted with each receptor type. Experiments were performed in the superfused retina eyecup preparation using intracellular recording procedures. Conductance measurements and synaptic blocking agents were used to evaluate the mechanism and site of action of bath-applied drugs Glutamate agonists and antagonists all have three apparent binding sites: 1) an alpha amino group, 2) an adjacent alpha carboxyl group, and 3) a more distant, terminal carboxyl group. When the spatial relationship between the first two binding sites was kept constant, the three types of glutamate receptors found in the distal retina could be distinguished by the distance between these two groups and the third, terminal carboxyl group. The ON bipolar synaptic receptors were selectively activated by L-2-amino-4phosphonobutyrate, L-O-phosphoserine, ibotenate, and amino dicar-boxycyclopentane. Comparisons of the three dimensional molecular structures of these compounds indicate that the ON bipolar recep-Structures of these composings indicate that the on signal tecep-tor binds to an extended conformation of glutamate in which the intercarboxyl distance  $\geq$  4A. The synaptic input to the horizontal cells was antagonized by cis 2,3 PDA and selectively by D-O-phos-phoserine. Matching the active sites of these two molecules sug-gests that the horizontal cell synaptic receptor binds to a par-tically folded conformation of alutamate with an interarchyrul tially folded configuration of glutamate with an intercarboxyl distance  $\simeq$  3.5A. The OFF bipolar was less sensitive to large, conformationally restricted glutamate agonists such as kainic acid and the synaptic input was blocked by cis 2,3 PDA but not by D-O-phosphoserine. Although this does not delineate the precise spatial relationship of the binding sites for the OFF bipolar receptor, it does indicate that this receptor is activated by glutamate in a folded conformation in which the intercarboxyl distance is < 3A. Three dimensional molecular models of the preferred ligands for each receptor will be presented.

213.18 DESENSITIZATION OF THE GABA RECEPTOR IN HIPPOCAMPAL NEURONS ISOLATED FROM THE ADULT GUINEA PIG. Randy Numann\* and R.K.S. Wong (SPON: L.Y. Huang). Dept. of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas 77550. Individual neurons were isolated from the adult guinea pig hippocampus by using an enzymatic dispersion procedure. The GABA action on the pyramidal type neurons were studied using a suction 'electrode voltage clamp technique. GABA at 10<sup>-4</sup> M was pressure ejected from a 10-15 MΩ pipette and found to elicit a hyperpolarizing-depolarizing response in these neurons. The reversal potentials were -70mV and -30mV for the hyperpolarizing response was minimally activated and often non-detectable when and depolarizing responses respectively. The depolarizing response was minimally activated and often non-detectable when GABA concentrations were reduced to 10<sup>°</sup> M. To examine the desensitization of the hyperpolarizing response neurons were voltage-clamped to -30mV. GABA pulses applied then induced only outward currents. It was observed that when long duration (1-3 sec.) GABA pulses (10<sup>°</sup> M) were applied, the outward current rapidly attenuated with a time constant of 1.7 sec. Double rapidly attendated with a time constant of 1.7 sec. Double pulse experiments also showed that the amplitude of the outward current induced by the GABA test pulse was reduced compared to the conditioning pulse. The time constant for recovery of the test pulse response was 5.0 sec. This type of fading of the GABA induced hyperpolarization

is commonly observed in mammalian central neurons. It has been considered that such fading can be attributed to at least three causes. (1) The gradual development of a separate depolarizing response, (2) accumulation of intracellular Cl and (3) true receptor desensitization. Since we can now clamp the membrane voltage to the reversal potential of the depolarizing response; contribution of (1) to our observed fading can be exlcuded. To evaluate the contribution of Cl accumulation upon desensitization we carried out paired pulse experiments using 10<sup>-5</sup>M GABA with the conditioning pulse applied at two different clamped potentials (-30mV and -70mV). In a typical example from 15 experiments the conditioning pulse applied at -30mV elicited a large outward current (660pA). The test response applied 3 sec. later was 280pA. When the cell was briefly clamped to -70mV, the conditioning pulse applied at this potential produced no significant outward current yet the following test pulse applied 3 sec. later at -30mV still showed attenuation (260pA). Since attenuation of the test response occurred even in the absence of causes. (1) The gradual development of a separate depolarizing attenuation of the test response occurred even in the absence of outward current flow during the conditioning pulse; we suggest that fading of the GABA response in hippocampal pyramidal cells cannot be attributed to intracellular chloride accumulation and that GABA receptor desensitization is the primary mechanism underlying this phenomenon.

213.19 KINETIC PROPERTIES OF CHOLINERGIC DESENSITIZATION IN VOLTAGE CLAMPED APLYSIA NEURONS (SPON: C. D. Anderson). <u>A. F. Hall\*</u>, N. T. Slater\* and D. O. Carpenter, NYS Dept. of Health, Albany, NY 12201

> The influence of agonist concentration and membrane potential on the kinetics of desensitization onset of excitatory acetylcholine (ACh) responses in <u>Aplysia</u> RB neurons have been studied. Neuronal cell bodies were mechanically isolated from abdominal ganglia and voltage clamped with two microelectrodes. ACh was rapidly microperfused over the cell for periods of several minutes, followed by 30 minute recovery periods, and the time course of the decline of the ACh-induced current at varying membrane potentials or agonist doses was recorded. Computer simulations of the current decline best fit the experimentally observed responses as the sum of two exponentials plus a constant (C):

With increasing agonist dose the peak ACh-induced current extrapolated to time zero ( $\rm I_p$ ) was increased and the time constants of both exponential components were reduced, resulting in an acceleration of the normalized rate of desensitization and sigmoidal relationship between  $\rm I_p$  and ACh dose (1 to 50  $\mu$  M).

For a fixed agonist dose (50  $\mu$ M), increasing membrane potential resulted in a linear increase of Ip; however, no change in the rate of either exponential component was observed over the range of membrane potentials studied (-50 to -110 mV).

Desensitization is currently viewed as a cyclic scheme in which the activated but closed state of the receptor-ionophore complex may switch to form an agonist-bound but inactivated ('desensitized') complex. The ACh dose dependency and voltage independence of desensitization onset of this response is consistent with this scheme. (Supported by USPHS NS 18435). 213.20 CALMODULIN INHIBITORS ACCELERATE CHOLINERGIC DESENSITIZATION IN VOLTACE CLAMPED APLYSIA NEURONS. N. T. Slater\*, A. F. Hall\* and D. O. Carpenter (SPON: J. A. Ramaley). New York State Department of Health, Albany, NY 12201.

The excitatory response of <u>Aplysia</u> RB neurons to acetylcholine (ACh) is pharmacologically similar to the vertebrate nicotinic response. In isolated, voltage clamped cell bodies of <u>Aplysia</u> abdominal RB neurons, the decline of the ACh-induced inward current is the sum of two exponential components plus a constant (Hall <u>et al.</u>, Neurosci. Abst., 1983). This preparation allows known concentrations of agonists and other compounds to be applied by rapid microperfusion, and the kinetics of desensitization to be studied in a quantitative fashion.

zation to be studied in a quantitative rasmion. We have studied the effects of the calcium antagonists D-600, SKF 525A and the neuroleptic trifluoperazine (TFP) on the kinetics of desensitization onset to microperfused ACh. Over the concentration range 0.1 to 20 M these compounds produce a dose-dependent acceleration of the rate of desensitization, the order of potency being TFP>SKF 525A>D-600. This acceleration of desensitization is associated with a dose-dependent increase in the relative contribution and rate of the fast exponential component and a decrease in the ratio C/Ip, where Ip is the peak ACh-induced current and C is the steady-state current to which the response declines. This effect does not appear to be related to actions of the compounds such as channel blockade, as the acceleration of desensitization is often maximal at concentrations which have little effect on Ip. Also channel blockars

Previous investigations of the mechanisms underlying cholinergic desensitization at the vertebrate neuromuscular junction have demonstrated that the rate of this process is accelerated by increases in intracellular free calcium (Chesnut, J. Physiol. 336:229, 1983). A diverse number of pharmacological agents, including neuroleptics and calcium antagonists, also accelerate desensitization by a mechanism generally attributed to some local anesthetic action. However, these compounds share an ability to inhibit the calcium-binding protein calmodulin, TFP being the most potent calmodulin inhibitor described (Volpi, <u>et</u> al., PNAS, 78:795, 1981). In light of these actions and the proposed calcium dependence of desensitization, we suggest that the acceleration of desensitization observed in these experiments may result from an inhibition of calmodulin, thereby increasing intracellular free calcium levels. It remains to be determined whether calcium ions act directly to accelerate the rate of inactivation of the ACh receptor protein, or whether a calcium-dependent protein kinase is involved. (Supported by USPHS grant NS18435).

## VESTIBULAR SENSORY ORGANS

214.1 PERILMPHATIC AND ENDOLYMPHATIC ACTION OF OUABAIN ON THE MEMBRANE POTENTIAL OF THE AXCLOTL (<u>AMBYCSTOMA MEXICANUM</u>) VESTIBULAR NEU-ROEPTTHELIAL CELLS. Enrique Soto E.\*, R. Budelli\*, M.T. González Estrada\* y H. Bracho\*. (SPON: Maria Mirta Rodriguez Budelli).Depto. Investigaciones Biomédicas, Instituto de Ciencias de la Universidad Autonoma de Puebla, y Unidad de Investigaciones Cerebrales del Instituto Nacional de Neurología y Neurocirugía.México.

The epithelium of the inner ear separates two fluids of different ionic composition: the endolymph, which has a high potassium content (above 100 mM) and the perilymph, with low potassium content (below 5 mM).

The mechanism responsible for this high endolymphatic  $K^{\dagger}$  concentration is unknown. The stria vascularis has been proposed as responsible for this high K concentration. Since the AxolotIs have no stria vascularis, neuroepithelial vestibular cells may be involved in endolymph production. In order to mantain this ionic distribution, it is necessary to actively transport K<sup>+</sup> from the perilymph. We propose that this transport is achieved by the concerted action of two pumps. One, located in the perilymphatic (basolateral) membrane would transport K<sup>+</sup> into the cell. The Na<sup>+</sup> - K dependent ATPase may be responsible for this. Another pump located in the endolymphatic (apical) membrane would transport K<sup>+</sup> form the inside of the cell to the endolymph. In this study we test if the Na<sup>+</sup> - K dependent ATPase is located in the basolateral membrane, by recording membrane potentials of neuroepithelial cells when perfusing with ouabain (10<sup>-4</sup> M) either the basolateral epithelium of the Axolatl.

While ouabain placed at the endolymphatic side exerted practically no effect, a clear depression of membrane potentials was observed when the drug acted on the perilymphatic basolateral side.

Our results suggest that  $Na^+ - K^+$  dependent ATPase is located only at the basolateral membrane of the neuroepithelial vestibular cells.

214.2 COMPARATIVE STUDIES OF OTOCONIAL GROWTH AND DEVELOPMENT IN BIRDS, AMPHIBIA AND REPTILES. J. Ballarino\* and H.C. Howland (SPON: R. Hoy). Sections of Physiology and Neurobiology and Behavior, W204 Mudd Hall, Cornell University, Ithaca, NY, 14853.

Otoconia are crystals of high specific gravity which form the weight of the gravity receptors of the inner ear. Each otoconial crystal consists of an organic matrix and crystalline calcium carbonate. In birds, mammals and some reptiles the calcium carbonate is crystallized in the form of calcite, while in amphibians and some reptiles, it is crystallized in the form of aragonite. Previously, we have investigated otoconial morphology in developing chicks using scanning electron microscopy and polarized light microscopy and have found various forms of otoconia (Ballarino, J. and H.C. Howland, Anat. Rec. 204:83, 1982). Based on the time of appearance and frequency of occurrance of the various forms, we have proposed a normal growth sequence for otoconia in the chick. Our studies of chick otoconial development indicate that the organic matrix may play some role in guiding the formation of calcium carbonate into a stable calcite crystal. This raises the question of whether the same is true of aragonite formation in amphibia and many reptiles. Is there a similar sequence of events for aragonite and calcite formation? In particular, how do some reptiles form both calcite and aragonite otoconia? What is the pattern of distribution of calcite and aragonite otoconia during the development of these reptiles? Based on scanning electron microscopy and polarized light microscopy of developing amphibian and reptilian otoconia, we will present data on the sequence of events in the formation of otoconial aragonite and calcite in amphibia and reptiles and compare their development to that of the chick.

QUANTITATIVE ANALYSIS OF HAIR CELL AND GANGLION CELL PROLIFERATION IN THE FISH SACCULE. <u>A. N. Popper and B. Hoxter\*</u>, Dept. of Anatomy, Georgetown University Schools of Medicine and Dentistry, Washington, D. C. 20007. 214.3

Dentistry, Washington, D. C. 2007. The complete complement of sensory hair cells in the ears of amniotic vertebrates appears to arise during embryonic development. The only post-embryonic change involves loss of sensory cells. In contrast, there is evidence that sensory hair cells continue to be added well into post-embryonic stages in some anamniotes (Corwin, J. T. J. <u>Comp. Neurol.</u>, 201:541-553, 1981; Platt, C., <u>J. Comp. Neurol.</u>, 172, 283-297, 1977). However, evidence for continuous proliferation has not been quantified, part a evitent has hore before hore unclear. In series the thin data on and so its extent has heretofore been unclear. In order to obtain data on sensory hair cell proliferation we have investigated the number of sensory hair cells and eighth nerve ganglion cells in the saccule of the cichlid fish Astronotus ocellatus (the oscar) using animals from 2.0 cm to 19.0 cm in standard length.

standard length. The smallest animals (2.0 cm) had about 5,000 hair cells while larger specimens (over 16 cm long) had over 150,000 sensory cells. The increase in number of sensory cells in animals from 2 to 15 cm in length was correlated ( $r^{2-0.7}$ ) with increases in both fish length and body weight. The density of sensory hair cells was greater at the margin of the epithelial region than in the more central region. However, the densities in any one selected region did not vary between fish, even when the overall number of hair cells in the saccule increased substantially. In contrast to the steady increase in sensory hair cell number in animals

up to 15 cm long, all larger animals had about the same number of hair cells even though the sensory epithelium itself grew somewhat. This was Cells even though the sensory epithelium itself grew somewhat. Inis was further reflected in differences of sensory cell density between the animals above 15 cm and the animals smaller than 15 cm. While the density of cells was similar in the peripheral regions of the epithelium for both groups, the larger group had a density of hair cells in the central region that was significantly smaller than the density in the smaller animals

Ganglion cells also increased with the size of the animal. The smallest fish had approximately 150 ganglion cells, while the largest animals had about 750 cells. If we make the assumption that all sensory cells are innervated by afferent fibers, it becomes apparent that the ratio of sensory cells to ganglion cells in large fish is much greater than in small fish. Thus, each afferent fiber innervating the saccule receives input from over 200 sensory cells in large animals and about 30 cells in small animals.

over 200 sensory cells in large animals and about 30 cells in small animals. The increase in number of sensory cells in <u>Astronotus</u> is the first detailed quantitative demonstration of substantial post-embryonic hair cell proliferation in the ear of any vertebrate. The implications of this increase for the function of the saccule in fishes in not yet clear, nor do we have any understanding of the functional significance of the substantial change in the sensory cell to ganglion cell ratio in different sized animals. (Supported by grants from NSF and ONR.)

RECEPTOR-CALYX JUNCTION IN THE CRISTA AMPULLARIS OF THE DEV-214.5 ELOPING CHICKEN, K.D. Peusmer, N.H. Lindberg<sup>\*</sup> and P.F. Mans-<u>field<sup>\*</sup></u>, Dept. of Anatomy, Geo. Washington Univ. Sch. of Med., Wash., D.C. 20037 and Jefferson Med. Col., Phila., Pa. 19107. Vestibular ganglion cells form colossal fibers that centrally

Vestibular ganglion cells form colossal fibers that centrally innervate the principal cells of the avian lateral vestibular nucleus (tangential nucleus) by large spoon endings. Peripheral-ly the colossal fibers synapse with hair cells of the cristae ampullaris by means of large calycine endings. The spoons undergo developmental changes in synapses as studied in 15 day embryos, hatchlings and 3 year old chickens (Peusner, '82). To determine if a relationship exists between developmental events in the orderene and the central connection, calyres and their in the endorgan and the central connection, calyces and their synaptic contacts were examined at corresponding ages. The linear surface of hair cells and their membrane special-

izations apposed to calyces ware measured on electron micro-graphs. Profiles of type I hair cells (HCI) are enclosed by a calyx except at the cell's apex. Type II hair cells (HCII) are not surrounded by calyces, but do juxtapose outer calycine sur-faces where synapses occur. Membrane specializations measured faces where synapses occur. Memorane specializations measured include: ribbon synapses, asymmetric membrane densities and agranular reticulum (AR). Membrane densities may be partial sections through ribbons. AR closely parallels portions of the hair-cell plasmalemma. The results are tabulated below:

			Embryo	Hatch.	3 Y.O.
HCI-Calyx	no. of	profiles:	49+	146	132
total linear surface me	easured		932um	4,266um	3,707um
a. ribbon synapses			0.64%	0.22%	0.48%
b. membrane densities			2.42%	0.18%*	0.48%*
c. AR			7.98%*	10.64%	10.54%
linear surface covered	by a,b,	c	11.04%	11.04%	11.50%

C. AR			0	0	0

alizations during development. From this and previous studies, it appears that birth or thereabouts marks a time for major developmental changes peripherally and centrally in the vestibular system, notably a decline in "chemical" transmission sites. (Supported by USPHS grants 2 RO1 NS18108 and 5 RO1 NS15633).

GROWTH OF TWO DISTINCT POPULATIONS OF HAIR CELLS IN THE LAGENA OF 214.4 THE GOLDFISH INNER EAR. Christopher Platt. Dept. Biological Sciences, Univ. Southern California, Los Angeles, CA 90089.

The lagena in the goldfish ear has an unusual macula because it contains not one, but two populations of hair cells having large ciliary bundles. The caudal patch is separated from the rostral patch by a zone of hair cells with small ciliary bundles; the caudal patch is covered by the otolith, but the rostral patch is covered only by otolithic membrane. During development of many frogs, the amphibian papilla fuses from two patches into a contiguous strip with the two ends showing different acoustic sensitivities (Lewis, E. R., <u>Brain Res., 219:149</u>, 1981). To see how the two separate patches in goldfish develop, scanning electron microscopy (SEM) was used on lagenar maculae from goldfish ranging in length from 20-100 mm and mass from 0.2 to over 20 g. After conventional fixation, dehydration and critical-point drying, tissues were photographed using SEM for The lagena in the goldfish ear has an unusual macula because

over 20 g. After conventional fixation, dehydration and critical-point drying, tissues were photographed using SEM for measurements primarily on three size classes of fish. From the tiniest through the largest fish, the rostral and caudal patches of hair cells with large bundles remained distinctly separate. Total macular, arga was as small as 5.2 x  $10^{4}$  µm for fish of 20-30 mm, 26 x 10 µm for 40-50 mm fish, and 39.8 x  $10^{4}$ µm for 70-80 mm fish. The rostral patch occupied 20-30% of this total area in all three classes, with larger relative areas in larger fish; the caudal patch occupied 15-20% of the total area in all three classes. At a pair of consistent sites of sampling in the largenar patches the populations showed sites of sampling in the lagenar patches, the populations showed a density of 500-600 hair cells/10  $\mu$ m<sup>2</sup>, in all size classes. The linear distance between the patches increased from 30  $\mu$ m in the smallest size, 90  $\mu$ m in the middle size, to over 160  $\mu$ m in the largest.

The results show that the area of the macula grows at a rate that initially may be near the square of linear growth proportion for body length, but slows with increasing size. Since the patches with large bundles maintain both a similar proportional area and similar cell density during growth, the expansion of the area and similar cell density during growth, the expansion of the patches and macula is not simply spreading of a fixed number, but must involve addition of cells. Also, since the inter-patch gap expands, either there must be two growth zones in the macula, or else cells would need to metamorphose from a type with a large bundle to a type with a tiny bundle. The second alternative is unlikely on the basis of present knowledge. These data suggest that in goldfish, the lagenar macula expands by adding new hair cells in at least two areas: 1) not only around the periphery, as usual, but also 2) between the margins of the rostral and caudal patches of hair cells with large bundles.

large bundles.

PATTERNS PERIPHERAL INNERVATION OF INDIVIDUAL 214.6

PERIPHERAL INNERVATION PATTERNS OF INDIVIDUAL VESTIBULAR NERVE AFFERENTS IN THE CHINCHILLA. R.A. Baird, C. Fernandez\* and J.M. Goldberg. Depts. Pharmacol. and Physiol. Sci. and Surgery (Otolaryngology), Univ. Chicago, Chicago, IL 60637 The detailed innervation patterns of individual afferents have not been described, nor have these patterns been related to afferent physiology. To study these innervation patterns, extracellular injections of HRP were made into the superior vestibular nerve in four chinchillas. Peripheral arborizations of 175 fibers, located in the superior or horizontal cristae or in the utricular macula, were reconstructed and were presumed to be the processes of afferent. rather than of efferent horizontal cristae or in the utricular macula, were reconstructed and were presumed to be the processes of afferent, rather than of efferent, neurons. The terminal fields can be divided into <u>calyceal</u>, <u>bouton-like</u>, or <u>dimorphic</u> patterns, depending, respectively, on whether they only have calyx endings, only have bud-shaped endings, or have both types of endings. Typically, all of the endings are located within 50 um of the parent process. All three patterns are seen both in the cristae and in the macula. Dimorphic patterns are more commonly seen in the macula, whereas calyceal and bouton-like patterns are more frequently seen in the cristae. seen in the cristae.

<u>Calyceal patterns</u>. These patterns have been found only in the apex of the cristae and in the striolar region of the macula. A fiber can run undivided to terminate in a single calyx ending or else can divide into two branches, each terminating in a calyx ending. The calyx ending can be simple, apparently containing a single hair cell, or complex, apparently embracing several hair cells. So far, complex endings have been seen only in the macula. <u>Bouton-like patterns</u>. In the canals, these patterns are found only in the base of the cristae. Only one example of this pattern has been seen in the macula, where it was located in the extrastriolar region. Typically, there are 15-30 bud-shaped endings, with a maximum of 50, per fiber. <u>Dimorphic patterns</u>. These patterns occur in all regions of the sensory ephithelia, including the base, slope and apex of the cristea and the striolar and extrastriolar regions of the macula. Usually, 1-3 calyx endings and 5-25 bud-shaped endings are seen for each fiber, although macular afferents with up to 8 calyx endings are found. Both canal and macular afferents can have as many as 50 bud-shaped endings.

afferents with up to 8 calyx endings are found. Both canal and macular afferents can have as many as 50 bud-shaped endings. Intracellular injections of HRP into physiologically characterized afferents have been started. Fibers with calyceal patterns are irregularly discharging, whereas fibers with dimorphic patterns can be either regularly or irregularly discharging. To date, no physiologically characterized afferent has had a bouton-like innervation pattern. (Supported by NIH grants F32 NS06679 and NS01330 and NASA grant NAG2-148.)

214.7 FUNCTIONAL AND MORPHOLOGICAL CHARACTERISTICS OF GRAVITY-SENSITIVE PRIMARY CANAL AFFERENTS. A.A. Perachio, M.J. Correia, and G.A. Kevetter (SPON: A.R. Eden). Depts. Otolaryngol., Physiol. & Biophys., Anat., Marine Biomedical Institute, Univ. Texas Medical Branch, Galveston, TX 77550-2778. In the anesthetized gerbil a large percentage of physiologically identified lateral (71%) and anterior (48%) canal afferents respond to static obmerse in bend tilt accidite (7000)

In the anesthetized gerbil a large percentage of physiologically identified lateral (71%) and anterior (48%) canal afferents respond to static changes in head tilt position (Perachio et al., Neurosci. Abstr. 7: 148; 1981). Since fluctuations in anesthetic level may alter the characteristics of the sensory elements of the labyrinth and/or of vestibular afferents, the experiment was replicated in unanesthetized, decerebrated gerbils. First the spontaneous activity of lateral and anterior canal afferents was measured while the head was held in the standard position (lateral semicircular canals co-planar with earth's horizontal plane). The average discharge rate (87.6 ± 44.2 imp/s, n = 91) was significantly faster than that measured in the canal afferent sample in anesthetized animals (66.2 ± 33.0 imp/s, n = 84). In both types of preparations, a significant inverse correlation was obtained between mean firing rate and the coefficient of variation (CV); decerebrate r = -0.48; unanesthetized r = -0.83. In decerebrated animals irregularly firing afferents (CV > 0.5) constituted a smaller percentage of the sample (13.2%) than that of the anesthetized sample (25%). In decerebrated preparations, significant changes in firing rate (> 10%) were measured when the head was tilde + 10 deg. about the pitch (left/right) axis: lateral 57% (n = 17/30), anterior 53% (n = 19/36). The magnitude of the response was significantly correlated to the CV (standard position) except for decerebrate anterior afferents. Preliminary studies have been injected (n = 50 to date) with HRP. As previously reported for cat Scarpa's ganglion neurons (Chat and Sans, Neurosci. 4: 651; 19/79). multipolar neurons have been identified with branching axonal or peripheral (dendritic) processes. These results suggest a possible mechanism for converging inputs from different receptors or interconnections between primary afferent neurons. (Supported in part by NAG2-26 (AAP) and NAS9-14641 (MJC).) 214.8 ACTIONS OF ATROPINE AND BICUCULLINE ON THE ACTIVITY OF AFFERENT FIBERS IN THE XENOPUS LAEVIS LATERAL LINE. R. P. Bobbin, S. Bledsoe, Jr., G. L. Jenison, S. Winbery, \* and G. Ceasar\*. L.S.U. Medical School, Dept. of Otorhinolaryngology and Biocommunication, Kresge Hearing Research Lab. of the South, New Orleans, LA 70119 and Kresge Hearing Research Institute, Univ. of Michigan Medical School, Ann Arbor, MI 48109.

An excitatory amino acid (e.g., glutamate, aspartate) has been proposed as an afferent excitatory transmitter and acetylcholine has been proposed as an efferent inhibitory transmitter in the lateral line of <u>Xenopus laevis</u>. On the other hand, GABA has recently been shown to supress, and both acetylcholine and carbachol to increase the spontaneous activity in the lateral line (Chihal et al., <u>ARO Midwinter Abstr.</u>, 1980, Winbery et al, <u>ARO Midwinter Abstr.</u>, 1983). Therefore, to further define these responses we examined the effects of the exogenous application of atropine sulfate, and bicuculline methiodide on afferent stimulation and the action of various agonists.

The compounds were dissolved in a frog ringer solution and then applied to the serosal surface of an isolated frog lateral-line stitch utilizing techniques previously described

The applied of the state of an isolated from the solution of

slight suppressant effect on spontaneous activity and excitation induced by water motion . Atropine and bicuculline had little effect on excitation induced by water motion at doses which blocked their respective agonists. Therefore, these results indicate that neither acetylcholine nor GABA are probably the excitatory afferent transmitter in the lateral line of <u>Xenopus laevis</u>. Future experiments with further explore the site of action of charbachol and GABA.

- 214.9 TERMINATION OF VESTIBULAR AFFERENTS IN THE VESTIBULAR NUCLEAR IERMINATION OF VESTBULAR AFFERENTS IN THE VESTBULAR NUCLEAR COMPLEX IN THE GERBIL. <u>G.A. Kevetter and A.A. Perachio.</u> Depts. Otolaryngol., Anat., Physiol. & Biophys., Marine Biomed. Inst., Univ. of Texas Medical Branch, Galveston, TX 77550-2778. Injections of horseradish peroxidase (HRP) were made into in-dividual ampullae of the peripheral vestibular apparatus in ger-bils to determine the terminal distribution of each receptor organ. Transganglionic transport allowed visualization of the central course and terminals of the vestibular nerve in the medial (MVN), descending (DVN), superior (SVN), or lateral (LVN) vestib-ular nuclei. Ganglion cells in either the superior or inferior division of Scarpa's ganglion were labeled. Both small and large ganglion cells (diameters 12.2-24.75  $\mu$ m) were labeled. Occasionally multipolar cells in the ganglion were labeled. Some animals received peripheral injections that spread to in-Some animals received peripheral injections that spread to in-clude many of the structures innervated by the anterior or pos-terior division of the vestibular nerve. The anterior division of the nerve had cell bodies located in the superior ganglion. De-scending fibers coursed in the DVN, leaving to travel and termi-nate medially in MVN. Terminals were also identified ventrally in DVN and LVN, particularly at the junction between these nuclei. Other terminals were found rostrally in SVN and the vermis of the cerebellum. After injection of receptors whose afferent fibers travel in the posterior division of the vestibular nerve, labeled ganglion cells were present in the inferior Scarpa's ganglion. Terminals in MVN were found more lateral than the terminal distribution after injection of structures innervated by the anterior nerve. Terminals were located ventrally in DVN, especially along the MVM/DVN border. Fibers and terminals were also seen in cell group y, SVN, and the cerebellar vermis. These studies have con-firmed differences in the terminal distribution of the anterior and posterior divisions of the vestibular nerve. After ionopho-resis of HRP into the lateral ampulla, ganglion cells were labeled rostrally in the superior division of Scarpa's ganglion. Terminals were found in the medial ventral part of MVN. Terminals and fi-bers were seen in the ventral part of LVN as the fibers traveled toward MVN. Fibers also traversed LVN in a dorsal direction, many terminating in SVN. When the ampulla of the posterior canal was injected, labeled ganglion cells were located in the inferior Scarpa's ganglion. Heavy fascicles of fibers descended through DVN. Terminals were found caudally in MVN and DVN and also more rostrally in SVN and in MVN, adjacent to the ventricle. This study has identified differences and similarities in the areas of the vestibular nuclei where primary afferent input from orthogonally oriented canals (horizontal vs. posterior) is received and processed.

214.PO APPLICATION OF A STOCHASTIC VERSION OF AN AFTERHYPER-POLARIZATION MODEL TO THE STEADY-STATE DISCHARGE OF VESTIBULAR-NERVE AFFERENTS. Jay M. Goldberg and Charles E. Smith\*, Dept. Pharmacol. and Physiol. Sci., Univ. Chicago, Chicago, IL 60637 and Dept. Statistics, North Carolina State Univ., Raleigh, NC 27650

An afterhyperpolarization (AHP) model, modified from Kernell [Brain Res. 11, 685-687 (1968)], simulates many features of the steadystate responses of vestibular-nerve afferents to natural stimulation of the end organs and to galvanic stimulation of the afferents themselves. Major assumptions are: a) There is a single spike-trigger site and firing occurs whenever the transmembrane depolarization there reaches a fixed critical level. b) Postsynaptic voltage fluctuations, due to the random times of occurrence of quantal synaptic inputs, are entirely responsible for interspike-interval variability. c) Following each spike, there is a time-dependent increase in potassium conductance ( $g_k$ ) that leads to an AHP. d) The  $g_k$ 's left over from previous spikes add linearly with that triggered by each spike. e) Galvanic currents act only at the trigger site. Many differences between regularly and irregularly discharging afferents can be explained if the units differ both in their synaptic noise and in the prominence of their AHPs. The more irregular the discharge of a unit, the greater is the assumed synaptic noise and the smaller and briefer is the assumed AHP. Of the two factors, variations in AHPs appear to be four times more influential in determining the relative discharge regularity across units. The model accounts for the interspike-interval statistics obtained during natural stimulation and their modification by galvanic stimulation; the positive proportionality between discharge regularity, measured by a normalized coefficient of variation, and galvanic sensitivity, the latter measured in spikes-sec<sup>-1</sup>/µA; and the lengthening of the mean interspike interval following an interposed, shock-evoked spike. (Supported by NIH Grant NS 01330, NASA Grant NAG 2-148, NSF Grant ISP 80-11451, and the South Carolina State Appropriation for Biomedical Research.)

ARACHNOIDITIS CHANGES PAIN SENSITIVITY IN MICE. B.T. Lipman 215.1 and V.M. Haughton\*. Allen Bradley Laboratory, Medical College of Wisconsin, Milwaukee, Wisconsin 53226.

The possibility that arachnoiditis causes increased pair sensitivity has been suggested by clinical studies but the effects of arachnoiditis on pain threshold has not been studied experimentally.

Tail-flick latencies were compared in 2 groups of mice, one with arachnoiditis after intrathecal injection of iocarmate, and a control group, after intrathecal injection of artificial cerebrospinal fluid (CSF). In both groups the lumbar subarach-noid space was punctured via a 27 G needle and 30 ul of arti-ficial CSF or iocarmate injected by a Hamilton syringe with the apier under blockbergerschule Trategerschule. the animal under halothane anesthesia. Intrathecal injection of iocarmate was verified radiographically. Sensitivity of tail-flick latency to intraperitoneal morphine sulfate was tested in each group. The arachnoid was studied histologically in both groups after necropsy to verify arachnoiditis. The threshold intensity of thermal stimulation producing a tail-flick response was measured in both groups.

Tail-flick latencies were significantly decreased at 2, 3, and 4 weeks after iocarmate myelography. No significant changes in tail-flick latency were measured in the control mice. The data suggests that arachnoiditis causes hyperalgesia in mice.

STUDIES ON THE PHARMACOLOGY OF SPINAL OPIATE RECEPTORS WHICH 215.2 MODIFY THE RAT'S RESPONSE ON CUTANEOUS THERMAL AND VISCERAL CHEMICAL EVOKED RESPONSES: TEST SELECTIVITY AND A DISASSOCIATION of  $\mu$ ,  $\delta$  AND  $\kappa$  RECEPTORS. <u>C. Schmaus\*</u>, T.L. Yaksh\*, Y. Shimo-higashi\*, T.S. Jensen\*, G. Harty\* and D. Rodbard\* (SPON: B.F. Westmoreland). Dept. of Neurosurgical Res., Mayo Clinic, Rochester, MN; NIH, Bethesda, MD; Max Planck Institut, Munchen, Germany; Aarhus Univ., Aarhus, Denmark. We have examined the pharmacological characteristics of spinal

opiate receptors which modify the animal's response to a strong stimulus. Dose response curves were carried out with a variety of putative opiate receptor selective agonists administered intra-thecally in the rat. Three measures were examined, hot plate (HP), tail flick (TF) in the same group, and the acetic acid evoked writhing response (AAEWR) in a separate group.

STUDIES ON THE ACTION OF MORPHINE IN THE PERIAQUEDUCTAL GRAY (PAG), RAPHE MAGNUS (RM) AND THE N. RETICULOGIGANTOCELLULARIS (NRGC). 215.3 EFFECTS OF INTRATHECAL PHENTOLAMINE, METHYSERGIDE, NALOXONE AND FLUPHENTIXOL. T.S. Jensen\* and T.L. Yaksh\* (SPON: J.F. Poduslo). Section of Neurosurgical Research, Mayo Clinic, Rochester, MN; Aarhus Univ., Aarhus, Denmark.

To determine whether opiate receptor linked systems in the brainstem produce their antinociceptive effects by the activation of spinopetal systems, the receptor antagonist for the proposed descending systems must be administered intrathecally (IT), near the spinal terminal fields of these systems. To carry out these experiments rats were stereotaxically implanted with guide cannula in the PAG, NRM or NRGC and a lumbar intrathecal catheter passed In the PAG, NRM or NRGC and a lumbar intrathecal catheter passed 7.5 cm caudally through the cisternal membrane. Rats in which morphine (5  $\mu$ g/0.5  $\mu$ l) produced at least a 2 sec increase in the tail flick (TF) latency and 20 sec increase in hot plate (HP) latency within 15 min of the microinjection were given either phentolamine (15  $\mu$ g), methysergide (15  $\mu$ g), fluphentixol (10  $\mu$ g) or naloxone (10  $\mu$ g). These antagonist doses were shown to block the changes produced by doses of exogenous agonists which comple-tely blocked the TF. The insertice table presents the account tely blocked the TF. The inserted table presents the percent maximum possible reversal of the effect, as compared to the response latency measured immediately prior to the IT injection.

sites; none of the antagonist treatments produced a change in baseline latencies.

Opiate linked brainstem receptor systems produced an effect on the  $\rm TF$  which was uniformly mediated by spinal 5-HT/NE receptors. NRGC, but not the PAG showed a significant spinal naloxone-NRM/ sensitive link. Perhaps most surprising was the failure of any of the treatments to produce a reversal of the HP effects of brainstem opiates comparable to that observed on the TF, even with higher spinal doses. These observations suggest that: 1) many of the effects observed on TF may only be relevant to motor processing; 2) that brainstem opiates either activate a pharmacolo-gically novel spinopetal system or produce their "analgesia" (as opposed to antireflexia by a supraspinal mechanism) (NS16541 and Mayo Foundation)

215.4 EFFECT OF MORPHINE, FENTANYL AND NALOXONE ON SPONTANEOUS AND

EFFECT OF MORPHINE, FENTANYL AND NALOXONE ON SPONTANEOUS AND EVOKED NEURONAL ACTIVITY IN THE INTACT AND DEAFFERENTED LUMBAR DORSAL HORN. J., Ovelmen-Levitt, B. Johnson, P. Bedenbaugh, and B.S. Nashold, Jr. Div. of Neurosurgery, Duke Univ. Med. Ctr., Durham, N.C. 27706 The activity of lumbosacral dorsal horn neurons in laminae III -VII was studied before and after IV administration of morphine SO4 (3mg/kg), fentanyl (.05 mg/kg), and naloxone HCI (.16mg/kg) in eleven control cats and in six animals with unilateral avul-sions of the dorsal roots  $L_4$  - SJ. Recordings were made using 3M KCI filled capillary micropipettes. The cats were lightly anesthetized with sodium pentobarbital at the time of the record-ings, and arterial blood pressure and end tidal CO2 were monitored. ings, and arterial blood pressure and end tidal CO2 were monitored. Spontaneous activity and receptive field properties were determined. In control animals, morphine was not found to alter res-ponses in cells driven by light cutaneous stimulation only. Morphine produced a decrease in the spontaneous activity in wide Morphine produced a decrease in the spontaneous activity in wide dynamic range (WDR) multimodal cells and also in the evoked res-ponse to cutaneous noxious stimulation. This was also the case with IV fentanyl in two neurons, while in another two cells there was a decrease in the response but not in the spontaneous firing. These effects were reversed by naloxone. By one month cells can be found in the avulsed dorsal horn which can be easily influenced from the ipsilateral flank and/or the contralateral flank and from the ipsilateral flank and/or the contralateral flank and limb. Morphine was found to depress the spontaneous firing of several cells one month after avulsion injury. One year after avulsions, fentanyl altered the firing pattern without decreasing the level of spontaneous firing in a cell in  $L_{G}-L_{J}$  which was dri-ven by strong pinch to the skin of the groin, bilaterally. The eyoked response was more fatigueable after fentanyl. These effect were also reversed by naloxone. In both the control and the were also reversed by nationals. In both the control and the deafferented preparation spontaneous activity and evoked responses were affected differentially. Because they were administered systemically, these subsances may be acting directly on the cells recorded, indirectly at the level of the substantia gelatinosa, at a supraspinal level on descending modulatory systems, or they may be acting presynaptically.

ANALGESIC EFFECTS AND BINDING PROPERTIES OF A FLUORINATED ANALOG 215 5 OF DYNORPHIN(1-13). J.M. Walker\*, E.A. Young\*, D.H. Coy\*+, and H. Akil (SPON: S. Berent). Mental Health Res. Inst., Univ. of Michigan, Ann Arbor, MI 48109; Dept. of Medicine, Tulane Univ., New Orleans, LA. Despite the high affinity of dynorphin for opiate receptors.

its analgesic effects have been difficult to establish. Its analgesic effects have been difficult to establish. In our hands dynorphin fails to produce analgesia upon micro-injection in either the periaqueductal gray or the lateral yentricle. We also failed to observe analgesic effects with D-Ala -dynorphin. We do confirm the figdings of Herman et al that C-terminal shortened analogs (D-Ala -dynorphin(1-11)-NH<sub>2</sub>) produce analgesia. These results are consistent with the previous suggestions that two active sites occur within the dynorphin sequence.

Generally, for enkephalin-containing peptides the aromatic character of position 4 (Phe) must be maintained for opiate activity. This limits the types of substitutions that can be made. One approach to the development of a potent analog is the substitution of a pentafluorophenylalanine residue which was found

substitution of a pentafluorophenylalanine residue which was found to greatly enhance the analgesic activity of methionine-en-kephalin. Presumably, fluorination increased the lipophilicity and perhaps the stability of the compound which underlies its greater biological activity. In view of the poor analgesic effects of dynorphin(1-13) this approach had considerable appeal. Consequently, a fluorinated compound, D-Ala'-F\_-Phe'-dynor-phin(1-13)-NH<sub>2</sub>, was synthesized by one of us (DHC) and tested for its analgesise effects. Upon micro-injection into the lateral ventricle it produced short duration (30 min or less) analgesia in the tail-flick test and "wet-dog shakes." These effects were highly consistent. and dose related. highly consistent, and dose related.

highly consistent, and dose reaced. Surprising preliminary results suggest that high (10 mg/kg s.c.) doses of naloxone do not prevent this response. Howeve we do find that this analog displaces [<sup>3</sup>H]dynorphin from its binding sites in rat and guinea pig brain homogenates. These results are difficult to explain in the context of the present literature and studies are underway to further address the mechanisms and binding properties of this analog.

THE ANTINOCICEPTIVE EFFECTS OF SELECTED OPIOID PEPTIDES DERIVED 215.6 FROM BOVINE PRE-PRO ENKEPHALIN A ADMINISTERED ALONE OR CONCOMIT-ANTLY WITH CAPTOPRIL, MK-422 OR THIORPHAN IN MICE. B.S. Barbaz\*

ANTLY WITH CAPTOPRIL, MK-422 OR THIORPHAN IN MICE. <u>B.S. Barbaz\*</u> and W.L. Autry\* (SPON: D.L. Cheney). Res. Dept., Pharm. Div., CIBA-GEIGY Corp., Summit, NJ 07901. [Met<sup>5</sup>]enkephalin Arg<sup>6</sup>-GLy<sup>7</sup>-Leu<sup>6</sup> (YGGFMRGL), [Met<sup>5</sup>]enkephalin Arg<sup>6</sup>-Th<sup>7</sup> (YGGFMRF), [Met<sup>5</sup>]enkephalin (Arg<sup>6</sup> (YGGFMR), [Met<sup>5</sup>]enkeph-alin (YGGFM) and [Leu<sup>5</sup>] enkephalin (YGGFL) are opioid peptides derived from bovine pre-pro enkephalin A. Biochemical studies (Benuck <u>et al.</u>, <u>Neurochem. Intl.</u>, 4,5:389, 1982; Benuck <u>et al.</u>, <u>Biochem. Biophys. Res. Commun.</u>, 107:1123, 1982) indicate the cleavage of YGGFMRF is mediated primarily by the angiotensin con-verting enzyme, a dipeptidyl carboxypeptidase. Thiorphan, an enkephalinase inhibitor (EI), is specific for the metalloendo-peptidase that cleaves the Gly<sup>3</sup>-Ph<sup>4</sup> bond of YGGFM in purified enzyme preparation but has no inhibitory effect on the dipeptidyl enzyme preparation but has no inhibitory effect on the dipeptidyl carboxypeptidase that cleaves the  $Gly^3$ -Phe<sup>3</sup> bond of YGGFMRF in synaptosomal plasma membranes. These peptides with the exception synaptosomal plasma membranes. These peptides with the exception of YGGMR have been reported to show transient and weak analgesic activity using the tail flick procedure (Inturrisi et al., <u>Proc.</u> <u>Natl. Acad. Sci.</u>, <u>77</u>;9, 1980). The purpose of our experiments was 1) to assess the antinociceptive effects of these peptides using the hot plate test (55  $\pm$  0.5° C) in mice and 2) to deter-mine whether the anglotensin converting enzyme inhibitors (ACEI) captopril and MK-422 and the EI, thiorphan enhance the activity of these opioid peptides. All test agents were dissolved in distilled water and administered intracerebroventricularly (ICV) in a volume of 10 ul. Fifteren minutes after drug administration in a volume of 10 µl. Fifteen minutes after drug administration, jump latencies were measured. Each trial was terminated after the first jump response or after 240 sec if no response occurred. All the peptides, except for YGGFMR produced naloxone reversible analgesia. YGGFMRF was the most potent with a minimum effective dose of 1.9 µg. YGGFMRCL, YGGFM and YGGFL were 100-fold less potent. YGGFMRF was inactive (7.5 µg) and doses of 15, 30 and 60 µg produced neurotoxicity in the form of clonic seizures. When subanalgesic doses of captopril (100  $\mu$ g) or NK-422 (7.5  $\mu$ g) were concomitantly administered ICV with subanalgesic doses of YGGFMRGL (60  $\mu$ g), YGGFMRF (0.94  $\mu$ g) or YGGFM (60  $\mu$ g) significant increases in jump latencies occurred. Concomitant ICV admin-stration of a subanalgesic dose of thiorphan (0.94 µg) with the peptides VGGFM (60 µg) or YGGFL (60 µg) significantly increased jump latencies, but thiorphan was ineffective when co-administered with YGGFMRGL or YGGFMRF. The results of our <u>in vivo</u> studies indicate that the ACEIS enhance the antinociceptive activity of YGGFMRGL, YGGFMRF and YGGFM. However, the facilitatory effects of thiorphan are restricted to the pentapeptides YGGFM or YGGFL.

- THE OPIOID RECEPTOR MECHANISMS FOR SPINAL AND SUPRASPINAL THE OPIDID RECEPTOR MECHANISMS FOR SPINAL AND SUPRASPINAL ANALGESIA IN THE MOUSE DIFFER. G.W. Pasternak and G.S.F. Ling.The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021, USA Opioid binding studies have suggested the existence of a common high affinity (mu) binding site for opiates and opioid peptides. Although the decrease in the analgesic potency of opiates and opioid peptides by the selective  $mu_1$  antagonist naloxone implied an important role for  $mu_1$  Sites, potency of oprates and oproted peptraes by the selective multiplantagonist naloxone implied an important rolle for multiplantagonist naloxone implied an important rolle for multiplantagonist. For example, morphine was shifted 12-fold while D-ala<sup>2</sup>-D-leu<sup>5</sup>-enkephalin (DADL) and metkephamid were shifted only 3.6-fold and 2.5-fold, respectively. If multiplantes were still mediating analgesia in naloxonazine-treated mice, the ED<sub>50</sub> shifts for the different drugs by naloxazone should have been the same. Correlations of these analgesic compound shifts in vivo with the ability of the compounds to displace the binding of a variety of H-DADL binding. Equally important, the ability of all the opiates studied to displace  $\frac{3H}{2}$ -ethyletocyclazocine binding correlated well (r2=0.95) with their ability to displace  $\frac{3H}{2}$ -ethyletocyclazocine, ketocyclazocine, SKF1004 ligands. Thus, distinguishing between kappa and delta actions using morphine, ethylketocyclazocine, ketocyclazocine, SKF10047, cyclazocine and nalorphine was not possible without including DADL. Spinal transection in mice had effects very similar to those of naloxazone. Transection shifted morphine's analgesic ED<sub>50</sub> 17-fold while metkephamid was shifted less than 3-fold. The greater analgesic potency of an enkephalin compared to morphine in transected mice suggested delta involvement in spinal analgesia in the mouse while the similar effects of transection and naloxazone implied a supraspinal localization of  $mu_1$  analgesia. However, caution should be used in extrapolating these findings to other species of animals or man. animals or man.
- EFFECT OF INTRATHECAL THIORPHAN, A PUTATIVE ENKEPHALINASE INHIBI-215.8 TOR, ON FOOTSHOCK INDUCED ANALGESIA (FSIA) & CLASSICALLY CONDIT-IONED ANALGESIA (CCA). R.M. Fay\*, L.R. Watkins, I.B. Kinscheck\* & D.J. Mayer (SPON: K. Corley). Dept. Physiol. & Biophys., Med.Coll.

Va./ Va. Commonwealth Univ., Richmond, VA 23298. Thiorphan, a putative enkephalinase inhibitor, has been shown to potentiate the analgesic effects of exogenous enkephalin. Since front paw (FP) FSIA & CCA are attenuated by morphine tolerance & by intrathecal (IT) naloxone, it is possible that enkephalins are involved in these phenomena at the level of the spinal cord (Sci., 216:1185). Hind paw (HP) FSIA, on the other hand, appears to be nonopiate since it is not attenuated by high doses of systemic naloxone, IT naloxone, or morphine tolerance. In order to determine whether spinal enkephalins are involved in any of these phenomena, Values of either 100 µg thiorphan or equivolume vehicle (1 µ1 5% sodium bicarbonate in 0.5 M phosphate buffer pH 7.4) were injected IT onto the lumbosacral cord of rats at 15 & 5 min prior to 90 sec exposure to either front paw shock, hind paw shock, or the condiexposure to either front paw snock, find paw snock, of the condi-tioned stimulus (<u>Sci.</u>, 216:1185). Analgesia was then assessed thr-ough 45 min using the tail flick (TF) test. Thiorphan potentiated FP FSIA throughout the 45 min timecourse (p<0.0001,ANOVA). CCA, however, was not reliably affected. Assuming that thiorphan is a highly specific enkephalinase inhibitor our results may be eviden-ce that CCA involves an endogenous opiate the effects of which are antagonizable by naloxone yet not affected by thiorphan. Alterna-tively, the tissue permeability of thiorphan is not presently understood; CCA may involve an enkephalinase at deeper dorsal horn laminae which are unaffected by our IT drug regimen. As such, the-se data would support the idea that differences exist in the micro circuitry of FP FSIA & CCA (Brain Res., in press). HP shock pro-duced maximal analgesia in both groups until 25 min; from 30-45 min, potentiated analgesia was observed in thiorphan-treated rats (p<0.0001, ANOVA). Since enkephalinase inactivates peptides besides enkephalin, the question of thiorphan's specificity must be carefully addressed before firm conclusions can be reached. IT thior-phan had no effect on TF latencies in the absence of an analgesiaproducing manipulation. The observed potentiations also cannot be accounted for by diffusion of the drug to the brain since neither FP FSIA nor HP FSIA was potentiated when thiorphan was injected onto thoracic rather than lumbosacral cord.

OPIOIDS IN THE MOUSE ZINGERONE TEST FOR ANALGESIA. Peggy J. K. Dobry, CNS Research, The Upjohn Company, Kalamazoo, MI 49001. The zingerone test for analgesia in guinea pigs (Miller et al., 1981, Neurosci. Abst. 7:504) was adapted for use in mice. Zingerone is the pungent principle of ginger. A drop of 1% zingerone placed into a mouse's eye elicited an immediate, vigorous, repetitive wiping of the eye. The response was measured as the number of continuous forepaw 215.9 eye. The response was measured as the number of continuous forepaw wiping motions in the initial, intense phase. Groups of 10 female CF-1 mice, 20-24 g, were injected subcutaneously (s.c.) with drugs 20 min before the test. Capsaicin was injected s.c. 24 hrs before the test. Groups were compared by the Mann-Whitney U-test. Morphine sulfate, pentazocine lactate, and codeine phosphate sup-pressed the wiping in a dose-dependent way. Nalorphine HCl was a weak analgesic. Naloxone HCl was not analgesic; 3 mg/kg actually increased the response by 58%. SKF-10047 also increased the response at a dose which caused ataxia and sedation.

which caused ataxia and sedation. Ketazocine did not cause analgesia, although ethylketocyclazocine

methanesulfonate was the most potent analgesic tested. Nefopam HCI caused dose-dependent analgesia, and aspirin was modestly analgesic. Ketamine, diazepam, chlorpromazine HCI, and d-amphetamine sulfate were not analgesic. Ketamine and diazepam actually increased the vigor of the response. However, imipramine HCl suppressed responding at 30 mg/kg, a dose causing ataxia. Capsaicin caused a dose-dependent analgesia. At the time of testing,

all mice looked normal, although the highest doses had caused prostra tion immediately after injection. In summary, the mouse zingerone test for analgesia is sensitive to

aspirin, narcotic analgesics of the mu type, capsaicin, imipramine, and nefopam, and slightly sensitive to nalorphine. It does not show analgesia netopam, and sugnity sensitive to halorphine. It does not show analgesia for the sedative compounds diazepam and chlorpromazine, the stimulant compound d-amphetamine, the sigma prototype SKF-10047, the dissocia-tive anesthetic ketamine, the narcotic antagonist naloxone, or the kappa agonist ketocyclazocine (ketazocine).

THE INTESTINAL ANTISECRETORY ACTION OF OPIATES IS MEDIATED AT CNS 215.10 SITES. <u>D.R. Brown and R.J. Miller\*</u>, Dept. of Pharmacol. and Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

Opiates such as morphine have long been used to arrest diarrhea. Although this antidiarrheal action has been attributed to decreases in gut motility, recent evidence indicates that it might also result from an opiate-induced reduction in active anion secretion mediated through enkephalin-selective (8) receptors situated in the intestinal mucosa. The possibility that these antisecretory effects could be mediated at sites within the CNS has not hitherto been addressed. Therefore, we examined the action of the stable enkephalin analog [D-Ala<sup>2</sup>-Met<sup>5</sup>]enkephalinamide (DAMA) administered intravenously (i.v.) and intracerebroventricularly (i.cv.) on intestinal fluid secretion induced by cholera toxin (CT). Male Sprague-Dawley rats (250-350 gm) were food-deprived, anesthetized (J; 13-23 cm from pylorus), proximal ileum (PI; 43-53 cm from pylorus) and distal ileum (DI; 10-20 cm from ileocecal junction) were filled with 0.5 ml saline containing 1  $\mu$ g CT. DAMA or saline (SAL) was administered 3 h after surgery and rats were sacrificed (onl) was administered of a area surgery and rats were satisfied 1 h later. Loops were weighed, emptied of residual fluid and re-weighed; results, expressed as ul fluid absorbed/cm length of loop/4 h, were:

	J	P1
SAL, 5 µ1/rat i.cv.	-33 + 12	- 92 + 13
DAMA, i.cv. 0.1 µg	- 34 + 15	-109 + 22
0.3 µg	- 2 + 4**	- 68 + 19
1.0 µg	+ 8 + 8**	- 18 + 20*
3.0 µg	+ 13 + 5**	- 53 + 13*
SAL, 1 m1/kg, i.v.	- 51 + 21	-124 + 34
DAMA, i.v. 100 µg/kg	-34 + 15	-175 + 12
300 µg/kg	$-9 \pm 16$	-129 + 32
1000 µg/kg	- 12 + 21	- 39 + 7*
3000 µg/kg	- 51 + 24	-151 + 32
(Two toiled	t + toot + t + n < 0 + 0.5 + t + n < 0	01)

I.cv. DAMA decreased CT-induced secretion in J and PI but had no consistent effect in DI or in any segment when given i.v. The antisecretory actions of i.cv. DAMA were blocked by the opiate The antagonist, naltresone, 1 mg/kg, s.c. 15 min before DAMA. More-over, they were eliminated after peripheral sympathectomy by guamethidine (20 mg/kg, i.p. for 2 days) or  $\alpha$ -adrenergic receptor blockade by phentolamine (1 mg/kg, s.c. 1 h before DAMA). These results suggest that the antisecretory effects of DAMA and possibly other opiates are mediated at CNS sites and are manifested by an increase in peripheral sympathetic activity in the upper small intestine. (Supported by NIH grants DA-02121 and MH-14274).

215.11 EFFECTS OF INTRAVENOUS B-ENDORPHIN ON INSULIN SECRETION IN INTACT AND ADENALECTOMIZED RATS, <u>C.Landau</u><sup>\*</sup>, <u>M.M.Palmour\*and</u>, <u>C.Chang</u><sup>\*</sup>. Dep't of Physiology/Anatomy Univ. of Cal-Berk. CA 94720 This study was designed to test the possibility that the opioid in times of stress. In an attempt to recreate the effects of stress-secreted endorphin without the other confounding variables of a stress response, B-endorphin was administered intravenously through indwelling jugular catheters. To test the possibility that B-endorphin has a dual effect on the glucoregulatory apparatus through its stimulation of a hyperglycemic agent from the adrenal, and insulin from the pancreas, Long Evans female rats were adrenalectomized or sham operated and then given saline, morphine, B-endorphin, or naloxene. Intravenously administered endorphin resulted in the stimulation of insulin secretion in all animals tested. At high doses (4mg kg) insulin levels rose and remained high for 25' fropping towards baseline by 60' postinjection. Intermediated doses (1mg/kg) produced a biphasis response with the first peak at 5' followed by a second peak at 25'. Low doses (0.5mg/kg) produced an insulin response resembling the first peak of the intermediate dose.

The experiments also demonstrate that B-endorphin does affect blood glucose concentrations. Intact and sham operated animals responded to intravenous endorphin with elevations in plasma glucose concentrations up to 40% over baseline levels. The hypoglycemic response to endorphin seen in adrenalectomized animals is consistent with the reported effects on insulin secretion.

The effects of B-endorphin, morphine and naloxone on insulin and plasma glucose levels in intact and adrenalectomized rats will be reported. In addition an hypothesis concerning the role that B-endorphin plays in physiological adaptation will be presented.

COMPARISON OF CHRONIC VS. ACUTE MORPHINE INDUCED CHANGES IN DIS-TRIBUTION OF CEREBRAL BLOOD FLOW. Law, W.R\*, K.A Steece, J. Lee, M.A. Kapin\*, J.L. Ferguson\*, and R.F. Ritzmann. Univ. of Ill. at Chicago, Health Science Center. Chicago, IL 60680 Changes in regional cerebral blood flow (rCBF) nave been shown to correlate with changes in neuronal activity in specific brain regions and with various regional metabolic activities. Changes in regional neural activity correlate with the uptake of 2-deoxyglucose. In addition, morphine nas been shown to have both stimulatory and inhibitory effects on neuronal activity. However, it has been assumed that morphine does not alter cerebral blood flow (CBF). Due to recent advancements in techniques available for measurement of rCBF, we thought it important to reassess the effects of both chronic and acute administration of morphine on rCBF. Male guinea pigs were surgically prepared by left ventricular cannulation for measurement of rCBF using tracer microspheres. In the chronic study morphine pellets (65 mg/pellet; 1.5 pellets/100 g body weignt) were implanted subcutaneously immediately after surgery. The percent cardiac output (%CO) to brain was assessed just prior to and 48 hours after pellet implantation as well as 30 minutes after i.p. naloxone (10 mg/kg) administration. Chronic administration of morphine resulted in a significant increase of 40.8% in the %CO received by the brain, the greatest increases being in the cerebellum (71.8%) and pons (60.9%). When withdrawal was pre-cipitated by naloxone, the %CO to the brain decreased toward control values. Naloxone alone had no significant effects on %CO to the brain. Brain morphine levels were found to be 9.00 + 2.1 µg morphine/gm tissue at the 48 hour time period. Measurement of brain levels 15 minutes after a series of acute doses of morphine indicated that intravenous administration of 200 mg/kg resulted in  $\mu$ g morphine/gm tissue at the 48 hour time period. Measurement of brain levels 15 minutes after a series of acute doses of morphine indicated that intravenous administration of 200 mg/kg resulted in brain morphine levels of 9.9 + 2.35  $\mu$ g/gm tissue. Another group of guinea pigs were surgically prepared as before sans pellet implantation. Following surgery (48 hours), the animals were administered 2, 20, or 200 mg/kg morphine i.v. %C0 to brain was assessed just prior to, 15, and 60 minutes post morphine. None of the doses produced any change in heart rate or mean ventricular pressure at the time periods studied. Lower doses of morphine did pressure at the time periods studied. Lower doses of morphine did not significantly alter the &CO to the brain at the 15 min. time period. However, at 60 min post morphine, using 2 mg/kg, there was a significant decrease in &CO to the brain which is in agreement with the findings of Buchweitz, et al (Fed. Proc.  $A(2) \ge 0.1983)$  415 min post 200 mg/kg morphine there are a Ag(2):306, 1983) At 15 min. post 200 mg/kg morphine, there was a significant increase in %C0 to brain (66.5%) which was greater than that observed in the 48 hour chronically treated animals. In contrast to the chronic study, the areas of greatest increase with acute administration of 200 mg/kg were the midbrain (77.3%) and cortex (74.9%). (Supported by CHA grant C82-13).

DOSE EFFECTS OF NALOXONE ON REGIONAL CEREBRAL GLUCOSE METABOLISM 215.13 IN MORPHINE DEPENDENT RATS. <u>GF Wooten and WA Geary</u>, Dept of Neuro-logy, Univ. of VA, Charlottesville,VA and Dept of Pharmacology,

Wash. Univ., St. Louis, MO. We have simultaneously studied regional cerebral glucose utilization (RCCU) and behavior during naloxone precipitated morphine withdrawal (MW). For RCGU studies, 25 brain regions were analyzed that previously had been shown to participate in MW (Wooten, et al PNAS 79:3360-3364,1982; Geary and Wooten, BRN.RES., in press,1983). Animals were treated for 11 days with twice daily subcutaneous in-Animals were treated in 11 days with twice daily subcludieous he-jections of increasing doses of morphine-sulfate (Mallinckrodt, St.Louis, MO). Just prior to the final morphine dose, polyethylene catheters were inserted in the right jugular vein. The MW was pro-duced by intravenous injection of variable doses (.0005-5.0 mg/kg) of naloxone-HCl (Endo Labs, Garden City,NY) in normal saline. A 25uCi pulse of 14C-2-deoxyglucose(2DG;Pathfinder Labs,St.Louis,MO) was injected IV 60 seconds after naloxone. Four behavioral indices of MW were recorded: wet shakes,jumps,acute weight loss(WL), and autonomic signs(ANS). Animals were killed 50min after 2DG injection and brains were removed, frozen, and processed for autoradiography. Control rats were treated with chronic saline and injected with variable naloxone doses. Four rats were used for each dose in all experiments; all experiments were conducted 11-13hrs after the final morphine dose(100 mg/kg).
No behavioral signs of MW were observed with .0005mg/kg of nal-

oxone. There was no dose effect of naloxone on wet shakes. Jumps were maximal at .005mg/kg. In contrast, WL and ANS were naloxone dose dependent. Changes in RCGU showed 3 classes of response to increasing naloxone dose in fixed dependence rats: Class I struc-tures (paraventricular, ventromedial, and lateral hypothalamus) exhibited their largest RCGU increases between .005-0.05mg/kg nal-oxone; Class II structures (pre-optic areas,basal ganglia,anterior and intralaminar thalamic nuclei, mamillary nuclei, and some mid-brain areas) showed gradual RCGU increases across the 10<sup>4</sup> naloxone dose range; <u>Class III</u> structures (diagonal band, the medial and lateral septum, and the central amygdaloid nucleus) displayed lar-gest RCGU increases between 0.50-5.0mg/kg naloxone. Regression analyses of RCCU vs behavior showed high correlations between Class I & ANS (r=.992;p<.001),Class I & WL (r=.964;p<.001),Class II & WL (r=.979;p<.001), and Class III & WL (r=.918;p<.05). correlations were found between any RCGU response class and jumps or wet shakes.

Thus, changes in RCGU show a graded, dose dependent response to naloxone precipitated MW. RCGU may be a more useful index of MW than behavior because of anatomical specificity, objectivity, and the relative freedom from state-dependent variables. The function-al relationship between changes in RCGU and behavior during MW remains to be determined.

CLONIDINE REVERSES THE BEHAVIORAL AND RESPIRATORY EFFECTS OF CONTINUOUS NALOXONE INFUSION. D.H. Malin, A.G. Hempel\*, R.J Exley\* and S. Addington\*. Univ. of Houston-Clear Lake. Hou 215.15 Houston, 77058

Blockade of the endorphin system by continuous infusion of .75 mg/kg/hr naloxone produces behavioral symptoms and respiratory hyperactivity reminiscent of opiate abstinence syndrome. Clonidine (an alpha-2 adrenergic agonist) has been reported to potently reverse many morphine abstinence symptoms in human patients and in rats. An experiment was performed to determine whether clonidine would also reverse the "endorphin blockade syndrome" produced by continuous naloxone infusion.

continuous naloxone infusion. Twenty male 135 g rats were implanted with Alzet model 2001 osmotic minipumps. Ten rats received pumps filled with saline. Ten rats received pumps filled with 50 mg/ml naloxone. These rats received 0.75 mg/kg/hr naloxone s.c. on a continuous basis. Prior to implantation, all rats were habituated to the chamber of an oxygen consumption apparatus, and baseline oxygen consump-measures were taken. Twenty eight hours after implantation, all rats were retested for oxygen consumption and were observed for 15 min in a clear plastic chamber for morphine-abstinence-like 15 min in a clear plastic chamber for morphine-abstinence-like behaviors, such as wet-dog shakes, abdominal writhes, hind foot scratches, etc.

The naloxone-infused rats had significantly, p <.001, higher oxygen consumption as percentage increase above baseline (48.4% vs 3.6%). They also showed significantly, p <.001, more abstinence-like behaviors (13.2 vs. 1.8). Following the s.c. injections, the saline-infused rats remained near baseline oxygen contions, the saline-infused rats remained near baseline oxygen consumption and near zero behavioral symptoms, regardless of whether they were injected with saline or clonidine. The naloxone-infused rats injected with saline retained their elevated  $0_2$  consumption (40.7% over baseline), while clonidine reversed  $0_2$  consumption to 9.7% below baseline. The naloxone-infused rats injected with saline also continued to display a high level of behavioral symptoms (11.2) while clonidine injection reduced the symptoms to zero. In each case, the difference between the saline and clonidine injected rats was significant, p < 0.01. Clonidine reversal of the "endorphin blockade syndrome" suggests a further point of resemblance to the opiate abstinence syndrome. It is also consistant with the hypothesis of hyperactive brain adrenergic mechanisms in both syndromes.

active brain adrenergic mechanisms in both syndromes.

THE EFFECTS OF SPINAL OPIATES ON MICTURITION IN UNANESTHETIZED 215.14 ANIMALS. C. Ronald Brent\*, Gail Harty\* and Tony L. Yaksh\* (SPON: F. W. L. Kerr). Section of Neurosurgical Research, Mayo Fndn., Rochester, MN 55905.

Urinary retention has been frequently reported in the clinical use of spinal and epidural opiates for analgesia. A preparation was devised to examine the spinal pharmacology of opiates in un-anesthetized rats and cats. Indwelling polyethylene catheters were placed in the urinary bladders of rats (PE-50) and cats (PE-90) and tunneled subcutaneously to exit through the scalp, allow-ing both ureters and urethra to remain intact. These animals were previously fitted with polyethylene (PE-10) intrathecal (IT) catheters directed to the lumbosacral enlargement. Rats were placed in a restraining cage, cats in a small circular chamber, over a collecting device attached to a strain gauge for measure-ment of urine volumes. The bladder catheters were attached to a during continuous infusion of normal saline. At a constant rate der contractions (54  $\pm$  22 cm H<sub>2</sub>O, n = 8 in rat) were observed at regular intervals and were associated with simultaneous and efficient expulsion (no residual volume) of discreet volumes of urine (mean volume = 0.84 + 0.12 ml, n = 8, in rat). The significance of using unanesthetized animals in studying this volume-evoked micturition reflex (VEMR) was demonstrated by the complete inhi-bition of this reflex in rats anesthetized with pentobarbital (50 mg/kg, i.p.), chloralose (130 mg/kg, i.p.), ketamine (100 mg/kg, i.p.) and halothane (by inhalation). In unanesthetized animals, a complete inhibition of the VEMR was produced by II administration of opiates. In the rat, 5 out of 5 were inhibited by a  $\mu$  agonist (morphine, 15  $\mu$ g) and 4 out of 5 were inhibited by a  $\delta$  agonist (d-ala<sup>2</sup>-d-leu<sup>5</sup>-enkephalin: DADL, 0.8  $\mu$ g). This dose-dependent effect was reversed with IT naloxone (15  $\mu$ g). The  $\kappa$ agonist, U-50488H (50-100 µg) failed to inhibit the VEMR. Systemic morphine (1 mg/kg, i.p.), IT naloxone (15 µg), and IT thiorphan (70-200 µg) administered individually had no effect on volume-evoked micturition. IT morphine (15 µg) was also observed to cause a naloxone-reversible inhibition of volume-evoked contractions in the automatic bladders of chronic (>7 days) spinal-transected (high thoracic) animals. Similar results were observed in parallel experiments carried out in cat. We conclude that volume-evoked micturition is modulated through  $\mu$  and/or  $\delta$ , but not  $\kappa$  opiate-receptor systems at the lumbosacral spinal level. Failure of naloxone or thiorphan to have any significant effect in the unanesthetized and spinally intact animal suggests that spinal opiate systems have little or no intrinsic activity during normal micturition. (Mayo Foundation)

215.16 POSTRADIATION MOTOR PERFORMANCE OF RATS PRETREATED WITH NALOXONE. C. J. Gosett-Hagerman\*, V. Bogo\*, S. A. Simpson\* and L. G. Cockerham. Physiology and Behavioral Sciences Departments, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814.

Naloxone, an opiate antagonist, has been shown to diminish the degree of hypotension and increase the survival time of rats subjected to either endotoxic or hypotential include the shock. Since blood pressure falls dramatically following radiation, this has been postulated as a possible explanation of following radiation, this has been postulated as a possible explanation of postradiation behavioral, early transient incapacitation and/or perfor-mance decrement. Behavior was assessed with the accelerod, a test of rodent motor performance in which rats perform on an elevated rod that accelerates at 1 rpm/sec to determine if pretreatment of rats with naloxone would alter radiation induced performance decrement. Fortyeight male Sprague-Dawley rats (200-400 gm) were trained to a stable level of performance on the accelerod, randomly assigned to one of four 10, 20, 30, 45, 60, and 90 min after radiation or sham exposure. Perfor-mance of the naloxone and saline treated radiation-exposed subjects were significantly different from controls during the initial two test periods, but they did not differ significantly from each other, which indicates that naloxone delivered with a mini-pump at a dose rate of 0.5 mg/kg/hr did not act as a radioprotectant for motor performance. In addition, neither radiation exposed group returned to baseline performance levels during the 90 min of testing, as has been suggested by other investigators.

SELECTIVE u & 6 RECEPTOR ANTAGONISTS AND NEUROFNDO-215.17 CRINE RESPONSES TO MORPHINE: EVIDENCE FOR  $\mu$  RECEPTORS IN

CRINE RESPONSES TO MORPHINE: EVIDENCE FOR  $\mu$  RECEPTORS IN PROLACTIN RELEASE. J.W. Holaday, L. Pennington\*, and S.J. Ward', Neuropharm. Br., Dept. Med. Neurosci., Div. Neuropsych., Walter Reed Army Institute of Research, Wash., DC 20307 and 'Dept. Pharmacol., Sterling Winthrop Research Institute, Rensselaer, NY 12144. Following injection of opioid agonists, variable neuroendocrine responses have been reported, including elevations of plasma corticosterone (CS) and prolactin (PRL). The purpose of these studies was to characterize the possible involvement of central  $\mu$  or  $\delta$  opioid receptors in CS and PRL responses following morphine administration in conscious rats. Male S.D. rats (250-3007) were surgically proceed with extent of the statement.

Male S.D. rats (250-300g) were surgically prepared with catheters in the external jugular vein as well as an intracranial guide tube for right lateral intracerebroventricular (icv) injections (20  $\mu$  l over 20 sec).  $\beta$  -fu-There in the there is a state of the second s treatment times for antagonists were shown to have selectively different effects upon antinociceptive, cardiovascular, and respiratory responses to MS (<u>Soc. Neurosci. Abstr.</u> Vol. 8, p 388-389, 1982). One day following surgery, venous blood was withdrawn from these conscious, unrestrained rats. One hour following intravenous MS administration in rats treated with  $\theta_{\rm c}$ -FNA, ICI or saline, a second blood sample was obtained. Plasma CS and PRL were measured by radioimmunoassay.

CS and PRL were measured by radioimmunoassay.  $\beta$ -FNA by itself was without effect upon resting levels of CS (10-15  $\mu$ g %) or PRL (5-15 ng/ml). ICI resulted in a doubling of resting CS levels, but was without effect upon basal PRL. Unexpectedly, at MS doses between 2 and 160 mg/kg, CS values remained within control ranges (<20  $\mu$ g %) regardless of treatment group. By contrast, MS evoked a dose related increase in PRL, with threshold response (30 ng/ml) occuring at a dose of 8 mg/kg MS, and a maximum PRL response (> 1000 ng/ml) at 40 mg/kg MS. ICI resulted in a twofold rightward shift, and  $\beta$ -FNA, a fourfold rightward shift of the PRL response to MS.

fourfold rightward shift of the PRL response to MS. Unlike prior reports, we were surprised to find that MS doses up to 160 mg/kg were without effect upon CS levels, indicating that MS is not a potent stimulus for CS release in the conscious rat. Based upon this evidence, the doubling of resting CS levels produced by ICI may or may not be related to opioid-specific responses. With regard to PRL release, MS resulted in a dose-related increase in PRL which was antagonized to a greater degree by  $\beta$ -FNA than by ICI. Parallel to earlier findings with the effects of these selective antagonists upon nociceptive responses to MS evidence indicates that w recentres plave a dominant role in both the MS, evidence indicates that  $\mu$  receptors play a dominant role in both the antinociceptive and PRL-releasing effects of MS.

SYMPOSIA

WEDNESDAY PM

EXCITATORY AMINO ACID NEUROTRANSMITTERS. <u>C. Cotman</u>, Chairman Univ. Calif., Irvine; <u>R. Altschuler and J. Fex</u>, NIH-NINCDS; <u>R. Wenthold</u>, Univ. of Wisconsin Med. Sch.; <u>R.F. Miller</u>, <u>M.M.</u> Slaughter, <u>S.C. Massey</u>, and <u>E. Dicks</u>, Washington Univ. Sch. of Med.; <u>J. Coyle</u>, Johns Hopkins Univ. Sch. of Med.; <u>M. Ito\*</u>, <u>Indiversity of Theore</u>, <u>P. Mildeit</u>, <u>J. Borkovt</u>, and <u>K. Dick</u>, <u>Australa</u> 216 Med.; J. Coyle, Johns Hopkins Univ. Sch. of Med.; <u>M. Ito\*</u>, University of Tokyo; <u>R. Miledi\*, I. Parker\*, and K. Sumikawa\*</u>, Univ. College London.

New evidence derived from several lines of experimentation points toward glutamate aspartate and perhaps related derivatives as major excitatory transmitters in the CNS. Acidic amino acid receptors are highly localized, exist as multiple types and differentially interact with various potent antagonists of excitatory amino acid synaptic transmission. Clutamate appears to be a transmitter at major projection pathways and several of these appear to be highly plastic. Cotman will summarize current information on the classes of receptors for acidic amino acids and present autoradiographic data on their distribution in the CNS. Autoradiographic data shows receptor classes for  $^{3}\mathrm{H}$ -glutamate are topographically organized and can be resolved into distinct classes. NMDA sensitive sites, for example, are particularly concentrated and differentiated in hippocampus, cortex, basal ganglia and thalamus. Altschuler will describe data showing that antisera against glutaminase or aspartate amino transferase, two enzymes involved in glutamate and aspartate metabolism, may serve to identify acidic amino acid neurons. Major suspected aspartate/glutamate pathways are labelled with one or both antisera. Miller will discuss the properties of acidic amino acid mediated neurotransmission in the vertebrate retina. Results are compatible with the idea that glutamate mediates the synaptic action of photoreceptors and at least some bipolars. The second order neurons have at least two types of specialized synaptic receptors which are segregated according to the polarity of the light response. Coyle will discuss the presence of endogenous brain neuropep tides as candidates for excitatory neurotransmitters. Ito w Ito will discuss the plasticity of parallel fibers. These fibers appear to use glutamate as their transmitters, and a decrease in To use glutamate as their transmitters, and a decrease in glutamate sensitivity appears to underlie the long-lasting de-pression in parallel fiber-Purkinje cell transmission after simultaneous activation of parallel fibers and climbing fibers. Therefore it may play a key role in the cerebellar plasticity. Finally, Parker will present new data on the induction of eurotransmitter receptors in Zenopus oocytes. This approach allows the study of complex receptor types in a simple system.

217 SYMPOSIUM. APPLICATIONS OF NEUROSCIENCE TO HUMAN PROSTHESES. F. T. Hambrecht, MINCDS, National Institutes of Health (Chairman); Richard B. Stein\*, Univ. of Alberta; P. Hunter Peckham\*, Case Western Reserve Univ.; Michael M. Merzenich, Univ. of California, San Francisco.

Rapid advances in technology and in the neurosciences are being combined to develop clinically useful human prostheses based on direct interfaces with the nervous system. This syn This sympo sium will attempt to inform the members of the audience, who represent many disciplines, about some of the progress that is Teplesent many disciplines, about some of the progress that is being made and to alert them to problem areas that may be in their fields. Stein will review the use of electromyographic signals to control powered artificial limbs and the current status of multi-joint prostheses for both the upper and lower extremities. Methods of controlling multiple powered movements will be out-lined such as multi-control control and potters resconding Methods of controlling multiple powered movements will be out-lined such as multi-state control and pattern recognition techniques. The use of signals from neurons and deep muscles, transmitted by means of telemetry, will be described. In addition to prostheses, robots can be adapted to do a variety of tasks for severely handicapped individuals. The problems of controlling wearable, multi-movement prostheses and free-standing robots will be compared. Peckham will demonstrate how the paralyzed muscles of a spinal cord injury victim can be functionally activated and placed under the individual's voluntary control. He will discuss the future of totally voluntary control. He will discuss the future of totally implanted, closed loop feedback control systems utilizing artificial sensory transducers. Merzenich will describe recent technological developments in multichannel cochlear prostheses and neurophysiological and psychoacoustical experiments in individuals with sensory deafness. Hambrecht will give examples of the important role that fundamental neuroscience and technology research have played in the development of stateof-the-art neural prostheses and will discuss problems that need to be solved by future research efforts. If time permits, there will also be a general discussion between the symposium participants and the audience.

218

SYMPOSIUM. THE NEUROGENETICS OF IDENTIFIED\_CELLS. <u>R.J. Wyman</u>, Yale (Chairman); <u>H.R. Horvitz</u>, MIT; <u>L. Buck</u> (Columbia U. CPS); <u>L.B. Salkoff</u>, UCSF; <u>R.J. Mullen</u>, Utah. Many of the most interesting properties of neurons are those that inhere in only a single cell or cell type (morphology, connectivity) or those that vary from cell to cell (transmitters or ion channels used). The application of genetic techniques to the study of identified cells has allowed a wholly new approach to these properties. to these properties.

In the nematode (C. elegans) the lineage, morphology and synaptic connections of every nerve cell is known. Horvitz et al. are studying the genes that establish these properties. He will describe lineage mutants which cause cells normally present to undergo programmed cell death, and other mutants which cause the production of supernumerary copies of cells. Other mutants

the production of supernumerary copies of cells. Other mutants affect function, morphology or transmitter systems. Recombinant DNA technology is being used to examine neuron specific gene expression in Aplysia. The genes for the peptides secreted by the <u>bag cells</u> and the atrial gland cells in Aplysia have been cloned and sequenced. Now Buck et al. have isolated messenger RNA from single cells (R2 and R15) and have identified a message coding for a peptide that appears to be expressed in P15 but the term of the relation of the period.

RI5 but not in any other cell in the abdominal ganglion. In <u>Drosophila</u>, Wyman et al. are seeking genes which code for signals required for the specificity of synaptic connection. They have isolated mutants in which single branches of identified cells grow abnormally and do not make their normal synapses. A second copy of these signals, in the wrong ganglion, can be created in bithorax flies. The giant fiber then grows two identical branching trees. Thus homeotic genes transform not just the cuticle, but also affect the CNS. In <u>Drosophila</u>, Salkoff et al. have studied the <u>DLM</u> muscle

cells. The cells were voltage clamped to identify the ion channels present. The different currents develop sequentially channels present. The different currents develop sequentially during metamorphosis; the first to develop is the fast transient K<sup>\*</sup> current (I<sub>A</sub>). Mutants at the <u>Shaker</u> locus were found to either alter the kinetics properties of the current, or eliminate the current altogether. The ground work has now been completed for a molecular characterization of this channel.

Although the mammalian cerebellum contains millions of cells, there are only a few neuronal and glial cell types (e.g. Bergman Glia, Purkinje Granule Cells) arranged in a simple and highly repetitious fashion making it a suitable subject for neurogenetic study of identified cells. Numerous mutations affecting specific cell types have been discovered. By producing mouse chimeras, Mullen et al. have defined the primary site of gene action and delineated cell-cell interactions

PEPTIDES: BIOSYNTHESIS AND METABOLISM I

MOLECULAR CLONING OF THE R3-14 NEUROPEPTIDE GENE IN APLYSIA. 219.1 John R. Nambu\* and Richard H. Scheller. Det. of Biological Sciences, Stanford University, Stanford, CA. 94305. We are interested in elucidating the molecular mechanisms involved in mediating extracellular communication within the involved in mediating extracellular communication within the nervous system. This necessarily requires a characterization of the chemical messengers involved. The abdominal ganglion of the gastropod mollusc Aplysia californica is a large asymmetric cluster of about 2000 neurons, many of which are phenotypically distinct. In order to examine the role of this tissue in modu-lating behavior and physiology we have taken an identifiable peptidergic neuron, cell R14, and characterized its neuropeptide recovering and the corresponding come

precursor and the corresponding gene. 50 Aplysia abdominal ganglia were dissected and individual neurons collected. Poly(A)+ RNA prepared from various cells was used to direct in vitro translation analysis, which indicated a predominant low molecular weight protein product (ca. 14,000 daltons) in the Rl4 neuron. cDNA was synthesized and utilized as a probe to screen for homologous sequences in an abdominal ganglion cDNA library. Nucleotide sequence analysis of R14 specific cDNA clones provided information on the primary structure of the protein product. The 108 amino acid protein contains both acidic and basic regions separated by a pair of internal dibasic residues (lys-arg, arg-arg), potential sites for proteo-lytic cleavage. The bioactivities of the various cleavage prod-

Typic cleavage. The blocktivities of the various cleavage products are currently under investigation. The corresponding gene was isolated from a total genomic library and characterized via restriction enzyme mapping and electron microscopy heteroduplex analysis. This has permitted us to determine the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as well and the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRNA transcript on the gene as the orientation of the mRN as to localize two intervening sequences (introns) within the coding regions.

We are currently pursuing similar studies using identifiable neurons from the abdominal and other Aplysia ganglia. It is hoped that the information generated, including the character-ization of the neuropeptide products from individual neurons, will contribute to our understanding of the mediation of the solution of the neuropeptide are being to provide function func-tions. cell-cell interactions which are basic to nervous system function.

REGULATION OF EXPRESSION OF PROENKEPHALIN mRNA IN CULTURED CHROMAFFIN CELLS OF BOVINE ADRENAL. Joan P. Schwartz, T.T. Quach\*, P. Panula\* and E. Costa, Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032 Biochemically and histochemically medullary chromaffin cells have been shown to contain not only catecholamines but also enkephalin-like peptides. Previous studies have shown that both the catecholamines and 219.2 peprides. Previous studies have shown that both the catecholamines and the opioid peptides can be released in vivo following splanchnic nerve stimulation and in vitro by acetylcholine and histamine. Since cyclic AMP participates in the regulation of tyrosine hydroxylase biosynthesis, we have now examined the effect of cyclic AMP on the regulation of enkephalin peptide synthesis. We have used a cDNA probe for human pheochromocytoma proenkephalin (Comb et al., Nature 295:663, 1982) to detect proenkephalin mRNA in bovine adrenal medulla. Total RNA was prepared by guanidine thiocyanate extraction of tissue or cells, followed by centrifugation on a cesium chloride gradient. Poly (A)<sup>7</sup>-RNA (mRNA) was prepared by two passages over oligo (dT)-cellulose. RNA was fractionated on a formaldehyde-agarose gel, blotted to nitrocellulose and hybridized to a 32P-labeled probe. Northern blot analysis of poly (A)<sup>7</sup>-RNA from bovine adrenal medulla revealed the presence of 3 RNA species; the predominant mRNA was approx. 1400 bases, as has been previously described while the other 2 species represented less than 15% of the total proenkephalin-positive RNA and were much larger (approx. 3.8 kb and 7.3 kb). Analysis of total RNA prepared from chromaffin cells which had been in culture for four days revealed the presence of the same three species of RNA. Treatment of the cells with ImM & B-r-cyclic AMP for 24 hrs led to an increase in the amount of all three RNAs (quantitated by densitometric scans of the autoradiograms). The largest RNA (7.3 kb) the optoid peptides can be released in vivo following splanchnic nerve tor 24 hrs led to an increase in the amount of all three RNAs (quantitated by densitometric scans of the autoradiograms). The largest RNA (7.3 kb) increased 3.7 fold, the 3.8 kb 2.0 fold and the 1.4 kb species 1.9 fold. The results suggest that the larger MW RNAs may be nuclear precursors to the cytoplasmic 1400 base mRNA. The effect of 8-Br-cyclic AMP on proenkephalin mRNA content is both time-and dose-dependent and is not reproduced by 8-Br-cyclic GMP. Three days of treatment with 8-Br-cyclic AMP results in a 10-12 fold increase in proenkephalin mRNA; however, at this time total RNA has also increased 3-5 fold, although however, at this time total RNA has also increased 3-5 fold, although there is no change in protein synthesis or cell number. In situ hybridization of biotinylated probe in chromaffin cell cultures, detected by streptavidin-horseradish peroxidase staining (Enzo Biochem), has demonstrated that approx. 30% of the chromaffin cells stain for proenkephalin mRNA. Those same cells exhibit PNMT- or met-enkephalin-arg -gly -leu-like immunoreactivity, thus demonstrating the coexistence of a catecholamine enzyme(s), an enkephalin peptide(s) and proenkephalin mRNA. This technique will allow us to examine the possibility of coordinate regulation of these cotransmitters by cyclic AMP.

HYPOTHALAMIC OXYTOCIN BIOSYNTHESIS: EFFECT OF DEHYDRATION. 219.3 M. Morris\*, G.S. Gallimore\* and D.K. Sundberg\* (SPON: P.B. Smith). Dept. of Physiol. & Pharmacol., Bowman Gray Sch. Med.

Winston-Salem, NC 27103 Oxytocin is synthesized as part of a larger precursor molecule which is then cleaved during transport to yield the nonapeptide. by the first synthesized as part of a larger precursor molecule which is then cleaved during transport to yield the nonapeptide. These experiments were designed to investigate the biosynthesis of oxytocin (OT) in various brain regions. Male rats were prepared with ghronic third ventricular cannula.  $40 \,\mu$ Ci (4  $\mu$ l volume) of <sup>3</sup>H-proline (102 Ci/mM) was injected intraventricularly and the animals were decapitated 3, 6, 12 and 24 hrs later. The tissues examined were the neurohypophysis (NP), median eminence (ME), and paraventricular (PVN) and supraoptic nuclei (SON). The tissues (pooled from 4 animals) were homogenized in 0.2 N acetic acid, purified by an initial Sep-Pak Cl8 separation (Waters Inst) and then subjected to reverse phase HPLC separation. The fractions were monitored for U.V. absorbance, radioactivity and in some cases immunoreactivity. There was a time dependent increase in neurohypophysal <sup>3</sup>H-OT reaching 825 dpms (total peak) at 24 hrs. The radioactive peak co-eluted with 0T as determined by both immunoreactivity and U.V. absorbance. Although there was incorporation of <sup>3</sup>H-proline into proteins in the other brain regions, the label was not associated with 0T. Thus, most of the label in the PVN, SON and ME is probably associated with precursor molecules. To determine the effect of a stimulus to this system, 0T biosynthesis was measured after 48 hrs of water this system, OT biosynthesis was measured after 48 hrs of water deprivation. There was a reduction in both peptide content and in the absolute amount of neurohypophyseal 3H-OT ( $187.3 \pm 7.9$  vs 121.6  $\pm$  9.2 dpms/NP; control vs exp). However, when expressed as specific activity (<sup>3</sup>H-OT/OT content), dehydration resulted in

as specific activity ( $^{9}$ H-OT/OT content), dehydration resulted ir an increased labeled pool of this neurohormone (.5  $\pm$  .03 vs .95  $\pm$  .03 dpm/ng). Thus, there is significant incorporation of a labeled amino acid precursor into a peptide which co-elutes with oxytocin. Dehydration stimulates both the secretion and <u>de novo</u> synthesis of this peptide. The fact that the newly synthesized peptide first appears in the neurohypophysis suggests that precursor processing occurs during transit from the nuclei to the neuro-hypophyseal axons.

SUBSTANCE P BIOSYNTHESIS AND AXONAL TRANSPORT IN THE RAT STRIATONIGRAL SYSTEM: EVIDENCE FOR RAPID PRECURSOR PROCESSING SIRIAIONIGKAL SISIEM: EVIDENCE FOR KAPID FREUENSOR FROCESSING AND FAST AXONAL TRANSPORT FROM FULSE-CHASE EXPERIMENTS. J.E. Krause and J.D. White, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794. The <u>in vivo</u> production and axonal transport of neural peptides to their respective terminal fields represent important aspects in

to their respective terminal fields represent important aspects in the functioning of neuronal networks. We have approached these questions by using as a model the striatonigral substance P (SP) projection. SP positive neuronal perikarya in the rostral corpus striatum project ipsilaterally via the ansa lenticularis to an ex-tensive terminal field within the substantia nigra. In the present studies, we have examined the kinetics of in vivo biosyn-thesis and axonal transport of radiolabeled SP along the trajectory of this peptidergic projection using a pulse-chase paradigm

and analytical procedures for the quantitation of SP biosynthesis as previously described (Krause et al., 1982). The right corpus striatum of rats was pulsed for 2 hrs with <sup>35</sup>S-methionine (500 µCi/rat) via 2 indwelling cannulae using an Alzet osmotic minipump delivery system. Rats were killed 2,4,8, Alzet Osmorre minipum derivery system. Rats were kined 24, no, 12,16 and 24 hrs after the start of amino acid infusion. Radio-labeled SP was extracted from the striatum, its striatonigral fasciculus and the substantia nigra and was purified by sequential High Performance Liquid Chromatography (HPLC). Chemical sulfox-idation of radiolabeled SP and further HPLC demonstrated the homo-mative if the radiolabeled meloacortide. genity of the radiolabeled undecapeptide. The present results suggest that SP is processed from its puta-

The present results suggest that SP is processed from its puta-tive precursor protein at the site of its cell bodies in the cor-pus striatum. Thus, 2 hr after the start of amino acid infusion, relatively large amounts of  ${}^{35}S$ -SP can be isolated from the stri-atum.  ${}^{35}S$ -SP can be harvested from the striatonigral fasciculus and the ipsilateral substantia nigra from 2 to 4 hr after the start of amino acid infusion. These observations suggest that either  ${}^{35}S$ -SP or its putative precursor protein is transported to these sites via a fast component of axonal transport (i.e.  $\ge 2$  to 4 mm/hr). The greatest amount of  ${}^{35}S$ -SP within the substantia nigra is observed from 4 to 8 hr after the start of amino acid infusion. The radiolabeled SP within the striatum may be used infusion. The radiolabeled SP within the striatum may be used locally, or may be axonally transported to other target sites. These studies demonstrate the feasibility of studying the in situ regulation of SP production and transport, and the kinetics of SP turnover in individual unrestrained animals. (Supported by NS 18942 to JEK.)

EFFECT OF CYSTEAMINE ON THE BIOSYNTHESIS <u>IN VIVO</u> OF VA-SOPRESSIN, OXYTOCIN AND SOMATOSTATIN.<sup>Q</sup> <u>R.E. Franco-</u> <u>Bourland</u>\*. (SPON: F. Antón-Tay). Departamento de Bioquí mica, Instituto Nacional de la Nutrición, Salvador Zubirán, 14000 México, D.F. <sup>Q</sup>CONACYT-México: PCCBBNA-001724 219.4 001716

The systemic administration in the rat of cystea-The systemic administration in the rat of cystea-mine, a thiol reagent, diminishes somatostatin-like immunoreactivity in the hypothalamus, without a conco-mitant rise of its levels in plasma. The mechanism of action of cysteamine in this instance is not known. The decrease in hypothalamic somatostatin (SRIF) levels might be the consequence of an accelerated degradation and/or an inhibited biosynthesis. Here I report the effect in the rat of cysteamine on the <u>in vivo</u> incorpo-ration of L-(35S)Cys into hypothalamic SRIF, and com-pare it to that into the other hypothalamic cysteine-containing peptides, vasopressin (AVP) and oxytocin (OT).

Guide cannulas, directed to the III ventricle, were Guide cannulas, directed to the III ventricle, were implanted in male rats weighing 250g. Ten days after surgery, paired rats were given subcutaneously 30 and 300 mg/kg of cysteamine-HCl in neutralized H $_2$ 0.Controls received 1M NaCl. Four hours after the administration of the drug, the rats received 40 $\mu$ Cl of L-(35S)Cys via the III ventricle and were decapitated 4h thereafter. Labeled AVP, 0T and SRIF were extracted from individu-al hypothalami and neurohypophyses into 2M HOAc, and were purified simultaneously by chemoadsorption to ocwere purified simultaneously by chemodsorption to oc-tadecyl-silane coupled to silica and 2 sequential HPLC steps. At the end of this procedure the labeled pep-tides were at least 90% radiochemically pure, as deter-mined by derivatization. The recoveries of the carrier peptides and the endogenous neurohypophyseal content of

AVP and OT were measured by absorbance at 206nm. Radio-activity was determined by liquid scintillation. Compared to controls, the mean values of incorpora-tion of L-(355)Cys into AVP, OT and SRIF in the hypotha lami and neurohypophyses of rats which had received 30 activity and received and activity and the second activity and the second activity and the second activity and the second activity and the second activity and the second activity activity activity and the second activity mg/kg of cysteamine were significantly reduced. The in-corporation of the label into OT and SRIF in animals which had received 300 mg/kg of cysteamine was undetec-table, whereas that into AVP was reduced but measure-able. It thus appears, that one mechanism through which a cysteamine reduces the hypothalamic content of SRIF is by inhibiting its biosynthesis. It also appears to have a greater effect on OT rather than on AVP biosynthesis.

219.6 FURTHER STUDIES ON AN ADRENAL ENKEPHALIN-GENERATING ENZYME:

FORMER STUDIES ON AN ADRENAL ENREPHALIN-GENERATING ENZIME: SUBSTRATE SPECIFICITY. I. Lindberg\*, H.-Y.T. Yang and E. Costa (SPON: J. Dahl). Lab. Preclinical Pharmacol., NIMH, Saint Eliza-beths Hospital, Washington, D.C. 20032 We have previously reported the presence of a serine protease in chromaffin granules which is capable of cleaving high molecular weight enkephalin-containing peptides to generate met<sup>2</sup>-enkephalin and other related peptides. This enkephalin-generating enzyme ex-bilities of UL protections of 0.0 and an enveropt molecular weight of weight enkephalin-containing peptides to generate met enkephalin and other related peptides. This enkephalin-generating enzyme ex-hibits a pH optimum of 8.0 and an apparent molecular weight of 20,000 by gel filtration. The substrate specificity of this enzyme was examined using 1) small synthetic fluorogenic peptides  $con_{\overline{7}}$ taining\_basic regidues; 2) the heptapeptides met enk-arg enzyme and met enk arg or phe; 3) peptides E and F and 4) the 8 to kdal N-terminal fragment of proenkephalin (which contains met enkepha-lin at its carboxyl terminus). The enzyme exhibited little re-activity toward the heptapeptides and the fluorogenic substrates; the Km's for Boc-glu-lys-lys-MCA and Boc-gln-arg-arg-MCA were 0.7 and 2.0 mM, respectively. In contrast, the Km of the enzyme for the 8.6 kdal fragment of proenkephalin was  $0.5 \mu$ M. Analysis of the enzymatic products of the 8.6 kdal fragment by HPLC followed by RIA revealed the generation of met enkephalin and another immunoreactive peptide (probably lys met enkephalin). \_flazymatic digestion of peptide F yielded arg -met enkephalin). \_flazymatic and arg -arg -arg -met - enkephalin. These results indicate that this adrenomedullary protease is capable of cleaving adrenal high molecular weight enkephalin-containing pep-tides at the paired basic sites. In addition, the Km for the 8.6 kdal (an endogenous high molecular weight peptide) was considerably lower than that for the synthetic fluorogenic substrates. Taken together, these results suggest that this adrenomedullary protease represents a possible candidate for a proenkephalin processing enzyme. enzyme.

ENKEPHALIN CONVERTASE: PURIFICATION AND CHARACTERIZATION OF BOTH THE SOLUBLE AND THE MEMBRANE BOUND FORM OF THE ENKEPHALIN SYNTHESIZING CARBOXYPEPTIDASE. L.D. Fricker, S. Supattapone\* and S.H. Snyder. Johns Hopkins University, Depts. of Neuroscience, Pharmacology and Psychiatry, School of Medicine, 219.7

Neuroscience, Pharmacology and Psychiatry, School of Medicine, Baltimore, Maryland 21205. Enkephalin convertase, the enkephalin synthesizing carboxypeptidase B-like enzyme, is present in brain, pituitary and adrenal medulla chromaffin granules in both a soluble and a membrane bound form. The membrane bound enzyme which constitutes 20-50°/° of the total enkephalin convertase activity in these tissues can be solubilized in high yield with 0.5°/° triton X-100 in the presence of 1 M NaCl. Both forms of enkephalin convertase have been purified to apparent homogeniety utilizing affinity chromatography on p-aminobenzoyl-L-arginine/Sepharose 6B as one of the steps. Purified enkephalin convertase shows a single band on SDS polyacrylamide gel electrophoresis with an apparent molecular weight of 50,000 daltons for the soluble enzyme, and 52,500 daltons for the membrane bound form.

weight of 50,000 daltons for the soluble enzyme, and 52,500 daltons for the membrane bound form. The regional distribution of soluble enkephalin convertase in rat brain and pituitary shows a 30-fold variation whereas the membrane bound enzyme is more homogeneously distributed. The specific activity of both forms of the enzyme is high in the anterior pituitary and low in the cerebellum and brain stem. With the exception of the adrenal medulla, enkephalin convertase activity was not detectable in any other tissues screened. Enkephalin convertase purified from both soluble extract and membranes of bovine brain, pituitary, and adrenal medulla behaves similarily with respect to substrates, inhibitors, pH and divalent cations. Dicarboxylic acid analogs of arginine and lysine are potent inhibitors of enkephalin convertase. Two of these active site directed inhibitors (guanidinoethylmercaptosuccinic acid and quanidinopropylsuccinic (guanidinoethy]mercaptosuccinic acid and guanidinopropy]succinic acid) inhibit enkephalin convertase with  $K_1$ 's of 7-8 nM, which is several hundred fold more potent than their influence on

other carboxypeptidase B-like enzymes. These results suggest that enkephalin convertase activity represents the same enzyme in the brain, pituitary and adrenal chromaffin granules. The only detectable difference between the two forms of enkephalin convertase is that the membrane bound form is 2-3000 daltons heavier than the soluble enzyme. This difference may be due to an additional fragment on the membrane bound enzyme which anchors it to the membrane.

ANTIBODIES AGAINST BOVINE PITUITARY CARBOXYPEPTIDASE B-LIKE PROCESSING ENZYME FOR HORMONE PRECURSORS, V.Y.H. HOOK\*, L.D. Fricker, M.J. Brownstein\*, and S.H. Snyder. (SPON: J. Axelrod). Lab. of Cell Biology, NIMH, Bethesda, MD. 20205, and Dept. of Neuroscience, Johns Hopkins University, Baltimore, MD.21205. Peptide hormones such as the enkephalins,  $\beta$ -endorphin, ACTH, vasopressin and others are synthesized as large peptide precur-sors which are cleaved to yield smaller biologically active forms. Characteristic pairs of basic amino acids (Lys, Arg) flank the N- and C-terminal ends of the hormone within the pre-cursor, suggesting that trypsin- and carboxypeptidase B-like peptidases are required to process the precursor. Carboxypepti-dase B-like enzymatic activity involved in processing of proen-kephalin has been identified in bovine adrenal medullary chro-maffin granules (Hook et al., Nature, 295:341, 1982; Fricker and Snyder, PNAS, 79: 3886, 1982) (previous]y referred to as enkepha-lin convertase) and appears to be a thiol metallopeptidase stimulated by Co<sup>++</sup> (Fricker & Snyder, PNAS, 79:3886, 1982; Hook & Eiden, submitted). Carboxypeptidase B has also been detected in granules from anterior, intermediate, and posterior lobes of rat pituitary. The pituitary enzyme(s) seem to be thiol metallo-peptidases similar to the chromaffin granule species (Hook & Loh, submitted). The carboxypeptidase B-like activity in pitui-tary granules may be involved in processing of proopiomelano-cortin and pro-vasopressin. The carboxypeptidase B-like enzyme from boyine pituitary has been purified to homogeneity by following Co<sup>+-</sup>-stimulated acti-vity throughout the purification procedure (Fricker & Snyder, <u>J.Biol.Chem.</u>, in press), and appears to be a glycoprotein of <u>50,000 mW. Monoclonal and polyclonal antibodies against the</u> purified enzyme were prepared. Monoclonal antibodies were pro-duced by an <u>in vitro</u> immunization method. Spleen cells from Balb/c mice were incubated in thymocyte 219.8

duced by an in vitro immunization method. Spleen cells from Balb/c mice were incubated in thymocyte conditioned RPMI (15% fcs) medium containing 1 ug/ml purified enzyme for 5 days at 37° C, 10% CO<sub>2</sub> - 90% air atmosphere. Spleen cells were then fused with NS-1 mouse myeloma cells and hybridomas producing antibody against the purified enzyme were screened by ELISA using 1251-sheep anti-mouse immunoglobulins. Hybridomas were cloned by the limiting dilution technique. Mouse antisera were prepared by injecting mice with 3 ug purified enzyme in complete Freund's adjuvant three times each 2 weeks apart Antiseras were adjuvant, three times each 2 weeks apart. Antiseras were screened by the ELISA method as used for screening monoclonal antibodies. These antibodies will be used to obtain information on the structure and cellular localization of the carboxypepti-dase B-like processing enzyme for hormone precursors.

GLYCINE-DIRECTED PEPTIDE AMIDATION: PRESENCE IN RAT BRAIN OF TWO 219.9 ENZYMES WHICH CONVERT P-GLU-HIS-PRO-GLY-OH INTO P-GLU-HIS-PRO-NH<sub>2</sub> (TRH). J.S. Kizer\*, W.H. Busby, Jr.\*, W.W. Youngblood\* (SPON: M.A. Lipton). Lab. of Developmental Neuroendocrinology, Biological Sciences Research Center, UNC School of Medicine, Chapel Hill, NC 27514.

The biosynthetic pathway for thyrotropin-releasing hormone The biosynthetic pathway for thyrotropin-releasing hormone (TRH) is currently unknown. To study the possibility of glycine-directed amidation in rat brain and its relevance to the me-chanisms of the biosynthesis of TRH, we synthesized the model substrate P-glu-his-pro-gly-OH. Both neonatal rat brain and adult rat pituitary were homogenized, sonicated and fractionated by gel permeation chromatography, and fractions from each tissue assayed for enzymatic activity capable of converting this model substrate into TRH. Addition of N-ethylmaleamide (0.5 mM) to the assay inhibited the degradation of TRH and facilitated the observation of two enzymes in both brain and pituitary catalyzing observation of two enzymes in both brain and pituitary catalyzing conversion of P-glu-his-pro-gly-OH into TRH. We conclude that these enzymes are of considerable importance to the post-translational processing of hormones into C-terminally amidated daughter peptides.

In addition, we also synthesized the model peptide, gln-his-The addition, we are synchronized in model projectice, given has pro-gly-OH and coupled it to BSA through an N-terminal  $\gamma$ -amino butyric acid bridge. Antisera raised were against this immuno-gen and a RIA developed for the model sequence. Neonatal rat brain was found to contain a protein which contained this amino acid sequence. This protein may represent an extended precursor form for TPU form for TRH.

219.10 HISTIDYL-PROLINE DIKETOPIPERAZINE (His-Pro DKP) BUT NOT TRH IS SE-CRETED BY FETAL HYPOTHALAMIC AND CORTICAL CELLS IN CULTURE: EVI-DENCE THAT His-Pro DKP MAY NOT BE DERIVED FROM TRH. R. Preston

DENCE THAT His-Pro DKP MAY NOT BE DERIVED FROM TRR. <u>R. Preston</u> Lamberton\*, Ronald Lechan and Ivor M.D. Jackson\*. Division of Endocrinology, Department of Medicine, Tufts-New England Medical Center, Boston, MA 02111. In order to study the physiologic role of His-Pro DKP, a cyc-lized dipeptide, which is a putative metabolite of thyrotropin releasing hormone (TRH), we have established a specific radioim-munoassay (RIA) for His-Pro DKP which does not recognize TRH or neleted estidies Contine for Day lead munoassay (RIA) for His-Pro DKP which does not recognize TRM or related peptides. Cortical and diencephalic segments from Day 17 fetal rats were dissociated in monolayer culture in flasks - 5 x  $10^6$  diencephalic or 10 x  $10^6$  cortical cells per dish - containing 4 ml Minimum Essential Medium, horse serum (10%) or fetal calf serum and antibiotics. The cells have been maintained in culture up to 21 days free of infection. The time course of His-Pro DKP release into the culture medium

was as follows:

	Day 5	Day 8	Day 14	Day 18	Day 21
Cortical	2,020	15,276	19,404	16,816	18,464
Diencephalic	2,160	15,320	20,352	15,808	17,008
•		(ng	/flack ner	dav •mean	of $3 \text{ or } 4$

Evidence for authenticity of immunoreactive (IR) His-Pro DKP in the medium was shown by a retention time similar to that of synthetic His-Pro DKP on high performance liquid chromatography

In the metrum was shown by a reletion rule of the similar to this of synthetic His-Pro DKP on high performance liquid chromatography (HPLC) (C18  $\mu$ -Bondapak:30 cm x 3.9 mm:solvent 2% CH3CM/0.1% TFA) following affinity chromatographic purification on an anti-His-Pro DKP Biorad-affigel column. Despite the high level of His-Pro DKP in the culture media, no TRH was detected in a RIA with a sensitivity of <1 pg. DKP and TRH were also assayed in various regions of the nervous system (NS) in the Day 17 fetal rat. While TRH was detectable only in the hypothalamus (85 pg/mg protein), His-Pro DKP was found throughout the NS in relatively high concentrations (spinal cord 816 pg/mg, brain stem 485 pg/mg and hypothalamus 375 pg/mg). We conclude that: 1) His-Pro DKP is an authentic neural pep-tide found throughout the NS; 2) His-Pro DKP is synthesized by neuronal cells in culture; 3) TRH may not be a prohormone for His-Pro DKP in some systems. Supported by NIH Grants AM 21863 and AM 06970.

INHIBITION OF PHENOL SULFOTRANSFERASE IN RAT BRAIN AS A POTENTIAL TOOL FOR STUDIES OF CHOLECYSTOKININ TURNOVER. 219.11 Giorgi and J. L. Meek Lab. Preclinical Pharmacol. NIMH St.
 Elizabeths Hosp. Washington DC 20032 Cholecystokinin octapeptide (CCK-8) is present in brain as a sulfate

conjugate. It is likely that a precursor of CCK-8 is sulfated during post-translational processing. If sulfation of CCK-8's precursor could be blocked pharmacologically, then estimation of CCK-8 turnover would be biocked pharmacologically, then estimation of CCK-o turnover would be possible. The enzyme responsible for sulfation is phenol sulfatransferase (PST), which catalyses the transfer of  $SO_{L}^{-}$  from phosphoadenosine phosphosulfate to a wide variety of phenolic acceptors. Since little is known about PST in rat brain, we investigated whether the best available inhibitor of PST (dichloronitrophenol, DCNP) was capable of inhibiting in yitro the sulfation of several behavior. <u>vitro</u> the sulfation of several phenols. Synthetic substrates were used since the endogenous precursors for CCK-8 have not been isolated. We since the endogenous pecursors for CCK-a hove how the permission with a solution of the solution of the solution of the pecursor of DCNP to determine its suitability as an <u>in vivo</u> inhibitor of brain PST. PST was assayed in whole rat brain homogenates (Foldes and Meek, J. Neurochem, 1974). K<sub>m</sub> values were determined from Eadie-Hofstee plots. Using Solution DCNP were calculated by log-probit analysis at saturating substrate concentration.

Substrate (µM)	V max pmol/min/mg	μ <sub>W</sub>	IС <sub>50</sub> µМ
p-nitrophenol(4)	22	.31	12
Phenol (100)	19	12	-
Dopamine(4,000)	22	1,300	14

DCNP was thus capable of completely inhibiting the sulfation of different phenols in vitro with similar  $IC_{50}$  values. For in vivo studies, the concentration of DCNP in plasma and brain was determined by HPLC after an injection at 100 µmol/kg, i.p. A peak concentration in brain of 25 µM was achieved 30 min after injection and decayed with a half life of 8 and 6 h in plasma and brain cortex, respectively. To establish if DCNP can inhibit sulfation in vivo, rats were injected with 150 µmol/kg, i.p. of the drug 30 min before intracortical administration of  $^{35}$ -SO<sub>4</sub><sup>-</sup>. Bgts were decapidated 4.5 h later. DCNP caused a 50% inhibition of  $^{35}$ -SCK-8 formation as measured by HPLC (Meek, ladrola, Giorgi, Br. Res. in press). DCNP concentration at decapitation was 13 µM. To determine if prolonged treatment with DCNP could induce a decrease in CCK-8 content in brain, rats were injected with an initial dose of DCNP (100 µmol/kg) followed at 8 h intervals with doses of 50 umol/kg for 2 and 4 days. No change in CCK-8 pmoi/kg) followed at 8 in intervals with doses of 30 dimoi/kg for 2 and 4 days. No change in CCK-8 content was detectable, probably due to incomplete inhibition of PST. Higher doses of DCNP could not be used due to toxicity. Our results show that DCNP can only produce a partial inhibition of PST in vivo. The drug is not adequate for studying the turnover rate of brain peptides with a long half life. Development of a better, preferably irreversible, PST inhibitor is required.

ISOLATION AND CHARACTERIZATION OF TWO PEPTIDES DERIVED FROM PROSOMATOSTATIN IN RAT BRAIN. <u>R. Benoit\*</u>, <u>P. Böhlen\*</u>, <u>F. Esch\*</u>, <u>N. Ling\*</u> and <u>B. Alford\*</u> (Spon: J.H. Morrison). Salk Institute, La Jolla, Ca. 92037. 219.13

Three peptides derived from prosomatostatin have already been char-acterized in mammalian brain: somatostatin-14 (SS14), somatostatin-28 (SS28) and somatostatin-28(1-12). Using a C-terminally directed antiserum to SS28(1-12), we have recently shown that two N-terminally extended SS28(1-12)-like peptides are present in acid extracts of rat hypothalamus, extra-hypothalamic brain and spinal cord. We describe here the isolation and partial characterization of these two new neuropeptides.

site partial characterization of these two new neuropeptides. 518 fresh female rat brains were homogenized in hot (95°C) 2 M acteic acid. The extract, after defatting and lyophilization, was subjected to carboxy methyl cellulose cation-exchange chromatography: three peaks of immunoreactive material eluted at 0.0025 M, 0.025 M and 0.15 M ammonium acetate (pH4.6) representing 16.1 (peak 1), 75.5 (peak 11) and 8.4 (peak 111) percent of the total SS28(1-12)-like immunoreactivity. Peak 1, when chromatographed on sephadex G75, yielded 7.3 nmol SS28(1-12)-like material eluting in a zone compatible with a 4,500 mol.wt. peptide (5 K). Peak II contained two major immunoreactive components after gel filtra-tion: one co-eluting with a SS28(1-12)-like material (8 K). Purification to homogeneity of the 5 K and 8 K peptides was achieved with 3 reverse phase HPLC systems using C18 columns. The mobile phases consisted of pyridine formate/n-propanol, triethyl ammonium phosphate/acetonitrile and finally trifluoroacetic acid/acetonitrile. 1.5 nmol pure 5 K and 2.1 nmol 8 K peptides were isolated. K peptides were isolated.

Microsequencing revealed that the N-terminal sequence of the 5 K peptide is LSEPNQITENDALEPEDL. These data, the amino acid composition and the specificity of the antiserum (S320) used during isolation together with information on partial cDNA sequence encoding rap prosomatostatin (Goodman, R.H. et al., J. Biol. Chem. 257:1156, 1982) demonstrate that the 5 K peptide contains 44 amino acids and has the SS28(1-12) sequence at its C-terminus. Similarly, microsequencing showed that the N-terminal sequence of the 8K peptide is APSDPRLRQF. This observation together with amino acid analysis data and antibody specificity indicate that the 8K is a 76 amino acid peptide containing the 5 K at its C-terminus. The 8K most probably represents the whole prosomatostatin sequence without Arg-Lys-SS14.

We propose that (1) rat prosomatostatin represents a 92 amino acid protein of 10,386 mol wt which generates several polypeptides, five of which are now characterized; (2) at least three of these peptides do not contain the SS14 sequence; (3) generation of the 5 K peptide from pro-somatostatin involves cleavage of a Leu-Leu bond. Prosomatostatin could be envisioned as a multivalent molecule highly preserved through evolution and possibly endowed with more than one role in neurotransmission.

219.12 PROCESSING OF DYNORPHINS 1-8, 1-13 and 1-17 BY A PURIFIED METALLOENDOPEPTIDASE. M. Benuck\*, M.J. Berg\* and N. Marks. Center for Neurochemistry, Rockland Research Institute, Ward's

Island, N.Y. 10035

Previous studies have shown that N-terminal inactivation of enkephalin containing peptides is inversely related to chain length. This would suggest that for longer peptides, such as the dynorphins-(1-13) and -(1-17), other mechanisms for inactithe dynorphins-(1-13) and -(1-17), other mechanisms for inacti-vation or conversion are dominant. Among the enzymes of interest is a membrane bound metalloendopeptidase recently purified from rat brain or kidney. The enzyme cleaves Leu-enkephalin (dynorphin-1-5) and Met-enkephalin-Arg-Phe at the Gly-Phe bond, a reaction inhibited by thiorphan (Ki 100 nM) and phosphoramidon (Ki 4 nM). For studies on the dynorphins-(1-8), -(1-13) and -(1-17), peptides were incubated with enzyme and breakdown monitored by an HPLC procedure as described elsewhere (Benuck et al., Biochem. Biophys. Res. Commun. (1982) 107, 1123) or by danceylation and detection of endergroups by oppoma-(Jenuck et al., Floring, Roys, Kes. Commun. (1962) 107, 1123) or by dansylation and detection of end-groups by chroma-tography on polyamide plates or by HPLC. In the case of dynorphin-(1-8), results indicate cleavage at the Gly-Phe bond to release Tyr-Gly-Gly and Phe-Leu-Arg-Arg-Ile; for dynorphin-(1-13) and -(1-17), cleavage occurred at Gly-Phe and Arg-Ile sites. Cleavage at Arg-Ile was more rapid than at the Gly-Phe bond. Studies with the various dynorphin fragments indicate a decreased vulnerability of the Gly-Phe bond with increase in chain length, suggesting that cleavage at the Arg-Ile bond becomes significant with respect to conversion processes.

In studies on metabolism by purified synaptosomal membrane fragments, different patterns of degradation were observed. For Leu-enkephalin (dynorphin 1-5) action of the aminopeptidase and metallocadopeptidase predominated, while with dynorphin-(1-13), rapid C-terminal release of lysine occurred (carboxy-peptidase) followed by sequential removal of C-terminal dipepperturbed to sequencial removal of C-terminal dipep-tides by an ACE-like enzyme. Similarly, for dynorphin-(1-7)C-terminal modification occurred leading to the formation of dynorphin-(1-8) as one of the intermediate products. Supported in part by a grant from the NINCDS (NS-12578) (NM) and the Health Research Council of the State of New York (HRC-13-099) (MB).

- EFFECTS OF PRETECTAL LESIONS ON COMPONENTS OF THE HORIZONTAL OPTO-220.1 KINETIC RESPONSE. V. Matsuo, J. Buettner-Ennever\*, B. Cohen, J. <u>Fradin\* and H. Blumenfeld\*</u>. Dept. of Neurology, Mt. Sinai Sch. of Medicine, New York, N.Y. (SPON: G. Cohen). Electrolytic and chemical lesions were made in the pretectum (PT), superior colliculus (SC) and mesencephalic reticular formation (MRF) of monkeys to determine their effect on the various components of optokinetic nystagmus (OKN) and optokinetic afternystagmus (OKAN). OKN can be divided into two components that re-flect processes which produce a rapid and slow rise in slow phase velocity. The rapid rise is thought to be mediated through the cerebral cortex and the flocculus, but the interconnecting path-ways are unknown. The slow rise reflects activation of a velocity storage mechanism and is associated with production of OKAN. The slow component is thought to be mediated through the pretectum via NRTP to the vestibular nuclei in rabbit, cat and rat (Precht, 1981); PT participation in OKN and OKAN has not been studied in the monkey. Destruction of SC with kainic acid caused ipsilateral spontaneous nystagmus, but did not affect either OKN or OKAN. It seems unlikely that SC participates in production of OKN or OKAN. Findings were similar after discrete electrolytic lesions of the MRF, leading to a similar conclusion. Small electrolytic and vas-cular lesions of the medial pretectum centered near the region of the nucleus of the posterior commissure transiently abolished the rapid rise in OKN, leaving the slow rise in OKN and OKAN intact. This suggests that activity related to production of the rapid rise in OKN slow phase velocity may be processed through this area. A large kainic acid lesion involving PT, SC and MRF caused ipsilateral spontaneous nystagmus, a loss of the slow rise in con-tralateral OKN, and abolished contralateral OKAN. However, the rapid rise in OKN was unaffected and time constants of vestibular nystagmus were unaffected. Findings were similar after a large electrolytic lesion that involved the lateral portions of PT and
  - the MRF. We interpret these data to indicate that the pretectum is an important processing center for OKN and OKAN in the monkey  $% \left( {{{\rm{D}}_{\rm{T}}}} \right)$ is an important processing center for OXA and OXAA in the monkey as in other species. It is inferred that cells are located in lateral PT whose axons project activity toward the vestibular sys-tem for production of the slow rise in OKN slow phase velocity and for OXAN. The loss of the rapid rise in OKN after vascular or electrolytic lesion of PT, but its preservation after a kainic coid locate that dearwards PT cells indicate the rest is inclusion. acid lesion that destroyed PT cells indicates that activity re-lated to the rapid rise in OKN is probably carried through medial PT in a fiber tract. The data also indicate the region of the MRF previously identified as being related to both slow and rapid eve movements is not primarily related to generation of horizontal OKN and OKAN.

A NEW VESTIBULAR AREA IN THE PRIMATE CORTEX. O.-J. Grüsser, M. Pause, U. Schreiter, Dept.Physiol., Freie Univ.Berlin, Germany. 220.3 Pause, U. Schreiter. Dept.Physiol., Freie Univ.Berlin, German Microelectrode recordings were performed in 6 awake Java monkeys (M. fascicularis) sitting in a monkey chair mounted on an el-ectronically controlled turntable and surrounded by a vertical striped cylinder (1.15 deg. period). Recordings were obtained from single units located in an insular and retroinsular area. All neurons responded directionally selective to horizontal and/or vertical head-in-space movement in the dark. Most of the units were al-so directionally selectively activated by trunk movements (neck receptor input) and by visual movement signals when the striped cylinder was rotated either to the left or to the right. The units exhibited predominantly very large, directionally selective, vi-ual receptive fields. Visual-vestibular interaction was studied: "agonistic" and "antagonistic" interaction of the input signals from these two modalities was found. The same was true for the interaction of the responses to horizontal semicircular canal r ceptor stimulation with the responses to neck receptor stimularetion. A considerable percentage of the vestibular

neurons also responded to vaguely defined somatosensory stimuli, such as tactile stimulation of the skin of neck and arms, of joint receptors of the extremities, slapping of the soles of the feet or general body vibration. On completion of the neurophysio-logical experiments, the recording sites were determined histologically. A region described in cytoarchitectonic studies by Pandya and Sanides (Z.Anat.Entwicklungsgesch., 139:127,1973) a candidate for vestibular cortex was found to be the area from which our recordings were obtained (fig. 1). Supported by a grant of the Deutsche Forschungsgemeinschaft(Gr161)

LOSS OF VERTICAL RAPID EYE MOVEMENTS AFTER KAINIC ACID LESIONS 220.2 IN THE ROSTRAL MESENCEPHALON IN THE RHESUS MONKEY, V. Henn\*, H. Schnyder\*, K. Hepp\* and H. Reisine (SPON: H. Krieger). Dept. of Neurology and Brain Research Institute, University,

Zürich, and Physics Dept., ETH, Zürich, Switzerland. The rostral interstitial nucleus of the MLF contains mediumlead burst neurons with vertical on-directions. Numbers of spikes per burst and burst frequency determine vertical components of rapid eye movements. Anatomical evidence indicates that neurons in the rostral nucleus of the MLF are directly connected with the oculomotor complex and eye movement triggering zones in the paramedian pontine reticular formation. To decide what role these meurons play in the causal chain of events to generate eye move-ments, they were destroyed chemically. Their precise location was determined by single neuron recordings. Local injection of Was determined by single neuron recordings. Local injection of kainic acid through a microsyringe destroyed all neurons but left fibers en passage unaffected. With a bilateral lesion of the rostral interstitial nucleus of the MLF all vertical rapid eye movements were lost: the animal made rapid eye movements only in the horizontal plane. During rotation in the vertical plane, the slow compensatory movements induced by the vestibular stimulus were intact.

Clinical data show that rapid eye movements might be lost in an upward or downward direction only. This proves that generation sites or pathways for vertical movements are separate. Work is in progress to place smaller bilateral lesions in the rostral mesencephalon to delineate these areas.

220.4 PREFRONTAL, FRONTAL EYE FIELD, AND AREA 6 PROJECTIONS TO THE

PARAMEDIAN PONTINE RETICULAR FORMATION (PPRF) IN THE MONKEY. <u>G.R. Leichnetz and D.J. Smith\*</u>. Dept. of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond,VA 23298. The paramedian pontine reticular formation (PPRF) has been recognized as having a central role in eye movement, since stimurecognized as having a central role in eye movement, since stimu-lation of the region results in ipsilateral horizontal eye move-ments whereas unilateral lesions of PFFF produce ipsilateral gaze paralysis. In this study we made small transcannular im-plants of solid horseradish peroxidase (HFP) polyacrylamide gel in the paramedian pons in four capuchin monkeys (<u>Cebus apella</u>) to determine the principal source of cortical input to this re-gion. In other monkeys, HFP gel implants were made in frontal and parietal cortex to anterogradely label corticopontine projec-tions. The brains were processed according to the TMB protocol o tions. The brains ware processed according to the TME protocol of Mesulam and the tissue was studied under dark field illumination.

Both paramedian tegmental and basilar pontine HRP gel implants resulted in retrogradely labelled small lamina V pyramidal neuresulted in retrogradely labelled small lamina V pyramidal neu-rons located predominantly in the ipsilateral rostral frontal lobe. Large numbers of labelled cells were observed in area 6, area 8 (frontal eye field, FEF), dorsal prefrontal convexity and dorsal medial prefrontal cortex. A lesser, but still consi-derable number of labelled cells were present in the sulcus principalis cortex, ventral prefrontal convexity, and medially in the cingulate gyrus. In the largest pontine tegmental implant where orbitofrontal cells were also labelled, there was an almost uninterrupted line of lamina V corticopontine neurons surrounding the perimeter of rostral frontal sections. Implants in the paramedian tegmental pons (involving nuc, ret, pontis, oralis, paramedian tegmental pons (involving nuc. ret. pontis oralis, nuc. ret. tegmental pontis and superior central nuc.) resulted in heavier prefrontal labelling, whereas paramedian basilar pontine implants resulted in heavier labelling of area 6, partipontine implants resulted in nearier labelling of area 0, parti-cularly in postarcuate cortex. There were considerable numbers of FEF cells labelled bilaterally even where there was clearly no possibility of spread across the midline of the pons. Anterograde studies following frontal (area 6), prefrontal,

and area 8 (FEF) implants, demonstrated the paramedian orienta-tion of corticopontine terminal fields with a partial decussation of FEF-pontine projections in the rostral PFRF, whereas parietal implants led to labelling of predominantly lateral basilar pons with a small terminal field in NRTP. The anterograde findings confirmed the retrograde results and raised the possibility of convergence of prefrontal and parietal projections in the paramedian pons, but clearly showed the rostral frontal lobe to be the main source of cortical influence on the region. Supported by NSF Grant BNS 8113387.

220.5 COMPARISON OF AFFERENTS TRACED TO THE SUPERIOR COLLICULUS FROM THE FRONTAL EYE FIELDS AND FROM TWO SUB-REGIONS OF AREA 7 OF THE RHESUS MONKEY. J.C. Lynch and A.M. Graybiel. Dept. of Anatomy, U. Miss. Med. Center, Jackson, MS 39216 and Dept. of Psychology and Brain Sci., Mass. Inst. of Tech., Cambridge, MA 02139. The inferior parietal lobule (IPL), frontal eye fields (FEF) and superior colliculus (SC) are major elements of the central mecha-

The inferior parietal lobule (IPL), frontal eye fields (FEF) and superior colliculus (SC) are major elements of the central mechanism controlling eye movements and behavioral attention in visuomotor tasks. The FEF are known to project massively to the intermediate and deep layers of the SC and fiber-degeneration findings suggested that these layers also receive a significant input from the IPL. In recent axon transport studies, however, only sparse projections from the IPL to the SC have been reported. We therefore studied parietal efferents in detail, comparing them with frontal projections to the brain stem. Autoradiographic tracing was used in 9 rhesus monkeys, and horseradish peroxidase (HRP) transport in one. Altogether, 12 hemispheres were injected.

Inductal projections to the brain stem. Autoradiographic tracing was used in 9 rhesus monkeys, and hern suboradiographic tracing transport in one. Altogether, 12 hemispheres were injected. The major finding of these experiments is that the cortex of the inferior bank of the intraparietal sulcus projects heavily to the intermediate and deep layers of the SC, whereas the cortex on the convexity of the IPL sends only sparse projections to the SC. Both sub-regions were included in area 7 by Brodmann and in area PG by von Bonin and Bailey. However, the bank cortex has been proposed as a distinct cytoarchitectural zone (POa) by Seltzer and Pandya, who also reported that input from visual area 19 to the IPL is restricted to this same sub-region. We observed both anterograde transport to the SC and retrograde filling of area 19 cells after placing HRP in area POa. The fibers from POa reach the entire rostrocaudal extent of the SC. Anteriorly, they are concentrated in the intermediate gray layer (IV); in the posterior SC they extend from layer IV into the deep gray (VI). Only rarely do they extend from layer IV into the deep gray (VI). Only rarely do they extend into the stratum opticum (III). FEF fibers terminate similarly, although there is more consistent invasion of layer III. In addition, the FEF distribution is characterized by "holes" where labelling is weak, whereas the POa distribution is more homogeneous. POa and convexity PG (PGc) both project to medial and lateral pulvinar, to n. lateralis posterior, pretectum, and lateral pontine nuclei. POa contributes also to a discrete horizontal band of label in the periaueductal gray matter.

band of label in the periaqueductal gray matter. POa receives the vision-related input sent from prestriate cortex to the IPL, contains a larger proportion of eye-movement related neurons than PGc, and contains all of the active reach and hand-eye coordination cells that have been observed in the IPL. The present demonstration of a selective projection from POA to a major preoculomotor center supports the proposal that POA represents a functionally independent sub-region of the IPL. 220.7 EFFECTS OF SUPERIOR COLLICULUS LESIONS ON SCANNING HEAD MOVEMENTS IN HAMSTERS. <u>J.-C. Lecas<sup>X</sup>, C. Thinus-Blanc<sup>X</sup></u> (SPON : P. Ellen), Laboratoire de Physiologie Nerveuse, C.N.R.S., 91190 Gif-sur-Yvette, France.

The aim of this study was to assess in adult hamsters the effects of bilateral colliculus lesions on scanning head movements during a visual discrimination learning. We used a new detection system involving the presence of two light-emitting diodes, affixed on the animal's head, and a computer analysis of the video signal from a TV camera installed above the training apparatus (Lecas & Dutrieux, in press).

With this equipment, we were able to continuously monitor (resolution 60 milliseconds) the head position and the horizontal head movements of free-moving hamsters subjected to a simultaneous visual discrimination task. Collicular hamsters do not differ from control ones in head

Collicular hamsters do not differ from control ones in head movement patterns but with regard to the occurrence of stops during which these movements are made. Normal animals exhibit slower and more irregular progression, intermingled with scanning movements, whereas collicular hamsters make straighter runs. Although the latter did not show any drastic impairment in the rate of learning, our data strongly suggest that they use difformed rejection exclusion scattering the task.

ferent orienting and learning strategies to master the task. Additional testing provides evidence that collicular hamsters do not ignore changes in the surrounding environment but react to novelty in a different way from normal animals. 220.6 DEFICITS IN EYE MOVEMENTS AFTER INJECTION OF GABA-RELATED DRUGS IN MONKEY SUPERIOR COLLICULUS. <u>R.H. Wurtz and O. Hikosaka</u>. Lab. of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20205.

Our previous studies (Hikosaka and Wurtz, J. <u>Neurophysiol.</u>, <u>49</u>: 1230, 1983) suggested that cells in the monkey's substantia nigra pars reticulata (SNr) exert tonic inhibition on saccaderelated cells in the superior colliculus (SC) and release the inhibition before a saccade to a visual stimulus or to the remembered position of the stimulus. The nigro-collicular inhibitory connection has been suggested to be GABAergic.

We now report that microinjections of muscimol (GABA agonist) and bicuculline (GABA antagonist) in SC produce severe deficits in eye movements in the alert, trained monkey. Through a guide tube directed to the SC we introduced a glass pipette filled with a drug solution which could be pressure injected. The pipette also contained a fine tungsten microelectrode which allowed stimulation and recording of single cell activity. The pipette was positioned in the intermediate layers of the SC where cells discharged before a saccade to a particular part of the visual field (movement field).

the visual field (movement field). Immediately after injection of muscimol (0.2-2.0 ug) saccades to visual or remembered targets in the movement field had increased latency (frequently over 300 msec), and were hypometric. Saccades to areas outside the movement field were relatively unaffected suggesting that the drug effect was restricted within the SC. Spontaneous saccades, particularly to the movement field contralateral to the side of injection, became infrequent; the eye stayed in a small area in the orbit usually symmetrical to the movement field.

usually symmetrical to the movement field. Bicuculline (0.2-1.0 ug) dramatically increased the frequency of saccades to the movement field of cells near the injection site. Its injection was immediately followed by repetitive, uniform saccades which brought the eye from the center of the orbit to the contralateral periphery. The repeated saccades then took the form of square wave jerks: a saccade to the movement field was followed by a saccade in the opposite direction. The eye tended to stay in a small area in the orbit which corresponded to the movement field. Under these conditions the monkey could not suppress contralateral saccades and therefore could not perform the task which required fixation of gaze. The effects of muscimol and bicuculline lasted no more than a day. Injection of saline in the SC produced no apparent change in eye movements.

The present results confirmed the important role of the SC in saccade generation and further emphasized the role of SNrinduced, GABA-mediated, inhibition in saccade initiation.

220.8 TECTAL ABLATION ARRESTS EYE MOVEMENTS ELECTRICALLY EVOKED FROM OCCIPITAL AND PARTETAL EYE FIELDS. E.G. Keating, S.G. Gooley\*, S.E. Pratt\* and J.E. Kelsey\*. Department of Anatomy, S.U.N.Y. Upstate Medical Center, Syracuse, New York 13210 Electrical stimulation of several cortical areas in monkeys

Electrical stimulation of several cortical areas in monkeys evokes saccadic eye movements. We have set about tracing the routes by which signals from these areas gain access to the midbrain and pontine premotor structures generating eye movements.

Eye movements of cynomolgous monkeys were measured with the magnetic search coil. Monopolar surface stimulation of the cortex (1 sec trains of 0.5 msec monophasic pulses at 200 Hz) confirmed the presence of a frontal eye field (PEF) along the anterior bank of the arcuate sulcus. There was also a group of posterior fields mapped across striate, prestriate and inferior parietal cortex where stimulation currents between 0.5 - 3 mamps reliably evoked a stereotyped staircase of saccadic eye movements.

These eye fields were remapped 2-6 weeks after surgery intended to remove the superior colliculus (SC) on one or both sides. Removing the SC silenced eye movements normally evoked from striate cortex (Schiller, 1977). In addition, eye movements could no longer be evoked from prestriate cortex (only V<sub>4</sub> was examined) or from area 7a of the inferior parietal cortex. Currents 2-3x threshold failed to trigger eye movements from these areas. However, saccadic eye movements could still be evoked from the frontal eye fields. If the tectal surgery was unilateral, eye movements could also still be evoked from posterior fields contralateral to the lesion. All of the tectal lesions invaded pretectum and medial thalamus to some extent, but ablations in one control monkey that mimicked the diencephalic pathology did not silence evoked eye movements. So, for their control of eye movements, posterior cortical visual areas seem to share a common dependence on a circuit that passes through the superior colliculus.

In tracing the network prior to the tectum we have preliminary evidence that neither FEP nor area 7a serves as a critical funnel of visuomotor control from occipital lobe to the superior colliculus.

These results continue the notion of there being 2 pathways of oculomotor control descending from the forebrain. One passes through FEF and does not require SC for its access to the oculomotor core. The second pathway arises in the posterior cortical eye fields, does not require FEF but does depend on superior colliculus for its access to brainstem premotor structures. EY02941 and EY04005.

NEURONS IN ATTENTION-RELATED REGIONS OF THE CEREBRAL CORTEX WHICH PROJECT TO INTERMEDIATE AND DEEP LAYERS OF SUPERIOR COLLICULUS OF 220.9 THE RHESUS MONKEY. L.J. Lobeck\*, J.C. Lynch, and N.L. Hayes. Dept. of Anatomy, U. Miss. Med. Center, Jackson, MS 39216. Both anatomical and physiological evidence suggest that the superior colliculus (SC) plays an important role in the control of eye and head movement and the modulation of selective attention. The superficial layers derive their primary input from the retina and visual cortex, the deeper layers from a multitude of cortical and subcortical regions. In the course of an autoradiographic study of the efferent connections of the inferior parietal lobule (IPL), a cortical area with functional characteristics similar to those of the SC, we observed (Lynch and Graybiel, this meeting) that only the cortex of the posterior bank of the intraparietal sulcus (IPS) (area POa of Seltzer and Pandya) projects to the SC

whereas the cortex on the convexity of the IPL (PGc) does not. order to study these connections of the IPL in more detail, we Tn injected horseradish peroxidase (HRP; 0.02 to 0.3 µl, 30% in distilled water) in the SC of three rhesus monkeys, using physiolog-ical criteria to center the injections in the intermediate and Ical criteria to center the injections in the intermediate and deep layers of SC. After 48 hours animals were sacrificed by per-fusion with mixed aldehydes and the brains cut frozen at 50  $\mu$ m. Alternate sections were reacted with either TMB or PPD:PC as chro-magen; sections reacted with PPD:PC were counterstained with cresyl violet for cytoarchitectonic analysis.

The cortical regions with the highest density of labelled neurons include the inferior bank of the IPS, the superior bank of the superior temporal sulcus (STS), and the anterior bank of the arcuate sulcus of the ipsilateral hemisphere. All of these areas are considered to be involved in the modulation of selective attention. There was no reliable difference in the average densi-ty of labelled cells among these 3 regions. Few labelled neurons were observed on the convexity of either the IPL or the temporal Almost all labelled neurons were layer V pyramidal cells. lobe. Significant numbers of labelled cells were also seen in the inferior bank of STS, in the superior bank of IPS, both banks of the principal sulcus, the superior bank of the lateral fissure, and in dorsal prestriate cortical areas. A few cells were observed in area 17, including giant pyramids in layer 6, indicating that the effective injection sites encroached upon the superficial layers of SC.

The present demonstration of neural connections between POa, FEF, the bank of the STS, and intermediate and deep SC supports The proposal that these regions may function as physically sepa-rate components of a single distributed system concerned with the control of selective attention and related eye and head movements. (Supported by NIH grants EV02640, EV04159, and 5 S07 RR05386)

220.11 CORTICAL REGULATION OF SACCADIC EYE MOVEMENTS IN MAN DEMONSTRATED BY POSITRON EMISSION TOMOGRAPHY, <u>R.M.Burde</u>, <u>P.T.Fox\* and N.E.kaichle</u>. Depts. of Neurology and Ophthalmology and Div. of Radiation Sciences, Washington Univ. School of Med., St. Louis, MO 63110.

St. Louis, MO 63110. Positron emission tomography (PET) is a non-invasive measure of regional cerebral blood flow (rCBF) able to quantify changes in regional cerebral activity due to motor tasks and sensory stimuli. We are employing PET to study the pattern of cortical activation during saccadic eye movements in man. Each subject undergoes a series of 8 H<sub>2</sub><sup>15</sup>0 PET scans during a single session. The initial and final scans of a series are unstimulated with eyes and ears occluded. The remaining 6 conditions are presented in random order and include: continuous

conditions are presented in random order and include: continuous bilateral peripheral target lights with eyes immobile at midline; continuous bilateral peripheral targets with 2Hz alternating saccades to the targets; peripheral targets alternating sides at 2Hz with eyes immobile at midline; deprivations sides at 2.42 with eyes miniorite at middline; peripheral targets alternating sides at 2Hz with saccades to the alternating targets; 2Hz alternating saccades with visual deprivation; bilateral 2Hz finger movements. Percent change in rCBF from unstimulated control is calculated for each pixel in the PET image. Cortical regions activated by the test condition the Det ind the variant intermediate activate at a second to be a se are localized by projecting the region coordinates onto a template of the cerebral hemisphere utilizing a lateral skull

template of the cerebral hemisphere utilizing a lateral skull radiograph to establish the horizontal reference plane. Peripheral visual stimulation without saccades or foveation induces no cortical response. Foveation during 2Hz saccades consistently induces a 16-20% activation of striate cortex. Saccades without visual stimulation produce no detectable activation of striate cortex, nor of any occipital or parietal cortex. Saccades under any condition produce rCBF activation of 10-20% in the posterior third of the middle and superior frontal gyri and of 11-17% in pre-Rolandic cortex within the inter-hemispheric fissure. These areas correspond well to the presumed positions of the frontal eye fields and of supplementary motor cortex. Finger movements, used as an internal anatomic reference, activated both the supplementary motor cortex and the precentral gyrus immediately posterior to the frontal eye fields.

the frontal eye fields. Several conclusions may be drawn. 1)  $H_2^{150}$  PET permits repeated non-invasive quantitative measurements of rCBF during sensory and motor activation in man. 2) Saccadic eye movements consistently produce regional cortical activation in the frontal eye fields and in supplementary motor cortex. 3) No parietal or occipital regions were measurably activated by saccades. Notably Brodman areas 7, 18 and 19 could not be demonstrated to take part in saccadic eye movements.

ATTENTION-RELATED CHARACTERISTICS OF CELLS IN THE FRONTAL CORTEX 220.10 AILBRITON-RESUS MONKEY. E. Bakay Pragay\*, A.F. Mirsky, R.K. Nakamura and R.U. Esposito. Lab. of Psychology and Psycho-pathology, NIMH, Bethesda, MD 20205. We have previously examined task-related units in the brain-

stem and in various forebrain areas. Some of these units, called Type II, showed peristimulus activity in relation to rewarded go and no go trials. Controls ruled out simple sensory or motor explanations for the responses and indicated their relation to the attentional demands of the task. Type II units were often found intermixed with Type I units; these responded to go trials only.

We report here characteristics of units related to a go-no go task in the region of frontal cortex extending from the rostral bank of the arcuate sulcus to the central sulcus and extending medially to the cingulate sulcus. To manipulate preparatory sets, we varied the fixed pre-stimulus waiting period (1,2,2.5, 3 sec). To test the stability of the no go related activity, we recorded during blocks of no go trials as well as during blocks with semi-randomized go-no go trials (standard task).

Type II and Type I units were found in all areas; their proportion and predominant subtypes varied across areas, largely

proportion and predominant subtypes varied across areas, largely following an anterior-posterior gradient. The rostral areas, expecially the anterior cingulate region, contained "symmetrical" Type II units. These showed phasic post-stimulus bursts nearly equal in size in go and no go trials. The majority showed anticipatory activity to the stimuli with marked sensitivity to changes in the intertrial interval. Their anticipatory response could be increased by using long (2.5 or 3 sec) waiting periods or eliminated by using a lise waiting period. Virtually any task-event encoded by Type II units could be made anticipatory by the appropriate task-manipulation.

be made anticipatory by the appropriate task-manipulation. The posterior regions, especially the rostral bank of the central sulcus, contained predominantly Type I units. In intermediate areas (dorsal convexity at the level of the superior precentral sulcus) Type II and Type I cells were equally numerous. Type II units in this area were typically "asymmetrical" showing more intensive and/or longer lasting response in go trials. The no go response, although small, did not detrivant during homeanous no go series

not deteriorate during homogenous no go series. The "asymmetrical" Type II activity may have stimulus-response association functions; the "symmetrical" activity is best explained as attention to or anticipation of behaviorally significant stimuli.

220.12 DISCHARGE PATTERNS OF TECTO-BULBO-SPINAL NEURONS DURING VISUO-MOTOR REACTIONS IN THE ALERT CAT. <u>A Grantyn\* and A. Berthoz\*</u> (SPON: R. Hudgin). Lab. de Physiologie Neurosensorielle, CNRS, Paris, France.

According to morphological criteria neurons of the cat superior colliculus (SC) projecting to the tecto-bulbo-spinal tract (TBSN) represent a homogeneous population (Grantyn & Grantyn 1982). They also display similar active membrane properties. Experiments on anaesthetized cats have shown that all TBSNs generate grouped discharges (extra spikes) when stimulated by constant transmembrane currents of intermediate intensity (Grantyn & Grantyn 1983). present study was undertaken to examine the activity of this class of neurons in alert cat. Intra and extracellular recordings were taken from axons of TBSNs, within the predorsal bundle at caudal pontine levels. TBSN axons were identified by their short latency (0.3-0.5 ms) direct orthodromic response to SC stimulation and an-tidromic response to stimulation of the spinal cord at Caleval tidromic response to stimulation of the spinal cord at C2 level. Behavioral tests consisted in presenting a variety of visual sti-muli to experimentally naive animals while monitoring eye movement and EMG of neck muscles. TBSN activity was also studied during spontaneous eye movements and vestibular nystagmus.

Out of 40 TBSNs, 29 were activated by discrete moving (15-100 deg/s) visual stimuli. Most neurons were directionally selective Twelve of them discharged more vigorously to presentation of real objects than to spots of light and 15 showed an additional en-hancement of discharge if the animal oriented towards the stimulus as judged from eye movements and contractions of neck muscles. A few cells only were identified as true presaccadic neurons. Eleven few cells only were identified as true presaccadic neurons. Eleven TBSNs were silent or generated sporadic spikes unrelated to senso-ry-motor performance. The absence of sustained spontaneous acti-vity was a typical feature of TBSNs in alert cat. Phasic dis-charges usually lasted 50-100 ms and attained mean frequencies of 50-100 imp/s. For a majority of neurons, one could find a beha-vioral situation during which they entered the range of doublet generation. The transition to this mode of repetitive firing occurred at critical mean frequencies of 70-100 imp/s. It is concluded that the mechanism of extra spike generation

It is concluded that the mechanism of extra spike generation which represents a characteristic active membrane property of TBSNs is mobilized during naturally occurring visuo-motor reac-tions. With respect to the behavioral correlates of their activity TBSNs cannot be regarded as a uniform population. Some of them appear to be engaged in motor and/or attentional aspects of orienting while the others transmit visual information independent -ly of whether or not it is used for the triggering or guidance of gaze shifts.

220.13 DYNAMIC PROPERTIES OF DIFFERENT CLASSES OF PURSUIT-RELATED PRE-MOTOR NEURONS IN THE PRIMATE BRAIN STEM R. Eckmiller and E. Bauswein\*. Division of Biocybernetics, University of Düsseldorf, D-4000 Düsseldorf, FRG. In a new search for possible input neurons to the final common pathway for the neural control of foveal pursuit eye movements (Eckmiller, R., Mackeben, M., Brain Res., 184:210,1980; Sparks, D.L., Sides, J.P., Brain Res., 77:320,1974), single unit activity was recorded in the vicinity of the abducens nuclei in alert monkeys (Macaca fascicularis). With their head attached to a primate chair, animals had been trained to pursue a horizontally moving visual target(8 min of arc in diameter) under three conditions: a) Joursuit during sinusoidal target movement(10 deg amplitude at frequencies between 0.4 and 1.1 Hz), b) pursuit during head rotation with the same amplitude and frequencies as in a) (chair rotation about the vertical axis in front of the stationary target), c) fixation of the target which moved with the sinusoidally rotating chair. Only those neurons which exhibited an impulse rate(IR) modulation in correlation with pursuit at least under condition a) and were clearly distinguishable from eye position coded neurons were found: 1.Pursuit Neurons which had recently been described by Eckmiller

Three main classes of pursuit-related neurons were found: 1.Pursuit Neurons which had recently been described by Eckmiller and Mackeben(1980) were found to be modulated in phase with eye velocity ipsilateral to the recording site(ipsi- $\theta_0$ ) only under a). Under b) max.IR dropped considerably and occurred 20 to 40 deg before contra- $\theta_c$ . Under c) max.IR exceeded the value under a) but had the same phase relationship as under b). 2.Pause Neurons were(with a few exceptions) pursuit-related at variance with several earlier reports. For individual neurons max.IR was in phase with either ipsi(or contra)- $\theta_c$  or  $\theta_c$  under a), but it was typically in phase with or even leading contra- $\theta_c$  under b) and c). For some neurons IR modulation was considerably stronger during the two conditions with vestibular stimulation. 3.Tonic Neurons were quite often pursuit-related and will need further sub-classification with respect to their activity changes during saccades or vestibular stimulation. For individual neurons max.IR typically occurred 20 to 40 deg before contra- $\theta_c$  or contra- $\theta_c$  under both conditions and b).

during the two conditions with vestibular stimulation. 3. Tonic Neurons were quite often pursuit-related and will need further sub-classification with respect to their activity changes during saccades or vestibular stimulation. For individual neurons max. IR typically occurred 20 to 40 deg before contra- $\theta_e$  or contra- $\theta_e$  under both conditions a) and b). The results suggest that only pursuit neurons have optimal dynamic properties as input neurons to the common pathway to assure foveal pursuit by generating the total required velocity signal under a), the necessary difference signal to supplement the vestibular velocity signal under b), or a strong compensatory signal under c). The functional role of pursuit-related pause neurons and tonic neurons in the neural control of foveal pursuit remains to be studied.

(Supported by the Deutsche Forschungsgemeinschaft, SFB 200-A1)

CIRCUITRY AND PATTERN GENERATION II

221.1 SELECTIVE RECORDING AND STIMULATION OF IDENTIFIED NEURONS IN FREELY-BEHAVING <u>APLYSIA</u>. David W. Parsons\* and Harold M. Pinsker. Marine Biomed. Inst. and Depts. of Physiol. & Biophys. and Psychiat. & Behav. Sci., Univ. TX Med. Br., Galveston, TX 77550. Three criteria currently used to establish the behavioral importance of an identified nerve cell are: 1) it is "necessary" if the normal behavior is abolished or severely disrupted when it is selectively destroyed or prevented from firing; 2) it is "sufficient" if the normal behavior is elicited when it is selectively stimulated; and 3) it is "appropriate" if the putative pattern of activity actually occurs during normal behavior. The last two criteria require a technique for selective stimulation and chronic monitoring of an identified neuron in an intact animal. We recently developed a simple technique for gluing a fine-wire electrode into the connective tissue above an identified cell body in <u>Aplysia</u>. By recording during implantation, signal-tonoise properties of the waveforms and selectivity of stimulation are maximized and the identity of the cell confirmed by its characteristic firing pattern. A cuff electrode implanted on an appropriate peripheral nerve or central connective provides an additional criterion (1:1 correlation between soma and axonal spikes) for identifying the target neuron during surgery. Rigorous behavioral criteria (including attachment to the substrate, normal withdrawal reflexes, and feeding) are used to establish that postoperative behavior and neuronal activity are normal.

that postoperative behavior and neuronal activity are normal. Representative selective cell-body and simultaneous wholenerve recordings in intact animals are shown for several different identified neurons in <u>Aplysia</u> central ganglia. We illustrate activity recorded during implantation; the signal-to-noise properties of soma and axonal spikes; the selectivity of soma compared to whole-nerve stimulation; subsequent impalement of the same soma in the exposed nervous system; and more prolonged monitoring of normal neuronal activity. It may be possible to record from identified cell bodies whose axons are too small for their spikes to be recorded with whole-nerve electrodes. The assumptions and requirements for using this technique in other preparations will be discussed. It combines the selectivity of intracellular approaches with the noninvasiveness of extracellular approaches and provides a direct link between neuronal activity in intact animals and reduced preparations. Selective soma stimulation and recording provide two additional methods for assessing the behavioral function of an identified neuron in an intact animal, and complement recently developed techniques for selectively destroying individual identified nerve cells. (Supported by NSF grant 80-16421 and NIH grants NS 16087 and NS 11255.) 221.2 CIRCUITRY UNDERLYING BURST GENERATION IN THE LOCUST FLIGHT SYSTEM. R.M. Robertson and K.G. Pearson, Department of Physiology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7. The flight motor pattern of the locust is generated at the interneuronal level. Many of the interneurons responsible for driving flight motoneurons and for generating the rhythm have now been described (Robertson and Pearson, J.Comp.Neurol. 215: 33-50 (1983). Currently we are investigating connections between these interneurons. In a deafferented preparation of <u>Locusta migratoria</u> able to express the flight rhythm the neuropile processes of interneurons were penetrated with Lucifer Yellow-filled micro-

interneurons were penetrated with Lucifer Yellow-filled microelectrodes. Neuronal interconnections were established with simultaneous double penetrations and the neurons were filled with dye for subsequent identification. Results obtained using these techniques enabled us to construct a partial circuit diagram of the locust flight system involving 18 interneurons. Of primary importance in this circuit is a bilateral pair of mesothoracic interneurons (301s). Each 301 has inhibitory

Of primary importance in this circuit is a bilateral pair of mesothoracic interneurons (301s). Each 301 has inhibitory connections (latency 2ms; duration 15ms) with other flight interneurons. More important, however, is that every spike in 301 is followed by a powerful delayed excitation (latency 5ms; duration 47ms) in a number of other flight interneurons. The basis of this postsynaptic potential is unknown at present but the fact that it can be reversed by passage of hyperpolarizing current is consistent with the idea that it is produced by a decreased conductance across the postsynaptic membrane (i.e. a direct decreased-conductance synapse or disinhibition with graded release of transmitter). The importance of the delay in the connection from 301 to other interneurons to fire in the depressor phase. One of the depressor-type interneurons excited in this way feeds back with a direct inhibitory connection to 301 thus establishing an elementary circuit by which burst activity may be generated. Support for this proposal is given by the observation that sustained suprathreshold depolarization of 301 with constant current can induce rhythmical activity resembling flight activity.

current can induce rhythmical activity resembling flight activity. This burst-generating circuit is linked to depressor motoneurons by other interneurons driven by 301. One of the interneurons involved in the activation of 301 has been identified. This interneuron (504) also excites elevator motoneurons. Thus we have found additional circuits which may underlie the generation of the basic elevator-depressor sequence seen in deafferented preparations.

221.3 IS LAMPREY RESPIRATION A ONE-PHASE RHYTHM?

David F. Russell. Univ. Bordeaux 1, 33120 Arcachon, France. The respiratory system of lampreys resembles that of fossil Ine respiratory system of lampreys resembles that of fossil pre-vertebrates, and may use basic mechanisms conserved in higher vertebrates. Water moves tidally in and out of a series of 7 gill sacs along each side of the head during respiration (1). The coordination of the system was studied here by simultaneous electromyographic records from several segments, in lightly anes-thetized young adult Petromyzon marinus. EMG electrodes were placed subcutaneous by batween pairs of gill press mecording from thetized young adult Petromyzon marinus. EMG electrodes were placed subcutaneously between pairs of gill pores, recording from branchial constrictor muscles and possibly others. During quiet branchial constrictor muscles and possibly others. During quiet breathing (Fig. 1), there was good burst synchrony between the two sides, and between rostral and caudal segments. The cycle period was 0.6 sec (at 10 °C); the duty cycle of bursts was 0.15 or less. A less complete synchrony was seen during another type of breathing, in which an intense discharge could occur every 10-30 cycles, with significant but variable delays between the MN discharges of different sides or segments. A pattern of brief MN discharges forming a one-phase rhythm was also seen in surting electrode proceeds from the vacue nerve made

also seen in suction electrode records from the vagus nerve, made intracranially in eviscerated in vitro preparations of the head These continued after 1-2 h exposure to 2-4 mM strychnine (Fig. 2).

The synchronous discharges of all the branchial constrictor MNs for all the segments, and their continuation under strychnine, tend to exclude models of the CNS pattern generator invoking inhibitory synaptic networks. Instead, as for the one-phase rhythm of the crustacean heart (3), I propose that lamprey respiration may be driven by the endogenous bursting cellular properties of certain pacemaker neurons in the medulla. 221.5 SEROTONIN MODULATES FICTIVE SWIMMING IN THE LAMPREY SPINAL CORD. Ronald M. Harris-Warrick and Avis H. Cohen. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853. Upon bath application of excitatory amino acids such as D-glutamate, the isolated spinal cord of the lamprey, Petromyzon marinus, generates the complete motor pattern for swimming (Cohen and Wallen, Exp. Br. Res. 41:11, 1980). To aid in the analysis of the central pattern generator (CPG) for swimming, we sought endogenous compounds that modulate the CPG output. Serotonin (5-HT) is one such agent. Two changes are seen in the D-glutamate-induced swimming motor pattern following bath application of 5-HT: 1) the frequency of ventral root (VR) motor bursts is reduced; 2) the intensity of each ventral root discharge is increased. This follows from an increase in the discharge rate of previously active motoneurons and recruitment of new motoneurons. These effects are dose-dependent; the threshold is 1-3 µM, and with 10<sup>-4</sup>M 5-HT, the burst frequency is slowed 20-fold. Intracellular recordings from myotomal oscillations during fictive swimming (Russell and Wallen, Acta Physiol. Scand. Abst., 1979). Serotonin induces a large increase in epsp frequency during the depolarizing phase of the motoneuronal oscillation, thereby depolarizing the MP further than usual and increasing spiking. During the hyper-polarizing phase of the oscillation, an increase in ipsp frequency strongly hyperpolarizes the cell. There appear to be no direct effects of 5-HT on myotomal motoneurons themselves: be no direct effects of 5-m on myotomal motoneurons themselves in the absence of fictive swimming (without D-glutamate in the bath), 5-HT does not directly affect the resting potential, input resistance or threshold for action potential initiation. However, in some preparations, in the absence of fictive swim-ming 5-HT induces a slow oscillation in the motoneuron resting potential. This oscillation has a period of about 1 minute and is due to periodic high frequency inhibitory synaptic input. In summary, 5-HT affects the CPG for fictive swimming by slowing and enhancing the motor output. While this may be due to an effect of 5-HT directly on the CPG, we cannot exclude a possible effect of 5-HT on other inputs to the CPG, thus only indirectly affecting CPG output. The lamprey could modulate the activity of a single CPG in this way to generate a family of related behaviors used in different environmental circumstances, such as swimming, crawling and burrowing, which have been described in the lamprey (Ayers, 1982). Supported by NIH Grant No. NS-17323 and an MDA Research Grant.

STRYCHNINE INDUCES "FICTIVE GALLOPING" IN THE ISOLATED SPINAL 221.4 CORD OF THE LAMPREY. Avis H. Cohen and Ronald M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The motor program for swimming in the lamprey is characterized by 1) bursts of motor activity in the left and right ventral roots (VRs) of a single segment alternating strictly out-of-phase, and 2) a constant phase delay between the VR bursts of segments along the cord. This pattern can be activated in the isolated spinal cord by bath application of excitatory amino acids such as D-glutamate (Cohen and Wallén, Exp. Br. Res., <u>41</u>:11-18, 1980). Pretreatment of the cord with low concentrations of the glycine antagonist, strychnine (5-10 µM) results in alteration in the motor pattern evoked by D-glutamate. The altered pattern, called fictive galloping, is characterized by in-phase bursting between left and right sides of a single segment. Such synchronized bursting is always more rapid than controls  $(X=0.99\pm.36$  Hz to  $\overline{X}$ =3.8+1.3 Hz) and can be highly stable, lasting 5 to 45 minutes Pretreatment with lower concentrations of strychnine (0.5-3  $\mu M)$ increase the burst frequency but retains alternation of VR Increase the burst frequency but retains alternation of VK activity between right and left sides, as was found by Grillner and Wallén (Acta Physiol. Scand. <u>110</u>:103-105, 1980). These effects are in contrast to seizures that can be induced by higher concentrations of strychnine (>10 µM). Seizures are generally long intense VR discharges followed by periods of

complete silence of the motoneurons lasting several seconds. Strychnine can produce a variety of changes in the intersegmental constant phase coupling. In all cords, the phase lag after strychnine is more variable than in controls. The mean phase value can be longer, shorter, or unchanged, compared to controls. In some cords, the phase value can decrease to zero, with the bursts along the cord fully synchronized.

The most likely interpretation of these results is that the central pattern generator for locomotion generates the synchronized bursting which follows strychnine pretreatment On the basis of mathematical modeling studies (with R. Rand and P. Holmes) we suggest that the normal pattern is generated by a pair of independent right and left neuronal oscillators in each segment (or small group of segments). In this view, the oscillators within a segment are reciprocally coupled via strong inhibitory and weak excitatory connections. Strychnine presumably acts by blocking the glycinergic inhibitory coupling. This exposes the weak excitatory coupling, which is apparently adequate to synchronize the pair of segmental oscillators. Strychnine-sensitive intersegmental coupling is demonstrated by the results, but at present its role remains unclear. Supported by NIH Grant No. NS16803 and an MDA Research Grant.

221.6 SEROTONIN IS PRESENT IN NEURONS AND FIBER TRACTS OF THE LAMPREY SPINAL CORD. Joan A. Filler\*, Kathryn Simmons\* and Ronald Harris-Warrick. (SPON: M. Salpeter) Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853. In an accompanying abstract (Harris-Warrick and Cohen), we show that servicing (SHT) modulates fictive swimming generated by the lamprey spinal cord. Here we show that 5HT is present in neurons and fiber tracts in the spinal cord of the lamprey, Petromyzon marinus. Formaldehyde induced fluorescence has labeled indolealkylamine-containing ventromedial cell bodies abeled indolealkylamine-containing ventromedial cerl bodies and endings along the ventral surface of the lamprey spinal cord (Baumgarten, <u>Progr. Histochem. Cytochem.</u>, 4:1-90, 1972; Ochi <u>et al.</u>, <u>Arch Histol. Jap.</u>, 42:327-336, 1979). We report that additional putative SHT-ergic projections are revealed in the cord with indirect immunofluorescent labeling techniques. Furthermore, we have biochemically demonstrated the presence of 5HT in the cord. To determine 5HT content, spinal cords were extracted in acid. The extract was fractionated by HPLC on a reverse-phase C-18 column, and analyzed by electrochemical oxidation of the eluate. Serotonin is detected in spinal cord extracts as a substance which coelutes with authentic 5HT in several running buffers, and which has an oxidation voltage dependence identical to that of authentic SHT. The lamprey spinal cord contains  $26 \pm 7$  pmol SHT/mg wet weight (n=9). For anatomical localization of SHT-like immunoreactivity (SHT-LIR), and tomical localization of only the immunoratory (on cryostat sections using the methods of Beltz and Kravitz (<u>J. Neurosci</u>. <u>3</u>:585-602, 1983). 5HT-LIR was localized in ventromedial cell bodies with processes running laterally and ventrally. At the ventral surface of the cord, just lateral to the midline, are regions of intense punctate labeling. Labeled processes dotted with large unique from the possible roleare of the for for 5MT are with large varicosities, possible release sites for 5HT, are seen running longitudinally in the lateral and medial fiber tracts and occasionally traversing the medial gray region. of the labeled fibers in the medial fiber tracts may originate from the ventromedial cell bodies; however, most labeled fibers do not appear to arise locally. While we do not know the origin of these fibers, they may constitute a previously unidentified descending 5HT-ergic input to the lamprey spinal cord. 5HT-LIR was specific and was eliminated by preadsorption of the first antibody with 5HT or 5HT-BSA, but not by BSA or other amines. These results show that 5HT is present and appropriately localized in the lamprey spinal cord to have a normal role in the modulation of the central pattern generator for swimming. Supported by an MDA Research Grant.

EXCITABILITY OF THE CRAYFISH LATERAL GIANT ESCAPE CIRCUIT IS DE-221.7 EXCITABILITY OF THE CRAYFISH LATERAL GIANT ESCAPE CIRCUIT IS DE-PRESSED DURING FEEDING. F. B. Krasme. Dept. of Psychology and Brain Res. Inst., University of Calif., Los Angeles, 90024. The probability of a given behavior occurring in response to a suitable stimulus is often modulated by factors such as motiva-tional state or ongoing activities of an animal. In invertebrate nervous systems there is a real possibility of discovering the sites at which, and the cellular mechanisms whereby such control is effected. The lateral giant (LG) tailflip escape reaction of the crayfish provides particularly desirable material for this sort of investigation because the mediating circuitry is well analyzed and is organized in such a way that one can plausibly. analyzed and is organized in such a way that one can plausibly identify certain neurons (mechano-sensory neurons and first-order analyzed and is organized in such a way that one can practicly identify certain neurons (mechano-sensory neurons and first-order interneurons) as being part of stimulus processing circuitry, others (the LGs themselves) as being decision and command ele-ments, and still others (fast flexor motor neurons and interneu-rons that are interposed between the LGs and the motor neurons) as motor pattern generating elements. Thus, discovery that the oper-ations of particular neurons in this circuit are subject to modu-lation could readily be equated with control of particular proces-sing tasks. However, the priority of LG escape, which is an emer-gency evasion tactic, might be so high that its likelhood of occurrence would be unaffected by motivation or other behavior. The experiments to be reported show, to the contrary, that excita-bility of LG escape is consistently depressed when a crayfish is feeding. This opens the possibility for experiments on locus and mechanisms of control. Stimuli for LG escape were single brief shocks to roots 2-4 of the last abdominal ganglion via chronically implanted electrodes in freely behaving animals. Tailflip behasnocks to roots 2-4 of the last abdominal gangiton via chronically implanted electrodes in freely behaving animals. Tailfip beha-vior was monitored visually, and firing of the LGs and first-order sensory interneurons were recorded with chronically implanted electrodes on the abdominal nerve cord. During feeding the stimu-lus threshold for LG-mediated escape responses and for firing of the LGs themselves almost invariably rose, though not always to a great extent. Thus, there is a site of modulation at or antece-dent to the LGs. Experiments to determine more precisely the site(s) of control, which are in progress, will be reported at the meeting.

ELECTRICALLY COUPLED PACEMAKER NEURONS RESPOND DIFFERENTLY TO 221.8 THE SAME PHYSIOLOGICAL INPUTS AND NEUROTRANSMITTERS. J.S. Eisen and E. Marder. Biology, Brandeis Univ., Waltham, MA 02254. The 2 pyloric dilator (PD) motor neurons and the single anterior burster (AB) interneuron form the pacemaker for the pyloric central pattern generator of the stomatogastric ganglion of the lobster, <u>Panulirus interruptus</u>. The PD and AB neurons are electrically coupled and always depolarize and release transmitter synchronously. We now show that in spite of their electrical coupling and synchronous activity, the AB and PD neurons differ dramatically in their physiological responses to known neuronal inputs and to a number of exogenous substances which are candidates for neurotransmitters in pathways likely to be important in regulation of the pyloric output. . The PD and AB neurons were studied in isolation from one another using the Lucifer yellow photoinactivation technique (Miller and Selverston, Science 206: 702-704, 1979). Bath application of  $10^{-4}M$  dopamine activated slow wave depolarizations (bursts) in 10 - A dopamine activated slow wave depolarizations (bursts) in the isolated AB neuron (following inactivation of the PD neurons), but hyperpolarized and inhibited the isolated PD neurons (after inactivation of the AB neuron). Bath application of  $10^{-4}M$  services in the isolated AB neuron, but was without detectable effect on the isolated PD neurons. Bath application of the muscarinic, cholinergic agonist, pilocarpine  $(10^{-4}M)$  activated bursts which had very different waveforms and frequencies in isolated AB and isolated PD neurons. Stimulation of the IVN input fibers produced an enhancement of the bursting properties of the isolated PD neurons but not of the isolated AB neuron. Previous work has demonstrated that the pyloric pacemaker is composed of neurons which differ in a number of ways and evoke distinct physiological actions on follower neurons (Eisen and Marder, J. Neurophysiol. 48: 1392-1415, 1982). The data presented here suggest that neurons of the pacemaker can be activated and modulated in a number of different ways, by a variety of neuronal inputs. Supported by NIH NS 17813 to E.M.

SEROTONIN AND LEECH SWIMMING: THE RETZIUS CELLS ARE NOT 221.9 REQUIRED. W.B. Kristan, Jr. & J. C. Glover\*. Dept. of Biology, B-022, UCSD, La Jolla, CA 92093.

The production of normal swimming movements in the leech has been shown to be critically dependent on serotonin in that destruction of all serotonin-containing neurons (5HT neurons) in the nerve cord renders the animal incapable of normal swimming (Glover & Kramer, Science 216:317-319, 1982). In investigating the essential role of servicini in this behavior, it is important to know whether all or only some of these neurons are required. There are 5 types of segmentally iterated SHT neurons in the nerve cord which can be distinguished from each other on the basis of position morphology. The selective ablation of the full basis of position morphology. The selective ablation of the complement of one of these cell types would determine whether that cell type is exclusively responsible for the serotonin needed in the expression of swimming behavior. Such an ablation has been achieved for the Retzius cells, the largest and best characterized 5HT neurons in the leech. Because the Retzius cells are the first of the 5HT neurons to develop a high-affinity serotonin uptake system (see Glover & Stuart, this volume), and 5,7-dihydroxytryptamine, the toxin used to ablate these neurons, exerts its effects via this uptake system, toxin-treatment of embryos at an early stage results in the selective ablation of the Retzius cells while most of the other 5HT neurons are spared. Subsequent behavioral examination of these embryos reveals that swimming is normal. Thus, the Retzius cells are not a requisite source of serotonin for swimming behavior, even though they are capable of releasing enough serotonin to initiate swimming in isolated nerve cords (Willard, J. Neuroscience 1:936-944, 1981). Later toxin-treatment of embryos results in the inability to produce normal swimming movements, and histological examination of these embryos reveals that in addition to the Retzius cells, at least 80% of the lateral 5HT neurons (cells 61 & 21) are ablated. There are two possible explanations for these results. One is that none of the 5HT neuron types is a requisite source of serotonin, and that ablating enough 5HT neurons of all types drops serotonin below some critical level necessary for normal swimming. The second is that one or both of the lateral 5HT neurons, which are known to have inputs to the swimming central pattern generator (Nusbaum, this volume), are required for swimming. Selective ablation of these neurons is being attempted to distinguish between these possibilities. Supported by NIH training grant CM 07048, NSF BNS79-23459 and NIH NS14410.

221.10 EFFECTS OF A SEROTONIN-CONTAINING NEURON (CELL 61) ON THE LEECH SWIM CENTRAL PATTERN GENERATOR. M.P. Nusbaum Dept. of Biology, UCSD, La Jolla, CA 92093.

Stimulation of the serotonin-containing neuron designated as cell 61 causes the initiation and maintenance of the leech swim motor program in the completely isolated nervous system (Nusbaum & Kristan, Soc. Neurosci. Abstr. 8: 161, 1982). Sometimes stimu-lation of cell 61 causes only a localized generation of the swim motor program, initiating the swim pattern in only several adjacent ganglia of a longer chain of segmental ganglia. In contrast, in the same preparations stimulating the swim-initiating interneuron cell 204 (Weeks & Kristan, J. exp. Biol. <u>77</u>: 71-88,1978) always initiates swimming in the entire chain of ganglia. These findings suggest that cell 61 can turn on the swim central pattern generator (CPG) independent of activity in cell 204. This difference in the swim-initiating abilities of these two cells may be due to the more limited extent of the axons of 61 as compared to cell 204. Each cell 61 has processes that extend over only three ganglia whereas the processes of a single cell 204 extend over at least fourteen, and perhaps all twenty-one, segmental ganglia. It may be that what determines whether cell 61 initiates a localized or cord-wide expression of the swim motor program is the strength with which it excites the local CPG interneurons to which it has access. Only if they are stimulated strongly would they provide enough excitation to cell 204 to activate the swim motor program along the entire nerve cord. Additionally, cells 61 and 204 have additive effects on the swim CPG so that in isolated nerve cords where stimulation of neither cell initiates swimming, simultaneous stimulation of both cells

does initiate swimming. That cell 61 does have direct access to the swim CPG is indicated by pairwise intracellular recordings showing that cell for causes a strong, apparently monosynaptic excitation of a swim pattern generating interneuron, cell 208. Preliminary results suggest that this EPSP is caused by the closing of voltage-sensitive channels selective to an ion with an equilibrium potential that is more humanalariad that the surface structure potential that is more hyperpolarized than the resting potential. Cell 61 activity does not excite cell 208 when this cell is hyperpolarized, either by inhibitory synaptic potentials or by current injection. In contrast to this, monosynaptic excitation of cell 208 from cell 204 is mediated by an increase in conductance in cell 208. It appears that the entire excitatory synaptic input to cell 208 during swimming comes from the serotonin-containing cells and cells 204. The relative contribution to swim initiation of the respective decrease and increase in conductance underlying the synaptic excitation of this CPG interneuron by cells 61 and 204 is being investigated. Supported by PHS Grant GM07313 & NIH Research Grant NS14410.

Leydig Cell Activity Modulates Heartbeat Pattern Generator 221.11 Cycling in the Leech. Edmund A. Arbas & <u>Ronald L. Calabrese</u> Biological Laboratories, Harvard Univ., Cambridge, MA 02]38. Bursts of action potentials in heart excitor (HE) motor neurons comprise the fundamental motor output of the central pattern generator that drives heartbeating in the leech. HE cells themselves tend to fire tonically, but their activity is shaped into rhythmic bursts through coordinated inhibition by a network of heart interneurons, the HN cells. All 7 pairs of HN cells contribute to the rhythm and coordination of the broader network, but the most rostral 4 pairs alone control

broader network, but the most rostral 4 pairs alone control the timing of network cycling through their ability to reset and entrain activity of all cells in the heartbeat system. The pattern generator cycles continuously, and in the absence of apparent perturbations, HN and HE bursts can be very regular, varying from the mean cycle period by 5% or less over long time intervals.

In prevous studies on rate control in this system, we have identified behavioral conditions and neural pathways by which pattern generator cycling is accellerated, i.e. HN and HE cell burst periods are reduced.

We report here that spiking activity in the electrically coupled network of Leydig neurons leads to an <u>increase</u> in HE cell burst period, that is, a transient decelleration of motor

When any of the bilaterally paired Leydig cells of ganglia or 4 is made to fire by intracellularly injected current, HN cells of the stimulated ganglion are made to fire spikes in concert and their normal side to side reciprocity is disrupted. They alternate in firing clusters of action potentials rather than bursts. This concomittant firing prolongs the duration of inhibition to HE cells, lengthens their burst period, and resets the rhythm of the network.

Levdig cells in the anterior 4 ganglia apparently exert their influence by acting on HN cells of the timing oscillator while Leydig cells of other ganglia influence the timing of the network to the degree that their activity conducts to the anterior Leydig cells via their electrical connections.

Levdig cell in fluence on NN cells has the following properties. 1) Onset of bilateral HN excitation is delayed by as much as tens of seconds from onset of Levdig firing, and for short bursts, outlasts Levdig firing. 2) No discrete psp's related to Levdig firing are evident in HN recordings.

Leydig cells are suspected to exert their actions in a neuro-secretory manner. Experiments are underway to test this possibility. Supported by N.I.H. 5 F32 NS 06453 (EA) and N.S.F. BNS-8121551 (RLC)

221.12 INTERGANGLIONIC COORDINATION OF THE LEECH SWIMMING RHYTHM. R.A <u>Pearce\* and W.O. Friesen</u>. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901. R.A.

The central pattern generator (CPG) underlying swimming in the leech <u>Hirudo medicinalis</u> produces its characteristic output even when the leech nerve cord is removed from the animal. The output pattern of the isolated nerve cord exhibits many of the features characteristic of swimming in the intact leech, including a rearward-directed metachronal progression of motor nerve activity as recorded from peripheral nerves. The motor neurons are driven by a small number of oscillatory interneurons whose interactions generate the rhythm and provide for whose intersections generate the flythm and provide for intersegmental phase lags. It is known that some of the oscillatory interneurons project at least five segments and possibly ten (Friesen et al., <u>J. exp. Biol.</u>, <u>75</u>:25, 1978; Weeks, <u>J. comp. Physiol.</u>, <u>148</u>:265, 1982). The present study was undertaken to determine the span over which interneurons coordinate swimming pattern generation in the isolated nerve cord.

Motor neuron spikes were recorded simultaneously from up to Motor neuron spikes were recorded simultaneously from up to seven dorsal posterior nerves. Nerve cords included segmental ganglion two through ganglion twenty. One to several ganglia in the middle of the cord were bathed in modified leech saline containing 20 mM Mg and 1 mM Ca, a solution which blocks chemically-mediated synaptic transmission in the leech (Baylor and Nicholls, J. Physiol., 203:591, 1969). In this way, the CPGs in those ganglia which were "blocked" could not contribute to the coellection in other ganglia although action potatiole and Nicholis, J. <u>Physiol</u>, 203:591, 1969). In this way, the CPGs in those ganglia which were "blocked" could not contribute to the oscillations in other ganglia, although action potentials in through-fibers were not blocked. It was found that the cord still exhibited normal coordination when up to four mid-body ganglia were blocked, with the following exception. The motor output of one or two ganglia immediately anterior to the block was delayed and of those immediately posterior was advanced. In one case this led to a reversal of the phase relationships across the block, even though normal phasing was maintained between the two ends of the cord. When five ganglia were blocked, the cord usually exhibited normal phase relationships, although occasionally the ends became uncoordinated. When more than five ganglia were blocked, swimming could not be elicited. We conclude from these results that information sufficient to coordinate the CPGs in different ganglia travels at least six segments, and possibly many more. It is curious that the ganglia adjacent to the synaptic blockade could express altered phase relationships, while normal phasing was maintained between the two ends. It is possible that the change in phase occurs at the motor level only and not at the level of the CPG. Supported by grants from NSF and NIH.

THE ROLE OF SWIM-INITIATING INTERNEURONS IN LEECH SWIMMING FLICITED BY MECHANOSENSORY SILMULATION. E.A. Debski and W.O. Friesen. Dept. of Biology, University of Virginia, Charlottesville, VA 22901. Intracellular stimulation of an individual N cell in an isolated leech nerve cord reliably initiates the patterned neural activity characteristic of swimming (Debski and Friesen, Neurosci. Abstr. 8:529, 1982). However, the effectiveness of N cell stimulation fatigues rapidly. We are currently investigating swim-related interneurons to define the pathway leading from the N cell to the swim oscillator and to identify the labile elements in that pathway.

leading from the V cell to the swim oscillator and to identify the labile elements in that pathway. Cells 204 and 205 are the only well-described interneurons whose depolarization reliably elicits swimming activity (Weeks, J. exp. Biol. 77:71, 1978 and J. Neurosci. 2:972, 1982). Both cell 204 and cell 205 monosynaptically excite cell 208, a candidate component of the central pattern generator for swimming (Weeks, J. Comp. Physiol. <u>148</u>:265, 1982). Kristan has proposed that sensory cells activate cell 204 in several ganglia as well as cell 205. Furthermore, it is the summed activity of these swim initiating interneurons, acting through cells 208, which produces swimming (TINS 6:84, 1983). In order to determine if swim initiation by N cell stimulation occurs via this pathway, we have investigated the input to cells 208 and 204 when stimulation of an N cell leads to swimming and then subsequently, when this response has fatigued. This has been done with the goal of first ascertaining whether the input to these cells differs in the two cases and second, determining if this input is predictive of whether or not the preparation will initiate swimming.

initiate swimming. Intracellular stimulation of an N cell eliciting swimming Intracellular stimulation of an N cell eliciting swimning activity evokes weak inhibition in cell 208 of the same and immediately adjacent ganglia. Neither the amplitude nor the duration of this inhibition appears altered when the ability of the N cell to initiate swimning has fatigued. We found that, as reported by Weeks, any single 204 receives only weak polysynaptic input from intracellular stimulation of individual N cells. Input from N to cell 205 is also polysynaptic but somewhat greater in magnitude. As with cell 208, the level of input into cells 204 in the same and the immediatedly adjacent ganglia does not predict subsequent swim initiation. In contrast to the data so far obtained for cells 204 and 208. ganging does not predict subsequent swim initiation. In contrast to the data so far obtained for cells 204 and 208, preliminary results for cell 205 show that this cell does undergo a large change in input that is correlated with the ability of the N cell to initiate swimming. This suggests that cell 205 may be more directly involved than cell 204 in this swim initiation pathway. Supported by NSF grant BNS 81-0243.

SELECTIVE CELL KILLING BY PHOTOINACTIVATION DISTINGUISHES 221.14 INDIRECT FROM DIRECT CONNECTIONS BETWEEN MOTOR NEURONS IN THE LEECH. <u>B. Granzow and W.B. Kristan, Jr</u>. Dept. of Biology, UCSD, La Jolla, CA 92093.

In the leech <u>Hirudo medicinalis</u> longitudinal muscles of the body wall are innervated by both excitatory and inhibitory motor neurons. During swimming, contractions in dorsal longitudinal muscles alternate with contractions in ventral longitudinal muscles. This occurs because the central pattern generator for swimming drives alternating bursts of action potentials in dorsal and ventral longitudinal muscle excitatory motor neurons. In addition, alternating bursts occur in the dorsal and ventral inhibitory motor neurons whose activity contributes to the relaxation of their respective target muscles between contrac relaxation of their respective target muscles between contrast tions. Each inhibitory motor neuron also centrally inhibits the excitatory motor neurons whose target muscles they antagonisti-cally innervate; i.e., dorsal inhibitors inhibit dorsal excitors and ventral inhibitors inhibit ventral excitors. Several lines of evidence indicate that this inhibition is monosynaptic. A or evidence indicate that this inhibition is monosynaptic. A complicating feature of this system, however, is that depolariz-ing current injected into dorsal inhibitors also causes an inhibitory post-synaptic effect in the ventral excitors; like-wise between ventral inhibitors and dorsal excitors. This effect is usually not as strong and is much more variable than that which occurs between dorsal inhibitors and dorsal excitors or ventral inhibitors and ventral excitors. We hypothesized, thereexcitors, and from ventral inhibitors to dorsal excitors were indirect and mediated by an electrical connection known to exist between the dorsal and ventral inhibitors. In order to test this hypothesis we photoinactivated the dorsal inhibitors, by injecting them with Lucifer Yellow and then illuminating them with blue light (Miller & Selverston, Science 206:702-704, 1979). Prior to inactivation of the dorsal inhibitors, depolarizing current injected into ventral inhibitors caused a substantial hyperpolar-ization in dorsal excitors. Following photoinactivation, this effect was no longer present although the ventral inhibitors still strongly inhibited the ventral excitors. We are now using the same photoinactivation method to test the contribution of the inhibitor motor neurons to the phasic inhibition of excitor motor neurons during swimming. Judging by the strength of the con-nections between inhibitors and excitors, dorsal inhibitor elimination should significantly weaken or even eliminate the oscil-lations which underlie phasic bursting in the dorsal excitor motor neurons.

This work was supported in part by NIH grant # 5 F32 NS06339-02 to B. Granzow.

LATEX BEADS COATED WITH FRAGMENTS OF THE FIBRONECTIN 222.1 MOLECULE AS PROBES OF NEURAL CREST MIGRATORY PATHWAYS. M. Bronner-<u>Fraser</u>. Department of Physiology and Biophysics, M. Bronner-Fraser. Department of rhystolog, University of California, Irvine, Ca. 92717.

Latex beads with defined surface coats can be used as probes of interactions involved in neural crest cell localization. In previous studies, latex beads were microinjected into embryos at the time of neural crest migration. The beads distributed along the ventral neural crest pathway in an analogous manner to endogenous crest cells. However, when the beads were coated with fibronectin (FN), the FNwhen the beads were coated with fibronectin (rM), the rM-beads remained at the implantation site and did not distribute along the ventral route (Bronner-Fraser, Devel. Biol., 91: 50, 1982). Fibronectin is a glycoprotein with multiple binding domains. In the present study, latex beads were coated with various fragments of the fibronectin molecule. Because each fragment represents a different functional domain, these studies examine specific binding interactions which are responsible for immobilization of the beads and their subsequent restriction from the ventral neural crest pathway.

neural crest pathway. Three proteolytic fragments which represent various parts of the fibronectin molecule (kindly provided by Dr. Erkki Ruoslahti) were used for these studies. The "120K" fragment contains the cell binding site. The major components of the "66K" fragment include the collagen-binding site and the amino terminal end of the polypeptide. The fragment referred to as the "45 + 32K" fragment represents the heparin-binding domain and the carboxyl terminal. Latex beads were coated with either the 120K, 66K, or 45 + 32K fragment. The coated beads were subsequently injected into the trunk somites of avian embryos at the time of

into the trunk somites of avian embryos at the time of neural crest migration. In the majority of embryos injected with 120K-coated beads, the beads <u>did not</u> translocate along the ventral pathway, but remained at the implantation site. In contrast, beads coated with the 66K or 45 +32K fragments did translocate along the ventral pathway in the majority of cases.

Thus, the 120K fragment, which contains the cell-binding moiety of fibronectin, appears to be the major fragment involved in bead immobilization. The results suggest that the cell-binding domain of the fibronectin molecule may be responsible for the restriction of fibronectin-coated beads from the ventral neural crest pathway. PROPOSED GREEK KEY FOLDING PATHWAY FOR B-STRUCTURE IN MYELIN 222.2

PROPOSED GREEK KEY FOLDING PATHWAY FOR S-STRUCTURE IN MYELIN BASIC PROTEIN (MBP). G. L. Stoner\* (SPON: H. deF. Webster) NINCDS, National Institutes of Health, Bethesda, MD 20205. Phosphorylation of nascent MBP in the cytoplasm of the oligo-dendrocyte may permit the cationic polypeptide to fold easily into a compact structure by reducing the positive charge at critical sites (Stoner, Trans. Am. Soc. Neurochem. 14:164, 1983). Secondary structure prediction by algorithms of Robson, Chou-Fasman, and Lim shows 5 hydrophobic B-strands in MBP (Martenson, J. Neurochem. 36: 1543, 1981). The strands are ideally located for folding as a Greek key B-structure (right) from the type of hairpin intermediate proposed by Ptifsyn and Finkelstein (Quart. Rev. Biophys.

Ptitsyn and Finkelstein (Quart. Rev. Biophys. 13:339, 1980). The hairpin loop contains the Pro-Pro-Pro (100-102) sequence, phosphorylated Thr-99, and methylated Arg-108. P-Thr-99 could form salt links with Lys-106 and with Arg-108 across the loop. The N-methyl of Arg-108 may interact with the side chain of Pro-97. With the 3 Pro residues in the trans conformation, models show that a reverse turn may occur at residues 102-105 (Pro-Ser-Gln-Gly). Each large loop could accomodate an a-helix. The proposed s-sheet (below) contains only 26% of the 170 residues in human MBP, but it has 69% of the hydrophobic residues (underlined). The strands are aligned for maximum interstrand hydrophobic interaction (dashes). Following dephosphoryl-ation, MBP interacts as an extrinsic protein with

ation, MBP interacts as an extrinsic protein with the cytoplasmic surface of the myelin membrane. If the highly polar large loops are extended as shown above, the hydrophobic residues in the B-sheet remain available for interaction with non-polar constituents of the membrane surface. Six cationic residues on the faces of the B-sheet (brackets) may be part of binding sites for phospholipid head groups. The prediction of a  $\beta$ -sheet in MBP is at variance with CD studies of MBP in solution which show little, if any,  $\beta$ -structure.

SCHWANN CELL-AXON INTERACTIONS STUDIED IN VITRO. 222.3 D. Hilt. L. Needham\*, E. Stanley, R. Schnaar, G. McKhann and G. Tennekoon

Departments of Neurology and Pharmacology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205. Schwann cells (SC) are known to interact specifically with axons. The basis of this interaction is poorly understood. We

axons. The basis of this interaction is poorly understood. We report here preliminary studies on the development of an assay for examining this interaction in <u>vitro</u>. Schwann cells from newborn rat sciatic nerves were isolated by a modification of the procedure of Raff et al. (Nature <u>273</u>:672, 1978). Approximately 4 x 10<sup>6</sup> cells were obtained from 10-12 Sprague Dawley rat pups of 1 to 3 days of age. By indirect immunofluorescence using anti-Thy 1.1, 10% of the cells were fibroblasts. One day after seeding, the rapidly dividing fibroblasts. Were killed with cytosine arabinoside ( $10^{-5}$  M). The remaining fibroblasts were removed using a complement mediated killing step with a monoclonal anti-Thy 1.1 (IgM antibody) and rabbit complement. The SC thus obtained were of greater than 99% purity. They were grown on bovine endothelial cell extracellular purity. They were grown on bovine endothelial cell extracellular matrix with Bottenstein-Sato's N2 medium with l ug/ml of cholera as monolayers with a doubling time of 48 hours, but did not elaborate a basal lamina.

Schwann Cell recognition and adhesion to the axon is required for synthesis of basal lamina components and eventual synthesis of We investigated this process by utilizing two different myelin. We investigated this process by utilizing two utilizing the uniterest neuronal cell cultures; rat spinal cord explant cultures and dissociated chick spinal cord anterior horn cell cultures (Schnaar dissociated chick spinal cord anterior horn cell cultures (Schnar et al. J. Neurosci. 1:204, 1981). Schwann cells, when co-cultured with these two types of tissues, appeared to bind to the neurites, elongate to adopt a spindle shape and form into bands. About one week after co-culturing, the SC processes became refractile but there was no convincing evidence of myelination. In order to quantitate the adhesion phenomenon, the Schwann cells were labeled by culture with  $[^{32}P]$ orthophosphate and the method of McClay et al. (Proc. Nat. Acad. Sci. 78:4975, 1981) was used. In summary, we have obtained cultured neurites and pure populations of SC and have demonstrated their interaction in vitro. Furthermore, we have demonstrated their interaction <u>in vitro</u>. Furthermore, we have developed a method for radiolabeling the SC so that we can now begin to quantify this interaction and examine its characteristics. By use of these techniques, the molecular requirements

for this interaction may be probed. (This research was supported by a grant from the KROC Foundation.)

ADHESION BETWEEN NERVE MEMBRANES AND GLIAL CELLS IS INHIBITED BY 2224 MONOCLONAL ANTIBODIES. <u>M. Grumet\* and G.M. Edelman</u>. Department of Developmental and Molecular Biology, Rockefeller University, New York, N.Y. 10021.

Studies on nervous tissues have suggested the hypothesis that the development of the nervous system and its mechanical and biochemical support are greatly dependent on interactions between nerve cells and glial cells. To test this hypothesis further, we studied the interaction between nerve and glial cells in vitro. Heterotypic cell-cell binding experiments indicated that neurons in suspension bound to monolayers of glial cells but not to fibro-blasts or to cells from the meninges during a 25 min incubation period. Fab' fragments of rabbit antibodies against neuronal membranes inhibited adhesion of neurons to monolayers of glial cells, but Fab' fragments from preimmune rabbit sera or sera from rabbits immunized with the neural cell adhesion molecule (N-CAM) did not inhibit adhesion. In order to search for cell surface antigens that may function as adhesion molecules between nerve and glia, an assay was developed that allowed quantitative measurement of adhesion between neuronal membrane vesicles and glial cells. As in the case of heterotypic cell-cell adhesion, neuronal membrane vesicles bound to glial cells but not to fibroblasts, and adhesion was inhibited by Fab' fragments prepared from anti-nerve membrane antisera, but not by Fab' fragments from preimmune sera or anti-(N-CAW) sera. Fractions extracted from neuronal membranes neutralized the inhibitory activity of the anti-nerve membrane Fab' In this manner, the neutralization assay was used to select fractions rich in neutralization activity during purification processes. Antigenic determinants were released from 14d chick embryo brain membranes with trypsin, partially purified by chromatography on DEAE-cellulose, lentil lectin Sepharose, and Sephacryl S300 columns, and used to generate monoclonal antibodies in mice. Mono clonal antibodies that inhibited neuronal membrane vesile binding to glial cells were obtained. Monoclonal antibodies that were coupled to Sepharose beads by the CNBr method, depleted neutrali-zation activity from solution. Indirect immunofluorescence stain-ing of cultures of live brain cells showed that neurons but not glial cells were recognized by the monoclonal antibodies. These results suggest that a nerve cell surface antigen may mediate adhesion between nerve and glial cells in vitro. The monoclonal antibodies described here are being used to isolate the antigen on neural cells and to determine the role of such a molecule in the adhesion between nerve and glial cells. NONERYTHROID SPECTRIN-LIKE PROTEINS: STRUCTURAL CHARACTERIZATION 222.5 OF A SPECTRIN ANALOGUE FROM MOUSE BRAIN. S.R. Goodman\*, I.S. Zagon, C.F. Whitfield\*, L.A. Casoria\*, P.J. McLaughlin and T.L. Laskiewicz\*. (SPON: T.A. Lloyd) Depts. of Physiology\* and Anatomy, The M.S. Hershey Medical Center, Hershey, PA 17033.

Spectrin is a long fibrous  $(\alpha\beta)_2$  tetrameric  $(\alpha = 240 \text{ K Dal}, \beta = 220 \text{ K Dal})$  protein, which along with actin and several other proteins forms the erythrocyte membrane skeletal network. proteins forms the erythrocyte memorane skeletal network. Our laboratory was the first to demonstrate that immunological and structural analogues of spectrin exist is diverse nonerythroid cells (Goodman et al, <u>PNAS</u> 78 7570-7574, 1981), and it is now known that these spectrin analogues exist almost ubiquitously in the cortical cytoplasm of eukaryotic cells, where they probably mediate the association of actin to the plasma membrane. Mouse brain demyelinated membranes contain two large spectrin-like peptides of 240 K and 235 K Dal which are present in a 1:1 mole/mole ratio, constitute 2.3% of the total membrane protein, and cross-react with antibodies against mouse rbc spectrin. Th membrane-associated brain spectrin has been purified by low ionic strength extraction of demyelinated membranes (37°C, lh) followed by rate zonal sedimentation through a 5-18% sucrose gradient (286,000 x g, 15h,  $2^{\circ}$ C), and removal of minor actin contaminants on an anti-actin-Sepharose 4B affinity column. Th purified mouse brain spectrin contains the 240 K (a) and 235 K ( $\beta$ ) subunits in a 1:1 mole/mole ratio and has a M.W. = 972,000 The (b) abduited from its hydrodynamic properties (R = 220 Å,  $S_{20,w}$  = 10.5, partial specific volume = 0.73). The mouse brain spectrum is therefore structurally similar to erythrocyte spectrin as a large asymmetric protein which is an  $(\alpha\beta)_{2}$  tetramer. While brain and erythrocyte spectrin share common functional regions such as a actin, calmodulin, and syndein inding sites, two dimensional peptide mapping analysis of  $^{12}$ I-labelled tryptic peptides indicates only limited overlap between their  $\alpha$  and  $\beta$ subunits. This suggests that erythrocyte and brain spectrin are distinct gene products, and is supported by our finding that distinct gene products, and is supported by our limiting that sph/sph mice with a severe inherited spherocytic anemia due to a 95% deficiency in erythrocyte spectrin have normal levels of membrane-associated brain spectrin. Only the 220 K  $\beta$  subunit of rbc spectrin and the 235 K  $\beta$  subunit of brain spectrin are phosphorylated by [ $^{32}$ P]orthophosphate in the intact animal, and in vitro analysis suggests that both are phosphorylated by cAMP independent protein kinases. Brain and rbc spectrin are therefore distinct gene products, which share structural and functional homology. (Supported by NIH grants HL-26059 and NS-19357 to S.R.G., and DA-01618 to I.S.Z.; S.R.G. is an Established Investigator of the American Heart Association).

NONERYTHROID SPECTRIN-LIKE PROTEINS: IMMUNOCYTOCHEMICAL LOCALI-222.6 ZATION IN MOUSE BRAIN TISSUE. <u>I.S. Zagon, S.R. Goodman\*, P.J.</u> <u>McLaughlin and L.A. Casoria\*</u>. Depts. of Anatomy and Physiology, The M.S. Hershey Medical Center, Hershey, PA 17033 Nonerythroid spectrin-like cytoskeletal components are actin-binding proteins found in the cortical cytoplasm of diverse ukaryotic cells and tissues (review by Goodman and Shiffer, <u>Am.</u> <u>J. Physiol</u>. 244: Cl21-141, 1983). We have raised antibodies in rabbits against mouse red blood cell (rbc) and mouse brain spectrin, and have demonstrated by immunoautoradiography that both antibodies crossreact with the  $\alpha$  and  $\beta$  subunits of rbc and brain spectrin, with preferential staining of the  $\alpha$  subunit. Both antibodies have been used to localize an immunoreactive analogue of spectrin in the adult mouse brain. Indirect immunofluorescence studies of the cerebellum with either rbc or brain spectrin anti-bodies revealed an intense fluorescence of the perikarya of internal granule neurons, with the pattern of staining being most intense at the cell membrane. The observed staining appeared to be localized within the cell rather than on the cell surface since specimens which were not permeabilized did not stain. Granule cell nuclei were unstained. Other neuronal cell types such as Purkinje, basket, and stellate cells also demonstrated fluorescence of the cytoplasm, and unstained cell nuclei. The molecular layer was less intensely stained than the internal granule layer. Except for long strands of fluorescent material that resembled nerve fibers, the medullary layer exhibited no staining. Oligodendrocytes and astrocytes in the crebellar cortex were often difficult to detect, having little cytoplasmic fluorescence. The localization of spectrin analogues in other parts of the brain was further examined by study of the hippocampus. The cytoplasm of the granule cells of the dentate sprus had intense staining, but cell nuclei were unstained. Although the pattern of staining within anti-brain and anti-rbc spectrin IgG were often similar, a more intense staining was observed with brain spectrin antibody as would be expected from immunoautoradiographic studies. The observed staining patterns were specific for brain spectrin, as anti-brain spectrin preabsorbed with a 10-fold excess of brain spectrin, anti-rbc preabsorbed with a 10-fold excess of brain spectrin, anti-rbc spectrin preabsorbed with a 10-fold excess of rbc spectrin, and preimmune IgG exhibited little or no staining in the cerebellum or hippocampus. Our results show that spectrin is an integral part of the cortical cytoplasm of neural cells. Moreover, while brain is a tissue rich in nonerythroid spectrin, the concentration of these immunoreactive analogues is quite variable within distinct cellular entities of the brain. (Supported by grant DA-Ol618 to I.S.Z. and grants HL-26059 and NS-19357 to S.R.G.; S.R.G. is an Established Investigator of the American Heart Association).

A MOLECULE RESEMBLING ACTIN IS INVOLVED IN CLUSTERING OF ACETYL-CHOLINE RECEPTORS IN CULTURED RAT MYOTUBES. <u>R.J. Bloch and W.G.</u> 222.7 Resneck\*, Department of Physiology, University of Maryland School of Medicine, Baltimore, Md. 21201.

Acetylcholine receptor (AChR) clusters can be purified >20-fold from cultured rat myotubes, with little change in their organiza-tion: AChR-rich regions (AChR domains) and AChR-poor regions in close contact with the tissue culture substrate (contact domains) remain clearly distinguishable. Cytoskeletal proteins associated with contact domains in intact cells are lost during cluster purification, however. This raises two questions. What structural proteins remain associated with the isolated AChR clusters? And, are they involved in maintaining cluster organization? Here we report that an actin-like molecule is present in isolated cluster preparations, and that its removal disorganizes AChRs.

preparations, and that its removal disorganizes ACNRs. The major band in SDS-PAGE analyses of isolated ACNR clusters has an apparent molecular weight of 43,000. It is metabolically labeled with  $^{35}$ S-methionine, but not with  $^{3H}$ -sugars, and it is de-graded by proteolytic enzymes. It is therefore a protein, which we call p43. At low ionic strength (a condition which solubilizes actin from skeletal muscle) most of the p43 is extracted from iso-lated ACNR clusters, together with two other, slightly larger proteins. AChRs remain associated with the membrane phase, but lose their characteristic domain organization. This suggests that p43 and other polypeptides extracted at low ionic strength are involved in maintaining isolated AChR clusters.

In immunofluorescence experiments, a monoclonal antibody prepared against actin (kindly provided by Dr. R. Anthony, Univ. of pared against actin (kindly provided by Dr. R. Anthony, Univ. of Md. Sch. of Med.) stains isolated AChR clusters. Staining is only over AChR domains. Upon extraction at low ionic strength, immuno-fluorescent staining is eliminated. Chymotryptic digestion, which also disrupts the AChR organization of isolated AChR clusters, simultaneously destroys the ability of isolated AChR clusters to stain with antibody. After dispersal of AChR clusters in intact cells using azide, AChR levels and staining by anti-actin of isolated clusters expected. clusters preparations are greatly reduced. These results suggest that an actin-like molecule is involved in maintaining clusters in isolated preparations and in intact myotubes. Preliminary evi-dence indicates that the antibody reacts well with p43 and with erythrocyte actin, but only poorly with rabbit skeletal muscle ac-Preliminary evip43 may be a membrane-bound form of actin which is tin. Thus, involved in AChR clustering.

SIALIC ACID REGULATES CALCIUM EXCHANGE IN SYNAPTOSOMES. <u>S. Lin-Liu, W.R. Adey and E.M. Helm</u>\*. VA Medical Center and Loma Linda University, Loma Linda, CA 92357 Sialic acids occupy the outermost position of the carbohydrate chains of cell surface glycoproteins. Their strategic position and charge properties may have led to their ability to regulate calcium exchange across the plasma membrane of cultured heart cells. We are now testing the possibility of a similar role for sialic acid in synaptosomes. Synaptosomes were prepared from Sprague-Dawley rats and calcium exchange was first studied by investigating the uptake of 45Ca<sup>++</sup> at 32°C. Synaptosomes (0.6 mg/ml) were incubated in a physiological medium (0.2 mM CaCl<sub>2</sub>) containing either low K<sup>+</sup> (5 mM) or high K<sup>+</sup> (40 mM) for various time intervals (10s - 10 min). Incubation was terminated by dispersing aliquots of synaptosomes on Millipore filters under vacuum filtration and rinsing immediately with 10 ml of an ice cold physiological medium containing either high Na<sup>+</sup> (135 mM) or low Na<sup>+</sup> (5 mM). In general, the time course curve exhibited throw has washing medium. No delay was observed with the low Na<sup>+</sup> washing medium. High K<sup>+</sup> enhanced both the rate and level of 45Ca<sup>++</sup> uptake of the first phase, but was rather ineffective in changing the rate of uptake of the second phase. Neuraminidase treated synaptosomes, resulting in an apparent increase in 5Ca<sup>++</sup> uptake during the second phase. Since no difference was observed with a low Na<sup>+</sup> washing medium, the total level of calcium exchange was gressent in an angular second phase was decreased (shifted to the left) in the euraminidase treated was probably not altered by neuraminidase treatement. Since high K<sup>+</sup> increases intracellular the total level of calcium exchanged was probably not altered by neuraminidase treatment. Since high K<sup>+</sup> increases intracellular calcium level and Na<sup>+</sup> enhances calcium efflux in synaptosomes, the difference between neuraminidase treated and control synap-tosomes may be explained by the ability of sialic acid to regu-late calcium fluxes across the plasma membrane. A TORPEDO MONOCLONAL ANTIBODY DEFINES A SUBSET OF MAMMALIAN NEURONS. P.D. Kushner and D.T. Stephense ALS Research Center, Pacific Medical Center, San 222.9 Stephenson Francisco, CA 94115. Neuronal cell surface molecules coordinate the

Neuronal Cell surface molecules coordinate the development and insure the maintenance of the nervous system in its organization and in the execution of its remarkable tasks. Some of these molecules may be found on all neurons, playing roles fundamental to neuronal function, such as axonal elongation or adhesion. Other molecules are found on some neurons and not on others. Such molecules, such as ion channel receptors, may play roles specific to those neuronal types on which they occur.

We have generated a library of monoclonal antibodies to the cholinergic synaptosome from the marine ray (Kushner and Reichardt, Neurosci. Abs. VII 40.4). From this collection of 141 synaptosome-specific antibodies we have identified an antibody which crossreacts strongly with the mammalian nervous system, reacts strongly with the mammalian nervous system, but is found associated with only a very limited population of neurons. Histochemical localization of this antibody's binding within the rat nervous system is distinguished by the fact that, although the antigen appears to be rare, where it is found, it is highly concentrated along the membrane of individual neurons. These neurons include both cholinergic ventral horn motor neurons of the spinal cord and noradrenergic principal neurons of the sympathetic ganglion. We report that the mammalian antigen defined by

We report that the mammalian antigen defined by this antibody is a protein and has an apparent molecu-lar weight of 180,000 daltons. Our studies indicate this antigen is evolutionarily conserved from elasmo-branche to mammale. Sodimentation coulibrium studies branchs to mammals. Sedimentation equilibrium studies reveal that the protein is peripherally associated with the membrane. The antibody binds the membrane fraction of freshly homogenized rat tissue centri-fuged at moderate speeds (12,000 g). Both freezing and high speed centrifugation (100,000 g) dissociate the protein from the membrane. This loose association of the protein with the membrane indicates it is not an integral membrane protein. It is therefore not an ion channel receptor. Studies of this protein help address the question of whether there are neuronal subsets defined by cell surface components which cor-respond to transmitter type. Supported by an MDA grant to L.F. Reichardt and grants from MDA and ALSSOA toPDK. branchs to mammals. Sedimentation equilibrium studies

222.10 PURIFICATION AND CHARACTERIZATION OF CALCIUM-ACTIVATED NEUTRAL PROTEASES FROM MOUSE AND POSTMORTEM HUMAN BRAIN. A. Vitto and R. Nixon. Harvard Medical School, McLean Hospital, Bellon, MA. 02176 We have purified Ca<sup>+2</sup>-activated neutral proteases (CANPs) from both mouse brain and postmortem human brain cortex using a rapid 02178. three-step column procedure that affords good recovery of stable protease, and avoids exposure of CANP to calcium or destabilizing protease, and avoids exposure of CANP to calcium of destabilizing ligand-affinity columns. Supernatants of brain homogenates are applied to DEAE-cellulose, and CANP activity against <sup>1</sup>C-azocasein eluted with a linear salt gradient. The main peak of activity eluting at 0.2-0.25 M NaCl is applied to Phenyl-sepharose and eluted with a low ionic strength buffer containing 15% ethylene glycol. Activity is pooled, concentrated, and applied to an Ul-trogel AcA 44 gel filtration column. CANP eluted from Ultrogel is pooled, concentrated, and stored at  $-70^{\circ}$ C in 10% glycerol. Molecular weights of 95-96K were obtained for both mouse and human en-zymes by Sephacryl S-300 analytical gel filtration. SDS gel elec SDS gel electrophresis indicated two subunits with molecular weights of 72-73 and 23-30K. The proteases were active at neutral pH but not at actd or alkaline pHs. No activity was detected in the presence of EGTA. Both enzymes were inhibited by leupeptin, antipain, TLCK, and by thiol-active reagents such as iodoacetamide, mersalyl, N-ethylmaleimide, and mercuribenzoate derivatives. PMSF, peptatin, TPCK, benzamidine, diphenylcarbamyl chloride, and soybean In, TPCK, benzamidine, diphenylcarbamyl chloride, and soybean typsin inhibitor did not inhibit protease activity. Mouse and hu-man brain CANPs were sensitive to 0.5 mM Ca<sup>-2</sup> and optimally active at 1-5 mM. Barium, and strontium stimulated activity but were less effective than Ca<sup>-2</sup>. Magnesium was without effect. Manganese slightly activated only the human enzyme. In addition to the major CANP from mouse brain, a second CANP of slightly lower molec-ular weight eluted from DEAE at 0.05 M NaCl. This lower molecular weight form partially co-eluted with an endogenous heat-stable inhibitor of CANP. The endogenous factor appeared more inhibitory toward this lower molecular weight form than the major CANP. Th The toward this lower molecular weight form than the major CANP. The endogenous inhibitor from mouse brain is also active against the major CANP from human brain attesting further to the similarity between the mouse and human enzymes. Both proteases degraded en-dogenous substrates and were especially active toward high molecu-lar weight proteins including neurofilament proteins. The foregoing results indicate that CANP can be assayed and purified from human brain and that the major CANPs from mouse and human brain How not the similar. These results will facilitate the analysis of  $c_1^{-2}$ -mediated proteolytic events in normal human brain and in a number of human neurological disorders. (Supported by NIH grants NS17535 & RR05484, the Alfred Sloan Foundation, and the Anna and Seymour Gitenstein Foundation).

222.11 PHOSPHORYLATION OF EXTRACELLULAR AND MEMBRANE PROTEINS OF GOLDFISH 222.12 OPTIC TECTA IN VITRO: EFFECTS OF CALCIUM AND ELECTRICAL STIMULA-TION. V. E. Shashoua and G. W. Hesse\*. Dept. of Biological Chem-istry, Harvard Medical School, Mailman Research Center, McLean Hospital, Belmont, MA 02178

Hospital, Belmont, MA 02178 Goldfish optic tecta can be maintained in a defined medium in an atmosphere of  $0_2/CO_2$  (99/1) for at least 72 hr <u>in vitro</u>. Stable extracellular field potential responses, identical to those obtained <u>in vivo</u>, are produced when the tectal optic nerve fibers or marginal fibers are stimulated. We have used this preparation as a model system for investigating the direct effects of elec-trical stimulation and alterations of  $Ca^{2+}$  levels in the incubatrical stimulation and alterations of  $Ca^{2+}$  levels in the incuba-tion medium on the patteru of phosphorylation of proteins in an intact neural tissue. We focused our studies on the influence of depletion of  $Ca^{2+}$  in the extracellular environment, since, under physiological conditions, intact neural tissues normally become exposed to transient reductions in the levels of  $Ca^{2+}$  as a result of neural activity. Moreover, we used ATP  $[5'-(\gamma-thio)^{35}S$  phos-phate] as the phosphorylating agent to restrict the reaction to external surface membrane proteine external surface membrane proteins, since ATP does not usually en-ter cells unless it is first hydrolyzed to release phosphate, and the <sup>35</sup>S phosphorylated proteins, once formed, do not tend to be as readily subjected to enzymatic breakdown as, <sup>32</sup>P-labeled products.

readily subjected to enzymatic breakdown as <sup>32</sup>P-labeled products. Under such conditions, ATP (5'-[γ-thio]<sup>35</sup>S-phosphate labeled), added to the incubation medium, was found to selectively label two tectal protein bands electrophoretically migrating at 45 kD and 45 kD on SDS-polyacrylamide gels. Subcellular fractionation of the labeled tecta, followed by one- and two-dimensional gel elec-trophoresis, indicated that both proteins were largely associated topologies, indicated that both proteins were largely associated with the membrane and crude synaptosomal fractions. In addition, certain proteins released into the extracellular medium migrating at 32 kD and 26 kD were heavily labeled. If the normal extracellular calcium level of 2.5 mM was lowered by the addition of 1.5 mM EGTA, then the incorporation of phosphate into the 54 kD and 55 kD hended proceeded by rest (000 KD the line of the part of 000 KD the li 45 kD bands increased by over 400%. The labeling of these same bands was also enhanced by 30-40% if the tecta were electrically stimulated at 20 Hz for up to 30 min via the marginal fiber input to the tecta

These findings suggest that the tectal extracellular environment may have an important role in the post-translational modifi-cation of specific membrane proteins. Thus long-term depletion of  $Ca^{2+}$  by chelation with ECTA or the transient local removal of  $Ca^{2+}$ that occurs during stimulation can result in an enhanced phosphor-ylation of the same membrane components. (This research was supported by NINCDS grant No. 09407.)

<sup>3</sup>H-INOSITOL INCORPORATION INTO PHOSPHATIDYLINOSITOL IN A SYMPA-THETIC GANGLION TREATED WITH 4-AMINOPYRIDINE. B.A. Patterson\*, and R.L. Volle. Dept. of Pharmacology, Univ. of Connecticut Health Center, Farmington, CT 06032.

Health Center, Farmington, CT 06032. Enhanced phosphatidylinositol (PI) turnover has been associated with activation of certain receptors, however the nature of the interaction and its role are not well defined. Rat superior cervical ganglia are incubated at 37°C in various drug containing and modified Locke's solutions, all of which contain 20 µM myo-inositol (MI). After an initial 30' equilibration in MI containing Locke's solution, ganglia are incubated for an additional 30' with blocking agents, when used, then transferred to test solutions containing <sup>3</sup>H-MI for 30' of uptake. Ganglia are then homogenized and the phospholipids extracted by a modification of the method of Lapetina and Michell (Biochem, J. 126: cation of the method of Lapetina and Michell (Biochem. J. 126: 1141-1147, 1972) and chromatographed against standards on silica gel TLC plates according to the method of Weiss et al. (Biochem.
 J. <u>204</u>:587-592, 1982).
 The <sup>3</sup>H label migrates almost exclusively with the PI spot on

TLC, typically accounting for 97% of the label applied to the plate, the remainder of the label being found at or near the ori-Aliquots of extract counted directly, without resort to

priors, the variable of the theory being bound to head the off gin. Aliquots of extract counted directly, without resort to TLC. Therefore, results are routinely obtained by that method. Ganglia exhibit a dose dependent increase in the incorporation of <sup>3</sup>H-MI into PI in the presence of 4-aminopyridine (4AP), an in-hibitor of K<sup>+</sup> conductance. Treatment of ganglia with  $10^{-3}$  M 4AP results in a 100% increase in the labeling of PI. The response is eliminated by incubation with  $10^{-5}$  M atropine and reduced by 73% in  $10^{-6}$  M atropine. Hexamethonium (5 x 10<sup>-4</sup> M) reduces the response by 40%. Tetrodotoxin, however, is without effect. Ex-periments in which all Ca<sup>2+</sup> in the bathing media is replaced by Mg<sup>2+</sup> are complicated by the fact that Ca<sup>2+</sup> free media alone pro-duces a 50% increase in label incorporation into PI and inclusion of 1 mM EGTA in the Ca<sup>2+</sup> free media results in a 120% increase. However, when  $10^{-3}$  M 4AP is added to the Ca<sup>2+</sup> free media, a fur-ther increase in uptake is clearly evident. Treatment of ganglia with  $10^{-4}$  M bethanechol brings about a 230% increase in uptake of <sup>3</sup>H-MI into PI. Ganglia denervated for 7-10 days exhibit a 30% increase in uptake into PI when compared with their contralateral increase in uptake into PI when compared with their contralateral controls. Nevertheless, denervated ganglia show increased incorporation of  $^{3}\mathrm{H-MI}$  into PI in response to  $10^{-3}$  M 4AP. Atropine (5 served with  $10^{-3}$  M 4AP.

These results suggest that acetylcholine is not involved in the atropine sensitive stimulation of  $^{3}\mathrm{H-M}$  uptake into PI brought about by 4AP. (Supported by NS 07540-16).
