D.C. 2002. High densities of calcitonin binding sites are found in the hypothalamus (Olgiati et al., <u>Brain Res.</u> 265:209, 1983). Injections of calcitonin (43 ng) into the lateral ventricle of the rat inhibit eating (Freed et al., <u>Science</u> 206:850, 1979). The medial hypothalamus, particularly the paraventricular nucleus, is a major site of regulation of feeding behavior, and infusions of norepinephrine into this area stimulate eating (Leibowitz, <u>Pharmacol. Biochem. Behav.</u> <u>8:</u>163, 1978). We therefore hypothesized that the paraventricular nucleus is the site at which calcitonin acts to inhibit eating behavior.

at which calcitonin acts to inhibit eating behavior. Cannulae were implanted into the paraventricular nucleus or surrounding areas and after recovery the animals were trained to eat wet mash on a 24-hour schedule. Synthetic salmon calcitonin (courtesy of Armour Pharmaceutical Company) in a dosage of 15 ng in 0.2 microliter was infused unilaterally and the intake of wet mash was recorded for 30 min starting 30 min after infusion. Injections which were histologically confirmed to be in the paraventricular nucleus inhibited eating markedly, while injections into the lateral hypothalamus were ineffective.

### Percentage Change (Means <u>+</u> S.E.M.) in Eating After Infusion of Calcitonin (Negative Indicates Decrease)

Infusion Site	Percentage Change*		
Paraventricular Nucleus	-82 <u>+</u> 4	(n=6)	
Lateral Hypothalamus	+15 <u>+</u> 21	(n=5)	

\*t=4.60, p<0.01, Behrens-Fisher t test

The animals were also satiated and given norepinephrine (40 nmoles in 0.3 microliter) into the same sites. After norepinephrine injections into paraventricular sites the animals ingested of 13 + 3 grams (mean  $\pm$  S.E.M.) of food, but infusions into the lateral cannula sites resulted in the ingestion of only  $2 \pm 1$  grams. Norepinephrine is therefore effective in stimulating eating only for those cannulae sites where an inhibition of eating by calcitonin can also be obtained.

We therefore suggest that calcitonin inhibits eating by acting directly on the hypothalamus. It is also possible that an interaction between norepinephrine and calcitonin in this area of the hypothalamus is involved in the regulation of eating behavior.

- 57.10 ANALYSIS OF PLASMA AND BRAIN CHOLECYSTOKININ LEVELS IN CANCER ANOREXIA. F.M. van Lammeren\*, W.T. Chance, M.H. Chen\*, W.J. Chen\*, R.F. Murphy\*, S.N. Joffe\* and J.E. Fischer\*. Department of Surgery University of Cincinnati Medical Center, Cincinnati, Ohio 45267
  - Although anorexia is often observed in cancer patients, the etiology of this dysfunction in appetite remains unclear. Recent investigations suggest that several peptides that are common to the gut and brain may be involved in regulating feeding. In particular, cholecystokinin (CCK) has been suggested to function as a satiety signal in several mammalian species. In order to determine whether abnormal concentrations of CCK were contributing to cancer anorexia, we assayed plasma and brain levels of CCK in anorectic tumor-bearing (TB) and control rats. Mehyl-cholanthrene (MCA) sarcomas were induced in 16 adult, male Fischer 344 rats by the sc. injection of 2 x 10° viable cells that were obtained as a cell suspension of the solid tumor. An additional 16 rats were injected (sc.) with normal saline (0.2 cc) and served as freely-feeding (FF) and pair-fed (PF) control groups. Body weight, food intake and water intake were monitored daily. Half of the TB rats (TB-16) were sarified 2 days after the development of significant anorexia (day 16), while the remaining TB animals (TB-28) were killed during severe anorexia (mean food intake less than 3 g/100 g body wi.). The food allowed to the PF group was further reduced to match their body weights to the individual carcass weights of the TB-28 rats. Levels of CCK were determined by radioimonassay (radioiodinated CCK-39) in the plasma as well as in the hypothalamus and cerebral cortex, after homogenization in boiling water. Assay mixtures containing the sample, antiserum solution and CCK-33 standards were incubated in 0.04 M phosphate buffer (pH = 7.4) for 48 hr. After the addition of labelled CCK-39, the mixture was again incubated for 48 hr.

Group	Food Intake	Plasma CCK	Hypothalamic	Cortical
	(g/100g)	(ng/m])	CCK (ng/g)	CCK (ṇg/g)
FF	7.38 ± 0.25	1.24 + 0.19	241 ± 13	526 ± 25
PF	1.59 ± 0.45	1.17 ± 0.19	264 ± 15	516 ± 37
TB-16	5.03 ± 0.40	1.55 ± 0.18	118 ± 11*	428 ± 16*
TB-28	2.91 ± 0.44	1.50 ± 0.16	143 ± 17*	414 ± 26*
Pre	esented values are	means ± S.E.№	1. *p<0.01	

These data demonstrate that plasma levels of CCK are not significantly altered in experimental cancer anorexia. Contrary to our hypothesis, concentrations of CCK in the hypothalamus and cerebral cortex were significantly reduced. If brain CCK is involved in satiety, the reductions in immunoreactive CCK in the hypothalamus and cortex may suggest that the TB rat is attempting to compensate for the anorexia by down-regulating CCK satiety mechanisms. "Supported by Ohio Division of the American Cancer Society.

57.11 INSULIN, TRIIODOTHYRONINE, GROWTH HORMONE AND SOMATOMEDIN CON-CENTRATIONS IN GROWTH RETARDED RATS WITH DORSOMEDIAL HYPOTHALAMIC NUCLEI ELECTROLYTIC OR KAINIC ACID LESIONS OR SHAM OPERATIONS. L.L. Bellinger, L.L. Bernardis, R.H. McCusker\*, and D.R. Campion\*. Dept. Physiol. Baylor College of Dentistry, Dallas, TX 75246; VA Med. Ctr. and Dept. Medicine, SUNY at Buffalo, Buffalo, NY 14214; USDA-ARS, R.B. Russell Agr. Res. Ctr. Athens, GA 30613. Un Functional (SPE) and the provided higher (1997) (SPE).

In Experiment (Exp.) 1 rats received bilateral (n=8) kainic acid lesion (1  $\mu$ g/0.5  $\mu$ l) or sham operations (n=10) at about 155g body weight [Bellinger et al. Am. J. Physiol. 224:R389, 1983], while in Exp. 2 the rats received bilateral electrolytic (n=12) lesions (1 ma, 10 sec) or sham (n=9) operations at about 70g body weight. Both groups of DMNL rats remained hypophagic (P<0.01) compared to their controls. The animals were sacrificed by decapitation within 20 sec of removal from their cages. At sacrifice the DMNL rats: weighed less (Exp. 1, 256.8±6.8g vs 314.8± 5.9g; Exp. 2, 216.3±7.0g vs 277.5±5.6g, both P<0.01) and were shorter, naso-anal length (Exp. 1, 203.4±2.1mm vs 219.4±4.0mm; Exp. 2, 200.8±1.6mm vs 213.2±1.3mm, both P<0.01) than the sham operated rats but the DMNL rats had normal Lee Obesity Indexes (Exp. 1, 314.6±1.9; Exp. 2, 286.5±1.8). Lesions were confirmed histologically and data were analyzed by parametric and nonparametric (i.e., growth hormone) tests. Insulin, growth hormone and triiodothyronine were determined by R.1.A. and somatomedini in Exp. 2 by bioassay (porcine). In Exp. 1, DMNL vs sham: Insulin, 1.04±0.04 vs 0.99±0.03 ng/ml; growth hormone, 178.9±45.7 vs 49.3± 8.8 ng/ml, P<0.04; triiodothyronine, 1.6±0.05 ng/ml, P<0.01; growth hormone, 138.8±75.9 vs 144.3±56.5 ng/ml; triiodothyronine, 0.59±0.1vs 0.60±0.10 ng/ml; and somatomedin, 0.94±0.05 vs 1.06± 0.05 units. Normal rat serum has a somatomedin value of 1.0 units. The data reveal that hypophagic growth retarded DMNL rats (whether lesioned electrolytically or by kainic acid) show no deficits in the growth promoting hormones analyzed. The data support the concept that DMNL produce a 'reset' of body weight, which is not due to an alteration of classical growth promoting hormones.

Supported by BCD and VA research funds, growth hormone was determined using materials supplied to L. Bellinger by NIADDR.

57.12 EFFECTS OF INTRACRANIAL ESTRADIOL ON INGESTIVE BEHAVIORS. P.C. <u>Butera\* & J. A. Czaja</u> (SPON: L. J. Pellegrino). Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907.

The present study examined the effects of central estradiol on food intake, water intake, and body weight in ovariectomized guinea pigs. Thirty-five adult females, selected from a heterogeneous stock (Topeka) of English short-hair guinea pigs, were implanted with double-walled bilateral cannulae (21 ga guide, 27 ga inner cannula) stereotaxically aimed at either the ventromedial hypothalamus, paraventricular nucleus (PVN), or preoptic area, and were stimulated unilaterally with cholesterol and estradiol 17beta. This yielded a total of 70 implant sites.

where stimulated unrateriarly with contention and estimated the beta. This yielded a total of 70 implant sites. Across all subjects, estradiol implants significantly reduced feeding, drinking, and body weight relative to implants of cholesterol. The occurrence of vaginal membrane rupture in some animals following central estradiol stimulation indicated that the hormone was leaking into peripheral circulation. The possibility that the behavioral changes observed were due to the peripheral rather than central effects of the implants was evaluated by comparing the results of females with vaginal membrane rupture to the results of females without vaginal membrane rupture. There were no significant differences between these groups on any of the dependent variables studied, indicating that the peripheral changes were neither necessary nor sufficient to account for the behavioral effects.

behavioral effects. Estradiol implants in the ventromedial-arcuate region (VM-ARC) and PVN significantly lowered food intake and body weight. Placements in the anterior hypothalamic-preoptic area, thalamus, or lateral ventricles had no significant effects on feeding or body weight. Only implants in the VM-ARC significantly reduced drinking, although this effect was much less robust than the changes in feeding and body weight. Additionally, the changes in water intake following central estradiol were uncorrelated with the changes in food intake.

These findings establish that estradiol applied to the brain of ovariectomized guinea pigs can lower ingestive behaviors and body weight. The results support the hypothesis that estrogen can suppress feeding and body weight by acting in areas outside VMR, possibly by interacting with catecholamine systems involved in the control of feeding behavior.

CENTRAL CONNECTIONS OF THE TONGUE IN NEONATAL RATS. W. W. Pugh, J. A. Browde, Jr.\* and W. G. Hall. N.C. Foundation for Mental 57.13 Health Research, Raleigh, NC 27611 and Dept. of Psychology, Duke Univ., Durham,NC 27706. 2-10 ul of 1% horseradish peroxidase (HRP) covalently linked

to wheat germ agglutinin (WGA) or to cholera toxin (CT) was in-jected into various antero-posterior and medial-lateral quadrants to a microsyringe. Survival times ranged from 48 to 96 hours at which time the animal was deeply anesthetized and perfused per procedure II of Rosene and Mesulam (<u>J. Histochem. Cytochem.</u>, <u>26</u>: 28, 1978) for TBM histochemistry. Subsequent sectioning and reacting of the brain with the TMB chromagen revealed both labeled cell bodies (retrograde transport) and labeled terminal fields (transganglionic transport) in the brainstem.

Retrogradely HRP filled perikarya, representing motor neurons having end plates within the tongue were found in n.intercalatus, having end plates within the tongue were found in n.intercalatus, n. XII, and in the parvocellular reticular formation dorsally ad-jacent to caudal n.VII. Additionally, HRP-CT extensively labeled the dendrites of these neurons. While n.intercalatus dendrites extended mostly laterally for short distances, some projected dorsally into n.X while others crossed (commissural) to the op-posite nucleus. N.XII dendrites only projected ventrally and laterally; however, some long lateral dendritic branches were seen to course nearly to the solitary and trigeminal sensory nuclei. Large and small peroxidase filled neurons in the par-vocellular reticular formation had radially oriented dendrites, and again \_ some of these dendrites could be followed to near the and again, some of these dendrites could be followed to near the NTS.

Transganglionic transport of conjugated HRP from peripheral sensory receptors in the tongue to the brainstem was seen in dorsal-lateral n.V. Labeling in n.V began caudal to the obex and some labeled terminal fields were seen projecting medially and some labeled terminal lields were seen projecting medially into the solitary complex at this level. This n.V projection pattern continued rostrally to slightly above the genu of the facial nerve in coronal sections. Although it is clear that not all sensory components of the tongue, particularly taste recep-tors, were labeled in this study, this technique avoids some of the difficulation of intervententies that enice ther wind nerve the difficulties of interpretation that arise when mixed nerves are dipped in HRP.

57.14 APHAGIA AFTER UNILATERAL MICROINJECTIONS OF A RETROGRADE FLUORESCENT TRACER IN RAT HYPOTHALAMIS OR GLOBUS PALLIDUS.
 G.F. Alheid<sup>1</sup>, J. Mogensen<sup>7</sup>, I. Divac<sup>7</sup>, and L. Heimer<sup>1</sup>.
 Clinical Neurosciences Research Center, Univ. of Va., School of Medicine, Charlottesville, Va. 22908, 2 Inst. Neurophysiology, Panum Inst, Copenhagen 2200 Denmark.

When granular blue (GB), a fluorescent retrograde tracer is injected in the CNS, a central zone of necrosis surrounded by labeled cells unvariably results. taken advantage of the fact that GB remains in neurons even after prolonged survival periods (Innocenti, 1981) to study the functional and anatomical consequences of tracer induced lesions. Implanted glass micropipettes were used induced resions. Implanted glass micropipettes were used to deliver GB; this approach results in small (500 µm) injections of regular size, with little or no labeling of the pipette tract (Alheid and Carlsen, 1982).

Unilateral globus pallidus or lateral hypothalamic "injections" of GB were made at several different anterior posterior coordinates of male albino rats. Nine of the 27 animals were aphagic for periods of 24-48 hours (food intake less than 1.0 gm). The most severe effects of GB on body weight were found for rats with injections made at A.P. 6.5 (de Groot). These animals lost 10% of their preoperative weight by day 9, before gaining weight again. Control body weights were never regained during the 24 day survival period. GB injections in the ventral or dorsal pallidum just below or just dorsal and posterior to the anterior commissure resulted in aphagia and weight loss that was similar to that of the anterior hypothalamic injection injections.

Post sacrifice, (26 µm) cryostat brain sections were examined for retrogradely labeled neurons. With hypothalamic injections, retrograde labeling with GB included the medial part of n. accumbens, amygdala, ventromedial hypothalamic area, substantia nigra, ventral tegmentum and brainstem parabrachial nuclei.

Labeling after dorsal or ventral pallidal injections Labeling after dorsal or ventral pallidal injections included neurons in the ventral caudate or n. accumbens respectively, substantia nigra, and ventral tegmentum area. In addition, neurons were labeled in the posterior lateral hypothalamic area just medial to the subthalamic nucleus (see Heimer et al., this meeting). This work was supported by the Danish Medical Research Council and by NIH grant R NS1774303 (L.H. and G.F.A.).

- ELECTROMYOGRAPHIC ANALYSIS OF INGESTION AND REJECTION RESPONSES 57.15 ELECTED BY SAPID STIMUL IN THE RAT. J.B. Travers and R. Norgren. The Rockefeller University, New York,  $\overline{NY}$  10021. Intraoral injections of sucrose (S) and QHCL (Q) produce differ-ential oro-facial responses in the rat (Grill and Norgren, '78). Several lines of evidence indicate that these oro-facial responses constitute the observable concomitants of ingestion and rejection, we respectively. In order to further specify this relationship we recorded electromyographic (EMG) responses from a subset of the muscles involved in both these behaviors and in swallowing in freely moving rats. The stimulating techniques (intraoral cantreely moving rats. The stimulating techniques (intraoral can-nula) and behavioral monitoring techniques (videotape) were identical to those described in Grill and Norgren ('78). In ad-dition, activity in up to 4 muscles was recorded simultaneously using chronically implanted fine wire electrodes ( $60\mu$  NiCr). Re-sponses to S and Q were easily differentiable in both the video-tape and EMG records. Intraoral infusions of  $50\mu$  of 0.3M suc-Rerose produced low amplitude mouth movements correlated with EMG activity in the anterior digastric (AD), zygomatic (ZYG), and styloglossus (STY) muscles. EMG activity in these muscles con-sisted of rhythmic contractions (6-8/sec) with each contraction lasting 20-40 msec (AD, ZYG) and 60-80 msec (STY). During these lasting 20-40 msec (AJ, 216) and 60-80 msec (SII). Buring these bouts of muscle activity, episodic bursts of synchronous activity in intrinsic laryngeal and pharyngeal muscles indicated the pres-ence of swallows. These bursts occurred regularly during the re-sponses to sucrose. Otherwise, the animal was motionless and no fluid was visible on its lips. In contrast, stimulation with S0  $\mu$ l of 0.01M QHCI produced large amplitude mouth movements (gapes) at a rate of 3-5/sec. Bursts of EMG activity in the AD, ZYG, STY and pharyngeal muscles were correlated with the gapes. Like the gapes themselves this muscle activity was of considerably longer duration (60-180 msec) than the contractions elicited in response to S. During a bout of gapes, little or no activity was observed in the laryngeal musculature, strongly suggesting the absence of swallowing. Moreover, fluid was invariably seen on the outer surface of the mouth and on the floor of the observation chamber. The behavioral responses elicited by intraoral S and Q apparently constitute the oral motor phase of ingestion and and Q apparently constitute the oral motor phase of ingestion an rejection, respectively. Responses to S are interspersed with frequent, regular swallows, while swallows are absent during the behavior accompanying Q stimulation. Many of the EMC responses differentiating S from Q stimulation also occur in a lightly anesthetized preparation in which non-traumatic stereotaxic proce-dures can be employed. These preparations have allowed us to be-gin characterizing the central neural activity correlated with the responses of ingestion and rejection in areas previously Supported by grants NS18731 and NS10150).
- HIERARCHICAL INFORMATION PROCESSING OF BLOOD CHEMISTRY BY CHEMOSENSITIVE ELEMENTS IN PERIPHERAL AND CENTRAL NERVOUS SYSTEM, Y. Oomura, Y. Mizuno\*, N. Shimizu\* and T. Minami\*, Dept. of physiology, Fac. of Medicine, Kyushu Univ. 60, Fukuoka 812, 57.16

HIERARCHICAL INFORMATION PROCESSING OF BLOOD CHEMISTRY BY GEMOSENSITIVE ELEMENTS IN PERIPHERAL AND CENTRAL NERVOUS SYSTEM, Y. Oomura, Y. Mizuno\*, N. Shimizu\* and T. Minami\*, Dept. of physiology, Fac. of Medicine, Kyushu Univ. 60, Fukuoka 812, Japan. A few behavioral experiments indicated that there may exist glucose responding neurons in the nucleus tractus solitarious (NTS). Therefore, 162 neurons were tested in rat brain slices containing the NTS. A statistically significant number (p<0.05) of glucose-sensitive (GS) neurons were observed in that region. In the caudal region, 25 (28%) GS, / (8%) glucoreceptor (GR), and 57 non responsive neurons (28%) were noted among 89 cells tested. 0f 73 cells tested in the rostral part, only a few responded, 8 (11%) GS and 4 (5%) GR. Differences in the left and right side populations were not statistically significant in either the rostral or the caudal parts. The GS neuron was hyperpolarized in solution at high glucose concentration and depolarized at low glucose concentration (somolarity, adjusted by sucrose) with a slight membrane conductance increase. The GR neuron was depolarized with a membrane conductance decrease in solution at high glucose increase at low glucose. In solution with low Ca and high Mg or with 0.1mM Cd, at the condition of a blockage of synaptic inputs, the GR neuron still exhibited the glucose response. This is the first to demonstrate that the GR neuron is depola-rized by glucose probably with potassium permeability decrease. From antomical and electrophysiological evidences the NTS is a relay point in the blood chemistry analysis pathway, and serves as a caudal counterpart to the more rostral hypothalamus. The NTS is close to ventricle IV as the hypothalamus is close to ventricle III, so the YMTS could consolidate peripheral information, including the presence of hepatic, pancreatic, and intestinal glucose or insulin with intraventricle or plasma levels and send the summarized information to one of two directions. It can return caudally as a refle

HYPOTHALAMICALLY ELICITED EATING, BUT NOT BITING, IS INHIBITED BY BLOATING IN RATS. Joel M. Kaplan\* and Samuel M. Feldman. Dept. of Psychology, New York University, New York, NY 10003. Electrical stimulation of the lateral hypothalamus (ESLH) that elicits feeding and/or other oral behaviors also facilitates re-flexive biting of a tactile probe applied to the perioral region (Smith, 1972). We have investigated stimulus-bound feeding (SBF) and the perioral response (POR) as functions of ESLH intensity and of the gastric loading that results from SBF. Rats were tested in a cloth harness to which they had been previously adap-ted. By reducing the range of behavioral options, the use of the harness simplified the detailed analysis of eating and reflexive biting. Videotaping permitted off-line analysis. The receptive field for the POR was studied by repeated application of a tac-tile probe to 7 loci in the perioral region: 3 on the upper lipfield for the POR was studied by repeated application of a tac-tile probe to 7 loci in the perioral region: 3 on the upper lip-line (midpoint and corners) and 2 on each side of the face at different distances from the mouth. Sensitivity of the POR at a given locus was defined as the proportion of bite responses to the probe as a function of current. SBF trials at a given cur-rent were run in blocks (with 2 min intertrial intervals) that terminated when a rat resisted eating for two consecutive trials. During 30 sec SBF trials, a dish of wet mash (3:2, water: lab chow) was placed under the rat's mouth. Amount consumed, latency and duration of eating, and bite frequency and pattern were and duration of eating, and bite frequency and pattern were

measured for each trial. Perioral responding and SBF were both ESLH-current sensitive. Perioral responding and SBF were both ESLH-current sensitive. The receptive field for the POR increased with ESLH intensity. On the earlier trials in SBF blocks, ingestion rate was also an increasing function of current, primarily the result of an in-crease in the average amount eaten per bite of food. The effect of bloating on reflexive biting was studied by testing the POR before and after SBF blocks. For all currents tested, POR sensi-tivity was unchanged by gastric loading. Analysis of the biting pattern during SBF showed that the biting of food, like reflexive biting (POR), was not inhibited by gastric loading. In fact, at higher currents, bite frequency markedly increased over trials with ingestion rate either remaining roundby constant or slowly with ingestion rate either remaining roughly constant or slowly declining over the course of a test session. The cessation of SBF was not accompanied by elimination of ESLH-elicited biting. Rats often bit the edge of the food dish, the cables that sus-pended the harness within its frame, a wood block (if presented),

where the markets within its frame, a wood block (if presented), we conclude that the POR and ESLH-elicited biting in general, unlike intracranial self-stimulation supported by the same elec-trodes that produce SBF (e.g., Hoebel, 1969), are insensitive to gastric loading or bloating.

LEVEL OF SATIETY: IN VITRO GABA-SHUNT AND PENTOSE-SHUNT ACTIVI-57.19

LEVEL OF SATIETY: IN VITRO GABA-SHUNT AND PENTOSE-SHUNT ACTUI-TIES IN THREE BRAIN SITES ASSOCIATED WITH FEEDING. T. R. Kasser\*, R. B. S. HARRIS\* AND R. J. MARTIN (SPON: J. M. Bowen ). Dept. Foods and Nutrition, Univ. of Georgia, Athens, GA 30602 Mechanisms by which long-term food intake and energy balance are regulated have not been clarified. Experiments were conducted to determine if the level of satiety (highly positive, normal, or highly negative energy balance) altered specific pathways of glu-cose oxidation in selected brain areas. The hypothesis addressed was that metabolic activity within specific brain areas may be altered to depict peripheral metabolic status. Sixty-three female Sprague-Dawley rats (225e) received 150.

Sixty-three female Sprague-Dawley rats (225g) received 150, 100 or 50% of normal intake by gastric intubation for seven days. Body fat at conclusion of tube-feeding was 20.9, 13.6 and 7.4% in 150, 100 and 50% fed rats, respectively. If permitted to return to a free-feeding state, 150%-fed rats would be hypophagic and 50% fed returns a cluster of 100% fed 50%-fed rats would be hyperphagic, relative to intake of 100%-fed rats, to achieve energy balance. Thus, the incentive for spontaneous feeding would be inhibited in 150%-fed rats (anorectic), stimulated in 50%-fed rats (hungry) and maintained in 100%-fed rats (control).

Cortex, ventrolateral hypothalamus (VLH), ventromedial hypothalamus (VMH) and a site in the caudal brainstem that included the area postrema-nucleus of the solitary tract (AP-NTS) were dissected from coronal sections obtained four hours after the last

dissected from coronal sections obtained four hours after the last tube-fed meal. Using the method described by Hothersall et al. (J. Neurochem. 37:1484, 1981), the yield of  $^{14}CO_2$  form  $^{14}C-2-$ glucose minus  $^{14}C-6$ -glucose equals GABA-shunt activity and  $^{14}C-1$ -glucose minus  $^{14}C-6$ -glucose equals pentose shunt activity. Glucose flux through the GABA-shunt was specifically altered in the VLH relative to the level of satiety. GABA-shunt activity in the VLH was 32% lower in hungry rats and 35% higher in ano-rectic rats relative to control values. No treatment effects ware observed for CABA-cput activity in the VMH AP-MS or corwere observed for GABA-shunt activity in the VMH, AP-NTS or cor-tex. Glucose flux through the pentose-shunt was altered in the VMH and AP-NTS relative to satiety. Pentose-shunt activity in the VMH was 111% lower in hungry rats and 152% higher in anorectic rats relative to control values. Pentose-shunt activity in the AP-NTS was 116% lower in hungry rats and 60% higher in anorectic rats relative to control values; however, hungry and anorectic rats had AP-NTS pentose shunt activities that were not different from control values but were different from each other. No treatment effects were observed for pentose-shunt activity in the VLH or cortex. The data demonstrate that within selective brain sites, specific pathways for glucose oxidation are affected by energy intake and may be used by the rat to assess and respond to changes in peripheral energy status.

57.18 Fourth ventricular phlorizin injection stimulates feeding but not hyperglycemia. F.W. Flyn\*, H.J. Grill and D. Rooney\*, Dept. Psychology and Inst. Neurol. Sci., Univ. of Pennsylvania, Philadelphia, 19104.

Injections of phlorizin, which competitively inhibits glucose transport, stimulate feeding. Previously, Glick and Mayer (<u>Mature</u>, 1968, 219, 1374) reported that infusions of 100-20001 of phlorizin into the lateral ventricle resulted in hyperphagia. It is not clear from this study the location of the neural mechanisms mediating the feeding behavior. Recent evidence indicates that the neural mechanisms responsive to reductions in glucose availability elicited by intracerebroventricular (ICV) 5-thioglucose (5TG) are in the caudal brainstem, in the vicinity of the fourth ventricle. We report that microinfusions of phlorizin and 5TG into the fourth ventricle of rats cause feeding. However, unlike 5TG, phlorizin does not elicit hyperglycemia. Rats (n=7) were implanted with cannulae aimed at the

Rats (n=7) were implanted with cannulae aimed at the fourth ventricle. Food intake was meaured 3 and 24 hours following 5 ul (ICV) injections of saline (0.95), phlorizin (3 mM and 6 mM) and 5TG (.76 uM and 1.07 uM). Food intake following ICV saline and 3 mM phlorizin was not significantly different. In contrast, three hour food intake following 6 mM phlorizin (3.9±.8g) was significantly greater than that following saline injection (1.0±.5g). In addition, compared to saline injection, 6 mM phlorizin injection caused a small but significantly more food in the three hour period following the two doese of 5TG commend to that amount invested the two doses of 5TG compared to that amount ingested following ICV saline. The increase in food intake was similar following the two doses of 5TG and 6 mM phlorizin.

Subsequently, tail blood was collected at 1, 2, 3, and 0 hours following ICV saline, 6 mM phlorizin, and 1.07 uM 5TG 3. and 6 nours following it's saline, o may phiorizin, and for on your objections were comparable following ICV saline and 6 mM phiorizin. Hyperglycemia was elicited in these rats only by ICV 5TG injection (1 hour post saline=133.0+2.6 mg\*, 1 hour post 5TG=236.1+36.1 mg\*). To verify that the phiorizin was acting centrally and not

at some peripheral site, food intake was measured 3 and 6 hours following 5ul IP injections of saline and 6  $\rm mM$ phlorizin. Food intake did not differ under these conditions. We conclude therefore, that inhibition of glucose transport by phlorizin in tissue in the vicinity of the fourth ventricle a potent stimulus for feeding but not hyperglycemia. (supported by T32-MH15012 and BNS82-10734)

ANALYSIS OF MACRONUTRIENT SELECTION FOLLOWING ABLATION OF THE 58.2 ARALFSIS OF MACKNOURIENT SELECTION FOLLOWING ABLATION OF THE AREA POSTREMA OF THE RAT. Jon N. Kott\*,Christine L. Ganfield\*, and Nancy J. Kenney. Department of Psychology, University of Washington, Seattle, WA 98195. Ablation of the area postrema and adjacent caudal-medial nucleus of the solitary tract (AP/cmNTS) results in a transient period of hypophagia and weight loss. While daily intake of

Ablation of the solitary tract (AP/cmNTS) results in a transfer nucleus of the solitary tract (AP/cmNTS) results in a transfer period of hypophagia and weight loss. While daily intake of laboratory chow returns to control levels within 2 weeks after lesioning, body weight of AP/cmNTS lesioned rats is permanently compared to that of unlesioned controls. This study

lesioning, body weight of AP/cmNTS lesioned rats is permanently reduced compared to that of unlesioned controls. This study examines the effect of AP/cmNTS lesions on intake of protein, fat and carbohydrate by rats in a "self-selection" situation. Ten rats were adapted to the "self selection" procedure for 3 weeks. Based on total caloric intake and on proportion of total intake from each of the macronutrients during the final 5 days of the adaptation period (baseline), rats were divided into 2 matched groups of 5 animals each. One group received thermal lesions of the AP/cmNTS. The other was sham lesioned. After a 4-day recovery period, daily intakes of the 3 macronutrients were analyzed for four consecutive 5-day periods. Body weights were measured daily throughout the experiment. experiment.

experiment. AP/cmNTS lesioned rats lost more weight (23 + 0.6 g) than did non-lesioned controls (8.6 + 1.9 g) during the first 4 days after surgery. Rates of weight change of lesioned animals did not differ from those of controls throughout the remainder of the experiment. Total caloric intakes of AP/cmNTS lesioned rats were significantly below those of controls during the first 2 postsurgery measurement periods. Sham-onerated animals showed no changes from baseline levels

first 2 postsurgery measurement periods. Sham-operated animals showed no changes from baseline levels in the number of calories taken as fat, carbohydrate or protein during any of the post-surgery measurement periods. The decrease of total caloric intake of lesioned rats was due entirely to a decrease in the number of calories taken as fat. Fat intake of lesioned rats averaged 42.0 + 15.6 Cal/day during the baseline period compared to 10.2 + 4.3 and 18.2 + 8.0Cal/day during the first two post-ablation test segments, respectively. Daily intake of carbohydrate and of protein did not change following AP/cmNTS ablation. Thus, in the "self-selection" situation, the reduction of food intake which immediately follows AP/cmNTS lesions is due to a specific decrease of the the number of calories taken as fat and does not reflect a general suppression of ingestion of

fat and does not reflect a general suppression of ingestion of all dietary components.

58.3 DISCRIMINATION BETWEEN EQUIMOLAR NaCL AND LICL IN RATS: ROLE OF THE AREA POSTREMA. R. Ladowsky\* and K.-P. Ossenkopp (SPON: F.V. Szeligo). Dept. of Psychology, University of Western Ontario. London, Ontario, Canada, N6A 5C2.

Area postrema (AP), a circumventricular structure at the caudal end of the fourth ventricle, has been shown to be involved in taste aversion (TA) learning in rats induced by injections of LiCl (Ritter et al., Brain Res., 1980, 201, 501). Rats are also able to form a discrimination between equimolar solutions of NaCl able to form a discrimination between equilating obtained in and and LiCl when presented simultaneously (Strom et al., Psychon. <u>Sci</u>., 1970, <u>18</u>, 290), possibly due to the development of a TA to the LiCl. We were interested in delineating any role AP might have in the formation and retention of this discrimination. In the first experiment, rats on a 23 hr/day water deprivation schedule were presented with equimolar (0.12 M) NaCl and LiCl in a two-bottle choice test for 1 hr/day over ten days. All rats learned to discriminate between the two solutions and showed a strong preference for the NaCl solution (p<.01). Half of the animals then received thermal cautery lesions of AP and the other rats were sham lesioned. After recovery and re-adaptation to the water deprivation schedule, all rats were again given the two-bottle choice test between NaCl and LiCl (l hr/day). Both the lesioned and the sham lesioned animals exhibited good retention of the discrimination (p<.01), however the AP lesioned group drank more LiCl over the ten days of testing than the sham lesioned group. When given only NaCl or only LiCl on Days 11 and 12 respectively, the AP lesioned rats drank as much NaCl as the sham lesioned rats (p>.05), but drank significantly more LiCl than the sham lesioned animals (p<.01). In experiment 2 rats received either AP lesions or sham lesions and after recovery were placed on a 23 hr/day water deprivation schedule. All animals were then given a two-bottle choice test (l hr/day) between equimolar (0.12 M) NaCl and LiCl over the next ten days. Both AP and sham lesioned rats acquired a strong preference for NaCl by the third test day. When challenged with only LiCl on Day 11, AP lesioned rats drank significantly more LiCl than sham lesioned rats (pc.01). Thus, AP does not appear to play an essential role in either the acquisition or retention of the Na - Li discrimination, but this brainstem structure does influence the amount of Li rats are willing to ingest.

IMPAIRED VASOPRESSIN SECRETION IN RATS WITH ELECTROLYTIC LESIONS OF THE "AV3V AREA" LOCALIZED TO NUCLEUS MEDIANUS. Thomas W. Gardiner\*, Joseph G. Verbalis, and Edward M. Stricker. De of Psychology and Medicine, Univ. Pittsburgh, Pittsburgh, PA, Depts. 15260

Lesions ablating the periventricular tissue surrounding the anteroventral border of the third cerebral ventricle (the "AV3V" area) in rats produce adipsia and excessive renal fluid losses. Wany rats resume drinking after a few days, but remain permanently impaired in their drinking responses to acute dehydration (Buggy & Johnson, <u>Am. J. Physiol.</u>, 233:R44, 1977). More discrete lesions within this periventricular area, limited to the ventral (subcommissural) part of nucleus medianus (NNM), also cause (ductaminister a) part of interest meetanis (vm/), also cause adipsia, polyuria, and long-term drinking impairments in rats (Gardiner et al., <u>Soc. Neurosci. Abstr.</u> 7:168, 1981). However, we find that several weeks later they exhibit significant capacity to concentrate their urine in response to both overnight water deprivation and sc injection of hypertonic NaCl. We therefore examined the plasma vasopressin (AVP) response to hypertonicity, 4-6 weeks following vNM lesions in rats. Two ml of 2M NaCl solution were infused (iv) over a 5 minute

period in each of 12 rats with vNM lesions and 7 controls (BWt= period in each of 12 rats with vNM lesions and 7 controls (BWt= 450-560 g). Thirty minutes later 1.2-1.5 ml of blood were remotely withdrawn via the same catheter. Food and water were withheld during testing. Plasma AVP was measured by specific radioimmunoassay. In 9 of the 12 brain-damaged rats, AVP levels were only 2.0-11. uU/ml ( $M \pm SE \pm 5.23 \pm 1.0$  uU/ml) despite plasma sodium concentrations of 151-166 mEq/1, whereas all control rats had AVP levels greater than 14.5 uU/ml (22.5  $\pm 2.5$  uU/ml) despite plasma sodium concentrations that did not exceed 153 mEq/1. Thus, it would appear that vNM lesions impair the rapid vasopressin secretion of rats in response to acute osmotic stimuli. These findings may be related to the fact that the brain damaged animals findings may be related to the fact that the brain damaged animals also do not drink rapidly in response to dehydration. However, most rats initiate drinking after a delay of 5-8 hr, when the dark period begins (Gardiner & Stricker, Soc. Neurosci. Abstr. 8:601, 1982), whereas their urine osmolalities are elevated much sooner; for example, they rise above 1500 mOsm/1 within 2-3 hr after sc injection of 2 ml of 2M NaCl soluiton. The latter findings may imply that vasopressin secretion in rats with VMM lesions is delayed for a few hours after the onset of osmotic dehydration, and we are now examining this possibility. Despite our present uncertainty about the time course of vasopressin secretion after osmotic dehydration, it seems likely that vMM lesions disrupt the normally close association between it and the drinking response. Supported by USPHS grant MH-25140.

DRINKING ELICITED BY ELECTRICAL STIMULATION OF THE LATERAL HYPO-THALAMUS AND THE ANGIOTENSIN-RENIN SYSTEM. <u>G. Mittleman, S.J.</u> <u>Block, and E.S. Valenstein</u> (SPON: R. Davis). Psych. Depart. and Neurosci. Lab, University of Michigan, Ann Arbor, MI 48109. Accumulating evidence indicates that angiotensin II is an im-portant stimulant of thirst. For example, Fitzsimons & Simons (J. <u>Physiol</u>,203:45-57,1969) demonstrated that vigorous drinking could be elicited from water sated rats by intravenous infusions of an-giotensin II. The role of angiotensin II in producing thirst has been further supported by the use of its competitive antagonist, saralasin. Rolls & Woods (<u>Pharm.Biochem.Behav</u>.,6:245-250, 1977) have reported that saralasin injected together with angiotensin II blocks drinking normally elicited by the latter. It has been pos-tulated that the neural substrate mediating drinking evoked by electrical stimulation of the lateral hypothalamus (ESLH) may be part of the same "thirst circuit" in which angiotensin II exerts its influence as a thirst cue. The purpose of these experiments was to compare natural drinking (elicited by water deprivation) with drinking elicited by ESLH by using saralasin to attenuate drinking. <u>EXP. 1</u>: Long Evans male rats were implanted with one cannula into the lateral ventricle. They were water deprived for 30 hrs and then allowed access to water for 1 hr. Water consump-tion was measured by a drinkometer record of the number of licks. Once reliable baseline water consumption was obtained, the rats were again water deprived for 30 hrs and then received an intra-ventricular infusion of saralasin (5ug/Sul/1 min.). At 60 or 75 min. following the infusion when saralasin has been reported to maximally inhibit drinking these animals were allowed access to 58.5 DRINKING ELICITED BY ELECTRICAL STIMULATION OF THE LATERAL HYPOwere again water deprived for 30 hrs and then received an intra-ventricular infusion of saralasin ( $\log/\beta_{\rm H}/1$  min.). At 60 or 75 min. following the infusion when saralasin has been reported to maximally inhibit drinking these animals were allowed access to water and consumption was recorded as in the baseline condition. Saralasin reduced water consumption by 66% after a 60 min. delay but by only 33% after a 75 min. delay. <u>EXP. 2</u>: A second group of rats was implanted with LH electrodes and a cannula into the lat-eral ventricle. They were tested for baseline water consumption and for the effectiveness of saralasin on water deprived drinking as in Exp. 1. These rats were then screened for ESLH elicited drinking. After stable and consistent drinking occurred during every 20 sec. trial of hypothalamic stimulation baseline water consumption during ESLH was recorded as the number of licks during 10 trials. This testing was repeated at least 5 times with testing sessions occurring every 48 hrs. These rats were then injected with saralasin as in Exp. 1 and tested for ESLH elicited drinking 60 min. later. Saralasin had no effect on ESLH elicited drinking although it again reduced water deprived drinking by an average of 66% when compared to baseline water consumption. Since the angio-tensin II blocking agent, saralasin, inhibits drinking caused by water deprivation and does not effect drinking caused by ESLH, it would appear that different physiological mechanisms underlie these two forms of drinking. CSF SODIUM CONCENTRATION IS INCREASED IN RESPONSE TO AN EXTRACELLULAR FLUID CHALLENGE. S.P. Frankmann and R.R. Sakai\*. Dept. of Psychology, U. Washington, Seattle, WA 98195. The mechanisms responsible for the initiation of saline ingestion in response to an extracellular fluid challenge(ECF) are not well understood. ECF challenges can be induced by polyethylene glycol (PEG), a colloid which osmotically draws salts and water from the ECF to form an edema at its injection as replenishes the losses by ingestion of water and salts. It has been proposed (Stricker, EM., JCPP, 95:1, 1981) that a lowering of cerebrospinal fluid (CSF) sodium (Na+) may represent the critical stimulus for the initiation of sodium ingestion.

Forty male Long Evans rats were given a one week acclimation to a choice of 0.3M NaCl and water. At 8am on test day each rat was injected s.c. with 16.7ml/kg of 20% PEG (PEG) or saline was injected s.c. with 16.7ml/kg of 20% PEG (PEG) or saline vehicle (CTRL). Each rat was then returned to its home cage from which all food had been removed. One group of rats (sampled at 8 hrs) had access to 0.3M NaCl and water, all others were denied fluid access. At an interval of 2, 4 or 8 hrs a given animal was weighed and anesthetized with Ketamine. At this time 100µl of CEP end callength for deliver the following for detivity of the saline terms of the saline for the saline for detivity of the saline Weighted and antestitetized with netanine. At this time rout of or CSF was collected followed by 1 ml of blood for determination of hematocrit and sodium concentration ([Na+]) by flame photometry.

In those rats tested without access to fluids there was no difference in the P[Na+] at 2, 4 or 8 hrs between PEG or CTRL. At 4 and 8 hours, PEG rats had significantly elevated CSF[Na+], (t=3.41, t=4.5,  $p_{-0.1}^{-1}$ ). When rats were given access to fluids during the 8 hours, PEG rats had significant elevation of hematocrit and P[Na+], (t=3.27, t=2.82,  $p_{-0.05}^{-1}$ ) however there was no difference in CSF[Na+] from CTRL. There was no significant difference in percent body weight loss, hematocrit of CSF[Na+] in PBG rats whether or not they were allowed access to fluids. The animals given access to fluids did have decreased Plasma[Na+] compared to those without access to fluids. PEG rats consumed 6.03+2.8 ml of water and 1.28+1.2 ml of 0.3M NaCl and CTRL rats consumed 0.04+0.0 ml water and 0.8+1.8 ml of 0.3M NaCl (mean  $\pm$  SD). There was no relationship between volume or ratio of fluid ingested and CSF [Na+].

At 8 hours post PEG injection CSF[Na+] is increased but P[Na+] unchanged when no fluid access is allowed. In contrast when fluid access is allowed, CSF[Na+] is not increased but P[Na+] is. These data do not support the hypothesis of a lowered CSF [Na+] being a stimulus for sodium ingestion. The observed elevation of CSF[Na+] may reflect altered fluid and electrolyte transport at tissues sensitive to the hormonal changes which occur during an ECF challenge. Possibly there is a synergistic action between elevated CSF[Na+] and circulating levels of hormones which triggers a sodium appetite. Supported by HL 21800.

### FEEDING AND DRINKING: CENTRAL MECHANISMS IV

EFFECTS OF CENTRAL CATECHOLAMINE DEPLETION ON INSULIN LEVELS IN 59.1 THE CENETICALLY OBESE AND DIABETIC MOUSE (db/db). J. F. Lorden, Dept. of Psychology, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The diabetes mouse (C57BL/Ks-db) is an autosomal recessive mutant that displays elevated plasma insulin levels at weaning. Levels peak at 2-5 mo of age and subsequent islet cell degranulation is accompanied by loss of body weight, hypophagia and premature death. Diabetes mice also have elevated hypothalamic norepinephrine (NE) levels in comparison with lean littermate controls, suggesting the possibility of central nervous system involvement in the diabetes syndrome. Intraventricular injections of 6-hydroxydopamine (6-OHDA) that deplete central NE

tions of 6-hydroxydopamine (6-OHDA) that deplete central NE cause weight loss and decreases in blood glucose and body fat. Furthermore, 6-OHDA treated mice show greater pancreatic islet granulation than vehicle-treated mice of the same age. The improved islet granulation and lower blood glucose levels of the 6-OHDA treated group suggested that the lesion or its consequences had a protective effect on the pancreas of the diabetes mice. To test this diabetes mice were treated with an 80 nmol intraventricular injection of 6-OHDA or a vehicle solu-tion at 6-7 wk of age. Food intake and body weight were depress-ed in the 6-OHDA or our in comparison with vehicle-treated comtion at 6-7 wk of age. Food intake and body weight were depress-ed in the 6-OHDA group in comparison with vehicle-treated con-trols. At sacrifice 7 wk later, blood glucose and plasma insulin levels were also significantly lower in the 6-OHDA treated group than in controls. Thus, the 6-OHDA treatment may have slowed the increase in plasma insulin levels usually seen in diabetes mice. A similar experiment was carried out in 100 day old mice. Diabetes mice of this age would be expected to show a decline in had under food diateke end alcore insulin if left urtracted. body weight, food intake and plasma insulin if left untreated In this experiment food intake was significantly depressed in the 6-OHDA group in comparison with controls for only two days after surgery. At sacrifice 3 wk later, there were no reliable differences between the 6-OHDA and vehicle groups in food intake, body weight or blood glucose. However, plasma insulin levels in the 6-OHDA group were significantly higher than those in the control group which had begun to show a decline in comparison with control group which had begun to show a decline in comparison with younger mice. These findings suggest that the 6-ORDA lesion does not prevent the increase in plasma insulin seen as the diabetes syndrome progresses. However, the earlier histological data that indicated that the 6-ORDA-treatment prolonged the insulin-secreting capacity of the pancreas in diabetes mice were surfaced. The number obtained in the clader mice where The results obtained in the older mice also indicate confirmed. that the effect is not due solely to a reduction in food intake. The lesions may reduce circulating levels of diabetogenic hor-mones and reduce insulin need. (Supported by NINCDS grant NS14755).

HYPOTHALAMIC NEUROTRANSMITTERS DURING ANOREXIA INDUCED BY ACUTE 59.2

HYPOTHALAMIC NEUROTRANSMITTERS DURING ANOREXIA INDUCED BY ACUTE DIETARY ZINC RESTRICTION OF ADULT RATS. D.L. Sparks, J.T. Slevin, and E.J. Kasarskis. Dept. Neurol. VA Med. Ctrs. and Univ. Kentucky, Sanders-Brown Aging Ctr., Lexington, KY 40536. Reduced food intake is an early manifestation of zinc (Zn) deficiency. Other investigators have shown increased whole brain norepinephrine (NE) and we have demonstrated elevated levels of NE, dopamine, and 5-HT in hypothalamus of rats fed Zn-deficient diets for 6 wks from weaning. Although hypothalamic NE has been implicated in regulation of food intake, the results of ourselves and others may reflect altered maturation of noradrenergic pathways rather than metabolic changes in severely growth retarded, Zn-deficient rats. In order to separate developmental retarded, Zn-deficient rats. In order to separate developmental from metabolic effects of Zn deprivation, we have determined levels of hypothalamic neurotransmitters following acute dietary Zn restriction of adult rats fed Zn-adequate diets from weaning.

Zn restriction of adult rats fed Zn-adequate diets from weaning. Male Sprague-Dawley rats weighing 200 g were fed diets containing (lppm Zn and offered water supplemented with 30 ppm Zn (as Zn acetate) in order to provide adequate Zn intake. Food consumption and body weights were determined daily for a 1 week equilibration period. Zinc was acutely restricted by offering deionized water ad libitum as the sole fluid source (Day 0). Groups of rats were sacrificed on Day 0 and 1,4, and 7 days following Zn restriction in order to evaluate neurotransmitter levels prior to the period of profound anorexia and weight loss. Plasma was obtained for determination of Zn by flame atomic absorption spectrombotometry: the hypothalamus was isolated and absorption spectrophotometry; the hypothalamus was isolated and extracted with 0.1M perchloric acid for neurotransmitter assay using HPLC. Plasma Zn fell from 149 ug/dL on Day 0 to 48 and 28 ug/dL on Days 1 and 7 respectively, preceeding a 20% decline in food consumption starting on Day 4 of Zn restriction. Hypothalamic NE did not change during 7 days of acute Zn restriction from pre-treatment levels (2.39 ng/mg wet wgt). However, the levels of dopamine and 5-HT decreased by 18% during the phase of reduced food intake and weight loss beginning on Day 4. The results of this study do not support the hypothesis that acute Zn restriction induces changes in hypothalamic NE which may

cue a reduction in food intake in developmentally mature rats. [Supported in part by VA Research Service and HIH grants Nos. 1-T32-AG0084 (Sparks), NS00732(Slevin), and NS00768(Kasarakis)].

59.5

NALOXONE INHIBITS AND THE KAPPA-OPIATE KETOCYCLAZOCINE FACILITATES 59.3 INTAKE OF PREFERRED SWEETS IN NONDEPRIVED RATS. W. C. Lynch Dept. of Psychology, Montana State Univ., Bozeman, MT 59717. Suppression of food and water intake by opiate antagonists

suppression of food and water intake by opfate antagonists appears to depend on oral, palatability, factors, (Apfelbaum and Mandenoff, <u>Pharmac. Biochem. Behav.</u>, <u>15</u>: 89, 1981). On the otherhand, while certain opiate agonists appear to facilitate feeding (Morley and Levine, <u>Life Sci</u>, <u>29</u>: 1901, 1982), it remains unclear whether oral factors may also influence their effects. In (1 mg/kg, sc) selectively suppressed intake of preferred concertrations of sodium saccharin, a non-nutritive sweetener. In the present work we extend our studies to include very low naloxone (NAL) doses and moderate doses of the kappa-opiate agonist, keto-cyclazocine (KC).

Two groups of adult male albino rats (n=10 each) were given repeated 2-bottle taste preference tests. Each test consisted of recording 1 hr intake of water or 1 of 3 concentrations of (.03%, 0.1% or 0.3%, w/v). All 3 concentrations were saccharin presented to each rat once per week in counterbalanced order. Drug treatments varied from week to week. In Group 1 saline and NAL treatments were alternated and NAL doses ranged from 0.01 to 1.0 mg/kg, sc. Both saline and NAL injections were given 15 min before intake tests. In Group 2, saline and KC treatments alter-nated, with KC doses ranging from 1.0 to 5.0 mg/kg, sc, given 30 min before tests. Due to the general inhibition of motor activity produced by KC at 30 min post-injection, a follow-up experiment examined the time-course of KC effect by measuring cumulative intake of 0.1% saccharin hourly for 10 hr following injection of KC (5 mg/kg, sc) or its vehicle (1 m1/kg). Repeated preference tests yielded a progressive increase in

intake of all 3 saccharin concentrations over weeks. NAL at a dose of 0.1 mg/kg or above consistently suppressed intake of all 3 saccharin concentrations by at least 50% but did not affect intake of water. The lowest NAL dose (0.01 mg/kg) suppressed intake of the lowest saccharin concentration but did not affect intake of the 2 sweeter solutions, thus suggesting that at very low doses NAL is only effective near the threshold of sweet taste perception. KC (5 mg/kg) produced a generalized inhibition of motor activity for approximately 2 hrs post-injection but following this, saccharin intake was markedly enhanced such that by 6 hrs post-injection, KC had facilitated saccharin intake by approximately 50%. These data suggest that endogenous opioids, possibly acting at k-receptors, may normally modulate the affective quality of gustatory stimuli. (Supported by MONTS-NSF project ISP-8011449.)

REDUCTION OF CLONIDINE-INDUCED FOOD INTAKE BY NALTREX-594 ONE AND A STEREOSPECIFIC OPIATE RECEPTOR ANTAGONIST IN RABBITS. N.L. Katz, R.F. Schlemmer and D.P. Waller\*. Dept. of Pharmacodynamics, Univ. of IL at Chicago, Hith. Sci. Ctr., Chicago, IL 60680.

Acute administration of the  $\alpha$ -noradrenoreceptor agonist, clonidine, to rabbits stimulates a short-term vigorous increase in food intake, a typical response characterized by 2-3 eating binges over one hour, each binge lasting about 5-10 minutes (Waller <u>et al.</u>, <u>Pharmacologist</u>, 24(3): 163, 1982). Studies using selective antagonists have suggested that

163, 1982). Studies using selective antagonists have suggested that presynaptic  $\alpha_2$ -noradrenoreceptors may be involved in the clonidine response (Katz et al., Fed. Proc., 42(4): 159, 1983). Since narcotic antagonists have been shown to reduce food intake in various species of rodents (e.g., Holtzman, J. Pharmacol. Exp. Ther., 189: 51, 1974), we determined the influence of the antagonist, naltrexone, on the clonidine feeding response. In a randomized block design, 8 male rabbits were given either 1 mg/kg naltrexone HCl, 2 mg/kg naltrexone HCl, or a saline control injection 10 minutes before receiving an i.m. injection of 0.075 mg/kg clonidine HCl or saline. The amount of food eaten during the first hour following the injections was measured. Rabbits given the saline + clonidine combination exhibited measured. Rabbits given the saline + clonidine combination exhibited increased feeding behavior. Acute injections of naltrexone in saline (saline + saline) levels. There was no significant difference between 1 and 2 mg/kg naltrexone.

The stereospecific requirements for the antagonism of clonidineinduced food intake were studied with optical isomers of  $5,9\alpha$ -diethyl-2-(3 furylmethyl)-2'-hydroxy-6,7-benzomorphan. Opiate antagonism resides predominantly in the (-)-isomer (MR2266), whereas the (+)-isomer (MR2267) is not a potent opiate antagonist. In a randomized block design, 3 sets of paired rabbits were given either 1 mg/kg MR2266, 1 mg/kg MR2267, or a vehicle (0.1N HC) control injection 10 minutes before receiving an i.m. injection of 0.1 mg/kg clonidine. MR2266 before receiving an i.m. injection of 0.1 mg/kg clonidine. MR2266 significantly decreased the clonidine feeding response, while MR2267 had no effect. Thus, the results suggest that the reduction by opiate antagonists of clonidine-induced food intake is due to an interaction with opiate receptors.

SHAM FEEDING OF SUCROSE INCREASES HYPOTHALAMIC DOPAC/DA. K. Bourbonais\*, C. Jerome\*, K.J. Simensky and G.P. Smith (SPON: ... Halmi). Department of Psychiatry, Cornell Univ. Med. Coll. and E.W. Bourne Behav. Res. Lab., New York Hosp., White Plains, NY 10605 Ingestion of food increases central dopaminergic (DA) activity hypothalamus, accumbens and amygdala (Heffner et al, 1980). It is not clear which aspects(s) of food intake (taste, reward, eat-ing movements, satiation and/or metabolic effects) was correlated with this increased DA activity. On the basis of the effect of DA postsynaptic receptor blockade by systemic administration of pimozide, Wise et al (1978) suggested that central DA activity mediated the rewarding effect of food, and Xenakis and Sclafani (1981, 1982) extended this hypothesis to the reward of sweet taste. We tested the hypothesized relationship between sweet taste and cen-tral DA terminal fields after rats sham fed 1,10 or 40% sucrose. Sham feeding was used because (1) it eliminated the satiating and direct metabolic effects of sucrose, but preserved taste, reward and eating movements; (2) sham intake was a sigmoid function of sucrose concentration (Bernz et al, 1983); and (3) pimozide de-creased sham feeding of sucrose in a manner that was similar to

decreasing the concentration of sucrose (Geary et al, 1983). After 17 h food deprivation, rats sham fed one of three concen-trations of sucrose--1, 10 or 40%. Control rats were adapted to the deprivation schedule, but they never sham fed. After sham intakes stabilized, rats sham fed for 9 min, then were decapitated and DOPAC and DA content of hypothalamus, olfactory tubercle, ac-cumbens, amygdala, caudate and frontal cortex were measured by HPLC and electrochemical detection. DOPAC/DA increased significantly as a function of sucrose concentration in the hypothalamus, but not in other regions.

		Hypothalamic	Sham Intake	
Group	n	DOPAC/DA (±SE)	(ml ± SE)	
Control	12	.28 ± .02	0	
l% sucrose	9	.30 ± .04	9 ± 2	
10% sucrose	26	.35 ± .02	16 ± 1	
40% sucrose	16	.50 + .03*	18 ± 1	

\*p <.001 compared to 10% sucrose

Since 9 min sham intakes of 40% and 10% sucrose did not differ, the larger hypothalamic DOPAC/DA correlated with sham intake of 40% sucrose is probably not related to ingestive movements, but is more likely to be a function of the sensory and/or rewarding effects of sucrose oropharyngeal stimulation. Supported by NIMH grants MH15455 and MH00149.

DIFFERENTIAL EFFECTS OF PIMOZIDE AND SPIPERONE ON HOMEOSTATIC AND NONHOMEOSTATIC DRINKING. J. H. Porter\*, J. J. McDonough\*, G. F. Heath\*, P. A. Goldsmith\* and D. N. Johnson. Dept. of Psychology, Va. Commonwealth Univ. and A. H. Robins Pharmaceutical Co., Richmond, VA 23284. Drinking in response to depletions in the cellular or extra-

cellular fluid compartments may be classified as Homeostatic drinking; whereas, drinking which is insensitive to imbalances in body water and operates heedless of the state of body water may be classified as Nonhomeostatic drinking(see Kissileff, H.R. in <u>The Neuropsychology of Thirst</u>, 1973). Recently, Robbins and Koob (<u>Nature</u>, <u>285</u>: 409-12,1980) demonstrated that lesions of the mesolimbic dopamine (DA) system attenuated the acquisition of schedule-induced polydipsia (SIP, a form of nonhomeostatic drinking, see Falk,  $J_{...}$  Sci., 133: 195-6,1961), but did not attenuate drinking induced by water deprivation (a form of homeostatic drinking). The present study further examined the role of DA in the regulation of homeostatic and nonhomeostatic drinking with the DA blockers, pimozide and spiperone. In Exp. 1, 5 groups of rats were given 15 sessions of Polydipsia Training (FI 1-min food schedule) with vehicle, 0.5 mg/kg pimozide, 1.0 mg/kg pimozide, 0.0625 mg/kg spiperone, or 0.125 mg/kg spiperone injections (ip., 1-hr before test sessions). As seen in Table 1, the acquistion of SIP was significantly suppressed by the DA blockers at all doses. The reduced water intakes were not due to any changes in food motivation as barpressing remained un-changed at all doses. In Exp. 2, injections of pimozide and spiperone did <u>not</u> suppress <u>established</u> SIP. In Exp. 3, pimozide and spiperone did <u>not</u> suppress <u>deprivation-induced drinking</u>(23.5 hr deprivation schedule). The results of Exps. 1 and 3 confirm Robbins and Koob's findings of the differential role of DA in Robbins and Koob's findings of the differential role of DA in the regulation of homeostatic (deprivation-induced drinking) and nonhomeostatic (SIP) drinking. However, once SIP was establish-ed (Exp. 2), pimozide and spiperone were ineffective in attenu-ating the SIP drinking. These data support the suggestion that an intact DA system is necessary for the <u>acquisition</u> of SIP, but also suggest that other mechanisms may be important for the re-gulation of <u>established</u> SIP.

SEROTONERGIC MODULATION OF NEUROPEPTIDE FEEDING SYSTEMS. <u>B.A.</u> <u>Gosnell, A.S. Levine and J.E. Morley</u>. Neuroendocrine Research Iab, Minneapolis VAMC, Minneapolis, NN, 55417. Serotonergic systems have been implicated in the regulation 59.7

of food intake and body weight, though the exact nature of their role is unclear. Depending on the route and locus of administration, scrotonin (5-HT) has been reported to enhance or depress food intake. Similarly, conflicting results have been obtained following the administration of the scrotonergic been obtained following the administration of the serotonergic neurotoxin 5-6-dihydroxytryptamine (5-6-DHT). As a part of a larger effort in pharmacological modelling of the feeding system, we depleted 5-HT in the rat by injecting 5-6-DHT (75  $\mu$ g) or vehicle (0.1% ascorbic acid) into the right lateral ventricle. At least ten days were allowed for recovery. During normal feeding, the 5-6-DHT animals ate 26.8 g/24 hrs (80% nocturnal) and the shams ate 27.6 g/24 hrs (82% nocturnal). Spontaneous nocturnal feeding was measured after s.c. injections of naloxone (0-5 mg/kg) and after i.p. injections of cholecystokinin-octapeptide (CXK, 0-20 µg/kg) and calcitonin (0-40 Units/kg). In a separate experiment, daytime feeding was induced by the s.c. injection of ketocyclazocine (KC, 0-10 mg/kg). At one hour after injection, sham and 5-6-DHT rats were approximately equal in their Subjective to the fraction of the set of th suggest that 5-m depiction may have caused slightly decreased sensitivity to the feeding effects of CCK and calcitonin, possibly indicating a partial role for serotonin in the mediation of their actions. Responses to an opiate agonist (KC) and antagonist (naloxone) were essentially unchanged, if not improved, by 5-HT depletion. At sacrifice, there were no difference in the control between the 5-6 CMT work of the second differences in ir-dynorphin between the 5,6-DHT and sham animals in the anterior cortex, striatum, hypothalamus, brain stem and thalamus. Further use of selective neurotoxins may provide valuable insights into the mechanisms of feeding and satiety.

59.9 Binge-eating Following Chronic, Continuous Administration of

Binge-eating Following Chronic, Continuous Administration of Picrotoxin. R. E. Davis and G. D. Ellison. Dept. of Psycho-logy, University of California, Los Angeles, CA 90024 Gamma-aminobutyric acid (GABA) may play a role in the con-trol of appetite and other food-related behaviors in animals. Yet, the effects of chronic GABA deficiencies on appettive behavior have not been extensively studied. We have developed techniques for the chronic continuous administration of picro-toxin, an antagonist of GABA-mediated changes in membrane chloride-ion conductance. Using these techniques we examined the long-term consequences of continuous picrotoxin treatment on variety of consummatory behaviors. Male, Long-Evans hooded rats (280-320) were housed indivi-dually with food and water available ad libitum except as noted. Picrotoxin was administered continuously for 10 days via chronically indwelling silicone reservoirs. Twenty-four hour food and water intake was monitored during the 10 days of picrotoxin administration and for the next 28 days following

picrotoxin administration and for the next 28 days following cessation of treatment. All animals were then food-deprived for 24 hours. After this the food was replaced and hourly food and water intake measures were taken. In addition, the number of food-pellets eaten and the average weight of food pellets was recorded.

Chronic, continuous picrotoxin treatment did not alter 24 hr food or water intake during or after drug treatment nor did it alter the body weights of the treated animals. However, this drug regimen did alter food and water intake following food-deprivation. Picrotoxin-treated animals consumed more food, sampled more food pellets and drank more water during the first 4 hrs after reintroduction of food. During the next 20 hrs food and water intake decreased in compensation for the overconsumption in the preceding period. These data suggest that chronic, GABA deficiencies do not influence the long-term regulation of food and water intake or body weight. However, such neurochemical deficiencies may be immortant to short-term Chronic, continuous picrotoxin treatment did not alter 24 such neurochemical deficiencies may be important to short-term energy regulation and the control of appetite.

SELECTIVE ANTAGONISM OF THE DIPSOGENIC, BUT NOT THE ANOREXIC. 59.8 ACTION OF SYSTEMIC SEROTONIN BY METHYSERGIDE: COMPARISON WITH DIHYDROERGOTAMINE AND OTHER SEROTONIN ANTAGONISTS. K.J. Simansky and T.A. Connell\*. Dept. of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129

Peripheral administration of serotonin increases drinking and decreases food intake in rats. These behavioral effects of systemic serotonin are mediated by different neural mechanisms because bilateral subdiaphragmatic vagotomy blocks the dipsogenic, but not the anorexic, action of this monoamine (Simansky, , тhe Bourbonais, & Smith, Soc. Neurosci. Abs., 1982, 8:605). The present study examined whether the pharmacologic mechanisms of the dipsogenic and anorexic actions of serotonin also differed.

We determined the effects of four doses of methysergide (5-40 umoles/kg, IP), an ergot amide antagonist of serotonin, on drinking produced by a 10 umole/kg (SC) dose of serotonin in male rats. The rats had free access to food pellets and water except during The drinking test-when food was removed. Rats injected with serotonin (n=6) drank  $14.0 \pm 1.4$  ml/kg during the two-hour test period. Administration of methysergide (n=6/dose) 30 min prior to period. Administration of methysergide (n-0/dose) so min priod set of serotonia model a dose-related decrease in drinking ( $F_{L-2}$ = 7.1;  $\mathbf{p}^{\boldsymbol{\xi}}$ .01). The apparent ID<sub>50</sub> for the antagonism of the dipsögenic response by methysergide was 10 umole/kg ( $\mathbf{p}^{\boldsymbol{\xi}}$ .01). In contrast, methysergide (15 umole/kg; n=8) failed to affect the anorexic action of serotonia (n=7) on 30-min intake of a liquid milk diet of for 1/2 for domination. action of serotonin (n=7) on 30-min intake of a liquid milk diet after 17-h food deprivation. Serotonin reduced eating by 32% ( $\rho$  < .05) compared to control intake (17.1 ± 2.3 ml). Methysergide altered neither the inhibition of feeding produced by serotonin (-35%) nor the baseline intake of rats injected with saline (17.5± 1.7 ml). In this same experiment, however, methysergide decreased the 2-h water intake of rats injected with serotonin by 36%. Dihydroergotamine (.5, 5 and 50 umoles/kg, IP), an ergot

peptide antagonist of serotonin and  $\ll$ -adrenoreceptors, also failed to antagonize the effect of serotonin on feeding, but the highest dose reduced drinking by 49%. In contrast, neither ketanserin (1-8 umoles/kg) nor the putative peripheral serotonin antagonist, xylamidine (1.8-20 umoles/kg 4 h prior to serotonin) antagonized the drinking produced by serotonin.

Our results demonstrate that the dipsogenic and anorexic effects of systemic serotonin are mediated by different pharmacologic mechanisms. Moreover, the selective antagonism of the dipsogenic effect of serotonin by the ergot derivatives, but not ketanserin or xylamidine, suggests that this behavioral action of serotonin is mediated by a distinct class of peripheral receptors. Supported by research funds from the Dept. of Public Welfare of the Commonwealth of Pennsylvania to KJS.

60.1

CHOLECYSTOKININ OCTAPEPTIDE DOES NOT DIFFERENTIALLY INHIBIT SHAM FEEDING OF SUCROSE DURING THE DAY AND NIGHT PHASES OF THE RAT'S

DIURNAL CYCLE. J.A. DiPoala\*, J.A. Goldstein\* and F.S. Kraly (SPON: W.E. Edmonston). Psychology Dept., Colgate Univ., Hamilton, NY 13346

The satiating potency of exogenous cholecystokinin octapeptide (CCK-8) varies diurnally when rats eat milk normally and when they (CCK-8) varies diurnally when rats eat milk normally and when they sham feed (pregastric stimulation of oropharynx and esophagus) liquid diet 116EC. The satiating potency of CCK-8 also varies inversely with the concentration of sucrose sham fed during the day phase. To determine whether CCK-8 differentially inhibits sham feeding of sucrose during the day and night, we tested rats sham feeding various concentrations of sucrose at the midpoints of the day and night phases after 1.p. CCK-8.

the day and night phases after i.p. CCK-8. Sprague-Dawley male rats (n=13; 400-600g), equipped with stain-less-steel gastric cannulas, were deprived of food for 20 hr prior to testing. Rats sham fed (with open gastric fistula) sucrose (2.5, 5 or 10% w/v) for a 30-min test which began immediately after i.p. 9% NaCl or CCK-8 (1 or 2 µg/kg). Rats sham fed at the midpoints of the day and night phases of a 12:12-hr cycle. The inhibition of sham feeding by CCK-8 was related to the con-centration of sucrose for both the 1 and 2 µg/kg doses: The per-centage inhibition of sham feeding was inversely related to the concentration of sucrose with the exception of the inhibition score for the effect of 2 µg/kg CCK-8 upon 5% sucrose sham fed during the day (Table 1). Table 1 (Median percentage inhibition)

Table	1 ()	Median	percentag	ge inhibi	tion)
1	μg/l	kg CCK-	8	2 µg/k	g CCK-8

Sucrose	Day	р	Night	Day	р	Night	
2.5%	60	ns	64	41	ns	50	
5%	35	ns	34	5	.065	44	
10%	29	ns	30	35	ns	24	
m) 0.000 (							-

The CCK-8 did not differentially inhibit sham feeding of su-crose during the day <u>vs</u>, night for each concentration of sucrose and for both doses of CCK-8, with the exception of the effect of 2  $\mu$ g/kg CCK-8 upon sham feeding of 5% sucrose: This dose produced less inhibition of sham feeding during the day than at night, but this difference did not reach statistical significance (Table 1). In summary, there was no systematic differential effect of CCK-8 upon sham feeding or in the day up night.

CK-8 upon sham feeding of sucrose in the day vs. night. Because CCK-8 is reported to have differential effects in the day vs. night when rats eat sweet milk normally and when they sham feed a complex sweet liquid diet (GIBCO 116EC), the findings reported here suggest that the interaction of CCK-8 with pregastric stimulation by sucrose (i.e., sweet taste) is not the primary factor determining the diurnal variation in the satiating potency of exogenous cholecystokinin in the rat.

- Brief Exposure to a Saline Stimulus Promotes Latent Learning in the Salt Hunger System. Robert E. Breger, Nick Strombakis and Robert W. Allan Dept. of Psychology N.Y.U. and Jay Schulkin Dept. of Anatomy, Univ. of Penn. (Spon. George Wolf) We all seem to learn things incidentally, and then later exploit the knowledge when it is useful to us. Yet this phenomenon, so evident to us in our sense of our daily life, was difficult to demonstrate in the laboratory (but see Rescorla 1981). Then, in an experimental setting using the salt hunger system, Krieckhaus and Wolf (1968,70) showed that salt hungry rats would remember how or where they found saline in **the** past even though they had no need for it at the time. In this and other studies the rats were given many repeated exposures to the saline and over a long period of time. **But** in one study Wirsig and Grill (1982) discovered that a strikingly brief exposure to the saline produced the 60.3 Brief Exposure to a Saline Stimulus Promotes Latent Learning that a strikingly brief exposure to the saline produced the same effect. We thought this phenomenon important and in this preliminary study, we also found that in an innate modular system, like salt hunger, a brief exposure to the saline is sufficient to trigger such learning. Rats were trained to bar press for water in a Skinner box when they were thirsty. Then, they were given 5 reinforcements of .05 ml of .15 molar saline instead of water within a five minute period on two successive days. Rats were them made salt hungry for the first time in their lives and then tested in the Skinner box under extinction conditions. They were not deprived of water at this time. We found that resistance to
  - extinction was about four times higher in these rats than in control rats which were treated identically except that they had never received the saline in the Skinner box.

60.2 CHOLECYSTCKININ, SUBDIAPHRAGMATIC VAGOTOMY AND FOOD INTAKE IN THE (SpOLDEN HAMSTER, <u>E. S. Corp\*, D. A. Fitts\* and S. C. Woods.</u> (Spon: G. Clark). Dept. of Psych., University of Washington, Seattle, WA 98195.

Golden hamsters (<u>Mesocricetus</u> <u>auratus</u>) are known to be in-sensitive to a variety of stimuli which increase (food depriva-tion, 2-deoxy-D-glucose) or decrease (naltrexone, dexamethasone) food intake (FI) in rats. By contrast, treatments such as in-sulin and progesterone stimulate feeding in both species. We now report that the octapeptide of cholecystokinin (CCK) suppresses meal size in hamsters in a dose-related fashion, as it does in rats.

Hamsters (n=39, 4-6 wks old) were adapted to a daily, 3-hr deprivation of food and to intraperitoneal injections of .15 M saline. FI was measured for 30 min immediately following the injection. On the test day, hamsters were given an injection of CCK or saline. Percentage change from the preceding day's postfast meal size showed a dose dependent suppression [F(4,34)=8.82, p<.001].

-	Dos	se of CO	K (ug/kg)		
	0	1.45	2.9	5.8	12.0
% Change	+24.1	-32.7	-38.7	-58.2	-67.3
± SEM	(14.4)	(6.9)	(12.5)	(4.8)	(15.5)
r the lowest	doco but	not the	highor de	eog th	o cuppro

For ession of FI in hamsters is comparable to that generally reported in rats. FI returned to baseline levels on the day following the test. In rats, subdiaphragmatic vagotomy attenuates the suppression

of FI by peripheral CCK administration (Smith, G. P. et al., Science 213:488, 1981). In a second experiment, 18 hamsters from Science 213:488, 1991). In a second experiment, 18 nameters from experiment 1 received either a vagotomy or a sham surgery (lap-arotomy without vagal transection). Vagotomy was verified by anatomical inspection. After one week of recovery, the animals were again adapted to the 3-hr food deprivation procedure. Con-trol 30-min FI for the post-fast meal was not significantly different from the levels attained prior to surgery. Injections of COX (12 tr d/m) into the char ground or procedure or more than a more of CCK (12  $\log/kg$ ) into the sham operated group resulted in a mean percentage reduction of -59 ±8.4%SEM, with nine of nine animals reducing meal size (range -85% to -8%). Of the vagotomized hamsters, four increased FI to CCK, while five reduced FI, for a net suppression of -22 ±19.3%SEM (range -90% to +62%). No sig-nificant difference from the sham controls was observed, owing to the variability in the response after vagotomy.

These results show a clear effect of CCK on short-term food intake in hamsters, although the role of the vagus nerve in mediating this effect is not conclusively demonstrated. Supported by HL 21800.

60.4 EFFECT OF PERIPHERAL PROSTAGLANDIN E, ON SODIUM INTAKE AND EXCRETION OF ADRENALECTOMIZED RATS. K. M. Skoog, Michelle Muggli\*, and Nancy J. Kenney. Department of Psychology, University of Washington, Seattle, WA 98195. Intraperitoneal (IP) injection of 10-100 ug/kg prostaglandin E, (PGE<sub>2</sub>) is effective in reducing intake of a 1.5% NaCl solution by intact rats maintained on sodium deficient food (Moe & Kenney, Neurosci. Abs., 1981). The following experiment was conducted to determine if IP PGE, treatment would reduce sodium intake of adrenalectomized (ADX) rats in which the need for salt is elevated. Six rats were maintained on sodium. solution in the of adrenate commerced (ADA) rates in which the meet for sail is elevated. Six rates were maintained on solumi-replete laboratory chow and presented with a 1.5% NaCl solution for 2 hr each day. After a 7-day adaptation period, all of the rates were adrenalectomized. PGE, was administered IP in doses of 5, 10, 50 and 100 ug/kg immediately prior to sodium-solution corrections. access. Sodium intake and urine sodium concentrations were measured over the next 2 hr and at the end of the 24-hr following injections. PGE, test days were separated by at least 2 control days on which the carrier solution for the PGE was injected.

was injected. ADX rats fed sodium-replete chow reduced their total 2-hr sodium-solution intakes following administration of either 50 (F(2,12)=5.80, p<.05) or 100 (F(2,12)=3.49, p<.05) ug/kg PGE\_, Following the administration of 10 ug/kg PGE\_, sodium-solution intakes of ADX rats were reduced for the first 15 min (F(2,12)=5.02, p<.05) but returned to control levels within 20 min after the injection. Sodium intake from food was unaffected by any dose of the PGE tested. Corresponding to the decreases of sodium-solution intake, urine sodium concentrations were reduced during the 2-hr immediately following administration of 50 (F(2,12)=3.18, p<.05) or 100 ug/kg (F(2,12)=4.86, p<.05) PGE\_. Urine volumes tested. Apparent sodium balance (total Sodium intake from the solution and from food - excretion of sodium in urine) was unaffected by any PGE\_ treatment.

unaffected by any PGE, treatment. Thus, although the dose required to effectively reduce sodium intake of ADX rats may be higher than that required to reduce intake of intact animals fed sodium-deficient chow, IP PGE<sub>2</sub> does suppress sodium intake to ADX rats.

ALDOSTERONE AND BODY FAT. L. D. Devenport, K. G. Goodwin\*, P. M. Hopkins\*, G. L. Manes\*, and K. L. Oltmanns\*. Depts. Psych-ology and Zoology, University of Oklahoma, Norman, OK 73019. Long-term aldosterone (ALD) injections elevate food intake and body weight in rats in the absence of measurable fluid retention (Devenport et al, Behav. Neurosci., in press), suggesting an ac-celerated body fat accumulation. And because body weight gains in ALD rats occur even when pair-fed we have suggested that aldosterone may inhibit lioplysis and/or enhance lipogenesis 60.5

in ALD rats occur even when pair-fed we have suggested that aldosterone may inhibit lipolysis and/or enhance lipogenesis (Devenport et al., Neurosci. Abstr., 1982). The present studies sought to determine if the weight gains of ALD-treated animals could be attributed to body fat and if this hormone impedes the mobilization of fat stores during starvation. For the first question, 44 d male rats were adrenalectomized (ADX) and implanted with continuous infusion devices (Alza Corp.)

(ADX) and implanted with continuous infusion devices (Alza Corp.) that provided sustained release of one of 6 doses of ALD (1.3- $10.4_{\mu}g/hr$ ) against a constant background of corticosterone (CRT). Other animals received only CRT. Following 13 d of free-feeding, the rats were exsanguinated by decapitation for RIA determination of ALD levels. These values ranged from 0-.5-750ng/ml. Most importantly, a significant increase in epididymal fat pad mass was found to accompany ALD administration, peaking at moderate doses and falling off at high doses. These changes paralleled differences in total body weight. In order to address the question of lipolysis, 350 g male ADX

In order to address the question of lipolysis, 550 g male ADA rats were implanted with infusion pumps containing maximally effective doses of ALD ( $2.6_{\mu g}$ /hr from previous study), CRT, a combination of these hormones, or no replacement at all. Two experiments were conducted. In one, rats were placed on a severely limited feeding regimen; in the other they were totally deprived. Although these were terminal deprivation experiments, animal disconfort was minimed by being import death on the animal disconfort was minimized by basing imminent death on the appearance of hypothermia. Rectal temperature was monitored every 8 hr and when it dropped by  $35^{\circ}$ C the rats were sacrificed by anesthetic overdose and autopsied. All measurements including anesthetic overdose and autopsied. All measurements including body temperature were taken without knowledge of hormone assign-ment. Regardless of deprivation condition, ALD alone and in combination with CRT significantly hastened the onset of hypo-thermia as compared to the other groups. Some ALD-infused rats became hypothermic in less than 24 hr. Besides bearing heavier fat pads at autopsy, the ALD rats lost weight at a rate signi-ficantly slower than that of other groups. Since this same dose of ALD increased body weight and fat pad mass in free-feeding rats, we suggest that ALD shifts the balance of fat metabolism toward lipogenesis and away from lipolysis. This chronic diversion of calories away from lean body mass may account for ALD's stimulation of hunger. Supported by NIH Biomedical Research Support Grant.

LIMITATIONS OF MEAL SIZE DO NOT PREVENT OVEREATING AND WEIGHT GAIN FOLLOWING OVARIECTOMY. Naomi J. Tomoyasu\*, David B. West, and Nancy J. Kenney. Department of Psychology, University of 60 7

LIMITATIONS OF MEAL SIZE DO NOT PREVENT OVEREATING AND WEIGHT GAIN FOLLOWING OVARIECTOMY. Naomi J. Tomoyasu\*, David B. West, and Nancy J. Kenney. Department of Psychology, University of Washington, Seattle, WA 98195. Ovariectomy results in an increase of food intake primarily due to an increase of meal size. Since ingestion of a fixed caloric load in a few, large meals results in greater fat deposition than eating the same number of calories over many smaller meals, the obesity following ovariectomy may be due in part to the shift of meal pattern toward larger meals. To examine this possibility, the effect of restriction of meal size on weight gain and total food intake following ovariectomy was examined. Spontaneous meal patterns of 11 adult, female Long-Evans rats were monitored over a 5-day baseline period. Noyes pellets were available ad libitum by means of a pellet-detecting eatometer and meal size and intermeal interval were recorded by means of a microcomputer. At the end of this baseline period, all rats were ovariectomized. Six ovariectomized (OVX) rats were then returned to the ad-libitum feeding situation. For the remaining 5 OVX rats, meal size after ovariectomy was limited to a maximum of 80% of their average presurgery meal size. Separate meal-size limitations were imposed for the light and the dark portions of the light:dark sequence. Meal frequency and total food intake were not restricted. Body weight was monitored for 10 days after ovariectomy and meal pattern recorded for days 6-10 post-surgery. OVX rats with ad libitum pellet access showed significant

OVX rats with ad libitum pellet access showed significant 0VX rats with ad libitum pellet access showed significant increases of rate of weight gain, total food intake, and meal size compared to presurgery measures. Restriction of maximum meal size of 0VX rats to 80% of presurgery average meal size did not prevent either the increase of body weight or the increase of total food intake. The increase of rate of weight gain and the increase of total food intake of restricted 0VX rats did not differ from those of free-feeding 0VX animals. Following gonadectomy, the rate of weight gain of the free-feeding 0VX rats averaged  $1.9 \pm 1.0$  g/day while that of the free-feeding 0VX rats averaged  $2.0 \pm 0.5$  g/day. Meal-size restricted 0VX animals increased their daily food intake by an average of 28.1  $\pm 7.1\%$  compared to an average increase of  $27.7 \pm 6.8\%$  for the free-feeding 0VX rats. Thus, the increase of average of  $28.1 \pm 7.1\%$  compared to an average increase of  $2/./ \pm 6.8\%$  for the free-feeding OVX rats. Thus, the increase of body weight following ovariectomy is apparently not dependent upon an increase of meal size. Increases of both food intake and body weight are observed following ovariectomy even if artificial meal-size limitations are imposed. Supported by funds from the Graduate School of Arts and Sciences of the University of Washington.

DOSE DEPENDENT REGULATION OF VOLUNTARY INTRAVENOUS INSULIN INTAKE IN THE STREPTOZOTOCIN-INDUCED DIABETIC RAT. <u>E.K. Walls\* and T.B.</u> <u>Wishart</u>. Dept. of Psychology, Univ. of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0. Although intravenous self-administration if insulin has been observed to be stable in normal rats, insulin intake increased initially and then paradoxically decreased to levels well below the prediabetic intake when these rats were made diabetic (Jouhaneau, J., & LeMagnen, J., Physiol. Behav., 20, 739, 1978). Recently it has been shown that diabetic rats rapidly learn to regulate their insulin intake when they have previous experience with a food delivery operant lever and are in a relatively stable metabolic state as a result of daily subcutaneous Lente Insulin treatment (Walls, E.K., & Singer, G., <u>Proc. Int. Conf. Physiol.</u> <u>Food & Fluid Intake</u>, Melbourne, 1983). To determine the capability of the diabetic rats to regulate its insulin intake six streptozotocin-induced diabetic rats with

To determine the capability of the diabetic rat to regulate its insulin intake six streptozotocin-induced diabetic rats with chronic vena caval catheters were maintained throughout the experiment with 1.2 U of regular insulin/day infused continuously at a rate of .05U/hour. In addition to the chronic infusion, rats were given continuous access to two operant levers; one delivering 45 mg food peliets and the other delivering a fixed bolus infusion containing .0125U, .025U, or .050U of regular insulin. All rats initially learned to self-administer insulin with the .025U does for a period of at least 6 dows and wore them insulin. All rats initially learned to self-administer insulin with the .025U dose for a period of at least 5 days and were then tested for periods of 5 days with each of the .0125U and .050U infusions. Compared to the .025U condition, daily infusions were significantly increased 53% in the .0125U condition. However, daily voluntary insulin intake did not differ significantly across infusion conditions suggesting that diabetic rats compensate for insulin dosage. Because daily water intake accurately reflects urinary glucose excretion as a result of urine volume, it was used as a measure of metabolic stability. Daily water intake within the .025U conditions respectively.

In addition to the finding that insulin self-administering diabetic rats learn to regulate their insulin intake in a dose dependent manner, reduced water intake reveals that substantial therapeutic benefit may accrue from voluntary insulin intake in the diabetic mat

the diabetic rat. Supported by: N.S.E.R.C. to T.B. Wishart and a Saskatchewan Health Research Board Post-Doctoral Felloship to E.K. Walls.

OVARIECTOMY INFLUENCES DIETARY SELF SELECTION DIFFERENTLY AS A 60.8 FUNCTION OF AGE OF THE RAT AT SURGERY. D. A. VanderWeele and V. I. Pulido\* Dept. of Psychol., Occidental College, Los Angeles, CA 90041.

Several studies have assessed the effects of ovariectomy (OVX) upon self selection of dietary macronutrients in rats. Geiselman, et al, found that OVX reliably increased animal's intake of fat while decreasing carbohydrate consumption but Kanarek, et al, found no effects of OVX on macronutrient selection. Recently, Bartness, et al, have reported that carbohydrate intake was in creased following OVX while fat ingestion was decreased and they indicated that OVX might produce preferences for more calorically dense diets. Other variables differ among these studies but age of the animal at OVX might be important. In Geiselman's study, rats were neonatally OVX while, in the others, adults were surgically altered.

We OVX rats at 3 days of age (n=4), or as adults (n=10) or gave them sham surgery (n=6). As adults, all animals were exposed to dietary regimes of solutions of 30% sucrose, 15% casein, pure vegetable oil and a mixture of alphacel, vitamins and essential inorganic salts, each in separate containers. Animals were then allowed to self select diets while separate nocturnal and diurnal ingestions were recorded and body weight gain noted. In-take data and body weight changes were analyzed by ANOVA.

Analyses showed no significant effects on macronutrient selection when rats were OVX as adults, however, there was a tendency to increase fat intake in spayed animals. OVX animals did display macronutrient preferences; see Table below. Rats OVX as neo-nates showed a significant elevation in fat and a decrease in carbohydrate intakes when adults. Comparisons appear in the Table. Both groups of OVX animals showed mild hyperphagia and increased body weight; body weight: neonate OVX=361+15.2, adult OVX=348.5+ 9.8, control=326+13.5 g. Rather than conclude that OVX induces rats to eat more calorically dense diets (an explanation of their increased weight), we conclude that removing estrogen during its organizational as opposed to its activational period, induces the rat to select diets high in fat (most often more calorically dense).

TABLE: % of nutrient intake as this macronutrient: CARBOHYDRATE PROTEIN

LUT	CARDONIDRATE	TROILIN
59.6%	30.2%	10.2%

61.1 PERIPHERALLY-ADMINISTERED CAPTOPRIL: EFFECTS ON SODIUM APPETITE. K. E. Moe, M. A. Stevenson\* and A. N. Epstein. Dept. of Biology, University of Pennsylvania, Philadelphia, PA 19104.

In experiments designed to assess the role of the hormone angiotensin II (Ang II) in the arousal of sodium appetite (natriorexia), we have previously shown that peripheral administration of captopril (a blocker of Ang I $\rightarrow$  Ang II) at doses which block Ang II formation only in the periphery enhances depletion-induced sodium appetite but that higher doses which block conversion universally suppress it. This suppression is not the result of malaise or behavioral incompetence.

To examine the specificity of these effects, animals exhibiting a mineralocorticoid-elicited sodium appetite were infused with captopril (Squibb). This form of sodium appetite is independent of the renin-anglotensin system.

Rats received daily subcutaneous injections of 2 mg deoxycorticosterone acetate (DOCA), a precursor of aldosterone, which produced a reliable sodium appetite (intake > 4 ml of 3% NaCl in a daily 1-hr test). Some were subsequently infused continuously through jugular vein catheters with saline for 2-3 days, followed by 22-hr IV infusion of 15 mg/hr captopril, a dose shown previously to reliably suppress depletion-induced sodium appetite. It had no effect on DOCA-induced sodium appetite.

b) to teriably suppress depiction induced solium appetite. It is no effect on DOCA-induced solium appetite. Other rats showing the DOCA-elicited appetite received a much lower dose of captopril administered in the drinking water (0.1 mg/ml) rather than IV, a procedure which enhances depletioninduced appetite and which can generate a sodium appetite in otherwise untreated rats. As reported here, this dose of captopril also enhanced DOCA-induced sodium appetite (average increase = 68%).

These results support the synergy hypothesis (Fluharty & Epstein, 1980) which proposes that during sodium deprivation or loss the two hormones aroused by sodium depletion, aldosterone and Ang II, act synergistically on the brain to produce sodium appetite, and which acknowledges that a very high level of either hormone is sufficient to arouse the appetite. Thus, universal blockade of endogenous angiotensin formation (by 22-hr of 15 mg/hr captopril IV) does not suppress the sodium appetite elicited by excess amounts of mineralocorticoid. The enhancement of the appetite by a treatment with captopril which blocks angiotensin formation only in the periphery (0.1 mg/ml in the drinking water for 1 night) is best explained by a "spillover" hypothesis; that is, the increase in peripheral Ang I known to result from this treatment can "spill over" into the brain where, in the absence of captopril, it can be converted to Ang II and can add its natriorexigenic effect to a pre-existing DOCA-induced sodium appetite. Supported by NS 03469 and MH 15092.

61.3 SUPPRESSION OF SODIUM APPETITE BY INTERFERENCE WITH THE CEREBRAL ACTION OF ANCIOTENSIN. Jacob F. Schultz\* and Alan N. Epstein. Dept. of Biology, Univ. of Pennsylvania, Philadelphia, PA 19104. If a synergy of angiotensin (Ang) and aldosterone is the cause of sodium appetite (Epstein, A.N., <u>Peptides</u> 3: 1983) then prevention of the action of endogenous Ang should suppress it and the suppression should be especially effective in animals in which aldosterone can not participate. This prediction was successfully tested in 5 adrenalectomized rats drinking excess volumes of 3% NaCl. The animals had been treated with dexamethasone (20 µg/day, sc) for at least 3 days before the experiment began. Their appetites for salt were reduced by 83% by continuous (overnight) intracerebroventricular (cICV) infusion with a dose of captopril (120 ng/hr) that was sufficient to block conversion of Ang I to Ang II in the cerebral ventricles. Concurrent water intakes were reduced by 55%.

To address the question of specificity we induced another type of salt appetite in 4 adrenalectomized rats. They were treated with deoxycorticosterone acetate (2-6 mg/day, sc, 4-6 days) until their preexisting salt appetite was abolished and then replaced by a DOCA-induced appetite. Indentical (cICV) infusion of captopril did not reduce that appetite.

The recent suggestion (Weisinger, R.S. et al., <u>Amer. J. Physiol.</u> 242: 1982) that CSF Na<sup>+</sup> is crucial for salt appetite was tested with overnight (cICV) infusion of hyperosmotic NaCl (0.2 M to 1.0 M at 5  $\mu$ /hr). It did not reduce the established appetite for 3% NaCl in 4 adrenalectomized rats.

These results encourage the proposal that in the adrenalectomized rat, hungry for salt, sodium appetite is dependent on the cerebral action of Ang II.

61.2 SODIUM APPETITE INDUCED BY SODIUM DEPLETION IS SUPPRESSED BY INTRACEREBROVENTRICULAR CAPTOPRIL. <u>M. Weiss\* and A.N. Epstein</u> (SPON: G.B. Koelle). Dept. of Biology, Univ. of Pennsylvania, Philadelphia, PA 19104.

Augiotensin and aldosterone are the hormones of sodium conservation. Their levels in plasma rise during sodium depletion and they play important roles in the renal retention of sodium. We have suggested elsewhere (<u>Peptides</u>, <u>3</u>: 1983) that the sodium appetite of sodium depletion may be aroused by their synergistic actions, and have shown in recent work (Fluharty & Epstein, <u>Behav</u>. <u>Neurosci</u>.) that an appetite can be rapidly and reliably aroused in the sodium replete rat by treatment of it with both angiotensin and aldosterone (given as its precursor DOCA). In work described here the role of angiotensin in the arousal of sodium appetite was studied with captopril, a competitive inhibitor of angiotensin converting enzyme, administered directly into the cerebral ventricles of sodium depleted rats at doses sufficient to block angiotensin formation in the brain. Sodium depletion was produced by furosemide (10 mg, sc) followed by sodium deficient diet in rats fitted with intracerebroventricular (ICV) cannulae, through which they were infused overnight with captopril (1.2 ng, 12 ng, 120 ng, 1.2 µg/hr) or its vehicle during the entire 18-hr depletion period (when sodium is not available) and during a subsequent 2 hr sodium appetite test when 3% NaCl was offered. This was followed by confirmation of the Ang I to Ang II blockade by failure of dipsogenic response to pulse ICV Ang I, followed by drinking to pulse ICV Ang II. The experiment was repeated (1.2 µg/hr captopril, CICV) in sodium replete rats in which a sodium appetite had been raised with excess DOCA (2 mg/day, 1 week).

Depletion-induced sodium appetite, but not overnight food and water intake or the sodium appetite induced by DOCA, was reduced in a dose related manner by the 12 ng, 120 ng, 1.2 µg/hr doses. The highest dose (12 µg/hr) had nonspecific effects on overnight water intake. The lowest dose (1.2 ng/hr) failed to block Ang I to Ang II conversion and did <u>not</u> block the salt appetite. The 1.2 µg/hr dose did not alter sodium excretion.

Thus, the infusion of captopril into the ventricles of the rat at doses that block conversion of Ang I to Ang II suppresses the sodium appetite induced by sodium depletion without reducing the animals behavioral competence to eat or drink overnight, or to drink 3% NaCl when a sodium appetite is induced by high doses of DOCA.

The cerebral action of angiotensin II may be essential for the arousal of sodium appetite.

61.4 COMPARISON OF INTRACEREBROVENTRICULAR AND INTRAVENOUS ANGIOTENSIN II ON THE NA APPERITE OF NA-REPLETE SHEEP. R.S. Weisinger\*, D.A. Denton\*, M.J. McKinley\*, J.B. Simpson and E. Tarjan\*. Howard Florey Institute, Univ. of Melbourne, Australia.

Previous research from this laboratory has shown that intracerebroventricular (IVT) infusion of angiotensin II (AII) causes increased Na intake of Na-replete but neither IVT nor intravenous (IV) infusion of AII cause increased Na intake in Na-deplete sheep. The present experiments evaluated the effect of IVT or IV infusion of AII on Na intake of Na replete sheep with limited Na access. In the present experiments, sheep were trained to bar press for water (50 ml/delivery) and 0.5M NaCl (12.5 mmol/delivery). Water was available continuously while Na was available for 2h/day. At the end of a Na access period a 48h IVT infusion of AII (3.8  $\mu$ g/h) or IV infusion of AII (24  $\mu$ g/h) was begun. Thus, the effect of AII on urinary Na loss as well as subsequent Na intake (i.e., after 22 and 46h of infusion) could be determined.

IVT infusion of AII caused a marked increase both in Na excretion and in Na intake. Without infusion of AII, the sheep bar pressed for 3.6  $\pm$  0.7 deliveries or 45 mmol of Na. During IVT infusion of AII, Na intake was increased (p's <0.001) to 220 mmol of Na on day 1 and 335 mmol of Na on day 2. Daily Na deficit caused by urinary loss prior to the two Na access periods were 250  $\pm$  96 and 295  $\pm$  73 mmol. For the two days of infusion combined, there was a significant correlation (r(8) = 0.73, p<0.02) between Na deficit (273  $\pm$  57 mmol) and Na intake (278  $\pm$  44 mmol). IV infusion of AII caused an increase both in Na excretion and Na intake. Without infusion of AII, the sheep bar pressed for 3.4  $\pm$  1.1 deliveries or 42 mmol of Na. During IV infusion of AII, Na intake was increased (p's <0.001) to 205 mmol of Na on day 2. Na deficit prior to the first Na access period was 75  $\pm$  37 mmol. No Na deficit was evident prior to the second Na access period.

These results demonstrated that IV infusion of AII can cause increased Na intake in Na-replete sheep in excess of previous loss. In addition, the increase in Na intake caused by IV infusion of AII was similar to that produced by IVT infusion of AII even though only the latter infusion was clearly associated with a marked Na deficit. One possible interpretation of these data is that the IV as well as the IVT hormone acted at neural structures involved in salt appetite located outside the blood-brain barrier (e.g., circumventricular organs). AII infused IVT could have acted at additional loci within the blood-brain barrier, thus inaccessible to the circulating hormone, to provoke the Na deficit. 61.5 TOGETHER INTRACRANIAL ANGIOTENSIN AND SYSTEMIC MINERALOCORTICOID PRODUCE AVIDITY FOR SALT. D.-M. Zhang\*, E. Stellar and A. N. Epstein (SPON: J. M. Sprague). Depts. of Anat. and Biol., Univ. of Pennsylvania, Philadelphia, Pa. 19104. These experiments use runway performance rewarded by minute volumes of 3% NaCl as a measure of increased avidity for salt.

These experiments use runway performance rewarded by minute volumes of 3% NaCl as a measure of increased avidity for salt. They were undertaken to assess the power of the synergy hypothesis to predict the appetitive as well as the consumatory aspects of the motivation that yields a sodium appetite.

Adult, male Sprague-Dawley rats were first trained under 23 hrs. water deprivation to run to a small water reward (2 drops) at the end of a one-meter runway. 18 rats were then implanted with intracerebroventricular (ICV) cannulas, were injected with different doses of angiotensin, for each of 3 days, and were allowed to run the runway to either water rewards or 3% sodium chloride rewards. These tests were repeated when the animal received no angiotensin but was primed for 3 days with subcutaneous DOCA (500 µg) intercione. and when it received DOCA Days [CV projecteries (60 pc)

but was primed for 3 days with subcutaneous DOCA (500 µg) injections, and when it received DOCA plus ICV angiotensin (60 ng). The major finding is that when Ang II and DOCA are used together, the animal runs for 3% NaCl and the effect appears to last for 60 minutes whereas DOCA or Ang II alone do not compel the animal to run for salt. Adding DOCA to Ang II produces only a slight potentiation of running forwater. While running speed to water is twice the running speed to 3% NaCl under all conditions, it is clear that only the combined treatment with Ang II and DOCA produces a robust appetitive response to 3% NaCl. The combination of treatments with doses of 1) systemic DOCA that are top low to elicit the search for strong salt solutions, and 2)

The combination of treatments with doses of 1) systemic DOCA that are too low to elicit the search for strong salt solutions, and 2) intracranial angiotensin that does not lead to an approach to salt, produces a remarkable change in the animal's behavior. It now leaves the start-box and runs the runway for the taste of salt. The treatment with angiotensin and a mineralocorticoid has aroused appetitive behavior for salt.

apetitive behavior for salt. Our animals were replete with sodium throughout the experiment. They were eating standard lab diet which is rich in NaCl. They had been treated for several days with a hormone that promotes renal conservation of sodium. And the behavior of salt seeking occurred within minutes after intracranial injection of angiotensin, long before it could have had natriuretic effects. The animals were therefore seeking salt that they did not need. These results are compatible with the idea that the brain is apprised of the need for salt not by salt depletion but by asynergy of the hormones that are mobilized to reverse the depletion. By showing that the two hormones of sodium conservation generate salt-seeking behavior when given together at doses that are each too low when given alone to alter behavior toward salt, these results suggest that the same hormones that act in the kidney to promote the seaving of sodium also act in the brain to promote the seaving of sodium also act

61.7 THE PRESSOR RESPONSE TO INTRAVENOUS INFUSION OF ANGIOTENSIN II INHIBITS THE DRINKING RESPONSE. <u>M. M. Robinson and</u> <u>M. D. Evered</u>\*. University of Western Ontario, London, Ontario, Canada, N6A 5C1.

Intravenous infusions of Angiotensin II (Ang II) at doses commonly used to study thirst mechanisms cause large increases in arterial pressure yet relatively small drinks. We have investigated the possibility that the pressor response suppresses the water intake. Ang II was infused intravenously into rats (200 - 400 g) at a rate of either 16.7 or 100 ng/min. Captopril (0.33 mg/min), an angiotensin-converting enzyme inhibitor, was infused during all experiments to block any endogenous synthesis of Ang II. Fifteen minutes after the start of the Ang II infusion, isoproterenol or diazoxide was injected subcutaneously in doses which returned blood pressure to normal. For example, Ang II infused at 100 ng/min increased mean arterial pressure 40 - 60 mm Hg (n = 6) and caused rats to drink 3.7 ± 0.5 ml/90 min (Mean ± S.F., n = 28). Injections of diazoxide (75 mg/kg) or isoproterenol (0.1 mg/kg), which returned blood pressure to normal, increased Ang II-induced drinking to 7.8 ± 0.6 (n = 7) and 7.3 ± 1.1 (n = 9) ml/90 min respectively. Similar results were obtained at the lower rate of Ang II infusion (16.7 ng/min) which alone increased arterial pressure 40 - 50 mm Hg and caused rats to drink 1.6 ± 0.5 ml/90 min; diazoxide (20 mg/kg) returned blood pressure to normal and again increased intake, to 4.2 ± 0.7 ml/90 min (n = 6). Increasing the dose of diazoxide to cause blood pressure to fall below normal did not increase the drinking response to Ang II further. The increased water intake cannot be attributed to a drinking response to the hypotensive agents themselves since the captopril infusion was adequate to completely block drinking to either isoproterenol or diazoxide alone. These results suggest that: (1) the rise in arterial pressure reduces the dipsogenicity of Ang II, and (2) with Ang II levels clamped, hypotension is not a stimulus to drink. Supported by Canadian MKC. 61.6 ANGIOTENSIN II AND OSMOSENSITIVE NEURONS IN THE OVLT REGION. D.O. Nelson and Carol A. Graham\*. Depts. Physiology, Surgery and Medicine, Northwestern Medical Sch., Chicago, IL 60611. Intraventricular injections of angiotensin II (AII) and hyper-

Intraventricular injections of angiotensin II (AII) and hyperosmolar solutions produce increased vasopressin release, water intake, intravascular volume and blood pressure. Binding studies have localized AII receptors in tissue near the organum vasculosum lamina terminalis region (OVLT) and extracellular recordings show neurons in this region to be sensitive to AII. Similarily, lesioning and microinjection studies in intact animals and hypothalamic explants indicate that the integrity of the OVLT is important for transduction of osmotic stimuli to appropriate behavioral and hormonal responses. In the present study we have examined the sensitivity of spontaneously active single OVLT neurons to iontophoretically applied AII and to changes in extracellular osmolarity using the <u>in vitro</u> brain slice technique and extra cellular recording. Hypothalamic slices containing the OVLT region were prepared from 10-12 wk. old Sprague-Dawley rats. Multibarrelled electrodes were used to simultaneously record and apply AII, Saralasin and other agents. Of 65 spontaneously active neurons examined for sensitivity to AII, 48 showed increases in activity or reduced the response to simultaneously applied AII. Application of Saralasin reduced or eliminated spontaneous ongoing activity or reduced the response to simultaneously applied AII. Approximately 65% of the cells were also responsive to application of either glutamate or acetylcholine. Addition of the calcium channel blocking agent Verapamil, to the perfusing medium or reduction of extracellular calcium levels reduced or eliminated responses to AII application. In the majority of AII application by several minutes. Application of the phosphodiesterase inhibitor isobutylmethylxanthine (IBMX) prolonged response periods to AII.

Twenty-two of 57 cells showed increases in spontaneous activity during perfusion with medium made hyperosmolar with mannitol or sodium chloride. Increases in activity were dose dependent and were detected with changes in osmolarity of approximately 5mOsm. The results of this study support the work of other investigators which implicate the OVLT as an AII and osmotic sensitive brain region. Preliminary results suggest the possibility that calcium influx and cyclic nucleotides may partially mediate the excitation to AII application. Current studies are concentrating on further understanding the cellular mechanism responsible for AII and osmosensitivity in OVLT neurons and possible interactions. (Supported by USPHS HLB 29033).

61.8 A LIMITED ROLE FOR ANGIOTENSIN II IN DRINKING ELICITED BY HISTA-MINE IN THE RAT. F.S. Kraly, A.F. Moore\*, L.A. Miller\* and A.P. <u>Drexler\*</u>. Psychology Dept., Colgate Univ., Hamilton, NY 13346 and Research & Development Div., Norwich-Eaton Pharm., Norwich, NY 13815.

Sprague-Dawley male rats ( $\underline{n}$ =4; 310-335g), equipped with catheters in the abdominal aorta for measurement of blood pressure, were tested for drinking after s.c. histamine diphosphate (1.25, 2.5, 5 and 10 mg/kg). Histamine decreased mean blood pressure ( $\underline{p}$ <.005) and increased water intake ( $\underline{p}$ <.005) from baseline. The 2.5 mg/kg dose was the smallest dose to significantly ( $\underline{p}$ <.05) decrease mean blood pressure (mean decrease  $\pm$  SE: 15.5  $\pm$  5.7 mmHg) and it was the smallest dose to significantly increase ( $\underline{p}$ <.05) water intake (mean increase: 1.8  $\pm$  .6 ml) in 45 min after the injection. Both hypotensive ( $\underline{r}$ =.96) and dipsogenic ( $\underline{r}$ =.89) effects were correlated with the dose of histamine.

Because hypotension accompanied drinking in response to doses of s.c. histamine above and including 2.5 mg/kg, and because doses of s.c. histamine above and including 6.6 mg/kg are reported to increase plasma renin activity in the rat (Leenen et al., 1975), it is possible that a renal-mediated angiotensin II (AII) response to restore circulatory homeostasis could contribute to drinking elicited by s.c. histamine. This hypothesis was tested by blocking the conversion of angiotensin I to AII using SQl4,225 (Captopril) p.o. prior to s.c. histamine (1.25, 2.5, 5, 10 and 20 mg/kg) in 12 rats (500-650g). Each dose of histamine was preceded by 60 min with either 50 mg/kg SQl4,225 or .9% NaCl. Tests (60 min) occurred every fourth day. Histamine preceded by .9% NaCl p.o. elicited drinking in a dose-related manner (p<.001). SQl4,225 p.o. inhibited drinking (p<.05) in response to only the largest dose (20 mg/kg) of histamine (mean water intake, after .9% NaCl: 8.6  $\pm$ .8 ml; after SQl4,225: 6.4  $\pm$ .8 ml). SQl4,225 failed to inhibit drinking elicited by doses of histamine ranging from 1.25-10 mg/kg.

That SQ14,225 attenuated drinking in response to only the highest dose of histamine is indirect evidence that peripheral AII, mobilized in response to the hypotensive effects of s.c. histamine, contributes to a normal drinking response to histamine only when hypotension is pronounced. This, together with the finding that peripheral AII is not necessary for drinking in response to 1.25-10 mg/kg s.c. histamine, is consistent with the report (Kraly & Miller, 1982) that selective transection of gastric vagi abolished that vagotomy together with SQ14,225 is necessary to abolish drinking in response to 20 mg/kg s.c. histamine and

IMMUNOHISTOCHEMICAL EVIDENCE FOR CENTRAL ANGIOTENSIN II-CONTAINING PROJECTIONS TO THE SUBFORNICAL ORGAN.  $\underline{R.W.}$ 61.9 Lind, L.W. Swanson and D. Ganten\*, The Salk Institute, La Jolla, CA 92037 and The University of Heidelberg, Germany.

Angiotensin II (AII) is a peptide hormone that acts at peripheral and central sites to promote fluid balance. Considerable evidence now indicates that there is a central source of All, in addition to the well known peripheral source, and immunohistochemical studies have identified an All-like substance in neuronal cell bodies and axons in the brain.

We recently mapped the distribution of All immunoreactivity in the rat central nervous system and identified several cell groups and fiber systems. Of particular interest was the consistent appearance of a dense (SFO). Since the SFO is a likely central receptor site for circulating All, it was first necessary to determine whether the immunoreactivity in the SFO was due to receptor-bound peptide. Nephrectomy, which greatly diminishes plasma titers of All, was performed 48 h before perfusion. No aminishes plasma filers of All, was performed 46 h before perfusion. No apparent diminution was seen in subsequent immunohistochemical staining for All in the SFO. Conversely, 3-day water deprivation greatly increases circulating levels of All, and this treatment produced no visible enhancement of All immunoreactivity in the SFO. These results indicate that simulation All immunoreactivity in the SFO. that circulating All is not the source of immunohistochemical staining in the SFO.

The next experiment employed knife-cut lesions to interrupt possible All-containing pathways to the SFO. It was found that horizontal cuts of the ventral stalk of the SFO consistently diminished All immunoreactivity in the SFO. Furthermore, bright, varicose fibers containing All immunoreactivity were observed ventral to the cut. These findings suggest that an All-containing neural input enters the SFO through its ventral stalk.

Finally, several double labeling experiments involving injections into the SFO of the retrograde tracer True blue, combined with immunohistochemical staining for All, have been conducted. Neurons containing both the retrograde tracer and All immunoreactivity were found in perifornical parts of the lateral hypothalamic area, in the zona incerta, and in the nucleus reuniens. Other known inputs to the SFO were also retrogradely labeled, but none were All-positive.

These findings suggest that certain diencephalic projections to the SFO contain All. It is possible, therefore, that humoral as well as neural signals involving All converge in the SFO to produce both visceral and behavioral responses related to fluid balance. (Supported in part by NIH grant NS-16686.)

ANGIOTENSIN II. D.W. Andrews\*, P.M. Gross, M. Kadekaro, and Laboratory of Cerebral Metabolism, National L. Sokoloff. Institute of Mental Health, Bethesda, Maryland 20205. The subfornical organ has an important role in the dipsogenesis produced by peripherally administered angiotensin II (AII). We examined the effect of AII on glucose metabolism in the subfornical organ of conscious rats in two sets of experiments: 1) intravenous infusion of AII (2.5  $\mu g/min$  for 45 min) which increased arterial pressure and stimulated drinking in water-sated Sprague-Dawley rats; and 2) intraperitoneal injection of captopril, an angiotensin converting-enzyme inhibitor (50 mg/kg 60 min before experiment + 1/3 total dose given i.v. 15 min before experiment) to homozygous Brattleboro rats, which normally have high circulating levels of AII and high rates of glucose metabolism in the subformical organ. Captopril caused a sustained reduction in arterial pressure. We determined rates of glucose utilization by the quantitative autoradiographic  $\begin{bmatrix} 14 \\ 2 \end{bmatrix}$ deoxyglucose method with the assistance of computerized image processing. Results are presented as the mean  $\mu$ mol/100 g/min ± SEM for the subfornical organ. The number of animals is indicated in parentheses.

61.10 METABOLIC STIMULATION OF THE SUBFORNICAL ORGAN BY PERIPHERAL

	Saline	Angiotensin II	% Diff	
Experiment 1	44±4 (4)	.66±4* (4)	+50	
	Untreated/Saline	Captopril		
Experiment 2	69±3 (11)	53±1* (4)	-23	

\* p < 0.05 compared to control animals by independent t-test.

Intravenous AII also increased glucose utilization in the pituitary neural lobe (+76%), but other structures having connections with the subfornical organ were not affected. Captopril did not lower the high rate of metabolism found in the neural lobes of Brattleboro rats. We conclude that circulating AII stimulates metabolic activity in the subfornical organ of normal and homozygous Brattleboro rats.

61.11 NEUROCHEMICAL LESIONS IN SUBFORNICAL ORGAN OR MEDIAN PREOPTIC NUCLEUS AFFECT DRINKING, BUT NOT PRESSOR, RESPONSES TO ANGIO-TENSIN S.I. Bellin, R.K. Bhatnagar and A.K. Johnson. Depts. of Psychology and Pharmacology, and the Cardiovascular Center,

University of Iowa, Iowa City, Iowa 52242. Recent work in our laboratory has demonstrated anatomical connectivity between several anterior forebrain structures that comprises a portion of the functional pathway involved in angio-tensin II (AII)-elicited thirst and pressor responses (Johnson, A.K., <u>Circulation</u>, <u>Neurobiology</u> and <u>Behavior</u> (Smith, Galosy and Weiss, eds.), p.277, 1982; Lind, R.W. and A.K. Johnson, <u>J.</u> <u>Neurosci</u>. <u>2</u>(8):1043, 1982). Using electrolytic lesioning and experimental knife cut techniques, several investigators have defined a neural substrate for the mobilization of thirst which involves the Subfornical Organ (SFO) and the Median Preoptic Nucleus (MnPO).

In the present study, 6-hydroxydopamine (6-OHDA, 4ug/2uL) was injected into either the SFO (SFOX) or MnPO (MnPOX) nucleus of ether-anesthetized rats. Following the recovery of normal overnight drinking behavior and rates of body weight gain, thirst and pressor responses to systemic and central challenges were tested. MnPOX animals exhibited a significant attenuation of water intake MnPOX animals exhibited a significant attenuation of water intake following peripheral AII injections (3 mg/kg; 3 mg/ml, S.C.) when compared to values observed in vehicle injected controls (1.2±1.0 vs 4.4±1.4 ml, respectively, p $\leq$ .001). Although there was a tendency for SFOX rats (6.9±2.6 ml) to drink more than control animals in response to systemic AII, this difference was not statistically significant. Peripheral osmotic challenges (12% NaCl, 1 ml/100gm, S.C.) caused SFOX animals to drink more water than that compared by apingle in citter MnPOX or control compared by apingle. Nati, I mirloogm, S.C.) caused STOA animals to drink more water than that consumed by animals in either MnPOX or control groups (13.5±2.6 vs 10.5±2.4 or 9.7±2.1 ml, respectively,  $p\leq$ .05). The drinking response to central AII (100ng/2ul, ICV) by rats from either of the lesioned treatment groups was indistinguishable from values observed in control animals. Pressor responses to central AII, NaCl (2µL of a 600 mOsm solution) or carbachol (250ng/2µL) were comparable across groups. Similarly, the immediate and robust rise in blood pressure that accompanied a systemic AII injection was virtually identical in all rats. These data suggest that there is an interaction between catecholamines and the thirst elicited by systemically administered AII at the level of the MnPO nucleus.

EVIDENCE FOR THE INVOLVEMENT OF THE LATERAL LATERAL PARABRACHIAL 61.12 NUCLEUS IN THE MAINTENANCE OF BODY FLUID BALANCE. L.E. OHMAN AND A.K. JOHNSON. Department of Psychology, University of Iowa, Iowa City, Iowa 52242.

The lateral parabrachial nucleus (LPBN) has been reported to receive ascending projections from the nucleus of the tractus solitarius (NTS) (Loewy and Burton, <u>J. Neurol.</u>, <u>181</u>, 421-450, 1978), and area postrema (AP) (Shapiro and Miselis, <u>Neuroscience</u> <u>Abstracts</u>, 74.4, <u>8</u>, 269, 1982), a circumventricular organ that has been shown to enhance drinking to systemic administration of AlI (Edwards and Ritter, <u>Physiology and Behavior</u>, 29, 943-947, 1982). The LPBN innervates a number of diencephalon nuclei, including the median preoptic nucleus (MNPO), a prominent com-ponent of the periventricular anteroventral third ventricle, or AV3V region. The existence of these projections suggests that LPBN may play a role in the maintenance of body fluid homeostasis. To test this hypothesis, rats with bilateral lesions of the

lateral portion of the lateral parabrachial nucleus (LLPBN) or bilateral sham tract lesions were tested for drinking in response to systemic administration of AII (3.0 mg/kg, 1.5 mg/kg)isoproterenol (100 ug/kg, 30 ug/kg), hypertonic saline (12%, 4%), and isotonic saline.

Animals in the lesion group were found to drink significantly more to both doses of AII than animals in the sham tract group. (p<.05). No differences were found between groups in response to the other dipsogens. A third group of animals became apparent after histological examination. In this group of rats, the LLPBN sustained partial but not complete bilateral damage. An analysis of the drinking response for this partial miss lesion group revealed no significant difference between their water intake and that of the control group in response to the low dose of AII. However, in response to the high dose of AII the partial aniss group did not drink significantly less than LLPBN lesioned animals, showing a graded effect of the lesion. The majority of complete and partial miss lesions appeared to bilaterally destroy an area through which AP afferents projecting to LLPBN have been reported to travel (Shapiro and Miselis).

These data lead us to conclude that LLPBN is involved in an inhibitory thirst pathway and further, we speculate that this nucleus may be a point of convergence for cardiovascular (NTS) and endocrine (AP) information.

CENTRAL VS. PERIPHERAL ORIGINS OF FEEDING: BEHAVIORAL AND 62.1 METABOLIC EFFECTS OF GLUCOSE AND FRUCTOSE RE-EXAMINED FOLLOWING INSULIN. J. Carlton and N. Rowland. Dept. of Psychology, Univ. Florida, Gainesville, FL 32611. The finding that intravenous (iv) infusions of glucose and of Florida.

fructose effectively suppressed the feeding which occurs in the 2hr after insulin administration to rats was taken as evidence for a peripheral origin of feeding, since fructose does not enter the brain (Stricker, <u>et al.</u>1977). However, it was reported that fructose, but not glucose, suppressed the feeding observed 6hrafter insulin (postglucoprivic feeding; Bellin & Ritter, 1981) This ineffectiveness of glucose is paradoxical, since it is used

In both brain and periphery. In the present study we first attempted to replicate the findings of Bellin & Ritter. Male Sprague-Dawley rats were injected s.c. with regular insulin (2U/kg) or saline, and chow was removed for 6hr. They were then given a 2hr feeding test, and those eating more after insulin than saline were included in the study. Jugular vein catheters were implanted and, after recovery, insulin was administered followed 90 min later by a 30 min iv infusion of 0.9% saline, D-glucose, or  $\beta$ -D-fructose (2.4 M; 4.4 ml). A feeding test was then performed 6 hr postinsulin as before. In three separate experiments (data combined in Table) both glucose and fructose abolished the

Mean Chow	Injection/Infusion			
Intake (g)	SAL/SAL	INS/SAL I	NS/GLU	INS-FRUCT
30 min	0.9	4.4*	1.6	2.0
120 min	1.7	5.2*	2.4	2.6
postglucoprivic	feeding.	The reductions	in food	intake were

calorically equivalent to the calories infused. The glucose suppression does not confirm the data of Bellin & Ritter, but consistent with the expected metabolic effects.

In parallel experiments we examined the plasma concentrations of these sugars following iv infusions. Two hr following insulin rats had plasma glucose (PG) levels of 60mg/dl (PC of non-treated rats = 130-160 mg/dl). Rats infused with glucose between 90 and 120 min postinsulin as above had PG 450 mg/dl at the end of the infusion, and this fell exponentially to 90 mg/dl after 1 hr (Conard K coeff. =-.031). Similar infusions of fructose produced plasma fructose (PF) levels of 250 mg/dl, falling to 61 mg/dl hr later (K for fructose = -.023). In these cases, small amounts of glucose and fructose (ca. 0.1 g) were lost in the urine.

Thus, both glucose and fructose suppress postglucoprivic feeding, but the effective infusions produce abnormally high PG and PF values. We are currently extending these data with studies of fructose utilization, and effects on hypothalamic NE turnover.

CENTRAL EFFECTS OF A NOVEL FATTY ACID-OXIDATION INHIBITOR: BIOCHEMICAL AND BEHAVIORAL ALTERATIONS. <u>A. Y. Deutch, T. R</u> Kasser**\*** and R. J. Martin. Department of Foods & Nutrition, University of Georgia, Athens, GA 30602.

Previous data from our laboratory indicate that there is regional heterogeneity in the ability of the CNS to oxidize fatty acids, that such fatty acid oxidation is linked to the uptake of peripherally-derived fatty acids, and that both central uptake and oxidation of fatty acids is altered by food deprivation in control but or to link or or the but or the second the certain, but not all, brain areas. We have therefore assessed the central activity of a novel fatty acid oxidation (FAO) inhibitor, MDL 14,514ZA, as a prelude to examination of possible alterations in food intake and body weight regulation induced by suppression of central fatty acid oxidation.

Adult male rats, trained to a 22 hour food deprivation schedule, were sacrificed two hours after the presentation of food, or after were sacrificed two hours after the presentation of food, or after 24 hours of food deprivation. One mm thick coronal slices were prepared from the removed brain, and the following areas microdissected from the slices: nuc. accumbens/olfactory tubercle, septum, striatum, amygdala, pyriform/entorhinal cortices, and ventrolateral and ventromedial hypothalamus (VLH and VMH). Tissue was incubated in the presence of  $1^{4}$ C-palmitic acid in Krebs buffer, and generated  $1^{4}$ C-CO<sub>2</sub> trapped and counted. MDL 14,514ZA addition to the incubation medium ( $10^{-9}$ - $10^{-3}$ M) induced a dose-dependent suppression of FAO in the liver and the

MDL 14,514ZA addition to the incubation medium (10 <sup>-</sup>-10 <sup>-</sup>M) induced a dose-dependent suppression of FAO in the liver and the two hypothalamic sites. Subsequent experiments were performed in the presence of  $10^{-5}$ M of the inhibitor. All brain areas examined exhibited similar sensitivity to the inhibitor; FAO rates were decreased to 46-63 percent of basal values. The suppression of FAO occured to an equal degree in both fed and fasted animals, although fasting markedly enhanced oxidation rates in the VLH. These data therefore suggest that the process of central fatty acid oxidation is a) similar to FAO occuring in the periphery, and b) similar across different brain regions, although fatty acid oxidation response to food deprivation is regionally distinct.

Preliminary data indicate that continuous osmotic minipump infusion (1 ul/hr for seven days) of the FAO inhibitor MDL 14 5142A through cannulae aimed at the lateral ventricle or VLH results in a loss of body weight. The recovery process appears to proceed at a faster rate in those animals sustaining lateral ventricular infusions of the inhibitor. These data therefore suggest that fatty acid oxidation at certain central sites may be an important peripherally-derived signal involved in the regulation of food intake and body weight.

62.2 DIABETES IN RATS: EFFECTS OF DIETARY FAT TYPE AND CONCENTRATION ON FOOD INTAKE AND PLASMA METABOLITES. L.L.Bellush & N.Rowland. Dept. of Psychology, Univ. of Florida, Gainesville, FL 32611.

Mildly diabetic (D) rats showed a preference for dictary fat compared with nondiabetics (ND) but severely D rats self-selected a high protein regimen (Bartness & Rowland, Soc.Neurosci.'82). We also confirmed Friedman's ('78) observation that D rats are no longer hyperphagic when fed the "Corbit & Stellar" high fat diet (1/3 Crisco shortening, 2/3 chow). However, many D rats deteriorated when fed this diet and, given the choice, preferred chow. We now report the metabolic effects of these diets.

We now report the metabolic errects of these diets. In the first experiment D (streptozotocin 70 mg/kg) and ND rats received either high protein (50%P, 40%C, 10%F), high fat-protein (50%P, 15%C, 35%F) or normal (25%P, 65%C, 10%F) purified equi-caloric diets for 4-6 weeks. Food intakes (FI), weight gain (W) and plasma glucose (PG) are shown in Table 1. The D rats fed the high fat-protein diet showed the greatest W gain for the lowest FI, suggesting that the fat calories were effectively utilized. These HiPro rats were clearly in better TABLE 1 HiFat Normal health that D rats on the D 45 39 53 FI(g/d) Corbit-Stellar diet. One ND 31 33 34 difference between the two diets is that the latter D -1.0 +1.2 -2.3 W(q/đ) +3.7 ND +2.8 +4.1 is made with saturated fat 551 473 664 D is made with saturated fat while the purified and self-  $\frac{PG\left(mg/d1\right)}{ND} \frac{D}{131}$  selection diets that we have used are made with oil 138 139 (relatively unsaturated).

In the second experiment we investigated whether the saturation of the dietary fat was an important factor. D and ND rats received high fat diets of either saturated (1/3 w/w coconut oil + 2/3chow) or unsaturated (1/3 w/w safflower oil + 2/3 chow) components for 10 days. The data are shown in Table 2. D rats on the unsaturated fat diet showed less weight loss per day and less elevation of

triglyceride levels compared with D rats on saturated fat diets. Dietary fat saturation (Table 2) as well as protein concentration (Table 1) are important determinants of food utilization in D rats.

Oral and Duodenal Hexose Loads Can Affect Food Intake. 62.4

Oral and Duodenal Hexose Loads Can Affect Food Intake. <u>Paula J. Geiselman and Donald Novin</u>. Department of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024. We have found that, following normal ingestion of 10 ml of 0.3M glucose, rabbits showed a significant increase in chow intake. This food-enhancement effect was potentiated by bilateral subdiaphragmatic vagotomy. We have further found that, when infused intraduodenally at a slow rate, glucose suppresed subcount chow; intake but, when subcose suppressed subsequent chow intake but, when glucose was infused into the duodenum at a rapid rate, the rabbits nearly doubled their food intake during the first half hour postinfusion. We have extended these results, investigating the roles of glucose, fructose, and galactose on subsequent

food intake in the rabbit. Female New Zealand rabbits were implanted with intra-duodenal cannulae and infused (10 ml/3 kg BW) with 0.3M glucose, 0.3M fructose, 0.3M galactose, and 0.15M NaCl delivered at 3 ml/min.

delivered at 3 ml/min. The results obtained with intraduodenal fructose were the most robust. Following intraduodenal infusion of fructose, the latency to the first meal was significantly reduced, and the size and the duration of the first meal were significantly greater than in the control condition. Further, after duodenal fructose infusion, measures of meal duration, meal size, and total food intake remained significantly greater throughout the four-hour measurement period. The effects of the hereses have implications for metabolic and castrothe hexoses have implications for metabolic and gastro-intestinal mechanisms that may be controlling food intake. We also allowed intact rabbits to ingest 10 ml of the

We also allowed intact rabbits to ingest 10 ml of the following solutions: 0.3M glucose, 0.3M fructose, 0.3M galactose, 0.0049 NaSac, and 0.15M NaCl. After the ingestion of either fructose or glucose, the rabbits showed an increase in chow intake in comparison with measures in the control conditions; but the food-enhancement effect was not obtained following ingestion of either galac-tose or NaSac. Preference tests were therefore conducted. The morular support that the pathit to ache the food The results suggest that the rabbits tended to show the food-enhancement effect in response to the more palatable solutions but not in response to the less palatable solutions.

 62.5 INCREASED GASTRIC EMPTYING PARALLELS INCREASED FOOD INTAKE IN RATS. <u>Monica J. McCann\* and Edward M. Stricker</u> (SPON: A. Caggiula). Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260. In recent years there has been renewed interest in the

contribution of peripheral mechanisms to the control of food intake. We now report our studies of gastric emptying in rats, using treatments known to reliably increase food intake: dietary dilution, and glucoprivation induced by 2-deoxyglucose (2-DG) or pharmacological doses of insulin.

Stainless steel fistulæe were implanted in the fundic portion of the stomach of adult male rats. Experimentation began after a 1 wk recovery period. Rats were deprived of food for 6 hr and then given 3.0 ml of 10%, 20%, or 25% glucose solution through the fistulæe. After a small bolus was evacuated in the first 2 min, emptying proceeded at a linear rate of approx. 0.35 kcal/min for 20-40 min regardless of the load. These findings replicate the important observations that McHugh and Moran (<u>Am. J. Physiol.</u> 236; R254, 1979) reported in similar experiments involving glucose and other nutrient loads in rhesus monkeys. Collectively, they are consistent with the hypothesis that gastric distention limits food intake, and that dilute diets permit more frequent meals because they leave the stomach more rapidly.

Glucoprivation induced by 2-DG treatment also increases meal frequency and food intake in rats. To determine whether gastric emptying is increased, rats were given a 3.0 ml load of 5% glucose solution 30 min after receiving 200 mg/kg 2-DG, ip. Gastric emptying was increased 5-6 fold. Similar results were obtained when glucoprivation was induced by sc injection of 3 U/kg regular insulin; gastric emptying was increased 7-fold. These results indicate that gastric distention is not sustained under conditions in which the postprandial satiety period is relatively brief, suggesting a causal relation between the two variables. We have begun to examine gastric emptying under conditions in which food intake is attenuated. Specifically, the food intake

We have begun to examine gastric emptying under conditions in which food intake is attenuated. Specifically, the food intake elicited by insulin treatment can be eliminated, despite continued hypoglycemia, by infusion of fructose, a sugar that does not cross the blood-brain barrier (Stricker et al., <u>Science</u> 196: 79, 1977). In preliminary experiments we have found that administration of fructose markedly attenuates the increase in gastric emptying that was induced by insulin. Together with other findings (Grannema & Friedman, <u>An. J. Physol</u>, 238: R346, 1980), the present results indicate that alterations in caloric utilization in some peripheral tissue, perhaps the liver, can influence gastric emptying and may thereby affect food intake, at least in part, by this indirect route. (Supported by research grant MH-25140.)

62.7 BODY WEIGHT REGULATION: DYNAMICS OF RECOVERY FROM OVERFEEDING AND UNDERFEEDING. <u>R. B. S. Harris<sup>3</sup> T. R. Kasser \*and R. J.</u> <u>Martin</u>. (Sponsor: L. Proenza), Univ. of Georgia, Athens,GA 30602. Evidence for the control of body weight by regulation of body energy stores is provided by studies in which previously overfed rats are hypophagic or underfed rats are hyperphagic until they return to control body weight. In most of these studies body composition was only measured at the end of recovery. We have investigated the pattern of change in body composition with recovery of weight to "set-point" in overfed, restricted and starved rats.

Female Sprague-Dawley rats, weighing 230g, were divided into 27 groups of 6 or 8 rats. Four groups were fed 160%, seven groups were fed 100% and eight groups were fed 40% of control intake. Liquid diet was fed as three tube-fed meals a day. Tube-feeding continued until the 40% fed rats had lost 50g. Six groups were then starved to lose 50g. Initial carcass composition was determined on one group from each treatment. The remaining rats were returned to ad libitum feeding. The 160% rats were initially hypophagic and lost weight. The restricted and starved rats were hyperphagic and gained weight rapidly. Body composition was determined on groups of 40% fed rats after 2,4,6,8,10 and 17 days of refeeding and on starved rats after 1,2,3,4,5 and 11 days. Composition of 100% fed controls was determined after 2,6 and 17 days and of ad libitum controls with the last group of 40% and starved rats. 160% fed rats gained 90 g during tube-feeding. Carcass composition was determined on 100% and 160% fed rats when the overfed rats had lost the same proportions of their 90g gain as the 40% rats had gained of their 50g loss after 2,6 and 17 days of refeeding. In starved and restricted rats approximately 26g of the weight loss was fat and 10g were protein. Although the

In starved and restricted rats approximately 28g of the weight loss was fat and 10g were protein. Although the composition of loss was similar the pattern of regain was different. Starved rats initially gained protein and then replaced fat so that it was at control levels at the same time as body weight. Restricted rats regained most of their fat before replacing protein. When control weight was reached fat content was still slightly less than in controls. In overfed rats 42g of the weight gain was fat and only 7g were protein. The protein was lost soon after the end of overfeeding. Fat decreased steadily but was still significantly greater than in controls 44 days after the end of tube-feeding. It seems that although all of the rats adjusted food intake to correct body weight to "set-point" different mechanisms were involved for each treatment. The cause of the difference is not clear, but change in body fat seemed closely related to change in weight only in the overfed rats. 62.6 BODY WEIGHT REGULATION: IN VITRO NEURONAL TISSUE METABOLISM OF GLUCOSE AND FATTY ACID. <u>R. J. Martin, T. R. Kasser<sup>\*</sup> and R. B. S.</u> <u>Harris.</u>\* Dept. of Foods and Nutrition. University of Georgia, Athens, GA 30602.

The purpose of this study was to identify specific neuronal metabolic patterns which may be important in body weight regulation. In vitro glucose and fatty acid metabolism was measured in selected brain sites in rats during hypophagic and hyperphagic recovery of a normal body weight (see R.B.S. Harris et al. this Mtg.) Rats were fed 40, 100 or 160% of normal intake (gastric intubation: thrice daily) for three weeks. As a result, 40%-fed rats weighed 29% less and 160%-fed rats weighed 25% more than 100%-fed rats. Groups of rats were killed at the end of tube feeding and at specific periods during the recovery of a normal body weight. Rats were killed by decapitation and brains quickly removed and dissected into ventromedial hypothalamus ventrolateral hypothalamus, area postrema-nucleus solitary tract and cortex. Tissues were incubated in Krebs Ringer bicarbonate buffer with labelled substrate for 2 hours. Labelled substrate was either  $1-C^{14}$  palmitate or  $U^{-14}C$  glucose (1 mM and 10 mM

During recovery, rats previously fed 40% of normal intake (hungry) were hyperphagic and maintained high rates of VLH fatty acid oxidation until deficient fat stores were repleted. Conversely, rats previously fed 160% of normal intake (anorectic) were hypophagic and maintained low rates of VLH fatty acid oxidation until excessive fat stores were depleted. Other alterations were observed but did not follow the consistant pattern seen between VLH fatty acid oxidation and peripheral energy storage. This experiment was important because our previous studies (Kasser and Martin-Fed. Proc. 42:393,1983) examined central metabolism at the conclusion of tube feeding, not permitting isolation of changes associated with excess energy intake from those associated with excess energy storage. The results demonstrated that rates of VLH fatty acid oxidation respond to peripheral energy storage, while changes in central glucose utilization may be more strongly associated with energy intake.

62.8 COMPENSATORY INTRA-MEAL RESPONSES OF OBESE WOMEN TO REDUCTION IN THE SIZE OF FOOD UNITS, E. E. Shrager\*, T. A. Wadden\*, D. Miller\*, A. J. Stunkard\* and E. Stellar. Obesity Research Group, University of Pennsylvania Sch. of Med., Philadelphia, PA 19104. It has been suggested that obese humans, like obese rats, dis-

It has been suggested that obese humans, like obese rats, display different behaviors as a function of the discrepancy between their current weights and their set points (Nisbett,1972). "Restraint"(Herman & Polivy, 1980) has been proposed as a characteristic of individuals who exert cognitive control over their feeding behaviors to maintain weights below set point. The present study examined the rates and amounts of food intake by 12 obese women after the number of bites needed to ingest a meal was increased by reducing the size of the available units of food. In addition, the intakes of the subjects on the smaller food units relative to the larger were examined with respect to subjects' scores on the Stunkard-Messick Eating Inventory, a 3-factor measure of Restraint.

Test meals consisted of either sandwich quarters (SQ's) or Solid Food Units (SFU's) which were prepared by spreading filling on a slice of bread which was rolled and cut into 8 equal portions. Four SFU's were equal in constituents and calories to 1 SQ; however, the shape of the SFU's effectively obscured this ratio from the subjects. Subjects refrained from eating for 12-14 hr prior to each of three, 30 min test lunches which were separated by intervals of at least one week. Subjects obtained food portions by reaching into the side opening of an insulated box. Removal of each food unit was recorded on a counter in a separate room from which subjects were also observed via a one-way mirror. At 0, 10, 20 & 30 min, subjects marked 100 mm analogue scales to indicate their levels of hunger and fullness. Water intakes were measured at 10 min intervals and food intakes at 5 min intervals. Trials 1 & 3 employed SQ's as the meal; Trial 2 used SFU's. Results in-dicated that food intake (in SFU or SFU equivalents) per 5 min interval for the two SQ trials was not significantly different over time; however, intakes of SFU's at 5, 10 & 15 min during Trial 2 were significantly reduced (p .01). While subjects did double the rate at which they took food (SFU's) from the box, they failed to adequately compensate for the four-fold difference in size between the SQ's and SFU's. A number of subjects did continue to eat at a relatively constant rate throughout the later time inter-vals of Trial 2 such that their total intakes approximated or sur-Vals of Trial 2 such that their total intakes apploximated of saf-passed their intakes on Trials 1 & 3. When SPU intake for Trial 2 was expressed as a percent of the average intake, in SFU equiva-lents, on Trials 1 & 3, these percent intakes were significantly correlated (r=0.7742, p. 0.1) with the scores of the subjects on factor 2, "Disinhibition" of the Stunkard-Messick Eating Inventory.

These data are discussed in light of previous findings from the laboratory regarding the patterns of food intake by lean and obese subjects during SFU test meals. 62.9

DECREASE OF THREONINE IN CSF, PLASMA AND BRAIN OF RATS FED A DECREASE OF THREONINE IN CSF, PLASMA AND BRAIN OF RATS FED A THREONINE DEFICIENT DIET. W. J. Hartman\*, C. C. Calvert\* and C R. Rogers\* (SPON: V. E. Mendel). Dept. of Physiological Sciences, Dept. of Animal Science and the Food Intake Laboratory, Univ. of California, Davis, CA 95616. It is well recognized that consumption of amino acid (aa) imbalanced or devoid diets by rats results in a rapid decrease in plasma and brain concentrations of the most limiting aa. This decrease is correlated to a decreased food intake. Bate (1860) on 20212 be light dark cycle, individully. \* and Q. Rats (185g) on a 12:12 hr light-dark cycle, individually housed in stainless steel suspended wire cages, were allowed to consume a thr limiting aa diet (21% aa) during the first 6 hr of consume a thr limiting aa diet (21% aa) during the first 6 hr of each dark cycle. After a 13 day adaptive period, each rat was assigned to one of three dietary treatments; 1) food deprived (FD), 2) thr devoid (DEV) or 3) an isonitrogenous thr corrected diet (COR) containing 0.6% thr. Cerebrospinal fluid (CSF), blood plasma and brain were sampled from the FD rats at the beginning of the next dark cycle while the rats assigned to treatment 2 and 3 consumed 2.0g of diet. All rats ate the diet in 10-30 minutes and CSF, blood and brain were obtained 2 hr after the initiation of feeding. Amino acids were determined using an LKB 4400 amino acid analyzer. Plasma thr was depressed (P < 0.05) in DEV and FD rats as compared to CDR rats: 31.2 uM. using an LKB 4400 amino acid analyzer. Plasma thr was depressed (P < .05) in DEV and FD rats as compared to COR rats; 31.2 µM, 79.9 µM and 163.0 µM, respective]y. A similar effect was noted for brain (DEV = 145.7 µM, FD = 222.6 µM, COR = 282.5 µM) although in this case only the DEV rats had a significant reduction (P < .05) in thr levels as compared to COR rats. These differences were greater in CSF where thr was depressed (P < .05) and bEV and FD rats as compared to COR rats, and 22.9 µM, respective]y. Plasma thr was most affected by dietary treatment, with DEV and COR rats having 39.1 and 204.0%, respectively, of the plasma thr levels found in FD rats. were 47.8 and 165.9%, respectively, of CSF thr in FD rats, while brain from DEV and COR rats had 65.5 and 126.7% of the total brain thr of FD rats.

total brain thr of FD rats. These results demonstrate that CSF amino acid levels can be

Inese results demonstrate that CSF amino acid levels can be altered by short term dietary feeding. This is consistent with the rapidity with which animals can detect an amino acid devoid diet. Changes in CSF amino acid concentrations induced by diet may play a role in altering food intake in the rat. (Supported in part by NIH grants AM 07355 and AM 13252)

## NEUROPEPTIDES AND REHAVIOR: VASOPRESSIN AND OXYTOCIN

63.1 VASOPRESSIN ANALGESIA: SPECIFICITY OF ACTION & NON-OPIOID EFFECTS J.H.Kordower, R.J.Bodnar, M.M.Manning, and W.H.Sawyer<sup>\*</sup>. Dept. of Psychology, Queens College, Flushing N.Y. 11367;Dept. of Biochemistry, Medical College of Toledo, Toledo Ohio,43699; Dept.

Biochemistry, Medical College of Toledo, Toledo (hio,43699; Dept. of Pharmacology, College of Physicians and Surgeons, Columbia University, N.Y. 10032. Vasopressin (VP) increases pain thresholds following intra-cerebroventricular (iv) administration. To characterize VP anal-gesia, the first experiment examined dose-response relationships of AVP (0,75,150,500ng/ $\beta$ ul,icv), DDAVP (0,150,500ng/ $\beta$ ul,icv) and oxytocin (0,150,500,1000ng/ $\beta$ ul,icv) upon tail-flick latencies in 3 groups of 8 rats. All AVP doses elevated tail-flick latencies at 5 and 15 min post-injection with the analgesic magnitude in-creasing as a function of dose. DDAVP increased tail-flick creasing as a function of dose. DDAVP increased tail-flick latencies up to 5 min (150ng) and up to 45 min (500ng) after in-jection. Oxytocin increased tail-flick latencies for up to 15 (150,500ng) and 30 (1000ng) min respectively, but these effects were paralleled by barrel roll seizures. The second experiment compared icv pretreatment (10 min) of either a VP entagonist (dPTyr(Me)AVP-500ng), naloxone (lµg), or vehicle to antagonize AVP and DDAVP analgesia. While vehicle pretreated rats display AVF and DDAVF analgesia. While vehicle pretreated rats display both AVF (500ng) and DDAVF (500ng) analgesia for up to 30 min after injection, pretreatment with dPTyr(Me)AVP eliminated these effects. In contrast naloxone pretreatment failed to alter either AVP or DDAVP analgesia. Moreover, the VP antagonist failed to alter tail-flick latencies at this dose. In a third reduced morphine analgesia (10mg/kg-sc). In contrast, icv pre-treatment with vehicle or dPTyr(Me)AVP (1µg) failed to differ treatment with vehicle or dFTyr(Me)AVP (lug) failed to differ from each other. The fourth experiment examined whether pre-treatment with dFTyr(Me)AVP (lug) would alter prolonged inter-mittant foot-shock (PIFS) or brief continuous foot-shock (BCFS). These parameters of FS are mediated through different mechanisms (<u>Science</u>, 208,623,1980). The VP antagonist significantly reduced PIFS analgesia, yet significantly potentiated BCFS analgesia. These data indicate that VP but not oxytocin elevates tail-

flick thresholds without apparently affecting other neurobehav-ioral systems. Also, VP appears to be acting independent of the endogenous opioids since the specific VP antagonist, but not naloxone blocks VP analgesia, while naloxone but not the VP ant-agonist reduces morphine analgesia. Lastly, VP appears to modu-late foot-shock analgesia in a reciprocal fashion, indicating that PIFS parameters may be dependent upon VP for its full expres-sion, while BCRS parameters may be inhibited by that same con-nection. (SUPPORTED BY NIH GRSG 5 SO5 RR07064). 63.2 DIFFERENT MECHANISMS MEDIATE THE

DIFFERENT MECHANISMS MEDIATE THE CENTRAL AND PERIPHERAL ACTIONS OF AVP ON BEHAVIOR. <u>G.F. Koob, R.</u> Dabizer<u>\*.</u> <u>P. Morméde\*.</u> <u>R.M. Bluthe\*, F.E. Bloom</u>, and <u>M. <u>4.</u> Mogl.Lab.Neurobiologie des Comportements, Université de Bordeaux II, Bordeaux, France, and A.V.Davis Ctr. for Behavioral Neurobiology, Salk Institute, San Diego, California, 92138. Previous work from our laboratories has suggested that the aversive properties of peripherally-injected arginine vasopressin (AVP) may mediate its putative "memory-enhancing" action (Ettenberg et al. Behav.Brain.Res. 7:331,1983). However, many previous studies have shown that AVP directly injected into the brain in nanogram quantities can also have behavioral actions. The purpose of the present study was to examine the possible mediating factors for the aversive effects of peripherally injected AVP by examining the effects of the pressor antagonist of AVP, dPTyr(Me)AVP, on the development of AVP induced taste aversion, and to examine the possibility that centrally- injected AVP could also produce aversive effects. Male Wistar rats were food deprived to insure consumption of the test solutions and then were habituated to drink a sucrose was replaced by a milk solution and after presentation of the milk each animal was injected with either saline, 6 ug/Kg of AVP, or 6 ug/Kg AVP plus 38 ug/Kg of the AVP antagonist. These pairings continued for 4 days. Results showed a clear and significant taste aversion following the AVP injection that was completely blocked by the concurrent injection of the AVP antagonist. In a second identical experiment, after each milk presentation the rats were injected with AVP intracrebroventricularly in doses of 6.1, 1.6, and 10.8 anaograms/rat (doses shown to prolong extinction of active avoidance behavior). No conditioned taste aversion was observed at the 0.1 or 1.8 doses. At 18 nanograms there was some aversion, but 5 out of 6 rats showed barrel-nolling immediately following the injection. Results suggest that the aversive properties of peri</u>

BEHAVIORAL VARIATION BETWEEN DIFFERENT COLONIES OF 63.3 BRATTLEBORO RATS. J.P. Herman\*, D.M. Gash, G.J. Thomas, J.F. Laycock\* and I.V. Gartside\*. Center for Brain Research, University of Rochester School of Medicine, Rochester, New York 14642, and Charing

Cross Hospital Medical School, London, England (Spon: C.K. Kellogg). Vasopressin (VP) deficiency observed in Brattleboro rats homozygous for the diabetes insipidus trait (DI rats) has been used extensively as an independent variable in experiments investigating the role of VP in behavioral processes. Unfortunately, behavioral data from some laboratories have proven difficult to replicate. This study addressed the hypothesis that substantial behavioral differences might exist between different colonies of DI rats, accounting for some of the problems in replication.

DI samples were drawn from the population maintained at Rochester (RO/DI animals) and from the colony maintained by Dr. Laycock in Great Britain (GB/DI animals). Samples from both colonies manifested the same degree of polydipsia and polyuria. Control rats were normal Long Evans animals from the respective colonies (RO/N, GB/N). Ten animals from each experimental group were tested in a straight runway animals from each experimental group were tested in a straight runway approach-avoidance paradigm, consisting of a) 3 approach trials per day for 10 days, where entry into a goal box is rewarded with presentation of food; b) a single shock trial (trial 30), where a 2.5 mA shock is delivered upon contact with the food dish; and c) 3 post-shock approach trials per day for 10 days (goal box entry again rewarded). Pre-shock approach speed is taken to be a measure of adaptation to the novel environment presented by the runway, while post-shock speed is taken to measure retention of shock avoidance. RO/DI animals adapt more slowly to the runway thad c RO/N rats (pc-0.05) while retaining avoidance to a similar degree as RO/N animals. Conversely, GB/DI animals adapt more quickly (pc-0.05) to the runway than do GB/N rats, while again retaining avoidance to a similar degree as normals. These data support the hypothesis that behavioral differences,

while again retaining avoidance to a similar degree as normals. These data support the hypothesis that behavioral differences, specifically in adaptation to novel situations, exist between different colonies of DI rats. The presence of such a colony effect introduces a confounding variable into experiments using the DI animal to study the relationship of VP to behavior, since hereditary behavioral traits may be potentially independent of the DI gene. More stringent control of polygenic variability must be employed before conclusions may be drawn linking VP deficiency to behavioral processes. In addition, these data do not support the hypothesis that VP deficiency is deleterious to retention of shock avoidance. Neither RO/DI nor GB/DI animals differ from normals in post-shock approach speed. Supported by NS 15109 and NS 17543.

INTRAVENTRICULAR APPLICATION OF A PRESSOR ANTAGONIST ANALOG OF 63.5 VASOPRESSIN PREVENIS BOTH THE 'MEMORY' AND 'AVERSIVE' ACTIONS OF VASOPRESSIN. A. Ettenberg, Department of Psychology, University of California, Santa Barbara, CA 93106

Many studies have reported an improvement in memory with post-training administration of the neuropeptide, arginine vasopressin (AVP). However, it remains to be determined whether the putative memory-enhancing properties of AVP result from some direct action on the neural substrates of memory or from some other modulatory or indirect mode of action. For example, we (Ettenberg et al. Beh-av. Brain Res., 1983, 7, 331) recently reported a correlation between the aversive actions of AVP and its performance-improving effects in an appetitive learning task. These data suggested that one might account for the "memory" properties of AVP by the arousing or alerting effects of administering an aversive agent. If this hy-pothesis is correct, then one would predict that treatments that prevent the aversive effects of AVP should also prevent its memory effects. The present study was designed to examine this possibility. In previous work (Ettenberg et al., Pharmacol. Biochem. Behav.,

In previous work (Ettenberg et al., Pharmacol. Biochem. Behav., 1983,18, in press) we observed that the concurrent administration facilitation observed with AVP alone. In the present study two ad-ditional factors were examined: 1) would intraventricular infusion of the AVP antagonist similarly prevent the memory effects of AVP, and 2) if so, would this same treatment also prevent the aversive properties of AVP.

properties of AVP. The aversive actions of 6.0 ug/kg s.c. injections of AVP were demonstrated in two behavioral assays: 1) a Conditioned Taste Aver-sion Test in which rats learned to avoid a preferred tasting sub-stance (i.e. saccharin) as a consequence of pairing the presentat-ion of that substance with injections of AVP, and 2) a Conditioned Place Test in which rats learned to avoid a distinctive environ-ment associated with AVP administration. The memory-enhancing prop-erties of AVP were observed in a one-trial food-finding task where non-deprived rats were briefly exposed to a large open-field that contained an alcove in which a high-incentive familiar food reward (sweetened milk) was freely available. AVP injections immediately upon removal from the open-field produced faster latencies to re-locate the alcove (compared to vehicle controls) when tested 48 h later. Both the memory and the aversive actions of AVP were prevent-ed by immediate pretreatment with intraventricular infusions (10ug later. Both the memory and the aversive actions of AVP were prevent-ed by immediate pretreatment with intraventricular infusions (loug /rat) of the AVP pressor antagonist analog 1-deaminopenicillamine-(0-methyl)-tyrosine AVP. Antagonist doses of lug & 5 ug/rat had weak and moderate effects respectively. The large doses required to block AVP's behavioral effects suggest that the critical site of action may be far removed from the lateral ventricles.AVP memory effects may, therefore, occur via peripheral aversive actions.

FACILITATION OF DEVELOPMENT OF RESISTANCE TO MORPHINE ANALGESIA 63.4 BY ARGININE VASOPRESSIN AND THE ROLE OF BRAIN SEROTONIN IN THE RAT. <u>M.S. Shahid Salles, and K. Sharifi Hossaini</u>. Departments of Physiology & Pharmacology, School of Medicine, Shiraz University,

NEUROPEPTIDE INFLUENCES ON MEMORY IN YOUNG COCKERELS. Davis, R. M. Pico\* and A. Cherkin. Aging and Behavioral Biology Research Lab. and GRECC. VAMC. Sepulveda, CA 91343. We have previously describe

We have previously described certain proline oligopeptides to be enhancing in a conditioned peck aversion paradigm (Davis, J. L. and Cherkin, A., <u>Neurosci</u>. <u>Abstr.</u>, <u>6</u>:169, 1980). In addi-tion we have described memory enhancement induced in chicks by oxytocin and its C-terminal tripeptide L-prolyl-L-leucyl-glycineamide (Davis, J. L., Pico, R. M., and Cherkin, A., <u>Neurosci</u>. <u>Abstr.</u>, <u>7</u>:365, 1982). We report here an expansion of these re-sults to include a demonstration of memory enhancement in a similar paradigm produced by the C-terminal tripeptide of arginine vasopressin, L-prolyl-L-arginyl-glycineamide (PAG).

In these experiments two-day-old cockerels were injected in-tracerebrally with 5  $\mu$ L/hemisphere of PAG (3.0  $\mu$ mol/chick) or saline 1, 9, or 59 min after one-trial training to suppress the peck response to a bead coated with EtOH. The aversant effects of EtOH are not noticeable 24 hr later without a memory enhancement manipulation. Enhanced memory was noted, 24 hr later, when chicks showed a lower mean peck rate (number of pecks in 10 sec) than the control chicks when presented with an uncoated bead. Further data (not shown here) indicate that decreased responding is not the result of a general depressive effect of the oligopeptide.

63.7 REVERSAL OF INDUCED ISCHEMIC NEUROLOGIC DEFICIT IN GERBILS BY VASOPRESSIN, <u>G. Delbarre, B. Delbarre and A. Ferger</u><sup>o</sup>. Lab. Ch. Exp., Faculté de Médecine 37032 TOURS, FRANCE

Mongolian gerbils (Meriones unguiculatus) are characterized by frequent anomalies of the circle of Willis. Their cerebral vessels lack arterial communication between the cerebral and vertebral system. Therefore ischaemia can be easily produced by unilateral ligation of the common carotid. The ligation-induced neurological signs are correlated with histopathological evidence of cerebral infarction and resemble the syndrome of middle cerebral arterial occlusion in man. Mongolian gerbils present an experimental model for cerebral ischaemia. Many workers have demonstrated a possible role of biogenic amines as norepinephrine, dopamine and serotonin in the pathophysiology of brain ischaemia.

We have tested vasopressin on the gerbil cerebral ischaemia, in order to evaluate its effects on the neurological signs induced by the ligation. The experiments vere carried out in adult Mongolian gerbils (60 - 80 g) of either sex. Mongolian gerbils were selected as previously described (Delbarre G. et al, Soc. Neurosci. Abstr. Vol 5, 333, 1979) and only positive animals (which respond immediately by ptosis resulting from transitory interruption of carotidian supply) were used in the experiment. They were anaesthetized with ketamine (50 mg/kg - IP) and two groups of 8 animals were constituted :

a control group : saline was administered IP
a treated group : vasopressin 0,1 U/animal ICV 10 µl 15 minutes before and 1 minute after ligation.

Neurological status was evaluated with the stroke index reported by McGraw et al. (Stroke 7 : 485, 1976) starting one hour after ligation and again at 4, 24, 48, 72 and 96 hours. Like saline, vasopressin 15 minutes before ligation did not affect the neurological status of the gerbils. In contrast, vasopressin after ligation significantly improved the mean stroke index.

6.9 OXYTOCIN ANTISERA BLOCKS REEMERGENT MATERNAL BEHAVIOR IN EXPERIENCED RAT MOTHERS. J. Caldwell\*, C.A. Pedersen\*, M. Johnson\*, and A.J. Prange, Jr. (SPON: M.C. McNamara). Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514 Primiparturient rats (Charles River Breeders) were allowed three durations of postpartum mothering experience before they were isolated from pups for 4-5 weeks. The incidence of full maternal behavior (FMB) during the first two hrs of renewed contact with foster pups (spontaneous rate) was then assessed for each group. Animals that had been allowed 4-24 hrs, 4-5 days, or 7-8 days of postpartum pup contact displayed respectively a 36% (5/14), 67% (6/9), and a 100% (11/11) spontaneous rate of FMB (p < .002, Fisher's exact probability, comparing the first and third groups).</p>

Primiparturient animals allowed to mother their offspring for 4-24 hrs and then separated from pups for 4-5 weeks were given ICV injection of either 800 ng of oxytocin (OXY) or saline and then given three young pups. Oxytocin recipients responded at a significantly (p < .005) higher rate of FMB (8/10) within two hrs than animals receiving saline (1/9). Other primiparturients allowed brief mothering experience and separated from pups for 4-5 weeks were ovariectomized ten days prior to behavioral testing. Ovariectomized animals receiving 800 ng of OXY ICV responded at a rate (8/11) significantly (p < .04) greater than those receiving saline (2/9).

Primiparturient animals allowed 4-5 days of postpartum mothering experience and separated from pups for 4-5 weeks received either 10 µl anti OXY antisera (AOA) or 10 µl normal rabbit serum (NRS) ICV one hr before introduction of foster pups. Recipients of AOA displayed a significantly (p < .025) lower rate of FMB (3/9) than recipients of NRS (8/9) in the first two hrs of renewed pup contact. These observations suggest that: 1) Parturition and/or brief

These observations suggest that: 1) Parturition and/or brief mothering experience produce a prolonged sensitivity to the maternal behavioral effects of OXY that is not ovarian steroid dependent; 2) the high spontaneous rate of reemergent FMB seen in primiparious animals allowed longer periods of postpartum mothering experience depends upon the release of endogenous OXY.

63.8 ANTAGONISM OF MEMORY ENHANCING EFFECTS OF VASOPRESSIN (AVP) BY A VASOPRESSIN ANTAGONIST PEPTIDE (ANTI-AVP). C.J. LeBrun\*+, H. Rigter++, J.L. Martinez, Jr.+, G.F. Koob+, M. Le Moal+++, and F.E. Bloom+ + Arthur Vining Davis Ctr. for Behav. Neurobiol., The Salk Inst., San Diego, CA 92138 (USA), ++ CNS Pharmacol. Dept., Organon, Oss, Netherlands. +++ Laboratoire de Neurobiologie des Comportements, Universite de Bordeaux II, F. 33076 Bordeaux, France.

33076 Bordeaux, France. The present study examined the effects of a potent anti-AVP [1 deaminopenicillamine-2-(0-methyl) tyrosine arginine vasopressin] [dPTyr(Me)AVP] on the ability of AVP to facilitate retention of a passive avoidance task. Both peptides were tested after s.c. injection. Replicate experiments were conducted in the USA, and Netherlands using the same training procedure and Wistar rats, but different passive avoidance tasks [(Martinez et al., Physiol. Behav. 19: 139-144 (1977); Ader et al. Psychon. Sci. 26: 125-128 (1972)]. On Day 1, the rat was placed in the shock compartment, for 2 min, and then given a pretraining trial in which the rat is placed in the start area and allowed to step through into the shock compartment without receiving shock. On Day 2, two more pretraining trials were given, followed by the acquisition trial, during which the rat received a shock. Immediately following the learning trial, the rat was injected s.c. in the neck [(USA) AVP = 1 µg/rat, antiAVP = 25 µg/rat; (Netherlands) AVP = 3 µg/rat antiAVP = 15 µg/rat]. A retention test was given 24 hours later. The results show (see table) that s.c. injection of AVP facilitated performance in both experiments. Peripheral injection of antiAVP reversed the effects of AVP. AntiAVP alone, produced, in the Netherlands study, an effect similar to that of exogenous AVP. These results confirm the posttrial efficacy of vasopressin in enhancing retention performance. The results obtained with antiAVP indicate that it may be a partial agonist. These data suggest that the peripheral action of AVP are in some way responsible for its behavioral action, since the antagonist is known to block the pressor actions of AVP. Table mean (+SEM). Latency to enter shock compartment 24 hours after trainIng.

HAIR-PIN LOOPS OF MICROTUBULES AT NEURONAL GROWTH CONES. H.T. 64.1 Tsui & K.L. Klein. Interdept. Prog. Neurosci., Northwestern University, Evanston, IL 60201.

Axons and dendrites contain numerous microtubules. These linear structures appear to play a role in maintaining cell shape and in intracellular transport. They are generally believed to be disassembled and degraded at axon terminals. However, antidisassembled and degraded at axon terminals. However, anti-tubulin immunofluorescence of developing neurons in culture showed a fibrous pattern at growth cones although the endings of individual microtubules could not be determined (Spooner B.S. & Halladay C.R. Cell Motility 1, 167-178). In order to understand the overall cytoskeletal organization at the ends of developing neurites, we have examined under the high voltage electron micro-scone. (WUW) thick contings, whole rownth act Tather extracted scope (HVEM) thick sections, whole mounts and Triton-extracted whole mounts of growth cones of chick retinal neurons that have been in culture for 4 to 6 days. In contrast to the generally accepted hypothesis that microtubules terminate at nerve terminals, we present evidence that over 50% of these growth cones have at least one microtubule that forms loops, bending around 180 degrees and back towards the cell body. Dissociated chick retina cells were plated onto either poly-

lysine- and formvar-coated gold grids for whole mount studies or polylysine-coated coverslips for sectioning studies. After 4 to 6 days in culture, the cells were fixed, dehydrated and either critical-point-dried for whole mount studies or embedded in epon-araldite for thick section studies. Detergent extracted whole mounts were prepared using 0.15% Triton X-100 in a microtubule-stabilizing extraction buffer according to Schliwas and van Blerkom (J. Cell Biol. 90, 222-233) before fixation. Thick sections, whole mounts and Triton-extracted whole mounts showed similar organization of the cytoskeleton at neurite terminals. Microtubules spread out, then either terminated or bent around at the growth cone regions. Very often individual microtubules were seen to make a 180 degree turn within a diameter as little as 5 um and return to the main microtubule bundle. Quantitative analysis of the occurrence of these microtubule hair-pin loops were done on Triton-extracted cultures. Of the 93 growth cones examined, 49 showed at least one microtubule that bent back and formed a loop. This unusual disposition of microtubules may be important for the control of neurite growth and bi-directional transport. Our findings also raise the interesting question of how microtubule configuration is controlled to give such elaborate loops.

64.3 REVERSIBLE NOCODAZOLE SENSITIVITY IN YOUNG, NGF ACTIVATED PC12 NEURITES.

ACTIVATED PC12 NBURTIES. Roger Jacobs and John Stevens, Playfair Neuroscience Unit. University of Toronto, and Toronto Western Hospital, Toronto, CANADA M5T 258. PC12 (pheochromocytoma) cultured cells, when activated with nerve growth factor (NGF), are known to produce long branched networks of neurites. We have observed, as have others, that the NGF activated neurites contain microtubules and organelles similar to those found in normal neuronal processes. Additionally, via long term time lapse, we have found that the ontogeny of neuritic branching is similar to that described by Bray (J. Cell Bio. 56:702, 1973) for sympathetic neurons: PC12 processes elongate via growth cone extension and new branches are formed by growth cone bifuraction. Thus, the ontogeny of PC12 process development appears to approximate the normal behaviour of PNs cells in vitro. We have found that within 45 to 90 minutes after

We have found that within 45 to 90 minutes We have found that within 45 to 90 minutes after the addition of 1-2 micrograms/ml of Nocodadole (a drug that leads to microtubular dissasembly), to a young PC12 culture (between 6 and 14 days after NGF activation), most neurites constrict to form beaded or varicose processes. These induced varicosites do not move, but correspond to regions of the neurite that were slightly expanded and moving before the drug was added. We believe, therefore, that varicosities represent organelles contained within the neurites. Within two hours of washing out the Nocodazole, the Within two hours of washing out the Nocodazole, the constrictions on the PCl2 processes "fill out", restoring a process that appears normal. Thus, we suspect that the microtubular array contained within the young PCl2 neuritic processes has been depolymerized and repolymerized within the time span of several hours. of several hours.

The same experiment carried out on mature cultures (more than fourteen days after NGF activation) shows a much weaker response. Experiments agents commonly used to disassemble microtubules, such as Colchicine, produce similar effects in both young and mature cultures (see Black and Greene, J. Bio. 95:379, 1982) but without any sign Cell of reversibility. Supported By Grant #1740 From Canadian MRC.

TAU-LIKE MICROTUBULE-ASSOCIATED PROTEINS (MAPs) IN RAT SYMPATHETIC 64 2 NUCLINE MICROTIDULE-ASSOCIATED FROTEINS (MAPS) IN RAI STAFATHET NEURONS CULTURED FOR VARYING PERIODS OF TIME. <u>M.M. Black\*</u> and <u>J.T. Kurdyla\*</u> (SPON: A. Lamperti). Dept. of Anat., Temple Univ. Sch. of Med., Philadelphia, PA 19140. The goal of the present studies is to determine whether the composition of tau-like MAPs in cultured sympathetic neurons

changes with time in culture. Sympathetic neurons were obtained from superior cervical ganglia of 1-3 d old rat pups. The neurons were enzymatically dissociated and then cultured with cytosine arabinoside to eliminate nonneuronal cells. In previous studies (Black, M.M. and J.T. Kurdyla, J. <u>Cell Biol</u>., in press). 24 proteins with molecular weights ranging from 60,000 to 76,000 were identified as MAPs in 2 week old neuronal cultures. These MAPs have similar properties to the tau class of brain MAPs. Studies by Francon et al., (<u>Eur. J. Biochem 129</u>: 465-471) have shown that the polypeptide composition of brain tau changes during growth and maturation. In the present experiments, we have showing and maturation. In the present experiments, we make examined the composition of tau-like MAPs in neurons as they age in culture. Cultures maintained for 7, 14, or 60 d were labeled with  $[^{35}-S]$ -methionine and then fractionated to enrich for the with [2-5]-methionine and then fractions were analyzed by iso-electricfocusing x SDS polyacrylamide gel electrophoresis and fluorography. 24 tau-like MAPs were identified in the cultures, regardless of their age. The tau-like MAPs from 7, 14, and 60 d old cultures had indistinguishable mobilities in isoelectricfocusing x SDS polyacrylamide gel electrophoresis. These data suggest that the composition of tau-like MAPs did not change between 7 and 60 d in vitro. Studies are in progress to characterize the tau-like proteins in cultures less than 7 d of age.

THE CYTOSKELETAL BASIS OF GANGLIOSIDE-MEDIATED NEURITE OUTGROWTH IN NEURO-2A NEUROBLASTOMA CELLS. <u>David A. Spero\* and Fred J.</u> <u>Roisen</u> (SPON: A. Gona). Dept. of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854. We have shown previously (<u>Science, 214</u>:577-578, 1981; <u>Anat.</u> <u>Rec., 205</u>:190, 1983) that a mixture of bovine brain gangliosides (BBG) applied to Neuro-2a neuroblastoma (Neuro-2a): 1) markedly increased the degree and rate of neurite formation and 2) stimulated the formation of a complex cytoskeleton consisting of a highly organized network of microfilament bundles. To study further the relationship between neurite outgrowth and of a highly organized network of microflament bundles. To study further the relationship between neurite outgrowth and cytoskeletal components, we employed cytoskeletal disruptive agents (Colcemid and cytochalasin D) to examine the role that microtubules and microfilaments play in BBG-induced neurite initiation and elongation. Neuro-2a cells were grown in Minimum Initiation and elongation. Neuro-2a cells were grown in minimum Essential Medium supplemented with 10% heat-inactivated fetal calf serum. Cells were plated on glass coverslips previously coated with poly-DL-ornithine. Cultures were grown in medium with or without BBG (250 µg/ml) and the appropriate test agent [Colcemid (0.25 µg/ml) or cytochalasin D (2 µg/ml)] for 24 hr in an atmosphere of 5% CO<sub>2</sub> in air at 35°C. Cultures were rinsed briefly in HankS' balanced salt solution, fixed in 2.5% glutaraldehyde in 0.1M cacodylate buffer (pH 7.3) for 2 hr, postfixed in 1% 00. for 30 min dehydrated in ethanol and glutaraldehyde in 0.1M cacodylate buffer (pH 7.3) for 2 hr, postfixed in 1% OSQ<sub>4</sub> for 30 min, dehydrated in ethanol and processed for scanning and transmission electron microscopy. Neuro-2a cells treated with BBG elaborated long, highly branched neurites. The surfaces of these cells possessed numerous microvillar spine-like projections on their perikarya. Simultaneous treatment with BBG and Colcemid resulted in cells with numerous spine-like projections which did not extend neurites. Cells treated with Colcemid alone did not possess either spines or neurites. In contrast, the simultaneous treatment with BBG and cytochalasin D resulted in cells devoid of spines, but exhibiting anomalous neurite outgrowth consisting treatment with BBG and cytochalasin D resulted in cells devoid of spines, but exhibiting anomalous neurite outgrowth consisting of many long, thin, unbranched neurites. These neurites lacked characteristic growth cones and had a tendency to grow in a circular fashion. Cells treated with cytochalasin D alone had smooth surfaces and did not exhibit any significant neurite growth. These findings suggest that, in BBG-induced Neuro-2a cells, microtubules are necessary for neurite elongation and that microfilaments are essential for spine formation and neuritic branching. In this culture system, microtubules appear to play a more central role in providing the forces for neurite extension than do microfilaments. (Supported by NIH grant NS 11299.)

64.7

VASOPRESSIN PROMOTES NEURITE GROWTH IN CULTURE. R. Gruener, R. 64.5 E. Brinton and H. I. Yamamura. Depts. of Physiology and Pharmacology, Arizona Health Sciences Center, Univ. of AZ, Tucson, AZ 85724.

Vasopressin, a neuropeptide, has been reported to enhance memory functions (De Wied, <u>Nature 232</u>:58,1971; Koob & Bloom, <u>Ann.</u> <u>Rev. Physiol. 44</u>:571, 1982). The mechanism(s) for this effect is unknown. One possible route by which vasopressin (AVP) could influence memory is through the induction of protein synthesis specific for information storage. In an attempt to find a cellular substrate for memory, Crick (<u>TINS</u> <u>5</u>:44, 1982) has postulated that an increase in dendritic spine formation may permit the <u>de-novo</u> establishment of neuronal circuits which permit the <u>de-novo</u> establishment of neuronal circuits which underlie memory engrams. Because neurite production is a specific expression of protein synthesis in CNS neurons, we examined the effects of AVP on this cellular process. Neurons were isolated from the cephalic portion of embryonic <u>Xenopus</u> spinal cords and grown in culture (Kidokoro et al., <u>Dev. Biol.</u> 78:464, 1980). Sister cultures were grown in a defined medium in the presence of  $10-200 \mu M$  AVP. Neurite production was estimated from the number of loci and total number of neurites in duplicate cultures. of loci and total number of neurites in duplicate cultures. Vasopressin-treated cultures showed a marked increase in the number of loci and in total number of neurites when compared to controls. This effect occurred in a dose-dependent fashion. Neurites in AVP-treated cultures were typically longer than in controls. In addition, neurites in AVP-treated cultures were characterized by numerous spines (filopodia) along their entire length. The vasopressin-induced increase in neuritic growth may reflect specific cellular alterations which may be involved in memory processes.

Supported by BRS and COG grants to RG and by an NIMH Pre-doctoral fellowship MH-08941 to REB.

INSULIN AND INSULINLIKE GROWTH FACTOR-II STIMULATE NERVE GROWTH FACTOR RECEPTOR ACTIVITY, NEURITE FORMATION, AND GROWTH IN CULTURED HUMAN NEUROBLASTOMA CELLS. <u>E. Recio-Pinto\* and D.N.</u> <u>Ishii.</u> Department of Pharmacology and <u>Cancer Research Center</u>, Columbia University, New York, NY 10032. Insulin and insulinlike growth factor-II (IGF-II) had direct and indirect offocto on particle outpactuation in human. 64.6

and indirect effects on neurite outgrowth in cloned human neuroblastoma SH-SY5Y cells. With respect to the direct effects, insulin reversibly increased neurite formation when cells were grown in media without serum (-S), a condition under which cells could survive for at least a week without loss in number. The half-maximal response was at 4 nM for porcine, bovine, and synthetic human insulin, and at 0.5 nM for IGF-II. Both values were lowered to 0.1 nM when bacitracin, a protease inhibitor, was present. In media with serum (+S), the anti-nerve growth factor (NGF) antiserum inhibited NGF-stimulated neurite formation, but not that stimulated by  $_{125}$  insulin. Moreover, insulin did not compete for binding of  $^{125}$  I-NGF to specific sites.

compete for binding of "1-NGF to specific sites. The indirect effects were due to modulation of NGF\_activity. In -S, the cells lost virtually all capacity to bind <sup>125</sup>I-NGF and respond to NGF with neurite formation; the loss of both functions was prevented by insulin or IGF-II. Moreover, both functions were restored by subsequent treatment with insulin or serum. The indirect effect of insulin and IGF-II on neurite formation could be readily distinguished from the direct effect because at very low concentrations these factors could potentiate the response to NGF. In +S, anti-insulin antiserum inhibited the response to NGF. In +S, anti-insulin antiserum inhibited the activity of insulin ordinarily present in serum and decreased the neurite formation response to NGF, and the spontaneous level of neurites. Insulin and IGF-II stimulated H-thymidine incorporation and coll projection; the holf moving response

Insult and IGF-II stimulated "H-thymidine incorporation and cell proliferation; the half-maximal response for insulin stimulated cell proliferation was at 0.3 nM. These effects could be dissociated from effects on neurite formation, since, in -S, in subjection was not sustained by insulin despite cell replication was not sustained by insulin despite continuously elevated neurite outgrowth. Ordinarily, peripheral neurons become postmitotic at early developmental stages. Thus, malignancy in human neuroblastoma cells may be due, in part, to inappropriate sensitivity to insulin and insulinitie factors. inappropriate sensitivity to insulin and insulinlike factors. Thus, at physiological concentrations, insulin and IGF-II have NGF-like effects on neurite formation and increase growth. Rat liver multiplication stimulating activity has been shown by others to have a structure homologous to human IGF-II, and was the source of activity used in these studies. (Supported in part by grants ROI NSI4218 from the National Institute of Neurological Communicative Diseases and Stroke, PHS Research Career Development Award 1K04 NS00375, and PHS training grant GM 07182.)

PERTURBATION OF NEURITE GROWTH BY PULSED AND FOCAL 64.8

PERTURBATION OF NEURITE GROWTH BY PULSED AND FOCAL ELECTRIC FIELDS. <u>N.B.Patel\* and M-m.Poo</u> (SPON: B.J.Vasquez). Dept. of Physiology and Biophysics, Univ. of Calif, Irvine, CA 92717. The growth and orientation of embryonic <u>Xenopus</u> neurites in culture are markedly affected by uniform DC fields (J. Neurosci., 2:483, 1982). The present study examined the effects of monopolar pulsed and focal electric fields, which are characteristic of fields associated with endogenous nervous activi-ties, on dissociated <u>Xenopus</u> embryonic neurons plated in monolayer culture. Three types of fields, and focal pulsed fields. Under pulsed uniform fields, neurites showed preferential orientation toward the cathode of the field in a manner similar to that previously found for DC fields. The extent of neurite orientation depended upon the width, amplitude, and frequency of the (square) pulse, but appeared to be equivalent to the effect produced but appeared to be equivalent to the effect produced by a DC field of the same average intensity. The threshold pulse amplitude and frequency required by a be the off of the subscript and the produce a detectable orientation of neurity. The growth within 24 hr in a pulsed uniform field was 1 V/cm at 10 Hz with a pulse duration of 5 ms. Focal DC fields were applied near the growth cone of the neurite by passing current through a micro-pipette. Positive field (current source) was found to deflect the growth cone away from the pipette, while negative field (current sink) attracted the growth cone. The threshold current density needed to orient a growth cone within 15 min was between 0.4 to 4 pA/µm<sup>2</sup> (or 5 to 50 mV/cm) at the growth cone. Pulsed focal currents of pulse amplitude of 8 pA/µm<sup>2</sup> at 100 Hz, or 80 pA/µm<sup>2</sup> at 10 Hz were effective in orienting the growth cone. The latter currents are similar to those which occur at the synaptic cleft during synaptic transmission, suggest currents are similar to those which occur at the synaptic cleft during synaptic transmission, suggesting attraction or repulsion of the nerve terminal by the electric field associated with synaptic activity is a plausible cellular mechanism underlying activity-dependent modulation of synaptic efficacy. This work is supported by a grant from NIH (NS-17558-01A1). 01A1).

ISOLATION OF A MONOCLONAL ANTIBODY THAT INHIBITS THE IN VITRO NEURITE PROMOTING ACTIVITY OF A HEPARAN SULPHATE PROTEOGLYCAN NEURILE PROMOTING ACTIVITY OF A HEFARAN SULPHATE PROTEOGLYCAN COMPLEX. <u>William D. Matthew and Paul H. Patterson</u>. Department of Neurobiology, Harvard Medical School, Boston, MA 02115. Several groups have described factors found in conditioned media (CM) which bind to polycationic substrata and stimulate neurite outgrowth from a variety of cultured neurons. Five monoclonal antibodies have been described which precipitate a heparan sulphate proteoglycan (HeS) from PC12 cell CM and, in doing so deplete (M efficiency in the induce reside neurite doing so, deplete CM of its ability to induce rapid neurite outgrowth (Matthew <u>et al.</u> 1982. <u>Soc. Neurosci. Abstr.</u> 8: 83.4). However, when these antibodies are adsorbed to CM coated dishes, they do not block the outgrowth promoting activity. Therefore, it is unclear if the HeS is directly responsible for promoting neurite growth or is merely required to adsorb an associated molecule to the polycationic culture surface. We hope to resolve this issue using a monoclonal antibody which actually blocks the function of the neurite promoting molecule. After generating 138 monoclonal antibodies that recognized the CM factor but did not directly block function, we decided to use a new approach. A mouse was immunized with an inactive HeS to initiate a response to non-functional, immunodominant determinants. Two days later, an immunosuppressant drug was injected. Our strategy was to kill the lymphocytes stimulated by these determinants. Three weeks later, the "tolerized" spleen was immunized in vitro with active CM and then fused to History and the second the neurite promoting molecule and determine if the HeS or an associated molecule is responsible for this activity.

Since the 4H8 antibody blocks the function of the neurite promoting molecule <u>in vitro</u>, we feel it is an appropriate probe for localizing the activity <u>in situ</u>. The 4H8 antigen has a distribution in developing tissue consistent with it having a role in neurite growth. Using immunohistochemical procedures, we have detected high levels of antibody binding in neonatal superior cervical ganglia but little or none in adult ganglia. However, when adult rats are sympathectomized with 6 hydoxydopamine, the antigen can be detected in adult superior cervical ganglia and the time course of its appearance parallels neurite regrowth.

PREFERENTIAL GROWTH OF CNS AND PNS NEURITES ON ASTROCYTES AND SCHWANN CELLS AS COMPARED TO NON-GLIAL CELLS IN VITRO Justin R. 64.9 John M. GENNE C. McKhann) MRC Neuroimmunology Project, Jept. of Zoology, University College London, London WCl, U.K. Growing axons in the developing embryo and regenerating nerve

are usually in intimate association with glial and other non-neuronal cells, and it has been suggested that such cells play an important part guiding axonal growth. To approach this question in vitro, I have studied neurite outgrowth on highly enriched monolayers of glial and non-neuronal cells. I have shown previously (Soc. Neurosci. Ahstr. 8:302 1982) that both CNS and PNS neurites grow vigorously (at rates of .6-1mm/day) and in fine fascicles on rat cortical astrocytes (>95% pure as judged by antibody labelling for GFAP). In contrast, on fibroblast monolayers PNS neurites extend at less than half the rate and tend to form large bundles, while most CNS neurites grow very little. I have extended these studies to show that sciatic nerve Schwann cells (>95% pure on the basis of antibody labelling for RAN-1) also promote vigorous neurite outgrowth from both CNS (E15 retina) and PNS (E20 SCG) explants.

I have also the studied the behaviour of neurites faced with a <u>choice</u> of cells in the same dish. Contiguous monolayers of astrocytes and skin fibrohlasts were constructed, and explants of retina or SCC were plated on either side of the border. CNS neurites growing on the astrocytes rarely crossed on to the fibrohlasts monolayer, instead they stopped or turned and continued to grow on the glial cells. Few neurites extended from retina explants plated on the fibrohlast side. While the majority of SCC neurites remained on the astrocytes, some crossed over to the fibrohlasts, but growth rate slowed. When SCC neurites growing on fibrohlasts reached the astrocyte frontier, they defasciculated and increased their rate of growth. Neurites of either type did not significantly change their behaviour when they crossed an astrocyte-astrocyte border. In all cases neurite outgrowth was characteristic of the monolayer contacted. I have also the studied the behaviour of neurites faced with a

Light and electron microscopic examination revealed that both Light and electron microscopic examination revealed that both CNS and PNS neurites grew on top of or between the glial cells. In contrast, the growth cone and distal segment of the PNS neurites were often seen under the fibroblasts, indicating that the growth cones chose to migrate on the culture substratum (or secreted extracellular matrix) and/or the ventral surface of the fibroblast in preference to the dorsal surface. These experiments suggest that the surfaces of astrocytes and Schwarp calls can particularly attractive to both CNS and PNS

Schwann cells are particularly attractive to both CNS and PNS neurite outgrowth. It seems likely that such interactions play neurite outgrowth. It seems likely that such int an important part in neural development and repair. Supported by NIH grant NS06475.

NEURITE EXTENSION BY PERIPHERAL AND CENTRAL NERVOUS SYSTEM 64.10 NEURONS IN RESPONSE TO SUBSTRATUM-BOUND FIBRONECTIN AND LAMININ. S.L. Rogers\*, P.C. Letourneau\*, S.L. Palm\*, J. McCarthy\* and L.T. Furcht\* (SPON: R. Jacobson). Dept. of Anatomy and Dept. of Lab. Medicine and Pathology, Univ. of Minnesota, Minneapolis, MN 55455.

Laminin (LAM) and fibronectin (FN) are components of extracellular matrices in vivo and mediate adhesion, migration, and differentiation of various cell types in vitro. We have studied neurite extension by peripheral (dorsal root and sympathetic ganglion) and central (spinal cord and retina) nervous system neurons cultured on purified LAM and FN in the presence and in the absence

of serum. Plastic tissue culture dishes were treated overnight with 10-100  $\mu$ g/ml human plasma FN or mouse EHS tumor LAM (Rogers et al., Dev. Biol., in press). In medium supplemented with newborn calf serum or with FN-depleted calf serum, both peripheral and central neurons attached to, and extended neurites on, LAM. In contrast, only peripheral neurons initiated neurites on FN. Number of neurites initiated, neurite lengths and extent of branching were evaluated and compared with similar measurements of neurite extension on poly-L-lysine-treated surfaces. Although poly-L-lysine tension on poly-L-lysine-treated surfaces. Although poly-L-lysin provides an adhesive surface for neurite initiation, elongation of neurites was more rapid on the two glycoproteins. Neuronal response to LAM- or FN-treated substrata was markedly reduced by pre-treatment of substrata with antisera to LAM and FN, respectively. The antisera did not diminish neurite outgrowth on poly-L-lysine. In serum-free cultures, neuronal behavior did not differ from that in serum-supplemented medium: both peripheral and central neurons extended neurites on LAM, while only peripheral neurons responded to FN.

Previous studies (L.T. Furcht, Mod. Cell Biol.1:53-117, 1983) have identified tryptic and catheptic fragments of FN containing discrete domains that mediate the multiple functions of this glycoprotein. These fragments include a 27 Kd fragment that weak-ly binds heparin, a 46 Kd collagen-binding region, a 110 Kd region That contains cell-binding activity but does not bind collagen or heparin, a 58 Kd heparin-binding fragment, and a 31 Kd fragment that contains a free sulfhydryl. Analysis of peripheral neurons cultured on these fragments indicates that the majority of neurite promoting activity resides in the 110 Kd region. Central nervous system neurons did not respond to this portion of the molecule. Additional powrite presenting activity use detected in the 58 Kd system neurons did not respond to this portion of the molecule. Additional neurite promoting activity was detected in the 58 Kd heparin-binding fragment but not in the 27 Kd, 46 Kd or 31 Kd preparations. These studies indicate that growing neurites inter-act with specific molecular features of extracellular environments.

64.11 INTERACTION OF A LATERAL LINE NERVE IMPLANT AND SPROUTS OF INJURED CENTRAL NEURONS IN THE GOLDFISH MEDULLA. JRUNS IN THE GOLDFISH MEDULLA. <u>S.J. Zottoli</u> Dept. of Biology, Williams College, and C. van Horne. Dept Williamstown, MA 01267

Neurons intrinsic to the central nervous system (CNS) of vertebrates exhibit limited regrowth after injury. Sprouts of injured central axons in the goldfish extend no more than 2-3 mm and few if any project across the lesion site. This limited regrowth may result from limitations imposed by the CNS micro-environment. To test the possibility that the sprouting and elongation of the Mauthner axon (M-axon) and other central neurons of the goldfish may be influenced by a peripheral nerve, we have implanted a piece of lateral line nerve into the medulla oblongata near axons injured by spinal cord transections. Goldfish, 9-12 cm in body length, were anesthetized and the brain was exposed. The central portion of the cervical spinal

brain was exposed. The central portion of the cervical spinal cord just caudal to the vagal lobes was cut with microdissect-ing scissors and one end of an autologous lateral line implant was placed close to the cut axons. Different procedures were used to maximize the chances that the implant and the retracted M-axon would be contiguous. The other end of the nerve was placed in adjacent muscle. After postoperative intervals between 90-120 days (sprouting is initiated by 60 days), both M-axons were filled with dye and only 7 sprouted. None of the sprouts entered the implant and there was no indication that the peripheral nerve influenced the direction of sprouting of the sprouts entered the implant and there was no indication that the peripheral nerve influenced the direction of sprouting even though M-axon processes were as close as 15  $\mu$ m to the tip of the implant. Three of 11 non-M-axons that were cut and filled sent sprouts into the implant. HRP backfilling of the lateral line implant in other fish confirmed that many injured central neurons sent processes into the lateral line nerve for distances up to 15 mm, 7 times the distance that non-M-axons were found to sprout within the CNS. In one instance, labeled neurons were found up to 7 mm rostral to the implant and as many as 248 cells were filled. These results indicate that once sprouts of injured axons

contact the implant, they elongate for substantial distances and that the microenvironment presented by the lateral line nerve appears to be more conducive to elongation of sprouts than the CNS. Special thanks is extended to Dr. A. Aguayo, who participated in preliminary experiments. Supported in part by NSF Grant No. BNS-7924655 and by a grant from the Research Corporation.

INCREASED LOW MOLECULAR WEIGHT MICROTUBULE-ASSOCIATED PROTEIN (MAP) IN PC12 CELLS FOLLOWING LONG TERM EXPOSURE TO NGF. S. H. Green and L. A. Greene\*. Dept. of Pharmacology, New York University Sch. Medicine. New York, NY 10016. In response to NGF, rat PC12 pheochromocytoma cells acquire properties characteristic of neurons. Among these is the elaboration of long, branched neurites. Concomitant with the growth of neurites is a decrease in colchicine-lability of microtubules (Black & Greene, 1982, J.C.B. 95: 379-86) and an increase in a high molecular weight microtubule-associated protein (HMW-MAP) (Greene et al., 1983, J.C.B. 96: 76-83). We now show further that a low molecular weight MAP (MW = 32,000 by SDS-PACE) is greatly increased in PC12 cells following SDS-PAGE) is greatly long-term NGF treatment. greatly increased in PC12 cells following

long-term NGF treatment. PC12 cells untreated with NGF or treated with NGF for 3 weeks were labeled with [<sup>35</sup>S]-methionine for 2-3 days. MAPs were prepared either by three cycles of assembly-disassembly with carrier bovine brain microtubules or by a NaCl extraction of taxol-precipitated microtubules (using purified bovine brain tubulin as carrier). Equal amounts of TCA-precipitable radioactivity were loaded on 7.5-15% polyacrylamide gradient gels and visualized by fluorography. Comparison of NGF-treated and -precipitable reportions reveale no effort changes in gels and visualized by fluorography. Comparison of NGF-treated and -untreated preparations reveals no significant changes in the tau proteins nor in MAPs of MW  $\approx 28,000$  and  $\approx 30,000$  which may correspond to MAP1 subunits (Vallee & Davis, 1983, PNAS 80:1342-6). A low molecular weight MAP (MW  $\approx 32,000$ ) is much more strongly labeled in the NGF-treated preparations. The increase in relative intensity of this MAP following 3 cycles of ascembly-disascembly and following home-term NGF treatment of assembly-disassembly and following long-term NGF treatment is greater than that of MAP1. This suggests that it is neither a subunit nor a fragment of MAP1. Furthermore, immunoprecipi-tation of MAP1 fragments does not reveal a polypeptide with a MW close to that of the 32K MAP. We suggest then that changes in the relative converte of one MWLWAP and one MWLWAP in the relative amounts of one HMW-MAP and one accompany NGF-induced phenotypic changes in FC12 Supported by NIH grant NS 16036. LMW-MAP cells.

## EFFECTS OF LOCALIZED NGF WITHDRAWAL ON DORSAL ROOT 64.13

EFFECTS OF LOCALIZED NGF WITHDRAWAL ON DORSAL ROOT GANGLION NEURITES IN VITRO, R. W. Gundersen, Biomedical Research Institute, Univ. of Wisconsin-Parkside, Kenosha, WI 53141. Initial growth and survival of dorsal root neurons is controlled by nerve growth factor (NGF). Does NGF exert its actions via the entire neuron, cell body, neurite, or growth cone alone? To address this question, dorsal root ganglia from 7 day chick embryos were placed in tissue culture in DMEM supplemented with 10% FCS and 10 ng/ml  $\beta$ -NGF. After 24 hours, the cultures were placed in a perfusion chamber and NGF locally withdrawn by microperfusing individual parts of a neuron with NGF-free medium delivered from micropipettes with 10-20  $\mu$ m tip diameters, and the neuronal arowth photographed and quantified.

the neuronal growth photographed and quantified. When NGF was withdrawn from growth cones, neurite growth rate decreased during the first 45 minutes, and ceased between 45 and 60 increased to normal values in 60 minutes. Application of background levels of NGF from micropipettes did not significantly alter neurite growth rate.

Withdrawal of NGF from either the cell body or a segment of the neurite 50  $\mu m$  distal to the growth cone had no significant effect on neurite growth rate.

NGF withdrawal from growth cones altered their gross morphology, as evidenced by a decrease in the number of lamellipodia and microspikes. However, the number of these extensions which could be identified as being identical between two successive observation periods increased. Upon NGF readdition, these parameters returned to their original values.

The above results indicate that short term growth of dorsal root neurons may only require the presence of NGF in the microenvironment of the growth cone. NGF may be controlling short term neurite growth by affecting growth cone motility. NS18214.) (Supported by NIH grant number

- BLOCKERS OF CALCIUM PERMEABILITY INHIBIT NEURITE EXTENSION AND 64.14 DEDGRAF OF NEUROMUSCULAR SYNAPSES IN CELL CULTURE. D.J. Pelto,\* <u>B.A. Suarez-Isla and S.I. Rapoport</u>. (SPON: J.C. Conti) Laboratory of Neurosciences, GRC, National Institute on Aging,
  - NHR, Baltimore City Hospitals, Baltimore, Maryland 21224. U.S.A. Inorganic blockers of calcium permeability, such as cobalt, manganese and lanthanum, were added to cultured trypsin-dissoci-ated retina neurons from chick embryos. They decreased the percent of cells that extended neurites after 24 h in culture, in a concentration dependent manner. Blockers also decreased the rate of neurite growth and the formation of synapses between retina neurons from 8 day chick embryos and rat myotubes, after 24 h in coculture. Fifty percent inhibition of neurite extension was produced at concentrations of 95  $\mu M$  for cobalt and 250  $\mu M$  for manganese. Adhesion to substratum and survival of retina cells in culture were not affected at concentrations of inorganic blockers that inhibited more than 90% of neurite extension. Organic channel-blockers, such as verapamil and D-600, prevented adhesion of 8 day retina neurons to substratum before affecting neurite extension. However, nitrendipine significantly inhibited neurite extension before preventing adhesion to substratum.

Growth of neurities <u>in vitro</u> was very sensitive to the extracellular calcium concentration. In medium containing 1.8 mM Ca, 0.8 mM Mg and 10% v/v fetal calf serum, about 16% of cells extended neurites after 24 h in culture. In calcium-free medium, neurite extension and cell substratum adhesion were blocked. neurite extension and cell substratum adhesion were blocked. However, after addition of 1% or 10% of servum, 6% and 9% of the cells, respectively, extended neurites. In contrast, high Ca concentrations or loading the cells with Ca after 24 h in medium with 25 mK<sup>+</sup> or 0.1  $\mu$ g/ml of the calcium ionophore A23187, reduced neurite extension.

With normal calcium concentrations (1.8 mM), inhibition of neurite extension by calcium channel blockers was related to the age of the donor chick embryo. 200  $\mu M$  cobalt decreased neurite extension by 20% in 6 day retina cells, as compared to 90% in 14 day retina neurons.

Eight day retina neurons, which were densely plated over rat myotubes, innervated 90% of the muscle cells after 24 h of coculture, as determined by intracellular recording. Pretreatment of retina neurons with cobalt or manganese reduced the percent innervation in a concentration-dependent manner, but similar pretreatment of the myotubes had no effect. These results demonstrate the central role of calcium flux in

extension of neurites from primary dissociated neurons, and suggest that synapse formation can be prevented by impairing calcium entry during development and aging.

64.15 FURTHER PURIFICATION AND CHARACTERIZATION OF A NEURITE OUTGROWTH-PROMOTING FACTOR. A. D. Lander\*, D. K. Fujli\*, D. Gospodarowicz\*, and L. F. Reichardt. Department of Physiology and Cancer Research Institute, University of California, San Francisco, CA 94143. Recently, we have reported the characterization of a factor that promotes neurite outgrowth in vitro (Lander et al., J. Cell Biol. 94, 574-585). The factor is found in medium conditioned by bovine corneal endothelial cells, as well as other cell types, and contains protein and glycosaminoglycan (heparan sulfate) as essential components. When dissociated rat or chick sympathetic or sensory neurons were plated onto polylysine (PLYS)-coated substrata that had been treated with conditioned medium, the neurons extended neurites rapidly and extensively even in the absence of nerve growth factor. Fractionation of serum-free conditioned medium ( $CM_{SF}$ ) indicated that the active factor behaves as a very large molecular species with a buoyant density in cesium chloride of 1.36-1.37.

We have further purified the factor from 35S-sulfate- and 3Hleucine-labeled CMSF, using ammonium sulfate precipitation, polyethylene glycol precipitation, ion exchange chromatography, and velocity sedimentation. Outgrowth-promoting ctivity remains associated with  $35\,\text{S-}$  and  $3\,\text{H-labeled}$  material. The  $35\,\text{S-label}$  associated with the factor is degraded by purified heparitinase, confirming the presence of a heparan sulfate proteoglycan. ever, our results suggest that the factor exists as a complex with other molecules. Preliminary findings indicate that as many as 3-4 proteins may be associated with the proteoglycan. Recently, others have reported that the extracellular matrix glycoproteins fibronectin (FN) and laminin (LN) can promote neu-

grycoproteins fibronectin (FN) and Laminin (LA) can promote near rite outgrowth (Baron-Van Evercooren et al., J. Neurosci. Res 8, 179-183; Manthorpe and Varon, unpublished). FN is not likely to be the active component of the CMgr-derived factor, since FN-sub-strata do not promote neurite outgrowth in our assay, and since the CMgr-factor does not bind to gelatin-Sepharose. It seemed plausible that LN might be a component of the CMsr-factor, since we have found LN-treated PLYS substrata to be reasonably effective at promoting outgrowth. However, the outgrowth-promoting ability of LN-substrata is lost following treatment with anti-LN antiserum, whereas neurite outgrowth on CMSp-treated substrata is not diminished after treatment of the substratum with this antiserum, or when the antiserum is included throughout the neuronal culture.

We are beginning to investigate the modes of action of the CM<sub>SF</sub>-derived factor and LN in promoting neurite outgrowth, in or-der to see what mechanisms are common to both substances. In this way, we hope to understand better the ways in which a growing axon can interact with its substratum <u>in vivo</u> and <u>in vitro</u>. Supported by grants GM07618 (NIH) and <u>BNS8100342</u> (<u>NSF</u>)

CHROMOSOMAL, TARGET AND SUBSTRATUM CONTROL OF SPINAL NERVE FIBER GROWTH RATE PARAMETERS IN VITRO. <u>G.M. Procento\*, W.L. Muhlach\*</u> and E.D. Pollack. Inst. Study of Develop. Disabilities and Dept. Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL 60608. Nerve fiber growth rate in vitro and its incumbent periodic cycling are primary features of neural development that aré under controls imposed by genetic information, target availability and growth substratum. Cyclic extension of spinal nerve fibers in tissue culture as a function of target tissue presence has been demonstrated by us previously (Muhlach and Pollack, Dev. Brain Res. 4, '82). A specific influence of chromosomal dosage on growth rate and cycling can now be shown through the use of a polyploid neural tissue culture model. Further, the nature of the attachment substratum for spinal cord explants appears to affect neurite growth and stability characteristics. Time-lapse cinephotomicro-graphic analyses have made it possible to compare the relative in their regulation of neurite elongation. Neurite extension from spinal cord explants derived from normal diploid or pressure-induced triploid frog tadpoles were filmed for 24 hours and subsequently analyzed for growth rates and periodic realing of the mere. Twieling of diploid controle were aroun on 64.16

24 hours and subsequently analyzed for growth rates and periodic cycling of the rates. Triploid and diploid controls were grown on poly-DL-lysine substrata, while other diploid explants were grown under varying target and substrata conditions. Neurites extending from triploid spinal cord explants did so at a mean rate (638µm/ 24 how N-71) appreximately 65° explants that for diploid control from triploid spinal cord explants did so at a mean rate ( $638\mu$ m/ 24 hr; N=71) approximately 65% greater than for diploid control neurites ( $380\mu$ m/24 hr; N=48). Periodic cycling of growth rates was also altered such that triploid neurites attained higher mean peak velocities (66%) and higher mean minimal velocities (93%) than the diploid neurites. Peak-to-peak interval time, representative of cycle frequency, was reduced, as would be expected, by 56% in triploid neurites (N=20) from those for diploid neurites (N=15). This indicates that a triploid neurite passes through about two cycles of growth for each one that a diploid completes. The cycles of growth for each one that a diploid completes. The available data suggests that the 50% increase in chromosomal dosage in triploid tissue is reflected in alterations of growth rate parameters of a similar order of magnitude. Just as increasing the chromosomal complement changes growth

Just as increasing the chromosomal complement changes growth rate, so does the presence of the natural limb mesenchyme target and attachment substratum affect the rate and cycle frequencies of diploid cord explants. Integration of information on nerve growth rate, growth cycles and neurite density with respect to the controls imparted by genetic and environmental (target and substratum) factors may permit a better understanding of nerve growth regulation. [Supported in part by NIH grant NS 13814]

EFFECTS OF EXTRACELLULAR MATRIX MOLECULES ON NEURAL RETINAL CELL 64.17 EFFECTE OF EXTRACELLULAR MATRIX MOLECULES ON NEURAL RETINAL CELL ATTACHMENT, SURVIVAL AND DIFFERENTIATION. <u>Ruben Adler and A. tyl</u> <u>Hewitt.\*</u> The Wilmer Institute, Johns Hopkins University. School The Wilmer Institute, Johns Hopkins University, School

of Medicine, Baltimore, MD 21205. Cell interactions with other cells and with extracellular ma-trix components are important for survival and phenotypic expression of many cell types, including neurons. We have tested influence of substrate-bound factors, and extracellular matrix components on the differentiation of 8-day chick embryo retinal neurons. Tissue culture dishes, either uncoated or coated with polyornithine, were derivatized with various materials prior to use. The dissociated cells were cultured for 6-72 hr on these substrata in serum-free medium containing the "N1" supplement of Bottenstata in serum-free medium concarning the Ni Supplement of Bottenstata in et al. (Exp. Cell Res., <u>125</u>;183, 1980). Neuronal survival and neuritic development were dependent upon

the composition of the substratum. Neurons did not attach to untreated tissue culture plastic but attached tenaciously to and flattened extensively on polyornithine-treated dishes. However, this attachment was not physiological since there was no neuritic development and the cells showed signs of degeneration within 24 hours In contrast, on polyornithine-coated dishes derivatized hours. In contrast, on polyornithine-coated dishes derivatized with either bovine serum albumin or chondronectin, cells were rounded and only loosely attached. Dishes pretreated with poly-ornithine followed by derivatization with fibronectin, fetal calf serum or fibronectin-free fetal calf serum permitted cell attach-ment and survival, but neuritic development was limited. Laminin treatment of polyornithine-coated dishes, on the other hand, per-nited processing and attention emitte fermine. mitted precocious and extensive neurite formation. This effect was dose-dependent and also required polyornithine pretreatment of the substratum, since cells remained rounded and only loosely attached on laminin-coated tissue culture plastic. The lamininpolyornithine effects were similar to those obtained with serum free schwannoma conditioned medium (SCM) which contains a factor (PNPF) that binds to polyornithine and stimulates nerve fiber formation by retinal neurons (Adler, R., J. Neurosci. Res., 8:165, 1982). When added to the medium within the first 6 hours culture, both laminin and SCM were able to "rescue" cells attached to untreated polyornithine. Laminin is distinct from PNPF, however, since affinity-purified antibodies against laminin suppressed laminin- but not conditioned medium-induced neurite formation.

Together with ongoing investigations using collagen types I-V and various glycosaminoglycans, these studies support the concept that extracellular matrix molecules have profound and specific effects on neuronal survival and differentiation. Qualitative properties of substrate-bound molecules, rather than the strength of cell-substratum adhesiveness, appear critical for controlling neuronal behavior.

64.19 AN IN VIVO ASSAY OF NEUROTROPIC ACTIVITY M.J. Politis and P.S. Spencer Albert Einstein Coll. Med., Bronx, N.Y. 10461

Previous studies in this laboratory support the contention that distal stumps of transected nerves can attract/support axonal regeneration via diffusible (e.g., neurotropic) factors (Brain Research 253:1, 1982). The present study was undertaken to (a) strengthen this hypothesis, and (b) begin to ascertain the nature of these factors.

The proximal stump of transected rat sciatic nerves was attached to the The proximal stump of transected for sclatic herves was attached in the single inlet end of 6-mm-long, Y-shaped implants made of Silastic tubing. To one of the paired outlet ends was attached an Elvax pellet containing lyophilized homogenete obtained from (A) a distal stump of a transected sciatic nerve obtained 14 days post-operatively (n=6), (B) distal-stump tissue exposed to  $80^{\circ}$ C (n=4) or trypsin (n=8) prior to lyophilization, or (C) an unoperated sciatic nerve (n=6). The other outlet was attached to a pellet containing no homogenate.

At three weeks post-operatively, a bridge containing well-organized, thinly myelinated axons had formed in the implant lumen in group A, preferentially (n=1) or exclusively (n=5) between the proximal nerve stump and the pellet containing nerve homogenate. No axonal growth was seen in either fork of the implant lumen in groups B and C.

These data lend support to the hypothesis that diffusible substances in distal stumps of transected nerves can attract/support axonal regeneration, and suggest that these "neurotropic" factors are proteins or that their activity is protein-dependent.

OPTIMIZATION OF METHODS TO MEASURE BIOLOGICAL CURRENTS USING A 64.18

CIRCULARLY VIBRATING MICROPROBE. <u>Paul B. Manis\*, Philip C.</u> <u>Samson\* and John A.</u> <u>Freeman</u> (SPON: D. Buxbaum). Dept. of <u>Anatomy</u>, Vanderbill Univ. Sch. of Med., Nashville, TN 37232. We recently developed a method to measure low level extracellular biological currents in the nA/cm range using a circularly vibrating microprobe and an ultra-low noise amplifier (Freeman et al., Neurosci., 1982). The extreme sensitivity of our probe allows detection of minute currents associated with single cells and cell processes. We report here technological improvements in the construction of the probe and in the on-line computer analysis of biological currents. Two probe designs have been developed and tested

Two probe designs have been developed and tested. One uses two miniature speakers driven in quadrature to move the electrode. This probe may be driven at frequencies between 10 and 500 Hz. Small mechanical nonlinearities in probe motion may be corrected. The speakers generate a phase-coherent magnetic field which must be subtracted from each measurement. We also developed a compact piezoelectrically driven probe which produces no magnetic field. However, the elements must be driven at resonance (200-300 Hz), making corrections for probe nonlinearities more difficult. The two probes are otherwise comparable in terms of ease of construction, cost, and noise. Two probe designs have been developed and tested. One uses miniature speakers driven in quadrature to move the comparable in terms of ease of construction, cost, and noise.

comparable in terms of ease of construction, cost, and noise. An inexpensive microprocessor-based system was developed in order to compare the use of a computer to a lock-in amplifier. The lock-in amplifier can determine the magnitude and phase of Jonly, whereas the microprocessor system can compute  $J, \nabla[J]$  (a only, whereas vector point: vector pointing towards the current source) permitting servo-controlled mapping of "hot spots". The computer also allows examination of the data during acquisition, displays computed vectors and rejects electrical or mechanical artifacts. Averaging acts as a narrowband filter to reduce noise. Finally, the driving voltage waveforms can be tailored to the specific mechanical configuration to compensate for loading and resonance phenomena.

to permit the quantitative correlation of measured In order currents with structures generating them, we have digitized the microscopic image using a video frame buffer, and have developed software to superimpose polar plots of the current vectors over their measurement location. Image differentiation and the use of a color monitor further enhance image contrast and the use of a striking increase in resolution. The combination of these technological improvements greatly increases the temporal and spatial resolution, and the accuracy with which biologically important currents may be measured. The probe has been used to measure currents from growth cones, and injured and regenerating optic nerve fibers.

STUDIES ON THE FACTORS THAT GOVERN DIRECTIONALITY OF AXONAL GROWTH 64.20 IN THE EMBRYONIC OPTIC NERVE AND AT THE CHIASM OF MICE.

Jerry Silver. Dept. of Developmental Genetics and Anatomy, School of Medicine, Case Western Reserve Univ., Cleveland, Ohio 44106 What are the forces residing at the presumptive chiasm of embryonic mice that control the directionality (i.e., side specifi-city) of the optic axons? In an attempt to answer this question, the overall trajectories of individual fascicles of axons and the various environments that they encounter along their pathway, have been charted from the eye, through the nerve and into the base of the diencephalon. Serial sections and reconstructive computer graphic techniques were used for the analysis.

The early optic axons (embryonic day 13.5) arrive at the chiasm in a stereotyped topographic arrangement. However, the fiber array at the primitive chiasm is not 'retinotopically organized nor is it maintained with the same level of spatial precision as it is at the disc. In the distal half of the stalk, the "pioneer" fascicles are organized in a marginally located annulus with inverted retinotopy. However, within the proximal half of the nerve about 17% of the fibers abandon their marginal positions, move randomly across the nuclei rich zone near the stalk's center, and join many other fascicles at the margin but in totally new locations. Thus, although the accuracy of the upside down fiber map deteriorates along the course of the stalk, about 80% of the fibers retain a gross retinotopy as they approach the chiasm. Within 75  $\mu m$  of the chiasm, the entire contingent of optic axons becomes reorganized into a ventrally located crescent shaped configuration, with fascicles from ventro-temporal and ventro-nasal retina at either side of the crescent and with fascicles from dorsal retina interposed. Because of their gross locations in the crescent, particular clus ters of fibers, each largely originating from different retinal sectors, but "contaminated" with fibers from other regions, come in contact with different types of non-neuronal structures at the chiasm. One, a dense, knot-like glial formation that lies along the diencephalic/telencephalic junction, directs all adjacent (ventro-nasal) fibers contralaterally. On the other side of the crescent, a discrete system of lengthy marginal glial processos separated by an anastomotic system of wide-bored extracellular spaces, guides all nearby fibers (ventro-temporal) ipsilaterally. The results suggest that fiber topography as well as local environmental factors may play important roles in guiding axons at the embryonic chiasm. (supported by NIH grant NS-15731)

64.23

GROWTH CONE GUIDANCE IN THE CHICK HINDLIMB. 64.21

K. W. Tosney<sup>\*</sup> & L. T. Landmesser (SPON: G. Pilar) Biol. Sci. Group, Physiol. Section, Univ. of Conn., Storrs, CT 06268 The early outgrowth of motoneurons in the chick hindlimb is specific, precise, and responsive to environmental cues (Lance-Jones & Landmesser, 1981, Proc. Royal Soc. 214:1). In order to analyze these features at the level of the growing tip of the neurite, we have labeled identifiable populations of growth cones with HRP and examined them and their relation to the embryonic environment in serial 25u plastic sections.

We find: (1) The morphology, search radius, and trajectory of growth cones vary with their identity and position in the . (2) Motoneurons do not send pioneer fibers into the (3) Growth cones within the pre-muscle masses make few embryo. limb. errors in projection, suggesting that pathway guidance is more important than target sampling in forming correct connections. (4) Different populations of growth cones make different but consistent pathway choices in both plexus and limb regions, often by changing their directions abruptly. Choices in case are customarily made over a definable 100u region. Choices in each These results suggest that guidance cues are local and specific. (5) all stages of outgrowth, we see large numbers of dead cells within regions of growth cone activity. This cell death may open a pathway for neurite elongation. Experiments are underway to test this hypothesis and to determine whether the death is related to or indepenent of growth cone activities,

such as their release of proteolytic enzymes. Analysis of surgically altered embryos has shown: (1) When tissues that provide information for the positional differentiation of the limb are removed or transplanted, growth cones still make correct decisions in the plexi. These tissues do not provide the essential cues used in pathfinding. (2) Growth cones are also able to make correct directional decisions in the plexus when their target is absent.

Our results suggest that cues for specific outgrowth lie within the reach of individual growth cones.

PATTERNS OF INITIAL WING INNERVATION IN NORMAL CHICK EMBRYOS AND IN EMBRYOS LACKING SOME BRACHIAL SPINAL CORD SEGMENTS. <u>Margaret Hollyday</u>, Dept. of Pharmacological and Physiological Sciences, Univ. of Chicago, IL 60637. The organization and development of innervation of the chick wing 64.22

has been studied using orthograde transport of HRP. The single plexus has been studied using orthograde transport of HRP. The single plexus and the adult-like pattern of branching to many major peripheral nerves have formed by stage 28, a stage prior to the onset of naturally occurring cell death. At this stage, injection of HRP into identified spinal segments indicate that axons project to a restricted subset of the peripheral nerves. The projection patterns are consistent with those predicted from the positions of motor pools in the hatchling, indicating that there is a high degree of specificity in initial outgrowth. Observations of axonal trajectories revealed that axons entering the plexus in an anterior position tended to maintain this position along their growth trajectory whereas axons arising from caudal wing along their growth trajectory, whereas axons arising from caudal wing segments tended to distribute to the posterior portion of the peripheral innervation pattern. In addition, however, axons from a given spinal segment could be seen to diverge from one another at several points along their peripheral outgrowth path. Similarly, axons from a given segment converged at several points with axons originating from other segments. These observations suggest that the normal, specific initial innervation pattern results from interactions of outgrowing axons with growth cues encountered at several points along the outgrowth path. The peripheral distribution of axons from spinal segments normally

Ine peripheral distribution of axons from spinal segments normally having a restricted distribution in the peripheral nerves was also analyzed in embryos at stage 28 in which neighboring spinal segments had been removed at stage 13-14. In many of these cases HRP injections into the remaining segments resulted in the appearance of labeled axons not only in the peripheral nerves labeled by such injections in normal animals but also in other peripheral nerves. Such expansions did not involve large numbers of axons but were seen frequently enough to indicate that abnormalities in the projection pattern from one segment result from removal of adjacent segments. The results suggest that among the cues influencing the outgrowth path of axons from a given segment may be interactions with axons from other segments. (Supported by PHS NS-14066.)

MIGRATION AND AXONAL GENERATION OF ANURAN TRIGEMINAL MOTONEURONS. K. Alley. Case Western Reserve University, Cleveland, Oh 44106 <u>K. Ailey</u>. Case western Reserve University, Cleveland, On 4410 Trigeminal motoneurons in the frog (<u>Rang pipiens</u>) are gener-ated during embryonic stages 13 to 20. These motoneurons inner-vate different muscle fibers in pre- and postmetamorphic frogs. As part of an ongoing investigation into the differences between the formation of the initial neuronuscular contacts and the subsequent redeployment of these motor axons during metamorphic turnover of the jaw muscles, I have analyzed the earliest events of trigeminal motoneuronal maturation. The goals of the present study are twofold: 1. to chart the migratory pattern of the Vtb motor neuroblasts (VMN) after their final mitotic division, and

to assess the timing of axonal outgrowth from these neurons. Light microscopic procedures including tritiated thymidine autoradiography and HRP histochemistry were used to locate and plot the position of the VMN at timed intervals after their gen-eration. Electron microscopy was also used to analyze the timing and events associated with axon formation and extension into the first branchial arch.

Trigeminal motoneurons are produced by the basal plate germinal epithelium of the rostral rhombencephalon. The postmitotic cells migrate in a strictly radial direction from the luminal surface to the intermediate-marginal zone interface. Transloca-Early born cells require only a few hours tion occurs rapidly. to assume their position in the Vth nucleus, while later born cells require up to a day. Axonal outgrowth was first detected at stage 16, during the height of neuron production. However, ARP studies indicate that these axons do not production. However, HRP studies indicate that these axons do not penetrate the exter-nal limiting membrane immediately, but seem to wait for the Vth sensory root to make its entry. Axons could be traced into the lst branchial arch in stage 18 embryos. From these observations I conclude that the migratory pattern

of frog VMN is quite different from the long medial to lateral migration found in the chick (Moody and Heaton, <u>Neurosci</u>.6:1707, 1981). In addition, these observations suggest that the VMN extend axons soon after formation and that their axons are held up at the external limiting membrane. Moody and Heaton (J. Comp. up at the external limiting membrane. Moody and heaton (J. Comp. Neur. 213: 327, 1983) have shown a close correlation between the migration of the VMN and the early development of the Vth sensory root in the chick. Perhaps the final extension of the motor axon into the first branchial arch of the frog is guided by the developing trigeminal ganglia and sensory root.

THE GROWTH OF MOTOR AXONS IN XENOPUS SPINAL CORD. Monte 64.24 Westerfield and Judith S. Eisen, Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

How is the path that axons take in innervating their targets determined during development? We have studied this problem by labeling the axons of primary motoneurons in the developing labeling the axons of primary motoneurons in the developing spinal cord of <u>Xenopus</u> embryos and tadpoles. The axons were lesioned early in development (NF 27) in the clefts between trunk myotomes, and HRP was applied. After a variable survival time, development of the HRP reaction product in whole mounts of the spinal cord and muscles revealed the pathway taken by indi-vidual motor axons at various developmental stages.

At the earliest stages studied (NF 27-28) the axons of moto-neurons were observed to leave the cord near their cell bodies (NF 35-50) the axon terminals in the muscles became more and more displaced toward the tail relative to their cell bodies. The axons of motoneurons in older animals were found to run caudally in the medial part of the ventral cord for several

caudally in the medial part of the ventral cord for several segments before entering a ventral root. These results show that the final pathway of motor axons within the spinal cord develops after their initial innervation of muscles. The relative displacement of the axonal terminals may in part be due to differential growth of the myotomal muscles relative to the spinal cord. The addition of later developing longitudinal fibers at the lateral aspect of the cord would account for the medial location of the axons of the older, primary motoneurons. Another possibility, which is being examined, is that the somata of motoneurons migrate rostrally within the cord during development. Supported by the NSF, MDA, MRF, and the Sloan Foundation.

NEW OPTIC AXONS IN THE GOLDFISH RETINA. S.S. Easter, Jr., Div. Biol. Sci., 64.26

New OFFIC AXONS IN THE GOLDFISH KEIINA. S.S. Easter, Jr., B. Bratton, S.S. Scherer, and C.A.O. Stuermer. Div. Biol. Sci., U. Michigan, Ann Arbor, MI 48109. We have examined electron microscopically the optic nerve fiber layer in the goldfish's retina. This tissue adds new ganglion cells, throughout life, along its annular margin. The axons of each generation of cells are known to cluster together in the optic nerve tract and tertum. But in the retina the axons of each generation of cells are known to cluster together in the optic nerve, tract, and tectum. But in the retina, the axons lie in fascicles arranged like spokes of a wheel centered on the optic disk. These fascicles cross all generations of ganglion cells and pick up axons from all. The more peripheral fascicles merge with other more central ones with older axons. This suggests that the intraretinal axons might not be segregated according to age, and this is the question we have examined. Retinas were fixed in glutaraldehyde followed by 0504, and ultrathin sections were cut perpendicularly to the spokes. The inner limiting membrane is formed by a vitreal basal lamina underlain by Muller cell end feet which separate the neural retina from the basal lamina over most of the vitreal surface. There were bundles of both myelinated axons (Ma), (invested by retina from the basal lamina over most of the vitreal surface. There were bundles of both myelinated axons (MA), (invested by a few loose wrappings of glial cell membrane) and nonmyelinated axons (NMA). The former were larger, and generally lay more sclerad than the latter, which always occupied the most vitread position in the axon layer. Almost all axons contained both intermediate filaments and tubules, transversely sectioned. The most vitread of the NMA contained only tubules. Many of the fascicles of NMA were in direct contact with the basal lamina, through openings between the glial end feet. In most of these cases there was one or more broad morecessed directly appreced to through openings between the glial end feet. In most of these cases there was one or more broad processes directly apposed to the basal lamina. These electron lucent processes contained transversely sectioned tubules but no filaments. Quasi-serial sections showed that the processes extended over at least 10's of um, elongated parallel to the spokes. We believe that the NMA are the new ones because: 1) they are the only one proceed in extreme marginal motions 2) they

We believe that the NMA are the new ones because: 1) they are the only ones present in extreme marginal retina, 2) they are continuous with the NMA in the nerve, which we have previous-ly shown to be the new ones, 3) their superficial position is similar to that noted for new axons elsewhere (Xenopus diencepha-lon: Gaze & Grant; Xenopus spinal cord: Nordlander & Singer), 4) the most superficial ones have tubules only, similar to the new optic axons elsewhere (rat: Peters & Vaughn), and 5) the flattened processes, most superficial, are very likely growth comes.

cones. We conclude that the new axons run superficially in the optic vitread to axons of slightly older cells. Thus the age-specific segregation of optic axons originates in the retina. (Supported by EY-00168 to SSE Jr.)

## SUBCORTICAL AUDITORY PATHWAYS I

65.1

EFFECTS OF KAINIC ACID ON THE SUPERIOR OLIVARY COMPLEX OF THE RAT. <u>D.A. Godfrey<sup>1</sup></u>, <u>J.L. Park<sup>1\*</sup></u>, <u>J.D. Dunn<sup>2</sup></u> and <u>C.D. Ross<sup>1</sup></u>, Depts. Physiol.<sup>1</sup> and Anat.<sup>2</sup>, Oral Roberts Univ., Tulsa, OK 74171 In an attempt to destroy neurons projecting cholinergic axons to the cochlea and cochlear nucleus, a solution of 5-10 nmoles of kainic acid in 0.5-1 µl saline was stereotaxically injected, over a 5-15 min period, into the right superior olivary complex of four 300-400 gram Sprague-Dawley rats. The rats were sacrificed by rapid decapitation 7 days later and the brains and cocheas frozen within 30 min. Frozen transverse 20 µm-thick sections through the brainstem were alternately stained with thionin or for acetylcholinesterase (AChE) activity, or freeze-dried to permit microdis-section for quantitative assay of choline acetyltransferase (ChAT),

AChE, or malic dehydrogenase (MDH) activity. In thionin-stained sections, few if any sizeable somata could be found in the right lateral superior olivary nucleus (LSO), while they were always seen, although not necessarily in the same numbers or sizes as on the left side, in the medial (MNTB) and ventral (VNTB) nuclei of the trapezoid body. In sections stained for AChE activity, the staining in the right LSO was much less than on the left side, that in the right VNTB slightly to moderately less, and that in the MNTB very little on either side. The residual stain-ing of the right LSO seemed localized to small somata and fine processes within it and its hilus regions. Enzyme activities per kg dry wt. of superior olivary complex subregions, right side/left side as mean + SEM for the 4 rats, were:

 
 ChAT(umoles/min)
 AChE(mmoles/min)
 MDH(moles/hr)

 397+27/560+52
 12.7+0.6/28.9+2.0
 11.3+0.7/17.4+0.7

 339+38/366+47
 19.5-4.2/32.7+3.0
 9.7+0.7/11.0+0.6

 209±17/361±11
 11.5±1.2/16.4±1.3
 10.7+0.6/11.7±0.7
 LSO VNTB MNTB The effect on enzyme activities was more marked in LSO than in VNTB, and, in both LSO and VNTB, the kainic acid injection had more effect on AChE and MDH activities than on ChAT, the more definitive marker for cholinergic neurons. In the large-cell portion of the anteroventral cochlear nucleus,

ChAT activities on both sides were similar to those of control rats (in contrast to about 70% loss of ChAT activity on the lesion side of rats with the superior olivary complex surgically destroyed). The AChE-positive bundles containing centrifugal fibers to the inner ear had ChAT activities on both sides comparable to those measured in control rats. ChAT activities of organ of Corti sam ples from the right cochleas of two of the rats were comparable to those measured in control rats. These results imply that the kainic acid injections into the superior olivary complex of rats did not destroy the neurons giving rise to the centrifugal cholinergic connections to the cochlear nucleus or cochlea. (Supported by NIH Grant #NS17176 and ORU Intramural funds.)

65.2

DURATION OF INHIBITION SEEN FOR IE NEURONS IN CHINCHILLA LATERAL SUPERIOR OLIVARY NUCLEUS. <u>D.M. Caspary, JoAnn McGee\* and Edward</u> <u>Walsh</u>, Dept. of Pharmacology and Surgery, So. Ill. Univ. Sch. of <u>Med.</u>, Springfield, IL 62708 The majority of lateral superior olivary (LSO) neurons receive excitatory input from the ipsilateral ventral cochlear nucleus (VCN) while the contralateral VCN inhibits the response to ipsi-lateral stimulation via secure synapses in the ipsilateral medial nucleus of the trapezoid body. This results in a marked suppres-sion of the ipsilateral excitatory response when binaural stimuli sion of the ipsilateral excitatory response when binaural stimuli are presented simultaneously. These IE neurons are thought to code for localization of sound in space. Recent studies suggest that glycine may be an inhibitory neurotransmitter synaptically released onto certain LSO neurons upon contralateral tonal stimu-lation (None et al. Conserve). released onto certain LSO neurons upon contralateral tonal stimu-lation (Moore and Caspary, J. Neurosci., 3:237-242, 1983). The present study investigated the time course of inhibition by vary-ing the time of occurrence of an ipsilateral (excitatory) tone with respect to the offset of a contralateral inhibitory tone ( $\Delta t$ ). One hundred presentations of short tone-bursts (3-10 msec) with 0 rise-fall time were presented at the rate of 4/sec;  $\Delta t$  was varied between 0 and 93.8 msec in 10 steps. Percent inhibitory tone was function of  $\Delta t$  from the time that the inhibitory tone was turned off until inhibition was no longer observed. A maximum value of inhibition was established by presenting the two tones simultaneously with the contralateral tone between 45 dB maximum value of inhibition was established by presenting the two tones simultaneously with the contralateral tone between 45 dB and 65 dB above best frequency threshold. Percent inhibition was maximal at small values of  $\Delta t$  and declined rapidly (>10%/msec for many neurons examined) as delay between dichotic tones was in-creased. Degree of suppression at any given delay was a function of the intensity of the contralateral inhibitory tone relative to the ipsilateral excitatory tone. As the intensity of the excita-tory tone was reduced the magnitude and duration of suppression was increased. Rate-intensity plots for monaural control condi-tions were plotted along with binaural responses at different values of  $\Delta t$ . These findings were compared to the effects of values of At. These findings were compared to the effects of iontophoretically applied glycine at different intensities of ipsilateral acoustic stimulation. The duration of inhibition may involve several different factors including duration of the IPSP and termination mechanisms of an acoustically-evoked inhibitory and termination mechanisms of an accusically-evoked minitory transmitter. Since iontophoretic application of strychnine, a glycine antagonist, abolishes the contralateral inhibition ob-served in these neurons, the loss of inhibition with increasing delay may partially reflect transmitter uptake proposed as the main termination mechanism of the action of glycine. This paradigm may be a useful way to more closely examine synaptic mechan-isms in the LSO nucleus. (Supported by Deafness Research Founda-tion, NIH grant 15640, and a gift from the Pearson Family Foundation.)

65.3 FUNCTIONAL ORGANIZATION OF THE BARN OWL'S INFERIOR COLLICULUS. T. <u>Takahashi</u>\* and <u>M. Konishi</u>(SPON.:C.R.Hamilton).Division of Biology 216-76, Caltech. Pasadena, CA 91125.

Auditory neurons in the anterolateral part of the barn owl's inferior colliculus (IC) have discrete, spatial receptive fields and are arrayed so that a continuous map of space is formed (Knudsen and Konishi, J. Neurophys.,41:870-884 '78). The remaining posteromedial part of the IC is tonotopically organized and is thought to be the source of afferents to the anterolateral region (Knudsen, In press, J. Comp. Neur.). We present evidence suggesting that the posteromedial part of the IC comprises at least three subdivisions, each of which has a characteristic binaural property and a characteristic set of afferent nuclei. Most medially, there is an area in which the units are excited only by stimulation of the contralateral ear. This was termed the "EO" area. Stimulation of the ipsilateral ear does not alter the

Most medially, there is an area in which the units are excited only by stimulation of the contralateral ear. This was termed the "EO" area. Stimulation of the ipsilateral ear does not alter the discharge rate. Units driven only by the ipsilateral ear (which would be termed "OE") were not observed. Immediately medial to the EO area is the "EE-phase" area, containing units that are excited by stimulation of either ear, and responding maximally when a noise or tone burst is presented to the ears with a discrete, interaural delay. At a given interaural delay, the discharge rate of EE-phase units depends upon the average binaural intensity and is independent of the interaural intensity difference.Immediately posterior to the EE-phase area is the "EI" area whose units are excited by the contralateral ear and inhibited by the ipsilateral ear. Their discharge rates increase as the intensity in the excitatory ear is increased over that in the inhibitory ear. Inreases in average binaural intensity difference is kept constant. Finally, the tonotopicity demonstrated by Knudsen and Konishi ('78) was confirmed. Units having lower best frequencies are found dorsal to those with higher best frequencies. This tonotopic organization extends across the functional zones described above.

Each of the functional zones are innervated by a different set of pontine auditory nuclei. Horseradish peroxidase injections of the EO area labels somas in the contralateral nucleus angularis (NA) and nucleus olivaris superior (SO) and the ipsilateral nucleus ventralis lemmisci laterale pars posterior (VLVP). Injection into the EE-phase area produces labeled somas in SO of both sides and in the contralateral nucleus ventralis lemmisci laterale pars anterior (VLVA), VLVP, nucleus laminaris (NL) and NA. Finally, injections into the EI area produces labeled somas in VLVP of both sides and in the contralateral SO,NL,NA, and IC. Projections from each of the functional zones to the anterolateral part of the IC is currently being investigated.

55.5 RESPONSE PROPERTIES AND DISPROPORTIONATE REPRESEN-TATION OF FM SENSITIVE NEURONS IN THE INFERIOR COLLICULUS OF THE CF-FM BAT, <u>PTERONOTUS PARNELLII</u>, W.E. <u>O'Neill</u>, Ctr. for Brain Research, Univ. of Rochester Sch. of Med., Rochester, N.Y. 14642.

The auditory system of the mustached bat apparently contains two semi-independent systems for the analysis of information conveyed by the constant frequency (CF) and frequency modulated (FM) components in its biosonar signal. CF signals best convey information about target movements, while the FM components are best suited to ranging, localization and characterization of fine features. Previous studies in the auditory cortex revealed two separate regions containing neurons specialized for processing the CF component (DSCF area) and the FM component (FM-FM area). Neurons in the FM-FM area are sensitive to specific pulse-echo time intervals which encode target distance, and are systematically arranged to represent target range according to place of excitation along the cortical surface.

The area tuned to the FM<sub>1</sub> frequencies (BF) increase form 30 to 50 kHz in the subcortical posterior to the FM<sub>1</sub> regresention, and the frequencies (BF) increase form 30 to 50 kHz in the anterior posterior direction, and also the the first of the first form a standard form to the frequencies within the FM sweeps of the first (FM<sub>1</sub>) and second (FM<sub>2</sub>) harmonics of the biosonar signal. Two large areas contain neurons tuned to frequencies within the FM sweeps of the first (FM<sub>1</sub>) and second (FM<sub>2</sub>) harmonics of the biosonar signal. The area tuned to the FM<sub>1</sub> frequencies lies in the anterior part of the IC, and unit best frequencies (BF) increase only slowly from about 25 to 29 kHz with depth of penetration. The area tuned to FM<sub>2</sub> has unit BFs from 52 to 57 kHz, is located posterior to the FM<sub>1</sub> representation, and is separated from it by a relatively small region where unit BFs' increase from 30 to 50 kHz in the anterior-posterior direction, and also with depth of recording site. In the FM<sub>2</sub>, and especially FM<sub>1</sub> areas, the thresholds of units to decreasing FM sweeps is equal to or even better than the thresholds to CF stimuli. This is generally not true for units tuned to other frequencies, where the threshold to FM is typically higher than to CF.

higher than to CF. FM1 and FM2 are the essential components for response of a large cluster of range-tuned units in the FM-FM area of cortex. It appears that two separate areas of the IC having FM sensitive neurons are appropriate candidates for conveying target range information to the cortex via the thalamus. The relative importance of these frequency bands to echo processing is reflected in the disproportionately large area of IC representing them. Exposure of bats to FM1-FM2 stimulus pairs after injection of  $^{14}$ C-2-deoxyglucose reveals uptake patterns highly consistent with the electrophysiological maps of frequency representation in these FM bands. The organization of the mustached bat IC is greatly modified from the pattern seen in more "typical" mammals and reflects the strong correlation of acoustic behavior and auditory organization in this species. NSF Grant no. BNS-8023109. 65.4 LOCAL ANESTHETICS DEMONSTRATE THE SEPARATION OF TIME AND INTEN-SITY PROCESSING BY THE OWL AUDITORY SYSTEM. A. Moiseff, T. Takahashi\*, and M. Konishi, Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

Space-specific neurons in the external nucleus of the owl's ( $\underline{Jyto\ alba}$ ) inferior colliculus owe their discrete auditory receptive fields to selectivity to narrow ranges of both interaural time differences and interaural intensity differences. Neurons of the pontine nuclei, which innervate the inferior colliculus, are sensitive to either time differences or intensity differences, but not both. Based on the binaural response properties that characterize the pontine nuclei and the connectivity among them, we hypothesize that interaural time and intensity differences are processed along separate neural pathways, and that space selectivity emerges through the convergence of these two pathways. We used a local anesthetic, which reversibly blocked activity in selected auditory nuclei, to test the sensitivity of this hypothesis. We present evidence that the sensitivity of space-specific units to time differences can be markedly decreased without drastically affecting their sensitivity if versity differences.

Silvity of space-specific units to time uniferences can be markedly decreased without drastically affecting their sensitivity to interaural intensity differences. The first two stages of the "time processing pathway" comprise nucleus magnocellularis (one of the cochlear nuclei) and nucleus laminaris (the avian homologue of the medial superior olivary nucleus). Neurons from n. magnocellularis project bilaterally to n. laminaris. Lidocaine, a local anesthetic, was injected into nucleus magnocellularis or nucleus laminaris through microelectrodes. The anesthetic effectively blocked neural activity to a distance of approximately 300 micrometers from the electrode tip. We placed a second microelectrode into the external nucleus of the contralateral inferior colliculus, where single spacespecific units were isolated. Normally, these units are "tuned" to a narrow range of time differences and a narrow range of intensity differences. When n. laminaris or n. magnocellularis was anesthetized, space-specific units retained their high selectivity to intensity differences. As the effect of the lidocaine wore off, the time sensitivity recovered to the normal level.

The ability to selectively modify the time sensitivity of space selective units supports the hypothesis of independent analysis of time and intensity differences.

65.6 STIMULUS-DEPENDENT LABELING WITH {14C} -2-DEOXYGLUCOSE IN THE INFERIOR COLLICULUS OF THE MUSTACHED BAT. D.M. <u>Gooler\*</u> and W.E. O'Neill (SPON: S. Demeter). Ctr. for Brain Research, Univ. of Rochester Med. Sch., Rochester, N.Y. 14642. A modification of the {14C}-2-deoxyglucose {2-DG} method for qualitative mapping of functional activity in brain was used to explore the dependent of the {14C}-2-deoxyglucose {12-DG} method for qualitative mapping of functional activity in brain was used to explore the dependent of the {14C}-2-deoxyglucose {12-DG} method for qualitative mapping of functional activity in brain was used to explore the dependent of the {14C}-2-deoxyglucose {12-DG} method for qualitative mapping of functional activity in brain was used to explore the dependent of the {14C}-2-deoxyglucose {12-DG} method for qualitative mapping of functional activity in brain was used to explore the dependent of the {14C}-2-deoxyglucose {12-DG} method for qualitative mapping of functional activity in brain was used to explore qualitative mapping of functional activity in brain was used to explore qualitative mapping of functional activity in brain was used to explore qualitative mapping of functional activity in brain was used to explore qualitative mapping of functional activity in brain was used to explore qualitative mapping of qualitative qualitative mapping of qualitative qualitative qualitative qualitative qualitative qu

A modification of the  $\{^{4*C}\}$ -Z-deoxyglucose (2-DG) method for qualitative mapping of functional activity in brain was used to explore the tonotopic organization of the inferior colliculus (IC) in the mustached bat, <u>Pteronotus parnellii parnellii</u>. The mustached bat emits orientation pulses consisting of a sustained constant frequency (CF) component followed by a short downward sweeping frequency modulated (FM) sound, at each of four distinct harmonics (CF<sub>1-4</sub>; FM<sub>1-2</sub>).

The purpose of this study was to explore the sensitivity of the 2-DG method for differentiating between regions of the IC activated by different, complex auditory stimuli. While electrophysiological maps of auditory activity are derived from individual recording sites, a map based on evoked 2-DG uptake will show the entire region that is activated by a specific stimulus.

Bats were injected intraperitoneally with 2-DG (1.25 uCi/10 gram body weight) and exposed to open field auditory stimuli for 45 min. Following the experiment, the bat was anesthetized and decapitated. The brain was rapidly removed and frozen to  $-70^{\circ}$ C. Sections (20 u thick) were cut in a cryostat at  $-22^{\circ}$ C, and were placed in contact with Kodak X-TL film and exposed for 14 days. Sections were counterstained with cresyl violet acetate.

In all autoradiographs, the uptake of 2-DG in IC was greater than in other local regions. When exposed to a stimulus composed of FM<sub>2</sub> alone (e.g., 57-45 kHz sweep), autoradiographs of horizontal sections showed a distinct crescent-shaped band of label in the caudal portion of the anterior half of the IC. For a paired FM<sub>1</sub>-FM<sub>2</sub> sound (e.g., FM<sub>1</sub> = 30.7-24.7 kHz; FM<sub>2</sub> = 58.8-46.8 kHz), similarly oriented sections show a dense band in the same region as the case with FM<sub>2</sub> alone. In addition, a second band of increased density is found in the rostral portion of the anterior half of the IC. The 2 bands occupy nearly the entire anterior half of the IC. For each band of increased autoradiographic density, cellular density observed in counterstained sections was not different compared to regions showing lower 2-DG uptake.

Évidence from electrophysiological studies of the anterior IC also shows disproportionately large areas representing FM<sub>1</sub> and FM<sub>2</sub> sounds. Also in agreement with electrophysiological evidence are the results of the autoradiographs showing that the FM<sub>1</sub> and FM<sub>2</sub> areas exist throughout the dorsoventral extent of the IC. These results indicate that the 2-DG technique can resolve differences between acoustic stimuli and that results are relevant to electrophysiological study of the IC.

THE ASCENDING CONNECTIONS OF THE TORUS SEMICIRCULARIS CENTRAL NUCLEUS IN CHRYSEMYS SCRIPTA ELEGANS. R.H. Browner. Department of Anatomy, New York Medical College, Valhalla, NY 10595. The central nucleus (CN) of the torus semicircularis is the major auditory nucleus in the reptilian mesencephalon. Ten red-eared turtles were anesthetized with sodium pentobarbital (I.P. 11.00 mg/kg-Fall and Winter). A portion of the temporal muscle was removed and an opening was drilled into the lateral wall of the cranial cavity over the mesencephalon. The meninges were cut and the dorsal dome of the optic tectum was were cut and the dorsal dome of the optic tectum was removed to expose the floor of the tectal ventricle. Glass micropipettes (tip diameter of 10-20 um) were filled with 25% Type VI horeseradish peroxidase diluted in reptilian ringers. This mixture was injected into the elevated floor of the tectal ventricle where the The elevated floor of the textal ventricle where the underlying central nucleus was located. Seven injections were ipsilateral to the surgery, three contralateral in the central nucleus. After pressure injections for 12 minutes the surgical area was packed and sutured and the animal allowed to survive from 2 to 4 days. Following reanesthesia the turtles were perfused and reacted with TMB and BDHC (Mesulam, IBRO Handbook Series, Wiley, 1982) to analyze the anterograde connections. Ascending fibers left the central nucleus laterally and formed the tectoreuniens tract (TRT). At the lateral edge of the mesencephalon, ventral to the optic tectum, the TRT turned medially and coursed into the caudal diencephalon in a ventrolateral position. Here the TRT turned medially and slightly dorsally to cross the diencephalon and terminate in the nucleus reuniens (NR) and adjacent neuropil. There was no HRP reaction in the contralateral NR. A second pathway coursed ventral to contralateral NR. A second pathway coursed ventral to the cerebral aqueduct to terminate within the contralateral CN. Both laminar nuclei were clear of reaction product. Finally there was a project to the deep layers of the ipsilateral optic tectum.

STRUCTURAL AND FUNCTIONAL ORGANIZATION OF MAMMALIAN 65.8

STRUCTURAL AND FUNCTIONAL ORGANIZATION OF MAMMALIAN AUDITORY BRAINSTEM AND PERIPHERY AS REVEALED BY A COMBINED ELECTROPHYSIOLOGICAL AND HRP TRACING METHOD: A.S. Feng and M. Vater\* (SPON: G. Neuweiler). Zoologisches Institut der Universität München, Luisenstrasse 14, D-8000 München 2, FRG. We made extracellular single unit recordings from various regions of the central nucleus of inferior colliculus (IC) and the cochlear nucleus (CN) of echo-locating CF bats, Rhinolophus rouxi, followed by focal injections of HRP into specific functionally identified recording sites. After a survival time of 24-48 hrs, individual brains were sectioned and processed accordindividual brains were sectioned and processed accord-ing to the tetramethylbenzidine (Mesulam, 1982) and ing to the tetramethylbenzidine (Mesulam, 1982) and diaminobenzidine (Adam, 1977) methods. In CN injected specimens, the cochlea on the injected side was de-calcified, sectioned and processed similarly. From CN injected materials, focal injections into individual bands of neurons with similar best frequencies resulted in retrograde labelling of spiral ganglion cells and fibers in specific regions of the cochlea. These results allowed us to generate a frequency map within the cochlea which can be compared to a similar map obtained with other methods (Bruns, 1976) and to define the "effective" HRP injection size in the CN. Central-ly, internal connections between various CN subdivis-ions were revealed. For instance, there was a 100 µm transverse slab terminal field in the anteroventral cochlear nucleus as well as a columnar terminal field in the dorsal cochlear nucleus following a focal inthe functional organizations and terminal heid the functional organizations and terminal heid the functions. Anterograde CN projections further revealed the functional organizations and terminal bouton types in individual brainstem nuclei of the superior olivary complex, lateral lemiscus complex and the IC. The projection patterns corresponded closely the retro-grade labelling patterns shown in IC injected speci-mens. Furthermore, data from IC injected animals re-vealed the internal connections between various IC cubdimidiant IC projections to the redicid conjugate subdivisions. IC projections to the medial geniculate body showed banding termination patterns for various tonal frequencies.

ASCENDING PROJECTIONS TO THE INFERIOR COLLICULUS OF 65.9

ASCENDING PROJECTIONS TO THE INFERIOR COLLICULUS OF THE RAT AND BAT. <u>Richard A. Burne</u>. Bendix Advanced Technology Center, Columbia, MD 21045. This study was undertaken with the general aim of comparing the organization of ascending auditory afferents to the inferior colliculus (IC) in the bat, <u>Eptesicus fuscus</u>, an echolocating mammal and in the rat, a nocturnal listening animal. The techniques of retrograde and orthograde transport of horseradish peroxidase (HRP) and tritiated L-leucine,

rat, a nocturnal listening animal. The techniques of retrograde and orthograde transport of horseradish peroxidase (HRP) and tritiated L-leucine, respectively, were employed to determine pathways from brainstem auditory nuclei to the IC. Injections of HRP into the central nucleus of IC in both bat and rat resulted in labeling a prominent number of neurons in the following contralateral regions: cochlear nuclei (dorsal, anterior and posterior ventral), lateral superior olive, dorsal lateral lemniscus and inferior colliculus. Labeled cells also were observed in the following ipsilateral structures: lateral and medial superior olives, dorsal and ventral medial periolivary nuclei, ventral trapezoidal nucleus and ventral and dorsal lateral lemnisci. In some cases with relatively large HRP placements in the IC, a few scattered cells were observed contralaterally in the ventral medial periolivary nucleus of the bat and ipsilaterally in the dorsal cochlear nucleus of the rat. HRP placements restricted to the pericentral nucleus of the IC yielded labeled cells only in ventral and dorsal lateral lemniscal nuclei. However, tritiated leucine injections in the cochlear nucleus (dorsal and ventral) of the rat resulted in autoradiographic grain labeling over the central and pericentral nuclei of the contralateral IC. A faint distribution of grains also was observed over the ventral region of the ipsilateral central nucleus

pericentral nuclei of the contralateral IC. A faint distribution of grains also was observed over the ventral region of the ipsilateral central nucleus supporting previous HRP results and suggesting a sparse ipsilateral projection from the cochlear nucleus to the IC.

These findings suggest that the organization of auditory afferents to the IC in <u>Eptesicus fuscus</u>, an echolocating bat that uses primarily a frequency modulated emission, is similar to that found in other non-echolocating mammals. Whether the correspondence in structural organization supports a functional similarity in processing acoustic signals is an issue for future investigation.

65.10 DETERMINANTS OF AUDITORY SPATIAL SELECTIVITY: A COMBINED DICHOTIC AND FREE-FIELD STUDY OF NEURONS IN THE BAT INFERIOR COLLICULUS. Z. M. Fuzessery and G. D. Pollak. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

The spatial selectivity of an auditory neuron is dictated by the directionality of the ears, and by its sensitivity to binaural cues. To directly evaluate how these factors influ-ence spatial selectivity, 60 KHz neurons in the inferior colliculus of the mustache bat (<u>Pteronotus p. parnelli</u>) were evaned for beth their constituity to binaural intervie examined for both their sensitivity to binaural intensity differences, using dichotic stimulation, and for their spatial selectivity, using free-field stimulation generated by an array of 15 speakers mounted on a hoop which could be rotated about the horizontal axis of the bat's head. Maximum spatial selectivity was found to shift in a predictable fashion as a function of binaural intensity sensitivity. These results were compared with those of a cochlear microphonic study evaluating the acoustic directionality of the ear, permitting a dissection of the contributions made to neuron spatial selectivity by the structure of the ear, and by the central integration of binaural input.

The mustache bat emits a constant frequency echolocation pulse of 60 KHz. Neurons were recorded in a large, anatomically pulse of 60 KHz. Neurons were recorded in a large, anatomical discrete subdivision of the inferior colliculus devoted to processing information at this frequency. At 60 KHz, the cochlea is maximally sensitive to a sound from  $20^{\circ}$  off the vertical axis and  $10^{\circ}$  below the horizontal axis, termed the acoustic axis. An area around the acoustic axis in which thresholds are within 5 dB of greatest sensitivity is termed the optimal area. At the cochlear level, the optimal area is roughly circular, extending about 20 ° radially from the axis.

Three main functional classes of colliculus neurons were studied: E-O cells responding to input from only one ear, E-I cells excited by one ear and inhibited by the other, and E-E cells excited by input from both ears. E-E cells could be facilitated or not by binaural input. E-D cells could optimal area similar to that of the cochlea, suggesting spatial selectivity was dictated primarily by the ear. Non-facilitated E-E cells had two optimal areas at the acoustic axes of the ears. Facilitated E-E neurons had a single optimal area which shifted systematically toward the vertical midline as the binaural excitatory thresholds approached equality. E-I cells, like E-O cells, had optimal areas centered at the acoustic axis of the cochlea, but these areas were smaller, with size decreasing as the relative inhibitory threshold of the decreased.

PHYSIOLOGICAL CELL CLASSES IN THE RAT INFERIOR COLLICULUS EXAM-INED BY FACTOR AND CLUSTER ANALYTIC TECHNIQUES. <u>G.R. Farley,</u> <u>E. Javel, B.J. Morley, and D.E. Goldgar\*</u>. The Boys Town National Institute for Communication Disorders in Children, 65.11

Omaha, NE, 68131. A fundamental issue in auditory physiology is whether res-A fundamental issue in auditory physiology is whether res-ponse variability in a structure represents continuous variation or reflects different physiological classes. We examine this question for neurons recorded from the inferior colliculi (IC) of rats anesthetized with urethane. Stimuli were 100 ms tone bursts delivered to the contralateral ear, repeated every 400 ms. For each unit, characteristic frequency (CF) was deter-mined, and a rate-intensity function was obtained at CF. Data analysis consisted of two steps. First, the set of post-stimulus time histograms (PSTHs) from

analysis consisted of two steps. First, the set of post-stimulus time histograms (PSTHs) from the study was subjected to factor analytic techniques to reduce the dimensionality of the problem. Derived factors appeared to represent time epochs in the PSTHs, including an onset period, a pause period, a build-up period, and an offset period. Fac-tor scores were calculated for each PSTH for use in clustering. Second, cluster analysis, including hierarchical and K-means techniques, was used to identify classes of cells having similar response properties. Clustering was done on two sets of data: 1) the PSTHs obtained at 20 dB above unit threshold and 2) the PSTHs from the entire intensity series. In each case, the anal-ysis suggested three major clusters: a group of onset units and two groups of primary-like/pause/build-up units, one having high response rates, and the other having moderate response rates. In order to confirm these findings, other methods for data reduction and clustering are currently under investigation. However, the results from the above analyses do not eliminate the possibility that the differences between primary-like, pause, and build-up units in the IC represents continuous variation rather than distinct classes. A comparison of results from different analyses, and a discussion of their implications for IC physiology, will be presented. [Work supported by NINCDS grant NS-14880 and NSF grant BNS-8006643.]

FUNCTIONAL CHANGES IN THE INFERIOR COLLICULUS OF ADULT GERBIL 65.12

FUNCTIONAL CHANGES IN THE INFERIOR COLLICULUS OF ADULT GERBIL AFTER UNILATERAL NEONATAL COCHLEAR ABLATION. L.M. Kitzes and M.N. Semple (Sponsor: E.A. Davis). Dept. of Anatomy, School of Medicine, University of California, Irvine, CA 92717. Neonatal destruction of the cochlea leads to transneural degeneration of the ventral cochlear nucleus and to changes in the connectivity of the inferior colliculus to each division of the cochlear nuclear complex on the unoperated side (Nordeen, et al., J. <u>Comp. Neurol.</u>, 214:144-153, 1983). In the present study, physiological consequences of such destruction were examined by comparing responses of single units in the inferior colliculus of normal adult gerbils with responses in adult gerbils which had been subjected to unilateral cochlear ablation at 2 days of age. All animals were anesthetized with sodium pentobarbital and ketamine hydrochloride. Tonal stimuli, presented through sealed ear pieces, were calibrated from 60 Hz to 30 KHz. to 30 kHz

In normal animals, contralateral monaural stimulation was in normal animals, contralateral monaural stimulation was typically excitatory, whereas ipsilateral stimulation was commonly ineffective in eliciting a response when presented alone, or suppressed contralaterally evoked responses under conditions of binaural stimulation. When present, excitatory responses evoked by ipsilateral stimulation had higher thresholds responses evoked by ipsilateral stimulation had higher thresholds and lower peak discharge rates compared to responses evoked by contralateral stimulation. In neonatally ablated animals, responses evoked by stimulation of the unoperated ear recorded in the ipsilateral inferior colliculus differed markedly from the normal pattern. Excitatory responses were readily evoked by ipsilateral stimulation and, in addition, had lower thresholds and much higher peak discharge rates compared to response evoked and much higher peak discharge rates compared to responses evoked by ipsilateral stimulation in normal animals.

This remarkable physiological change indicates that responses to ipsilateral stimulation in normal animals depend at least in part on the functional integrity of the contralateral ear during development.

CONNECTIONS OF A LATERAL TEGMENTAL REGION IN THE MIDBRAIN OF THE CAT WITH THE MEDIAL GENICULATE BODY AND THE INFERIOR COLLICULS: THE NUCLEUS SAGULUM. C. K. Henkel and J. M. Whitley\*. (SPON: W. K. O'Steen). Department of Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103. Several lines of evidence suggest that the lateral tegmentum is associated with the afferent and efferent pathways of the midbrain and contributes to adjunct systems that interact with processing in the inferior and/or superior colliculus. In the first part of this study, the nucleus sagulum was identified as one of several lateral tegmental sources of subcollicular projections to the medial geniculate body (MG) in the cat using the HRP method. The results of six experiments with large HRP injections in MG showed that neurons wedged in the margin ventral to the inferior colliculus and neighboring the nuclei of the lateral lemniscus have thalamic projections. Labeled cells in the nucleus sagulum. In the second part of this study, efferent axonal projections from the region of the nucleus sagulum. Axonal projections to the medial geniculate body ended ipsilaterally in three territories: first, in a ventral region associated with the brachium; second, in a dense field within the caudal part of the datas division; and third, in the medial division. These thalamic projections for MG was observed in three cases. In all of the cases, labeled axons followed the central reticular course to hypothalamic and/or ventral tegmental reas. Two other major systems of fibers were labeled at the level of the midbrain reticular formation. Contralaterally, a projection to the medial division of MG was observed in three cases. In all of the cases, labeled axons followed the central reticular course to hypothalamic and/or ventral tegmental reas. Two other major systems of fibers were labeled at the level of the midbrain in the sagulum cases. A commissural system crossed dorsally in the tegmental region. The major target of the other system of fibers fro

65.14 A model of interaural intensity sensitivity. <u>Tom C.T. Yin.</u> <u>Judith A. Hirsch. and Joseph C.K. Chan.</u> Dept. of Neuro-physiology, Univ. of Wisconsin, Madison, WI. 53706. Most neurons in the cat's superior colliculus (SC) that respond to sounds receive input from both ears and are sensitive to changes in behaviorally significant interaural intensity difference (IID). Many such cells, EO/I, produce a discharge in response to monaural contralateral, but not ipsilateral, sumulation which is supressed when tores are presented to both response to monaural contralateral, but not ipsilateral, stimulation which is supressed when tones are presented to both ears. Neurons of another class, 00/F, require binaural input to trigger action potentials. Since the time interval from stimulus onset to neural response decreases with increasing sound pressure level, the cellular mechanism of IID detection could involve an analysis of the delay between the arrival times of binaural inputs, as Jeffress (1948) proposed. In order to that this experimentally, uncomputed the constitution of circle

of binaural inputs, as Jeffress (1948) proposed. In order to test this experimentally, we compared the sensitivity of single cells to both IID and interaural time disparity (ITD). Extracellular recordings were made from the intermediate and deep layers of the SC in barbiturate-anesthetized cats. Acoustic stimuli were delivered dichotically. We found the general shapes of the IID and ITD functions to be similar. For example, spike-counts of 00/F neurons are nonmonotonic with respect to both IID and ITD. If a cell fires maximally when contralateral intensity is higher than ipsilateral, then it will also be maximally excited by isointensity stimuli if the contralateral signal is given a sufficient temporal lead. Analogous relationships exist for EO/I neurons. The steepness of the IID and ITD profiles are well correlated as well. These results are consistent with a model that uses the

These results are consistent with a model that uses the dependence of response latency on sound intensity to demonstrate how IID sensitivity can be generated by differences in the timing of the arrival of inputs from the two ears. For 00/F cells the model assumes that afferents from each ear cause a transient wave of subliminal excitation at the binaural neuron. Coincident arrival of both inputs evokes maximal discharge. As the two waves of excitation overlap less and less in time spikecount falls. Asymmetry about zero IID is modelled by a temporal mismatch of the responses from the two sides at equal intensity mismatch of the responses from the two sides at equal intensity stimulation. EO/I cells differ in that ipsilateral input is inhibitory and that contralateral excitation is suprathreshold. We think it likely that this model is also useful in describing the detection of IID at other auditory loci.

RESPONSE PROPERTIES OF PRIMARY AFFERENTS IN THE MECHANOSENSORY 66.1 SYSTEM OF THE CRAYFISH. <u>M.R. Plummer, J.P.C. Dumont<sup>\*</sup> and J.J.</u> <u>Wine</u>. Neurosci. Prog., Dept. of Biol. and Dept. of Psychol., Stanford Univ., Stanford, CA 94305.

The last addominal ganglion of the crayfish contains a population of identified mechanosensory interneurons that respond to oscillatory fluid displacements (Sigwardt, K.A., respond to oscillatory fluid displacements (Sigvardt, K.A., Hagiwara, G., Wine, J.J., <u>J. comp. Physiol.</u>, <u>148</u>:143-157, 1982). We have determined the frequency response characteristics of these interneurons and have found that within the range of 4 - 400 Hz particular identified neurons are selective for low frequencies, selective for high frequencies, or are nonselective. Our present work is an attempt to understand the mechanisms responsible for this frequency selectivity. frequency selectivity.

The interneurons receive their input chiefly from the animal's tailfan which is covered with numerous cuticular hairs, some of which are sensitive to water currents (Wiese, K., J. Neurophysiol., 39:816-833, 1976). We examined the <u>Neurophysiol</u>, <u>39</u>:816-833, 1976). We examined the mechanoreceptive hairs on the rostrolateral part of the telson using S.E.M. and light microscopy and found four morphologically distinct hair types. One hair type (termed 'guard hair' by Wiese) lies parallel to the surface of the telson. The other three types: long feathered hairs (ca. 800 um long), feathered hairs (ca. 300 um long) and smooth hairs (which are somewhat shorter and thicker than feathered hairs) are oriented perpendicular to the telson surface. There are roughly 70 upright hairs on this part of the telson and the ratio of long feathered hairs to feathered hairs to smooth Neurophysiol.. hairs is approximately 1:4:16.

Intracellular recordings from primary afferent axons that innervate these hairs reveal that the frequency responses of some afferents duplicate the frequency responses of certain of the aforementioned interneurons. For example, one type of afferent is excited by low frequencies, supressed by high frequencies and receives what appears to be presynaptic inhibition at intermediate frequencies. We are presently trying to match morphological hair types with afferent response types and are testing the hypothesis that selective connectivity of afferents to interneurons generates the

frequency response properties of the interneurons. Supported by NSF grant BNS 80-15583, NIH Training Grant MH 17047-02 and an NSF Graduate Fellowship (M.P.).

POST SYNAPTIC INHIBITION MEDIATES SUPPRESSION OF ULTRASOUND AVOIDANCE IN THE CRICKET <u>TELEOGRYLLUS</u> <u>OCEANICUS. T.G. Nolen and R.R. Hoy</u>, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853. 66.2

Tethered, flying crickets avoid bat-like ultrasound by making Tethered, flying crickets avoid bat-like ultrasound by making steering movements away from the source (Moiseff, Pollack, Hoy, <u>PNAS</u> 75:4052). This behavior is mediated by an ultrasound sensitive interneuron (Int-1) (Nolen and Hoy, <u>Neurosci</u>, <u>Abst</u>. 8:529). Int-1's ultrasound response can be suppressed by simultaneous presentation of a tone pulse at the calling song frequency (4-5 kHz) (Moiseff and Hoy, <u>J</u>. <u>Comp. Physiol</u>., in press). We show that the avoidance behavior is also suppressed, at high sound levels of calling song, and that suppression is likely due to post synaptic inhibition of Int-1 by sound pulses of the calling song calling song. Single, short pulses (1 to 30 msec) of ultrasound (15 to 100 kHz)

Single, shote pulses it to so insect of ultrasonic tip wind the wind the solution of the solut simultaneous, two-tone stimulus pulses. At equal sound levels, avoidance steering took precedence over attraction to the calling song. Removal of the contralateral ear showed that suppression could be mediated monaurally.

Intracellular recordings showed that Int-1's ultrasound response was suppressed by 5kHz, which increased the latency to spike, decreased the mean spike rate, decreased the burst duration, and shunted compound EPSPs. Maximal suppression occurred only when the 5kHz pulse was 10 to 15 dB louder than the ultrasound and only when the two pulses overlapped in time.

Sound pulses between 3 and 10 kHz produced an inhibitory post synaptic potential (IPSP) in Int-1, with a best frequency between 4 and 5kHz and thresholds as low as 50 dB SPL. The IPSP was mediated by the ipsilateral ear, had a short latency (31 msec near threshold and 10 msec at higher sound levels) and had a reversal potential at, or just hyperpolarized from, the resting potential. The IPSP lasted the duration of the 5kHz tone pulse and decayed quickly after the stimulus was presented. It had little or no effect on the rising phase, but caused a more rapid decay of unitary EPSPs. Finally, by recording from Int-1 in a flying animal, we found that

5kHz inhibition was sufficient to prevent the cell from reaching the critical spike rate (about 200 spikes/sec) necessary to elicit the avoidance steering.

These results suggest that calling song suppression of the ultrasound avoidance steering of flying crickets can be explained by post synaptic inhibition of the neuron that initiates the behavior. Supported by NIH Training Grant T32MH15793 and NIH NSH630-10.

66.3 ANATOMICAL CIRCUITRY OF LATERAL INHIBITION IN LIMULUS. W. H. Fahrenbach\* (SPON: C. Sell). Oregon Regional Primate Research Center, Beaverton, OR 97006.

The neuronal plexus under the compound eye of the horseshoe crab, <u>Limulus polyphemus</u>, consists of an open, three-dimensional filigree of fine fiber tracts punctuated at intersections by knots of neuropil. This meshwork is the site of lateral inhibition between eccentric cells (second-order visual neurons), a process that yields contrast enhancement and has been studied for more than 30 years. Specific interconnections in the plexus are largely conjectural beyond results inferred from neurophysiology. This study is based on an unbroken, 1,100-section series, cut at a 50-nm thickness, encompassing the plexus of about 25 ommatidia from an animal with a 13-mm prosomal width. Given the caveat that the animal is immature, that it shows ample neuronal sprouting, and that the reconstruction to date embodies 45 axonal aborizations and 600 synapses in one synaptic knot, the following generalizations can be extracted. Retinula cell axons pass through the plexus without branches or contacts. Octopaminergic efferent fibers receive rare synaptic input from eccentric cell collaterals and in turn have scattered synaptoid terminations on retinula cell axons and eccentric cell collaterals. Eccentric cell axons are devoid of direct synaptic input. Their collaterals. Excentic cell axons are devoid of direct synaptic input. Their collaterals travel through the plexus as extremely fine fibers (0.1-0.2  $\mu$ m). They ramify in synaptic knots and subserve both pre- and postsynaptic functions simultaneously. Arborizations near the axon of origin have a high synaptic density (mean of 5 per  $\mu$ m of neurite length), a high synaptic input:output ratio (up to about 10:1), and a rich branching pattern. Eccentric cell collaterals arborizing at distances of several ommatidal diameters have low synaptic density (2.5 per µm) and input: output ratios (about 1:1), as well as sparse branching. Density of presynaptic sites is largely invariant with distance of the The presumption of the parent axon. The structural basis for spatial summation is provided by compact groupings of input synapses, up to 15 per  $\mu$ m, each from a different neuron of origin. Decreasing synaptic input with increasing distance from the parent axon supplies the explanation for spatially graded lateral inhibition. Closely adjacent reciprocal synapses are common and may be recoverible for calf-inhibition. are common and may be responsible for self-inhibition. The simplest hypothesis that combines the known neurophysiology, observed structure, and implied morphogenetic demands, consists of the plexus functioning by decremental conduction of de- and hyperpolarization.

66.4 ANTENNULAR STRUCTURES MEDIATING PHEROMONE RECEPTION IN THE CRAYFISH ORCONECTES PROPINQUUS. Ann Jane Tierney\* and C.S. Thompson. Department of Zoology, University of Toronto, Toronto, Canada M5S 1A1.

Our experiments demonstrate that chemical cues are important in sex and species recognition in the crayfish Orconectes in sex and species recognition in the crayfish Orconectes propinquus. Males and females perceive the chemicals released from their own and a sympatric species 0. virilis, and are attracted only to the chemicals of conspecifics of the opposite sex (Tierney and Dunham, J. Crustacean Biol., 2:544-548, 1982). This response is mediated by the lateral antennular flagella. Experiments were performed in which the medial or lateral antennules were bilaterally ablated from male crayfish. In "medial ablation" animals, behavioral responses to female phero-mones were unchanged relative to controls (response reduced 4.7%). However, a highly significant (P < .005) reduction in response occurred in "lateral ablation" animals (response reduced 92% relative to controls). reduced 92% relative to controls).

Scanning electron microscopy was used to examine the medial and lateral antennules to identify potentially chemoreceptive sensilla. The flagella are approximately 10 mm long and com-posed of 25-30 segments. Common to both antennules are rows of feather-shaped setae situated along the distal margin of each segment. These setae are abundant on proximal segments and gradually become more sparse distally. An additional setal type occurs only on the lateral antennule. These setae consist of clumps of 6-9 hairs located ventrally and are present only on the 10 or 11 most distal segments. Two separate hair clumps occur on each segment. The hairs are directed distally and are approximately 150 µm long. The similarity of these structures to other identified arthropod chemoreceptors and their presence on the lateral, but not the medial, flagella suggest that these structures function in pheromone reception.

Extracellular recordings from antennular nerve bundles indicate a possible mechanosensory function for the feather-Axons from the medial antennule fire in response shaped setae. to vibration, touch and deflection. Axons from the lateral antennule respond to similar stimuli, but have a higher response threshold and action potentials are of a consistently lower amplitude. We suggest that the medial antennules are primarily

amplitude. We suggest that the medial antennules are primarily mechanoreceptor structures, while the lateral antennules function primarily as chemoreceptors, and secondarily as mechanoreceptors. This study was supported by an operating grant to D.W. Dunham from The Natural Sciences and Engineering Research Council of Canada.

66.5 NEUROTRANSMITTER HISTOCHEMISTRY OF NEURONS IN THE ANTENNAL LOBES OF MANDUCA SEXTA. S.G. Hoskins and J.G. Hildebrand. Dept. of Biological Sci., Columbia Univ., New York, NY 10027. In each antennal lobe (AL) in the brain of the moth Manduca sextion of the moth Mandu

In each antennal lobe (AL) in the brain of the moth Manduca sexta, several hundred neurons have their somata in 3 superficial clusters (lateral, medial and anteroventral) bordering on a neuropil in which the dendrites of the AL neurons interact synaptically with primary-afferent axons and with each other in glomeruli. The AL neurons have been classified as multiglomerular local interneurons (confined to the AL) and uniglomerular output neurons (which send axons into the protocerebrum) [Matsumoto and Hildebrand, *Proc. Roy. Soc. Lond. B213:1249* (1981)]. Previous neurochemical studies [Maxwell et al., Comp. Biochem. Physiol. 61C:109 (1978)] called attention to neurotransmitter candidates in the ALs. We have now begun to use histochemical methods to explore the cellular locations of some of those candidates. In preliminary experiments we have sought neurons that may use acetylcholine (ACh) and serotonin (5-hydroxytryptamine, 5HT) as neurotransmitters.

To reveal possibly cholinergic neurons, we use an enzyme-histochemical method that stains neurons having high levels of intracellular acetylcholinesterase (AChE) activity as specifically shown for known cholinergic neurons in the CNS of the leech [Wallace and Gillon, J. Neurosci. 2:1108 (1982)]. We incubate desheathed brains of pharate-adult Manduca in a solution of echothiophate iodide to inhibit extracellular AChE irreversibly and then reveal uninhibited intracellular AChE activity by a histochemical procedure. In the AL only a small group of neurons at the ventrolateral border of the lateral cell cluster stain under these conditions. These neurons appear to have uniglomerular dendritic arborizations near the lateral cluster and axons that project to the lateral protocerebrum. As part of our studies of the role of afferent inputs in the development of the ALs, we have also found that output neurons which stain for intracellular AChE activity develop in the stunted, chronically deantennated AL that forms after excision, prior to metamorphosis, of the ipsilateral antennal imaginal disk.

To stain putatively serotonergic neurons, we use antibodies directed against a 5HT-albumin complex (Immuno Nuclear) in immunohistochemical experiments based on a modification of the wholemount method of Bishop and O'Shea [J. Comp. Neurol. 207:223 (1982)]. At least 6-10 neurons in the anteroventral cluster of the AL are immunoreactive, suggesting that those neutral-red staining, uniglomerular output neurons [Matsumoto and Hildebrand, op. cit.] may be serotonergic.

Thus, we have obtained evidence that 2 different types of AL output neurons may use different neurotransmitters -- ACh and 5HT.

66.6 PROJECTIONS OF ANTENNAL-LOBE OUTPUT NEURONS IN THE BRAIN OF MANDUCA SEXTA. R.A. Montague\*, K.S. Kent\*, M.T. Imperato\*and J.G. Hildebrand. Dept. of Biol. Sci., Columbia Univ., New York, NY 10027. Each antennal lobe (AL) in the brain of the moth Manduca sexta

Each attennal tobe (AL) in the brain of the moth Marduca sexta possesses several hundred neurons, which have their cell bodies in 3 clusters (medial, lateral, anteroventral) and dendrites ramifying in the glomeruli of the AL neuropil, and which have been classified as local interneurons and output neurons (ONS) [Matsumoto and Hildebrand, *Proc. Roy. Soc. Lond B213*:249 (1981)]. ONs are projection neurons with axons extending into the protocerebrum and dendritic arborizations confined to one of the AL glomeruli. Based on the form and location of their glomerular arborizations, Matsumoto and Hildebrand described 3 major types of ONS, 2 of which have cell bodies in the lateral (LC) and medial (MC) clusters of the AL. A Type-I cell (ONI) has its dendritic arborization in a single ordinary glomerulus. Type-III cells (ONIII) are sexually dimorphic, having dendrites exclusively in the male-specific macroglomerular complex in the AL. We have now examined in greater detail the morphology of ONI and ONIII cells by means of intracellular staining with cobaltous sulfide [according to Strausfeld and Hausen, *Proc. Roy. Soc. Lond. B199:4*63 (1977)] followed by silver intensification in whole-mounts or sections. This approach has permitted us to describe 3 subtypes of ONI and ONIII neurons.

Neurons of the first subtype send axons out of the AL through a medial tract that joins the *tractus olfactorioglobularis*. These axons traverse the protocerebrum in a mediolateral direction, sending out collaterals that ramify in, and terminate mainly within the "lips" of, the calyces of the mushroom bodies and ultimately terminate in the lateral protocerebrum. All ONII neurons of this kind have exhibited somata in the MC. Neurons of the second subtype have somata in the LC and send axons out of the AL through a different, more ventral tract to project directly (not via the calyces) to the lateral protocerebrum. The third subtype of neurons, also with somata in the LC, have axons that exit the AL in an even more ventral tract and, after entering the protocerebrum, make a "hairpin" turn and ramify diffusely in a region of neuropil rostral to the calyces.

These findings show that AL ONS, which transmit integrated olfactory information to the protocerebrum, do not necessarily project to the calyces, as has been widely believed, and suggest that higherorder processing of olfactory information involves at least 3 centers in the protocerebrum. We are currently examining ONs in chronically deafferented ALs and in ALs of moths with surgically grafted antennae of the opposite sex. Preliminary findings suggest that at least some ON axons (of the first subtype) have normal projections and patterns of termination in animals deantennated (by excision of an antennal imaginal disk) throughout adult development.

These studies have been supported by NIH grant AI-17711 and NSF grant BNS 80-13511.

66.7 INFLUENCES OF AFFERENT INNERVATION ON THE DEVELOPMENT OF AN IDENTI-FIABLE CLOMERULUS IN THE ANTENNAL LOBE OF MANDUCA SEXTA. K.S. Kent\* and J.G. Hildebrand (SPON: E. Holtzman). Dept. of Biol. Sci., Columbia Univ., New York, NY 10027.

A single, identifiable glomerulus in the posteroventral region of each antennal lobe (AL) of adult male and female Manduaa sexta receives primary afferent inputs from sensory neurons in the ipsiand contralateral labial-pit organs (LPOs) [Harrow et al., companion abstract] and possibly the ipsilateral antenna. As part of a study of the functional significance and development of the AL glomeruli, we have (a) followed the normal postembryonic development of the inputs from the LPOs to this unique glomerulus, (b) examined the development of this LPO-to-AL projection in ALs deprived of antennal inputs throughout adult development, and (c) studied the development of the AL and its "LPO glomerulus" (LPOG) when chronically deprived of LPO afferents. This system allows investigation of the roles of, and dependency upon, 3 distinct sources of sensory innervation in the development of their mutual target in the CNS.

Using anterograde filling of cut LPO fibers with a  $CoCl_2$ -lysine complex followed by precipitation of CoS and silver intensification, we observed the development of the central LPO projection beginning soon after initiation of adult development in the pupa. By day 4 of the 18-day adult development, a few fine LPO fibers are growing from the subesophageal ganglion toward the ipsilateral AL but have not reached it. A bundle of fine fibers enters the AL during the next 2 days, and by days 7-8 the LPO projections to both ALs attain adult-like appearance, defining the shape of their target glomeruli. Thus the LPO axons innervate the ALs about the time of emergence of glomeruli [Tolbert et al., *Soc. Neurosci. Abstr.* 7:3 (1981)]. In animals deantennated throughout adult development, an "LPOC" forms in the ipsilateral AL as a discrete, posteroventral region of the "protoglomeruli" (rudiments of glomeruli characteristic of deantennated ALs), and the stained LPO axons entering that AL describe a corresponding, restricted neuropil region possibly more extensive than the normal LPOG. Thus the antennal afferents are not required for the formation of an LPOG, but they may ordinarily influence its final form. Finally, to test for possible influences of the LPO fibers on the development of the AL, we amputated the distalmost segments of both labil palps at the time of pupation. Histological observations suggest that the LPO inputs do not significantly affect the general organization of the AL, the formation of most glomeruli, or the production of "protoglomeruli" in simultaneously deantennated ALs. But the development of the LPOG in the AL may depend on LPO afferents. Recently we have begun to examine the AL interneurons that have arborizations in the LPOG and how they are affected by chronic deprivation of LPO afferent inputs. (Supported by grants NSF BNS-80-13511 and NIH At-17711.) 66.8 CENTRAL PROJECTIONS AND POSSIBLE CHEMOSENSORY FUNCTION OF NEURONS IN A SENSORY ORGAN ON THE LABIAL PALP OF MANDUCA SEXTA. <u>I.D. Har-</u> row, P. Quartararo<sup>\*</sup>, K.S. Kent<sup>\*</sup> and J.G. Hildebrand. Dept. of Biol. Sci., Columbia Univ., New York, NY 10027. In moths like Manduca sexta, each of the labial palps, which are paired, modified mouthparts that embrace the coiled proboscis, posunities of the second sexta and the second seco

In moths like Manduca sexta, each of the labial palps, which are paired, modified mouthparts that embrace the coiled proboscis, possesses within its diminutive third, distalmost segment a sensory organ comprising a cavity open to the surface and a number of enclosed sensilla. This "labial pit organ" (LPO) was described in several insect species by 0. vom Rath in 1886, who suggested that it is an olfactory organ, but little is known about its function. We have studied the structure and function of the LPO in Manduca by histological and physiological methods and the central projections of the axons emanating from it by anterograde filling of the cut axons with CoCl<sub>2</sub> complexed with lysine, followed by precipitation of CoS, silver intensification, and examination in cleared wholemounts or sections.

The LPO dominates the third segment of the labial palp. Within the cavity of the LPO and exposed to the environment through its anteriorly directed mouth are numerous sensilla, which resemble the sensilla basiconica of antennae. The sensory neurons of these sen-silla send their axons through a small nerve that joins the first labial nerve (LN1) to the subesophageal ganglion (SEG). Cobalt-sul-fide staining of a cut LN1 reveals profuse terminal processes and a few somata (presumably labial-palp motor neurons) in the SEG as well as a bilateral projection to one particular glomerulus in each antennal lobe (AL). When both LNIs are filled with cobalt, only that glomerulus in the AL receives stained fibers from both ipsi- and contralateral palps. If the third segment of the palp (and with it the LPO) is ablated several days prior to filling the corresponding LN1, then the pattern of stained fibers in the SEG is relatively normal while the projections to the ALs are absent. This finding suggests that the axons projecting bilaterally to the ALs are those of the LPO neurons. Further evidence is obtained by applying cobaltlysine to the third segment of the palp to reveal the bilateral AL projections and only a few other terminal processes in the SEG. Histological sections and computer-graphic reconstruction of ALs show that the "LPO glomerulus" lies in the posteroventral region of the glomerular neuropil, adjacent to the lateral cluster of AL neuronal somata. Because the AL glomeruli in *Manduca* are principally sites of olfactory information processing, the projection of the LPO neurons to an AL glomerulus supports the hypothesis that these cells are olfactory receptors. We have begun to investigate the function of the LPO neurons by extracellular recording methods. Preliminary physiological evidence suggests that the LPO neurons do respond when presented with certain volatile chemical stimuli.

66.9 COMPUTER RECONSTRUCTION OF ALL THE NEURONS IN THE OPTIC GANGLION OF DAPHNIA MAGNA. S.J. Sims\* and E.R. Macagno. (SPON: K.J. Muller). Department of Biological Sciences, Columbia University, New York, NY 10027

There are two important reasons to undertake a detailed anatomical reconstruction of a neuronal network. One is that the data obtained, such as the branching patterns and distribution of synaptic contacts of each neuron, and the patterns of synaptic connections among the neurons of the network, can be essential to an understanding of the functions of each element within the network and of the network as a whole. The second reason is that detailed information about the structure of the end product tells us what requirements are placed upon the mechanisms responsible for the assembly of the network during neurogenesis. For these two reasons we have undertaken the computer-aided 3-D reconstruction from serial electron micrographs of the approximately 200 neurons in one half of the adult optic ganglion of the small crustacean <u>Daphnia magna</u>. The reconstructions were carried out using the Columbia CARTOS system (Macagno et al. (1979), Ann. Rev. Biophys. Bioeng. <u>8</u>: 323-351). The Daphnia optic ganglion (OG) is bilaterally symmetric and consists of two regions, the lamina and the medulla. Photoreceptor axons enter the lamina through its distal surface and axons of ganglionic neurons exit proximally from the medulla and enter the supraesophageal ganglion (SEG). The reconstructed neurons were classified into groups according

The reconstructed neurons were classified into groups according to (1) which neuropils (lamina, medulla, SEG) their processes innervate and/or (2) the locations of their cell bodies. Individual neurons that innervate each neuropil alone or any combination of them were identified. Seven cells were found which branch only in the laminar neuropil and 17 cells which branch only in the medullary neuropil. Among cells that innervate two neuropils, we found: (a) 82 cells that branch in both laminar and medullary neuropils (55 with cell bodies on the distal surface of the lamina and 27 with cell bodies located at the laminar-medulla boundary); (b) 16 cells that branch in the laminar and SEG neuropils. We found also 18 interneurons that have branches in all three neuropils, and 17 which send major branches across the midplane and thus innervate neuropils on both right and left sides. Although cells were reconstructed in only one hemiganglion, inspection of the other half revealed similar cells in approximately mirrorsymmetric locations. Within each of these groups, cells were of the aninar and/or medullary neuropils. Current efforts are directed towards elucidating the synaptic connectivity patterns of cells in each of these groups.

66.11 CIRCADIAN CHANGES IN THE FREQUENCY RESPONSE OF VISUAL CELLS IN THE LIMULUS COMPOUND EYE. G.H. Renninger, Biophysics Group, Univ. of Guelph, Guelph, Ontario NIG 2W1, Canada The response to modulated light of optic nerve fibers from the

The response to modulated light of optic nerve fibers from the compound eye of <u>Limulus</u> undergoes changes during the animal's circadian cycle, which is regulated by a clock located in the brain (Batra et al., Soc. Neurosci. Abstr. 7, p. 61, 1981). Intracellular studies reported here, indicate that these changes in optic nerve response originate in the light-absorbing retinular cells of the photoreceptor unit. The eccentric cell, which receives input from the retinular cells and generates optic nerve impulses, appears to be unaffected by the circadian clock.

nerve impulses, appears to be unaffected by the circadian clock. Responses of cells to sinusoidally modulated light and, in the case of the eccentric cells, to modulated injected current were observed by means of glass microelectrodes during the day and after the transition to the high-sensitivity nighttime state. These observations were made in intact animals in which subjective night occurred naturally. Light intensity was adjusted so that the mean response level of each cell at night was equal to the daytime level. Because of the increased sensitivity of the eye to light at night, this was achieved by attenuating the light. The average response of the eccentric cells to injected current was 15-20 impulses/s.

The amplitude and phase of the response of eccentric cells in situ to sinusoidally modulated current do not depend on circadian time, and they are in general accord with those found in excised eyes (Knight et al., J. Gen. Physiol. 56, pp. 421-437, 1970). The response of the retinular cell to modulated light, however,

The response of the retinular cell to modulated light, however, does depend in a significant way on circadian time. During the day, the frequency response resembles the light-to-voltage transfer function reported for the excised eye. At night, the amplitude decreases and the phase lag increases more rapidly for frequencies above 1 Hz. The highest frequency used was 10 Hz. The maximum amplitude was achieved under these conditions at 4-6 Hz during the day and at 0.6-0.8 Hz at night. The increase in phase lag is consistent with an observed increase at night in the latency of the response to light onset. This may reflect in part an increased delay in the phototransduction process at night. (NSERC Canada Grant #A6983) 66.10 TWO STAGES OF INTEGRATION IN A LEECH VISUAL INTERNEURON E.L. Peterson. H3A IBI

The medicinal leech has 5 bilateral pairs of eyes each containing 30-50 photoreceptors. The axons of the photoreceptors of the most posterior 3 eyes on one side are electrically coupled to the ipsilateral LV cell, an interneuron in the first segmental ganglion. Light or injected current elicits a spike in the photoreceptor soma, an impulse in its axon in the optic nerve and a small ( < 1 mV) EPSP in the LV cell. I blocked chemical synaptic transmission and spontaneous activity with 40 mM Mg saline, then stimulated axons in the optic nerve and a small ( < 1 mV) EPSP in the LV cell varied as a function of its direct input. Weak shocks produced a few individual EPSPs; slightly stronger shocks produced several EPSPs which summated linearly but never surpassed 2-3 mV. At a well-defined threshold a qualitatively different and much larger event (15 mV) appeared in the LV cell. As the stimulus strength was increased further the event grew by discrete steps until it reached 40 mV. The 40 mV event apparently represents the nonlinear summation of 5-10 components, each similar to the 15 mV event. These events arise in the CNS, not in the optic nerve. They are probably spikes that arise locally in individual dendrites but fail to invade the soma actively. Accordingly I call them d-spikes, while noting that they could arise in unidentified interneurons electrically coupled to the LV cell. D-spikes produced by shocking one nerve evidently have a distinct origin from those produced by shocking an action potential synaptic potentials d-spikes show temporal and spatial summation at the soma. In normal saline a burst of d-spikes summate to generate axon spikes. The propensity of an LV cell to produce d-spikes varies from preparation to preparation, and thus the first integration stage may be modulated to regulate the sentivity of the LV cell. In addition there are inhibitory synaptic inputs to the LV cell which affect the second integration stage

66.12 IRON CONTAINING CELLS OF BEES. D. A. Kuterbach\*, <u>B. Walcott</u>, and <u>P. Brink</u>, Dept. Anatomical Sciences, State University of New York, Stony Brook, N.Y. 11794.

Since intracellular iron granules have been found to be necessary for the magnetic field response of bacteria and since honey bees ( $\Delta pis$  mellifera) respond behaviorally to magnetic fields and contain iron, we have been examining the cellular localization of iron in bees. We have previously reported (Science 218:695, 1982) that the oencytes of mature honey bees which occur in sheets around each abdominal segment contain 0.5µm iron containing granules. These granules were not present in the newly emerged adult bee but rather develop over a ten day period. In a newly hatched bee there were no other tissues that show positive iron staining so that the iron probably comes from an external source.

Other Hymenoptera have also been examined. Both <u>Bombus sp</u>. (Bumble bee) and <u>Scaptotrigona postica</u> (Brazilian stingless bee) have oencottes with iron positive staining granules as shown by the potassium ferrocyanide technique. In <u>Bombus</u> the granules were larger than <u>Apis</u> but by x-ray microanalysis have the same composition with large amounts of iron. These three species are social bees with a nest to which they return. <u>Ceratina calcarala</u> and <u>Halictus ligatus</u> however are not known to be social, yet they have the same diet as the other species. Adults of these species have oenocytes but are lacking the iron granules. Physiological examination of sheets of <u>Apis</u> oenocytes was performed to determine if the cells were dye and/or electrically

Physiological examination of sheets of <u>Apis</u> oenocytes was performed to determine if the cells were dye and/or electrically coupled. Isolated sheets of cells were pinned on sylgard and viewed with an inverted microscope. Visually identified cells were impaled with microelectrodes filled with 1% lucifer vellow-CH and the dye was electrophoretically injected (90 nA for 5 min.). The dye filled the impaled cell and spread to adjacent cells but did not fill the fat cells that occur among the oenocytes. In one hour the dye spread to a circular patch of cells with a radius of about 7 cells. Thus there appears to be extensive coupling between the iron containing oenocytes. Supported by GM 28804 to BW. 66.13 THE EFFECTS OF BEHAVIORALLY RELEVANT TEMPERATURES ON THE NEURO-PHYSIOLOGY OF GRASSHOPPER MECHANOSENSORY HAIRS. <u>C.I. Miles</u>\* (SPON: J. Palka). Dept. of Zoology, Univ. Washington, Seattle, Wa. 98195.

J. Palka). Dept. of Zoology, Univ. Washington, Seattle, Wa. 98195. Grasshopper mechanosensory hairs increase their firing frequency if given stronger stimuli at a constant temperature or if temperature is increased for the same strength stimulus. If the surface temperature of a part of the body changes, it is not obvious that the animal would be able to tell whether the change in firing frequency of the affected hairs is due to a different stimulus or simply to the change in temperature. Furthermore, in nature, microclimates can create steep thermal gradients over very short distances, so it is likely that different hairs will be operating at different temperatures at any given time.

I have monitored the temperatures of the head, thorax, abdomen and feet of freely moving <u>Schistocerca americana</u> placed in thermally heterogeneous environments in the laboratory. Thoracic temperature was found to be the least variable. Animals spent a majority of the time positioned where this was  $35^{-}40^{\circ}$  c. The other parts of the body varied around this range to different extents, with the head experiencing a somewhat wider variability and the feet the widest. Temperature differences ranging from  $0.5^{\circ}-10^{\circ}$  c could be recorded between head and thorax. Even wider differences were found between thorax and feet.

Electrophysiological recordings were then made from mechanosensory hairs of the head, thorax and feet. The resonse of an individual hair to a constant stimulus was recorded as the temperature of the cuticle was varied. The response vs. temperature curve for foot hairs is linear up to about 32°c. From 32°-40°c, the foot hairs' response are largely independent of temperature, and above  $40^\circ$  the hairs' response decreases with further increases in temperature. The curves for thoracic hairs have about the same slope as the linear portion of the foot hair curves, but these continue to be linear through the full range of behaviorally relevant temperatures. Curves for the generally distributed head hairs are also linear, but with lesser slopes. The special fields of wind sensitive head hairs, however, have by far the highest sensitivity to temperature. The behavioral significance of this is being investigated.

Taking into account the range of temperatures which animals maintain when given the choice, then, the foot hairs, which see the widest variability within this range are the most strongly temperature compensated. Thoracic hairs, which are exposed to the least variability are much less compensated, while at least some head hairs are intermediate in both temperature variability and compensation. The neurophysiology of mechanosensory hairs can therefore be adapted to the kinds of temperature variations to which they are regularly exposed.

## LIMBIC SYSTEM: HIPPOCAMPUS AND AMYGDALA

67.1 LIGHT AND ELECTRON MICROSCOPIC STUDIES OF RAT HIPPOCAMPAL CELLS CONTAINING CHOLECYSTOKININ IMMUNOREACTIVITY IN AREA CAI. P.E. Marshall\*, K.M. Harris and D.M.D. Landis, Neurology Service, Massachusetts General Hospital, Boston, MA 02114

Within the rat hippocampus, cholecystokinin (CCK) immunoreactivity exists in cells whose shape and size correspond to interneurons visualized in Golgi impregnations. As part of our examination of synaptic structure in the hippocampus, we have used light and electron microscopic immunocytochemical methods to determine the synaptic interactions of cells containing CCK.

After aldehyde fixation, the hippocampus was dissected from adult male rats, and vibratome sections were reacted with antiserum to CCK-8 (Immunonuclear). Antibody binding was visualized with avidin-biotin-peroxidase techniques.

antiserum to CCK-8 (Immunonuclear). Antibody binding was visualized with avidin-biotin-peroxidase techniques. 207 cells with extensive dendritic and axonal staining were identified in CA1, distributed throughout the septo-temporal axis. 11% were in the alveus and s. oriens; cells in the alveus were multipolar, and s. oriens cells tended to be fusiform. 25% were in the s. pyramidale, and appeared similar to basket cells. 46% were in the s. radiatum and s. lacunosum-moleculare, and 18% were found adjacent to the fissure, all of multipolar shape. These observations are similar to those of other investigators (e.g. J. Comp. Neurol. 203:335; Brain Res. 224:180).

In serial thin sections, cells containing cholecystokininlike immunoreactivity in s. radiatum had invaginated nuclei and spine-poor proximal dendrites. Large, unstained, irregularlyshaped boutons containing pleomorphic synaptic vesicles formed symmetric synaptic junctions on the immunoreactive perikarya and proximal dendrites. CCK-containing axons formed symmetric synaptic junctions with large diameter, unstained dendrites in s. radiatum. The immunoreactive axons appeared to have pleomorphic synaptic vesicles, but few or no large granular vesicles. No clear instances of CCK-containing axons synapsing with spines have been identified in s. radiatum.  67.2 IMMUNOCYTOCHEMISTRY OF SOMATOSTATIN IN CA1 OF RABBIT HIPPOCAMPUS.
D. D. Kunkel<sup>\*</sup>, P. A. Schwartzkroin and A. E. Hendrickson (SPON: A. A. Ward, Jr.). Depts. of Neurological Surgery and Ophthalmology, University of Washington, Seattle, WA 98195. The neuropeptide somatostatin (SRIF) has recently been local-

The neuropeptide somatostatin (SRIF) has recently been localized in several areas of the rodent brain including the hippocampus. Electrophysiological studies of hippocampal pyramidal cell responsiveness to SRIF application have shown both excitatory and inhibitory effects of somatostatin. Utilizing intracellular recordings we have recently demonstrated SRIF excitatory actions on CAl pyramidal cells (Mueller and Schwartzkroin, this meeting).

In order to study the anatomical correlates of this SRIF effect, light and electronmicroscopic immunocytochemical investigations were carried out on immature (8 day) and mature (30 day) rabbits. The peroxidase/antiperoxidase (PAP) antibody enzyme technique was used. Immunoreactive somatostatin (ISRIF) neurons were found localized in stratum oriens, particularly at the oriens-alveus border. These cells were most frequent in the CAI subfield; ISRIF neurons were also found within the hilus of the dentate gyrus. ISRIF neurons, located in stratum oriens, are spindle-shaped, with a bipolar dendritic tree. Dendrites run parallel to stratum pyramidale and occasionally ascend into the pyramidal cell layer. Prominent ISRIF processes ascend through stratum pyramidale and run parallel to the hippocampal fissure. A light immunoreactive band (presumably terminals) is evident within stratum pyramidale.

Electronmicroscopic İmmunocytochemistry of SRIF revealed highly immunoreactive fusiform somata in stratum oriens. ISRIF dendrites are aspinous and receive numerous synaptic inputs (asymmetric synaptic contacts). ISRIF axons are evident throughout the various laminae of the CA1 subfield; terminals have been found in stratum pyramidale, as well as in stratum lacumosummoleculare.

From this investigation it is evident that SRIF neurons have a local circuit termination within the hippocampus, although extrinsic projections are possible. SRIF neurons may thus be a significant population of interneurons, the function of which is still unknown. Conceivably, these cells act as excitatory interneurons in local hippocampal circuitry. (Suported by NS 15317, NS 00413, NS 17111, and BNS 8209906)

ELECTROPHYSIOLOGICAL ACTIONS OF SOMATOSTATIN (SRIF) IN RABBIT 67.3 HIPPOCAMPUS STUDIED IN VITRO. A.L. Mueller and P.A. Schwartzkroin. Dept. of Neurological Surgery, University of Washington, Seattle, 98195. WA

Intracellular recording techniques were utilized in order to examine the electrophysiological actions of the peptide, somato-Statin (somatorropin release inhibiting factor, SRIF), in area CA1 of hippocampal slices prepared from mature (age 1 month) and immature (age 6-10 days) rabbits. SRIF was applied locally to the somata of CA1 pyramidal neurons via pressure ejection (0.1 mM SRIF in 5 mM sodium acetate, pH 6.5; applied pressure 30 pounds per square inch; duration of ejection 20-150 msec; interejection interval 10-30 sec).

Application of SRIF typically evoked a robust depolarization of up to 20 mV amplitude, often associated with a burst of action potentials, in both mature and immature CAl pyramidal neurons. This SRIF-evoked response appeared to undergo some type of rapid "desensitization," in that the magnitude of the depolarization sometimes decreased greatly from one ejection period to the next. No consistent changes in cellular input resistance were observed. Rarely, SRIF was seen to trigger an episode of spreading depression in immature tissue. Preliminary experiments suggest the SRIF-evoked depolarization persists in conditions in which synaptic transmission has been abolished.

We have recently demonstrated the existence of SRIF-containing neurons (interneurons?) in rabbit hippocampus (see Kunkel, Schwartzkroin and Hendrickson, this volume). Taken together, our results suggest that SRIF may function as an excitatory neurotransmitter in the hippocampus. One can speculate further that SRIF might be the transmitter of the proposed hippocampal excitatory interneuron.

- SEQUENTIAL ELECTROPHYSIOLOGICAL CHARACTERIZATION OF THE 67.5 RAT HIPPOCAMPAL SLICE PREPARATION. <u>A. Schurr</u>, <u>H. L. Edmonds Jr., K. H. Reid and M.T. Tseng</u> Cellular Neuroscience Lab, Depts of Anesthesiology, Physiology and Anatomy, University of Louisville, Louisville Kentucky 40292.

Kentucky 40292. An essential element of any assay system is a knowledge of its stability. Although the in vitro hippocampal slice preparation is widely used in cellular neuroscience, precise data on its stability and viability are not available. The purpose of this study was to determine the viability of rat hippocampal slices in a linear flow chamber (H. Haas, et al., J. Neurosci. Meth. 1:323, 1979), with a small volume, gas interface oxygenation, and a bathing fluid flow of 0.5 ml/min. The experiment involved two phases. The first explored the properties of the CA1 population response, to identify those which could predict changes in tissue viability. Properties selected were population spike to identify those which could predict changes in tissue viability. Properties selected were population spike latency, amplitude of rising phase, slope of rising phase, duration of spike latency, amplitude of falling phase, slope of falling phase, and amplitude of the EPSP. The second phase was confirmatory: in 22 experiments responses were recorded automatically every 10 min until complete electrical failure occurred. To test for predictive efficacy (utility as a predictor of impending electrical failure), measures of each property were averaged over a 3 hr period, and successive values compared with the average. Significant deviations (P<.001) in any of the measures were detected, and records containing them were not included in the running average. The distribution of included in the running average. The distribution of significant deviations was used to rank properties in order of predictive efficacy. Lifetimes ranged from 6-19 hr (11.7  $\pm$  4.0, N=22). The property most reliably predicting slice deterioration was the latency of the predicting slice deterioration was the latency of the population spike. Amplitude measures were less stable and slope measures were too unstable to be useful. No specific combination of signal properties was a better predictor than latency alone. In summary, the hippocampal slice preparation, in our hands, is stable for a minimum of 6 hr (90% confidence). Companion morphological studies indicate that structural integrity is preserved at 6 hr. The best single predictor of impending electrical failure is a significant increase in the latency of the population spike. spike.

RESPONSES OF BRAIN TISSUE TO GRADED HYPOXIA: A STUDY USING THE IN VITRO HIPPOCAMPAL SLICE PREPARATION. K. H. Reid, A. Schurr H. L. Edmonds, Jr. and B. M. <u>Rigor</u>, Cellular Neuroscience Lab, Departments of Anesthesiology and Physiology, University of Louisville, Louisville KY. 40292 674

An est he siology and Physiology, University of Louisville, Louisville KY. 40292 In vivo, brain responses to hypoxia are a result of a complex interplay between tissue and cerebrovascular responses. The in vitro hippocampal slice preparation provides access to tissue responses in the absence of cerebrovascular changes, since this preparation has no blood supply. Hippocampal slices 400  $\mu$ m thick were maintained in a linear-flow chamber (Haas et al, J. Neurosci. Meth. 1:323, 1979) with gas interface oxygenation. Oxygen tension was measured continuously in the gas phase close to the slice with a mass spectrometer. The CA1 population spike was used as an index of tissue electrical activity. Schaffer collateral stimulation (2x threshold, 0.1 msec, 1/min) evoked near-maximal (10-30 mV) population spike responses from the pyramidal cell layer. Slices were maintained in 95% 02, 5% CO2, until the population spike was stable in amplitude and latency. The gas was then restored, and after 40-60 min of restabilization a second hypoxic challenge ware found. The first was a sustained but reduced population spike with a 10-20% increase in latency. This was seen in 9/13 slices on the first exposure to hypoxia, and in 5/11 on the second exposure. The second was a rapid fall in amplitude followed by a recovery. during the hypoxic The first exposure to hypoxia, and in 5/11 on the second exposure. The second was a rapid fall in amplitude followed by a recovery, during the hypoxic exposure, to 40-90% of control amplitude. This recovery persisted for 5-30 min before collapsing abruptly to electrical silence. This was seen in 2/13 slices on first exposure, and in 5/11 on the second exposure to hypoxia. On restoration of 95\% 0<sub>2</sub>, the population spike returned, usually reaching control level within 20 min. Latency changes paralleled amplitude changes, but occurred more rapidly. Biochemical data (Duffy et al, J. Neurochem. 19:959, 1972) indicate that hypoxic neurons become electrically silent without loss of ATP. Our results suggest that episodes of controlled graded hypoxia may be useful in studying the transition to this 'dormant' state.

SEQUENTIAL ULTRASTRUCTURAL CHARACTERIZATION OF RAT HIPPOCAMPAL SLICES, IN VITRO M. T. Tseng\*, K. H. Reid, <u>A. Schurr and H. L. Edmonds</u>, Jr., Depts of Anatomy, Physiology and Anesthesiology, University of Louisville, Louisville, Kentucky 40292 Functional slices of hippocampal formation, as indicated by their ability to respond to electrical stimulation, can be maintained for extended periods. To ascertain the structural integrity of the brain slices samples were removed at 0, 6 and 12 hr after incubation. A small piece of the slice that included stimulation and recording sites was fixed in glutaraldehyde and osmium tetroxide, dehydrated, embedded in plastic, sectioned at a plane parallel to the long axis of pyramidal cells, stained and examined. the long axis of pyramidal cells, stained and examined. Pyramidal cells contained a large nucleus filled with finely dispersed chromatin and a prominent nucleolus. Cytoplasmic components included stacks of rough endoplasmic reticulum (RER), ovoid mitochondria, Golgi complexes, microtubules and microfiliments. Some of these cells were quite electron-opaque. Their densely these cells were quite electron-opaque. Their densely packed chromatin suggested that they were less metabolically active. Microtubules and microfilaments were readily discerned in the apical dentrites. Small capillaries were found both in the neuropil and among the pyramidal cells. Following 6 hr incubation the general cytoarchitecture was well-preserved. Pyramidal cells remained tightly packed, though a slight increase in dark cell variant was evident. Nuclear envelopes were tightly adherent, mitochondria appeared normal and cisternae of the RER were within the normal range. Some disorganization of microtubules near origins of apical dendrites was apparent in most cells. In the neuropil, large clear perivascular spaces were occasionaly noted. By 12 hr, the majority of the pyramidal cell nuclei appeared pyrontic. Scattered microtubular bundles appeared in the electron-opaque microtubular bundles appeared in the electron-opaque cytoplasm. Some cells accumulated vacuoles. Among the neuropil, darkly stained neurites mingled with swollen dondoites. Among the second statement of the second statemen A marked increase in perivascular space was nt. These ultrastructural analysis indicate dendrites. also evident. that the in vitro hippocampal slice remains viable from 6 to 12 hr. Companion electrophysiological studies strongly support this conclusion.

FACTORS INFLUENCING THE FIRING PROBABILITY OF PYRAMIDAL NEURONS 67.7 IN THE HIPPOCAMPAL SLICE. <u>Anita A. Roth\*</u> and <u>Raymond Digledine</u>, Dept. Pharmacology and Neurobiol. Curric., University of North Carolina, Chapel Hill, NC 27514. Orthodromic electrical stimulation of fibers in stratum radia-

drites a spatially distributed EPSP on pyramidal cell den-drites and also activates feed forward and feed back inhibitory circuits. We wished to determine the influence of spatial summa-tion and inhibitory circuits on the firing probability of pyramid-al cells in response to a single orthodromic stimulus. The dendritic field EPSP was recorded by an electrode placed in stratum radiatum, while an electrode placed in stratum pyramidale record-ed the extracellular population spike or, in some experiments, intracellular potentials. Stimulating electrodes were placed in the stratum radiatum at different distances from the recording electrodes. Sigmoid input-output (1/0) curves were generated by plotting population spike amplitude as a function of the initial slope of the field EPSP. For a given field EPSP the amplitude Slope of the field EFSF, for a given field EFSF the amplitude of the population spike was taken as a measure of the firing prob-ability of the pyramidal cell population. Drugs were applied by perfusion and drug effects determined by calculating the lateral shift of the I/O curve (J. Pharmacol. Exp. Ther. <u>233</u>:502, 1982). For a given size field EPSP a stimulating electrode placed within 200 µm of the recording array was usually less effective in acti-vating the pyramidal cell population than a stimulating electrode placed more than approximately 800 µm away. Thus the 1/0 curve generated with the near stimulating electorde lay to the right of the I/O curve generated with the far electrode. A laminar analy-sis of EPSP magnitude showed that the spatial distribution of EPSPs was usually somewhat wider for the far than for the near stimulating electrode, which could partially account for the dif-ference in lateral position of 1/0 curves. However, a difference in the 1/0 curves was still obvious even when a microlesion restricted spatial divergence. For a given extracellular EPSP the intracellular EPSP was larger for the far than for the near stimulating site. Morphine, pentobarbital and penicillin had a lar-ger effect on the near than on the far I/O curve. Morphine (20  $\mu$ M) shifted the near curve to the left. Pentobarbital (0.3-0.5 mM), when it had an effect shifted the near 1/0 curve to the right, while penicillin (0.5-1.0 mM) shifted the near curve to the left. In summary, both spatial summation of EPSPs and feed-forward inhibition influence the position of I/O curves. The sel-ective drug effects on the I/O curve generated by the near stimulating electrode suggest a spatially restricted form of inhi-bition that is GABAergic and morphine sensitive. This form of inhibition acts to reduce the ability of an orthodromic stimulus to activate pyramidal cells. Supported by DA-02360 and NS-17771.

INTRACELLULAR FILLING OF RAT DENTATE GRANULE CELLS WITH HIRP: ANALYSIS OF MOSSY FIBER COLLATERALS. B.J. 67.8 Claiborne, D.G. Amaral, and W.M. Cowan. The Salk Institute, La Jolla, CA 92037

It has been known for some time that the axons of the dentate granule cells - the so-called mossy fibers - collateralize immediately below the granule cell layer. It has been difficult, however, to determine the extent and distribution of these collaterals in Golgistained material. We have begun, therefore, to investigate mossy fiber structure using in vitro slice preparations and intracellular HRP filling. We have determined thus far that individual mossy fibers give rise to an extensive network of collaterals which extend well beyond the subgranular region and, in many cases, ramify throughout the hilar region of the dentate gyrus.

Transverse slices (350 µm thick) of the hippocampal formation, taken from 35 to 50 day-old rats, were maintained with oxygenated saline in a recording chamber. Electrodes filled with 2% HRP in Tris/KCI were used to impale granule cells generally near the middle of the slice. HRP was injected with depolarizing current pulses (3nA, 250 ms, 2/s for 5 to 10 min) into those neurons that exhibited stable resting potentials of at least - 45 mV. After a further incubation of 2 to 5 hours, the slices were fixed overnight in 1% paraformaldehyde, and 2% glutaraldehyde in 0.1 M phosphate buffer, rinsed briefly, and then reacted with DAB. To facilitate DAB penetration into the 350 µm slices, they were first placed in 1% Triton-X for 1 hr and then preincubated in DAB for 1 hr before reaction with DAB and H<sub>2</sub>O<sub>2</sub> for 30 min. Slices were cleared and mounted in glycerol. The filled neurons were examined using brightfield mounted in glycerol. The tilled neurons were examined using originited optics and subsequently reconstructed in three dimensions using a Zeiss Universal microscope that is interfaced with a PDP II-03 computer. Most of the neurons which have been analyzed were located in the supropyramidal blade of the dentate gyrus, but neurons in the infrapyramidal blade which have been examined appear to have a similar pattern of collateralization.

Each mossy fiber has about 6 or 7 collaterals which are of the order of 0.3 µm in diameter. They are variable in length, but many are as long as 500  $\mu$ m, and occasional collaterals extend across the entire hilos even reaching the subgranular region of the opposite blade. In a few cases, collaterals have been followed into the granule cell layer, but none have been seen to enter the molecular layer. The majority of the stained collaterals have been found to be contained within the  $350~\mu m$  slice, but, in a few cases, they extended beyond the borders of the slice. Each collateral has a number of small, rounded voltas of site sheet tuded unevenly along its length, and most collaterals have 1, or occasionally 2, larger, irregularly shaped varicosities which resemble mossy fiber expansions in all respects except size; the collateral expansions are only about 2  $\mu$ m in diameter whereas the mossy fiber expansions, found in the stratum lucidum of field CA3, are between 4 and 8 µm in diameter.

67.9 TOPOGRAPHY OF LATERAL ENTORHINAL NEURONS LABELED FROM SEPTAL AND TEMPORAL DENTATE GYRUS. <u>M.L. Miller<sup>#</sup>, J.H. Haring and</u> J.N. Davis (Spon: E. Busse). Departments of Medicine (Neurology), Pharmacology and Pathology, Duke Univ. Med. Ctr., Durham, NC 27710.

We have been interested in differences between the afferents We have been intersteen in uniterstees between the arter to the dorsal and ventral hippocampus. During studies with horseradish peroxidase (HRP), we noted a difference in the pattern of labeling in lamina II of lateral entorhinal cortex (LEC) after injections of each locus. Injections of HRP or WGA-HRP (50-100  $\mu$  1) were made in either the septal or temporal dorted curve of Sprance During mote (JTE CDE c). dentate gyrus of Sprague-Dawley rats (175-225 g). Septal injections were generally well localized in the dentate gyrus and produced labeling in the dorsal part of LEC. LEC neurons in lamina II immediately below the rhinal fissure contained light to moderate amounts of HRP. No labeling was seen in more ventral parts of LEC. Temporal dentate injections were less focal than dorsal injections since the injection traversed a considerable septo-temporal distance and spread more readily into the hippocampus as shown by labeling of lamina III neurons in LEC. Temporal dentate gyrus injections yielded heavily labeled LEC neurons in the ventral two-thirds of lamina II. A few LEC neurons of the dorsal third contained small numbers of HRP granules. This pattern was present at all rostrocaudal LEC levels; no heavily labeled neurons were observed in the region adjacent to the rhinal fissure.

These data show a topographic distribution of LEC axons to the dentate gyrus with septal HRP injections labeling lamina II neurons adjacent to the rhinal fissure while temporal injections heavily labeled more ventral parts of lamina II. The observed differences in both density and intensity of labeling from each locus are most likely attributable to the larger volume of tissue exposed to tracer in the temporal injection cases. The labeling observed in dorsal LEC neurons after temporal injections probably reflects uptake by fibers of passage. These observations of differential LEC labeling of passage. from dorsal and ventral dentate gyrus extend the previous observations of lamina II labeling seen after dentate injections at a single septotemporal level. Moreover our data confirm the results of an anterograde degeneration study which suggested a similar spatial arrangement for LEC afferents to the septal and temporal parts of the dentate gyrus. These data together with our previous studies of brainstem afferents emphasize the differences in inputs to the septal and temporal dentate gyrus of the hippocampal formation. Supported by NS 06233.

67.10 NON-LINEAR SYSTEMS ANALYSIS OF PERFORANT PATH-TO-DENTATE SYNAPTIC TRANSMISSION IN THE HIPPOCAMPUS. T.W. Berger, J.L. Eriksson\* D.A. Ciarolla\* and R.J. Sclabassi. Depts. of Psychology, Psychiatry and Neurosurgery (R.J.S.), University of Pittsburgh, Pittsburgh, PA 15260.

Characteristics of synaptic transmission in the entorhinal-todentate system were examined in New Zealand white rabbits anesthetized with halothane. A pseudorandom series of intervals to felectrical stimulation pulses (0.1 msec duration) was applied to the perforant path, and extracellular field potential re-sponses were recorded from the granule cell body region of the dentate gyrus. The stimulation intervals consisted of a Poisson distribution with a mean frequency of 2Hz and a range of 0.2-1K Hz. Stimulation current remained constant at a level just exceeding threshold for a population spike. A total of 4064 pulses was applied in trains of approximately 500 pulses each. Using amplitude of the field potential population spike as the output measure, first-, second- and third-order kernels were computed.

Significant second-order interactions were found that are consistent with what has been described with the use of twin-pulse stimulations of the perforant path. Specifically, stimulation intervals of 10-30 msec resulted in complete or near-complete suppression of the population spike. This high frequency (30-100 Hz) stimulation-induced inhibition decreased at frequencies less than 30 Hz and was typically non-existent at 20 Hz. Stimu-Stimulation frequencies ranging from less than 20 Hz to typically 3-4 That the transformation of the population spike. This factl-itation was greatest at 10-15 Hz and resulted in an augmentation of spike amplitude of 100-200%. In some experiments facilitation was also seen at 4-5 Hz (i.e., the second-order kernel was bi-modal in the 3-20 Hz range), though the magnitude of the second-orm facilitation are accordingly been defined by the the ary facilitation was considerably less. At frequencies less than 3 Hz, a depression in population spike amplitude was almost always seen. The depression was on the order of 20-30%, and was observed at frequencies ranging from 1.25-3 Hz. Significant third-order interactions were also found. Computation of thirdorder kernels revealed that a given stimulation pulse resulted in a population spike amplitude that could not be accounted for solely in terms of the sum of the first- and second-order inter-actions of the intervals of the two pulses preceding it. For example, within certain frequency ranges, amplitude of the population spike was determined not only by the immediate and preced-ing frequencies of stimulation, but also by the direction of the change in those frequencies (i.e., lower to higher vs. higher to

lower stimulation frequencies). Supported by grants from the McKnight Foundation, NSF (BNS 80-21395) and NIMH (MH 00343).

SINUSOIDAL FLUCTUATIONS IN THE THICKNESS OF RAT DENTATE GYRUS 67.11 AFFERENT LAMINAE. M. A. King, R. L. Keep, B. E. Hunter, D. W. Walker. Department of Neuroscience, University of Florida College of Medicine, and VAMC, Gainesville, FL 32610. The rat dentate gyrus is frequently used as a model system in

investigations of CNS neuroplasticity and toxicity phenomena. Discretely staining bands in sections prepared for Timm's metal to the segregated axon terminal fields of the major afferents to the granule cells. In principle, the width of these bands can be quantified and used in between-subjects designs to assess the ef-fects of various independent variables on the pattern of afferentation. However, protocols for matching tissue sections, deter-mining sampling frequency, and consistently applying the measure-ment technique are often based not on empirical anatomical foundations, but upon assumptions that 1)qualitative, visual section matching accurately selects equivalent regions for comparison, matching accurately selects equivalent regions for comparison, and 2)the stain bands parallel the granule cell body layer. In the course of quantitative experiments to determine the effects of chronic ethanol consumption on dentate reactive synaptogenesis, we found that neither assumption is strictly valid. By comparing the relative distance between 7 discrete intra- and extrahippocampal anatomical features in coronal sections through the brains of 47 adult male Long Evans rats, 2 landmarks were chosen to define a region of the dorsal hippocampal formation with minimum interanimal variability. Between the sections containing the landmarks, 10 equally spaced sections were selected for band width measure-ments. With the aid of a Spatial Data Systems EyeCom II image an-alysis system interfaced to a MINC 11/23 minicomputer, Timm's alysis system interfaced to a MiNC 11/25 minicomputer, item s stain band widths were measured automatically at 10 equally spaced medial-lateral positions, for each blade of the right den-tate gyrus, for each of the 10 sections. Analysis of this 10x10 array of values revealed an unexpected and fascinating pattern in the architecture of the afferent terminal fields: sinusoidal the architecture of the afferent terminal fields: sinusoidal fluctuations in both the M-L and A-P directions contribute to the formation of a series of peaks and troughs in the three dimension-al structure, relative to the granule cell layer. The fluctuation in any one band appears to be independent of the others, although a similar "egg carton" effect is seen for total molecular layer width, and the pattern cannot be attributed to blood vessels, histological artifact, or measurement error. This pattern emphasizes the need to consider carefully the fine structure of the dentate gyrus when planning quantitative methods, and raises im-portant questions about the effects of this organization on dendritic input integration and the mechanisms by which this pattern of afferent targeting and distribution might occur.

THE DISTRIBUTION OF ACETYLCHOLINESTERASE IN THE HIPPOCAMPAL FORMATION OF THE MONKEY. I. Bakst\* and D.G. Amaral, The Salk Institute, La Jolla, CA 92037. As part of an ongoing series of studies of the structure and connections of the monkey hippocampal formation, we have stained serial coronal sections through the brains of six macaque monkeys for the demonstration of the enzyme acetylcholinesterase. The tissue was fixed either by 4% paraformaldehyde or by a mixture of paraformaldehyde and glutaraldehyde and the staining was carried out according to two yarjants of the Koelle, acetylthicholine method. 67.13 according to two variants of the Koelle, acetylthiocholine method. have found that the pattern of staining differs in a number of respects from that seen in the rat. In the <u>dentate gyrus</u>, there is intense staining of the inner one third of the molecular layer, with much lighter staining in the rest of the molecular layer except for a thin band of moderate in the rest of the molecular layer except for a thin band of moderate staining at its outer edge. In the caudal half of the <u>dentate gyrus</u>, the deeply stained inner one-third of the molecular layer appears to be further stratified; there is a distinctly denser band of staining just superficial to the granule cell layer. The granule cell layer is unstained but the hildr region is intensely stained at rostral levels where there are but the hild region is intensely stained at rostral levels where there are two distinct bands of staining, one, just subjacent to the granular layer, being especially intense. In the <u>regio inferior</u> of the hippocampus the stratum oriens is intensely stained, and some of the staining extends into the pyramidal cell layer; the stratum radiatum and the stratum lacunosum-moleculare are also stained and here the staining shows some degree of stratification. By contrast, the alveus, the pyramidal cell somata and the layer of mossy fibers are unstained. The region of field CA2 is especially heavily stained. The <u>regio</u> superior is lightly but uniformly stained in all layers except the alveus. The only staining in the subiculum is in the molecular layer at about the middle of its rostrocaudal extent. The outer cell dense layer of the <u>presubiculum</u>, is lightly stained and this is separated from the unstained molecular layer by a more heavily-stained band in the superficial rim of the cellular layer. More heavily-stained band in the superficial rim of the cellular layer. All the layers of the <u>parasubiculum</u> show moderate staining but there are distinct, wedge-shaped areas that are devoid of stain at several levels. Layers 2 and 3 of the <u>lateral entorhinal cortex</u> are stained as are layers 2, 4, and 6 of the <u>medial entorhinal cortex</u>. In the lateral half of the <u>medial entorhinal cortex</u> layer 1 is also stained, and there is a tendency for the AChE to accumulate into small, wedge-shaped islands at intervals in layers 1 and 2 of the <u>medial entorhinal cortex</u>, especially at caudal levels. caudal levels

COLCHICINE IS INEFFECTIVE IN DESTROYING DENTATE GRANULE CELLS 67.12

COLLHILINE IS INFFECTIVE IN DESIRVING DENTATE GRANULE CELLS IN RHESUS MONKEYS. L. Ramirez\* and R. Dasheiff (SPON: M. Javid). Division of Neurosurgery and Department of Neurology, University of Wisconsin and VA Hospitals, Madison, WI 53705. Colchicine is a potent neurotoxin to granule cells of the dentate gyrus in rodents (Goldschmidt and Steward, PNAS 77:3047, 1980 [rats]; McMartin and Schedlbauer, J. Neurobiol. 9:453, 1978 [mice]). Intradentate injection of 2.5 µg will occult in collular obspace observable with Nicel strip by the //:304/, 1980 [rats]; MCMartin and Schedibauer, J. Neurobiol 9:453, 1978 [mice]). Intradentate injection of  $\overline{2.5 \ \mu g}$  will result in cellular changes observable with Nissl stain by the first day. Larger doses and longer postinjection intervals will produce local and remote loss of dentate granule cells and destruction of surrounding pyramidal cells. The use of colchicine as a selective neurotoxin was investi-ated in the primate macace mulatta. Adolector Phoeue

destruction of surrounding pyramidal cells. The use of colchicine as a selective neurotoxin was investigated in the primate <u>macaca mulatta</u>. Adolescent Rhesus monkeys, weighing 5 kg (l M, l F) were given general anesthesia and placed in a stereotaxic frame. Drugs were dissolved in distilled water and sterilized by passing them through a 0.2- $\mu$  Millipore filter. The first subject had 50  $\mu$ g of colchicine (5 $\lambda$  over 15 minutes) injected at each of four equidistant sites in the left hippocampus. The right hippocampus received 50  $\mu$ g of DL-N-methylaspartate (NMA) at each site (5 $\lambda$ /15 min). The heart was perfused with formalin/saline 48 hours later and the brain sectioned with a freezing cryostat and stained with cresyl violet. Other than minimal trauma from the injecting needle, there was no evidence of damage from the colchicine. In contrast, the NMA caused local liquifaction necrosis. The second monkey received 2 intrahippocampal and 2 intraventricular right-sided injections of colchicine, 200  $\mu$ g in 20 $\lambda$  over 5 minutes. The contralateral side received distilled water. This subject died 5 days later. Autopsy was unremarkable. Both hippocampi showed no cellular damage except along the needle tract. There was a mild proliferation of polynucleated cells around some blood vessels and the periventricular space on the colchicine side. It is concluded that colchicine does not express the same neurotoxicity towards dentate granule cells in monkeys as it does in rodents.

EFFECTS OF SEPTAL LESIONS AND SYMPATHETIC INGROWTH ON HIPPOCAMPAL AND PINEAL HISTAMINE LEVELS. <u>E. Orr\*, K. Pace\*, J. Howard\* and</u> <u>D. Barke</u>r. Depts. of Anatomy and Physiology, Texas College of Osteopathic Medicine and North Texas State University, 67.14 Fort Worth, TX 76107.

Fort Worth, TX 76107. Lesions of the dorsal pathway to the hippocampus (fimbria, for-nix, cingulum) cause a 50-60% decrease in rat hippocampal histi-dine decarboxylase (HD) activity and histamine (Hm) levels. A similar decrease in hippocampal HD activity occurs after lesions of the medial forebrain bundle and fornix. This suggests that his-taminergic input to the hippocampus from the brainstem is by way of either the postcommissural fornix or the septum. To determine which of these pathways is involved, we lesioned the septal area in rats and measured the change in hippocampal Hm levels. Since the septal ablation induces ingrowth of sympathetic fibers into the hippocampus and enhances sympathetic innervation of pineal, we also investigated the effects of ingrowth and no ingrowth on hippocampal and pineal Hm levels.

the hippocampus and enhances sympathetic innervation of pineal, we also investigated the effects of ingrowth and no ingrowth on hippocampal and pineal Hm levels. Subjects were 30 male hooded rats divided into the following groups: normal, normal+bilateral superior cervical ganglionectomy (Gx), septal lesions (lateral+medial) and septal lesions+Gx. Ab-lations of the septal area were of the size and location necessary for sympathetic ingrowth, and the hippocampus and pineal were dissected for Hm analysis. Hm levels were determined radio-enzymatically with labelled reaction products separated by thin-layer chromatography. Septal lesions did not affect hippocampal Hm levels. The levels (ng/g) were: normal=11.5 and septal=11.4. This suggests that histaminergic neurons reach the hippocampus via the postcommissural route. In both Gx groups, hippocampal Hm increased significantly: normal=57%, septal=43%. This effect may be due to changes in vascular Hm stores. Septal lesions decreased pineal Hm by 38%. However, pineal Hm was increased by Gx: 20% in normals and 42% in septals. We interpret this to mean that the degree of sympathopineal innervation is inversely related to pineal Hm levels. This research was supported by TCOM Faculty Research Grants 20126 (E 0.) and 20100 (D B.) and M00 Grant 81 11.010 (D B.)

TOPOLOGICAL DISCRIMINATION: A BEHAVIORAL PARALLEL TO HIPPOCAMPAL UNIT ACTIVITIES. Lauren K. Gerbrandt<sup>1</sup>, Richard M. Pico\*<sup>1</sup>,<sup>3</sup>, Gwen Ivey<sup>2</sup> and Joel L. Davis<sup>3</sup> 1)Dept. Psychology, Calif, State Univ., Northridge, CA 91324. 2)Dept. Psychobiology, Univ. Calif., Irvine, CA 92717. 3)Aging and Behav. Biol. Res. Lab., VA Med. Ctr, Sepulveda, CA 91343. 67.15 The hippocampus may be essential to the learning of con-figurations between directly perceived and other, pot-entially-perceivable,stimulus elements. In rats trained to discriminate reward locations solely in relation-ship to the topological pattern of four widely-separat-ed extra-maze stimuli, hippocampal single-unit activi-ties are readily observed that are unaffected by the deany single stimulus from the topological letion of cue letion of any single stimulus from the topological cue set; furthermore, the presence of any two stimuli from the original cue set is usually sufficient to activate these units (O'Keefe & Conway, 1978). The objective of the following study is to determine whether similar, stimulus-independent, topological-cue effects can be observed at the behavioral level, using a stimulus-deletion methodology parallel to that used in these unit studies The objective of unit studies. In the first phase of this experiment, sham-lesioned

In the first phase of this experiment, sham-lesioned (S) and fimbria-fornix lesioned (FF) rats were trained extensively to discriminate 4 constantly-rewarded loca-tions among 8 radial-maze arms. Reward locations were based solely on position in relationship to a constant extra-maze pattern of 4 stimulus elements (2 auditory, 2 visual). The radial maze was rotated in relationship to the topological-cue set after each of 8 daily choices; the cue set was rotated each day in relation-ship to the room environment. In the final of two 15-day blocks of trials testing the effectiveness of this pretraining, both S and FF groups performed vir-tually alike at better than 85% correct choices(rela-tive to chance). The effects of stimulus deletions (1,2,or 3 deletions)

tive to chance). The effects of stimulus deletions (1,2,or 3 deletions) from the 4-cue set were then studied. Sham-lesioned rats were not affected by deletions of any 2 stimuli (leaving only a 2-cue set); fimbia-fornix lesioned rats fell to 48% correct choices using a 3-cue set and to chance levels with a 2-cue set. Sham-lesioned rats were suddenly unable to perform above chance using a 1-cue set. It is suggested that the capacity to behave in relationship to topological-cue sets is closely derived from the topological information provided by hippocamfrom the topological information provided by hippocam-pal pyramidal cells.

EXCITATORY PROJECTION OF THE RAT SUBICULAR COMPLEX TO CINGULATE CORTEX AND SYNAPTIC INTEGRATION WITH THALAMIC AFFERENTS. <u>David M. Finch, Edie L. Derian\* and Thomas L. Babb.</u> Reed Neurological Research Center and Brain Research Institute, University of California, Los Angeles, CA 67.17 90024

90024. Retrograde and anterograde tracing studies in rat using horseradish peroxidase-wheat germ agglutinin showed a projection from the subicular complex to layer II-III of the posterior cingulate cortex that rivaled afferents from the anterior thalamic group of nuclei (see also Meibach and Siegel, <u>Exp. Neurol.</u>, 47 (1977) 264-274). Laminar analysis of field potentials showed that subicular stimulation evoked a negative-positive wave in layer V of the posterior cingulate cortex and a purely negative wave in layers I and II-III. If these potentials reflected active synaptic currents, then they indicate an excitatory-inhibitory sequence of activation in layer V cells and a source of synaptic excitation in or near layer II-III, where the subicular afferents terminate. the subicular afferents terminate.

Intracellular recordings (with action potential amplitudes of greater than 40 mV) and "quasi-intracellular" recordings (with action potential amplitudes between 20 and 40 mV) from layer V cingulate neurons showed that electrical stimulation of the presubiculum or postsubiculum evoked EPSPs and action These were followed by shallow IPSPs lasting 20-200 potentials. These were followed by shallow IPSPs lasting 20-200 msec. Frequency potentiation of the EPSPs was demonstrated in one case. The responsive cells had spikes and spontaneous discharge patterns that were similar in several respects to pyramidal cells of the hippocampal formation. Intracellular injection of HRP showed that the responsive cells were layer V pyramids. One cell with physiological properties thought to be associated with inhibitory interneurons was recorded in layer V. Stimulation of the nucleus lateralis and nucleus anterior ventralis of the thalamus also evoked EPSPs and action potentials in layer V cingulate neurons. In one cell it was possible to show that EPSPs evoked by thalamic stimulation and by subicular stimulation summed. potentials.

by subjicular stimulation summed. Taken together with other published reports, these results indicate that subicular and thalamic afferents make excitatory synaptic contact onto different regions of the apical dendrites of the same layer V cingulate pyramids; that spatial summation integrates the input from these two sources; and that recurrent inhibition from local interneurons limits the duration of this excitatory influence. Supported by NIH Grant NS 16721.

ARCHITECTONICS AND CONNECTIONS OF THE POSTERIOR PARAHIPPOCAMPAL 67.16 GYRUS IN THE RHESUS MONKEY, <u>D. L. Rosene and D. N. Pandya</u>. Dept. of Anatomy, Boston University School of Medicine, Boston, MA and Bedford Veterans Administration Medical Center, Bedford, MA.

The posterior parahippocampal gyrus (PPG) in the monkey begins The posterior parahippocampal gyrus (PPG) in the monkey begins caudal to the rhinal sulcus, is bounded laterally by the occipi-totemporal sulcus (OTS) and continues posteriorly as far as the rostral lip of the calcarine sulcus. In sharp contrast to the allo- and periallocortical characteristics of the anterior para-hippocampal gyrus, the PPG is mainly composed of proisocortex and neccortex, areas designated as TH and TF by Bonin and Bailey. A reassessment of the cytoarchitectonics of the PPG has identified reassessment of the cytoarchitectonics of the Fro has identified a more complex series of distinct cytoarchitectonic subdivisions. In the rostral part of the PPG, the presubiculum is bounded laterally by area TH, a proisocortex characterized by its lack of a granular layer IV, the heavy accumulation of pyramids in an undifferentiated layer V-VI and a homogeneous layer II-III. Area TH merges laterally with a second proisocortical area that we have designated area TL. This area is similar to TH except for the emergence of an incipient layer IV and the differentiation of layers II and III. Lateral to area TL, area TF occupies both banks of the OTS and has characteristics typical of neocortex including a well-developed layer IV and the clear differentiation of layers V and VI. In the caudal part of the PPG, area TH is replaced by area prostriata, an agranular proisocortex that con-tinues posteriorly into the depths of the calcarine sulcus. Are Area TL is replaced posteriorly by a region that we have designated area TLO since it has features that are intermediate between those of area TL and the caudally adjacent area OA (19).

Injections of radioactively labeled amino acids were placed into the PPG in order to investigate the efferent projections of these different areas. Our initial analysis has identified a number of features of these connections. First, areas TH, TL and TF each send efferents to the entorhinal and presubicular cortices but each projection terminates in a distinct subdivision with a unique laminar pattern. Second, areas TH and TL have strong reciprocal connections while area TF has only limited connections with area TL. Third, areas TH, TL, TLO and TF all project caudally to the ventral peristriate visual cortex and terminate in layer I of area OA and in clusters in area pro-striata. Finally, the long corticocortical connections to the association areas of the superior temporal sulcus arise through-out all four areas but those to the association cortex of the posterior parietal lobe and the orbital and lateral prefrontal cortex as well as to the cingulate gyrus originate from only the most rostral parts of areas TH, TL and TF. (Supported by NIH grants NS-19416 and NS-16841)

- 67.18 ELECTROPHYSIOLOGICAL CHARACTERISTICS OF AMYGDALOID CENTRAL NUCLEUS NEURONS IN THE AWAKE RABBIT. J.P.Pascoe\* & B.S.Kapp (SPON: D.Lor-enz). Dept. of Psychology, Univ. of Vermont, Burlington, VT 05405.

Recent investigations have indicated that the amygdaloid cen-tral nucleus (ACE) and its efferent projections to the brainstem may provide an important anatomical substrate for the mediation of forebrain contributions to cardiovascular/autonomic regulation, particularly during emotional states (Kapp et al., <u>Brain Res.</u>, 234 1982; Schwaber et al., <u>J. Neurosci.</u>, 2, 1982). Lacking, however, has been comprehensive data concerning the electrophysiological characteristics of ACE neurons. The present experiments were therefore performed in order to characterize the spontaneous ac-

Therefore performed in order to characterize the spontaneous ac-tivity and sensory-evoked responses of ACE neurons in the awake, restrained New Zealand rabbit, with particular attention given to those ACE neurons which project to the brainstem. Extracellular single-unit recordings were obtained from 59 histologically verified ACE neurons. Brainstem projection neurons were antidromically identified by stimulating ACE descending fibers coursing through the mesencephalon. The cardiovascular offorth of a timulation and the course were were under used to accurate effects of stimulation applied during surgery were used to assure accurate placement of the stimulating electrode in this pathway.

Twenty-four ACE neurons satisfied the usual criteria for antidromic activation, and exhibited a mean antidromic response latency of 9.2  $\pm$  3.5 ms. These neurons exhibited infrequent (n=16, 0.4  $\pm$  0.6 Hz) or virtually no (n=8, < 0.01 Hz) spontaneous activity and were unresponsive to the presentation of simple visual, acoustic and somatic stimuli.

Additional ACE neurons did not meet the criteria for antidromic activation and conformed to one of five profiles: (a) Neurons exabiliting spontaneous activity and sensory characteristics comparable to antidromically activated neurons (n=18), (b) neurons exhibiting infrequent spontaneous activity (0.8  $\pm$  0.8 Hz) and latent hibiting infrequent spontaneous activity (0.8  $\pm$  0.8 Hz) and latent (200-250 ms) excitatory responses to the presentation of all sensory stimuli (n=4), (c) spontaneously active (15.2  $\pm$  6.5 Hz) neurons exhibiting a comparatively rapid onset (50-60 ms) excitatory response to the presentation of all sensory stimuli (n=4), (d) spontaneously active (21.3  $\pm$  6.8 Hz) neurons that were unresponsive to sensory stimuli (n=3), and (e) neurons exhibiting spontaneous thythmical bursting activity (n=6); further analysis of three even presentation for a stimular extension of the sensor stimuli (n=2). such neurons revealed that their spontaneous activity was entrain-ed with the inspiratory phase of the respiratory cycle. Neurons exhibiting modality-specific or inhibitory responses to the presentation of sensory stimuli were not observed.

These data indicate the heterogeneous nature of ACE neuronal activity and provide a basis for evaluating the effects of experi-mental manipulations upon neuronal activity within this nucleus. (Supported by Institutional grant PHS 07125-99.)

67.19

A DIRECT PROJECTION FROM THE BASOLATERAL NUCLEUS OF THE AMYGDALA

TO THE MOTOR AND SENSORY CORTICES IN THE RAT. K. Sripanidkulchai and J. M. Wyss, Dept. of Anatomy, Univ. of Alabama in Birmingham, Birmingham, AL 35294. The amygdala not only plays an important role in the processing of information within closely related limbic structures, but als participates more directly in sensory and motor system function. Several studies have demonstrated that direct ascending projections of this subcortical region, are directed at the ventral basal complex of the thalamus as well as the midline cortex and the lateral cortex immediately dorsal to the rhinal fissure. Projections from these cortical areas could provide a route for the Probasolateral nucleus to participate in these functions. Our present results, however, demonstrate that in addition to these indi-rect projections, a significant direct projection also exists. Injections of the retrograde fluorescent marker fast blue (50-100 nl of 4% in H<sub>2</sub>0; 20 animals) or of horseradish peroxidase (10% in In of 4% in H<sub>2</sub>O; 20 animals) or of horseradish peroxidase (10% in H<sub>2</sub>O; 5 animals) were made into the lateral motor and sensory neo-cortex of adult, male, albino rats, via a 0.5 or 1.0µl Hamilton syringe. Following a 1-4 day survival, the animals were sarri-ficed by transcardial perfusion with saline and the appropriate fixatives. The brains were removed, sectioned at 25µm and a 1 in in the case of HRP injections). The basolateral nucleus was easily identified in adjacent Nissl and AChE stained sections. Cortical regions were identified on the basis of cytoarchitecton-ics, selective thalamus labeling and in the case of the motor cortex, backfilling of the layer five corticospinal neurons by injections of nuclear yellow into the lateral spinal cord at lower cervical levels. The results clearly demonstrate a large number of neurons within the basolateral nucleus are labeled by the injections into either the motor cortex or somatosensory cortex. These neurons were typically scattered throughout this nucleus but cells outside of the nucleus, in other divisions of the amygdala were not labeled. Injections into the lateral cortex immediately dorsal to the rhinal fissure also resulted in a similar labeling pattern in the basolateral nucleus; however, midline cortex injections did not result in extensive labeling in the amygdala. terior cingulate cortex injections resulted in no labeling of Poscells in the basolateral nucleus, whereas anterior cingulate cortex injections resulted in creasy, whereas anterior tingulate Cor-tex injections resulted in consistant labeling of only a few neurons in this region. The direct projection of the basolateral nucleus to primary motor cortex is quite intriguing in light of our recent demonstration that the lateral entorhinal cortex pro-jects to this nucleus. Thus this nucleus may provide a rather direct route for hippocampal modulation of motor output. Supported by N.I.H. Grant NS 16592.

67.20 PROJECTIONS FROM THE AMYGDALOID COMPLEX TO MAGNOCELLULAR NUCLEI OF THE BASAL FOREBRAIN IN THE MONKEY (MACACA FASCICULARIS). F.T. Russchen\*, D.G. Amaral and J.L. Price. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110; The

Salk Institute, LaJolla, CA. Anterograde tracing experiments in which <sup>3</sup>H-amino acids were injected into the various nuclei of the amygdaloid complex indi-cate that virtually the whole extent of this complex gives rise to fibers which reach the nucleus basalis and other magnocellular nuclei of the basal forebrain. Different amygdaloid nuclei project most heavily to different portions of this area. The most extensive projections originate in the basal, accessory and central amygdaloid nuclei. basal

To determine more precisely which nuclei of the amygdaloid complex give rise to these fibers, injections of WGA-HRP were placed in several locations in the magnocellular basal forebrain. Retrogradely labeled neurons were present throughout the amyqdala, but in all cases the highest density of labeled cells was found in the parvicellular part of the basal nucleus, the magnocellular part of the accessory basal nucleus, and adjacent parts of the cortical nuclei and periamygdaloid cortex. Substannucleus and in the medial part of the lateral nucleus. Few retrogradely labeled cells were also found in the central nucleus and in the medial part of the lateral nucleus. Few retrogradely labeled cells could be detected in the magnocellu-lar part of the basal nucleus, the parvicellular part of the accessory basal nucleus, and the medial nucleus. Surrounding the amygdaloid complex there were high densities of labeled cells in deep layers of the entorhinal and perirhinal cortices. It the could also be determined from these experiments that the pattern of anterograde axonal labeling in the amygdaloid complex largely coincides with the distribution pattern of fibers staining for

AChE activity. The heaviest labeling is in the basal nucleus. In an attempt to investigate more closely the appearance of In an attempt to investigate more closely the appearance of amygdaloid fibers reaching the magnocellular basal forebrain, injections of the lectin PHA-L were placed in the amygdaloid complex of rats and monkeys. In these brains anterogradely labeled fibers, identified immunohistochemically, were found among the large cells of the basal forebrain. These fibers showed varicosities along their length which resemble synaptic boutone. This success the although these fibers may also proboutons. This suggests that although these fibers may also pro-ject to other terminal fields, along their course they interact with neurons in the magnocellular basal forebrain.

67 21 THE AMYGDALA: A CONTRIBUTION TO REGULATION OF AGGRESSIVE BEHAVIOR

THE AMYGDALA: A CONTRIBUTION TO REGULATION OF AGGRESSIVE BEHAVIOR IN DIFFERENT STATES OF CONSCIOUSNESS J. Zagrodzka\*, <u>C.E.Washington\*, A.R. Morrison.</u> Nencki Instituite of Experimental Biology, Warsaw, Poland and School of Veterinary Medicine, University of Pennsylvania, USA. Small, bilateral pontine tegmental lesions induce paradoxical sleep (PS) without atonia in cats. (Hendricks <u>et al.</u>'83). Instead of the usual paralysis in PS cats can right themselves, stand and walk. Lesions that unilaterally involved the fibers descending from the central nucleus of the amygdala (CA) to the lateral from the central nucleus of the amygdala (CA) to the lateral pons (Hopkins & Holstege, '78) led to aggressive displays during PS. Earlier, Wood('58) had found that lesions in CA evoked aggressiveness in cats. We examined whether removal of a modulatory influence from CA might be responsible for attack behavior during PS without atonia. 12 cats received combined amygdala-pontine or pontine-amygdala lesions, and their sleep and social behavior, i.e. interactions with a conspecific, an experimenter and predation on mice were observed and videotaped. Usually sleep behavior was monitored electrographically. None of 7 lesions placed bilaterally in CA, in the basal nucleus or outside the amygdala produced any changes in aggressive behavior. Lesions confined strictly to the unilateral CA released aggressive behavior toward other cats and increased irritability on handling approximately 3 days postoperatively for a period of 2-3 weeks while pontine lesion alone produced attack behavior 2-4 weeks after surgery. No changes in predation were observed. Amygdala lesions alone did not alter PS. Pontine lesions added to those in CA at least a month later released aggressive behavior during PS without atonia that would not have been released after such pontine lesions alone. Moreover, the attack behavior, especially biting, in PS after combined lesions was more especially biting, in PS after combined lesions was more pronounced and vigorous than after pontine lesion alone. In 2 cases with pontine lesions first, which produced non-aggresssive PS without atonia, CA lesions added later evoked attack behavior and biting during PS. These data indicate that unilateral lesion of CA releases aggressive behavior and that such lesions potentiate the pontine lesion effect. We suggest that besides the system inducing atonia of PS, pontine lesions also damage a system normally modulating aggressive behavior. One source of fibers in this system is CA, especially those damaged that result in released biting in PS. Furthermore, this study, employing small, selective lesions adds to those few others that have demonstrated heightened rather than reduced aggression after amvgdala damage.

67.22 EFFECTS OF AMYGDALOID SEIZURES UPON AGGRESSIVE BEHAVIOR IN THE CAT. M.B. Shaikh\*, M. Brutus, H. Edinger and A. Siegel. Dept. of Neurosciences and Dept. of Physiology, University of Medicine and Dentistry of New Jersey, NJ Medical School, Newark, NJ 07103. That the amygdala plays a central role in the control of ag-gressive behaviors has been well documented in the literature. Perhaps the clearest demonstration of amygdaloid involvement in hypothalamically elicited aggressive behavior was provided by Egger and Flynn (1963). In a recent analysis, Block et al. (1980), demonstrated that lateral and central amygdaloid nuclei facilitate attack behavior upon electrical stimulation while stimulation of basal, cortical and anterior amygdaloid nuclei suppressed this response.

The purpose of the present study was to examine the effects of amygdaloid seizures upon two forms of aggressive behavior elici-ted from the hypothalamus in the cat--quiet biting attack and affective defense. Electrodes for stimulation and recording were stereotaxically implanted into the medial and lateral aspects of hypothalamus and amygdala. Initially, threshold values for each form of attack elicited by hypothalamic stimulation were deter-mined over a period of 5-14 days. Then, sites in the amygdala were selected which significantly modulated at least one form of aggression. The experimental paradium included alterate trials aggression. The experimental paradigm included alternate trials in which seizures were elicited from amygdaloid modulating sites In which seizures were elicited from amygdaloid modulating sites and were followed by a determination of the behavioral threshold. Our results have suggested that the induction of amygdaloid sei-zures can systematically modify attack thresholds. Concerning affective defense behavior, amygdaloid seizures generated from sites which facilitated this response were followed by a reduction in the behavioral threshold while an elevation in threshold occurred when seizures were generated from sites in the amygdala which supressed this mercence. In contrast an opposing apteen which suppressed this response. In contrast, an opposing pattern Which Suppressed this response. In contrast, an opposing pattern was observed for quiet biting attack. Seizures generated from sites which suppressed quiet attack were followed by a lowering of threshold for this response, while an increase in quiet attack thresholds followed seizures from electrode sites linked to facilitation of quiet attack behavior.

SPECIFIC INTERACTIONS OF DIFFERENT SENSORY MODALITIES IN THE 68.1 DRAFICOULUS OF THE RAT. <u>S. Ausim Azizi and Donald J. Woodward</u> Dept. Cell Biology, Univ. of Texas Health Science Center at Dallas, TX 75235

Previous anatomical and electrophysiological studies from this laboratory have demonstrated the existence of visual and auditory cortical inputs to the paraflocculus of the cerebellum.

It was also shown that natural visual and auditory stimuli converge upon single Purkinje cells in the paraflocculus. In this report we describe data indicating that the convergence and subsequent facilitation of spike activity of the parafloccular neurons by the combined auditory and visual inputs is specific to these two modalities and that these inputs may originate

to these two modalities and that these inputs may originate mainly in the sensory association cortices. Recordings were made from the parafloccular neurons of unanesthetized immobilized rats. Visual, auditory and somatosensory stimuli were presented with the use of a computer based system. Retrograde transport of horseradish peroxidase (HRP) and nuclear yellow was used to identify corticopontine projection neurons. These stimuli were moving light bars at specific orientations in the visual field, pure tones (sinusoidal waves 200 Hz to 20 kHz, 65 - 80 db intensity) and light electrical shocks to the forenaw. light electrical shocks to the forepaw.

Single unit recordings from 32 Purkinje cells and other neuronal elements showed evidence, through histogram analysis, for excitatory and/or inhibitory mossy fiber and climbing fiber inputs following either auditory or visual stimuli but not to electrical shocks to the paw. Some units (15) showed evidence of facilitation when combined auditory and visual stimuli were presented to the animal at the same time. No alteration in activity was observed when either or both of these stimuli were paired with the electrical shock to the paw, indicating that the facilitation observed is modality specific, dependent on correct timing, and not due to a general arousal.

Hydraulic injections of HRP or nuclear yellow into the basilar pons resulted in retrograde labeling of neurons predominantly located in the regions just surrounding the primary receiving areas of the visual, auditory and somatosensory cortices. The delineation of these regions was aided by computer imaging of cell distributions.

These data indicate that specific interactions of inputs from visual and auditory modalities occur in the cerebellum and that this information may originate in the "association cortices". (Supported by NIAAA grant 3901, DA 02338 and the Biological Humanics Foundation.

68.2 THE CEREBELLAR AUDITORY AREA IN THE CAT. Chi-ming Huang and Kuo-long Liu .Departments of Physiology and Anatomy, University of South Alabama, Mobile, Chi-ming AL 36688.

We studied the topographic distribution of We studied the topographic distribution of auditory responses in the posterior cerebellum of the cat in order to determine the extent of the cerebellar auditory area and whether it contains subdivisions. Electrophysiological recordings were made from the surface of the cerebellar cortex with silver ball electrodes and in cortical penetrations with glass-coated tungsten microelectrodes. Auditory evoked potentials were present over the posterior vermis including lobules VI and VII of Larsell, but not over the paramedian lobules or the cerebellar hemispheres. Recordings tungsten microelectrodes during p from the penetrations through the cerebellar cortex. Suggested that these auditory evoked potentials were generated locally from the cerebellar cortex. There was substantial from the cerebellar cortex. There was substantial variations across individual animals on the topographic distribution of auditory evoked potentials over the cerebellar surface. Positive evoked potentials were usually found in lobule VI whereas negative evoked potentials were found more posteriorly in lobule VI1. Peak latencies for both the positive and negative evoked potentials were between 7.7 and 17.7 msec. Within the cerebellar auditory area, the amplitudes of evoked potentials from adjacent cortical points 1 mm apart could from adjacent cortical points 1 mm apart could differ significantly, suggesting that there may be a microscopic organization within an area of the order of a fraction of a millimeter. We conclude that the cerebellar auditory area in the cat is located entirely within the posterior vermis. It may contain two subdivisions, each characterized by a different polarity of evoked potentials. Within each subdivision, there may be a pattern of patchy organization in which auditory impulses interact organization in which auditory impulses interact with impulses from other modalities. We also have evidence from single cell recordings and from HRP tracing studies, both of which support the above hypothesis on the pattern of subdivision and micro-organization within the cerebellar auditory area. (This work was in part supported by a grant from the US Public Health Service NS 16935 which we gratefully acknowledge.)

68.3 RED NUCLEUS ACTIVITY RELATED TO FINGER MOVEMENTS, P.R. Kenned A.R. <u>Gibson</u> and J.C. <u>Houk</u>. Dept Physiol, Northwestern Univ Med Sch, Chicago, II 60611. Magnocellular red nucleus (RNm) neurons were recently shown to

discharge in burst sthat precede hand movements (Kohlerman N.J., <u>Science, 217</u>:857, 1982). Here we sought to determine if these neurons are also related to individual finger movements. A monkey was rewarded for pressing microswitches mounted on a "piano" device and acquiring visual targets. Single RNm neurons were recorded extracellularly while the monkey performed this task. For 53 RNm neurons sampled during piano performance, the average response rate was 85 pulses per second (pps) while closing thumb switch, 71 index, 61 middle, and 60 ring. Mean spontaneous rate in between switch operations was 30 pps. All 53 neurons had response rates 2 to 5 times their spontaneous rates. Neurons responded differently on individual switches: 31 were were

highest on thumb, 7 on index, 2 on middle and 4 on ring. For 30 neurons, discharge during piano performance was compared with activity on a push-pull device requiring movement of the whole arm. Average firing rates were higher on the piano for 24 neurons and higher on the push-pull for 6 neurons. All of for 24 neurons and higher on the pash-pull for 6 neurons. All of the latter showed modulations on the piano that were lower by no more than 25%. Conversely, of the 24 higher rate piano neurons, only 6 showed rates on the push-pull that were within 25%. EMG analysis of 7 forelimb muscles (deltoid, latissimus, pectoralis, biceps, triceps, and long finger flexors and extensors) during Diceps, triceps, and long finger flexors and extensors) during performance on the piano showed phasic activity in distal muscles only (he rested his elbow on a cushion). Prominent phasic activity was seen in the 5 proximal muscles during push-pull operation; lesser activity was also seen in distal muscles since the animal was required to grasp the handle. Thus, RMm activity on the piano was unlikely to have resulted from proximal muscle involvement whereas activity on the push-pull arm device could have involved distal movements. RNm activity, therefore,

appeared to be related to finger movements. Photodiode sensors were placed on the monkey's digits to measure their velocity, duration and timing during piano operation. Activity in 9 of 19 neurons showed statistically significant rate/velocity AND duration correlations to movements of a single digit. The average lead time of firing onset to movement onset was 90+26 ms for correlated neurons. There were no lag times. Recording sites were recovered postmortem based on lesions and electrode tracks. 89% of all sites were within, and 11% near, the magnocellular region as defined by retrograde labeling from the spinal cord in 2 control monkeys. The results labeling from the spinal cord in 2 control monkeys. The results indicate that most RNM neurons are related to distal movements and poorly related to proximal movements. Some neurons correlate with velocities and durations of single digit movements.

FUNCTIONAL CEREBELLAR METABOLISM DURING FORELIMB MOVEMENT IN THE 684 T. Der, E.M. Santori\* and R.C. Collins, Dept. Neurology, Washington University, St. Louis, MO 63110. The functional anatomy for forelimb movement in the cerebellum

is not well known. To study this problem we have used electrical

Is not well known. To study this problem we have used electrical stimulation of wrist extensor muscles in rat combined with quan-titative deoxyglucose autoradiography. Male albino rats (300-380 gms) were fasted overnight. Under halothane anesthesia, catheters were inserted into femoral vein and artery. Two 003 gauge insulated wires with exposed ends were inserted into the loft forgligh. The negative pole was hooked inserted into the left forelimb. The negative pole was hooked into wrist extensor muscles at the elbow through a small incision in the skin. The positive pole was inserted into the dorsum of the paw. Animals were restrained on a lead brick and allowed to the paw. Animals were restrained on a lead brick and allowed to recover from the anesthesia for greater than 2 hours. Bipolar pulse stimuli (0.1 msec., 5-10 Hz. 12-25 volts) were used to cause a consistent dorsiflexion of the forelimb. The rate of stimulation was varied from 2 pulses per second (pps) to 10 pps in order to determine a dose-response relationship for the metabolic responses. Quantitative regional glucose utilization was determined by the method of Sokoloff et al. (1977).

Repetitive electrical stimulation of left wrist extensors produced increases in glucose utilization in afferent pathways to the cerebellum. At ten pps there was an increase in the medial the tereberrum. At ten pps there was an increase in the medial aspect of lamina III and IV of the dorsal horn (2.24 times con-trol) but no change in the ventral grey. There were increases in ipsilateral cuneate nucleus (1.39 x control) and contralateral inferior olive (1.54 times control).

Metabolic changes occurred bilaterally in the cerebellar hemispheres in the paramedian lobule, posteriorly, and in lobules five and simplex, anteriorly. Within these lobules the greatest metabolic response occurred in the granule cell layer with less response in the molecular layer. The metabolic activity in the granule cell layer of the paramedian lobule was 1.78 x control ipsilaterally and 1.55 x control contralaterally. Anteriorly, in lobule 5 it was 2.15 x control ipsilaterally and 1.38 x control contralaterally. Metabolic activity in simplex lobule was 2.08 x control ipsilaterally and 1.49 x control contralaterally. Glucose utilization in the deep cerebellar nuclei was unchanged by the stimulation.

Five pps produced approximately the same pattern of metabolic changes as described above. These changes were smaller in magni-tude compared to the ten pps. With two pps no change in glucose utilization was detected. These results indicate that graded electrical stimulation of forelimb muscle groups can be used to map functional activity in cerebellum. The specific role of muscle afferents, joint receptors and cutaneous sensation in pro-ducing this pattern remains to be determined. ducing this pattern remains to be determined.

- TOPOLOGICAL FEATURES OF CLIMBING FIBER INPUT IN THE ROSTRAL ANTERIOR LOBE OF THE CEREBELLUM OF THE CAT. L.T. Robertson and K. Logan\*. Neurological Sci. Inst., Portland, OR 97209. 68.5 Robertson and
  - K. Logan\*. Neurological Sci. Inst., Portland, UK 97209. Anatomical and physiological studies have demonstrated the climbing fiber (CF) projection to the cerebellar cortex is organized in a series of parasagittal strips. Previous work in this laboratory has shown the CF parasagittal organization can be further subdivided into a series of elongated patches, each of which cortain a verse paragraphic time of the hold workford. of which contain a unique representation of the body surface. The goal of this study was to describe the CF topology in rostral anterior lobe using techniques similar to our previous work

Data were obtained from 36 cats that were anesthetized with Na-pentobarbital. Systematic exploration was made of both the vermal and intermediate zones of lobules III, IV, and Va, using a 300 µm distance between electrode penetrations. Single Purkinje cells were recorded extracellularly and an attempt was made to elicit a CF response by manual tapping or manipulation

Purkinje cells were recorded extracellularly and an attempt was made to elicit a CF response by manual tapping or manipulation of body surfaces or by a computer-controlled punctate stimulus. On the basis of force thresholds the units were classified as cutaneous, kinesthetic or nonresponsive. Receptive fields were delineated at the lowest threshold of stimulation. CF responses were identified in 1375 Purkinje cells, of which 699 were located in the vermal zone and 677 were in the intermediate zone. In the vermal zone the majority of CF responses were classified as cutaneous (52%) versus kinesthetic (20%) or nonresponsive (28%), whereas in the intermediate zone most were kinesthetic (44%) rather than cutaneous (32%) or nonresponsive (24%). The cutaneous input was represented mainly in lobules IV and Va in vermal zone but was found predominately in lobule III of the intermediate zone. The kinesthetic representation was primarily located in Va in both vermal and intermediate zones. The vermal cortex consisted of a medial zone, which contained CF responses that were either nonresponsive (70%) or related to the tail (26%), and a lateral vermis, where 90% of the receptive fields were of the distal area of the hindpaw. The intermediate cortex displayed a more complex mixture of patches representing the distal and proximal areas of the hindlimb (particularly in lobules III and IV), forepaw (mainly in lobule Va), abdomen, face, and portions of the tail and back. In commarison with the caudal anterior lobe the rostral the tail and back.

In comparison with the caudal anterior lobe, the rostral anterior lobe has a similar: (1) distribution of receptor modality, (2) distinction between the vermal and intermediate zones, and (3) patchy mosaic topography. However, the rostral anterior lobe has a greater representation of the hindlimb with many receptive fields restricted to the distal paw.

INCREASED ACTIVITY OF CEREBELLAR NUCLEAR CELLS DURING THE 68.6 RECIPROCAL INHIBITION AND ANTAGONIST CO-CONTRACTION OF FOREARM MUSCLES IN THE AWAKE MONKEY. Richard Wetts, John F. Kalaska and Allan M. Smith. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

Two mutually exclusive modes of muscular activation are antagonist cocontraction and reciprocal inhibition. Previous work from our laboratory suggested that the cerebellar cortex plays a role in switching between these two patterns of activity. This study was designed to examine the contribution of cerebellar nuclear cells to the control of these two patterns. To produce reciprocal activity in forearm muscles, monkeys were trained to alternately flex and extend the open hand and to hold the wrist against a mechanical stop for 1.5 sec. The same monkeys were also trained to pinch a force transducer between the thumb and forefinger in order to elicit simultaneous co-contraction of agonist and antagonist muscles.

So far, 67 cells have been found which were related to the prehension task. In general, most nuclear cells have a high rate of spontaneous discharge, yet  $65\,$ cells (97%) further increased activity during the task. Most of these cells (29) had a large peak of activity at the onset of co-contraction and had a less pronounced increase during the maintained pinch. Of the 67 cells analyzed, discharge frequency was significantly correlated with the rate of force increase for 9 cells, or with the maintained force level (5 cells) or with both parameters (3 cells). Most noteworthy is the fact that the vast majority of nuclear cells were excited during the co-contraction accompanying prehension, whereas a clear decrease in discharge frequency was seen in only two units. Data from the wrist flexion-extension task are also available for 40 of the 67 cells. Discharge frequency was significantly correlated with velocity of wrist movement (14 cells) or with the torque applied to the stop during the maintained wrist position (8 cells) For most cells (73%) the discharge frequency was significantly different (P < .05) between the isometric flexion and extension. This pattern of activity was not unexpected since most of the Purkinje cells, which are the major inhibitory input to the deep nuclear cells, also displayed a reciprocal discharge pattern during wrist movement. During the prehension task, the majority of Purkinje cells decreased activity, and so it was expected that most of the nuclear cells would be disinhibited. However, the number of nuclear cells which increased discharge frequency (97%) was surprisingly large in view of the fact that about 37% of the responding Purkinje cells increased their activity during the task. Whatever the explanation for the powerful excitation of nuclear cells during cocontraction may be, this study adds further evidence that the cerebellum plays an important role in the reciprocal versus co-active control of muscles This research was supported by the Medical Research Council of Canada

68.7 RESPONSE OF CEREBELLAR CORTICAL UNITS TO MUSCLE STRETCH AND SPINAL CORD STIMULATION. Daniel Bourbonnais\*, Charles Krieger\*, Centre de recherche en sciences neurologiques, Smith. Allan M. Université de Montréal, Montréal, Québec, Canada. The effect of stretching the tibialis anterior and gastro-

The effect of stretching the tibraits anterior and gasto-cnemius muscles on the activity of cerebellar cortical neurones of lobules II to V was evaluated in chloralose anesthetized cats (50 mg/kg, i.v.). A ramp stretch of 4 mm at a velocity of 40 mm/s was applied to these muscles separately or simultaneous ly. Simultaneous stretch of antagonist muscles is unphysiological but was used to reflect the symmetrical pattern of muscle afferent activity during co-contraction of antagonist muscles. The firing frequencies of 94 of the 204 cerebellar units were increased or decreased by muscle stretch. Twenty-one Purkinje cells, identified by their complex spikes, responded only to the dynamic component of muscle stretch. Only three Purkinje cells which had shown a modulation of activity to muscle stretch were examined with electrical stimulation of the dorsolateral funi-culus in the upper thoracic spinal cord. One of these Purkinje cells showed a long latency (20 ms) increase in the simple spike activity and another responded with a single complex spike. The remaining Purkinje cell showed no response to spinal stimulat-ion. The activity of 44 unidentified units also had dynamic and maintained stretch. The response of 15 unidentified units was tested with spinal cord stimulation. Two units responded units cal but was used to reflect the symmetrical pattern of muscle was tested with spinal cord stimulation. Two units responded to single pulses with variable latencies suggesting a synaptic activation by the spinal stimulation. In contrast eight units responded at fixed latencies and followed without failure double pulses delivered at frequencies exceeding 300 Hz. The latencies ranged from 1.6 to 3.5 which correspond to conduction velocities of about 30 to 75 m/s. It would appear that these units can be identified as action potentials recorded from mossy fiber spino-cerebellar afferents. In addition, the majority of these units (7/8) had a dynamic and static response to muscle stretch.

These results indicate that although spinocerebellar afferents convey information about muscle length, the Purkinje cell discharge does not reflect this parameter. It may be that this information is filtered within the glomerular complex or at the level of the Purkinje cell itself. These results are nevertheless consistent with the view that Purkinje cells integrate inputs from different sources and that a specific muscle stretch is not sufficient to obtain a sustained discharge of Purkinje cells.

COMPARISON OF RESPONSE PROPERTIES OF DSCT AND VSCT NEURONS TO THE SAME PHYSIOLOGICAL HIMDPAW STIMULI. J.H. Kim, T.J. Ebner and J.R. Bloedel. Depts. of Neurosurgery and Physiology, Univ. of Minnesota, Mpls., MN 55455. The dorsal spinocerebellar tract (DSCT) and ventral spino-

systems projecting directly to the cerebellum from the lumbar spinal cord. Despite apparent differences in their physiological and anatomical properties, both tracts respond to a similar spec-trum of peripheral inputs. The purpose of this study was to de-termine differences and similarities in the way DSCT and VSCT neurons process the same physiologic cutaneous stimuli applied to the hind footpads. In cats anesthetized with alpha-chloralose to the hind tootpads. In cats anesthetized with alpha-chioralose (60 mg/Kg, IP), DSCT neurons were identified by their antidromic activation from the ipsilateral inferior peduncle. In another group of cats VSCT neurons were identified antidromically by stimulating in the contralateral superior peduncle. Only neurons responding to exteroceptive stimuli with their receptive field on responding to exteroceptive stimuli with their receptive field on the ipsilateral hind footpad were studied. The stimulus probe consisted of a flat surface contacting the entire plantar surface of the foot. Three different wave forms were used: (1) a step displacement of varying amplitudes (0.2-3.0 mm), (2) constant amplitude ramp displacements of different slopes (5-60 mm/sec), (3) constant amplitude sinusoidal displacement of varying fre-quencies (1-20 Hz). Interestingly, responses of DSCT and VSCT neurons were remarkably different to sinusoidal inputs. DSCT cells were extensively modulated by sinusoidal stimuli in the frequency range of 1-20 Hz. VSCT neurons were only weakly mod-ulated over the same frequency range. A comparison of the refrequency range of 1-20 Hz. VSCT neurons were only weakly mod-ulated over the same frequency range. A comparison of the re-sponses of VSCT and DSCT neurons to step inputs revealed system-atic differences in their sensitivity to this type of stimulus. The amplitude of the phasic discharge of VSCT neurons at the on-set of the step increased with increasing step amplitude, whereas the phasic component of the DSCT neurons' response saturated at relatively low amplitudes. The response characteristics of these two groups of cerebellar afferents to the ramp stimuli were also different. VSCT neurons responded with a phasic peak at a short latency after the beginning of the ramp with little activity in the late phase. In contrast the discharge of most DSCT neurons was increased throughout the ramp, although some showed a phasic response at ramp onset. This increase in discharge was either re-latively constant throughout the duration of the ramp or it conlatively constant throughout the duration of the ramp or it con-tinued to increase proportionally to the ramp amplitude. These data show that although VSCI and DSCT respond to the same cutan-eous stimuli, the characteristics of their modulation by the same input are quite different. CONTROL MODEL APPLIED TO THE CEREBELLUM OF THE SHARK 68.9 Richard S. Babb, Iona College, New Rochelle, N.Y 10801 Stability in the swimming shark is produced by; the

geometry of the shark's body, the inertial guidance provided by the vestibular system, and "critical damping" provided by the vestibulocerebellum. A model system is presented in which the stability of the shark is discussed in terms of levels of control. In order to simplify the problem, stability about the yaw-axis only will be considered.

The classical wind-tunnel studies of Harris (1936) on the shark moving relative to a surrounding fluid, have shown that its static stability is dependent on the shark's geometric form, in particular the configuration of its vertical fins. For small angles of deviation of the body-axis from the swimaxis in the yaw plane, the shark possesses neutral stability, whereas for angles larger than  $10^{\circ}$  a restoring moment about the center of gravity provides static stability. The region of neutral stability allows higher order stability and control to be effective for small angles. Within this window of neutral stability maneuverability and feedback stabilization activity stabilized to the model, the neural basis of feedback would be provided by fibers of the ampula of each horizontal semicircular canal which project to the vestibular nuclear complex, the neurons of which would project via the descending medial longitudinal fascile to the spinal motor neurons. Activity in this three-neuron arc would modify ongoing winning activity in produce superimposed angular moments and hence angular acceleration. These angular accelerations would be such as to counter any external disturbances which have the effect of exciting the horizontal semicircular canals. Such restoring moments produce oscillations which, in a stable system. scorverge on the course setting. Oscillations of a negative feedback system can be "critically damped" by adaptive control. Such control is based on superimposing an adaptive section onto the feedback control system. The adaptive section compares an ideal output with the actual output giving a generalized error which modifies one element of the feedback loop thereby modifying the gain. Intentional and actual movement information is fed to the vestibulocerebellum making it a good candidate for the role of the adaptive section, with its known output to the vestibular nuclear complex, which is part of the feed-

back control system. Knowledge of the function of the vestibulocerebellum of the shark may help in understanding the homologous structure in humans, the nodulus of the cerebellum.

68.PO EXTENSIVE CEREBELLAR REPRESENTATION OF CUTANEOUS TACTILE SENSI-TIVITY IN OPOSSUM (Didelphis virginiana). Wally Welker and Georgia M. Shambes. Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Recent studies of the albino rat revealed extensive cutaneous projections to the granule cell (GC) layer of the cerebellar hemi-spheres and caudal vermis (Shambes, et al, 1978; Joseph, et al, 1978). Adjacent body parts projected a-somatotopically in a mosaic of columnar GC patches (called "fractured somatotopy"). To determine whether similar circuits exist in a marsupial, we explored the GC layer cerebellar cortex of the opossum using microelectrode micromapping and juxtathreshold cutaneous natural stimulation. We used adult opossums of both sexes anesthetized with sodium pentobarbital supplemented with ketamine hydrochloride. Tungsten ball-tip microelectrodes (5-8  $\mu$  tip dia.; impedances of 0.8-1.2 megohms) recorded multiple-unit GC layer

responses evoked by gentle stimulation of the skin. To date we have mapped RF's for 284 active punctures in 7 animals. Results were: (1) Receptive field (RF) maps were obanimals. Results were: (1) Receptive field (RF) maps were ob-tained for nearly all hemispheric folia and three folia of the caudal vermis (2) Submodality of most RF's was light "touch" cutaneous, but muscle, joint and deep RF's were also found. (3) GC projections were organized in patchy, fractured a-somatotopic columnar patterns. (4) Ipsilateral projections predominated Most contralateral punctures were medial in all hemispheric folia. (5) Mechanoreceptors from face, snout, mouth and teeth activated the bulk of the GC loci on crus I and crus II. Projections to the paramedian lobule (PML) came from the entire body. The pyramis received hindlimb projections, the rostral uvula received input from hindlimb and forelimb, and the caudal uvula had pro-jections from the face. (6) The largest patches of projections on form forelimb and finder to the form vibrissae, and on the vermis and PML from forelimb and hindlimb. (7) Adjacent body parts projected to disjunctive GC loci - the overall projections form a patchy mosaic. (8) Individual differences in folial pattern and body representation were apparent.

Except for differences in mosaic pattern and relative size of different projections in rat, gray squirrel and cat (Kassel & Shambes, in preparation), this research suggests that cutaneous inputs to cerebellum are not only functionally important, but that they may exist widely among mammals. Supported by NSF grant BNS 8022321.

In vivo tests of a Multichannel Intracortical Recording Array, <u>D. J. Anderson, S. L. BeMent<sup>\*</sup> and K. D. Wise<sup>\*</sup></u> Dept. of Electrical and Computer Engineering, Univ. of Michigan, Ann Arbor, MI 48109. We are applying techniques for integrated 68.10 to the development of a multichannel array for chronic recording from closely spaced cortical neurons. Previous work (Wise, K.D., et. al., IEEE Trans Biomed Eng, 17, 238-247, 1970) indicated the feasibility of active probe electronics to improve the signal-to-noise ratio of the neuron-recording electronics interface. Methods for the fabrication of multichannel probes had also been developed (Pochay, P., et. al., IEEE Trans. Biomed. Engr., 26, pp 199-206, 1979). The present study is directed toward fabrication of a multiple-recording site microelectrode with on-board interface amplifiers and multiplexer to combine the multi-channel signals into a single output channel to the external electronics. The project can be broken logically into 3 subprojects. 1) Design and fabrication of the microelectronics and off-chip reconstruction electronics, 2) Determination of the relative physical characteristics of various recording materials, 3) In vivo testing to study the ability of the various probe sites and configurations to record well isolated neural activity.

In vivo tests to date have been on single channel siliconsubstrate probes with a shank width of about 75  $\mu$ m and a thickness of about 20  $\mu$ m. The recording sites are tantalum conductors which protrude into an opening in the protective dielectric about 5  $\mu m$ . Successful recordings have been obtained from gerbil cerebellar cortex. We have demonstrated that the probes have the structural strength to penetrate into cerebellum and can isolate single neurons satisfactorily. Work is proceeding to 1) reduce the substrate size 2) improve the electrical characteristics of the recording sites and develop satisfactory methods for the introduction and maintenance of cronic probes in cortex. The amplifier and multiplexer parts of the chip have been fabricated and tested, and design modifications are underway. This work is supported by NIH Contract NINCDS-ND1-NS-1-2384.

FURTHER EVIDENCE FOR TAURINE OR TAURINE-LIKE SUBSTANCE AS A TRANSMITTER IN FROG SPINAL CORD. A. L. Padjen, P. Metrakos\* and C. Karamitsos\*. Department of Pharmacology and Therapeutics, McGill University, Montreal, Quebec. It was reported that AMBD (6-aminoethyl-3- methyl-4H-1,2,4-benzothiadiazine-1,1-dioxide HCl) is a specific blocker of taurine (TAU) and beta-alanine (BALA) receptors in central nervous system (Yarbrough et al., 1981, JPET 219, 604). We have reexamined the effect of AMBD on synaptic and amino acid evoked responses recorded from isolated hemisected frog spinal cord by means of sucrose gap technique (Barker et al., 1975, J. Physiol. 245, 537). When indirect responses were blocked by addition of Mn (2 mM), AMBD (conc 0.01 - 0.5 mM) selectively antagonized TAU and BALA evoked depolarizing responses of primary afferents (dorsal roots) without affecting depolarizations by glutamate, GABA and glycine (the latter usually increased). Depolarizing responses to 0.5 mM TAU or BALA were antagonized 50% by 0.075 mM AMBD and often completely blocked by 0.25 mM AMBD. In normal Ringer, AMBD selectively antagonized fors al noot potential evoked by ventral root stimulation (VR-DRP; threshold at 0.02 mM, 90% block at 0.25 mM); other synaptic potentials (dorsal and ventral root responses evoked by dorsal root stimulation) increased in amplitude and duration due to strong convulsant activity caused by higher concentrations of AMBD.

These results are in agreement with the proposal that taurine or a taurine-like substance is involved in VR-DRP of frog spinal cord (Barker <u>et al.</u>, 1975, J. Physiol. <u>245</u>, 537). (Supported by MRC.)

A TECHNIQUE FOR MICROIONTOPHORESIS IN THE FREELY MOVING RAT. 69 2 M.O. West and D.J. Woodward. Dept. Cell Biology, University of Texas Health Science Center, Dallas, Texas 75235.

A limitation of acute iontophoretic studies is determining to what extent experimental results are influenced by anesthetics or by immobility. The implementation of such studies in awake, freely moving animals has been hindered by formidable technical obstacles. Single-barreled glass micropipets have been used to Obstacles. Single-parreled glass micropipets have been used to obtain stable recordings from freely moving rats by means of a detachable miniature microdrive (Deadwyler <u>et al</u> 1980. Electroencephalogr. Clin. Neurophysiol. 47:752). We now report on progress in conducting single unit recording and microiontophoresis in freely moving rats with the microdrive adapted to accommodate multibarrel glass. The adapter, which fits into the center of the microdrive

(Biela Engineering, Anaheim, Ca.), contains a bore with the shape of a cloverleaf for holding 4-barrel glass. Pipets pulled to a fine tip (3-10 microns total tip diam.) and filled with to a fine tip (3-10 microns total tip diam.) and filled with drug or salt solutions are press-fitted into the microdrive, which is then attached to a base implanted on the animal's skull. Rotation of the threaded outer cylinder of the microdrive advances the pipet, without rotation, to the desired depth (up to 7 mm). Signals are led to and from drug, balance and recording barrels by means of silver wires and a harness, through which the animal is attached to a 23-lead rotating slip ring assembly.

In preliminary studies, stable unit recordings have been obtained from cerebellum, thalamus, hippocampus and striatum. The number of drug barrels (two) can be increased to three by recording unit activity through a tungsten microelectrode that is affixed to the pipet in "piggyback" fashion. This has the further advantage of allowing various configurations between recording and pipet tips, permitting drug application at selected distances from the soma.

selected distances from the soma. With further development the procedure is anticipated to become a powerful technique, useful for example, in determining the effects of putative neurotransmitters on the behavioral correlates of single brain cells. IONTOPHORETIC STUDIES OF RESPIRATORY NEURONS IN THE UNANESTHETIZED CHRONICALLY IMPLANTED CAT. M. Denavit-Saubié, A.S. Foutz\*, Y. Pavi\*, E. Boudinot\*, M-P. Morin-Surun\* and J. Champagnat\*. Laboratoire de Physiologie Nerveuse and LA 204, C.N.R.S., 91190 - Gif-sur-Yvette, France.

We have previously shown that the firing pattern of respiratory-related neurons located in the cat medulla could be modified by local application of exogenous or endogenous substances (1). These pharmaexogenous or endogenous substances (1). These pharma-cologic manipulations were performed on anesthetized or decerebrated animals. The aim of the present study was to perform local iontophoretic drug applications to respiratory neurons of intact, undrugged animals in which the respiratory system is not depressed by anesthesia or deprived of forebrain afferents. Four adult cats were chronically implanted for recording the EEG, respiratory activity (nasal thermistor), and for cranial restraint. A 10 mm capped opening above the cerebellum allowed penetrations of multibarreled micropipettes into the medulla. A catheter in the jugular vein was used for i.v. drug administration. After habituation to the restraint, up to 40 pene-trations were carried out in 3-4 h recording sessions over a period of several months, and histological After habituation to the restraint, up to 40 pene-trations were carried out in 3-4 h recording sessions over a period of several months, and histological control was performed post-mortem. Micropipettes were lowered stereotaxically using as a reference a pole embedded in the acrylic mound. In this preparation stable recordings (5-75 min) were obtained and almost one half of units were respiratory-related (35 of 90 neurons in one cat). In these animals respiratory neurons fired more tonically and with a higher discharge rate than in acute preparations. Most neurons were sensitive to L-glutamate application, which showed that the recorded activity originated from the soma. Neurons were sensitive to GABA application, showing that this substance was still effective in the absence of pentobarbital anesthesia (2), which is known to potentiate the effects of GABA. In conclusion the present method allows stable recordings of respiratory-related neurons and iontophoretic application of pharmacologic compounds in intact, undrugged animals presenting natural sleep-weking states. (1) Denavit-Saubié M. et al., Brain Res., 155 (1978) : 55-67. (2) Champagnat J. et al., Brain Res. 237 (1982) : 351-365. IN VIVO BRAIN DIALYSIS CONFIRMS IN VIVO VOLTAMMETRIC EVIDENCE THAT ASCORBIC ACID IS RELEASED FOLLOWING DOPAMINE RECEPTOR STIMULATION. L. A. Phebus\* and J. A. Clemens. The Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

40285. We reported that in experiments using in vivo voltammetry in the striatum of awake rats, dopamine (DA) agonists increased the current peak at approximately +0.12 volts versus an Ag/AgC1 reference. This increase was blocked by DA antagonists. This peak results primarily from the oxidation of extracellular ascorbic acid (AA), with lesser contributions from dihydroxy-phenylacetic acid (DOPAC) and DA. The rise in this peak follow-ing DA agonists cannot be explained by changes in DA or DOPAC correntrations since these would be expected to decrease. We

ing DA agonists cannot be explained by changes in DA or DOPAC concentrations since these would be expected to decrease. We carried out <u>in vivo</u> brain dialysis experiments to determine the identity of the substance released into the striatal extracellu-lar fluid by DA agonists. Adult, male, Sprague Dawley rats were anesthetized, and a min-iature, graphite paste-tipped working electrode was lowered into the corpus striatum for electrochemical measurements. A stain-less steel auxiliary and Ag/AgCl reference electrode were placed in the contralateral cortex. The leads from these electrodes were attached to a miniature electrical connector and the entire assembly was cemented to the skull. Animals were allowed at least 3 days to recover from surgery. Semidifferentiated volta-mmograms were recorded at 1/2 hour intervals. Drugs were admin-istered i.p. after a stable voltammetric baseline was achieved. For brain dialysis experiments, minature dialysis loops were lowered into the striatum of anesthetized rats and the cannulae

For brain dialysis experiments, minature dialysis loops were lowered into the striatum of anesthetized rats and the cannulae holding these loops were cemented into place. Animals were allowed at least 3 days to recover. In an experiment, saline was perfused through the loop at a rate of 4 microliters per minute and collected in 15 minute samples. These samples were assayed for AA using HPLC. Pergolide, a DA agonist, produced an increase in the oxidation peak occurring at a uppervised by 40 20 wolts. In the in vivo

peak occurring at approximately +0.12 volts. In the in vivo brain dialysis experiments, 6 of 8 rats showed a large increase in extracellular AA following 600  $\mu$ g/kg of pergolide. We concluded that the increase in voltammetric signal following pergolide was due to a receptor mediated release of AA into the extracellular fluid.

Using the in vivo dialysis technique we also found high con-centrations of uric acid in the extracellular fluid of the rat striatum. We believe the oxidation of uric acid contributes to the voltammetric peak at approximately +0.3 volts (vs a Ag/AgCl reference) heretofore ascribed solely to 5-hydroxyindoles.

PERSISTENT CHANGES IN CNS DOPAMINERGIC ACTIVITY FOLLOWING PRENATAL EXPOSURE TO NEUROLEPTICS. <u>Helen Rosengarten</u>, <u>Kenneth Carr and Arnold J. Friedhoff</u>. Millhauser Labs., <u>New York University School of Medicine</u>, New York, NY 10016. 69.5

We have shown previously that the density of striatal D<sub>2</sub> We have shown previously that the density of striatal D2 dopamine receptors in pups exposed in utero to neuroleptic treatment is smaller than that in controls (H. Rosengarten and A.J. Friedhoff, Science 203, 1133-1135,1979). We now report that, although by 60 days of age, dopamine receptor density is still low it is no longer significant. However, tail-shock threshold in inducing simple vocalization was significantly lower at this time. Moreover, these rats were also statistically less sensitive to apomorphine when vocaliza-tion after discharge was measured and also were more resistant to neuroleptic inducing the donamine precentor un regulation. These tion after discharge was measured and also were more resistant to neuroleptic-inducible dopamine receptor up regulation. The data therefore provide evidence to indicate that the neuro-leptic induced changes observed initially by means of receptor binding have, as well, enduring behavioral consequences. These

EVIDENCE OF APOMORPHINE-INDUCED UP AND DOWN REGULATION OF 69.6 DOPAMINERGIC TRANSMISSION. M. Rodriguez\*, R. Castro\* and R Alonso. Dept. Physiology, La Laguna Sch. of Med., Tenerife, Spain

Spain. To further investigate the effects of dopaminergic agonists on motor behaviour, two different patterns of apomorphine administration were tested on male Wistar rats. Experiments were carried out on intact animals as well as on those with unilateral lesions of the nigrostriatal pathway. Lesions were made by injecting rats stereotaxically with 6-OH-dopamine (8  $_{\rm M}$  in 4  $_{\rm M}$  0.9  $_{\rm X}$  saline with 0.1  $_{\rm X}$  accorbic acid) into those votor intact or insponding to both the substantia nigra and the medial forebrain bundle. Apomorphine (1  $_{\rm M}/{\rm Kg}$  in 1 ml 0.9  $_{\rm X}$  saline) was given intraperitoneally either every two hours or two days to a total of four injections. In intact animals motor activity was measured between 15 and 20 minutes after each injection by using an actimeter. In lesioned animals, fifty days after 6-OH-dopamine injections and once denervation supersensitivity was developed, apomorphine was given at the same doses and the moral pattern as described above, and In both intact and previously lesioned rats the effect of apomorphine was apparently dependentupon the interval between injections: respectively were increased after each apomorphine injection when To further investigate the effects of dopaminergic agonists on respectively were increased after each apponprine injection when given every two days, while the opposite was observed when administration of the drug was made every two hours. It is well known that prolongued administration of drugs affecting neuro-transmission may induce up or down regulation phenomena (Kurlan, transmission may induce up or down regulation phenomena (Kurlan, R., Shoulson, I., <u>Clin. Neuropharmacol.</u>, <u>5</u>:345, 1982), the effect depending of the type of drug. Chronic administration of any drug that reduces neurotransmitter influence at its receptor site can lead to receptor up regulation (Baldessarini, R.J., Tarsy, D., <u>Int. Rev. Neurobiol.</u>, <u>21</u>:1, 1979), whereas chronic use of drugs that increase neurotransmitter action can cause receptor down regulation (Weiner, W.J. et al., <u>Life Sci.</u>, <u>28</u>:2173, 1981). The ersults reported here indicate that a well characterized dopamin-ergic agonist such as apomorphine is able to produce, at the same doses, an opposite effect on motor response depending upon the interval between successive injections. It may suggest a transitinterval between successive injections. It may suggest a transit-ory modification of dopaminergic synaptic transmission, probably due to up and down regulation phenomena.

SEROTONERGIC MODULATION AND SYNAPTIC MEMBRANE PROPERTIES IN THE 69.7 ADAPTATION OF RAT CORTICAL ADRENERGIC, NEURONS AFTER, REPEATED ANJIDEPRESSANT TREATMENTS. N.Brunello, I.Mocchetti, G.Calderi-ni, B.Di Perri<sup>2</sup>, and G.Racagni. 1 Institute of Pharmacology and Pharmacognosy, University of Milan, Italy and<sup>2</sup> Fidia Research

Laboratories, Abano Terme, Italy. The temporal sequence of changes in cortical noradrenergic neurons after repeated administration with desmethylimipramine (DMI) indicates that a transient increase in the concentration of normetanephrine (NMN), the O-Methylated metabolite of norepine-phrine (NE), is followed by the desensitization of the NE depen-dent adenylate cyclase and the down regulation of beta adrenergic receptors. NMN has been taken as an index of the amount of NE pre sent in the synaptic cleft. After two weeks of treatment these per sistent events are paralleled by a decrease in the NMN content, indicating that noradrenergic neurons have reached a new functio-nal state. The maintenance of this reduced functional level seems to be due to transynaptic mechanisms which involve serotonergic neurons. In fact a prolonged treatment with antidepressants elicits an increase in the uptake system for serotonin (5 HT), thus Temoving a possible modulatory input on noradrenergic system. In fact serotonergic denervation after lesion of the serotonergic sys tem following intracerebral injection of 5, 7 dihydroxytryptamine (5,7 DHT) produced a reduction in the concentration of cortical NMN. Moreover in 5,7 DHT lesioned rats the decrease of NMN concen-tration effort arealeneed dehicitateich with NJ use reduction attacts tration after prolonged administration with DMI was markedly atte-nuated. In addition 5-hydroxytryptophan (5 HTP) given repeatedly

was able to potentiate the down regulation of beta receptors. Chemico-physical properties of the synaptic membranes may also be involved in the modulation of noradrenergic trasmission in rat cerebral cortex after antidepressant treatment. We have recently shown that acute treatment with DMI elicited an increase of phospholipid methylation which disappeared after chronic treatment. This effect was further enhanced by a concomitant administration Ints effect was further enhanced by a concomitant administration with a mixture of phospholipids. When animals were treated with DMI and the phospholipid mixture, the incressed efficiency of 5HT uptake complex and the down regulation of beta receptors were already apparent after six days, indicating that changes in mem-brane composition can influence receptor adaptation to chronic antidepressant treatment.

The results obtained demonstrate that the hyposensitivity of the noradrenergic system produced by a chronic treatment with anti-depressants may be indicative of adaptive and integrative changes which bring the noradrenergic neurons to a lower functional level. 3H-VERAPAMIL BINDING SITES IN RAT CEREBRAL CORTEX. I.J. Reynolds, R.J. Gould and S.H. Snyder. Johns Hopkins University, Depts. of Neuroscience, Pharmacology and Psychiatry, School of Medicine, Baltimore, Maryland 21205. Binding sites for tritiated dihydropyridines, such as

Binding sites for tritiated dihydropyridines, such as  $^{3}H$ -nitrendipine, have been demostrated in smooth, cardiac and skeletal muscle and in neural tissue. These sites are believed to be associated with potential-operated calcium channels. Thus dihydropyridines prevent  $K^+$ -stimulated. Ca $^{2+}$ -dependent contractions of smooth muscle, and exert a negative inotropic effect in cardiac tissue. This lab, as well as others, (F.J. Ehlert <u>et al., Life Sci., 30</u>:2191, 1982) has demonstrated a non-competitive interaction between the  $^{3}H$ -nitrendipine binding site and drugs such as verapamil, methoxyverapamil (D600) and lidoflazine. The observation that these drugs increase the dissociation rate of  $^{3}H$ -nitrendipine is taken to indicate an allosteric interaction between the  $^{3}H$ -nitrendipine binding site and the site of action of verapamil. These agents also inhibit Thus.

allosteric interaction between the <sup>3</sup>H-nitrendipine binding site and the site of action of verapamil. These agents also inhibit calcium dependent processes in smooth and cardiac muscle. We have demonstrated binding of <sup>3</sup>H-verapamil (75 Ci mMol, NEN) to rat cortical membranes. Cerebral cortices were removed immediately following decapitation of male Sprague-Dawley rats (150-200 g) and homogenized in 20 vol of 50 mM sodium phosphate buffer (pH 7.4) containing 1 mM disodium EDTA. The homogenate was spun three times at 50,000 g and resuspended to a concentration of 5 mg/ml (wet weight) in phosphate buffer. Membranes were incubated for 1 hour with 1.4 nM <sup>3</sup>H-verapamil at room temperature, filtered, and rapidly washed in 10 ml ice-cold buffer. Tritium was extracted into a scintillation cocktail (Formula 947, NEN) and counted. This technique, using 1 µM D600 to determine non-specific binding gave 1200 displaceable cpm, with total and non-specific binding say performed on the same basis respectively. A centrifugation assay performed on the same basis gave a similar number of displaceable counts, but with an

gave a similar number of displaceable counts, but with an inferior signal/noise ratio. Calcium exerts a complex effect on <sup>3</sup>H-verapamil binding. Low concentrations ( $10^{-7} - 10^{-6}$  M) added after the EDTA wash increased specific and, to a lesser extent, non-specific binding. By contrast, higher concentrations, ( $10^{-4} - 10^{-3}$  M) decreases total binding. In the presence of  $10^{-6}$  M calcium various agents displace <sup>3</sup>H-verapamil. These include D600 verapamil, lidoflazine and diltiazem with apparent IC50's of approximately 15, 30, 560 and 600 nM respectively. Thus, these agents, which inhibit <sup>3</sup>H-nitrendipine binding. The observations on the effect of calcium are consistent with the hypothesis that the site of action of verapamil is intracellular (J. Heschler et al., <u>Pflugers Arch., 393</u>:287, 1982).

THE CHARACTERIZATION OF <sup>3</sup>H-NITRENDIPINE BINDING SITES IN RAT BRAIN. <u>R.J. Gould and S.H. Snyder</u>. Johns Hopkins University, Depts. of Neuroscience, Pharmacology and Psychiatry, School of Medicine, Baltimore, Maryland 21205. We have previously described the binding characteristics of <sup>3</sup>H-nitrendipine binding sites in various regions of rat brain. These binding sites in various regions of rat brain. These binding sites may be associated with voltage-operated calcium channels. A variety of structurally distinct calcium channel blockers interact with <sup>3</sup>H-nitrendipine binding sites in a fashion that is not strictly competitive, suggesting several sites of action of calcium channel blockers within the calcium channel. Antischizophrenic drugs of the diphenylbutylpiperidine class inhibit <sup>3</sup>H-nitrendipine binding with potencies similar to their potencies at dopamine receptors. This suggests that these drugs may exert therapeutic action via sites associated with <sup>3</sup>H-nitrendipine binding. Autoradiographic studies have previously shown distinct localization of <sup>3</sup>H-nitrendipine binding sites to many, but not all, synaptic zones. This is consistent with these sites playing a role in neuromodulation. We have sought to further characterize these binding sites from various brain regions. various brain regions.

various brain regions. First, structure-activity studies reveal that the second, or verapamil-like site has structural specificity similar to that for calmoculin. This suggests that a number of agents believed to be specific for calmodulin may have actions via voltage-operated calcium channels. Second, (3 methyl-3H) 1,4-dihydro-2,6-dimethyl-4-(2-isothiczyanatophenyl) -3,5-pyridine-dicarboxylic acid dimethyl ester (3H-ITC-DHP) binds to rat brain membranes and is irreversible or very slowly dissociates. The t 1/2 for dissociation of [3H]-ITC-DHP is greater than 60 min, while the t 1/2 for dissociation of 3H-nitrendipine is 18 min. The use of this apparently irreversible tritiated ligand allows for preliminary biochemical characterization of 3H-nitrendipine binding sites from various regions of the rat brain. regions of the rat brain.

INVOLVEMENT OF GABA- AND GLYCINE-MEDIATED TRANSMISSION IN THE 69.10

INVOLVEMENT OF GABA- AND GLYCINE-MEDIATED TRANSMISSION IN THE CONVULSANT-ANTICONVULSANT EFFECTS OF OPIATES. <u>M. Massotti\* and</u> <u>L. Mele\*</u> (SPON: S. Mazzari). Laboratorio di Farmacologia, Istitu-to Superiore di Sanità, Roma, Italy. Endogenous opioid systems play a role in a variety of physio-logical functions in central nervous system, other than pain perception. Increasing evidences indicate that opiate agonists and antagonists are furthermore involved in the convulsive phenomena.

Howerea. Electroencephalographic (EEG) behavioural and binding tech-niques were consequently utilized to analyze the interactions of naloxone and morphine with GABA and glycine-mediated transmission in vivo.

The administration of a high dose of naloxone (> 40 mg/kg iv) and morphine (> 100 mg/kg iv) elicits behavioural and EEG convuland morphine (> 100 mg/kg iv) elicits behavioural and EEG convul-sions in laboratory animals. Such convulsant effect is character-ized by the occurrence of high voltage spikes accompanied by tonico-clonic manifestations in the case of morphine and tonic manifestations in the case of naloxone. The intermediate doses of naloxone (5-20 mg/kg iv) elicit a proconvulsant effect in animals previously challenged with drugs which inhibit GABA-(bicuculline, picrotoxin, Ro 5-3663, cardiazol and local penicillin) and gly-cine- (strychnine) mediated transmissions at post-junctional level. On the contrary, the administration of low doses of mor-phine (0.25-1.0 mg/kg iv) inhibits the naloxone-induced convul-sant and proconvulsant effects as well as the convulsant effect sant and proconvulsant effects as well as the convulsant effect due to administration of the above mentioned GABA and glycine ant agonists.

Binding studies show that naloxone modulates, in an inhibitory fashion, the high and the low affinity components of  $_{2}^{H-GABA}$  binding when tested "in vitro" at final concentration  $10^{-5}$ M, and H-glycine binding when administered at the dose of 40 mg/kg iv or higher.

The possible relevance of the above data will be discussed. This work was in part financed by CNR-ISS contract n. 82.02048. 56 (pos. n. 115.14523).

ELECTROCONVULSIVE TREATMENT ATTENUATES HALOPERIDOL-INDUCED INCREASE OF <sup>3</sup>H-IMIPRAMINE BINDING IN RAT BRAIN. <u>Barkai</u>, <u>A.I.\*<sup>1</sup></u>, <u>Kowalik</u>, <u>S.</u>, <u>Reches</u>, <u>A.<sup>2</sup></u>, <u>and</u> <u>Fahn</u>, <u>S.<sup>3</sup></u> (<u>SPON</u>: <u>D.F.</u> <u>Klein</u>). N.Y. Psychiatric Institute and Departments of Psy-chiatry<sup>1</sup> and Neurology<sup>3</sup>, Columbia University College of Physicians and Surgeons, and Department of Neurology, Hadassah Medical Center, Jerusalem, Israel<sup>2</sup>. Binding sites for <sup>3</sup>H-imipramine (<sup>3</sup>H-IMI) in brain are associated with the regulation of neuronal uptake of seroto-69.11

associated with the regulation of neuronal uptake of serotonin (5-HT) and appear to have a function in regulating 5-HT<sub>2</sub> receptors. Cerebral 5-HT<sub>2</sub> receptors bind butyrophenone neuroleptics with high affinity and their density can be modified by repeated electroconvulsive treatment (ECT). To investigate whether chronic haloperidol treatment, ECT, or a combination of both also affect <sup>3</sup>H-binding, four groups of rats were treated for 28 days as follows: 1) control; 0.2 ml saline i.p. daily, 2) haloperidol; 2 mg/kg i.p. daily, 3) ECT; 20-30 mamp, 60 Hz, 1.5 sec, 3 times a week, and 4) haloperidol plus ECT. Following a recovery period of 5 days animals were sacrificed and frontal-cortex membranes prepared for  $^{3}H-IMI$  binding assays. A marked increase in the density of  $^{3}H-IMI$  binding sites (Bmax) was seen in the haloperidol-treated rats compared to controls (Bmax 1190±185) haloperiod -treated rats compared to controls (bmax 1190-185) vs.  $350\pm40$  fmol/mg protein) whereas no significant change in Bmax was induced in the ECT group. Treatment with both haloperidol and ECT resulted in a Bmax of  $300\pm51$  fmol/mg protein indicating that ECT acts to attenuate the increase of <sup>3</sup>H-IMI binding sites observed after withdrawal of chronic haloperidol. Supported by NIH grant NH 33690 and grants from the Parkinson's Disease Foundation and the Dustonia Medical the Parkinson's Disease Foundation and the Dystonia Medical Research Foundation.

PHOTOAFFINITY LABELING OF THE IMIPRAMINE BINDING SITE IN HUMAN PLATELET MEMBRANES WITH [<sup>3</sup>H]-2-NITROIMIPRAMINE. <u>L.P.Wennogle\*</u>, <u>R.A.Ashton\*1</u> and <u>L.R.Meyerson</u>. Dept.CNS Res., Med.Res.Div. of Amer.Cyanamid Co., Lederle Labs, Pearl River, NY and <sup>1</sup>Dept. Chemistry, NYU, New York, NY. The imipramine (IMI) binding site of human platelets and other tiscues is considered to alloctomically mediate to study of 69.12

The impramine (IMI) binding site of human platelets and other tissues is considered to allosterically modify the activity of the serotonin (5-HT) uptake system.  $[^{3}H]$ -2-Nitroimipramine ( $[^{3}H]$ -2NI) is considered a reversible, "slowly-dissociating," high-affinity probe of the IMI binding site (Rehavi, et.al. 1983 The present study was conducted to exploit the photoactivatible potential of  $[^{3}H]$ -2NI and its utility to characterize the molec-ular components of this allosteric system.  $[^{3}H]$ -2NI (20nM) was incubated with platelet membrane mean time in the preserve 1983). potential of [24]-2NI and its utility to characterize the molecular components of this allosteric system. [34]-2NI (20nM) was incubated with platelet membrane preparations in the presence and absence of selected displacers at 0° C. Ultraviolet irradiation of these samples followed by SDS-PAGE with subsequent fluorographic analysis resulted in labeling of one major band of 30K apparent mol.wt. This band was quantitatively chased when photolysis was conducted in the presence of specific 5-HT uptake inhibitors (e.g., fluoxetine, citalopram, femoxetine, indalpine, and imipramine). In the absence of UV light, no photolabeled bands were detected. Drugs specific for other receptors (e.g.,  $a_1, \alpha_2, H_1, H_2, B$ , muscarinic and  $D_2$ ) did not inhibit labeling of the 30K band. Several other bands in the gel were photolabeled to a lesser degree, but were not chased by any of the drugs tested. The 30K band is a minor membrane protein (< 0.10 total protein as judged by coomassie staining) labeled to high specific activity. Due to the high selectivity of photoincorporation into this site, and the differential drug displacement that is germaine only to the 5-HT uptake-IMI receptor complex, it is reasonable to associate the 30K band as a polypeptide component of this system. Curiously, when IMI was used (10-100  $\mu$ M) to inhibit photoincorporation in the 30K band, a dose-responsive enhancement of label into other bands was observed. This effect enhancement of label into other bands was observed. This effect may be due to membrane altering viscosity changes by imipramine, although IMI-induced conformational changes of the uptake complex cannot be eliminated. Photoaffinity labeling with [3H]-2NI will likely prove to be a valuable tool in the ultimate purification and characterization of the serotonin uptake/allosteric regulator complex.

69.13 BETA-ADRENERGIC/CYCLIC AMP MEDIATED REGULATION OF BENZODIAZEPINE BINDING SITES IN C6 CELLS. <u>M. D. Dibner, R. A. Lampe\* and M. A.</u> <u>Bailey.\* Neurobiology Group, Central Res. & Dev. Dept., E. I. du</u> Pont de Nemours & Co., Clenolden Lab., Glenolden, PA 19036.

We have previously demonstrated that exposure of C6 glioma cells to fetal bovine serum or to benzodiazepines regulate the expression of benced azepine binding sites. The current studies indicate that the regulation of  ${}^{3}\text{H-flunitrazepam}$  (FLU) binding to this receptor (a "peripheral" benzodiazepine receptor) is under the influence of adrenergic agonists. Growth of cells with the beta-adrenergic agonist isoproterenol (10 µM) for longer than one day leads to a significant increase in the Bmax of FLU binding with no significant alterations in the affinity of the receptor for FLU. Thus, 48-96 hr exposure to isoproterenol (changed daily) led to a 30-50% increase in FLU binding sites per cell. The addi-tion of low concentrations of isoproterenol (10 nM) had no effect whereas 100 nM and higher concentrations protocerenol (10 nM) had no effect whereas 100 nM and higher concentrations produced increases in FLU binding. Treatment with isoproterenol did not lead to a sig-nificant increase in the amount of protein per cell. Thus, FLU binding site numbers were increased whether expressed per unit cell or per unit protein. Isoproterenol (10 µM) also increased binding sites on cells grown in servember (10 µM) also increased binding sites on cells grown in servember defined medium. It appears that these changes are mediated via stimulation of cyclic AMP in the cells. Exposure of cells to 1 mM dibutyryl cyclic AMP for 1-2 days significantly increased FLU binding sites per cell with no alterations in the Kd. Dibutyryl cyclic AMP had no effect after only two hours of exposure. With two days of exposure, lower concentrations (100  $\mu$ M) of dibutyryl cyclic AMP also increased binding site numbers in serum-free cells, but there was The offect with 10  $\pm$ M dibutyryl cyclic AMP. In addition to dibutyryl cyclic AMP, cyclic AMP (1 mM) or isobutylmethylxanthine (500  $\mu$ M) exposure can increase FLU binding sites. It does not appear that these effects are mediated via direct interaction with the benzodiazepine binding site since high concentrations of dibutyryl cyclic AMP or isoproterenol did not directly inhibit FLU binding to intact C6 cells. This effect appears, however, to be mediated via the  $\beta$ -adrenergic receptor and can be blocked by co-incubation of propranolol along with isoproterenol. Lastly, although in most cases growth of cells with isoptotetenol. Lastry, although in most cases growth of cells with either isoptoteneol or dibutyryl cyclic AMP led to a decreased cell growth rate, several lines of evidence indicate that the observed increase in FLU binding sites was not due to changes in the cell cycle or cell density.

 69.14 CHRONIC CLONAZEPAM TREATMENT INCREASES THE DENSITY OF SERO-TONIN<sub>1</sub> AND SEROTONIN<sub>2</sub> BINDING SITES IN RAT FRONTAL CORTEX. H.R. Wagner, E. Yablonskaya\*, A. Reches, S. Fahn (SPON: E. Housepian). Departments of Pharmacology and Neurology, Columbia University, College of Physicians and Surgeons, New York, New York 10032.

The benzodiazspine, clonazepam, is an effective drug in the management of reflex myoclonus. Low CSF levels of the serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), often occur in myoclonus and increased 5-HIAA levels are associated with clinical improvement. Because of this correlation between serotonin (5-HT) and clinical status in myoclonus, we have studied effects of clonazepam on brain serotonergic function. Male Sprague Dawley rats were treated with clonazepam (5 mg/kg/day, i.p.) for ten days. Two days after the final dose rats were killed and various brain regions were assayed for levels of 5-HT<sub>1</sub> and 5-HT<sub>2</sub> binding sites, 5-HT and 5-HIAA. <sup>3</sup>H-5-HT was used to measure 5-HT<sub>1</sub> binding sites; specific binding was defined with 10 uM unlabelled 5-HT. <sup>3</sup>H-Spiperone (SPIP) was used to measure 5-HT<sub>2</sub> binding sites; specific binding was defined with 1 uM unlabelled spiperone. Chronic clonazepam exposure increased the number of both 5-HT<sub>1</sub> and 5-HT<sub>2</sub> binding sites (Bmax) with no change in affinity (Kd). Binding increases for both ligands occurred in frontal cortex but not in brainstem. A significant increase in the binding of <sup>3</sup>H-5-HT occurred in rats treated chronically with clonazepam for 10 but not 5 days. <sup>3</sup>H-SPIP binding was significantly increased doses of 5 mg/kg/day but not t doses of 2.5 mg/kg/day. Binding changes did not reflect a direct effect of clonazepam mo the receptors based on competitive binding studies. Levels of frontal cortex >-BT and 5-HTA. Sidding studies, Binding changes did not reflect a direct effect of clonazepam mo the receptors based on competitive binding studies. Levels of frontal cortex >-BT and 5-HTA. As determined by HPLC and electrochemical detection, were unaffected by clonazepam, suggesting that receptor increases were not mediated by transvancie events.

69.15 ACUTE AND REPEATED ADMINISTRATION OF DESMETHYLIMIPRAMINE AFFECTS FINEAL GLAND cAMP-DEPENDENT PROTEIN KINASE ACTIVITY. J.A. Moyer, P.J. Silver, and E.B. Sigg\*. Dept. of Exp. Therap., Wyeth Labs. Inc., P.O. Box 8299, Philadelphia, PA 19101. Previous experiments have shown that repeated but not acute

Previous experiments have shown that repeated but not acute desmethylimipramine (DMI) treatment reduces the ability of isoproterenol (ISO) administered either in vico or in vitro to elevate the concentration of adenosine  $3^{1}$ : $5^{1}$  cyclic monophosphate (cAMP) in rat pineal glands. This effect is postulated to be due to a decrease in  $\beta$ -adrenergic receptor number and a reduction in norepinephrine-stimulated adenylate cyclase activity (Life Sciences 24:2237, 1979: Molecular Pharmacology 19:187, 1981). However, additional studies have shown that acute and repeated treatments with DMI result in changes in cAMP responsiveness which are temporally and quantitatively dissociated from the alteration in receptor number (Neuroscience Abstracts <u>8</u>:377, 1982). Accordingly, we have examined cAMP-dependent protein kinase (cAPK) activity in this model since activation of cAPK and subsequent phosphorylation of specific phosphoproteins is the primary mechanism of action of cAMP

quent phosphorylation of specific phosphoproteins is the primary mechanism of action of cAMP. The concentration of soluble cAPK was determined in male rat pineal glands exposed to constant light following acute (1 injection; 10 mg/kg i.p.) and repeated (9 injections; 10 mg/kg i.p.; 5 days) DNI administration. Total cAPK activity (pmol/mg protein/min; X - SE) was reduced following both acute (4007  $\pm$  236) and repeated (4191  $\pm$  369) DMI administration compared to saline-treated controls (5450  $\pm$  399). Cyclic AMP independent protein kinase activity, measured in the presence of saturating amounts of cAPK inhibitor, was not found to be different among saline (1260  $\pm$  104), acute DMI (1055  $\pm$  106), or repeated DMI (1407  $\pm$  99)

ISO-stimulated (2 µmol/kg i.p.) cAPK activation was also measured in rats treated acutely or repeatedly with DHI by determining cAPK activity ratios (cAPK activity-cANP/cAPK activity 2 µN cAPP). cAPK activation was apparent in saline-treated rats  $(\overline{X} \pm SE;$  basal 39  $\pm$  3; ISO 86  $\pm$  12); DMI treatment alone also activated basal cAPK activity in acute (66  $\pm$  6) and chronic (69  $\pm$  4) DMI groups. Further activation of cAPK by ISO was apparent in the acute (83  $\pm$  4) but not the chronic (66  $\pm$  3) DMI groups. Thus, these changes in cAPK activation paralleled alterations in cAPP responsiveness observed following acute and repeated DMI treatment in previous experiments.

Peated DMI treatment in previous experiments. In summary, these results show that the concentration and activation of cAPK is altered following DMI treatment in the rat pineal gland. Therefore, modulation of cAPK may be a locus of regulation for DMI-mediated depression of 2-adrenergic responsiveness. 69.16 INTERACTIONS OF GENTAMICIN AND CALCIUM ON REFLEX ACTIVITY IN THE ISOLATED NEONATAL RAT SPINAL CORD PREPARATION. James M. Tolliver\* and Jordan E. Warnick (SPON: N. BROOKES). Dept. of Pharmacol. 6 Exp. Ther., Univ. of MD School of Medicine, Baltimore, MD 21201.

The injection of aminoglycoside antibiotics in the subdural space at lumbar segment 1 in rats results in an immediate flaccid hindlimb paralysis lasting 3 to 7 hours, depending on the dose and the particular antibiotic injected. Electrophysiologic recordings (membrane and action potentials, ACh sensitivity, spontaneous and evoked transmitter release) at the neuromuscular junction of extensor digitorum longus and soleus muscles as well as standard in vivo twitch experiments did not demonstrate any abnormalities in neuromuscular transmission during the period when hindlimbs were paralyzed. These facts and the observation that the 'H' reflex, but not the 'M' response, is absent during the paralytic state in rats indicates that the paralysis is mediated at the spinal cord level and not in the nerve or at the neuromuscular junction. We therefore elected to further study the effects of gentamicin (GEN) on spinal reflex activity using the isolated hemisected spinal cord of neonatal rats. Spinal cords from 5- to 7-day old neonatal rats were isolated, hemisected and superflued with oxygenated Krebs' solution. Suction electrodes were used to stimulate the dorsal root and record reflex activity from the corresponding ventral root. The frequency-dependent depression of reflex activity was measured as the ratio of the l0th/lst reflex responses evoked by stimulating the dorsal root with a train of 10 pulses at 0.1, 0.2, 0.5, 1.0 and 2.0 Hz. Reflexes were displayed on a storage oscilloscope and recorded on tape for later computer assisted analysis. Reflex activity was 90% of that observed at 5 mM. In ME (Ga<sup>2+1</sup>), reflex activity with a gradual increase in [Ga<sup>2+1</sup>], reflex activity increased reaching a maximum at 5 mM [Ga<sup>2+1</sup>], at 10 mM (creased the [Ca<sup>2+1</sup>], co 6 mM. Increasing the [Ca<sup>1+</sup>], from 0 to 10 mM decreased the frequency-dependent depression whereas increasing concentrations of GEN [1-8 mM] greatly attenuated this depression. Elevation of the [Ca<sup>2+1</sup>], antagonized the increase in frequency-dependent depression

69.17 D-AMPHETAMINE INHIBITS MEMBRANE METHYLTRANSFERASE ACTIVITIES. B. H. Rohde and J. C. Flynn. Inst. Research Childhood Learning Disorders, Baylor University, Waco, TX 76798.

Food colorings are reported to exacerbate hyperkinetic behavior in children and D-amphetamine can alleviate this behavior. We have earlier reported that a mixture of common food colorings can inhibit membrane phospholipid methyltransferase (<u>Fed. Proc.</u> 42, 1983), an enzyme system reported to be involved in synaptic transmission (Hirata and Axelrod, <u>Science</u> 209: 1082, 1980). We therefore sought to determine the effects of D-amphetamine on methyltransferase activity in rat brain synaptic plasma membrane fractions (SPM) and in human red blood cell ghosts. Synaptic plasma membranes were prepared from whole brain of

Synaptic plasma membranes were prepared from whole brain of male Long-Evans rats. Human red blood cell ghosts were prepared from blood of adult males. Membranes were incubated with  $^{3}\text{H}$  - S-adenosyl methionine (SAM) according to the procedure of Hoffman and Cornatzer (Lipids 16: 233, 1981). A mixture of common food colorings and/or varying concentrations of D-amphetamine sulfate were added to the samples prior to the addition of SAM.

Addition of D-amphetamine caused a consistent decrease in the activity of methltransferase in rat brain SPM at concentrations as low as l.l uM. The maximal inhibition was about 30% and the  $IC_{50}$  around 10 uM. Addition of food coloring and D-amphetamine together resulted in inhibition equal to that of D-amphetamine alone.

Addition of food coloring to human red blood cell ghosts prior to incubation reduced methyltransferase activity by about 10%; this agreed with data obtained using rat brain SPM. D-amphetamine reduced activity by 14% (5.4 uM) or 19% (21.5 uM); food colorings did not potentiate the inhibition produced by 21.5 uM D-amphetamine. These results suggest that food colorings and D-amphetamine inhibit phospholipid methyltransferases, possibly by a similar mechanism involving the lipid bilayer. (Supported by Wacker Foundation Grant and Frost Foundation Grant) 69.18 LITHIUM EFFECTS ON NEURONAL MEMBRANES IN RATS OF DIFFERENT AGES. I.J. Wajda, M. Banay-Schwartz\* and A. Lajtha. Center for Neurochemistry, Rockland Research Institute, Ward's Island, N.Y. 10035

In our previous studies on lithium we found that chronic In our previous studies on lithium we round that chronic administration of lithium produced a number of changes in the brains of treated rats. The binding sites of  $[{}^{3}H]$ naloxone,  $[{}^{3}H]$ dihydromorphine, and  $[{}^{3}H]$ spiperone were reduced in the corpus striatum and the cerebral cortex. The levels of potas-sium increased significantly by 15-30%, and those of sodium showed a smaller, nonsignificant increase of 10%. The content of cluster of the certe and rolino of glycine, GABA, glutamic acid, lysine, alanine, and valine increased to different extent in several brain regions. Those experiments were performed on adult rats kept on lithium-containing diet for 3-4 weeks or three months. Changes in containing diet for 3-4 weeks or three months. Changes in receptor binding, ionic content, and amino acid composition occurred only when the level of lithium in the brain was close to or higher than 1.0 ueq/g of tissue. Recently the clinical action of lithium salts administered during pregnancy was con-sidered in a number of obstetrical cases. We examined, there-fore, two groups of rats (3-day old and 6-week-old pups) kept on lithium diet during the entire gestation period and during extrauterine life. The dams fed lithium diet had high levels of lithium in the brain and plasma; increases in potassium, sodium, and a number of free amino acid levels; and a reduction solution, and a humber of free antibolate tweeds, and a federation in  $[^3H]$ spiperone binding sites. In the three-day-old pups there was no lithium present, and the binding of  $[^3H]$ spiperone and the levels of ions and amino acids were the same as in controls. Lithium was also absent from the brains of fetuses iso-lated by caesarean section after decapitation of the lithiumtreated dams. In the six-week-old rats kept on lithium diet treated dams. In the six-week-old rats kept on fitnium diet during the gestation period and during the six weeks of extra-uterine life we found high levels of lithium in the brain and plasma, changes in the kinetic constants of  $[{}^{3}\mathrm{R}]$ spiperone binding sites, and increases in potassium and sodium levels. The analysis of free amino acids in different regions of the brain showed increases in glycine, GABA, lysine, and taurine. The results indicate that there is a barrier preventing accumulation of lithium during pregnancy and during the latation period in the offspring. It is only when the pups start the lithium-containing diet that the drug accumulates in the brain and changes in receptor, ion, and amino acid levels can be shown.

This work was supported in part by NYS Health Research Council Grant  $13{-}098{\,}\text{.}$ 

9.19 IMMUNOCYTOCHEMICAL LOCALIZATION OF THE REGULATORY SUBUNIT OF TYPE II CAMP DEPENDENT PROTEIN KINASE ( $R_{1T}$ ) AND OF BINDING SITES FOR THIS SUBUNIT IN THE CENTRAL NERVOUS SYSTEM. P. De Camilli', M. Moretti\*', F.Navone\*', S.M. Lohomann-Walter\*' and U.Walter\*', 'CMR Center of Cytopharmacol. and Dept. of Medical Pharmacol., Univ. of Milano, Italy;' Depts. of Physiol. Chem. Würzburg Univ., West Germany. We have studied the distribution of R<sub>11</sub> in the central nervous system of the rat using a specific antiserum directed against rat R<sub>11</sub>. R<sub>11</sub> was found to be highly concentrated in the neuronal tissue but was also detectable in nonneuronal cells, in particular in ependimal cells (cili and basal bodies) and in cells of the choroid plexus. Neuronal R<sub>17</sub> was present at high concentrations in the gray matter while it was practically undetectable in the major white matter tracts. Its pattern of distribution showed large variations from region to region of the CNS. In the spinal cord, and in the isodendritic core of the brain stem and of the forebrain it was detectable in all neurons. In contrast, it was present at very variable concentrations in individual cells of certain neuronal classes. For instance, it was present at very high concentrations in pyramidal cells of some cortical layers. In the cerebelum, Purkinje cells (which are rich in cGMP-dependent protein kinase) were unstained images outlined by immunoractive material which appeared to be localized in axon terminals of other neurons. In order to study the bases for the compartmentalization of R<sub>11</sub> in neurons (suggested by the absence of R<sub>11</sub> immunoreactivity from the white matter) we have further extended our previous studies on the existence of binding sites for R<sub>11</sub> on insoluble components of the neuronal dendrites, when incubated with fixed-frozen sections of brain tissue. As also previously showed by us, this binding appeared to be primarily mediated by MAP 2, a major substrate for the catalytic subunt of CAMPdependent protein kinases. In

SODIUM CURRENTS IN HUMAN MUSCLE UNDER VOLTAGE CLAMP. 70.1 W.M. Roberts,\* R.L. Ruff, and W. Almers.\* Dept. of Physiology and Biophysics, SJ-40, Univ. of Washington, Seattle, WA 98195.

The losse patch clamp method (Stühmer & Almers, Proc. Natl. Acad. Sci. <u>79</u>, 946, 1982), which uses an extracellular pipette to apply voltage steps and measure the resulting membrane currents, was modified to employ pipettes having two concentric barrels. Currents were measured through the center portion (5-15  $\mu m$  diam.) of a larger (15-25 µm diam.) isopotential patch. This method allows voltage clamp recordings from intact, minimally dissected muscle fibers without enzymatic cleaning of the cell surface. Patch voltage clamp recordings were made from biopsy samples of human intercostal muscle obtained from patients undergoing surgery for reasons not involving muscle disorders.

Sodium channel kinetics were examined in 14 fibers to give the Solum channel kinetics were examined in 14 fibers to give the following average values (mean  $\pm$  S.E.M.): Resting membrane potential -70  $\pm$  3 mV; peak I<sub>Na</sub> = 9  $\pm$  2 mA/cm<sup>2</sup>; reversal potential = +43  $\pm$  2 mV; potential to elicit half-maximal I<sub>Na</sub> = -52  $\pm$  1.4 mV; potential to cause 50% inactivation in 100 ms = -86  $\pm$  2.8 mV. Recordings were also made from rat omolyoid muscle fibers which yielded similar values for the above measurements, as well as for the values domendrone of cativation and juscitivation time. the voltage dependence of activation and inactivation time constants.

Three striking features of these currents are: (1) The maximal peak inward current was highly variable, with an average value (9 mA/cm<sup>2</sup>) that was larger than previously reported average value (9 mA/cm<sup>2</sup>) that was larger than previously reported for rat extensor digitorum longus (3.8 mA/cm<sup>2</sup>) or sternomastoid (6.8 mA/cm<sup>2</sup>; Pappone, J. Physiol. 306, 377, 1980), or frog semi-tendinosus (4.7 mA/cm<sup>2</sup>; Hille & Campbell, J. Gen. Physiol. <u>67</u>, 265, 1976). (2) All fibers showed a marked slow component of inactivation of the Na<sup>+</sup> current. (3) The observed late outward current densities were small relative to the peak inward currents. R.I.R. was a recipient of an NIH Teacher-Investigator award (#NO0/0400, Supported by USPUE crost #NSIR748 (#NS00498). Supported by USPHS grant #NS18748.

- Na<sup>+</sup> CONDUCTANCE INACTIVATION IS MODEL DEPENDENT. 70.2
  - Dexter M. Easton, Department of Biological Science, The Florida State University, Tallahassee, Florida 32306 The increase of Na<sup>+</sup> current during V-clamp depolarization of The increase of Na<sup>+</sup> current during V-clamp depolarization of excitable membrane is generally thought to involve opening of molecular gates in the membrane conductance channels, while the fall of the current from its maximum is credited to inactivation of conductance. These processes are inferences from the m and h terms in the mathematical model devised by Hodgkin and Huxley (1952) to describe the V clamp currents. A new mathematical theory describes each current, INa<sup>+</sup> or IK<sup>+</sup>, as the resultant in each instance of 2 opposing processes. According to this theory, depolarization increases the existing conductance probability of both ion species in both directions, inward and out-Theory, depolarization increases the existing conductance probability of both ion species in both directions, inward and outward through the membrane. There is no "inactivation" term. Instead, as t  $\pm^{\infty}$ , a new steady-state net conductance develops, which is the sum of the oppositely directed conductances, one nearly equal to the other in the instance of Na<sup>+</sup>, more unequal for  $t^+$ . The Na<sup>+</sup> virtual currents grow at different rates but attain nearly equal (but opposite) levels as t  $\pm^{\infty}$ . Thus, there is an INa<sup>+</sup> peak. In the K<sup>+</sup> system, the levels as t  $\pm^{\infty}$  are ordinarily sufficiently different that no IK<sup>+</sup> peak occurs. The theory suggests that net movement of an ion species may be attributed to the efficacy of the specific ion rejection/ attraction system in relation to the electrochemical gradient. Conductance channels, according to this view, remain open, to an extent depending on the membrane potential. Thus the new theory does not require turn-off of conductance during V-clamp but instead attainment of a new steady state of inward-outward virdoes not require turn-off of conductance during v-clamp but instead attainment of a new steady state of inward-outward vir-tual conductance. The theory appears to shift control of charge movement away from the conductance channels. Instead it empha-sizes the molecular organization responsible in the first instance for the ion distribution discrepency between inside and outside of the axon. Aided by computing center and Psychobiology Research Center, FSU.

70.3 THE EXISTENCE OF DISCRETE CHANNEL-ASSOCIATED Ca2+ 'DOMAINS' MAY The EXISTENCE OF DISCRETE CHANNEL-ASSOCIATED Ca<sup>-1</sup> DUMAINS MAY INFLUENCE THE RELATIONSHIP BETWEEN  $I_{Ca}$  AND Ca<sup>-MEDIATED</sup> PHENOMENA. J.E. Chad\* and R. Eckert. Department of Biology and Ahmanson Laboratory of Neurobiology, UCLA, Los Angeles, CA 90024. The properties and distribution of single-channel currents un-

The properties and distribution of single-channel currents underlying the macroscopic calcium current,  $I_{Ca}$ , may be implicated in the kinetics of Ca-mediated processes taking place at the membrane. The dispersion of  $Ca^{2+}$  entering the cell is severely limited by buffering that produces steep gradients perpendicular to the membrane surface (Levy et al., 1982, Biophys. J. 37:182a). Assuming that dispersion is limited equally in all directions from the inner mouth of the Ca channel, each channel may control aCa<sub>1</sub> predominately within a miniature hemispheric 'domain' centered on that channel. Thus, aCa<sub>1</sub> associated with  $I_{Ca}$  may be distributed as the several of the several domain acca control action. that channel. Thus,  $\underline{aCa_i}$  associated with  $I_{Ca}$  may be distributed as a mosaic, with individual domains each controlling local Ca receptors, rather than as a laterally uniform layer controlling all Ca receptors. The density and distribution of active Ca channels may therefore be significant in determining quantitative relations between the macroscopic current and the overall response

relations between the macroscopic current and the overall response of a Ca-mediated process. Rates of channel cycling as well as domain size and overlap should influence these relations. Evidence for the existence of functional  $Ca^{2+}$  domains appears in voltage-clamp measurements of Ca currents in <u>Aplysia</u> neurons. The apparent efficacy of entering  $Ca^{2+}$  in producing Ca-mediated inactivation of the Ca channels decreases with depolarization, contrary to the effect expected for  $Ca^{2+}$  reacting with a binding its within the membrane field. contrary to the effect expected for  $Ca^{2+}$  reacting with a binding site within the membrane field. The voltage dependence of the apparent efficacy is linear in the range -40 to 0 mV, and has an extrapolated voltage intercept of +16 mV. This is closely cor-related with the predictions of the constant field equation for the single-channel current in this voltage range, which also ap-proaches linearity and has an extrapolated intercept of +18 mV. The apparent efficacy of  $Ca^{2+}$  in producing inactivation thus appears to depend more directly on the single-channel current than on the macroscopic current, just as predicted if  $Ca^{2+}$ accumulates in discrete domains, rather than in a uniform layer.

Dependence of Ca-mediated responses on single-channel currents and their domains might also be expected to produce hysteresis in and their domains might also be expected to produce hysteresis in the relationship between  $I_{\rm Ca}$  and a Ca-mediated, saturating response at membrane potentials beyond the peak of the  $I_{\rm Ca}/$  voltage curve, for with increasing positive potential more channels are activated whereas the single-channel current diminishes. Hysteresis which may arise in this way has been seen in Ca-dependent transmitter release at the squid giant synapse (Llinas et al., 1981, Biophys. J. 33:323). These examples suggest that is apatially discrete, channel-associated Ca<sup>2+</sup> domains' may indeed have significance for certain membrane-related phenomena. PASSIVE ELECTRICAL PROPERTIES OF NONUNIFORM TAPERED DENDRITES:A 70.4 PASSIVE ELECTRICAL PROPERTIES OF NONUNITORM TAPERED DEMORTIES A MATHEMATICAL COMPARISON WITH CXLINDRICAL DENDRITES. S.A. Elliss<sup>4</sup> and J.K. Stevens (SPON: M.A. Dichter). Dept. of Neurol., Mass. General Hosp., Boston, MA 02114 and Playfair Neuroscience Unit, University of Toronto, Toronto, Ont. Canada. In order to assess the functional consequences of the well

documented dendritic taper of many vertebrate neurons, the differential equations for passive voltage propagation were analyzed for idealized cell geometries. These included cells with either one or seven dendrites (all either cylindrical or tapered). All geometries had a 10u diameter soma. Each unbranched dendrite had a length of 180u, and a diameter of 1u initially. The tapered dendrites had an exponential decrease in diameter to a final value of 0.1u. The model parameters were a specific membrane resistance of 2000 ohm-cm<sup>2</sup>, an axial resistance of 100 ohm-cm, a specific membrane capacitance of 1uF-cm<sup>-2</sup>, a synaptic driving potential of 100 mV, and a synaptic conductance change of 2.0 nanosiemens of 1.0 msec or infinite duration. The transient problem was solved by a Crank-Nicholson procedure; the steady-state by back-solving an equivalent tridiagonal matrix for Kirchkoff's voltage law.

With dendritic taper, the soma voltage, Vs, is more sensitive to the location of solitary inputs in the unipolar and multipolar cells: e.g.,in the steady state, Vs varied from 9.7 mV to 5.7 mV (cylindrical multipolar cell), as compared with 26.7 mV to 4.5 mV (tapered multipolar cell). In both cases,the inputs were at 20u and 180u, respectively, from the soma. Moreover, all but the most proximal inputs on the tapered dendrite are more effective at the soma than identically placed inputs on the cylindrical cell: e.g., in the steady state, Vs is 9.9 mV for an input at 120u from the soma in the tapered multipolar cell, while it is only 9.6 mV for an input as close as 20ų to the soma in the cylindrical multipolar cell. Th effects are due to the higher local input impedance of the These tapered dendrite and the decreased load of each tapered dendrite on the soma. These factors can produce a higher Vs in the tapered dendrite in spite of a higher percentage voltage drop from input site to the soma in this geometry. The transient analysis has the same qualitative results, and demonstrates a faster rise time for Vs in the tapered dendrites for proximal inputs up to 100u from the soma. These results show that for one input, tapered dendrite

segments can lead to an increased sensitivity of Vs to synaptic location, and an increase in proximal synaptic efficacy with earlier arrival times as compared with cylindrical processes. Optimal shapes for axons and dendrites will be discussed.

SYNAPTIC LOCATION: DISTAL, NOT PROXIMAL, SHUNTING Synapses are both effective and selective. 70.5 Katherine Graubard and William H. Calvin, Departments of Zoology and Neurological Surgery, University of Washington, Seattle

has been suggested that critically located (such as at a branch point) proximal synapses might effectively shunt most of the synaptic current arriving from more distal synapses in that part of the dendritic tree, thus permitting one synapse to adjust the synaptic strength of whole dendrites, etc. We have tested this intuitive hypothesis in a variety of dendritic tree types and find that it is typically incorrect Indeed, for the same synaptic conductance change, distal synapses are

Indeed, for the same synaptic conductance change, distal synapses are effective at shunting current developed at more proximal synapses. Calculations were done using the Rall (1959) steady-state method. The test synapse was simply a 60 mV reversal potential in series with a on-or-off synaptic conductance of 1-10 nS (producing about 1 mV at the soma). The conditioning synapse was a pure shunt tenfold larger with reversal potential at the resting potential, as such, it is equivalent to a dendritic branch attached at the same location.

We examined the following cells: an equivalent cylinder model of cat spinal motoneuron with input to only one branch; models of the AM cell of lobster stomatogastric ganglion, the B4-5 and B8 motoneurons of Aplysia buccal ganglion, the L13 cell of Aplysia abdominal ganglion, and the rat superior colliculus' horizontal cell (see Graubard and Calvin, The Neurosoiences Fourth Study Program). The graphs below, from the AM cell with 0.25 electrotonic length and the equivalent cylinder of 1.5 length, show typical results:

Thus the most effective place for a shunting synapse is adjacent to the - but more distal sites for the SHUNT are sometimes TEST synapse quite effective because they too cause a large change in the input resistance seen by the test synapse. Though not as selective as presynaptic inhibition, a distal shunt diminishes those synaptic inputs on its dendrite far more than those on other dendrites (which are more insulated from the shunt's conductance increase). (Supported by NIH grants)

70.7 ELECTROTONIC ANALYSIS OF MOUSE VENTRAL HORN NEURONS IN CULTURE: A.C. ANALYSIS. P.B.Guthrie and G.L.Westbrook. Lab.Developmental Neurobiology, NICHD/NIH, Bethesda, MD 20205.

Neurobiology, NICHU/NIH, Bethesda, MD 20205. The complex morphological structure of most neurons produces a complex electrical structure. In order to model interactions between synaptic inputs on different processes of a neuron, a detailed description of both the morphological and the electrical structure is necessary. An a.c. (alternating current) analysis should provide a more detailed electrical description of the neuron than other methods of electrotonic analysis.

neuron than other methods of electrotonic analysis. Whole-cell patch electrode recording was used in experiments analyzing the a.c. properties of mouse ventral-horn (VH) neurons in dissociated cell culture. The low-impedance, low-capacitance patch electrodes generated lower noise and gave higher input impedances (suggesting that less damage was done to cells) than standard microelectrodes. As a result, the use of small currents (0.01-0.1nA) and small voltages (1-5mV) prevented activation of non-linear membrane properties. Patch electrodes could be unam-biguously balanced to greater than 500 Hz (allowing a single electrode to be used for both current-passing and voltage-record-inpub. For a.c. analysis patch electrodes rouged to be simplifiing). For a.c. analysis, patch electrodes proved to be significantly better than standard microelectrodes. To further improve the signal-to-noise ratio, luM TTX was added to the bath medium to suppress spontaneous activity. Impedance and phase shift (frequency range 1-500 Hz) were

Impedance and phase shift (frequency range 1-500 Hz) were determined by using either single-frequency sine wave currents or complex sinusoidal currents consisting of up to 50 linearly summed sine waves. Voltage output and current-monitor output were averaged for 16 repeat cycles of the complex stimulus. Magnitudes and phase-shifts were obtained using a discrete fourier transform. Both a.c. methods gave similar results. The characteristic frequency ( $F_0$ ) of the Bode plots (impedance vs. frequency) compared closely with the membrane time constant ( $ta_m$ ) determined with step currents or with short impulse currents quency) compared closely with the membrane time constant (taum) determined with step currents or with short impulse currents (range :  $F_0$ =36H2,taum=5msec to  $F_0$ =6H2,taum=20msec). Of interest interest, at high frequencies the phase-shift appeared to approach a maximum of less than 90° (range :  $50^\circ$  to  $80^\circ$ ). This might be attributed to reflection at the ends of dendrites. We have extensively modified SPICE2 (an electronic-circuit analysis computer model) to develop a compartmental neuronal modelling system : NEUROS. We are presently using NEUROS to model the response of HRP-filled VH neurons to step currents and to sinusoidal currents.

THE SOMATIC SHUNT CABLE MODEL OF NEURONS: DERIVATION AND 70.6 SOLUTIONS. D. Durand. Addiction Research Foundation, Inst. of Biomed. Eng., U. of Toronto, Toronto, Ont. Applied Neural Control Lab., Dept. of Biomed. Eng., Case Western Reserve University, Cleveland, OH.

The Rall cable model has been widely used to determine the electrical properties of nerve cells. The dendritic tree is replaced by an equivalent cylinder and the soma by a lumped impedance. The specific membrane resistance is assumed constant over the whole surface of the cell. Although this model has been very successful at predicting the voltage decay following the injection of current pulses in some neurons, data generated both in motoneurons and hippocampal granule cells suggest the presence In motoneurons and hippocampal granule cells suggest the presence of a shunt at the soma to account for voltage decays faster than expected by the Rall model. This shunt can be interpreted by electrode penetration damage, electronic junctions or a lower specific membrane resistance at the soma than in the dentrites. A new model was implemented consisting of an equivalent cylinder attached to a soma with a membrane time constant lower than in the

dentrites. A variable  $\epsilon$  was then introduced and defined as the ratio of the somatic to dentritic membrane time constant. A value ratio of the somatic to dentricic membrane time constant. A value of  $\varepsilon$ =1 corresponds to the Rall model with  $\tau$ s= $\tau$ m and  $\varepsilon$ <1 corresponds to the shunt model with  $\tau$ m>rs. The cable partial differential equation was then solved using this new boundary condition. The voltage decay following the injection of a short current pulse of width W into the cell is given by: #1 V(t)=CO.exp(-t/\tau0)+Cl.exp(-t/\tau1)+...+Ci.exp(-t/ti)+... where G is are the coefficients and ti are the enualizing time

where Ci are the coefficients and ti are the equalizing time constants determined by:

#2 τi=τm.(l+αi\*\*2) is the membrane time constant and ai the solutions of the 710

following transcendental equation: #3 ai.Bi.L.cotai.L=ai.L.cothL=k where:

L and p are the electronic length of the neuron and the somatic to dendritic conductance ratio. Bi is defined by: #4  $\beta i=(1-\epsilon.(1+\alpha i**2))/\alpha i**2$ 

If I is the current injected and Rn the input resistance of the neuron, the coefficients Ci are then given by: #5 Ci=2IRn(1-exp(-W/τi))(ρ+1)(τi/τm)/(βi+2ε+k+(αi.βi.L)\*\*2/k)

The inverse problem of estimating  $L, \tau m, \rho, \varepsilon$  and Rn from the measured values of CO,Cl,  $\tau O, \tau l$  is solved by reducing the system of equations #1 to #5 to a system of 2 equations (#5 for i=0 and 1) with 2 independent variables L and  $\tau m$ . Initial values for these

variables are fed into a computer program and an algorithm is then used to minimize the error between the measured and calculated values of coefficients and time constants. These equations were successfully tested on a compartmental model. Supported by NIH grant ROINSI6660-02 AND THE ADDICTION RESEARCH FOUNDATION.

MEASUREMENT OF COMPLEX IMPEDANCE BY SINE-WAVE ANALYSIS IN TRIGEMINAL GANGLION NEURONS. <u>B. Gimbarzevsky\*, R. M. Miura\* and</u> <u>E. Puil.</u> Department of Pharmacology, Faculty of Medicine, and Department of Mathematics, The University of British Columbia, Vancouver, B. C., V6T 1W5, Canada. An objective of our in vivo investigations has been to devise a methodology for estimation of certain electrical properties of neurons, not subject to the uncertainties associated with con-ventional methods using hidden balance. We have found that the 70.8

neurons, not subject to the uncertainties associated with con-ventional methods using bridge-balance. We have found that the spherical, pseudo-unipolar cells of the trigeminal root ganglion present simple electrical behaviour; their intracellular vol-tage responses indicate a circuit comprised of a resistance and capacitance in parallel. Estimates of membrane input resistance capacitance in parallel. Estimates of membrane input resistance and complex input impedance were obtained from neurons at their resting membrane potential ( $\ell = 60 \text{ mV}$ ) using single microelec-trodes (3M KCl or 5% Lucifer Yellow in 2M LiCl). These neurons were injected with small sinusoidal currents in the form of a multispectral current excitation function (MSCEF) such that MSCEF( $l = I \sin(Bte^{Ct} + D)$  or  $I \sin(BtC^{-} + D)$  where I is the amplitude of the current employed and B, C, D are empirically assigned constants. Complex impedance was calculated on-line using a pair of PDP-11 processors which were employed (1) to generate the MSCEF and sample the voltage response of the neuron and (2) to compute the total complex impedance from the ratio of the fast Fourier transforms (FFTs) of the intracellular voltage response and MSCEF(t). The amplitude of MSCEF was adjusted for a peak-to-peak displacement of membrane potential of 2-5 mV. Electrode capacitance was obtained after subtraction of the eleccomplex impedance was obtained after subtraction of the electrode resistance from the total complex impedance. When the input resistance of the neuron was calculated from a 10-20 mVinput resistance of the neuron was calculated from a 10-20 mV displacement in membrane potential caused by the injection of a pulse of current via a balanced bridge, and from a 'flat', low frequency portion of the membrane transfer function, nearly identical values were obtained. Because it became necessary to monitor electrode resistance at frequent intervals during the intracellular recordings, a second method based on a least squares fit of the theoretical transfer function to the experi-mental data was developed for estimation of electrode resist mental data was developed for estimation of electrode resist-ance, neuronal input resistance and neuronal input capacitance. Application of the conventional and FFT methods to various networks of resistors and capacitors, and to neurons, revealed the greater accuracy, and especially precision, of the FFT methodol-ogy. Another important advantage is that estimates of neuronal input resistance obtained with FFT methodology contain a smaller contribution of voltage-activated channels.

70.9 PASSIVE MEMBRANE PROPERTIES OF THE MAUTHNER CELL. W.D. Cranktand D.S. Faber (SPON: C. Smith). Div. Neurobiology, SUNYAB, Buffalo, N.Y. 14214. The membrane resistivity, Rm, of the goldfish Mauthner cell

The membrane resistivity, Rm, of the goldfish Mauthner cell (M-cell) has previously been estimated to be about 60-120  $\Omega$ cm<sup>2</sup> (Furshpan & Furukawa, J. Neurophysiol.,25:735, 1962), which is surprisingly low compared to other neurons. To more accurately determine Rm of the M-cell, a combined histological and computer modeling study was undertaken. The objective was to base the Rm estimate on accurate, detailed knowledge of cell shape and size.

M-cells were reconstructed from 30µm serial sections after iontophoretic HRP fills at the soma. Each reconstructed cell was divided into about 50 branches which were outlined on the digitizer tablet of a computer. Each branch was divided into many short (0.5 to 1.0µm) segments. Assuming circular Xsection, each segment was taken to be a truncated cone. Total cell surface area was computed by summing edge surface area of all such segments from all branches. A resistive model of the cell was formed by representing each segment with axial and surface membrane resistances. Resistance values depended on segment dimensions and assumed resistivities. Analysis of branch diameters showed that neither the lateral

Analysis of branch diameters showed that neither the lateral nor ventral M-cell dendrites follow the 3/2 power relationship, which implies that an equivalent cylinder representation is not justified. M-cell surface area averaged  $2.65 \times 10^{-3}$  cm<sup>2</sup>. Multiplying by an input resistance value of 167 kg (Faber & Korn, J. Neurophysiol., 248:654, 1982), we estimate an upper bound for Rm of 442 g cm<sup>2</sup>. The resistive model made possible a more accurate estimate of Rm by taking into account the cell's cable-like behavior. For different assumed membrane resistivities, maps of input resistance over the entire cell were computed. Computed input resistance at the soma agreed with the experimental value when Rm was about 200 gcm<sup>2</sup> (n=3 cells). Our Rm estimate is higher than that of Furshpan and Furukawa, but is still low compared to other neurons.

cells). Our Rm estimate is higher than that of Furshpan and Furukawa, but is still low compared to other neurons. From this Rm estimate and the 0.39 msec time constant of the M-cell (Fukami, Furukawa, & Asada, <u>J. Gen. Physiol.</u>, 48:581, 1965), we estimate M-cell specific capacitance to be about 2.0 µF/cm<sup>2</sup>. This value is within the range expected of a biological membrane (Cole, <u>Membranes, Ions, and Impulses</u>, 1968). Previous estimates were significantly higher. One might suspect the low Rm to be due to coupling with the fibers forming electrotonic junctions on the M-cell. However, uncoupling with co<sup>++</sup> injections does not markedly affect input

One might suspect the low Rm to be due to coupling with the fibers forming electrotonic junctions on the M-cell. However, uncoupling with Co<sup>++</sup> injections does not markedly affect input resistance (Faber, Kaars, & Zottoli, <u>Neurosci.,</u>5:433, 1980). Therefore, the low Rm may be an inherent property of the membrane itself. (Supported by NIH grant NS15335)

70.11 DIGITAL ANALYSIS OF RELATIONS BETWEEN OLFACTORY RECEPTOR MORPHOLOGY AND UNIT FIELD POTENTIALS <u>G. D. Adamek and R. C. Gesteland</u>. Nose City, Northwestern Univ., Evanston, IL 60201 Unit field potentials recorded from olfactory receptor neurons of terrestrial vertebrates have more complex waveforms than any reported from elsewhere in the nervous system. The symmetry of the epithelial anatomy and the regular changes in cell morphology with developmental age permit identification of the processes contributing to the field potential. Knowing these we can infer the mechanisms of impulse initiation and propagation. We use ultra-low noise metal filled electrodes fabricated from patchtype glass blanks to record single units extracellularly. Waveforms are digitized at sampling intervals of 20 us using a processor with dual-bus architecture for direct memory access. In this work we examined how these waveforms varied with electrode position and between spontaneous and odor-evoked events, and as a function of regenerating epithelium thickness. We also found extracellular noise changes with durations comparable to those of action potentials. These are probably local membrane conductance increases which are subthreshold for action potential initiation. These have not been reported before. Action potential waveforms recorded from shallow penetrations are simple and of low amplitude. The receptor dendrites lie in this region. Below this, multiphasic, notched waveforms are seen. The relative amplitudes of the peaks and notches change systematically as the electrode the tayer occupied by the receptor somata. The depth of the soma of a cell and its dendrite length depend upon the developmental age of the cell. The most recently differentiate neurons lie deepest and have the longest dendrites. As new neurons are added just above the basement membrane, the somata of older cells are displaced upward and the dendrites shorten. Our results show that spike waveform can be used as a measure of the maturation state of the r

Supported by NSF BNS-8117075 and NIH NS18490 and NS14663.

70.10 CABLE PROPERTIES, SURFACE HETEROGENEITY AND CIRCUITRY OF CULTURED MURINE SPINAL CORD NEURONS MEASURED USING MULTIPLE PATCH ELECTRODE EXTRACELLULAR RECORDINGS. <u>R.P. Rand and B.</u> <u>Middagh</u>\*. Brock University, St. Catharines, Ontario L2S 3A1 Canada.

We have previously demonstrated that the patch electrode can be used as an extremely sensitive, non-destructive extracellular electrode of high spatial resolution. It measures to a large extent membrane patch capacitive current. In co-cultures of DRG and Raphe cells 'minispiking' in the submicroscopic architecture of neural processes could be detected and, rarely, the coupled activity of interconnected cells could be seen (Brain Res. 249; 371). We have extended these initial studies to the rather well characterized murine spinal cord tissue cultures in an attempt to measure the cable properties of neural processes, the possible heterogeneity of membrane conductance over the surface of neurons and the nature of the circuitry in this system. Unlike the former system 'minispiking' is rare. Simultaneous recording from two moveable patch electrodes provides an easy measure of conduction velocity of neurites, derived from multiple pairs of recording sites on the same neuron. When derived from the high spontaneous activity of these cultures the spatial-temporal relationships of the signals in these paired recording soften suggest that signal origins are multiple and the connectivity too complex to derive unambigious circuits. We have grown these cells in microcultures of 5-7 cells but the spontaneous activity is still too complex. Although often the measured patch current is a simple time derivative of the simultaneously measured membrane potential, at different sites on the same cell its time course can be qualitatively different. We are attempting to determine the contribution of intrinsic cable properties, surface heterogeneity of membrane conductance and possible artefacts derived from the patch technique to this difference. 71.1 DIFFERENCES BETWEEN MYELIN-ASSOCIATED GLYCOPROTEIN FROM CENTRAL AND PERIPHERAL MERVOUS SYSTEMS DETECTED WITH MONOCLONAL ANTI-BODIES. L.S. Marton\* and K. Stefansson\* (SPON: E.M. Stadlan). Department of Neurology and The Brain Research Institute, University of Chicago, Chicago, Illinois 60637. Myelin-associated glycoprotein (MAG) (approximately 100,000 daltons) is a minor component of myelin. Originally it was found to be associated with myelin of normal brains. Immunocutochemical studies tweine melanal actionen here chem MC

Myelin-associated glycoprotein (MAG) (approximately 100,000 daltons) is a minor component of myelin. Originally it was found to be associated with myelin of normal brains. Immunocytochemical studies using polyclonal antisera have shown MAG to be located in the periaxonal region of mature myelinated axons and in the cytoplasm of oligodendroglia just before and during myelination. (Sternberger, N.H. et al. <u>PNAS</u> 76:1510, 1979) Subsequent biochemical investigations have demonstrated the presence of MAG in the peripheral nervous system (PNS). Our work with monoclonal antibodies indicates that CNS and PNS MAG may be different.

We have raised and characterized a rat monoclonal antibody (mab) that in Western blots binds to MAG purified from human hemispheric white matter. In tissue sections the mab stains brain and spinal cord myelin, and it stains peripheral nerve myelin very intensely. No staining of tissues outside of the nervous system was found. We have also studied a patient with monoclonal gammopathy and neuropathy whose monoclonal antibodies bind to MAG on Western blots and show the same immunohistochemical staining pattern of human central and peripheral myelin as the rat mab. (Stefansson, K. et al, <u>Acta Neuropath</u>. <u>59</u>, 255, 1983) When we used Western blots to compare binding of the rat mab and the patient's mab to chloroform-methanol extracted homogenates of cerebral white matter and peripheral nerve we found some differences between the antibodies. Although both the patient's serum and the rat mab gave intense specific staining of CNS MAG, only the rat mab bound to peripheral nerve MAG. There was insignificant staining with the patient's serum. In addition, we were unable to block binding of the rat mab to CNS MAG with the patient's serum and vice versa. These results indicate that the rat and patient mab's recognize different antigenic determinants and furthermore they imply that PNS MAG may be distinct from CNS MAG. 71.2 IMMUNOBLOT IDENTIFICATION OF MYELIN BASIC PROTEIN IN GOLDFISH CNS MYELIN. <u>B.I. Roots</u>, <u>D. Agrawal\*</u>, <u>G.</u> <u>Weir</u> and <u>H.C. Agrawal\*</u> Dept. of Zool. Univ. of Toronto, Erindale College, Mississauga, Ont., L5L 106. <sup>2</sup> Dept. of Ped., Wash. Univ. Sch. Med., St. Louis, Missouri, 63178.

Louis, Missouri, 65176. Coldfish were acclimated to 5°, 15° and 30°C and myelin was subsequently isolated. The myelin isolated from the brain and spinal cords exhibits a characteristic multilamellar structure with distinct major dense lines and intraperiod lines. When the proteins of brain myelin from fishes acclimated to these temperatures were analyzed by SDS-slab gel electrophoresis, there was a progressive increase in the proteins with a molecular weight of 13.5K with the increase in temperature ( $5^{\circ}C-30^{\circ}C$ ). In order to establish that the 13.5K protein is, in fact, related to myelin basic protein of rodents, proteins of goldfish and rat brain myelin were separated by SDS gel electrophoresis, transferred to nitrocellulose sheets, and immunostained with anti-serum to human large basic protein (LBP) by the immunoblot technique. Since this protein in it is reasonable to conclude that this protein in goldfish myelin was recognized by anti-serum to LBP, it is reasonable to conclude that this protein in goldfish myelin has antigenic sites similar to rat and human brain myelin basic protein. Surprisingly, the three proteins migrating to the position of 21K, 18K and 15.5K basic proteins were also immunostained. In addition, a number of high molecular weight proteins were also immunostained with anti-LBP serum. Furthermore, when proteins of goldfish myelin were immunostained with anti-PLP serum, no protein migrating to the position of proteolipid protein was seen. These observations induce us to postulate that the presence of PLP may Induce us to postulate that the presence of the intraperiod line. The significance of these observations in relation to the formation of the multilamellar myelin sheath will be discussed. This work was supported by grants from NIH, NS-19414 (H.C.A.) and NSERC, A6052 (BIR).

71.3 APPEARANCE OF THE GLIAL FIBRILLARY ACID PROTEIN AND PHOSPHORYLATION OF THE NEUROFILAMENT PROTEINS IN THE DEVELOPING RAT NERVOUS SYSTEM. Michael J. Noetzel, Betty I. <u>Roots</u> and <u>Harish C. Agrawal</u>. Washington Univ. School of Medicine and University of Toronto, Erindale College, Ont., Canada L5L IC6.

We have systematically studied the appearance of the glial fibrillary acidic protein (GFAP) in the nervous system of rats from birth to 37 days of life. Filaments were prepared from spinal cord and whole brain according to the method of Chiu, <u>et al.</u> (J. Neurochem. 27:147, 1981). Neurofilament preparations isolated from newborn spinal cord and brain were examined by electon microscopy; morphlogically distinct neurofilaments were clearly observed at birth. Filament proteins were separated by SDS-slab gel electrophoresis, transferred to cellulose nitrate sheets and immunostained with monospecific antiserum to bovine GFAP. This protein was present in spinal cord and whole brain preparations at birth. These studies were extended to determine if GFAP is phosphorylated at any stage of development. Rats (ages 0, 7, 14 and 36 days) were injected intracerebrally with  $^{32}$ P-orthophosphate and sacrificed 24 h later. The filaments were isolated as described above. To determine if GFAP may be phosphorylated, the filament proteins were fluorographed. The glial fibrillary acidic protein preserve fluorofilament specific neurofilament proteins (NFP: 210K, 145K and 70K) were clearly phosphorylated at all ages. The significance of phosphorylation of each of the individual neuronal specific neurofilament proteins (NFP: 210K, 145K and 70K) were clearly phosphorylated at all ages. The significance of phosphorylated at all specific neurofilament proteins (NFP: 210K, 145K and 70K) were clearly phosphorylated at all ages. Supported by NH Grants 2-807-RN05389-22 and NS 19414.

71.4 SCHWANN CELLS CONTAIN A PROTEIN SIMILAR TO THE CNS ASTROCLIAL FILAMENT PROTEIN. <u>S.-H. Yen\*</u> and <u>K. L.</u> <u>Fields\*</u>, (SPON: W. T. Norton). Dept. of Pathology<sup>1</sup>, Neurology<sup>2</sup> and Neuroscience<sup>2</sup>, Albert Einstein College of Med., Bronx, NY 10461.

Med., Bronx, NY 10461. An antiserum raised against the 49,000 dalton major protein subunit of human glial filaments (GF) binds to some elements in the peripheral nervous system. The GF related antigens in the peripheral nerve (PNS-GF) are detected by immunofluorescence in rat sciatic nerve, vagus nerve and bovine splenic nerve. They are distributed as single fibers or bundles of long thin fibers and are more abundant in unmyelinated nerves than in mixed nerves. In the rat sciatic nerve they develop postnatally after day 12 and they remain in the nerve after transection. In teased nerves the immunofluorescent positive elements appear to be Schwann cells closely associated with unmyelinated axons. The PNS-GF are insoluble in Triton X-100 but could be extracted by 2% SDS. Electrophoresis of sciatic or splenic nerve cytoskeleton on SDS polyacrylamide gels shows that each preparation contains a protein band at the same molecular weight as the glial filament protein of rat brain astrocytes. Bovine splenic nerve preparations appear to have a higher concentration of PNS-GF than the sciatic nerve judging by Coomassie blue stain. Immunoblots of peripheral nerve cytoskeleton preparations show that the anti-GF antiserum reacts strongly with the protein band that tomigrates with CNS-GF. The antiserum, in addition, binds weakly to a 58,000 dalton protein, which is more abundant than the PNS-GF band and comigrates with vimentin. Both the 58k and the GF (50k) bands react with the Pruss anti-IF monoclonal antibody. Incubation of the anti-GF antiserum with the cytoskeleton preparation of cultured rat astrocytes or chromatographically purified rat brain glial filament protein removes the antibody that binds to Schwann cells in tissue sections or the protein bands in SDS gels. The results demonstrate that Schwann cells of unmyelinated nerves contain a protein of immunological and biochemical properties indistinguishable from the CNS astroglial

PROLIFERATON AND SPECIFIC PROTEIN PRODUCTION IN OLIGODENDROCYTES 71.5

AND OTHER GLA FOLLOWING TRAINA. S.K. Ludwin\*. Dept. of Pathology, Queen's University, Kingston, Ontario. Gliogenesis in the developing mammalian brain has been well studied, but it has long been felt that mature oligodendrocytes were post-mitotic cells, and did not proliferate in the mature central nervous system. In experimental models of demyelination and remvelination oligodendrocytes have been been to duride. In and remyelination, oligodendrocytes have been shown to divide. In addition, oligodendrocytes during remyelination have also shown addition, oligodendrocytes during remyelination nave also snown the presence of both myelin basic protein (BP) and myelin associated glycoprotein (MAC) in their cytoplasm, recapitulating the pattern seen in normal development. In order to determine whether the oligodendrocyte proliferation and specific production of proteins were a specific response to demyelination or remyelination or represented a more general response to central nervous system injury, small pieces of cortex were removed from adult male mice, and the proliferation of glial cells was studied by light and electron microscopic autoradiography. In some of the animals the fragments of tissue removed were replaced by explants of fetal and adult tissue. The brains were examined for the presence of both myelin oligodendrocyte proteins (myelin basic presence of both myelin oilgodendrocyte proteins (myelin basic protein MBP and myelin associated glycoprotein, MAG) and astrocyte specific protein (glial fibrillary acid protein, GFAP). Three days after the induction of trauma a brisk mitotic response was seen in all the animals. Astrocytes and microglia showed marked uptake of tritiated thymidine. Labelled oilgodendrocytes, indicating recent division, were found easily not only adjacent to injured tissue, but also in apparently normal tissue away from the site of the lesion. Although medium oligodendrocytes were most frequently labelled, occasionally dark oligodendrocytes also Mitosis occurred in intrafasicular (white contained label. perineuronal satellite oligodendrocytes. The frequency of labeling diminished the further away from the lesion, but labeled cells were seen across the corpus callosum into the white matter of the opposite hemisphere, as well as in the basal ganglia. Concomitant with the astrocytic proliferation, was a marked increase in the production of GFAP. In contrast only very scaling was seen in oligodendrocytes after injury, but the amount did not appear to be that much greater than that seen in normal animals. The results tend to suggest that oligodendrocyte proliferation can occur following nonspecific injury, but that the production of proteins specifically related to myelin is not necessarily stimulated by the same factors as those causing proliferation.

MYELIN DEVELOPMENT IN HUMAN INFANT BRAIN (VICTIMS OF SUDDEN INFANT DEATH SYNDROME), S. E. Poduslo and Y. Jang\*. Dept. of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD 21205. Johns Hopkins University School of Medicine, Baltimore, MD 21205. Infants in Maryland who are victims of Sudden Infant Death Syn-drome (SIDS) are required to undergo autopsy. Brain tissue from these infants was obtained through the SIDS Institute at the University of Maryland School of Medicine. Ten samples were evaluated (including two controls), with ages ranging from 24 to 350 days. Gray and white matter samples from each age were dis-sected for analysis. Myelin and other membrane subfractions were also isolated from each brain. Lipids were extracted from all the samples and were analyzed. No abnormalities in lipid composition samples and were analyzed. No abnormalities in lipid composition were found with any of the SIDS samples. It was found that the lipid composition of whole gray matter

It was found that the lipid composition of whole gray matter showed little change during development. Total galactolipids showed a slight increase (1.5% to 3.0% of the total lipids), while phosphatidylcholine declined (32% to 25% of the total lipids). The cholesterol and plasmalogen content remained relatively constant. The developmental changes in the lipid composition of whole white matter were more interesting. There was very little white matter present in whole brain during the younger ages examined. The amount of lipid as a per cent of the total wet weight increased from 4% to 9% during development. Total galactolipids increased from 12% to 23%, with the increase primarily in cerebrosides (9% to 19%). Total phospholipids decreased (65% to 54%), with the decrease mostly in phosphatidyl-choline (23% to 15%). The plasmalogens also increased (10% to 14%). 14%).

Even though there was little white matter present at the younger ages, it was possible to isolate myelin from the tissues. The yield was quite low as expected. The yield of myelin increased during development from 0.5 to 5.8% of the total wet weight. Surprisingly the lipid composition of the myelin samples obtained even from the younger infants was quite similar to adult wyelin. Galactolipids were 22% of the total lipid, cholesterol, 23%, and phospholipids, 52%. There did appear to be a slight increase in plasmalogens (11% to 16%) and a possible decrease in phosphatidylcholine (20% to 14%).

Thus myelin was isolated from infant brains during the first year of life. While the yield of myelin increased during develop-ment, the lipid composition was similar to adult myelin. Since the control samples fit quite well into this developmental pattern, it is concluded that there are no abnormalities in the lipid composition of myelin obtained from victims of Sudden Infant Death Syndrome.

- Complement Activation by Myelin: The binding and Activation of Ci in serum by isolated myelin results in formation of myelin mem-71.6 brane-associated membrane attack complex (MAC) of complement. M.L. Shin\*, B.A. Sliverman\*, P. Vanguri\*, and D.F. Carney\* (SPON E. Glaser). Dept. Path., Univ. Md. Sch. Med., Balt., MD. 21201. Many pathological conditions of the central nervous system involve damage to and removal of myelin membrane. Extensive phago-cytosis of myelin by macrophages and astrocytes and release of myelin constituents into cerebrospinal fluid and into systemic circulation following CNS injury have been well documented. How-ever, very little is known about the initiation of this membrane damage and mechanism of disposal of the damaged tissue. We are interested in the interaction between complement and myelin membranes and its possible role in the disposal of damaged myelin in vivo because activation of complement generates both opsonin(s) and membrane attack complexes (MAC, C5b-9). Myelin isolated from brains of rat, mouse or human directly activates serum complement, while non-myelin membranes from the same brain do not. Activation while non-myelin memoranes from the same brain do not. Activation of complement is shown by Cl transfer from myelin, cleavage of C3, and C5 consumption by myelin. Such activation generates C3b, an opsonic fragment, as well as inflammatory peptides such as C3a and C5a. We are further interested in whether activation of early acting complement components by myelin leads to the generation of MAC and the formation of myelin membrane-associated MAC, since activation and consumption of complement proteins does not always result in membrane damage (Joiner et al., J. Exp. Med. result in membrane damage (Joiner et al., J. Exp. Med. 155:797-919). Purified rat myelin was incubated with fresh human serum or with heat inactivated human serum for 60 min at 37°C. Myelin was then washed with 0.3M NaCl, 0.02M EDTA buffer, and solubilized with 1% Triton X-100 and 0.25% DOC. Aliquots of this solution were placed on a 40%-5% linear sucrose gradient. Gradi-ents were centrifuged at 36,000 rpm for 16 hrs in a Beckman ultra-centrifuge with SW 50.1 rotor, and fractionated. Each fraction was dialyzed and tested for the presence of MAC antigen by ELISA with Rabbit IgG against human MAC neoantigen, kindly supplied by Dr. Bhakdi. Detection of MAC in similar gradients of zymosan acti-vated human serum or untreated human serum served as positive and negative controls. In this control gradient, fractions were as-sayed for MAC as well as the functional activities of C5. A sin-gle peak of MAC was observed at the base of the gradient of myelin incubated with human serum. MAC antigen was not detected in any fractions from gradient of myelin incubated with heat inactivated result fractions from gradient of myelin incubated with heat inactivated serum. MAC-containing fractions were further analyzed for subunit structure of MAC by SDS-PAGE, electroblotting and immunostaining. The results showed the presence of subunit structure of MAC, C5-C9. The lane stained with anti-C9 revealed bands corresponding to both C0 dimon can woll as concerned. to both C9 dimer as well as monomer.
- SAXITOXIN BINDING TO AMYELINATED MUTANT RAT BRAIN AND SAXITOXIN BINDING TO AMYELINATED MUTANT RAT BRAIN AND SPINAL CORD, A. L. Oaklander\*, R. G. Pellegrino\* and J. M. Ritchie\*<sup>1</sup> (SPON: P. S. SPENCER). Institute of Neurotoxicology, Departments of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, N.Y. 10461, and <sup>1</sup>Dept. of Pharmacology, Yale University School of Medicine, New Haven, CT 06011. Myelin deficiency (md) is an X-linked mutation in the Wistar rat characterized by failure to develop CNS myelin, tremors that worsen with age, and death at about 25 days of age. In this study, the md mutant was used to determine the effects of myelination on saxitoxin-binding

used to determine the effects of myelination on savitaxin-binding capacity during postnatal development of the rat CNS. Saxitaxin (STX) is a taxin which binds specifically to voltage-sensitive sodium channels. 3H-STX binding was assayed in the brain and spinal cord of 6- and 21-day-old md rats and their normal littermates. These timepoints encompass the period of most active myelination in the rat CNS.

Maximum binding values (fmol/mg wet weight) were as follows:

	BRAIN		SPINAL CORD		
	md	<u>control</u>	md	<u>control</u>	
6 DAY	18	17	40	40	
21 DAY	71	57	53	64	

No significant change in apparent  $\mathsf{K}_{\mathsf{d}}$  was observed between md and control.

No statistically significant differences in STX-binding capacity were No statistically significant differences in STX-binding capacity were detected between md rats and normal littermates. This suggests that the presence or absence of myelin does not influence voltage-sensitive sodium channel density in rat CNS. A statistically significant increase (p 0.01) in STX-binding capacity was detected between 6 and 21 days in both brain and spinal cord. Thus, increased STX-binding capacity is associated with postnatal neural maturation in the rat CNS. In addition, at 6 days, STX binding is significantly greater (p 0.01) in spinal cord than in brain. This is consistant with the caudorostral axis of CNS maturation.

In summary, STX-binding capacity in the rat CNS appears to increase with maturation, but seems unaffected by amyelination.

71.9 THYROID ABNORMALITIES IN MYELIN DEFICIENT JIMPY MICE. R.P. <u>Skoff and K.M. Liu\*</u>. Dept. of Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

of Med., Detroit, MI 48201. In a previous report (Skoff et al, Life Sciences, 24:2099, 1979), we reported morphologic abnormalities in the pftuitaries and thyroid glands of jimpy-Tabby mice. As the animals were examined shortly after birth, we were unable to determine whether these changes were due to the jimpy gene or to the Tabby gene which is closely linked to the jimpy gene. To determine which gene is responsable for the abnormalities, we have studied crossover animals which express the jimpy gene but lack the Tabby marker gene (+jp/Y). Jimpy males (+jp/Y) were compared to normal males (++/Y), Tabby males (Ta/Y), Tabby-jimpy males (Tajp/Y) and female carriers of the jimpy gene (Tajp/Ta+). The mice examined ranged in age from 14 to 22 days postnatal. At these ages, the animals exhibit tremors characteristic of the jimpy mutation and show the tabby coat color due to the Tabby gene. A light and electron microscopic quantitative analysis was performed on 7 jimpy males, 7 normal males, several Tabby-jimpy males and female carriers. The results of this analysis show that the thyroid glands of the jimpy-non-Tabby animals are similar to that of the newborn jimpy-Tabby mice. In the jimpy thyroids, the follicular cells are columnar and sparsely distributed around the colloid. In contrast, the follicular cells of the normal animal are cuboidal and somewhat evenly spaced around the follice. The number of follicular cells surrounding the colloid of the jimpy mice is half the normal values. The follicular cells themselves are very densely stained and some of them appear pyknotic in the jimpy. A the ultrastructural level, large extracellular spaces are present between the jimpy follicular cell in the jimpy is accompanied by a small capillary. Quantitative analysis reveals a twofold increase in the number of vessels associated with a follicle. However, other parameters of the thyroid gland are normal including the size of the gland, the number of follicules and the surface volume of the colloid. Thus, the development and 71.10 ACYLATION OF PLP AND DM-20 IN THE QUAKING MOUSE. M.M. Garwood\* and H.C. Agrawal (Spon: T.W. Jasper). Dept. of Pediatrics, Wash. Univ. Med. Sch., St. Louis, MO 63178.

Myelin isolated from quaking mouse brains has been reported to have a severe deficiency of PLP. This study was designed to examine, in vitro, the synthesis and acylation of PLP and DM-20 in the whole brain and myelin of quaking, littermate control,  $_3$  bomozygous domigant control and albino mice, using  $^{35}$ -cystine and  $^{34}$ -palmitic acid. Proteins of the whole brain and myelin were separated by SDS-gel electrophoresis, the gels were stained with Commassie blue and the radioactivity determined by liquid scintillation spectrometry or fluorography. Evidence will be presented that a band migrating exactly to the position of PLP is apparently absent while DM-20 is present in the whole brain extract and myelin of the quaking mutant. These findings were confirmed by transferring the proteins from acrylamide gels to cellulose nitrate sheets, followed by immunostaining with antiserum to rat brain myelin PLP by the immunoblot technique.

the immunoblot technique. Since PLP has been shown to be acylated in vivo (Agrawal, H.C., et al., J. Biol. Chem., 257; 4588, 1982) and in vitro (Townseqd, L.E., et al., J. Biol. Chem., 257; 9745, 1982) by "H-palmitic acid, brain sliges from the four groups of animals were incubated with "Hpalmitic acid and "35 s-cystine, and the myelin proteins and Folch-Lees proteolipid protein fraction from the whole brain were subjected to SDS gel electrophoresis. The gels were sliced into 1 mm sections and the tradioactivity was determined. DM-20 was clearly labeled in quaking brain as well as in the brains of the three control groups. However, there was little labeling of PLP in brains of quaking mice, whereas PLP from the three control groups was well labeled under identical conditions. The significance of these results will be discussed.

71.11 MODULATION OF EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS (EAE) IN GUINEA PIGS BY POST-SENSITIZATION ADMINISTRATION OF AN ANTI-T CELL MONOCLONAL ANTIBODY. R.A. Sobel\*, B.W. Blanchette\*, J.L. Hanzakos\* and R.B. Colvin\*. (SPON: L.R. Wechsler). Dept. of Pathology. Massachusetts General Hospital, Boston, MA 02114.

Pathology, Massachusetts General Hospital, Boston, MA 02114. EAE is a well characterized, T-cell mediated, neuroimmunological disease model. To investigate the role of T cell immunoregulation in vivo in EAE, adult (>500g) strain 13 guinea pigs (GP) were sensitized with GP spinal cord and complete Freund's adjuvant. Ten days after sensitization, 12 GP were given a single intraperitoneal dose of 3.4 mg 8BE6, an anti-GP pan-T cell monoclonal antibody (E. Shevach, NIH). In preliminary studies, this dose caused a transient decrease in circulating T cells and suppressed delayed hypersensitivity skin reactions. Controls received 3.4 mg MOPC 21, the parent mouse myeloma (5 GP), normal saline (3 GP), or no treatment (2 GP). CNS tissues were analyzed in luxol-fast blue-H.& E.-stained paraffin sections and 4 micron cryostat sections stained with monoclonal antibodies to T cells and IgM, using avidin-biotin immunoperoxidase techniques. 10/10 MOPC 21, saline, and untreated controls and 4/12 8BE6-treated GP developed acute, paralytic EAE, 11-21 days after sensitization (p<.002) and had typical mononuclear infiltrates composed of many T cells and few IgM+ cells. The other 8BE6-treated GP were well or showed mild neurologic deficits. They had large demyelinative plaques and persistent parenchymal and meningeal T and IgM+ cell CNS infiltrates characteristic of chronic FAE. Five other GP were treated with 8BE6 from days 11-13 at the earliest arapid neurologic deterioration within hours after treatment and showed loss of T cell staining, necrosis of inflammatory cells, and prominent acute inflammatory cells and fibrin deposits in CNS sections. These experiments demonstrate: 1) a new model of chronic EAE (previously only occurring consistently in GP sensitized as juveniles) produced by post-sensitization modulation with an anti-T cell monoclonal antibody and 2) acute neurologic deterioration associated with T cell lysis following anti-T cell monoclonal antibody therapy given after the onset of neurological signs. The 71.PO PROCEDURE FOR ISOLATION OF GANGLIOSIDES FROM SMALL- AND MEDIUM-SIZE SAMPLES IN HIGH YIELD AND PURITY. <u>R.W. Ledeen, M.C. Byrne\*</u>, J.R. Sclafani\* and D.A. Aquino\*. Depts. Neurol. and Biochem., Albert Einstein College of Medicine, Bronx, NY 10461. Now that gangliosides have been shown to induce neurite growth

Now that gangliosides have been shown to induce neurite growth and to manifest other biological properties in neural cells, greater attention is being paid to the purity of ganglioside preparations. This aspect was not dealt with in detail among the several published methods for ganglioside isolation; our study has found some of these to yield preparations with considerable levels of phospholipid and peptide contamination. Lipophilic peptide contaminants are a particular problem in gangliosides isolated from CNS white matter and peripheral nerve. We have found that both purity and yield can be significantly enhanced by a procedure employing Sephadex LH-20 chromatography as the first step, which removes much of the peptide. A key feature of this method is mild acidification (0.05 N HCl, final conc.) of the mixture <u>after</u> thorough homogenization of the tissue in 10 vols of chloroform (C)methanol (M)-water (W) 5/5/1. This insured complete extraction, especially for white matter and nerve, presumably by dissociating gangliosides from (basic) proteins. The supernatant resulting from centrifugation is applied to a 17 g colum of LH-20 (16 x 585 mm) packed in the same solvent (no acid). This removes most of the low MW contaminants as well as the acid. The gangliosidecontaining fraction is then passed through DEAE-Sephadex A-25 and the eluted gangliosides treated with base as described (J. Neurochem. <u>21</u>:839,1973). Base and salt are removed from this mixture by a second Sephadex LH-20 column, 18-19 g packed in M-W 95/5 (16 x 500 mm). Before packing, the LH-20 is thoroughly washed with M-W 95/5 containing 0.3 M KOH and then M-W 95/5. The sample in 4 ml of this solvent, after centrifuging, is applied to to column and eluted with the same solvent. Some of the residual peptide contaminants are also removed in this step. Repetition of this chromatography may be carried out to insure a completely saltfree sample. The gangliosides are finally purified on a small silica gel column of latrobeads or Unisil as described (

NODE-LIKE COMPLEXES IN THE SPINAL CORD OF MYELIN-DEFICIENT MUTANT 71 PO BENTS. J. Rosenbluth. Depts. of Physiology and Rehabilitation dicine, N.Y.U. School of Medicine, New York, N.Y. 10016. Nodes of Ranvier in the CNS are known to have an "undercoated" RODENTS. Medicine. axolemma surrounded by a widened extracellular space containing a matrix material. Astrocytic microvilli have also been shown to surround the node in some cases. Based on these characteristics, several examples of node-like specializations associated with astrocytic processes have been identified in fiber tracts chronastrocytic processes have been identified in fiber tracts chron-ically demyelinated by EAE (Soffer & Raine, Brain Res., 186:301, 1980) or a glial toxin (Blakemore, personal communication) as well as in a region normally lacking myelin, the retina (Hilde-brand & Waxman, Brain Res., 258:23, 1983). Equivalent aberrant nodal specializations have also been seen in the amyelinated spinal roots of dystrophic mice (Rosenbluth, J. Neurocytol., 8: 655, 1979) at sites of contact with Schwann cells.

525, 1979) at sites or contact with Schwann cells. In the present study, two mutants having grossly deficient CNS myelin, the jimpy mouse and the myelin-deficient rat, have been examined in order to determine whether such node-like complexes occur here as well. Survey of the spinal cord by electron micros-copy of thin sections in both cases shows examples of axons that display a dense undercoating, usually extending only part way around their circumference, and a coextensive widened extracellular space. A matrix material is often visible in this space, usually in the form of a discontinuous, fuzzy lamina just outside the axolemma. Astrocytic processes surround the specialized region but usually do not form microvilli. No such complexes have been seen where axons are directly apposed to each other.

Since peripheral myelin is relatively normal in these mutants, the deficiency in the CNS myelin presumably arises from a defect in the oligodendrocytes. Thus, axons can form complexes resem-bling nodes of Ranvier in the CNS, even in the absence of contact with normal oligodendrocytes, where they are associated with astrocytic processes. Freeze-fracture studies have not so far shown corresponding E face particle accumulations in the axolemma. This could merely reflect the rarity of such node-like complexes or could indicate that undercoating of the axolemma in aberrant lo-cations is not necessarily associated with intramembranous particle accumulation.

CELL AND TISSUE CULTURE: BEHAVIOR OF NEURAL, GLIAL, MUSCLE, AND MODEL CELLS

A REPLICA PLATING TECHNIQUE FOR DETECTING MUSCLE CELL VARIANTS 721 THAT ARE DEFICIENT IN THE ACETYLCHOLINE RECEPTOR. R.A. Black\*, R. Brown\*, and Z.W. Hall (SPON: J. Bixby). Div. Neurobiol. Dept. Physiol., Univ. Calif., San Francisco, CA 94143. Genetic variants of established cell lines offer a powerful tool for defining physiological roles and the pathways of tool for defining physiological roles and the pathways of assembly and maturation of particular proteins. Application of this approach to problems of synaptic differentiation in muscle cells has previously been limited by the availability of suit-able cell lines and by the difficulty of selecting appropriate mutants. Mutant selection is complicated by the fact that many of the proteins of interest are synthesized only after the cells have withdrawn from the cell cycle and have fused to form myotubes.

We have attempted to establish a system in which muscle cell we have attempted to establish a system in which muscle cell variants can be selected using C2, a mouse cell line whose pro-perties in culture resemble those of primary muscle cells (Inestrosa et al, <u>Exp. Cell Res.</u> in press). The system is based on a replica plating technique for animal cells devised by Raetz et al (PMAS, USA 79, 3223 (1982)). As an initial test we have attempted to select variants that lack normal levels of the acetylcholine receptor (AChR).

We screened for variants by plating myoblasts at clonal den-sity in a tissue culture dish and overlaying them with a poly-ester cloth. As the cells proliferated, each colony partition-ed between the cloth and the dish. After several days, the cloth was removed and placed in medium which induces myotube formation. Myotubes were found to form on the cloth and to synthesize AChRs, which were detected by autoraliography of the cloth after incubation with  $^{125}\mathrm{I-}\alpha\text{-bungarotoxin}$ . The cloth was subsequently stained to make the colonies visible, and AChRdeficient clones were located by comparing the stained cloth with the autoradiogram. Myoblasts from clones of interest were then recovered from the original plate. In an initial screen with 2500 colonies derived from cells

mutagenized with ethyl methanesulfonate, six colonies were identified as deficient in AChR. These were recloned and, after growth in fusion medium, the amount of AChR in cell extracts was quantitated by binding of  $^{125}\mathrm{I-}$   $\alpha-\mathrm{bung}$ arotoxin. All had less than 25% of the wild-type level of AChR; control clones which were AChR-positive in the screen had levels of AChR 70-100% that of the wild-type cells. Of the six variants, five fused poorly, suggesting that they were defective in some aspect of differentiation. The sixth showed excellent fusion. Further characterization of this mutant is in progress. (This work was supported by Fellowship DRG-612 of the Damon Runyon-Walter Winchell Cancer Fund and by grants from NIH and MDA.)

72.2 SERUM AND SUBSTRATUM-MEDIATED INFLUENCES OF NEURITE GROWTH.

S. Varon, S.D. Skaper, G. Davis\*, I. Selak and M. Manthorpe. Dept. Biol., Sch. of Med., Univ.of Calif. San Diego, La Jolla, CA 92093. Modulation of neuritic growth involves both influences exerted directly on the growth cone by factors present in its humoral en-vironment and influences mediated by or presented from the surfaces (cellular or extracellular) with which the growth cones come into contact. The classical example of a humoral influence is Nerve Growth Factor (NGF). The importance for neuritic growth of surface interactions has been well-established, and there is evidence for soluble biological macromolecules which promote neuritic outgrowth only after they have become surface bound.

In the present study, we have compared neuritic behaviors of selected neural tissues under the influence of i) the appropriate neuronotrophic agent, ii) serum-containing and defined serum-free media, and iii) three different culture substrata. Using first explant cultures of embryonic day 8 (E8) chick dorsal root ganglia (DRG) in the absence of NGF, serum-containing cultures displayed neuritic outgrowth that was negligible on collagen, sparse on polyornithine (PORN), and considerably more developed on PORN coated with a PORN-bindable neurite-promoting factor (PNPF-PORN) obtained from RN22 schwannoma cell-conditioned medium. The sub-strata also affected the outgrowth and/or morphology of ganglionic nonneurons. In the serum-free N1 medium neuritic outgrowth was markedly enhanced while retaining the differential influences of the substrata. In the presence of NGF, serum and substratum effects on DRG neurite outgrowth were masked by the massive re-sponse to NGF. Similar results were obtained with chick Ell sympathetic ganglia.

The more general occurrence of this serum-inhibitory effect on neurite growth was shown using monolayer cultures of chick E8 incuring gaughia (CG) and PCl2 cells, a clonal line of rat pheo-chromocytoma. Ciliary gaughion neurons, supplied with their trophic factor (CNTF), showed little, if any neurite growth on either collagen or PORN in the presence of serum, but extensive neurite development (especially so on PORN) in NI medium. Serum delays the onset of neuritic growth using the PNPF-PORN substra-tum; however, there still is extensive neuritic growth at 24 hrs of culture. PCl2 cells, cultured on PORN in the presence of se-rum, will extend neurites slowly (7-10 days) when NGF is added. In the N1 medium, however, neurite development with NGF occurs far more rapidly (1-2 days). Presentation of serum to such PCl2 cells results in the rapid (15 min) retraction of all neurites. The se-rum susceptibility of PCl2 neurites to serum decreases with increasing time in culture. This PC12 neurite response to serum has been used to define a bioassay for the inhibitory factor(s). Preliminary characterization indicates a slightly acidic protein species of 50-100,000 molecular weight.

COMPETENCE TO RESPOND TO NEURITE OUTGROWTH PROMOTING FACTOR(S) IN CELL CULTURE DECLINES WITH TIME, IS PROLONGED BY RESIDUAL AXON, AND COMPLETELY REGAINED BY REAXOTOMY. <u>D. A. Bodnar and</u> 72.3 S. B. Kater. Depart Iowa City, IA 52242. Department of Zoology, University of Lowa

Isolated neurons of the snail <u>Helisoma</u> respond to a brain derived factor by producing extensive neurite outgrowth (Wong et al., 1981, J. Neurosci., 1:1008-1021). Identified neurons co-cultured simutaneously with brains (to condition the media) can initiate outgrowth either from spherical the media) can initiate outgrowth either from spherical somata of isolated neurons or from neurons with a residual axon stump (see Haydon and Kater, these abstracts). There is a steady decline in the percentage of neurons producing neurites when co-culture brains are added at later times. However, the presence of residual axons slows this decline. For instance, brains added at 48 hours evoke only 20% of neurons plated as spheres to grow neurites, as compared to 50% of those with residual axons. Responsiveness to co-cultured brains is completely regained by reaxotomy.

This data set indicates that there is a requirement of temporal proximity of signals from axotomy and environmental factors in order to initiate neurite outgrowth. Supported by PHS grant NS 18819.

QUANTITATION OF THE <u>IN VITRO NEURONAL RESPONSE TO EXOGENOUS</u> GANGLIOSIDES. <u>K. C. Leskawa<sup>\*</sup> and E. L. Hogan</u> (SPON: J. Blackburn). Department of Neurology, The Medical University of South Carolina, 72.5 Charleston, SC 29425 Many laboratories have reported that the inclusion of a

ganglioside mixture (sialoglycosphingolipids from bovine brain) in tissue culture media stimulates the extension of neurites from cultured neuroblastoma cells. The effect of the individual gangliosides comprising this mixture remains to be critically assessed. We have purified to homogeneity individual assessed. we have purified to homogeneity individual gangliosides (possessing the gangliotetrose oligosaccharide backbone) from bovine brain and applied them at varying concentrations to mouse neuroblastoma cells (N2A) <u>in vitro</u>. After 48 hours of incubation, the cells were stained and examined with a Zeiss Videoplan, employing a program to measure neurite length, degree of sprouting (arborization) and other parameters. All the individual gangliosides tested promoted neurite extension in a dose-dependent fashion. Asialo-ganglioside GM1 was without significant effect however, which suggests that the presence of sialic acid (N-acetyl neuraminic acid) is important in eliciting this cellular response. With increasing concentrations of GM1 (5 to 500 ug/ml), average cellular neurite length increased significantly, ug/ml), average cellular neurite length increased significantly whereas the number of neurites per cell decreased. Trisialosyl ganglioside GTib exhibited slightly different effects. Neurite length did not increase to the magnitude seen with GM1, but promoted a significant increase in the number of neurite branching (arborization). These results suggest that the <u>in vitro</u> neuroscient decrease to an engency acellogide mixture may be a carbonization, these results suggest that the  $\frac{1}{10}$  verse neuronal response to an exogenous ganglioside mixture may be a combination of specific responses to each individual glycolipid

THE PCI2 CELL LINE AS A MODEL FOR STUDY OF INTRACELLULAR 72.4 TRANSGLUTAMINASE. J.C. Byrd, J.P. Schwartz, E. Costa. Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032

Transglutaminase (TGase), an enzyme which catalyzes the formation isopeptide bonds between protein molecules, has been recently or isoperiae bonds between protein molecules, has been recently implicated as a mediator of several important cellular functions, including receptor-mediated endocytosis, regulation of plasma membrane rigidity, increased cellular adhesion, and mediation of RNA synthesis. Thus far these effects have been primarily studied by examining the effects of TGase inhibitors on these various processes in fibroblast or epithelial cell

lines. We have found the pheochromocytoma cell line PC12 to be a useful we have found the pheochromocytoma cell in paural crest cells. We have found the pheochromocytoma cell line PC12 to be a useful model system in which to study the role of TGase in neural crest cells. TGase activity in these cells is quite low (approximately 0.2 pmol/mg/min, using H-putrescine as a substrate), and can be inhibited still further by a variety of well-known TGase inhibitors (dansylcadaverine, Ki = 260  $\mu$ M; methylamine, Ki = 650  $\mu$ M; ethylamine, Ki = 10.25 mM; and bacitracin, Ki 235  $\mu$ M). Alternatively, TGase activity can be increased 20-fold by treatment with sodium butyrate. This increase in activity requires protein synthesis, reaches a maximum after 2 days of treatment, and is dose-dependent, with maximal after 2 days of treatment, and is dose-dependent, with maximal stimulation at butyrate concentrations of 6 mM. Admixture studies stimulation at butyrate concentrations of 6 mM. Admixture studies suggest that this increase in activity is not due to the presence of an activator in the treated cells or an inhibitor in the control cells. While TGase activity in control cells is approximately equally divided between the soluble and particulate fractions, the TGase activity in butyrate-treated cells appears to be principally located in the soluble fraction. In addition to these enzymatic changes, PC12 cells exhibit morphological changes in response to butyrate. Within approximately 12 hrs after treatment the cells begin to cease dividing, become flattened, and the amount of protein per cell increases about 2-fold during this time. This treatment does not alter cell viability.

We are currently using the PC12 model to study the many putative roles of intracellular transglutaminase, including the following: regulation of internalization of nerve growth factor and epidermal growth factor (PC12 has receptors for both), the role of isoperide bonds in regulating the proliferative state of the cell, and the role of TGase in the regulation of protein synthesis.

72.6 MODIFICATION OF HYDROPHOBIC SURFACES BY FLAMING PERMITS ADHESION

MODIFICATION OF HYDROPHOBIC SURFACES BY FLAMING PERMITS ADHESION OF DISSOCIATED MAMMALIAN CNS TISSUE. <u>M. H. Hightower\*</u>, J. H. Lucas\*, G. W. Gross and L. E. Czisny\*. (SPON: L. Uphouse). Dept. of Biology, Texas Woman's University, Denton, Texas 76204. Insulation of materials for multiple electrode plates (MEPs) must fulfill strict requirements of (1) optical clarity, (2) long-term stability under warm saline and after repeated steril-ization, and (3) allow convenient electrode deinsulation. Suit-ble materials grupped as a polycilogram prosin (NC648, Deu Corning) able materials such as a polysiloxane resin (DC648, Dow Corning) in use in our laboratory are generally highly hydrophobic and do not permit cell adhesion. We have determined that such hydro-phobic surfaces can be modified (i.e. made hydrophilic) by brief exposure to a gas flame.

exposure to a gas flame. Surface areas of water droplets were used as a quantitative measure of surface wettability. Flamed glass (FG) and flamed DC648-insulated (FI) glass plates exposed for 5 sec to the outer regions of a propame flame demonstrated average 350% and 850% droplet area increases respectively over unflamed controls (UC). Droplet area increases on FI and FG plates fell to less than 150% above UC plates after 20 min exposure to dry heat ( $100^{\circ}$ C), autoclaving ( $130^{\circ}$ C) or boiling. FI and FG plates under culture medium at  $37^{\circ}$ C for 20 d revealed gradual decreases in the hydro-philic effect (avg. 4.5%/d). philic effect (avg. 4.5%/d).

Dissociated spinal cord tissue from 11-14 d mouse embryos was seeded (10<sup>6</sup> cells/ml) onto FI and UC surfaces. Visual observations at 24 h revealed little cell adhesion to UC plates. tions at 24 h revealed little cell adhesion to 00 plates. Attachment to FI plates was much greater and characterized by small clumps and single cells. Polylysine coating of FI plates (PFI) improved adhesion greatly. PFI plates demonstrated the highest proportion of adhered cells generally attached singly. Process extension and interconnection were most extensive on PFI. A similar superiority of PFI could be observed after 14 d in culture. Polylysine coating of unflamed DC648 was ineffect-ive. Adhered cells were removed from FI, PFI and UC plates at various times post seeding and counted. After the first 4 h cell adhesion to UC surfaces remained approximately 7.5%. Adhesion on FI plates increased linearly until by 26 h more than 25% of the cells had adhered. PFI plates showed a greater initial adhesion (>30% by 10 h) but no further significant increase by 26 h.

This surface modification has permitted recording of vigorous, spontaneous activity from mammalian CNS neurons grown on FI and PFI MEPS (Gross and Lucas, JEPT 9 1982). Recordings for periods up to 75 d have been obtained (Gross and Lucas. Neurosci. Abstr. 1983).

Supported by NIH grant NS15167.

NEURONAL RESPONSES TO PROCESS AMPUTATION VIA LASER MICROBEAM 72.7 CELL SURGERY: ELECTROPHYSIOLOGICAL AND ULTRASTRUCTURAL, CHANGES. J.H. Lucas\*, G.W. Gross and M.L. Higgins\* (SPON: J. Kirkpatrick) Department of Biology, The Texas Woman's University, Denton, Texas 76204

Cell surgery with a laser microbeam offers unique advantages cell surgery with a last microbeam offers unique advantages of precision and control to the study of trauma on the single cell level. Responses to process amputation of single neuronal cells in vitro were monitored using standard techniques of intracellular recording. Surgery was performed on cultured spinal neurons from 12-14 day mouse embryos. Precise transections of primary cell processes were effected by the application of multiple, low-energy pulses from a UV laser microbeam (337 nm) focused to a diameter of 2.2  $\mu\,m$ . Cumulative energy densities at the target ranged from 0.5 to  $3.0 \,\mu$  J/ $\mu$ m<sup>2</sup>. Resting potentials prior to surgery ranged from 48 to 56 mV with an average of 52.7 mV. The average culture age at the time of surgery w

24 days. A variety of responses to neurite amputation was observed. In most cells, a loss of potential occurred following transec-tion. In 37.5% of these the loss was irreversible. Complete recovery of resting potential was observed in 30% of the cells and partial, temporary repolarization in the other 31%. Overall depolarization rates ranged from 0.14 to 1.68 mV/sec with an average of 0.48 mV/sec. Rates of repolarization ranged from 0.04 to 0.49 mV/sec with an average of 0.22 mV/sec. Depolarization rates varied inversely as a function of target distance from the perikaryon. Target distances did not affect repolarization rates.

LM and TEM have revealed that multiple shot laser microbeam LM and TEM have revealed that multiple shot laser microbeam transections are preceded by process constriction in the target area. Local ultrastructural changes during pinching included loss of microtubules, mitochondrial disruption and increased tautness of the plasma membrane. In some cases loss of neuro-filaments was also observed. Cells failing to transect com-pletely usually recovered their prelasing dimensions.

We hypothesize that laser transection is initially a photo-biological event involving absorption by NADP and NADPH which causes calcium release from mitochondria followed by subcellular contractile events and cytoskeletal collapse. At present we believe that recovery of resting potential, prevention of damage spread and cell survival after amputation depend on the rapidity of membrane resealing. Future experiments utilizing various will test these hypotheses. Supported by NIH grant NS15167.

72.8 CHARACTERISTICS OF NEURONAL MONOLAYER NETWORK ACTIVITY RECORDED IN CULTURE WITH MULTIMICROELECTRODE SURFACES. G. W. Gross and J. H. Lucas\*, Dept. of Biology, Texas Woman's University, Denton, Texas 76204

With techniques described previously (Gross and Lucas, JEPT 9, 1982), we have been able to monitor vigorous, spontaneous activity from monolayer circuits of dispersed mouse spinal neurons for as Irom monolayer circuits of dispersed mouse spinal metrons for as long as 75 days. Under present culture conditions, an average of 20 out of 32 photoetched electrodes carry spontaneous activity with mean signal-to-noise ratios of 3:1. This ratio may exceed 20:1 if a neuron covers a recording crater. Glial cells usually do not cover these craters but tend to move around this surface of income being methods. irregularity. The signal-to-noise ratios as well as the number of active electrodes increase from the earliest observation times of 6 days to reach a peak at about 40 days in culture. This is followed by a gradual decline over the next 30 days. However total loss of activity has so far always resulted from contamination or equipment failure and culture life spans of over 100 days can be anticipated. Although spontaneous activity has been recorded from apparently isolated cells, most activity is complex and depends on interconnections made over the entire 0.5 x lmm recording matrix. Functional connections have been confirmed by laser microbeam cell deletion and process transection during re cording. Almost all types of firing patterns have been observed, with high frequency bursting being the most commonly observed pattern that becomes increasingly prominent as the culture ages. Average bursting cycles are 2 sec at 30 days and increase to 8

Average bursting cycles are 2 see at 30 days and increase to see at 60 days. Tonic discharges occur, especially in younger cultures, in random or widely varying cyclic patterns. We are presently testing a transparent metal oxide as our thin film conductor. This substantially improves optical monitoring of circuits over the previously used opaque gold conductors without sacrificing electrode stability and durability. However, transmission electron microscopy indicates that about 20% of the putative neuronal fibers at 30 days in culture are too small to be resolved by phase contrast microscopy. Although an unprecedented correlation between morphology and spike activity is, in principle, possible with this approach, the C-fiber content of cultured monolayers will complicate the interpretation of longterm optical and electrophysiological data. Supported by NIH grant NS 15167.

72.9 HISTOCHEMICAL AND ULTRASTRUCTURAL ANALYSIS OF CILIARY GANGLION REURONS IN CULTURE. <u>G. Crean and G. Filar</u>. Physiology Section, The Biological Sciences Group, The Univ. of Connecticut, Storrs, CT 06268

The endoplasmic reticulum of chick ciliary ganglion cells ir vivo undergoes a typical organization during development. At St 34 the ribosomes are present as monosomes and polysomes. Scarce 34 the ribosomes are present as monosomes and polysomes. endoplasmic cisternae can be seen in the cytoplasm. At St 40, when peripheral synapses are formed, the ribosomes are organized in a highly structured rough endoplasmic reticulum (RER) localized in the periphery of the cell body. Since these changes did not occur in neurons deprived of the target it was hypothesized that contact with the target is important in development of ultra-structural characteristics of the neuron, which coincides with increase in enzymes in cholinergic metabolism (Landmesser and Pilar, 1978). Experiments were done to ascertain the influence of the target upon the ultrastructural characteristics of cultured neurons. Ciliary neurons were isolated at St 34 and 40 and histo-logical studies were done at different times after plating, in culture medium containing 10% horse and 10% embryo extract serum. St 34 neurons, one day after plating, have dispersed ribosomes. After 5-7 days they develop a peripherally organized RER. When co-cultured with muscle the development of the reticulum was simi-lar to that of neurons alone. RNA staining follows a similar pattern. St 40 cells when isolated and cultured lose the organi-zation of the RER and fail to regain it. St 40 neurons extend neurites within 24 hours similar to St 34 neurons, but within 7

days all cells die in these culture conditions. In an attempt to correlate the RER organization with the syn-In an attempt to correlate the RER organization with the syn-thesis of a cholinergic enzyme, acetylcholinesterase (AChE) was localized histochemically after designated periods in culture. Preincubation in prostigmin and iso-OMPA were used to determine the specificity of the reaction. At the light microscopic level 75% of the cultured cells stain specifically for AChE. The stain covers the entire cell body. The remaining cells appear un-stained. There was no difference in staining characteristics after the different times in culture, thus the AChE staining does not correlate with the presence of RER.

after the different times in clutter, thus the Acht standing does not correlate with the presence of RER. Since neurons in <u>vitro</u> make synaptic contact among themselves (Crean et al, 1982) it is possible that these putative contacts (non specific) are sufficient to trigger the fine structural maturation of the St 34 neuron we have observed. Alternatively the neurons may develop in vitro following an independent program for cytological development. The ability of neurons to survive for long periods in vitro seems to be related to the capacity of the neuron to develop an organized RER. Supported by U.S. Army Research Office and NS 10338. 72.10 DISPERSED CELL CULTURES FROM THE DENTATE GYRUS OF NEONATAL RATS. B.D. Boss, T.P. Condon\*, E. Lanz\*, and W.M. Cowan. The Salk Institute and Clayton Foundation for Research/California Division, P.O. Box 85800, San Diego, CA 92138.

To study the morphology and development of dentate granule cells in vitro, we have grown dissociated cells from the dentate gyrus of 4 or 5 day old rats in a variety of media and on different substrates. or 5 day old rats in a variety of media and on altterent substraites. We have found that the cells survive optimally when first plated in a serum-containing medium and then switched to the chemically-defined medium N2 of Bottenstein and Sato (<u>PNAS 76</u>:514-517, 1979) with the elevated K+ (25 mM) level recommended by Lasher and Zagon (<u>Brain Res. 41</u>:482-488, 1972). Under these conditions, dentate granule cells have been maintained for periods of up to 6 weeks.

During the first few days in culture (in the presence of serum), the granule cells are widely scattered, extend a number of neurites, and assume a complex multipolar form quite different from that of normal granule cells <u>in vivo</u>, but not unlike the ectopic granule cells seen in the reeler mouse (Stanfield and Cowan, <u>J. Comp. Neurol</u>. <u>185:393-422</u>, 1979). This suggests that the normal morphology of dentate granule neurons is largely shaped by local factors within the stratum granulosum and the overlying molecular layer. After switching to N2 medium, the granule cells remain multipolar but become clumped together, and their processes form a complex network of fine fascicles. In co-cultures of hippocampal and dentate neurons maintained under the same serum-free conditions, interneurons become more prominent and many can be stained, as in The interneurons become more prominent and many can be stained, as in the intact dentate gyrus, by antibodies against either cholecystokinin or glutamic acid decarboxylase (Ribak, Vaughn and Saito, <u>Brain Res.</u> <u>140</u>:315-332, 1978). The increasing prominence of such cells suggests that they are not only favored by the culture conditions but also grow and differentiate in vitro.

Glial cells also appear to differentiate in serum-free medium. In In the presence of serum they generally form a complete monolayer, but in N2 medium their rate of proliferation (as judged by <sup>3</sup>H-thymidine autoradiography) is appreciably slowed and they only underlie the clumps of neurons and fascicles of neurites. Under these conditions, most of the glial cells become stellate in form with many short, radiating processes that can be heavily stained with anti-glial fibrillary acidic protein and with a monoclonal antibody against S-100 100.

MAINTENANCE OF IMMUNOCYTOLOGICALLY IDENTIFIED PURKINJE 72.11 CELLS FROM MOUSE CEREBELLUM IN MONOLAYER CULTURE. Andrée Weber<sup>+</sup>, Udo Sonnhof<sup>+</sup> and Melitta Schachner, partment of Neurobiology, University of Heidelberg,

Ped. Rep. Germany. PC1 antigen, a Purkinje cell-specific intracellular constituent recognized by monoclonal antibody, is localized in histological sections of cerebella from localized in histological sections of cerebella from adult mice in Purkinje cell bodies, axons and dend-rites (Weber and Schachner, Cell and Tissue Res. 227: 659-676, 1982). To investigate under which conditions Purkinje cells can be maintained in culture, PC1 anti-body was used to identify Purkinje cells by indirect immunolabelling procedures in monolayer cultures of trypsin dissociated cerebellar cells from embryonic and carbu protection form the four found to immunolabelling procedures in monolayer cultures of trypsin dissociated cerebellar cells from embryonic and early postnatal mice. PC1 positive cells were found to express other Purkinje cell-specific markers, such as PC2, PC3 (ibid.) and UCHT1 (Garson et al., Nature 298: 375-377, 1982), the neuronal marker L1, tetanus toxin receptors and the PC4, M1 and Thy-1 antigens. The glial markers, glial fibrillary acidic protein and O4 antigen were not expressed by these cells. Survival of Purkinje cells was best when cerebella were taken from mice not older than one day of age and cultured in chemically defined medium which facilitates the survival of neu-rons (Fischer, Neuroscience Letters 28: 325-329, 1982). PC1 antigen developed in vitro on the same time scale as in vivo, i.e. it was first detectable at postnatal day 3 to 4. At this stage cell bodies had a diameter of 13-14  $\mu$ m and few processes. Dendrite-like arborizations, extension of usually one thin and long (0.5-1.6 mm) axon-like process with collaterals and cell body dia-meter of up to 18-19  $\mu$ m developed with time in culture until the final form was reached by the equivalent of postnatal day 16 approximately. This form was reminis-cent of the one described for Purkinje cells in certain cerebellar mouse mutants and in experimentally agranul-ar cerebella. Ultrastructural features of these cells correlate with those described for their in vivo coun-terparts. Electrophysiological measurements showed that correlate with those described for their in vivo coun-terparts. Electrophysiological measurements showed that the cultured Purkinje cells were capable of spontaneous action potential discharges and excitatory and inhibi-tory synaptic potentials. These observations document that under the present culture conditions Purkinje œlls are synaptically connected to other neurons.

72.12 PRIMARY CULTURE OF RAT CEREBELLAR NEURONS IN MEDIUM SUPPLEMENTED

WITH BOULDAR OF MALE CAREBELLAR MEDICING IN MEDICING SOFFLEMENT WITH BOULDAR OF THE CAREBELLAR MEDICING IN MEDICING SOFFLEMENT Bergdall\* and C. Phelps\*. Indiana Univ. Sch. Med., Depts. of Microbiol. and Anatomy, Fort Wayne Ctr., Fort Wayne, IN 46805 Before studying the effects of lead on the physiology of cerebellar neurons and glial cells grown in primary culture, bovine salivary glands were reexamined as an inexpensive source of neuronal and glial growth factors.

Bovine parotic glands were minced in PBS, pH 7.2, containing DNase, RNase, and PMSF. The minced tissue was homogenized in a blender and centrifuged. The resulting supernatant constituted the crude extract (CE). The CE was subjected to precipitation with ammonium sulfate (AS) (30%, 55%, 75%, and 85% saturation). The precipitates (AS-CE) were each resuspended in Tris-NaCl buffer, dialyzed against the same, assayed for biological activity then applied to a column of Sephadex G100 and eluted with Tris-NaCl buffer. Eluted fractions were combined, lyophilized, dialyzed against PBS, and assayed for biological activity.

The biological activity of the extracts was determined by their ability to support neuron growth and process development ther a birly to support neuron growth and process development in primary cultures. One to three day old rat cerebellums were collected, minced in PBS, and dissociated with trypsin. Cell viability ranged between 85-95% (trypan blue exclusion) and normally 1 x 10<sup>6</sup> cells/ml were recovered. The cells remaining in suspension following a 30-60 min. preattachment were distributed into culture flasks or micro-culture plates containing complete medium (DMEM, 10% FBS) w/ or w/o the AS-CE and G100 combined medium (DMEM, 10% FBS) W/ or W/o the AS-CE and G100 combined fractions. Neurons were distinguished from non-neuronal cells based on their phase-contrast morphology and staining reaction with cresyl violet. The 55% and 75% AS-CE yielded cultures containing consorted by 60% bioche and rubicals requeres with

approximately 60-80% bipolar and multipolar neurons with extensive process development. Only non-neuronal cells were recovered in the abscence of the gland extracts. The G100 combined fractions corresponding to a mol. wgt. range of 50K-75K supported the growth of a mixed neuronal and non-neuronal culture. The G100 combined fractions corresponding to a Culture. The GIOU combined fractions corresponding to a molecular wgt. range of 25K-30K yielded nearly pure cultures of multipolar neurons. SDS and Analytical PAGE of the GIOU combined fractions indicated the presence of a wide range of mol. wgt. polypeptides, including a 25K-30K dalton band which may correspond to the low mol. wgt. form of NGF (2.5.5). Additional results will be presented concerning the metabolic effects of the parotid extracts on neuronal and nonneuronal cells as well as the effects of sublethal concentrations of lead on neuron survival and process development in culture.

GROWTH AND DEVELOPMENT OF REASSOCIATED VASOPRESSIN 72.13 NEURONS IN VITRO. S.L. Scharoun, D.M. Gash and M.F.D. Notter\*. Dept. of Anatomy, Univ. of Rochester, Rochester, N.Y. 14642.

Results from our laboratory using a transplant model involving the grafting of vasopressin neurons into vasopressin-deficient Brattleboro frating of vasopressin hearons into vasopressin-derictent brancher of rats for study of hypothalamic neuroscretory neuron development and function in vivo has been quite successful. To complement and extend these findings, we have recently developed both a reaggregate culture system and a monolayer culture system to study the effects of growth system and a monorayer current system to study the effects of growth factors and hormones on the growth, development and innervation patterns of vasopressin neurons. The results of the experiments on the <u>in</u> vitro model system used in this present abstract will be used to select hormones and factors for test <u>in vivo</u>. By comparing the effects of these substances, both in cultured vasopressin neurons and neurons growing in the brain, our knowledge of factors important in regeneration and development should increase.

development should increase. The anterior hypothalamus, including the supraoptic nucleus containing vasopressin neurons, was dissected out from normal embryonic and neonatal Long-Evans rats 12, 15, 17, 19 and 21 days post coitus (dpc) as well as from neonatal ages, day 1 and day 5. The cells were dispersed and resuspended in an MEM dispersion media. Various wells were co-cultured with their known target tissue, the posterior pituitary, to further analyze the influence of the target tissue on hormone production further analyze the influence of the target tissue on hormone production. further analyze the influence of the target tissue on hormone production. At a designated end point, cultured cells were fixed and stained immunocytochemically with a rat neurophysin common to both vasopressin and oxytocin neurons. Radioimmunoassay of the media samples was performed for vasopressin quantification. Hypothalamic cells from all ages produced vasopressin quantification. Hypothalamic cells from all ages produced vasopressin as indicated by the RIA results of the media. Vasopressin (VP) levels in tissue after four days were 336.5 pg/10<sup>6</sup> cells while 507.7 pg VP/10<sup>6</sup> cells could be measured after eight days in culture. Hypothalamic cells co-cultured with dispersed pituitary tissue were shown to produce a significant increase in VP production. By varying serum factors for example replacement of fetal production. By varying serum factors, for example, replacement of fetal calf serum with maternal rat serum, an increased VP production of at least doubled levels was seen in reaggregate cultures. With the present study, we have shown that both the reaggregate culture s, with the present monolayer culture system can be adapted to a microassay of neurosecretory activity of selected regions of hypothalamus. Further, this microsystem can be employed quite readily to examine the effects of co-cultivation with target tissues as well as manipulation of various however ad traching fectors co brain development at critical times. hormones and trophic factors on brain development at critical times. Supported by Grant NS 15109.

72.14 ORGANOTYPIC CULTURES IN DEFINED MEDIUM CONDITIONS. W.J. Hendelman, N. de Savigny<sup>\*</sup> and K.C. Marxhall, Departments of Anatomy and Physiology, University of

Departments of Anatomy and Physiology, University of Ottawa, Ottawa, Ontario, Canada, KlH 8M5. The experimental use of organotypic cultures of the central nervous system has been limited to a certain extent by the complex medium required for their growth and maintenance. A completely defined medium would facilitate the use of these cultures in studies invol-ving drugs and toxic agents. We have found a defined medium that results in satisfactory organotypic cul-tures of the cerebellum and the locus ceruleus. Parasagittal fragments of newborn mouse cerebellum were explanted onto collagen-coated coverslips and cul-

were explanted onto collagen-coated coverslips and cul-tured in the Maximow chamber. The adjacent peduncular region of the brain stem containing locus ceruleus neu-rons was explanted and co-cultured with some of these fragments. rons was explanted and co-cultured with some of these fragments. The standard medium used in such cultures consists of 50% Eagle's minimal essential medium (MEM), 25% chick embryo extract, 25% human serum, and a glu-cose level of 1100mg%. The completely defined medium has a basal component consisting of a 1:1 ratio of Dul-becco's MEM with either Ham's F12 or Ham's MCDB104, with the following additions: glutamine, insulin, progesterone, triiodothyronine, corticosterone, sele-pous acid, human transforrin, accorbic acid putresnous acid, human transferrin, accorbic acid, putres-cine, and bovine serum albumin. Glucose levels were adjusted to 500-600mg% to produce a medium of approxi-mately 330 mosm. HEPES was added to stabilize the pH. It has been found that the development of the cul-

It has been found that the development of the cul-tures requires an outgrowth of glia and processes, and "spreading" of the explant. In order for this to oc-cur, serum-containing medium is used for the first 48 hours in vitro, and fibronectin is included in the de-fined medium. The main differences between the serum-fed (SF) and defined-medium (DM) cultures are: (i) myelin appears in abundance in DM cultures earli-er than in SF cultures; (ii) at 3-4 weeks, there is better development of Purkinje neurons in SF cultures and more myelin; (iii) SF cultures with locus ceruleus and more outgrowth. In cultures with locus ceruleus neurons, the catecholamine histofluorescence seemed comparable in both media conditions. The DM cultures The DM cultures are currently being investigated with electron microscopy.

SLICE CULTURES OF NERVOUS TISSUE, <u>B.H. Gähwiler</u>, Preclinical Research, Sandoz Ltd., CH 4002 Basel, 72.15 Switzerland

An attempt was made to combine the advantages of the slice and the culture techniques by culturing slices prepared from young animals. Cultured cells are organized in an organotypic monolayer and individual living neurons may be directly visualized

vidual living neurons may be directly visualized and identified. 400 µm thick slices were prepared from 7-day-old rats and cultured for 1 to 3 months by means of the roller-tube technique. In cerebellar cultures, Pur-kinje cells and cells derived from the deep nuclei were recognized on the basis of their size, location within the culture and dendritic arborization as visualized following intrasomatic injection of lucifer yellow or horseradish peroxidase. The overall struc-ture was preserved in cultures of the hippocampal formation. Pyramidal cells retained their binolar ture was preserved in cultures of the hippocampal formation. Pyramidal cells retained their bipolar orientation, with basal as well as optical dendrites, whereas the dendritic arbor of granule cells was always monopolar. Timms sulfide staining demonstrated the projection of granule cells to the dentate hilus and to the CA3 pyramidal cells, where the mossy fibers predominantly terminated within the supra-pyramidal layer. Like their in situ counterparts, the mossy fibers respected the CA3/CA1 borderline. In cultures prepared from the anterior hypothalamus, Goloi-like immunoperoxidase staining allowed visua-

In cultures prepared from the anterior hypothalamus, Golgi-like immunoperoxidase staining allowed visua-lization of groups of neurophysin-neurons bilaterally bordering on the third ventricle. Co-cultivation of slices derived from different brain regions may be instrumental in elucidating mechanisms involved in synaptogenesis. As an example, AChE-positive fibers originating from a co-cultured septal explant were shown to provide a massive inner-vation of hippocampal neurons.

72.16 A GLIAL GROWTH FACTOR PRODUCED BY CEREBRAL ENDOTHELIAL CELLS IN CULTURE. D. N. Krause, I. E. Goetz\*, J. N. A. Van Balgooy\* and E. Roberts. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010. We recently reported that conditioned medium from cultures of cerebral capillary endothelial cells (CCE) contain a factor(s) which stimulates the proliferation of cultured glia cells (J. Cereb. Blood Flow Metab., 1983, in press). Cultured glial cell lines derived from bovine cerebral cortex all responded to CCE conditioned medium with a significantly greater increase in cell number as compared to controls. Preliminary observations with one line suggest that the conditioned medium also may promote differentiation of glial progreater increase in cell number as compared to controls. Preliminary observations with one line suggest that the con-ditioned medium also may promote differentiation of glial pro-cesses. Glial growth factor (GGF) was found in the medium of all bovine CCE lines, regardless of passage number (primary culture up to 18 passages). Serum was not required for GGF production. Soluble extracts of CCE cells also stimulated glial proliferation. It is not known whether the same factor(s) is responsible for the growth-promoting activity seen in the CCE conditioned medium and the CCE cell extract. In both cases, the activity was stable to freezing and heat labile (56°C). Cell extract activity was trypsin-sensitive. GGF in CCE conditioned medium is precipitated by 35% ammonium sulfate and is retained by an Amicon XM50 filter and a Sephadex Gl50 column. Preliminary results suggest that the GGF is a protein with a molecular weight between 50,000 and 100,000. This fac-tor is much larger than a previously described smooth muscle/fibroblast growth factor derived from aortic endothelial cultures (Gajdusek, C. et al., J. Cell. Biol. 85:467). Production of GGF may be specific to endothelial cells because glial growth also was stimulated by media of cultured endothe-lia derived from either bovine middle cerebral artery or aorta. However, no growth-stimulating activity was seen with media from bovine aortic smooth muscle cells, human skin fibroblasts, or glial cells themselves. In situ, crebral capillaries are or glial cells themselves. In situ, cerebral capillaries are seen in intimate association with astrocytic endfeet; thus an seen in intimate association with astrocytic enoreet; thus an endothelial-derived glial growth factor may be important in the development and/or maintenance of glial-vascular relationships in brain. [Supported in part by USPHS grant NS18586 and the Hereditary Disease Foundation.]

72.17 OLIGODENDROCYTES DIFFERENTIATE EARLY IN SERUM-FREE MEDIUM. P.A. Eccleston\* and D.H. Silberberg. Department of Neurology, Univ. of Penna. School of Medicine, Philadelphia, PA 19104. Univ. of Penna. School of Medicine, Philadelphia, PA 19104. Galactocerebroside (GalC) is a cell surface marker for oligo-dendrocytes. It is not expressed on immature precursors of oligo-dendrocytes, but is first detected by the use of anti-GalC anti-bodies at approximately the time of birth, in cultured rat CNS tissue. In order to study the effect of hormones and growth factors which control this stage of oligodendrocyte differentia-tion, we have formulated a serum-free medium. The medium (SE-2) consists of a hose (SE hase) of Dulhercols

The medium (SF-2) consists of a base (SF base) of Dulbecco's Modified Eagles Medium and Ham's F12 (1:1) with glucose (2 mg/ml) Hepes buffer, penicillin and streptomycin, supplemented with insulin, transferrin, selenting and streptomyclin, suppremented with insulin, transferrin, selentum, and triiodothyronine (T3). Hydro-cortisone and putrescine were found to have no effect on oligo-dendrocyte differentiation when included in this medium. Dissociated cells from fetal (15-17 day embryonal) spinal cord

or cerebrum or neonatal cerebrum were seeded in a medium contain-ing 2.5% fetal calf serum on poly-1 -lysine coated 12 mm glass coverslips. The next day after washing, the serum containing

coversips. The next day after washing, the serum containing medium was replaced by serum-free medium or control medium. To compare the number of oligodendrocytes present in various media, rabbit anti-GalC antisera was used followed by a rhodamine conjugated goat anti-rabbit 1gG second antibody, for indirect immunofluorescence. For each experiment, the relative number of GalC+ cells was enumerated by counting 20 or occasionally 100 high power fields.

Deletions of single supplements from SF-2 resulted in a decreased number of GalC+ oligodendrocytes as compared to the complete medium. When each supplement was added singly to the SF  $\,$ base for six days of culture, no improvement was noted over the base alone, indicating that insulin, selenium, transferrin, and T3 have a synergystic effect when used in combination. In serum-free medium (SF-2) GalC+ oligodendrocytes appeared

erlier than in serum containing controls. This effect was most pronounced for cultured fetal tissue. In all cases tested, GalC+ cells were detected up to three days earlier than expected. Furcells were detected up to three days earlier than expected. Further studies revealed that this early differentiation occurred in both SF-2 and SF base, but not when 2.5% serum was added to either medium. In SF base, oligodendrocytes were demonstrated only at early time periods; after a week most cells were dead. From this we can conclude that the major function of the four supplements in SF-2 is one of promoting survival of GalC+ oligodendrocytes, rather than one of inducing differentiation, and that the removal of a factor present in fetal calf serum allows differentiation to occur. (Supported by NIH NS1037, the National Multiple Sclerosis Society, and the Kroc Foundation.)

72.18 HORMONAL CONTROL OF ASTROCYTE PROLIFERATION IN CELL CULTURE Douglas A. Kniss and Richard W. Burry, Department of Anatomy, The Ohio State University, College of Medicine, Columbus, Ohio 43210. Proliferation of glial cells is a common response to CNS trauma. This proliferation is often responsible for the forma-tion of scar tissue which may impede regeneration attempts by neurons. Thus we used a cell culture model to investigate a way of controlling glial cell proliferation.

A dissociated cell culture system of CNS tissue was used to examine the ability of glucocorticoid hormones to control prolif-eration of glial cells. Dispersed cell cultures of 2-day rat cerebellum were prepared with standard methods and plated into Ham's F12 medium containing 3 mM potassium and 10% FCS. This low Ham's F12 meatum containing 3 mm potassium and 10% FCS. Inis low potassium concentration selects against neurons thus enriching the cultures in astrocytes and other non-neural cells. Immuno-cytochemistry with anti-GFAP (a gift from L. Eng) and anti-fibronectin (Cappell Laboratories) confirmed that the vast major-ite of culture culture content of CFLP continued. ity of cells in the culture were astrocytes (GFAP-positive) while, only a minority of cells per culture were immunoreactive for fibronectin.

On 3, 5, and 12 days in culture the cells were rinsed with boffer and switched to a chemically defined, serum-free medium containing: putrescine (100  $\mu$ m), selenium (30  $\mu$ M), insulin (5  $\mu$ g/ml), transferrin (100  $\mu$ g/ml), and BSA V (50  $\mu$ g/ml). One group of cultures remained in this medium, while another group received 0.5  $\mu$ M corticosterone in this same medium. Cells rereceived 0.5  $\mu$ M corticosterone in this same medium. Cells re-mained in these media for 48 hours. Twenty-four hours prior to harvesting, cells were exposed to 2  $\mu$ Ci/ml of <sup>3</sup>H-Thymidine (<sup>3</sup>H-TdR) (20 Ci/mmole). On the day of harvest, cells were rinsed, scraped from culture dishes, and precipitated with 10% TCA. Cel. pellets were resuspended and aliquots were counted by liquid scintillation for acid-insoluble radioactivity (<sup>3</sup>H-TdR incorpor-ation). Four cultures were pooled per sample and triplicate cultures were result acase. Cell

At days 5, 7, and 14 <u>in vitro</u> cultures receiving cortico-sterone incorporated significantly less <sup>3</sup>H-TdR into the acidinsoluble fraction than untreated cultures. Statistical significance was confirmed by a one-way analysis of variance (p <.01).Dexamethasone was also tested for its ability to inhibit prolif-eration and was found to be slightly more effective than corticosterone.

These results suggest that glucocorticoids may be effective in controlling astrocyte proliferation in vitro. Because of their action at the genomic level these hormones may provide a useful probe for the study of the control mechanisms of astrocyte pro-liferation. (Supported by NIH Grant NS-15894 to RWB and funds from the Spinal Cord Injury Research Center at The Ohio State University, NIH Grant NS-10165).

CYTOLOGICAL CHARACTERISTICS OF TRANSFORMATION IN TWO DISTINCTIVE 72.19 CELL TYPES CULTURED FROM A CLIOMA. <u>P.E. McKeever</u>. Surgical Neurology Branch, Natl. Inst. of Neurol. and Commun. Dis. and Stroke, Bethesda, MD 20205.

Cells which retain a marker present in the parenchyma of glial tumors, glial fibrillary acidic protein (GFAP), and other cells which instead have fibronectin (FN) grow from a number of gliomas in early passage. The cells in explants of one of these gliomas were evaluated by phase contrast, by a nuclear fluorochrome and by the Giemsa method of predicting neoplastic transformation, correlated with double immunofluorescence for GFAP and FN.

Cells with GFAP and lacking FN had the following cytological features: cytoplasmic bascophlia, reduced cytoplasmic spreading, hyperchromatic nuclei and high nuclear/cytoplasmic ratio. The average nuclear/cytoplasmic ratio was 0.30. These cells were smaller and less abundant than cells with FN and not CFAP. Features of cells with FN and not CFAP varied. Some abnormal

groups of cells had hyperchromatic nuclei and high nuclear/cyto-plasmic ratio, while others resembled non-neoplastic fibroblast controls. The average nuclear/cytoplasmic ratio of the abnormal group was 0.32, more than triple the ratio of fibroblasts. Cells in this group had variation in nuclear and nucleolar size, shape and number, and abnormal mitses. Cytologic features shape and y transformed cells were present among each of the two distinctive types of cells which grew from this glioma. Not all features were recognized in each cell type.

72.21 A SPECIFIC GLIOTOXIC EFFECT OF DL-ALPHA-AMINOADIPIC ACID IN PRI-MARY CELL CULTURES, <u>S. Huck</u>. Institute of Neuropharmacology University of Vienna, A-1090 Vienna, Austria.

According to previous reports, DL-alpha-aminoadipic acid (aAA) is a specific gliotoxic agent not only <u>in vivo</u> (Olney et al., Neurosci.Lett.<u>19</u>,277,1980) but also in short-term incubated chick retinas (Casper et al., J.comp.Neurol.209,79,1982). We now report on DL-aAA effects in a recently characterized (Huck, Brain Res. Bull., in press) culture system with dissociated postnatal mouse cerebellum. The dissociated cerebellar cells essentially grow in a monolayer and can therefore be traced individually without sectioning or staining. In addition to previously reported transient changes of glial

cell morphology, DL-aAA induced karyopyknosis in astrocytes (identified by indirect immunoflurescence labelling of GFA) when applied in concentrations higher than 0.085mM. The number of astrocytes with pyknotic nuclei depended on the concentration of the substance and, in addition, on the duration of drug action. The presence of 0.21 mM DL-aAA for 40h caused karyopyknosis in 50%of the GFA-positive cells. In a small number of astrocytes, even high concentrations of DL-aAA did not induce karyopyknosis. The majority of these resistant cells were of flat appearance and therefore differed morphologically from the affected cells which had distinctive processes. In accordance with previous studies, cells of neuronal morphology remained unaffected.

While D-aAA was found to be almost completely ineffective, a half-maximal effect could be induced by 0.097mM L-aAA in the same culture system. Since the purity of the preparations was esta-blished by gaschromatography (kindly conducted by Prof.Dr.E.Bayer, Univ. Tübingen, FRG), these data suggest that the active component of the racemate is L-aAA.

Interestingly, astrocytes in primary cultures of dissociated newborn mouse and rat cerebral cortex, but not  $C_6$  glioma cells were found to respond to aAA.

Our data suggest that DL-AAA may be of great value to signifi-cantly reduce the number of astrocytes in primary cultures of the central nervous system. On the other hand, tissue culture experiments may take a key position in future studies on the mechanism of the gliotoxic lesion caused by aAA. 72.20 NEUROTROPIC RETROVIRUS SPECIFIC VIRAL PROTEIN SYNTHESIS IN MURINE ASTROCYTES IN VITRO B.R.Brooks and E. Priester\*. Department of Neurology, University of Wisconsin School of Medicine and William

S. Middleton Veterans Administration Hospital, Madison, WI 53705 Non-cytopathic virus infection of cells by murine neurotropic retrovirus can be shown by co-cultivation of cells with XC cells retrovirus can be shown by co-cultivation of cells with XC cells which are transformed by Rous Sarcoma Virus and react with the viral glycoprotein on the surface of infected cells to result in fusion from without. We have prepared glial fibrillary acidic protein positive cells from the brains of mice at day 17 gestation and newborn day 1 as well as postnatal day 21 by trituration and enzyme dissociation. Such cells can be infected by murine neuro-tropic retrovirus without evidence of cell lysis and fuse with XC cells indicating the presence of viral glycoprotein. We have labelled cells with H-leucine, prepared cell lysates, and formed immunoprecipitates with homologous heteroantibodies to the murine neurotopic retrovirus(CasBrM)or heterologous heteroantibodies to murine non-neurotropic retrovirus(AKR,RLV). Immunoprecipitates were also formed with homologous heteroantibodies to glial fibrillary acidic protein. The immunoprecipitates were electrophoresed in 10%, 3-12% and 3-27% polyacrylamide-SDS gels under reducing conditions. Fibroblasts were prepared from the muscles of mice at the above ages. Compared with fibroblasts, astrocyte cultures at all three ages showed a 50 kdalton protein which was precipita-ted with anti-glial fibrillary acidic protein. These astrocytes infected with virus showed the presence of virus specific pl0, pl2, pl5, p30, Pr60, Pr80, and gp69/70 which were precipitated with heterologous antibody to intact virus or monospecific heter ologous antibody to the above proteins. Synthesis of the precursor proteins Pr60 and Pr80 is similar in astrocytes and fibroblasts. The gag polyproteins and their cleaved subunits are identical in astrocytes and fibroblasts. In mouse embryo astro-cytes Pr80 and gp69/70 are present but in mouse fibroblasts there is evidence for a new species of intermediate molecular weight which is demonstrable. In fibroblasts from older animals similar proteins are present. In newborn astrocytes Pr80 and gp69/70 are present but decreased gp69/70 is present in older astrocytes. These data suggest, but do not confirm, that virus specific protein synthesis is similar in embryo and newborn astrocytes and that cleavage of Pr80 to gp69/70 is decreased in astrocytes from older animals. In fibroblasts of all ages there may be a from older animals. In fibroblasts of all ages chiefe may be a buildup of an intermediate cleavage product which is not present in astrocytes from younger animals. Therefore, virus specific protein synthesis is different for glycosylated proteins in astrocytes following infection than for non-glycosylated proteins compared to virus specific protein synthesis in fibroblasts. A MONOSYNAPTIC SENSORY PROJECTION FROM THE KIDNEY TO THE BRAIN-73.1 STEM. <u>M. K. Donovan, N. Aboukarsh, S. R. Winternitz and J. M.</u> <u>Wyss</u>. Depts. of Anatomy and CVRTC, Univ. of Alabama in Birming-Birmingham, AL 35294.

Recent evidence has suggested that renal afferent nerves par-ticipate in the pathogenesis of experimentally induced hypertension in the rat (Winternitz and Oparil, Hypertension 4, 1982). Although previous morphological and physiological studies have identified these afferents, only within the past two years have the central connections of these sensory neurons been traced. Most authors considered that these central processes would be made Most authors considered that these central processes would be mad-up of small unnyelinated fibers which had only short central pro-jections; however, the experiments considered below indicate that at least a portion of the primary sensory afferents reach the level of the lower brainstem. Twenty adult, male, albino rats were anesthetized with nembutal and the left kidneys were surgically exposed through a dorsal incision. An injection of 2.021 of fast blue (2% in H $_2$ 0) was placed into the kidney using a 10 $\mu$ 1 Hamilton syringe. Four days later, the animals were reanesthe-tized and a separate injection of 0.25µ1 of nuclear yellow (2% in H20) was placed bilaterally into the posterior medulla. Twenty-four hours later, the animals were transcardially perfused with saline followed by 10% buffered formalin. The kidney, brainstem and dorsal root ganglia (DRG) were removed and the dorsal root and brainstem were cut at 30µm on a freezing microtome and placed on clean uncoated slides. All tissues were viewed under fluoresof the sections of the kidney indicated that the fast blue dye was restricted in most cases to a 1.5mm diameter area of the cortex and did not diffuse into the medulla of the kidney or into the renal nerve. The nuclear yellow injections were confined to the caudal one third of the medulla oblongata. Three populations of labeled DRG neurons were detected. One category included neurons labeled only by the posterior medullary injections. The nuclei o The nuclei of Tabled only by the posterior meduliary injections. The nuclei of these cells were yellow and the cytoplasm was unlabeled. These cells were observed bilaterally at all DRG levels. Second, kidney injections resulted in the blue cytoplasmic labeling of ipsilateral DRG cell bodies at the  $T_{8-L_2}$  levels with the greatest concentration at  $T_{13}$ . Of these labeled renal sensory neurons approximates the transmission of the sensor of Tration at  $T_{13}$ . Of these labeled renal sensory neurons approximately 8% were also labeled by the medullary injection. When nuclear yellow was injected into the rostral third of the medulla oblongata no such double labeling was present. These results demonstrate that the central processes of these DRG neurons do reach caudal medullary levels, thus providing a monosynaptic renal sensory input to this region. This work was supported by NIH Grants HL 25451, HL 00707 and

? grants from the American Heart Association.

73.3 CONNECTIONAL ANATOMY OF THE SOMATOSENSORY SYSTEM OF THE PIGEON. M. Wild. Dept. of Behavioural Biology, R.S.B.S., Australian National University, Camberra, A.C.T. Australia. In order to investigate the connectional anatomy of the dorsal In order to investigate the connectional anatomy of the dorsal column-medial lemniscal system in the pigeon, 2 groups of experiments were performed. In the first, horseradish peroxidase-wheatgerm agglutinin (HRP-WCA) was (1) injected into primary feather follicles of the wing or tail; (2) applied to severed mixed, muscle or cutaneous nerves of the wing or leg; (3) injected into muscles of the wing. Frozen sections collected from the brainstem and cervical and lumbosacral spinal cord were processed with TMM and H.O. Extraorerikarual torringal labeling use observawith TMB and H<sub>2</sub>O<sub>2</sub>. Extraperikaryal terminal labeling was observed in the spinal grey following all HRP treatments: That from feather follicles was located at the dorsal periphery of the dorsal horn; that from cutaneous nerves was concentrated in the upper three dorsal horn laminae; and that from muscles and muscle nerves was located near neurons of Clarke's column and in more ventral laminae. In the medulla terminal labeling was observed following all HRP treatments except that involving tail feather follicle injections. At caudal levels the mixed leg nerves were represented in the gracile nucleus adjacent to the midline, and the mixed wing nerves in the cuneate nucleus slightly more laterally, although there was considerable overlap in their mediolateral representations. At successively more rostral medullary levels both these representations spread further and further laterally to occupy not only the dorsal column nuclei (DCN) but also the external cuneate nucleus (CuE) and parts of the descending trigeminal column (TTD). Terminal labeling was observed as far rostral as the eighth nerve. The large majority of the labeling appeared to be of cutaneous origin. In a second series of experiments  $^3\!H-\!proline$  was injected into DCN and/or CuE and frozen sections were processed for autoradiography. No clear evidence for a cerebellar projection was found, but a dense accumulation of silver grains was distributed over the contra-lateral (and to a lesser extent the ipsilateral) dorsolateral posterior and anterior thalamic nuclei (DLP and DLA-DLM), particularly their ventral regions. Injections of HRP into these regions consistently retrogradely labeled neurons throughout the Contralateral (and to a lesser extent the ipsilateral) DCN and CuE. Large injections of HRP into the cerebellum labeled only a few scattered neurons in DCN. These data demonstrate a substantial projection from the integument onto the DCN and CuE, and further show that these nuclei provide a major projection to the thalamus. The spinothalamic system was also investigated in these experiments, but very few retrogradely labeled neurons found anywhere in the spinal cord following large injections of HRP covering the entire thalamus.

ASCENDING SPINAL PATHWAYS IN THE TELEOST FISH, PRIONOTUS 73.2 <u>CAROLINUS. Thomas E. Finger</u>. M.B.L., Woods Hole, MA 02543 and Dept. Anatomy, Univ. Colorado Sch. Med., Denver, CO 80262. Searobins, <u>Prionotus carolinus</u>, possess modified pectoral fin rays which are moved actively to explore the substratum. Although the fin

rays possess no taste buds and are innervated only by spinal nerves, the fin rays are chemosensitive and are used to locate food. The fin ray nerves terminate centrally in enlarged dorsal horns (spinal accessory lobes) located at the rostral end of the spinal cord (Finger, \*82). Few dorsal root fibers ascend directly to the caudal medulla. HRP was injected into the spinal cord and elsewhere in the CNS to trace ascending spinal pathways.

spinal pathways. The accessory spinal lobes project ipsilaterally to three main targets: the underlying spinal motor pool, the cerebellum, and a lateral funicular nucleus at the spinomedullary junction. Injections into the lateral funicular nucleus reveal two major ascending systems: 1) to the ipsilateral cerebellum, and 2) to a number of contralateral targets including the torus semicircularis, optic tectum and most importantly, nuc, preglomerulosus of the diencephalon. Both the direct and indirect spinocerebellar systems enter the cerebellum in the inferior cerebellar peduncle and terminate as mossy fibers in a limited paravermal portion of the cerebellar cortex.

The major fiber system emanating from the lateral funicular nucleus crosses the midline in the caudal medulla and ascends through the rostral medulla and pons along the ventrolateral margin of the tegmentum. In the caudal midbrain, the fiber bundle turns dorsally to end in a lateral subnucleus of the torus semicircularis and in a restricted ventrolateral portion of the mid optic tectum. The fibers which reach the optic tectum terminate predominantly in that portion of the optic tectum whose receptive field corresponds to that area of visual space in which the fin rays are present. The bulk of the fibers continue rostrally past these mesencephalic areas to terminate in a specific diencephalic target nucleus, the nuc. preglomerulosus. This pathway from spinal cord to ipsilateral funicular nucleus to contralateral specific thalamic target nucleus seems analagous to the dorsal column-medial lemniscus system reported in amniote vertebrates. The major difference is that in mammals, the dorsal column system consists mostly of collaterals of primary dorsal root fibers with an admixture of second-order fibers; whereas in <u>Prionotus</u>, the equivalent system consists almost entirely of second-order fibers. If these systems are homologous, this would lend further weight to the concept that the preglomerular nuclear complex in teleosts is homologous to the ventrobasal complex of mammals, a portion of the dorsal thalamus.

Supported by NSF grant #BNS 79-04310

MORPHOLOGY AND TOPOGRAPHIC ORGANIZATION OF FUNCTIONALLY IDENTIFIED TRICEMINAL (V) PRIMARY AFFERENT FIGURIONALLI Jacquin, R.D. Mooney and R.W. Rhoades. Dept. of Anatomy, UMDNJ-NJSOM & RMS, Piscataway, NJ 08854. Intra-axonal injections of HRP were used to define the morpho-M.<u>F.</u>

Intra-axonal injections of HRP were used to define the morpho-logy of functionally characterized V primary afferents in rats. Thus far we have recovered 21 fibers (identified as primary afferents on the basis of high frequency following and invarient latency--range 0.4-0.9 ms--in response to V ganglion shocks). All labelled axons were visible in the V spinal tract for <u>at least</u> the length of subnucleus caudalis (Vc) and our analysis is restricted to this subnucleus. The topography of the primary afferent innervation of Vc was consistent with that shown in previous experiments. Fibers with rostral facial receptive fields (RF's) gave off collaterals in anterior Vc while those with caudal RF's innervated the posterior part of the subnucleus. Mandibular fibers innervated dorsomedial Vc while ophthalmic-maxillary afferents terminated ventrolaterally. There were also maxillary afterents terminated ventrolaterally. There were also differences in the laminae innervated by ophthalmic and maxillary fibers. Low threshold maxillary afferents provided bouton-like swellings primarily in layers III and IV of central Vc. Ophthal-mic fibers innervated laminae III and IV in ventral Vc and layer V in central Vc. Afferents innervating different vibrissae also had segregated arborizations. Dorsal and caudal vibrissae were represented in caudal and ventral Vc, primarily in lamina IV while terminale of fibers innervating restral and wentral whisk while terminals of fibers innervating rostral and ventral whisk-

ers were located anteriorly and dorsally, largely in lamina III. All of the collaterals from a given parent axon (an average of 4.4 were observed in Vc; no differences with respect to submodality or V division were noted) resembled each other as did those of functionally equivalent primary afferents. Differences between functional types were reflected in the shapes, laminar distributions and densities of terminal arbors. Shapes, faminar distributions and densities of terminal abovs. Vibration sensitive afferents had widely distributed arbors in laminae II-V and an extremely high (117) number of boutons/collateral. Rapidly adapting guard hair afferents also had widely distributed collaterals in layers III-V, but a somewhat lower number (77) of boutons/collateral. Rapidly adapting vibrissae afferents had circumscribed arborizations in lamina III or IV and an average of 51 boutons/collateral. Slowly adapting vibrissae afferents had a similar laminar distribution, but a slightly higher number (60) of boutons/collateral. Whisker afferents characterized as having a "wide dynamic range" had arterents characterized as having a wide dynamic fange" had restricted terminal arborizations along the layer III-IV horder and the fewest (40) boutons/ collateral. Supported by BNS8004601, DE06578, EY04710, EY03546, The March of Dimes and the UMDNJ Foundation (RWR); and BNS8205598 (awarded to be Devid Forent)

to M. David Egger).

ARRANGEMENT OF TERMINAL ARBORS OF PHYSIOLOGICALLY IDENTIFIED 73.5 VIBRISSA AFFERENTS IN THE RAT TRIGEMINAL SYSTEM. H. Hayashi\* (SPON: S. Gobel). Dept. Physiol., Fac. Dent., Tokyo Med. Dent. Univ., Bunkyo-ku, Tokyo 113, Japan. Cutaneous primary afferent axons carrying sensory information

from the facial skin enter the brain stem, ascend and/or descend within the spinal trigeminal tract, and give off collaterals into the underlying spinal trigeminal nucleus. The terminal arbors of these collaterals are thought to form a continuous sagittal sheet. The HRP-intracellular staining method was used to determine whether collateral arbors of vibrissa afferents conform to this description.

Adult rats were anesthetized and their brain stems exposed. Intra-axonal recordings were made in the spinal trigeminal tract with HRP-filled glass pipettes from 5 different kinds of vibrissa afferents classified according to Zucker and Welker (Brain Res., 1969) and then HRP was injected with current pulses. After the animals were perfused, frozen sections were made and processed

with CoCl, and 3,3'-diaminobenzidine. Forty-Eight axons innervating vibrissa follicles on the muzzle were stained for distances of 2-11 mm. Collaterals issued from the parent axon entered the nucleus and arborized inside the nucleus. The parent axons were located in the middle of the tract.

Within the subnuclei interpolaris (Vi), oralis (Vo) and main sensory nucleus (i.e., rostral to the obex) the terminal arbors were restricted to the outer half of the nucleus with only a were restricted to the outer half of the nucleus with only a small gap separating their outermost extent from the overlying tract. Near the obex (i.e., the beginning of subnucleus caudalis, Vc), however, the arbors suddenly shifted deeper into Vc's lamina V. Within Vc, the terminal arbors of successively more caudal collaterals shifted superficially from lamina V into laminae III and IV.

These data indicate that the sheet-like terminal arbors of single vibrissa afferents are discontinuous at the level near the obex and consist of 2 sheets. The rostral sheet is located superficially while the caudal sheet begins deeper and then gradually shifts to a superficial location in the caudal part of Vc. Since sudden shifts of the sheets take place at the level between 0.5 mm rostral and 1 mm caudal to the obex, the rostral and caudal sheets of multiple axons overlap at this level.

73.6

PATTERN OF TRIGEMINAL AFFERENTS IN THE BRAINSTEM TRIGEMINAL COMPLEX OF THE RAT. <u>C. A. Bates and H. P. Killackey\*</u>. Dept. of Psychobiol., Univ. of Calif. Irvine, Irvine, CA 92717 In the brainstem trigeminal complex, clusters of dense suc-cinic dehydrogenase (SDH) staining are related in a one-to-one fashion to the mystacial vibrissae on the face. It has been suggested that the clusters of SDH activity are related to the terminals of trigeminal afferents (Balford and Killarya, ICN) terminals of trigeminal afferents (Belford and Killackey, JCN 183: 285, 1979). This study attempts to bridge the gap between the pattern of SDH activity and the pattern of trigeminal afferents in the brainstem.

in the brainstem. Injections of 3-5  $\mu$ l of WGA-HRP (Sigma) were made into the rostral portion of the trigeminal ganglion of six day old (PND 6) rat pups. The animals were sacrificed on PND 8 and processed according to the method of Itoh et al (Br. Res. 175:341, 1979). Fiber labeling was observed at all levels of the brainstem trigeminal complex. In horizontal sections, four distinct areas can be distinguished by the pattern of labeled trigeminal affer-ents. We tentatively identify these areas as the principal sen-sory nucleus (PSN), and the three subnuclei of the spinal tri-ceminal nucleus (oralis, interpolaris, caudalis).

sory nucleus (rsh), and the three sublucter of the spinar three geminal nucleus (oralis, interpolaris, caudalis). Rostrally, at the level of the trigeminal motor nucleus, dense terminal labeling is present in the principal sensory nucleus. No obvious pattern is apparent at this level, although there are variations in terminal density.

variations in terminal density. Posterior to PSN, in the spinal trigeminal nucleus, the most rostral portion has the lowest density of terminal arborizations and corresponds to subnucleus oralis. Trigeminal fibers leave the tract at right angles and extend across the nucleus in large bundles. Further caudally, in interpolaris, fibers are more dis-persed, extending in small groups rather than large bundles. Fibers do not branch until they form terminal arborizations. These arborizations are aligned, forming a narrow rostrocaudal band extending the length of interpolaris. This pattern of ter-minal arborizations corresponds to the bands of SDH activity which extend rostrocaudally through interpolaris. This finding supports the idea of a one-to-one relationship between the vibrissae and trigeminal afferents as demonstrated by SDH studies. In the area trigeminal afferents as demonstrated by SDH studies. In the area related to caudalis, the arrangement of trigeminal afferents re-sembles that of interpolaris, however the band of dense terminals is located slightly lateral to the band in interpolaris.

73.7 ULTRASTRUCTURE OF TRANSGANGLIONIC HRP TRANSPORT IN CAT TRIGEMINAL SYSTEM. M.A. Henry\*, L.J. Johnson\* and L.E. Westrum (Spon: J.D. Loeser). Depts. of Neurological Surgery and Biological Structure and Center for Research in Oral Biology, Univ. of Washington, Seattle, WA 98195.

Recent interest in dental projections has resulted in light microscopic (LM) reports of transganglionic HRP transport from teeth to brain stem. Since some controversy persists in this area ultrastructural (EM) correlates of these transport studies are essential. Since EM protocols for transganglionic transport of HRP have proven difficult the present study attempts to standard-ize these procedures so that the complete distribution pattern may be reproducibly seen. This would allow consistent identifi-cation of each type of ganglion cell, axon, terminal and synapse. An inferior alveolar nerve soak procedure which demonstrates consistent and dense labeling in the brain stem is used to manipulate variables in order to select the protocol that results in the maximum retention of transported HRP and optimum tissue preser-vation. The TMB method was used throughout. Variables to increase the amount of transported HRP to the brain stem include: survival time, use of WGA-HRP, and additives such as DMSO and poly-L-ornithine. Technical modifications to improve tissue preservation and the retention of transported HRP include: pH and H2O2 concentration of the incubation solutions, pH and storage time in the postincubation solution, pH and temperature of the osmication solution, and time and concentration of dehydration solutions. The standardized procedure was then used in experiments with HRP implants into single canines. Adjacent sections are processed for LM and reveal a periobex distribution of the TMB-HRP reaction product in partes interpolaris and caudalis simi-lar to that seen in our earlier experiments. EM of these areas demonstrate a reaction product, within terminals, that is dense demonstrate a reaction product, within terminals, that is dense to pale with a lamellated or crystalline appearance. Terminals may contain either a single or multiple crystals. The terminals containing the crystals are from 1.5 to 3.0 microns in diameter, having round synaptic vesicles and aggregates of mitochondria. Sites of synaptic specialization are sometimes identifiable and are suggestive of Gray type 1 contacts. The size of some of the crystals of TMB-HRP reaction product is below the resolution for the light microscope. This further indicates that ultrastructural studies are necessary to demonstrate the submicroscopic but com-plete distribution of transported HRP for this or any given path-

73.8 FINE STRUCTURAL ORGANIZATION OF THE BRAINSTEM SENSORY TRIGEMINAL

FINE STRUCTURAL ORGANIZATION OF THE BRAINSTEM SENSORY INTGEMINAL COMPLEX IN THE RAT. L. S. Ide and H. P. Killackey\*. Dept. of Psychobiology, University of California, Irvine, CA 92717. The fine structural organization of the brainstem sensory tri-geminal complex was investigated in normal tissue from adult albino rats. The main sensory nucleus as well as each of the sub-nuclei of the spinal trigeminal nucleus was examined. Observa-tions on subsuplous caudalis was restricted to the does lawers tions on subnucleus caudalis were restricted to the deep layers. Direct comparisons indicate that a similar synaptic organiza-

Direct comparisons indicate that a similar synaptic organiza-tion characterizes the main sensory nucleus, the spinal subnucleus oralis, subnucleus interpolaris, and subnucleus caudalis (deep layers). Our observations on the synaptic organization of the sensory trigeminal complex generally agree with the description that Gobel and Dubner ('69) provided for the main sensory nucleus. Throughout the sensory trigeminal complex dendrites and typi-cally one or more synaptic terminals containing flat synaptic ves-icles (F terminals) are grouped together with a large terminal containing round vesicles (R terminal) in characteristic "synaptic glomerul1." Within these glomerular arrays the large R terminal makes multiple asymmetric synaptic contacts onto dendritic elements. The F terminals make symmetric synaptic contacts onto the same elements. In addition, axo-axonic contacts occur between F and R terminals in which the R terminal is the postsynaptic ele-ment. F and R terminals in non-glomerular regions are heterogenment. F and R terminals in non-glomerular regions are heterogen-eous in appearance. Occasional non-glomerular F terminals make distinctively long synaptic contacts onto dendrites in a manner not seen within glomeruli. Both large R and relatively large F terminals are occasionally seen to emerge from myelinated axons. Further, both of these types of synaptic terminal commonly occur as boutons en passant. In addition to contacting smaller-diameter dendrites (and spines) such terminals also make multiple synaptic contacts onto single large-diameter dendrites or onto the surface of perikarva

of perikarya. While the main sensory and spinal trigeminal nuclei share many while the main sensory and spinal trigeninal nuclei share many features of fine structural organization, some differences are evident. One of these is that cells receiving large numbers of axosomatic contacts are seen more commonly in the spinal nucleus. These contacts are made by both F and R synaptic terminals. Larg numbers of axosomatic contacts are particularly characteristic of the larger neurons that distinguish much of the spinal trigeninal nucleus. Large nucleus. Comparable neurons are rarely seen in the main sensory nucleus.

- A GOLGI ANALYSIS OF TRIGEMINAL NUCLEUS INTERPOLARIS IN THE ADULT 73.9 RAT. K. D. Phelan and W. M. Falls, Department of Anatomy,
  - Michigan State University, East Lansing, MI 48824 Neurons in trigeminal nucleus interpolaris (TNI) were examined in the adult rat using the Golgi method. On the basis of their overall morphology and the distribution of their axons and dendrites, at least seven distinct populations of TNI neurons were recognized. Three types of <u>SMALL</u> cells with rounded to fusiform somata (10-15 µm in diameter) were identified throughout TNI. T The dendritic arbors of one type extended 700  $\mu$ m or more in the rostrocaudal axis and were characterized by long (up to 400  $\mu$ m) sprimary dendrites. The other two types of small cells displayed spherical to elliptical-shaped dendritic fields up to 300 µm in They differed from each other by the presence of either diameter. beaded or spine-laden dendrites. Many spiny cells were located near the spinal V tract and some exhibited extensive unmyelinated axonal arborizations confined within the dendritic trees of the parent cells. On the basis of this axonal morphology these spiny neurons are thought to function as Golgi Type II interneurons involved in the intrinsic circuitry of TNI. Three types of MEDIUM cells (15-30 µm cell bodies) were distributed throughout TNI. The first type had fusiform to triangular-shaped somata which gave rise to 3 to 4 widely spaced primary dendrites. T dendrites branched infrequently and formed spherical to The elliptical-shaped dendritic arbors up to 500 µm in diameter. second type of medium neuron was distinguished by a pyramidal-shaped cell body which generated apical and basal cone-shaped dendritic fields which together spanned nearly 350 µm of TNI. The The remaining type of medium cell possessed a polygonal-shaped cell body which emitted 4 to 6 primary dendrites. Its highly branched dendritic arbor occupied an elliptical domain up to 400  $\mu$ m in diameter. The latter two types of medium cells were observed in both spiny and aspiny varieties. The <u>LARCEST</u> cells in TNI were concentrated in the rostral half of the nucleus. They had  $25-40 \ \mu m$  polygonal-shaped somata which emitted 3 to 4 primary dendrites. These primary dendrites gave rise to extensive dendritic fields extending over 700  $\mu$ m in the rostrocaudal axis. The dendrites of these cells emitted widely scattered spines and some The higher order branches traveled up to 300 µm without branching. Both medium and large TNI cells are considered to function as Golgi Type I projection neurons on the basis of the morphology of their initial axonal segment. This study provides for the first time detailed information concerning the dendritic and axonal patterns of TNI neurons and demonstrates that the populations of small and medium neurons observed in Nissl preparations are each composed of at least three morphologically distinct types. Supported by NIH/BRSG to the College of Osteopathic Medicine, M.S.U.
- INTRACELLULAR LABELLING WITH HRP OF IDENTIFIED NEURONS, PRIMARY 73 11 AFFARENTS AND CORTICAL AFFERENTS IN THE CUNEATE NUCLEUS OF THE CAT. S. Cheema, R. Fyffe,\* A. Light and A. Rustioni. Departments of Anatomy and Physiology, University of North Carolina, Chapel Hill, NC 27514

Intracellular or intraaxonal injection of horseradish peroxidase (HRP) enables the investigator to tackle questions related to structural correlates of neuronal function. In the present study thalamic projection neurons, primary and cortical afferents in the feline cuneate nucleus were investigated. Neurons were identified by antidromic activation from the ven-

trobasal nuclei of the thalamus, their receptive fields deter-mined, and then, if successfully impaled, were iontophoretically injected with HRP. After HRP histochemistry, sections were injected with HKP. After HKP instochemistry, sections were embedded in plastic wafers and viewed by LM prior to EM examina-tion of HRP-labelled profiles. Soma diameters of thalamic pro-jection neurons ranged from 10 to 25  $\mu$ m. Dendritic ramifications were often extensive and carried many appendages and complex axon-like profiles which had "en-passant" and terminal enlarge-ments. The axons of cuneo-thalamic cells coursed to the media locations and gave rise to collateral schorizations in the year lemniscus and gave rise to collateral arborizations in the ventral parts of the cuneate nucleus, and occasionally in dorsal re-gions which did not overlap with the cell's dendritic domain. Single primary afferent axons in the cuneate fasciculus were

identified following natural stimulation. Axons activated by cutaneous stimulation of the forepaw terminated in the dorsal part of the middle cuneate nucleus; the terminal arborization of each axon appeared to be focussed upon a small group of neurons with occasional side branches that terminated outside this focal point. A cutaneous primary afferent sometimes gave rise to more than one bouquet of terminal boutons. Ia fibers from forelimb muscles terminated both in a marginal zone and in the ventral parts of the cuneate. Electronmicroscopical examination of primary afferent boutons showed these to contact mainly dendritic profiles.

Corticofugal fibers were recorded ventral to the cuneate nucleus and were identified by cortical stimulation. Cortico-nuclear axons coursed rostrally from the pyramidal decussation and issued collateral branches which gave rise to bouton-bearing arborizations which extended up to 2.5 mm in the rostrocaudal axis of the ventral cuneate nucleus. Other corticocuneate projections arose as collateral branches of corticospinal axons; their arborizations were restricted rostro-caudally (0.1 - 0.5 mm), and bore fewer boutons than corticonuclear axons. Synapses of corticocuneate fibers were located on small and medium dendrites.

TRIGEMINAL AND SPINAL PROJECTIONS TO THE PARABRACHIAL AREA IN THE 73.10 CAT. W.M. Panneton and H. Burton. Dept. Anat., St. Louis Univ., St. Louis, MO 63104 and Dept. Anat. and Neurobiol., Washington Univ., St. Louis, MO 63110.

In recent investigations on intratrigeminal pathways in the cat (<u>Brain Res.</u> 236:463, 1982) we noted numerous neurons retro-gradely-labeled with horseradish peroxidase (HRP) in lamina III and lamina IV of the medullary dorsal horn (MDH) while only a few labeled cells were found in lamina I and lamina V after injections centered in the principal trigeminal nucleus. However, when the injection spread into more dorsal and lateral pontine areas, including the parabrachial and Kolliker-Fuse (KF) nuclei numerous labeled neurons also were found in laminae I and V. The projection to the dorsolateral pons now has been investigated more fully.

In five adult cats 20-100 nl of 1% WGA-HRP was injected into the parabrachial area. After a 48-hr. survival, the brainstem was sectioned serially through the levels of the trigeminal sensory complex. In three other cases with similar injections either transverse or horizontal sections through the spinal cord also were cut. In those cases where the injection was confined to the parabrachial complex retrogradely-labeled neurons were found in lamina I, outer parts of lamina II and in lamina V in the MDH. These were especially prominent in dorsal and medial areas of the rostral MDH. In one case where the injection did not include the Kolliker-Fuse nucleus, neurons in lamina V were not labeled. Most labeled neurons were ipsilateral to the injection but some were seen in laminae I and V on the contralateral side. Neurons in lamina I in the spinal dorsal horn (SDH) at both the cervical and lumbar levels also were labeled bilaterally, and were best seen at the apex of the SDH. In th In the subnucleus interpolaris a few labeled neurons were scattered throughout the dorsal half of the nucleus after such injections. Most prominent, however, was the labeling of neurons interstitial to the spinal trigeminal tract especially dorsally in the para-trigeminal nucleus on the ipsilateral side.

Injections of HRP into the MDH (2 cases) and the cervical spinal cord (1 case) were done to define the peribrachial targets of these medullary and spinal neurons. Diffuse, granular reaction product was evident in the lateral parabrachial nucleus Such label was evenly distributed bilaterally in all cases. after the injection into the spinal cord but was mostly ipsi-lateral after the injections into the MDH. The injections into the MDH, especially that placed closer to the obex, also produced dense label in the KF area and the caudal part of the para-brachial nucleus along the medial edge of the brachium conjunctivum. 73.12 POST-SYNAPTIC DORSAL COLUMN FIBER TERMINAL PATTERNS IN THE NUCLEUS CUNEATUS OF THE CAT. J. Pierce, A. Rustioni, S. Cheema, and R. Fyffe\*. Departments of Anatomy and Physiology, University of North Carolina, Chapel Hill, NC 27514. The dorsal column system of the spinal cord has traditionally

viewed as an ascending pathway for primary afferent colla terals projecting to the dorsal column nuclei. However, the exis-tence of a distinguishable post-synaptic dorsal column pathway, tence of a distinguishable post-synaptic dorsal column pathway, with distinct anatomical and electrophysiological characteris-tics, has been known for several years. Earlier studies using the successive degeneration technique (Rustioni, <u>Brain Res.</u>, 1974) indicated that these fibers ascended in both the cuneate fascicu-lus and the dorsolateral fasciculus (DLF), terminating primarily in the ventral and rostral parts of the cuneate nucleus. We are now reexamining this projection using degeneration and

(WGA-HRP) transport, in series. Initially, dorsal root ganglio-nectomics are performed unilaterally from C2 to T1, and the ipsilateral dorsal columns are transected at Tl. Two weeks later, at a time when most or all of the involved primary afferent fibers are not expected to transport WGA-HRP, a series of ten 0.1 µl WGA-HRP injections are made ipsilaterally, from C2 to T1. After a further 48 hours the animals are sacrificed, and the tissue is prepared for light or electron microscopy, after HRP histochemistry. This approach allows for both a more sensitive mapping of the terminal field, and an examination of individual synapses at the ultrastructural level.

Post-synaptic fibers, as shown by this approach, distribute within the cuneate nucleus in a pattern similar to that described in the earlier successive degeneration studies, although their termination in the dorsal cell cluster region appears more prominent than previously observed. The electron microscopic demonstration of synapses of post-synaptic fibers is made possible by a cobalt chloride intensification reaction using pyrocatechol and p-phenylenediamine as chromogens, with remarkably good preserva-tion of the tissue. Current experiments are also underway to tion of the tissue. Current experiments are also underway to investigate the spatial relationship between the projections of primary and post-synaptic afferent fibers by combining the above approach with intraaxonal iontophoresis of HRP. Supported by USPHS NS 12440.

SOMATOSENSORY RESPONSES OF DORSAL COLUMN NUCLEI NEURONS PROJECTING TO THE DORSAL MESENCEPHALON. Linda L. Cooper and Jonathan O. Dostrovsky, Department of Physiology, University of Toronto, Toronto, Canada, M55 1A8. 73.13

Anatomical studies have identified a projection from the dorsal column nuclei (DCN) to the dorsal mesencephalon (DM) and have shown that only a very small proportion of the neurons which project to the DM also project to the thalamus. of this investigation was to verify the projection from the DCN to the DM using electrophysiological techniques and to determine the functional characteristics and receptive field properties of both DCN neurons with projections only to the DM and DCN neurons with projections to both the DM and the thalamus. Extracellular single unit recordings from DCN neurons were

obtained in 20 chloralose anesthetized cats. Arrays of bi-polar stimulating electrodes were introduced into the contralateral DM and thalamus and were used to antidromically excite DCN neurons (0.1ms, 600uA maximum). Antidromic stimulation was used to identify the axonal projections of the DCN neurons. DCN neurons projecting to the DM were characterized with regard to their functional inputs and the location and size of their receptive fields.

Fifty-two DCN neurons were antidromically excited from the DM. 59% of these neurons could also be antidromically excited from the thalamus. Stimulating sites in the DM effective in antidromically exciting DCN neurons were within the external nucleus of the inferior colliculus, the intercollicular area and the caudal region of the ventrolateral superior colliculus. 77% of the DCN neurons with projections to the DM responded only to cutaneous stimulation, 18% of these neurons responded only to deep inputs and the remainder responded to both cutaneous and deep inputs. Responses to cutaneous stimulation resulted primarily from light mechanical stimulation of hairy skin and were rapidly adapting in nature. The receptive field sizes were similar to those previously reported by others and these examined by us for DCN neurons which projected only to the thalamus. However there was a clear trend for receptive fields of neurons projecting to the DM to be located on the proximal parts of the limbs, the torso or the neck. No clear differences were found between the receptive field properties of neurons projecting only to the DM and neurons projecting to both the thalamus and the DM.

These findings reveal that the DCN relay primarily information from rapidly adapting cutaneous receptors to the DM and are consistent with the proposed role of the DM in orientation toward external stimuli. Supported by the Canadian Medical Research Council

73.15 THE TOPOGRAPHY OF DORSAL COLUMN NUCLEAR PROJECTIONS TO SENSORI-The IOPOKRATH OF DOSAL COLUMN NUCLEAR PROJECTIONS TO SENSOL MOTOR CORTEX THROUGH THE THALAMIC POSTERIOR NUCLEAR COMPLEX IN RATS. <u>E.Luke Bold\*, R.J. Kosinski and E.J. Neafsey</u>. (SPON: M.A. Collins). Dept. of Anatomy, Loyola University Stritch School of Medicine, Maywood, IL 60153. The present study was undertaken to compare the distribution of lower and the second stribution.

of dorsal column nuclear projections to the thalamic posterior nucleus (PO) with the location of PO neurons projecting to fore-limb sensory and motor as well as hindlimb sensorimotor cortical areas in the rat.

Prior to surgery, animals were anesthetized with Ketamine HCl (100mg/kg,IM) and placed in a stereotaxic apparatus. Within the same animal, 1% WGA-HRP was injected (0.02-0.05µl) into nucleus cuncatus or nucleus gracils while True Blue or Nuclear Yellow (2%) was injected (0.3-0.5µ1) into the corresponding electrophys-iologically defined forelimb sensory, forelimb motor, or the hindlimb sensorimotor cortical area. After 1-4 day survival periods animals were overdosed with sodium pentobarbital and perfused transcardially with physiological saline followed by a 4% buffered paraformaldehyde solution and then a 10% buffered sucrose solution. Brains were removed and frozen sections serially cut at 40µm. Every other section was processed for HRP histochemistry according to the method of Mesulam (1978) and then examined under the point of the method of a state of the st

Retrogradely labeled PO neurons seen following sensorimotor hindlimb cortical injections closely overlapped with nucleus gracilis terminations within PO as demonstrated with anterograde Furthermore, retrogradely labeled PO neurons observed lowing sensory forelimb cortical injections showed overlap with the nucleus cuneatus terminations within PO. However, retrogradely labeled PO neurons seen following motor forelimb inject-

ions showed virtually no overlap with the terminations of the DCN. Additionally, there appeared to be a somatotopy within PO in that sensorimotor hindlimb cortical injections resulted in the labeling of cells located dorsolateral and caudally within PO while sensory forelimb injections resulted in labeled cells more rostral and more medial to the motor hindlimb labeled cells. The motor forelimb labeled cells were found dorsal to the sensory

forelimb labeled cells within PO. The lack of overlap between DCN projections and PO neurons mission of sensory input to the motor cortex. Supported by NIH grant NS 16146 and BRSG RR 05368 from Loyola

University.

MODULATION OF THE SENSORY RESPONSES OF CAT TRIGEMINAL AND 73.14 CONEATE NEURONS BY ELECTRICAL STIMULATION OF THE RED NUCLEUS. Bruce G. Gray and Jonathan O. <u>Dostrovsky</u>, Department of Physiology, University of Toronto, Toronto, Canada, M5S 1A8. Anatomical studies have shown that the red nucleus of the

cat projects to both the trigeminal subnucleus caudalis and the dorsal column nuclei in addition to its well known projection to the spinal cord. These facts suggest that the red nucleus may play a role in modulating the transmission of somatosensory information at various relay points. The aim of this study was to determine whether electrical stimulation of the red nucleus modulates the sensory responses of either trigeminal subnucleus caudalis or cuneate neurons.

Experiments were performed on chloralose anesthetized adult cats. Extracellular single unit recordings, using glass-coated platinum-plated tungsten microelectrodes, were obtained from both trigeminal subnucleus caudalis and cuneate neurons in each cat. Bi-polar stimulating electrodes were stereotaxically placed in the contralateral thalamus and red nucleus. All stimulation sites were subsequently verified histologically. A total of 23 trigeminal neurons (14 low threshold mechanoreceptive, 6 wide dynamic range and 3 nociceptive specific) and 20 cuneate neurons were studied in 5 cats. Neurons were excited to just suprathreshold levels with either electrical or mechanical stimuli applied to their receptive fields. Conditioning stimuli delivered to the red nucleus preceded the peripheral test stimulus by 130 ms and consisted of a 100 ms, 500 Hz train of 0.1 ms pulses. A current intensity of 150 uA was used as the cutoff point for establishing if inhibition was present. Over 90% of the cells in each region where found to be inhibited, including 2/2 trigeminothalamic and 8/8 cuneothalamic neurons. The mean current intensity needed to inhibit the trigeminal neurons was 55 uA while that needed to inhibit the cuneate neurons was 39 uA. Stimulation of the red nucleus caused excitation of 4 cells, 2 in each region. None of these latter cells were found to project to thalamus. These results, together with those previously reported for the spinal cord dorsal horn, indicate that the red nucleus can exert a powerful modulatory effect on neurons receiving somatosensory inputs. Thus one function of the red nucleus may be to inhibit the rostral flow of sensory information which is not relevant to the motor task being performed. Supported by the Canadian MRC and USPHS (DE-05404).

RESPONSES OF RACCOON VENTROBASAL NEURONS TO RAMP DISPLACEMENTS 74.1 OF GLABROUS SKIN. Andrew M. Kelahan, Susan Warren\*, and Benjamin H. Pubols, Jr. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209, and Department of Physiology, New York University, New York, NY 10016.

Single neurons of the raccoon thalamic ventrobasal complex were examined for their response to controlled ramp displace-ments of the glabrous skin of the hand, and the results were compared with findings in primary mechanoreceptive afferent fibers. Subjects were anesthetized with either pentobarbital sodium or methoxyflurane. Displacement velocities were varied between 0.1 and 100 µm/msec, with final displacements up to 1000 µm

1000 µm. As displacement velocity increases, depending upon the unit, the number of spikes per ramp may (1) first increase to a peak at velocities between 2 and 10 µm/msec, and then decline with further increases in velocity, (2) remain fairly constant, or (3) decrease continuously. However, we have not observed a monotonic increase in spikes per ramp with increasing ramp velocity, as has been reported for some primary afferent units (e.g., Pubols, B., J. Neurophysiol., 1980). For a given displacement velocity (e.g., 10 µm/msec), the discharge pattern of both rapidly and slowly adapting units typically is one of deceleration or constant discharge rate, but rarely the acceleration characteristic of slowly adapting primary afferent fibers (Pubols, B., and Pubols, L., Fed Proc., 1983).

1983).

For most ventrobasal neurons, instantaneous discharge frequency during ramp stimulation is adequately described as a power function of ramp velocity (Warren and Pubols, <u>Neurosci</u> power function of ramp velocity (Warren and Pubols, <u>Neurosci</u>. <u>Abstr.</u>, 1981). However, there is a smaller population of units whose behavior is perhaps best described as a discontinuous function of ramp velocity: As ramp velocity increases, discharge rate remains relatively constant until velocities of 10-20 µm/msec are reached, at which point the discharge rate suddenly increases by a factor of 5-20 X, and remains at this higher level throughout further increases in ramp velocity. We have also observed this discontinuous response function in ventrobasal neurons of barbiturate-anesthetized cats. ventrobasal neurons of barbiturate-anesthetized cats. We conclude that the discharge properties of ventrobasal

we conclude that the discharge properties of ventrobasar neurons in response to ramp displacements of glabrous skin are highly complex and variable and cannot necessarily be predicted from knowledge of the discharge properties of individual primary afferent neurons. (Supported by research grants NS-13418 and NS-19486, USPHS.)

MOTION- AND DIRECTION-SENSITIVE NEURONS IN S-I CORTEX OF ALERT

RESPONSES TO DIFFERENT RETRACTION VELOCITIES AND INTERRAMP INTER-74.2 VALSOF RAPIDLY ADAPTING NEURONS IN CAT SI CORTEX. J.P. Guillemot, <u>R. Proulx\*, A. Samson\* and L. Richer\*</u>. Dept. of Kinesiology and Psychology, Université du Québec, Montréal, Canada.

Psychology, Universite du Quebec, Montreal, Lanada. Cutaneous stimulus identation and retraction seem psychophysi-cally difficult to discriminate when high velocity and short tem-poral interramp interval (IRI) are used. These ON and OFF soma-tic sensations may have their substrate in the rapidly adapting (RA) cutaneous neurons. In ordre to study the nature of OFF dis-charges of RA neurons at higher levels of information treatment, we recorded the unit responses in cat's forepaw representation in SI area.

Acute recordings were carried out in the conventional manner with tungsten microelectrodes using curarized and N<sub>2</sub>O: 02 anaes-

with tungsten microelectrodes using curarized and N<sub>2</sub>O: O<sub>2</sub> anasathetized cats. The recording site was area 3b. Suprathreshold skin displacement were used (2000  $\mu$ m). The velocity of the stimulus for both indentation and retraction was equal. Stimuli were applied with a servo-controlled vibrator on cutaneous receptive fields previously determined with a von Frey calibrated hair. Various velocities of stimulus application and withdrawal were used with either an IRI of 10 sec. or different short IRI. Analysis of 113 RA neurons showed 3 classes of units: (class A units (70%) had ON responses higher than OFF, class B units (12%) showed the inverse relationship between the ON and OFF responses and, class C units (18%) responded only with ON discharges. When indentation and retraction stimulus velocity was increased, discharge rate increased in all neurons. Different OFF responses were obtained for class A and B units with various IRI: both increasing IRI's. In addition, higher velocity was positively cor-

creases or decreases in discharge rate were observed with in-creasing IRI's. In addition, higher velocity was positively cor-related with discharge rate. Moreover, few units showed an in-teraction between IRI and velocity. These results suggest that the stimulus retraction is more dif-ficult to discriminate such as demonstrated in the majority of neurons showing lower OFF discharges. The visco-elastic proper-ties of skin acting on RA neurons may explain the relation between velocity and discharge rate. In addition various beha-viors observed with different IRI's indicate that temporal fac-tors may also affect discriminative properties of skin receptors.

RESPONSES OF VIBRISSA UNITS IN RAT SMI BARREL CORTEX TO MULTI-WHISKER STIMULATION. D.J. Simons, Dept. of Physiology, Univer-sity of Pittsburgh, School of Medicine, Pittsburgh, PA 15261 Responses of single cortical units in the SmI barrel cortex of unanesthetized rats were observed following combined deflections of contralateral vibrissae. Compact multi-angular stimulators were used to deflect whiskers in controlled temporal and spatial patterns. Following deflection of a vibrissal hair, unit dis-charges to subsequent deflections of the same or a different whisker were substantially reduced or abolished altogether. This suppression was strongest at short interoeflection inter-vals, i.e. 10 ms, and decreased progressively during the 50-100 ms following the first deflection. In many cases this time period also corresponded with a reduction of a single whis-ker. Several spatial factors determined the presence and degree of a cell's response to the second of two whisker deflections a) the angular direction(s) in which the individual hairs were a) the angular direction(s) in which the individual hairs were moved, b) the sequence in which two whiskers were deflected, i.e. which one was deflected first, and c) the particular combination of whiskers stimulated.

Response suppression could be elicited by prior deflection of whiskers within the normally-defined excitatory RF as well as by whiskers within the normally-defined excitatory RF as well as by whiskers which when deflected alone failed to elicit unit dis-charges; in a number of important respects this latter phenome-non is similar to surrond inhibition. Although the effects of a given whisker generally decreased with its distance from the maximally exciting hair, i.e. usually the principal whisker of a cortical column, inhibitory regions of a RF could be distributed asymmetrically with respect to the principal whisker. More-over, in multi-whisker RF's vibrissae eliciting the most vigor-ous excitatory responses when deflected alone were not necessar ous excitatory responses when deflected alone were not necessar-ily the same as those that caused the strongest inhibition when

ily the same as those that caused the strongest inhibition when whiskers were deflected in combination. In some cases a combination of temporal and spatial factors appeared to interact. These data suggest that cortical vibrissa units are differentially responsive to patterns of stimuli pro-duced by objects moving in particular directions and/or veloci-ties across the mystacial pad. The findings are consistent with previous observations of temporal responsivity and spatial or-ganization of RF's in the somatosensory cortex in other spe-cies. At least some of these effects appear to be due to active inhibitory mechanisms within the cortex itself. Supported by NSP Grant #BNS 80-21854. Supported by NSF Grant #BNS 80-21854.

MONKEYS: TEXTURE AND VELOCITY CODING. S. Warren\*, H. Hamalainen\*, D.R. Kenshalo, Jr. and E.P. Gardner. Dept. of Physiology and Biophysics, NYU School of Medicine, New York, NY 10016. Direction sensitivity in SI cortex has been attributed to an asymmetric distribution of excitation and inhibition within the receptive field (Gardner and Costanzo, J. Neurophysiol. 43: 1342, 1980). Movements in the least preferred direction are thought to feed forward inhibition to adjacent skin areas which have not yet been stimulated. Therefore, if the spacing between stimulated points is increased, the directional preference should lessen. test this hypothesis, we have stimulated receptive fields of 66 motion- or direction-sensitive SI neurons (MSNs and DSNs) with a graded series of toothed wheels of equal diameters and tooth spacing of 0.8-9.0 mm. The wheels are mounted on low torque potentiometers, and rolled across the hand and arm with only the tips of the teeth contacting the skin surface. Despite the punctate nature of the stimulus, on both glabrous and hairy skin, the wheel response qualitatively resembled that observed when stroking the skin with brushes, edges or blunt probes. DSNs also differentiated the textures of the wheels. The clearest distinction between on- and off-directions of motion was seen with the finest textures. With 0.8 mm gaps, DSNs responded weakly to off-direction stimuli, while the on-direction response was vigorous. Increasing the gap between teeth did not significantly modify the on-direction response. However, movements in the off-direction elicited higher firing rates as the gap spacing increased. Never-theless, even with gaps as large as 9 mm, DSNs still showed a preference for movements in the on-direction. These findings suggest that DSNs are poorly suited for quantitative texture discrimination, since their firing patterns in the preferred direction of motion are unrelated to spatial frequency.

MSNs, which showed no direction preference, did not respond differentially to textured wheels. We found no difference in responses to the finest and coarsest wheels, nor was there a preference for intermediate textures. MSNs responded in a graded fashion to velocity of wheel rotation, over the range 5-40 cm/sec, showing the most vigorous activity to rapid motion.

These data suggest that both DSNs and MSNs can integrate information from widely spaced points in their receptive fields, and that rapid temporal sequencing of stimulation is more important than spatial contiguity in determining responses. The data also support the hypothesis that direction sensitivity is conferred by lateral inhibition of input from immediately adjacent skin areas, as differentiation of direction of motion is weakened by increasing the spatial separation of stimulation sites. - THE REPRESENTATIONS OF THE HAND IN AREAS 3b AND 1 OF THE MACAQUE MONKEY, MACACA MULATTA. T. P. Pons, P. E. Garraghty, C. G. Cusick, J. T. Wall, and J. H. Kaas. Department of Psy-chology, Vanderbilt University, Nashville, TN 37240. Currently there are different interpretations of the somato-topic organization of cytoarchitectonic Areas 3b and 1 in maca-que monkeys. Since some investigators used Macaca mulatta while others used Macaca fascicularis, the possibility of major species differences has been raised. In the present experi-ments, the hand representations in Areas 3b and 1 of Macaca mulatta (rhesus monkeys) were mapped in detail with micro-electrodes, and results were compared with our previous findings 74.5 <u>mulata</u> (rhesus monkeys) were mapped in detail with micro-electrodes, and results were compared with our previous findings in <u>Macaca fascicularis</u> (cynomolgus monkeys) (Nelson et al., J. <u>Comp. Neurol., '80).</u> Results were obtained from nine rhesus mon-keys anesthetized with Ketamine hydrochloride and as many as 580 recording sites were obtained in a single animal. Minimal cutaneous receptive fields were determined at each recording site from a multiunit response.
  - The hand representations in rhesus monkeys were devoted largely to the glabrous surface. The representations of the glabrous digits were joined at the proximal bases at the 3b/1 border and progressively more distal parts of the digits were represented progressively more caudal in Area 1 and deeper in the represented progressively more caudal in Area 1 and deeper in the central sulcus in Area 3b. Due to the considerable cortical mag-nification of the distal phalanges of the digits, the represen-tations of the distal phalanges approached the 3b/l border, especially in Area 1. For both areas, representations of the glabrous pads of the palm were displaced medially and laterally, district for the second sec glabrous pads of the palm were displaced medially and laterally, digits 1-5 were represented in order in a lateromedial sequence, and much more tissue was devoted to digits 1 and 2 than to digits 4 and 5. Representations of the dorsal hand and digits were located medially and laterally in the respective hand repre-sentations. In Area 1, islands of tissue representing the dorsal surface of the digits varied in location from animal to animal, and commonly disrupted and displaced the representations of the glabrous digits. In Area 3b, dorsal surfaces of the digits were often found represented in the depths of the central sulcus near the representations of the glabrous digit tips. The hand repre-sentations were bordered laterally by the face and medially by the wrist. The results indicate that the hand representations in both <u>Macaca fascicularis</u> and <u>Macaca mulatta</u> are quite similar. Supported by NIH Grant NS-16446.

SOMATOTOPIC ORGANIZATION OF THE SECOND SOMATIC SENSORY AREA, SII, IN THE CEREBRAL CORTEX OF THE MOUSE (SPON: T.M. Plant). G.E. Carvell\* and D.J. Simons. Depts. of Anatomy and Physical Therapy, and Physiology, Univ. of Pittsburgh, Pgh., PA 15261. The parietal cortex of barbiturate-anesthetized, adult mice was studied using tungsten microelectrodes to record single- and multiple upit activity in records to generate stimulation 74.6

was studied using tungsten microelectrodes to record single- and multiple-unit activity in response to gentle tactile stimulation of the face and body. A complete representation of the contralateral body surface occupying approximately 3.5 sq. mm, was found immediately posterior and lateral to the representation of the face in SI. Within SII: A) Substantial areas of tissue were devoted to representations of the forepaw and face, especially the sinus hairs associated with the nares, esterior incord bie ord myterial within for forepaw and face, especially the sinus hairs associated with the nares, anterior upper lip and mystacial vibrissae. Receptive fields on these body regions were small and contralateral, though larger than RF's of similar regions in SI. In particular, vibrissa RF's always included at least several adjacent whiskers. B) In regions representing proximal body parts, RF's were considerably larger, were often bilateral and sometimes included the entire body surface. C) The responsiveness of many cells was labile, waxing and waning over relatively short periods, i.e. 1-2 minutes. When present, responses could be reliably elicited by light tapping or brushing of clearly defineable body regions. Loci responding to the face were the most reliably driven. D) In some but not all animals, responses could also be elicited by auditory stimuli; overlap of auditory and somatosensory regions was largely restricted to the representation of the limbs and proximal body and was rarely found in the face region. E) The face was represented most anteriorly and the hindlim most posteriorly. Forepaw digits and anterior aspects of the face, e.g. nares and upper incisor, were represented laterally while the back and neck were represented medially. Within SII a the back and neck were represented medially. Within SII a "musculus" can be viewed as being upright in the medial-lateral plane with the midline representation of the face and nares lying immediately adjacent to the representation of these areas Tying immediately adjacent to the representation of these areas in SIL F) By comparison with SI, SII is characterized by a less pronounced layer IV, which is of irregular thickness and packing density, and by less uniformity in the layering of pyramidal cells in layer V. These results are in general accord with previous findings

response results are in general accord with previous ratings from evoked potential studies of mouse cortex but are at variance with some reports that the mystacial vibrissae are not represented in SII in mice. Of particular interest is confirmation of the finding that, compared to SI, SII appears to be proportionally larger in the mouse than in the closely-related rat. Supported by NSF grant BNS 80-21854.

74.7 THE SECOND SOMATIC SENSORY AREA (SII) IN A PROSIMIAN PRIMATE, GALAGO CRASSICAUDATUS. M. Carlson and H. Burton. Depts. of Anatomy & Neurobiology and Psychiatry, Washington Univ. Sch. Med., St. Louis, MO 63110.

SII in the <u>Galago</u> was located in a highly granular type cortex of approximately 12  $mn^2$  along the upper bank of the lateral sulcus (LS). In anesthetized animals, closely spaced microelectrode penetrations that were parallel to the LS were used to map the distribution of multi- and single neuron responses to low threshold, cutaneous stimuli at 50-100  $\mu$ m intervals; the survey approached 30 sites/mm<sup>2</sup>. The recordings activated from well-defined receptive fields (rfs) were distributed in a single, precise, somatotopic representation of the body in which contraprecise, somatotopic representation of the body in which contra-lateral input was dominant under these recording conditions (Fig. 1). Within this general pattern, several features were determined: (1) glabrous surfaces of the fore- and hindlinbs were separately represented; (2) hairy dorsal surfaces of the distal limbs surrounded the glabrous regions superficially and posteriorly; (3) small areas that received exclusively ipsi-lateral input from the hand or foot were located within the distal limb zones; and (4) an area receiving bilateral input from large, poorly defined rfs was located posterior to SII. The representation of the distal limb zones in anterior to

posterior, elongated strips in the <u>Galago</u> SII resembled the rf distribution described previously in <u>Macaca</u> SII whereas the relative segregation of fore- and hindlimb zones anteriorly and posteriorly, respectively, was reminiscent of the erect body plan of SII seen in nonprimates. The exceptional segregation of glabrous skin areas and the relatively easier accessibility of SI and SII in this species may indicate that the <u>Galago</u> is an ideal primate for the study of the interactions between these cortical somatic sensory areas in manual tactile discrimination. (Supported by NSF 81-15044 and NS09809.)

Somatosensory Corticotectal and Corticothalamic Projections from 74.8 Somatosensory Corticotectal and Corticothalamic Projections from Anterior Ectosylvian Sulcus in Newborn Cats. Barry E. Stein and Lawrence Kruger. Dept. of Physiol. and Biophys., Med. Coll. of VA Richmond, VA 23298 and Dept. of Anat., UCLA Center for the Health Sciences, Los Angeles, CA 90024. The fourth topographic somatosensory cortex (SIV) is located in the superior bank of the anterior ectosylvian sulcus (AES) (Clemo, H.R. & Stein, B.E. Brain Res., 235, 162-168, 1982). Somatosensory cells are also found in the funding and inforcion bank of the culour

cells are also found in the fundus and inferior bank of the sulcus but are not discretely organized. Yet, both areas project heavily to the superior colliculus and thalamic posterior group. The pro jection from the AES represents the principal source of descending Jection from the ALS represents the principal source of descending somatosensory information to the superior colliculus (Stein, B.E., Spencer, R.F., & Edwards, S.B., Neurosci. Abst., 8, 853, 1982; Clemo, H.R. & Stein, B.E., Neurosci. Abst., 7, 758, 1981). Since somatosensory cells are present in the superior colliculi of newborn cats (Stein B.E., Labos E., & Kruger, L. J. Neurophysiol. 36, 667-679, 1973) we sought to determine if a somatosensory corticotectal projection was already present at this time. Injections of <sup>3</sup>H-leucine (.1-.3 ul) were centered in the sup-

erior bank of the rostral AES in five kittens. Three animals were 12-12 hrs., one was 3 days and one was 5 days of age, at the time of injection. All animals were allowed to survive for 20-24 hrs. The injections labeled most of the rostral two-thirds of the sul-cus and spread to the inferior as well as to the superior bank.

Dense corticotectal and corticothalamic projections were seen even in the youngest animals studied. The projections appeared to be as dense or denser than that previously seen in adult cats and showed the same terminal distributions. The corticotectal projec-tion was bilateral, much heavier ipsilaterally than contralaterally and paralleled the distribution of somatosensory cells. The distribution of terminal labeling appeared as two bands; the upper band was centered in the stratum griseum intermediale and appeared band was centered in the stratum griseum intermediale and appeared to have a puff-like organization, the lower band was centered in the stratum griseum profundum, and extended medially to invade the periaqueductal gray. Laterally the bands were fused at the border of the superior colliculus. The corticothalamic projection ap-peared to penetrate the ventral group in discrete fascicles term-inating in a portion of the intralaminar wing and in the posterior group of thalamic nuclei. Axons running in the internal medullary lamina and running rostrocaudally in the ventral group did not re-veal clear terminal labeling in the ventral group comparable veal clear terminal labeling in the ventrobasal complex comparable to that seen following SI or SII injections in adults. These experiments indicate that the organization of the major somatosen-sory efferents at this cortical region occur prenatally.

Supported by NSF grant BNS 8021559, NIH grant NS-5685, and a grant from the Jeffress Foundation.

74.9 SOMATOTOPIC ORGANIZATION OF CORTICOTECTAL PROJECTIONS FROM THE AN-TERIOR ECTOSYLVIAN SULCUS IN CAT. <u>H.R. Clemo & B.E. Stein</u>. Dept. of Physiology and Biophysics, Medical College of Virginia, Richmond, VA 23298. (SPON: L. Bruce).

A dense cortical projection to the superior colliculus (SC) arises from two somatosensory zones of the anterior ectosylvian sulcus (AES): SIV, and an area deeper in the sulcus for which so somatotopic organization has been observed. We previously showed that projections from both regions contact somatosensory cells in the SC (Clemo and Stein, <u>Neurosci. Abst.</u>, <u>7</u>:758, 1981). The present study was initiated to determine the spatial (topographic) features of this projection.

Tungsten microelectrodes were used to record and stimulate; standard orthodromic and antidromic techniques were used in 30 adult cats. Many somatosensory SC cells could be activated with low current intensities  $(30-100\mu A)$  from several sites in SIV and a few from the somatosensory area of the AES deep to SIV. Regardless of the source of corticotectal influence, a simple rule prevailed: a cortical site would influence only SC cells whose receptive fields overlapped that of the cortical site. Yet within this framework there was considerable corticotectal convergence and divergence. Thus, SC cells with receptive fields covering the entire forelimb could be influenced by much of the forelimb region of the AES. Similarly, a single cell in cortex representing the forepaw could project to a wide 'territory' in the SC in which cells had receptive fields that included the forepaw. The corticotectal projection from the AES was modality specific; somatosensory SC cells could be activated only from regions of the AES and somatosensory-auditory (multimodal) SC cells could be activated from both areas of the AES.

We also tested SI-SIII for corticotectal influences, but only cells in the AES gave rise to a direct, monosynaptic corticotectal projection. No responses to stimulation of SIII were observed and stimulation in SI-SII was often ineffective. If effective, these sites were usually near the borders of other corticotectal zones, required high current intensities (200-800 µÅ) and cells in these regions could not be antidromically activated from the SC. Thus, their influences on SC cells appear to be indirect. The only other cortical area that influenced somatosensory SC cells was in the rostral part of the suprasylvian sulcus, where an expanded representation of the forelimb has been described and corticotectal projections have been shown anatomically. The scheme of corticotectal topographic register described above was found between the suprasylvian sulcus and the SC. Supported by Grant BNS 8021559, 8209857, and a grant from the

74.10 CONTRIBUTION OF THALAMO-CORTICAL AND CORTICO-CORTICAL CONNECTIONS TO RECEPTIVE FIELD PROPERTIES IN RAT SI CORTEX. J.L. Uhr and J.K. Chapin. Dept. of Cell Biology, U. Tex. Hlth. Sci. Ctr., Dallas, TX 75235.

The aim of this study was to investigate interactions between thalamo-cortical (T-C) and cortico-cortical inputs to the vibrissae area ("barrelfield") of the primary somatosensory (SI) cortex of the rat. In neuroanatomical studies we have shown that granular aggregates (barrels) in layer IV of this region receive the strongest T-C inputs, while layer V receives the strongest cortico-cortical inputs. Furthermore, receptive fields (RF's) of single neurons recorded in layer IV barrels include only one or a few whiskers, while RF's in layer V are much larger. To quantitatively define these RF's, post-stimulus histograms were generated of responses of single units to standardized

To quantitatively define these RF's, post-stimulus histograms were generated of responses of single units to standardized vibratory stimulation of each whisker in the RF. Both layer IV and V neurons typically responded to stimulation of the center whisker in their RF's with 6-10ms latencies. However, response latencies of layer V units increased up to 24ms post-stimulus as whiskers progressively more distant from the RF centers were stimulated.

To determine whether cortico-cortical (C-C) connections may subserve the layer V neuronal responses to these distant whiskers, adjacent regions within the barrelfield (2-3mm away from recording site) were microstimulated with a bipolar concentric stimulating electrode. Layer V neurons responded orthodromically with 3-5ms latency to stimuli between 12 and 20uA. Very few layer IV neurons responded to stimulation under 400uA. Furthermore, when such sites were lesioned  $(10uA_75s)$ , the recorded layer V neuron no longer responded to stimulation of the whisker corresponding to the lesioned barrel. Next, we investigated spatio-temporal interactions between

Next, we investigated spatio-temporal interactions between short-latency responses to peripheral stimulation (ie.T-C input) and stimulation of nearby cortex (ie.C-C input) presented at different conditioning (C) and test (T) intervals relative to each other. Histograms were generated to measure the modulation of the T by the C stimulus. Irrespective of whether the C stimulus was peripheral or cortical, C-T intervals less than 5ms produced facilitation of the response to T and also reduced its latency by 1-2ms. With C-T intervals exceeding 5ms, a deep long-lasting inhibition of the response to T was seen. Layer IV cells exhibited a shorter and weaker inhibition than layer V cells. This pattern of interaction between peripherally and cortically driven inputs may reflect processes involved in the detection of moving objects in the spatio-temporal domain. Supported by grant NS18041.

74.12 INTERHEMISPHERIC TRANSFER OF SOMESTHETIC INFORMATION IN THE COR-PUS CALLOSUM. F. Lepore, L. Prévost\*, L. Richer\*, J.P. Guillemot, Dept. of Psychology, Univ. of Montréal and Dept. of Kinesiology, Univ. of Québec, Montréal, Canada. Corpus callosum (C.C.) is involved in the interhemispheric transfer of sensory information. Previous electrophysiological and anatomical experiments have shown that neurons belonging the conticel compteneous among (SI and SU) competibility information.

Corpus callosum (C.C.) is involved in the interhemispheric transfer of sensory information. Previous electrophysiological and anatomical experiments have shown that neurons belonging the cortical somatosensory areas (SI and SII) sent somesthetic information to the other hemisphere through axons crossing at the rostral portion of the C.C.. In the present study callosal somesthetic receptive fields (R.F.) were identified and they were characterized in terms of localization and specific sensory modalities.

Acute recordings were carried out in curarized cats using tungsten microelectrodes and N<sub>2</sub>O: O<sub>2</sub> anaesthesia. The recording site in the rostral C.C. was identified visually using an operating microscope and fiber activity amplified in the conventionnal manner. R.F.'s were determined using von Frey calibrated hairs, puffs of air, light touch or pressure, and passive movement of the limbs.

Results indicated that various functional sub-modalities were represented originating from cutaneous, deep and paciniform receptors. Some neurons also responded to hair and whisker displacements. Moreover, both slowly and rapidly adapting axonic responses were found. R.F.'s were situated in pelvic limb (10%), trunk (15%), head (35%) or thoracic limb (25%) regions. Of the latter 75% concerned the proximal limb areas whereas 25% represented the distal limb or forepaw. These neurons all represented unilateral body parts. R.F.'s touching the midline of the body including the head and proximal limb structures were over represented in regards to distal body parts. In addition, a small number of bilateral R.F.'s were found in the face, trunk, thoracic or pelvic limbs.

These results suggest that callosal connections may be associated to different sensory functions such as midline fusion of the two halves of the body or processing of complex sensory discrimination.

RESPONSES OF CORTICOTHALAMIC CELLS TO CALLOSAL AND THALAMIC 74.11 STIMULATION IN CAT SOMATOSENSORY CORTEX. <u>P. Diadori,</u> Landry and <u>R.W. Dykes</u>. (Dept. of Neurology Landry and R.W. Dykes. (Dept. of Neurology and Neurosurgery, McGill University, Montreal, Quebec H3A 1A1.) To examine the effects of input from the corpus callosum onto somatosensory neurons we have recorded intracellularly and extracellularly from cells in areas 3b and 1 of the cat while driving them with peripheral, thalamic and callosal stimuli. In 19 barbiturate- anesthetized mongrel cats the cisterna was opened and a craniotomy performed. Thalamic stimulating electrodes were inserted stereotaxically into the ventroposterolateral nucleus and the contralateral somatosensory cortex was exposed and aspirated to allow stimulating electrodes to be placed in the anterior part of the corpus callosum at the midline. The depth of both sets of electrodes were adjusted to maximize the surface evoked potentials recorded in the forelimb region. Following these preparations, a 3M sodium acetate-filled pipette (20-40M ) was positioned at the cortical surface and the cranitoting was scaled with 3% agar. Responses of 109 neurons were recorded along vertical trajectories through the forelimb region using conventional stimulating and recording equipment. A subset of the neurons activated from the callosum were also activated antidromically from the thalamus (latencies ranged from 1.8 to 7.6ms). Excitation from the corpus callosum ranged from 7 to 17 ms. Excitation from the corpus callosum ranged from 7 to 17 ms. Increasing the stimulus intensity of the corpus callosum generated IPSP's with latencies between 8 and 20ms. In individual neurons, callosal and thalamic stimulus intensities were adjusted until the IPSP's were the same amplitudes. Under this condition the duration, the time to peak and the reversal potential of the IPSP's were the same successing that both thalamic and corpus callogue same suggesting that both thalamic and corpus callosum inputs share a common inhibitory interneuron. However unlike other cortical neurons which were synaptically driven by thalamic stimulation with latencies between 2 and 5 ms, no EPSP's were detected in these corticothalamic cells. Instead of the EPSP-IPSP sequence encountered in other cortical neurons, corticothalamic cells responded with a short latency IPSP (3-4ms) lasting approximately 80ms followed by a rebound excitation at 200ms. Their receptive fields were difficult to define or were absent. We suggest that perhaps corticothalamic neurons act as relay cells, receiving information from the contralateral cortex and sending it to the thalamus to modulate thalamocortical signals.

THE MORPHOLOGY OF SPECIFIC THALAMOCORTICAL AXONS PROJECTING TO THE BARREL FIELD OF THE RAT. <u>K. F. Jensen and H. P. Killackey\*</u>. Department of Psychobiology, Univ. of Calif. Irvine, Irvine, CA. 74.13 92717

The organization of thalamocortical projections to a portion of the parietal cortex of the rat (the barrel field) is very discrete and appears to preserve the spatial arrangement of receptors on the body surface, specifically the sinus hairs and vibrissae of the face. We have examined the morphology of individual thalamocortical axons which project to the barrel field.

Axons were labeled by injection of horseradish peroxidase (5% WGA-HRP, Sigma) either subcortically into fasicles of the internal WGA-NKF, SIGMA) either subcortically into fasicles of the inte capsule coursing through the caudate-putamen or into the lower portions of layer VI. The labeled axons were visualized in coronal sections with the DAB-GOD histochemical method of Itoh et al. (1979).

Individual parent axons, about one micron in diameter, ascend from the internal capsule in a step-like fashion with an occasional branch which bears terminals in layer VI. (Terminals were identified as one micron swellings, generally located on small diameter fibers.) The parent fiber courses through layer Vb and begins to branch extensively in layer Va. The vast between branch points is short. This results in a highly branched but relatively restricted busy terminal field that branched but relatively restricted bushy terminal field that spans the height of layer IV. Within layer IV the larger diameter fibers are relatively terminal-free while the finer branches bear the majority of terminals. A few of the small caliber terminal branches extend into layer III. The terminal field of a parent fiber appears to be associated with a single barrel. The terminal field may fill a large extent of a barrel. A number of parent fibers may have overlapping terminal fields within a circle bareal.

of a barrel. A number of parent fibers may have overlapping terminal fields within a single barrel. There are variations in the size of the most extensively filled arborizations. The terminal fields of the layer IV arborizations in the posteromedial apsects of the barrel field appear wider than those in the anterolateral aspects of the barrel field. The present observations confirm and extend previous descriptions of the specific thalamocortical afferents in this system based on Golgi (Lorente de No' 1922) and Fink-Heimer (Killackey 1973) methods. Supported by NSF grant BNS 81-20658

74.14

A VIBRISSAE RELATED PATTERN OF CALLOSAL CONNECTIONS IN THE PRIMARY SOMATOSENSORY CORTEX OF THE RAT. H. Killackey\*, J. Olavarria\* and R. C. Van Sluyters (Spon: R. Josephson). Department of Psychobiology, University of California, Irvine, CA. 92717, and School of Optometry and Neurobiology Group, University of California, Berkeley, CA. 94720. Previous light microscopic investigations of the callosal

Previous light microscopic investigations of the callosal connections of the rat somatosensory cortex have concluded that the face region is largely acallosal. However, at least one physiological study (Pidoux and Verley, 1979) and one electron microscopic study (Perentes, 1979) have suggested the existence of such connections. Hence, we decided to reinvestigate this question using a more sensitive neuroanatomical tracing method.

Adult pigmented rats were given multiple injections of about 0.1 ul of horseradish peroxidase (HRP) across the surface of one 0.1 ul of horseradish peroxidase (HRP) across the surface of one hemisphere. After 24 hr the rats were sacrificed and the brains removed. The cortex contralateral to the injection sites was separated from the rest of the brain, flattened, sectioned parallel to its surface and reacted for HRP histochemistry using tetramethyl benzidine as the chromogen. Following this procedure, labelled neurons and terminations are distributed in a honeycomb-like fashion within the portions of primary somatosensory cortex in which the mystacial vibrissae and facial sings heirs are represented. This pattern seems clearest in

primary somatosensory cortex in which the mystaclal vibrissae and facial sinus hairs are represented. This pattern seems clearest in the portion of somatosensory cortex where the sinus hairs of the snout, bucal pad and lower lip are represented. It is also detectable, although in a somewhat modified form, in the region of the vibrissae representation. In this region the callosal the Vibrissae representation. In this region the Callosal projections occur in broad bands that run between the representations of vibrissae rows, and narrow strands of less dense projections that cross from band to band between representations of individual vibrissae within a row. Thus, the to what has been termed the "septa".

74.15 SOMATOTOPIC ORGANIZATION OF THALAMO-CORTICAL PROJECTIONS IN THE NEWBORN RAT. D. R. Dawson\* and H. P. Killackey\* (SPON: J. Leon). Department of Psychobiology, Univ. of Calif. Irvine, Irvine, CA. 92717

Department of Psychobiology, Univ. of Calif. Irvine, CA. 92717 At the time of birth, the trigemino-thalamic afferents have begun but not completed their invasion of the ventrobasal complex (VB), and the vibrissae-related pattern of segmentation is not yet discernable. Further, the ventrobasal afferent end processes are located in the white matter beneath somatosensory cortex (Wise and Jones 1978). The present study examines the degree of topography in the thalamo-cortical afferents at this early time. Subjects received discrete cortical injections (0.1 ul) of a 5% lectin-bound HRP solution on the day of birth, and were allowed to survive for 12 to 18 hours. The brains were cut in the coronal plane and were processed according to the technique of Mesulam (1976). The pattern and distribution of retrograde labelling in VB was determined, and lateral reconstructions of the cortical injection sites were generated. The ventrobasal complex can be subdivided into two regions; a wedge-shaped main body and a narrow ventro-lateral crescent. Discrete cortical injections result in discrete groups of labelled cells within these areas, and there is a topographic order in this labelling. Cortical injections near the midline produced labelled cells in the medial tip of the ventral crescent, whereas slightly more lateral injections labelled the lateral portion of the crescent. Injections made in the most lateral portion so the parietal cortex (the presumptive barrel field) labelled the cells in the lateral and central portions of the main body of VB, where-as more ventro-anterior injections labelled the most medial area. The topography of the thalamo-cortical projections at birth is the same as that reported in physiological studies of the adult (Welker 1971, Waite 1973). Cortical representation of torso and limbs is dorso-medial, whereas the head is more lateral. In the

(Welker 1971, Waite 1973). Cortical representation of torso and limbs is dorso-medial, whereas the head is more lateral. In the representation of the face, the vibrissae are represented poster-iorly and the buccal pad more anteriorly. In VB, the torso and limbs are represented in the ventral crescent, with the tail most medial and the forelimbs more lateral; the main body of VB contains a representation of vibrissae and buccal pad, with the nasal-most region represented most medially.

In summary, the thalamo-cortical projections of the newborn rat appear to be as specific as that of the adult. This orderly rat appear to be as specific as that of the adult. This orderly projection forms before trigeminal input to VB is complete or the fibers have invaded their cortical target. This implies that the thalamo-cortical fibers rely at least partially on intrinsic guiding factors to align themselves and are not fully dependent on either input or target information. Supported by NSF grant BNS 81-20658

DIFFERENTIAL EFFECTS OF COMPLETE AND SUBTOTAL SENSORI-

DIFFERENTIAL EFFECTS OF COMPLETE AND SUBTOTAL SENSORI-MOTOR CORTEX LESIONS ON TACTILE PERFORMANCE IN INFANT-AND ADULT-OPERATED RATS. <u>5. Finger and D. J. Simons</u>. Psychol. Dept., Washington Univ., St. Louis, MO 63130 and Physiol. Dept., Univ. of Pitt. Sch. Med., Pittsburgh, PA 15261. In an earlier study (Finger, Simons and Posner, Exp. Neurol., 60:347, 1978), it was found that enucleated adult rats with very large lesions of the sensorimotor cortex performed extremely poorly on a battery of five tactile discriminations, regardless of whether the lesions were made in rat pups I-2 days old or in sexually mature adults. On the other hand infant-operated rats with I3-28% of SmI spared (typically in the antero-lateral aspects of SmI) performed significantly better. although still lateral aspects of SmI) performed significantly better, although still more poorly than control animals. Because adult-operated animals with comparable spared fragments of Sml were not tested at the time, it was not known whether they would have learned the discriminations as quickly as the infant-operated rats with incomplete lesions. Nevertheless, it was hypothesized that while infant- and adult-operated animals may perform equally poorly after virtually complete lesions of SmI and SmII, the infant-operated rats with incomplete lesions would be some what less impaired than adult-operated rats with closely comparable lesions

In the present study adult-operated rats with lesions sparing 15-30% of the same regions of SmI as the infant-operated rats examined previously were tested for their ability to learn the battery of tactile discriminations used before. The infant- and adult-operated rats were carefully matched on the basis of lesion size and locus by reference to remaining aggregations of cells in layer IV, i.e., "barrels", which are known to correspond to particular regions of the contralateral body. The new data showed that like the infant-operated animals with sparing of SmI tissue, adult-operated rats exhibited some learning deficits but performed better than animals with complete lesions. Infant- and adult-operated rats then were compared as two groups and as individually matched pairs of subjects. In both types of analyses support emerged for the hypothe-sis that infant-operated animals may be better able to use spared frag-ments of target tissue to guide tactile behaviors than adult-operated rats although the cells in the spared areas of infant SmI cortex seemed

These data confirm the general finding that developmental status at the time of brain damage can be an important determinant of post-traumatic performance. The role of the age variable cannot be consi-dered alone, however, but must be viewed in the context of other experimental variables such as the presence of functionally intact tissue spared by the lesions. This observation may account for why some infant lesion studies find recovery of behavioral function while others do not.

THE S-I HINDPAW REPRESENTATION AFTER HINDPAW DEAFFERENTATION IN THE S-I HINDPAW REPRESENTATION AFTER HINDPAW DEAFFERENTATION IN NEONATAL AND ADULT RATS. J. T. Wall, C. G. Cusick, and J. H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240. When the hindpaw skin of an adult rat is partially deafferent-ed by sciatic nerve transection, regions of S-I cortex usually representing sciatic inputs become responsive to hindpaw zones which remain innervated by the saphenous nerve (Wall et al., <u>Soc. Neurosci. Abstr</u>., 1981, <u>7</u>, 758). Due to this change the cortical area representing saphenous inputs is about three times larger than that of normal adults. Even with this expansion, however, some regions of the original hindpaw representation remain unre-sponsive to cutaneous stimuli many months after injury. This re-sult suggests there are limitations in the capacity of cortical neurons to recover cutaneous responsiveness if normal inputs are 74 1 7 neurons to recover cutaneous responsiveness if normal inputs are removed during adulthood. The present experiments tested whether similar limitations are seen if sciatic deafferentationoccurs neonatally.

Hindpaws of 1 day old rats were deafferented by transecting and ligating the sciatic nerve and the S-I hindpaw representation was subsequently mapped when rats reached adulthood. During mapping, fields to light tactile stimuli were defined from multiunit re-sponses recorded in the middle cortical layers at 60-100 locations across the hindpaw region. Areas representing hindpaw inputs were then measured with a planimeter and compared to similar data from

then measured with a planimeter and compared to similar data from normal rats and from rats denervated as adults. The main result is that the cortical area (mean =  $0.18 \text{ mm}^2$ ,N=6) representing saphenous inputs from the hindpaw in neonatal denerv-ates is: (1) significantly smaller [t(14) = -10.75, p<.00] than the area of the hindpaw representation (saphenous and sciatic in-puts) in normal adults (mean =  $0.94 \text{ mm}^2$ , N=10), and (2) signifi-cantly smaller [t(11) = -3.51, p<.01] than the area representing saphenous inputs from the hindpaw in adult denervates (mean =  $0.47 \text{ m}^2$ , N=2)  $0.47 \text{ mm}^2$ N=7). Thus, sciatic section results in a decrease in the size of the hindpaw representation regardless of age of the animal at the time of injury. Age at injury is important, however, in determining the extent of this decrease. Neonatal denervates suffer larger losses of cortical space than adult denervates. One interpretation of these findings is that primary sensory cells in present that make more accountly attended to the more object that make the more company. interpretation of these findings is that primary sensory cells in neonatal rats may be more severely affected by nerve injury than cells of adult rats. This peripheral effect may secondarily di-minish responsiveness of central neurons receiving convergent sa-phenous and sciatic inputs, and thus result in differences in the responsiveness of parts of the saphenous representation which de-pend on these neurons for input. Cortical neurons may be more limited in their capacity to recover cutaneous responsiveness after neonatal deafferentation because skin to cortex connections are more vulnerable to disruption during development.

TIME-DEPENDENT EFFECTS OF DIGIT REMOVAL ON THE FUNCTIONAL ORGANI-ZATION OF SOMATUSENSORY (Sml) CORTEX OF RACCOONS. G. S. Doetsch and A. M. Kelahan. Depts. of Surg. (Neurosurg.) and Physiol., Med. Coll. Ga., Augusta, GA 30912, and Neurol. Sci. Inst., Good Samaritan Hosp. Med. Cent., Portland, UR 97209. Surgical removal of the third forepaw digit in raccoons pro-74.18

duces striking long-term and short-term changes in the functional organization of Sml cortex. At 9-12 months following digit ampu-tation in neonate and adult raccoons, electrophysiological study of these animals under barbiturate anesthesia showed that neurons in the digit 3 cortical zone had become responsive to low-inten sity stimulation of "new" forepaw skin regions, primarily on digits 2 and 4. Comparable shifts in neuronal responsiveness were found within one hour following digit removal in adult ani-mals anesthetized with nitrous oxide or with barbiturate. The "novel" receptive fields (RFs) of neurons within the digit a contract location within the digit of the shift of the shif cortical sector were larger and included the hairy skin and/or claws more frequently than in normal animals; RF location varied considerably as a function of the site of recording within corti-

cal tissue; i.e., no orderly somatotopic representation of the "new" skin fields was found. To determine if time-dependent variations occur in the pattern of cortical reactivation, the effects of digit 3 removal were exof cortical reactivation, the effects of digit 3 removal were ex-amined at one, two and four weeks post-amputation in adult ani-mals anesthetized with nitrous oxide or with barbiturate. At these intermediate times, the digit 3 cortical zone differed greatly from that of animals studied immediately or long after amputation. The vast majority of neurons were excited only by high-intensity stimulation of small RFs on the digit 3 stump; relatively few neurons were responsive to low-intensity stimula-tion of adjacent intact skin fields. Again, there was no orderly relationship between RF location and recording site. Statistical analysis of the RF data showed that cortical reac-tivation at all nost-amputation times more closely resembled a

Statistical analysis of the RF data showed that cortical reac-tivation at all post-amputation times more closely resembled a random distribution than a strictly topographic pattern. The combined results indicate that, over a period of several months, the digit 3 cortical territory undergoes a dynamic se-quence of changes in functional organization: after amputation, neurons normally responsive to stimulation of digits 2 and 4, then to the digit 3 stump, and finally again to digits 2 and 4. Mech-anisms which might be responsible for this time-dependent reacti-vation are: 1) the "unmasking" of normally-present but relatively ineffective synapses, by the shifting of inhibitory and/or facil-itatory influences; 2) physiological changes in peripheral nerve fibers terminating in amputation neuromas and 3) anatomical changes, including the growth of new synaptic connections within the central somatosensory system.

## SPINAL CORD: CYTOCHEMISTRY AND PHARMACOLOGY

BRAIN STEM STIMULATION EFFECTS ON THE DEAFFERENTED SPINAL CORD. A. V. Apkarian, C. J. Hodge, Jr., M. P. Owen and B. S. Hansen Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Some central pain states that occur after nerve or spinal cord injury may be due to chronic deafferentation. Stimulatio of locus coeruleus (LC) or nucleus raphe magnus (NRM) causes potent preferential inhibition of the dorsal horn interneurons Stimulation responding to noxious afferent input in the intact spinal cord. Since deafferentation pain is difficult to control with either oplates or brain stem stimulation, the experiments described here were undertaken to determine if there is a change in the bulbospinal modulation of dorsal horn units consequent to deafferentation.

Seven cats underwent unilateral section of lumbar dorsal roots L1-L6 under barbiturate anesthesia. Two weeks after rhi-zotomy the animals were anesthetized with chloralose and the lumbar spinal cord exposed. After occipital craniectomy, stimu lating electrodes were placed stereotaxically in NRM and LC. Extracellular recording were made from 110 dorsal horn units from both the intact and denervated sides of the spinal cord. The effects of brain stem stimulation were determined on the ongoing activity of the units. On the intact (control) side the effect of LC stimulation upon noxious cutaneous stimulation was determined in 15 cells. Of these, 11 were inhibited and 4 showed no effect. The effect of NRM stimulation was determined on 13 of these cells, 10 of which were inhibited and 3 showed no effect. These results are similar to earlier reports. Ninetyfive cells were studied on the deafferentated side. Of these 38 were located in lamina 4 or 5 and are reported here. In 1 In 19 cells the effects of LC or NRM stimulation were either inhibi-tory or absent, similar to the intact side. The other 19 cells showed facilitatory effects either from LC or from NRM stimula-tion. In 11 of the 19 cells the effects of LC stimulation were excitatory and the effects of NRM stimulation on the same cells were inhibitory. The remaining 8 cells were facilitated by NRM stimulation but inhibited by LC stimulation. Despite rhizotomy, ll of the 38 dorsal horn cells had receptive fields. The effects of brain stem stimulation was not related to the presence or absence of receptive fields on the denervated side.

These results show that the effects of descending brain stemspinal pathways are altered in the chronically deafferented cat spinal cord, and that, at least in this preparation, LC and NRM effects can be antagonistic and independent of each other.

EXPANSION OF CUTANEOUS RECEPTIVE FIELDS OF DORSAL HORN CELLS INDUCED BY 4-AMINOPYRIDINE IN THE CAT. <u>Kazue Semba, Herbert M.</u> <u>Geller and M. David Egger</u>. Depts. of Anatomy and Pharmacology, 75.2

INDUCED BY 4-AMINOPYRIDINE IN THE CATS. Kazue Semba, Herbert M. Geller and M. David Egger. Depts. of Anatomy and Pharmacology, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854 The receptive field (RF) organization of dorsal horn cells has been demonstrated to be altered following lesions of the spinal cord and peripheral nerves. To explain these alterations, it has been hypothesized that dorsal horn cells receive, in addition to the normally effective afferent input, some sensory input that is usually ineffective in driving the cells postsynaptically. These 'silent' synapses, when unmasked or potentiated, may give rise to altered RF of dorsal horn cells. Aminopyridines have been shown to potentiate synaptic transmission in general by enhancing transmitter release. To obtain insight into the plasticity of the RF organization of dorsal horn cells, we used 4-aminopyridine (4AP) to examine its effects on dorsal horn cell RF in the cat. Single dorsal horn units were recorded extracellularly in laminae III-V of the L7 segment in adult cats anesthetized ( $\alpha$ -chloralose), immobilized, and functionally spinalized at the

Single dorsal horn units were recorded extracellularly in laminae III-V of the L7 segment in adult cats anesthetized ( $\alpha$ -chloralose), immobilized, and functionally spinalized at the II2-13 level. All the units tested had cutaneous RF on the hindlimb. These cells were activated by various low-threshold mechanical stimuli, including brush, touch, and pressure; some cells, in addition, responded to high-threshold, noxious stimuli. Following the administration of 4AP (0.3, 0.6, 0.9 mg/kg, i.v.), the RF of almost all the cells expanded in a dose-related manner, in some cases up to approximately twice the original area. The new RF contained the original RF, usually at the center. We did not observe the appearance of new RF remote from the original RF. We typically observed that mechanical stimuli that were previously effective activated the cells more vigorously following 4AP. In addition, in some cells, noxious mechanical stimuli which previously induced only phasic responses became effective in inducing tonic responses. Also, the level of spontaneous activity generally increased following 4AP administration. In some cats, recordings were also made from an S1 or L7 ventral root. The amplitude of compound action potentials in response to the electrical stimulation of the sural nerve increased up to 8 times following systemic injections of 4AP in parallel with the RF expansions. Similar, but less pronounced dose-related in-creases were observed in ventral root reflex potentials elicited by electrical stimulation of the plantar cushion. This facilitation of by electrical stimulation of the plantar cushion. This facilitaby electrical schulation of the plantar cushion. This factifica-tion of spinal reflex pathways activated by the stimulation of the sural nerve and plantar cushion is consistent with previously reported general facilitatory effects of 4AP. In summary, our principal findings suggest that 4AP is effec-tive in revealing at least a portion of a subliminal fringe of RF of dorsal horn cells.

EFFECTS OF DORSAL ROOT SECTION ON UPTAKE AND RELEASE OF D-ASPAR-75.3 TATE IN THE GUINEA PIG SPINAL CORD S.J. Potashner and P.L. Tran\*. Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032

This study attempts to determine if L-glutamate and/or L-aspartate (L-GLU/L-ASP) are transmitters of primary sensory fiber endings in the cervical spinal cord. The uptake and the release of D-[<sup>3</sup>H]aspartate (D-ASP), a putative marker for L-GLU/ L-ASP, was measured in the spinal cord in vitro before and 2-4 days after section of several dorsal roots.

days after section of several dorsal roots. The cervical enlargement (segments C4-T1) was dissected into left and right halves. Each half was divided into dorsal and ventral pieces. Pieces of spinal cord from unlesioned animals took up D-ASP, achieving concentrations in the tissues which were approximately 14 times that in the medium. Subsequently, elec-trical stimulation of the tissues evoked a Ca<sup>++</sup>-dependent release of D-ASP. Section of dorsal roots C5-T1 on the right side de-pressed both the uptake (by 22-29%) and the evoked release (by 50%) of D-ASP in tissue dissected from the left side had uptake and release activities similar to those in control tissue taken from intact animals. Since the dorsal horn of the spinal cord contains a dense

Since the dorsal horn of the spinal cord contains a dense population of GABA'rgic neurons, the uptake and release of  $[^{14}C]GABA$  was measured to determine if these activities also are lost 2-4 days after dorsal root lesions. Section of dorsal roots C5-T1 on the right side had no effect on the uptake or on the release of GABA, unless dorsal radicular or other blood vessels were damaged. When blood vessels were damaged, there was a decrement on the right side in the uptake and release of GABA as well as a larger than normal depression of the uptake and release of D-ASP.

These findings suggest that, in the absence of vascular damage, degeneration of primary sensory fibers produces decrements in the uptake and release of L-GLU/L-ASP. Therefore, these ments in the uptake and release of L-OLD/B-AST. Interestors, the findings support the hypothesis that primary sensory fibers use L-OLU/L-ASP as a transmitter. However, when blood vessels are damaged and presumably some spinal neurons are destroyed, there is an additional decrement in the uptake and release of L-OLU/ Is an additional decrement in the uptake and release of L-OLU/ L-ASP and of GABA. These findings imply that, in addition to primary sensory neurons, other cells which provide synaptic end-ings in the spinal cord may use L-GLU/L-ASP as a transmitter. (Supported by grant NS17219 from the NINCDS).

75.5 SPONTANEOUS DORSAL ROOT POTENTIALS IN THE IN VITRO FROG SPINAL CORD. J.C. Hackman, G.P. Ryan, C.J. Wolhberg & R.A. Davidoff. Neurology Service VA Medical Center and Departments of Neurology and Pharmacology, University of Miami School of Medicine, Miami, FL 33101.

Electrical activity in the dorsal root (DR) in the absence of stimulation has been previously observed in both frog and cat. However, the mechanisms underlying the generation and regulation of spontaneous DR activity are largely unexplored. Our present experiments were designed to investigate the nature of spontaneous slow wave activity in the frog spinal cord.

Sucrose gap recordings were made from the DR of the isolated, hemisected frog spinal cord superfused with HCO<sub>3</sub><sup>-</sup>-buffered Ringers solution (15°C).

Spontaneous dorsal root potentials (sDRP's) were present in all prep-arations. They had the same polarity as evoked DRP's (i.e., negative potentials indicating depolarization of intraspinal portions of DR's) and ranged in amplitude from just discernible to 6 mV. The largest were 25-40% of the amplitude of DRP's evoked by supramaximal stimulation of adjacent DR's. Hypoxia did not appear to be the cause of these potentials since omitting O<sub>2</sub> resulted in reduction of the frequency of sDRPs. Recording with K<sup>+</sup>-sensitive microelectrodes revealed that only during the largest sDRPs did a measurable change in extracellular K<sup>+</sup> occur (circa 0.15 mM). This change was not large enough to account for the amplitude of the potentials. Enhancement of sDRP's by the GABA antagonists bicuculline meth-

iodide (10  $\mu$ M) and picrotoxin (0.1 mM), the glutamate decarboxylase inhibitor, semicarbazide (2.5 mM) and low CI -containing Ringer's solution indicate that GABA is not responsible for the generation of sDRP's.

Intact, synaptic transmission is required to generate sDRP's since addition of tetrodotoxin  $(1.25_{M}M)$  or Mn<sup>++</sup>  $(1.5_{M}M)$  to the Ringer's solution or lowering of external Na<sup>+</sup>  $(57_{M}M_{Li}^{+})$  blocked, and addition of 4-aminopyridine enhanced sDRP's.

The excitatory nume emine acids antagonists (-)baclofen, D,L- $\alpha$ -amino-adipic acid (1.0 mM), 2-amino-4-phosphonobutyric acid (1.0 mM) and D,L- $\alpha_s \epsilon$ -diaminopimelic acid (1.0 mM) reversibly blocked the generation of sDRP's. In addition the substance P antagonist, [D-Pro<sup>2</sup>-D-Phe<sup>4</sup> - D-Trp<sup>2</sup>]-substance P (0.5  $\mu$ M) markedly and reversibly depressed sDRP's.

In summary, it appears that intact synaptic transmission mediated by excitatory anino acids, L-glutamate and L-aspartates, or by substance P is necessary for the production of spontaneous dorsal root potentials in the isolated frog spinal cord. Supported by VAMC #1769 and USPHS grants #NS 17577 & HL 07188.

PAROXYSMAL VENTRAL ROOT ACTIVITY AND EXCITATORY 75.4

AMINO ACIDS. R.J. Davidoff, J.C. Hackman & G.P. Ryan. Neurophysiology Laboratory, VA Medical Center & Department of Neurology, University of Miami School of Medicine, Miami, FL 33101. There is controversy about the role of excitatory synaptic transmission in the genesis of epileptiform activity. In particular, there is disagreement about whether the prolonged depolarizations which characterize paroxysmal activity consist of synchronized ("giant") EPSPs or are the result of endogenous regenerative membrane currents. Our present experiments were designed to determine the role of excitatory synaptic transmission mediated by amino acids in the generation of convulsive activity produced in spinal motoneurons by

generation of convulsive activity produced in spinal motoneurons by exposure to penicillin. We used the isolated, hemisected frog spinal cord continuously super-fused with HCO<sub>3</sub><sup>-</sup>-buffered Ringers at 15°C. Reflex and spontaneous responses were recorded from ventral roots (VR's) using sucrose gap techniques.

Exposure of the spinal cord to the antibiotic (4.0 mM, 5 min) caused the occurrence in the VR of spontaneous, slow (5-30 sec), quasi-rhythmic (0.01-0.04 Hz) depolarizations (amplitude, 6-8 mV) with superimposed action potentials (paroxysmal VR potentials, pVRP's). It is assumed that pVRP's represent electrotonically conducted activity from motoneurons since they were eliminated by severing the VR at its entrance to the cord. Application of penicillin also caused considerable augmentation of polysynaptic reflexes caused by dorsal root stimulation (DR-VRP's).

pVRP's are generated by a synaptic process since they were eliminated by exposure of the cord to  $Mn^{++}$  ions applied in a concentration (1.5 mM) sufficient to block chemical synaptic transmission in the frog cord

Dicarboxylic amino acids (e.g. L-glutamate, L-aspartate) released by afferent terminals and by interneurons are thought to mediate excitatory synaptic transmission in the cord. (-) $\beta$ -(4-chlorophenyl)- $\gamma$ -aminobutyric acid (0.1 mM), the active

stereoisomer of baclofen, a drug which is thought to prevent the presynaptic release of excitatory amino acids, eradicated pVRP's and reduced DR-VRP's. Similar effects were produced by application of (+)Baclofen was without these actions on pVRP's and DR-VRP's and glutaric acid dethylester (1.0 mM), a weak antagonist of synaptic activity in the frog spinal cord, had minimal and inconsistent effects.

In sum, these results indicate that epileptiform activity and increased reflex transmission produced in motoneurons by the action of penicillin equire the synaptic release and subsequent postsynaptic action of pentermin excitatory amino acid such as L-glutamate or L-aspartate. Supported by VAMC Funds (MRIS 1769) & USPHS grant # NS 17577.

EXPRESSION OF SPECIFIC Fcg2b BINDING SITES BY SUBPOPULATIONS OF RAT SENSORY NEURONS. J. Dodd\*, W.D. Matthew and T.M. Jessell Department of Neurobiology, Harvard Medical School, Boston, MA Small-diameter dorsal root ganglion (DRG) neurons involved in the central processing of cutaneous sensory information can be identified by the differential procession and the sensory information and be 75.6

the central processing of cutaneous sensory information can be identified by their differential expression of neuropeptides and acid phosphatase isoenzymes. To examine the biochemical properties of these neurons in more detail, we have generated several mono-clonal antibodies that identify antigens present in discrete sub-populations of sensory neurons. In addition, we have found that some sensory neurons express a highly selective binding site for the Fc domain of mouse IgG2b molecules. Sections of rat DRG and spinal cord were incubated with cul-ture supernatant or ascites fluid obtained from IgG2b-secreting murine hybridomas and then screened for specific binding, using indirect immunofluorescence techniques. Intense labelling was

and the hydromas and then scheme techniques. Internet binding, dsing indirect immunofluorescence techniques. Internet labelling was observed in approximately 40% of DRG neurons independent of the specificity of the variable region of each antibody and indicated the presence of an Fcg2b binding site in these neurons. Immune staining was present throughout the cytoplasm of small-diameter neurons but was absent from large-diameter neurons. Stained fibres were visible within the DRG and in bundles in the dorsal roots. The axons of afferent fibres in the dorsal root entry zone and the tract of Lissauer were brightly labelled. In the dorsal horn, labelled fibres were present in laminae I, IIo and III, whereas fibres projecting to lamina IIi and to other regions of the spinal cord were not stained. No immunoreactivity was observed in neurons originating in the CNS, Subpopulations of neurons in other sensory originating in the CNS. Subpopulations of neurons in other sensory ganglia and neuronal cell bodies in the superior cervical ganglion also displayed Fcy2b binding, however, parasympathetic neurons were not labelled. Incubation of sections, under identical condi-tions, with IgG1, IgG2a, IgG3, IgM or IgA murine antibodies pro-duced no detectable Fc domain-related binding. Most DRG neurons exhibiting Fcy2b binding sites also contained the sensory neuron-specific acid phosphatase, and some overlap with substance P-immunoreactive neurons was also observed. Selective Fcy2b receptors are known to be expressed on the surface of lymphocytes and macrophages. The interaction of IgG2b antibodies with these receptors leads to the activation of phospholipase A, the release of arachidonic acid metabolites and membrane depolarization. We are currently examining the possibil-ity that the Fcy2b binding site in small sensory neurons is associated with similar membrane events. - 75.7 ATP EXCITES RAT DORSAL HORN AND DORSAL ROOT GANGLION NEURONS GROWN IN DISSOCIATED CELL CULTURE. <u>C.E. Jahr and T.M. Jessell</u>. <u>Dept.</u> Neurobiology, Harvard Medical School, Boston, MA 02115. Holton provided evidence that ATP is released from peripheral to for the second seco
  - Holton provided evidence that ATP is released from peripheral terminals of primary sensory afferents and may be responsible for producing antidromic vasodilation (<u>J. Physiol.</u> <u>145</u>, 494-504, 1959). To investigate the possibility that ATP may act as a sensory transmitter in the spinal cord we have examined the actions of ATP tracellular recordings were obtained from neurons from 4 to 12 weeks in culture. Nucleotides and other drugs were applied by pressure ejection or iontophoresis. ATP (10-6 to 10-5 M) produced a rapid depolarization associated with a conductance increase in 27% of neurons tested. The response was unchanged after synaptic transmission was blocked by 200 M CdC1. Similar depolarizations were evoked regardless of the ATP salt used (disodium, magnesium, calcium, Tris). EDTA (10-5 M) and pyrophosphate (10-4 M) were without effect. It therefore seems unlikely that the depolarization remarkally selective for ATP. Adenosine, AMP, UTP and GTP were inactive at 10-4 M whereas ADP and CTP were less than one tenth as potent as ATP. Analogs of ATP that are only slowly hydrolyzed by ATPases (Agmethylene ATP, AMP-PNP, adenosine terraphosphate) were effective agonists indicating that hydrolysis of the phosphate chain was dependent on extracellular Na<sup>+</sup>. When 90-95% of the Na<sup>+</sup> was replaced with either choline or sucrose, the response was blocked polarization was also unaffected by 8-phenyltheophylline, an adenosine receptor blocker, and isatogen derivatives which have been reported to antagonize ATP response on smooth muscle. In addition to dorsal horn neurons. The major difference in the response of the two cell types was that the dorsal root ganglion neurons in culture were also excited by ATP. The pharmacological and ionic specificities of the DRG response were essentially the same as that of dorsal horn neurons. The major difference in the responses of the two cell types was that the dorsal root ganglion neurons displayed a marked desensitization to ATP (see also ATP (see also ATP) (see also ATP) (see

G. Holz</u> <u>IV, S. A. Shefner and E. G. Anderson</u>. Depts. Pharmacol., and Physiol. and Biophys., and Alcohol and Drug Abuse Res. and Trn. Prgm. Univ. Illinois Col. Med., Chicago, IL. 60612 We have recently reported extracellular studies showing that

We have recently reported extracellular studies showing that serotonin (5-HT) directly depolarizes primary afferent terminals and cell bodies in isolated builfrog spinal cord and dorsal root ganglia (DRG) (Holz, G.G. and Anderson, E.G., <u>Soc. Neurosci</u>. <u>Abstr.</u>, 8:791, 1982). Intracellular studies were undertaken to examine which types of primary afferents respond to 5-HT and the resistance changes which accompany 5-HT-induced depolarizations. Lumbar DRG with attached dorsal root and peripheral nerve were removed from builfrogs, desheathed and pinned in a superfusion bath. Intracellular recordings were made at room temperature from DRG somata using 2M KCl-filled glass microelectrodes (40-80 MG). Neurons were classified by the latency of somatic action potentials following dorsal root or peripheral nerve stimulation. Atype cells showed conduction velocities of 5 to 18 m/sec ( $\bar{x} = 11$ 4.0.5 m/sec, S.E.M., n =40), mean input resistance of 59 + 4 MA. (n = 17) and mean resting potential of 65 + 3 mV (n = 16). Since C-type neurons had conduction velocities of 0.2 to 0.8 m/sec ( $\bar{x} = 0.5$  + 0.04 m/sec, n = 19) and a mean input resistance of 57 + 4 MA (n = 8), they were clearly distinguishable from A's. The mean resting potential for C's was 59 + 3 mV (n = 12). Serotonin (500 M/ = 10M) was tested on 24 A-type neurons; 42% showed depolarization (4 - 12.5 mV). In all A's in which resistance measurements were obtained, the depolarization was accompanied by a decreased input resistance (35 - 38%, n = 5). The re-

Serotonin (500  $\mu$ M - lmM) was tested on 24 A-type neurons; 42% showed depolarization (4 - 12.5 mV). In all A's in which resistance measurements were obtained, the depolarization was accompanied by a decreased input resistance (15 - 38%, n = 5). The response in A's showed pronounced tachyphylaxis to subsequent 5-HT radministration. Serotonin (50  $\mu$ M - 1 mM) was also tested on 20 C-type neurons. Of these, 75% were depolarized. The 5-HT-induced depolarization was of two types: an initial fast, transient depolarization (9 - 33 mV, n = 4) and a more slowly developing, maintained depolarization (4 - 20 mV, n = 11). These two actions could occur independently or sequentially in the same neuron. The fast response was associated with a decreased input resistance (40 - 56%) and resembled the response seen in vagal afferents in the nodose ganglion (Higashi, H., Nature, 267: 448, 1977). The slow depolarization was decreased input resistance (15 - 40%) and sometimes caused spontaneous firing. These findings support the direct depolarizing action of 5-HT on primary afferents noted with extracellular recording but also indicate that tot all primary afferents in 5-HT is qualitatively different on A- and C- type cells. This suggests a differential modulation of activity in specific subopp-

75.9 EXCITABILITY CHANGES AT INTRASPINAL TERMINALS OF AFFERENT C- AND A-FIBERS PRODUCED BY MIDBRAIN STIMULATION AND IONTOPHORENTIC APPLI-CATION OF TRANSMITTERS IN CAT. M. Zimmermann\*, E. Carstens, H. <u>Schreiber\* & H. Gilly\*</u>. II. Physiologisches Institut, Universität Heidelberg, Im Neuenheimer Feld 326 (FRG). (SPON: R.P. Scobey).

Stimulation in the midbrain periaqueductal gray (PAG) and lateral reticular formation (LRF) inhibits responses of spinal dorsal horn neurons to noxious skin stimuli. To study a possible presynaptic inhibitory action, we used the excitability testing method to determine if PAG or LRF stimulation affects the threshold for intraspinal antidromic activation of single afferent C- and A-fibers in the cat's sural nerve. We additionally tested effects of intraspinal iontophoretic application of 5-hydroxytryptamine (5-HT), noradrenaline (NA), morphine and GABA on fiber excitability, and compared these with effects of midbrain stimulation.

In cats anesthetized with sodium pentobarbital, single sural fibers were identified by their antidromic responses to intraspinal microstimulation (L6-L7 segment) using a glass-coated platinum electrode. When the threshold current to antidromically excite the fiber was stable within  $\pm 5\%$ , midbrain stimulation (100 msec pulse trains at 100 Hz, 3/s) was delivered through a bipolar electrode positioned in PAG or LRF. Drugs were iontophoretically applied from a multibarrel pipette glued to the intraspinal stimulating electrode (tip separation <50 µm). Drugs were: 5-HT HCl, morphine HCl, Na bitartrate (all 50 mN, pH 4-5), GABA (0.5 M, pH 4.5) and NaCl control (165 mM). Threshold changes during midbrain stimulation or drug application were expressed as % deviation from

the control threshold. Of 81 threshold measurements made in 42 C-fibers during PAG stimulation (100-900  $\mu$ A), 60 were within  $\pm$ 10% of control, while 18 showed increases greater than  $\pm$ 10% and 3 decreases of more than  $\pm$ 10%. The mean threshold increase (3.6%) was significant. LRF stimulation similarly had mixed effects on C-fiber thresholds, but the mean threshold increase (1.5%) was not significant. Midbrain stimulation had mixed effects on A6 fiber thresholds, with PAC but not LRF stimulation producing a significant threshold increase.

stimulation similarly had mixed effects on C-fiber thresholds, but the mean threshold increase (1.5%) was not significant. Midbrain stimulation had mixed effects on A6 fiber thresholds, with PAG but not LRF stimulation producing a significant threshold increase. Thresholds of C-fibers were predominantly raised during iontophoretic application of 5-HT (20/29 fibers), NA (10/13) and morphine (15/21), while GABA produced 3 increases and 2 reductions. Drug effects were dose-related, and control ejection of NA<sup>±</sup> ions did not produce threshold changes. Each drug produced threshold increases in nearly all A-fibers tested. Effects produced by each drug were plotted against the effect of PAG or LRF stimulation in the same fiber. While the majority of fiber thresholds were raised by both, the correlation coefficients were low, being highest for PAC-5-HT, PAC-NA, and LRF-NA comparisons. The observed threshold increases may correspond to a presynaptic inhibitory action. Supported by the Deutsche Forschungsgemeinschaft. 75.10 CORRELATION OF PHYSIOLOGY WITH MORPHOLOGY AND 5-HT OR SP INPUT IN CAT SPINAL DORSAL HORN LAMINA I NEURONS. <u>V. Miletic, M.J. Hoffert,</u> <u>M.A. Ruda and R. Dubner</u>. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, Maryland 20205. Two distinct physiological types of neurons have been described

Two distinct physiological types of neurons have been described in dorsal horn lamina I. Nociceptive-specific (NS) cells are activated exclusively by noxious stimuli. Wide-dynamic-range (WDR) neurons respond to innocuous stimuli but are activated maximally by noxious stimuli. We utilized the intracellular NRP technique to examine whether these distinct physiological types are associated with separate morphological neuronal classes. In addition, we combined this technique with immunocytochemistry to examine the serotonin (5-NT) or substance P (SP) input to these neurons.

Neurons in the cat lumbar dorsal horn were characterized physiologically by their responsiveness to natural stimulation of the skin, and then injected intracellularly with HRP. The spinal cord was sectioned, reacted with CoCl\_-intensified DAB and processed for 5-HT or SP using the PAP method. Camera lucida drawings of the HRP-filled cells and 5-HT or SP immunoreactive axons were made using a 100X objective.

reactive axons were made using a 100X objective. We examined a total of 18 lamina I neurons, 10 of which were classified as NS and 8 as WDR. Morphologically, these 18 neurons were subdivided into four classes based on the shape of their somata and dendritic trees, number of primary dendrites, and presence or absence of spines (Gobel, S., J. Comp. Neurol., 180:375, 1978). None of these classes was associated exclusively with a distinct physiological type. In the class of aspiny pyramidal neurons (n = 9), 7 cells were NS and 2 WDR. Among spiny pyramidal neurons (n = 4), and multipolar neurons with compact dendritic trees (n = 4), 3 cells were WDR and one cell was NS in each class. In the class of multipolar neurons with loose dendritic trees only one NS cell was stained. The distribution of 5-HT or SP immuoreactive axonal contacts was similar in the dendritic trees of both NS and WDR neurons. However, somatic contacts on these cells were differentially distributed. All 10 NS neurons received 5-HT or SP axosomatic contacts. In contrast, axosomatic contacts were absent from all 8 WDR neurons.

These findings indicate that NS and WDR lamina I neurons are not exclusively associated with separate morphological classes, although there is a tendency for NS neurons to be more numerous among the aspiny pyramids, and WDR cells to appear more frequently in the spiny pyramidal and multipolar-compact neuronal classes. In addition, the absence of 5-HT or SP axosomatic contacts on the WDR cells suggests that the postsynaptic modulation of afferent input occurs on dendrites. This may explain the selective inhibition of noxious input on some WDR neurons by descending systems.

EFFECTS OF SPINALLY-ADMINISTERED MORPHINE AND NOREPINEPHRINE ON RAT DORSAL HORN INTERNEURONS AND SPINOTHALAMIC TRACT CELLS. J.L.K. Hylden and G.L. Wilcox, Dept. of Pharmacology, University of Minnesota, Minneapolis, MN 55455. Given the spinal site of action of opioid and monoaminergic 75.11

agents, the spinal cord dorsal horn is an important area to study in an effort to increase our understanding of the basic mechanisms involved in pain and analgesia. In this study, we have chosen to concentrate on the inhibitory actions of spinally-administered morphine (M) and the effects of the endogenous monoamine

morphine (M) and the effects of the endogenous monoamine norepinephrine (NE) on M-induced antinociception. Experiments were performed on rats anesthetized with chloralose (70 mg/kg, i.v.), paralyzed with gallamine triethiodide (55 mg/kg, i.v.) and maintained on a mitture of gallamine (8.3 mg/ml) and sodium pentobarbital (1 mg/ml) delivered i.v. via the jugular vein sodium pentobarbital (I mg/ml) delivered i.v. via the jugular vein at 1.6 ml/hr. After laminectomy, a small agar reservoir was formed around the exposed lumbar spinal cord and filled with artificial c.s.f. solution (approximately 0.2 ml). Mineral oil was then poured over the c.s.f. and other exposed tissues in an effort to prevent excessive loss of body heat due to evaporation. Extracellular recordings were made from dorsal horn neurons with glass microelectrodes filled with 2% Pontamine Sky Blue in 0.5M sodium acetate. Spinothalamic tract (STI) cells were loctated by stimulation in the ventral basal complex of the thalamus with a single stainless steel electrode (800 µA or less, rectangular pulses of 0.1 msec duration at 10/sec). Neurons were identified with respect to natural stimulation of the skin (touch, pressure, noxious pinch and/or heat). Drugs were delivered directly to the spinal cord by addition to the agar reservir or systemically through the jugular vein. We have studied the effects of M on 20 dorsal horn cells (9 STI

We have studied the effects of M on 20 dorsal horn cells (9 STT cells, 11 interneurons). Spinally-administered M (0.1 mg/ml) inhibited the response of wide dynamic range (WDR, 7 cells) and nociceptive specific (4 cells) interneurons and STT cells to noxious stimuli by 25-100%. A lower dose of M (0.05 mg/ml) inhibited the response of 3 out of 5 cells. The peak inhibitory effect of spinally-administered M occured within 10-15 min. Naloxone (1-5 mg/kg, i.v.) totally or partially reversed the action of M in 7 out of 10 cells. M (0.1 mg/ml) had no effect on low threshold cells (6/6 cells). NE (0.001 mg/ml) had no effect alone on the nociceptive responses of WDR neurons (3/3 cells), but was able to potentiate the inhibitory action of M (4/4 cells). NE, at this dose, had no observable effect on spinal cord blood flow. The data indicate that M can selectively inhibit nociceptive responses of STT cells and interneurons at the spinal level. This inhibitory action appears to be potentiated by the endogenous monamine NE. (Supported by USPHS Grants DA01933, RR05385, T32GM07397 and a grant from the Procter and Gamble Co.) We have studied the effects of M on 20 dorsal horn cells (9 STT

75.13 NALOXONE ON CAT SPINAL CORD MULTIRECEPTIVE NEURONES. P. J. Soja\* and J. G. Sinclair. Division of Pharmacology and Toxicology, Faculty of Pharmaceutical Sciences, University of B.C., Vancouver, B.C., Canada V6T 1W5. Naloxone has been tested on several nociceptive systems with

the hope of detecting the presence of tonically active endogenous opioid peptides. Previously, Sinclair et al. (Q. J. Exp. Physiol. 65: 181, 1980) reported that naloxone was without effects on cat spinal cord multireceptive neurones i.e. those that respond to both noxious and innocuous peripheral stimuli. Henry (Neuroscience 4: 1485, 1979; Neuroscience 6: 1935, 1981), however, found that all such neurones were enhanced by naloxone. The major difference between these studies was that Henry performed his experiments in spinal cord transected cats. Therefor we have re-examined this question by testing naloxone (2 mg/kg) on cells in the presence or absence (by cold-blocking the spinal Therefore cord) of descending influences. Naloxone was administered between 14:00 and 20:00 hours. The drug failed to produce a sigusing noxious radiant heat in 7 cells tested in this manner. also tested naloxone in 6 spinal cord transected animals. In We only 1 case was there a marked increase in both spontaneous and evoked activity after naloxone (up to 2 mg/kg). In 4 other experiments there was a slight increase in only the spontaneous experiments there was a slight increase in only the spontaneous activity while in the remaining cell naloxone produced a decrease in both spontaneous and evoked activity. Although there is a suggestion that naloxone may increase the response of these cells in spinal cord transected animals, the changes were not statisti-cally significant when the data were grouped together. These results are consistent with the work of Sinclair et al. (1980) and Duggan et al. (Brain Res. 138: 185, 1977).

AN INHIBITION OF SPINAL TRIGEMINAL NUCLEUS CAUDALIS NEURONS BY 75.12 LOCUS COERULEUS AND ADJACENT STRUCTURES IN THE CAT. K.V. Anderson, and M. Bailey\*. Dept. Anatomy, Univ. RUCTURES IN THE CAT. H. Hirata, Dept. Anatomy, Univ. Mississippi 1. Ctr., Jackson, MS 39216 Previous studies (e.g., Sasa et al., 1974) showed that elec-Med.

trical stimulation of locus coeruleus (LC) inhibited the responses of neurons in the spinal trigeminal nucleus of the cat and rat. The present study differed from theirs in the following respects: (1) we recorded exclusively from neurons in subnucleus caudalis, while they recorded from more rostral subnuclei; and (2) we classified the units into three major types, low threshold mechano-receptors (LTM), wide dynamic range (WDR) neurons, and nociceptive specific (NS) neurons.

Extracellular single unit discharges were obtained from the cat subnucleus caudalis from the level of the obex to 5 mm caudal Cat submittleus caudalis from the level of the obset to 5 mm caudal to the obset. Animals were initially anesthetized with a combina-tion of Nembutal and urethane, i.p., and, subsequently, with urethane, i.v., when needed. Stimulating electrodes were stereo-taxically lowered into LC (P 3.5; t 2.2; m -2.2 mm) at approxi-mately a 25° angle from the vertical and were advanced in a rostral-to-caudal direction. At the end of an experiment, radio-frequency lesions were made to mark the stimulated areas.

Thus far, the response of LTM and WDR neurons (over 70% of the units tested) were inhibited by stimulation of LC and/or adjacent structures, such as tegmental fields and nucleus cuneiformis. We Structures, such as regumental iterus and notes concrete to establish have not been able to isolate a NS neuron long enough to establish an inhibitory effect. The effective stimulus parameters used were normally 100-400  $\mu$ A, 200 Hz (0.1 msec pulses), and 100 msec train. Mean percent reduction in response was 83% of the control (range= 74-100%). The responses to electrical percutaneous stimulation of 74-100%). The responses to electrical percutaneous stimulation of receptive fields were inhibited by conditioning stimulation which usually preceded the skin stimulation by 50 msec. The responses to natural stimuli such as heat and brushing, as well as sponta-neous activity, were also suppressed during and following brain stem stimulation. Histology revealed that the lesioned areas where clear inhibitions were observed included not only LC proper, but also adjacent regions and that for the latter the threshold current intensities for inhibition correlated poorly with the distance from LC.

We conclude that LC exerts non-selective inhibition on the we conclude that LC exerts non-selective infinition on the evoked and spontaneous activity of LTM as well as the neurons re-ceiving nociceptive inputs in the spinal trigeminal nucleus cauda-lis of the cat. It remains to be determined, however, whether this effect is mediated by nor-adrenergic pathways or other systems (LC of the cat is known to contain serotonergic neurons).

75.14 SLOW EXCITATORY TRANSMISSION IN RAT DORSAL HORN: POSSIBLE MEDIA-SLOW EXCITATION IN RANSMISSION IN RAI DURAL HUNN: POSSIBLE MEDIA-TION BY PEPTIDES. L. <u>Urban\* and M. Randic</u>. Dept. of Vet. Phys-iology and Pharmacology. Iowa State University, Ames. IA 50011. Electrophysiological experiments were performed in an attempt to demonstrate the presence of slow synaptic potentials in rat dorsal horn neurons and their possible mediation by peptides known

dorsal horn neurons and their possible mediation by peptides known to be present in the spinal dorsal horn. Rats 9-16 days old were used. After lumbosacral laminectomy 300µm thick horizontal or transverse spinal cord slices were made. Intracellular recordings from dorsal horn neurons were performed with micropipettes filled with 3M potassium acetate. Substance P, substance P antagonists and capsaicin were applied by bath per-fusion in known concentrations.

Substance P antagonists and caparism were appreced by barriers fusion in known concentrations. In about half of examined cells, high intensity repetitive stimulation of a dorsal root (1-20 Hz for 3-5 sec) elicited, in addition to the monosynaptic and polysynaptic excitatory synaptic potentials, a slow depolarization, which reached a peak in 28  $\pm$  10 sec (mean  $\pm$  S.D., n = 29) and lasted 130  $\pm$  53 sec. The mean amplitude of 7  $\pm$  5 mV was recorded at resting membrane potentials between -60 and -75 mV. Although in some neurons single shock stimulation evoked a detectable depolarization, repetitive stimulation usually resulted in an augmentation of the slow depolarization and generation of synaptic and action potentials. A low Ca<sup>2+</sup> high Mg<sup>2+</sup> solution or tetrodotoxin (10<sup>-6</sup>M) reversibly abolished the slow depolarization in all of the ten cells tested. When the membrane potential was manually clamped, the slow depolarization was associated either with an increase or a decrease in membrane input resistance. In a few tested cells, conditioning hyperpolarization was also depressed or abolished in the presence of in membrane input resistance. In a few tested cells, conditioning hyperpolarization depressed the slow depolarization. The slow depolarization was also depressed or abolished in the presence of substance P, substance P antagonists and capsaicin. Attempts were made to determine the origin of the fibers eliciting slow depolarization by administering capsaicin to neonatal rats (50 mg/kg., s.c. on day 2). In these animals, the slow depolariza-tion was evoked only in 10% of cells (n = 18). In some cells, besides the slow depolarization, a hyperpolari-zation of loop duration was observed. The hyperpolarijing noten-

In some cells, besides the slow depolarization, a hyperpolari-zation of long duration was observed. The hyperpolarizing poten-tials were of synaptic origin, usually associated with a decrease in membrane input resistance and were blocked by naloxone. The present findings demonstrate the presence of the slow synaptic potentials in dorsal horn neurons. In addition, they suggest that a peptide, including substance P, may be the trans-mitter responsible for the generation of the slow depolarization, while enkephalins may mediate slow hyperpolarizing synaptic notentials potentials

EFFECTS OF SUBSTANCE P ANALOGUES ON SUBSTANCE P EXCITATION AND SLOW EXCITATORY TRANSMISSION IN THE MAMMALIAN SPINAL DORSAL HORN. C. D. Raspantini, L. Urban,\* S. Jeftinija,\* K. Folkers,\* and M. Randić. Dept. of Vet. Physiology and Pharmacology, Iowa State University, Ames, IA 50011 and Inst. for Biomed. Research, Uni-versity of Texas, Austin, TX 78712. Although synthetic analogues of substance P (SP) with antago-nist properties have been recently developed, specificity of their central actions is presently controversial. We have, therefore, examined effects of (D-Pro<sup>2</sup>, D-Trp<sup>7,9</sup>)-SP and (D-Pro<sup>2</sup>, D-Phe<sup>7</sup>, D-Trp<sup>7</sup>)-SP on the SP-elicited excitation of dorsal horn neurons and on Slow excitatory transmission in the mamalian 75.15

neurons and on slow excitatory transmission in the mammalian spinal dorsal horn.

Extracellular recordings were made from single functionally identified dorsal horn neurons in halothane-anesthetized cats using multibarrelled microelectrodes and iontophoretic application of SP (3.7 mM), the presumed SP-antagonists (3.7 mM), and L-glutamic acid (0.2 M). Concurrent application of (D-Pro<sup>2</sup>, D-Trp<sup>2+</sup>)-SP (25-100 nA for 1-6 min) reduced excitatory responses to SP in about 60% of examined cells (n=26) irrespective of their afferent inputs. However, a depression of the L-glutamate evoked excitation, and spontaneous activity was also observed in about 10% of the cells. In addition, when larger currents or prolonged application of the analogue was used, the peptide exhibited SP-agonist activity in about 25% of examined neurons. (D-Pro<sup>2</sup>, D-Trp<sup>3</sup>)-SP proved to possess similar SP-agonist activity as (D-Pro<sup>2</sup>, D-Trp<sup>7,9</sup>)-SP, but weaker SP-antagonist properties. Extracellular recordings were made from single functionally properties.

Possible interaction between (D-Pro<sup>2</sup>,D-Trp<sup>2,1</sup>)-SP and the SP-induced depolarization and the slow excitatory synaptic poten-tials of dorsal horn neurons has been further investigated by tials of dorsal horn neurons has been further investigated by means of intracellular recordings in the immature rat in vitro spinal cord slice preparation. Bath-application of  $(D-Pro^2, D-Trp^{7,9})-SP$  (1-3 x  $10^{-5}$  M for 2-4 min) markedly reduced both SP-induced depolarization and the slow excitatory synaptic poten-tials, the latter elicited by high intensity repetitive stimula-tion of dorsal roots, in more than half of examined cells (n=19). The depressant effect of  $(D-Pro^2, D-Trp^{7,9})-SP$  outlasted the app-lication period but was reversible. In several cells, the ana-loque reduced L-olutamate-induced depolarization, although to a logue reduced L-glutamate-induced depolarization, although to a smaller degree. In higher concentrations,  $(D-Pro^2, D-Trp^{7,9})$ -SP exerted depolarizing action on dorsal horn cells. The results of these experiments indicate that  $(D-Pro^2, D-Trp^{7,9})$ -SP is a partial agonist, exercising also antagonism to SP. Eur-ther improvement to proceed the second 
ther improvement of SP-antagonists with respect to potency and

selectivity is desirable. Supported by NH grant (NS 17297) and the United States Depart-ment of Agriculture.

75.17 VASOACTIVE INTESTINAL POLYPEPTIDE (VIP): DISTRIBUTION THROUGHOUT THE LENGTH OF PRIMATE SPINAL CORD. C.C. LaMotte and N.C. de Lanerolle. Sections of Neuroanatomy and Neurosurgery. Yale Univ. Lanerolle. Sch. Med., New Haven, CT 06510.

VIP immunoreactivity in the macaque spinal cord was mapped in vibratome sections using the ABC method. VIP was localized in In vibratome sections using the ABC method. VIP was localized in beaded axons, terminals, and possibly in dendrites. In <u>cervical</u> segments C3-C6, a few terminals and thin axons were found in lamina I; lateral to the central canal, the central cervical nu-and the intermediomedial nu. (IMM) were moderately innervated. In C8 the density of terminals increased in laminae I,IIo, and IMM; thin axons also crossed in the dorsal and ventral grey commisures (DGC and VGC). In the <u>thoracic</u> sample (T3), laminae I and IIO were heavily supplied with axons and a few penetrated into laminae III, III, IV and into medial and lateral V. Label was moderate in 111, 111, 1V and into mealar and rateral v. Laber was moderate in the DGC and VGC; somata and dendrites lateral to the central canal and in IMM were outlined also. A few terminals were seen in the ventral horn. In <u>lumbar</u> sections, laminae I and IIo were less heavily supplied than in the thoracic region. The IMM and region lateral to the central canal were moderately innervated. However, scattered VIP axons of medium diameter in the lateral and ventrolateral white matter traversed the cord into the grey matter. few axons were found in the dorsal columns.

In <u>sacral</u> sections, VIP was denser than any other cord region. Radially oriented axons were found mainly in Lissauer's tract and in the lateral white; there were fewer in the ventral white and the dorsal columns. Large and small terminals and thin axons were densely distributed in laminae I and IIo. A heavy bundle of axons distributed along the lateral border of the dorsal horn, and continued into the lateral area of lamina V and into the lateral sacral parasympathetic nu. Axons also passed in the medial border of the dorsal horn and then coursed along the midline toward and into the central canal region where many terminals and axons were seen. In addition, large diameter, very long structures resembling dendrites were found either along the structures resembling dendrites were found either along the lateral and medial borders of the dorsal and ventral grey, or oriented transversely, crossing the midline in the DGC. These suspected VIP containing dendrites appeared to have spines and were also accompanied by similarly oriented VIP axons. Immunoreactivity was quite sensitive to aldehyde fixation; mod-erate concentrations of aldehydes eliminated labeling except in the heavily innervated sacral regions. This may account for re-

ports that VIP is confined to visceral afferents which supply the sacral cord. The present report indicates a broader role for VIP. Its higher density in both thoracic and sacral levels suggests its presence in visceral afferents from thoracic and abdominal as well as pelvic structures. Supported by NIH Grant NS13335. 75.16 LAMINAR ORGANIZATION OF FIVE NEUROPEPTIDES AND SEROTONIN IN THE MONKEY DORSAL HORN. N.C. de Lanerolle and C.C. LaMotte. Sections of Neurosurgery and Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT. 06510

Immunohistochemical techniques were used to identify the locations of terminals and axons containing substance P(SP)somatostatin(SS)-, cholecystokinin(CCK)-, vasoactive intestinal
polypeptide(VIP)-, met-enkephalin(ENK)-, and serotonin(5-HT)like immunoreactivity in the macaque monkey spinal cord. A modified picric acid-formaldehyde fixative (Zamboni fluid) best preserved the antigenicity.

Direct comparisons were made of adjacent vibratome sections from the same cord segment (C6), each reacted for a different neurochemical. Each neurochemical was found to have a unique neurochemical. Each neurochemical was round to mate a sample pattern of distribution, and each dorsal horn lamina received different combinations of neurochemicals. The distribution of terminal patterns is summarized in the following table.

	Lamina I	IIo	IIi	III	IV	Ret V
SP	***	***	*	*	*	**
SS	-	***	*	***	*	*
ССК	*	***	-	-	-	*
VIP	***	*	-	-	-	-
ENK	**	***	*	-	-	**
5 – HT	***	*	-	-	**	*

(l= reticular nu. of lamina V; IIo and IIi = outer and inner regions of lamina II)

These data indicate some species differences from those reported for the rat (Gibson et al., 1981), particularly for CCK and VIP. The distinctive patterns closely follow traditional laminar borders, and the differential distributions imply that

laminar borders, and the differential distributions imply that significant interactions between different neural systems must be quite specifically localized. We have previously determined the ultrastructural charac-teristics of terminal types immunoreactive for SP, ENK & 5-HT in laminae I and IIo (Brain Res., in press). Preliminary electro-microscopic analysis of VIP-, SS-, and CCK-like immunoreactive structures in the same laminae has revealed both simple termi-nals containing large granular vesicles (LGV) and glomerular C-type terminals with LGV's (LGV-C type). These terminal types are similar to those found to be immunoreactive for SP. The coexistence of two or more of the neurochemicals in these terminal types is under investigation. (Suported by NS13335). terminal types is under investigation. (Supported by NS13335).

75.18 IMMUNORFACTIVE LEUCINE ENKEPHALIN (I-lEnk), METHIOTNINE ENKEPHALIN-ARG-GLY-LEU (I-mEnk) AND DYNORPHIN (I-Dyn) IN THE SPINAL CORD OF THE CAT. L. J. Cruz\* and A.I. Basbaum. Department of Anatomy, School of Medicine, University of

SPINAL cond of Anatomy, School of Medicine, University, California, San Francisco, CA 94143 Numerous studies have reported on the distribution of the endogenous opioid peptide, Enk, in the spinal dorsal horn. Since none of the earlier studies checked whether the antisera cross-reacted with Dyn, we repeated these studies using antisera (Weber, E.) directed against the ProEnk product, mEnk-arg-gly-leu and against the C-terminal ProDyn product, Dyn B. Absorption controls and RIA established the specificity of arg-gly-leu and against the C-terminal Probyn product, \_\_\_\_\_ Absorption controls and RIA established the specificity of these antisera. The staining pattern produced by these antisera was compared with a commercially available L-Enk antiserum (Immunonuclear Corp). The studies were performed on cats perfused with 4% paraformaldehyde. Fifty micron frozen antiserum (immunondolear corp). The studies were performed on cats perfused with 4% paraformaldehyde. Fifty micron frozen sections of spinal cord were cut and immunostained with the PAP method.

The L-Enk antiserum produced a pattern of staining identical to that previously described. There is dense terminal immunoreactivity in the superficial dorsal horn, Lamina I and and the region around the central canal are also heavily stained, as is the column of Onuf located in the ventral horn of the first sacral segment. Staining with the mEnk-arg-glyleu antiserum was similar except that Lamina IIo was consistently unstained. In contrast, the Dyn B antiserum stained Laminae I, IIo and V most densely; there was little reactivity in Lamina IIi and none in the column of Onuf. Peculiar to the S1 segment was the presence of I-Dyn cell bodies in Lamina I and IIo (without colchicine) and very dense, varicose, axonal staining in the tract of Lissauer and in the attached dorsal root. This particular staining pattern is very similar to that of immunoreactive vasoactive intestinal polypeptide in the sacral dorsal horn of the cat. Sections of spinal cord rostral to S1 showed neither the cellular, nor the Lissauer tract/dorsal root I-Dyn staining.

These data indicate that the choice of antiserum can markedly affect the pattern of dorsal horn immunoreactive different ProEnk products, L-Enk and mEnk-arg-gly-leu are differentially distributed in the superficial dorsal horn. Finally, these data demonstrate that the distribution of I-Dyn is very distinct from that of L-Enk and there is a suggestion that I-Dyn may be present in some S1 dorsal root ganglion cells.

DIFFERENTIAL DISTRIBUTION OF SUBSTANCE P, SOMATOSTATIN, AND CHOLECYSTOKININ IN RAT DORSAL ROOT GANGLIA. <u>Mary M. Tuchscherer</u> and Virginia S. Seybold. Department of Anatomy, University of Minnesota Medical School. Minneapolis, Minnesota. 55455. Substance P (SP), somatostatin (SOM), and cholecystokinin (CCK) immunoreactivities have been shown to be present in the small type-B cells of dorsal root ganglia (DRG). A quantitative study regarding the distribution of these peptides in DRG at five different spinal levels using fluorescence immunohistochemistry was undertaken. Male Spraque-Dawley rats (280-220mms) was implacted with

different spinal levels using fluorescence immunohistochemistry was undertaken. Male Sprague-Dawley rats (280-320gms) were implanted with chronic intrathecal cannulae of varying lengths corresponding to the DRG level to be surveyed. Colchicine was administered via the cannulae in two 50ug doses over a period of two days. The animals were then perfused with Zamboni fixative, and the appropriate ganglia were removed. Serial 10um cryostat sections were cut, and adjacent sections were processed for SP-, SOM-, and CCK-like immunoreactivities (IR) using fluorescence immuno-histochemistry. An ethidium bromide counterstain was used to reveal cellular detail. Immunofluorescent cells were counted on each section and the data were statistically evaluated with reference to the total number of small cells counted. The five levels surveyed (C6, T6, T10, L2, and S1) showed significant differences in the distribution of peptide immuno-reactive cells. SP-like IR occurred at its highest percentage in the L2 DRG (32%), and its lowest in the C6 DRG (10%). CCK-like IR occurred at its highest percentage in the L2 DRG (13%), SOM-like IR occurred at its lowest in the C6 BRG (13%, C13%), and at its lowest in the C6 BRG (13%, and 4%, respectively). Overall, the frequency of SP and CCK positive cells was similar within a level, whereas the frequency SOM positive cells was always less than that of the others. Thus, variability in the distribution of these peptides occurred within each level as well as between levels. We have shown there to be significantly different proportions each level as well as between levels. We have shown there to be significantly different proportions

so fSP, SOM, and CCK immunoreactive cells in DRG at the levels CG, f6, T10, L2 and S1. Correlates of these findings with the peripheral distribution and modality sensitivity of these peptide-containing primary afferents remain to be determined. Supported in part by NS 17702.

## SPINAL CORD: AFFERENT INPUT AND LOCAL CIRCUITS

76.1 NEURAL PROJECTIONS FROM GENITAL TRACT IN FEMALE RATS: AXONAL NEURAL PROJECTIONS FROM GENITAL TRACT IN FEMALE RATS: AXONAL COMPOSITION AND SEGMENTAL DISTRIBUTION. J.L. Steinman\*, S.M. Carlton\*, C.E. Hulsebosch, R.E. Coggeshall & W.D. Willis, Marine Biomedical Institute, Galveston, TX 77550 (SPON: B. Haber) The present study analyzes the axonal composition and location

of cell bodies of afferent neurons that innervate the vagina and cervix in rats. The myelinated (MY) and unmyelinated (UN) axons cervix in rats. The myelinated (MY) and unmyelinated (UN) axons in hypogastric (HYP), pelvic (PEL) and pudendal (PUD) nerves were counted from electronmicrographs. On the average, the HYP nerves had 24 MY and 2263 UN axons, the PEL had 639 MY and 2575 UN axons and the PUD had 648 MY and 1711 UN axons. In these nerves there were fewer MY axons than in the same nerves of the male. The HYP

were fewer MY axons than in the same nerves of the male. The HYP nerve also had 2 times more UN axons than the male counterpart. The segmental distribution of sensory cell bodies innervating the vagina and cervix was determined. Horseradish peroxidase (HRP: 25% in DMSO) or HRP-wheat germ agglutinin (WGA: 5% in DMSO) was injected bilaterally into the mucosal wall of the vaginal canal after distension of the vaginal os with retractors. Rats (n=7) were sacrificed 3-5 days later and dorsal root ganglia (DRG) were removed and reacted with tetramethylbenzidine. HRP labelling was seen bilaterally in 19-T11. L1-L2 and L6-S1 DRG. labelling was seen bilaterally in T9-T11, L1-L2 and L6-S1 DRG. Vagina, cervix, uteri and bladder were reacted with diaminobenzidine and showed heavy labelling in the epithelial layer of the vagina and cervix only. Labelling was not present in the adven-titia. In 3 rats, the HYP nerve was soaked in HRP-WGA for 2-3 hrs. Reaction product was seen in L1-L2 and T9-T11 DRG on the side ipsilateral to the nerve.

These preliminary findings suggest that there is a sexual dimorphism in the axonal composition of nerves innervating the reproductive organs in the rat. We also demonstrate that HRP transport from the vagina to thoracic spinal cord levels shows a similar distribution of labelled cells as transport via the HYP nerve alone. The abundance of UN axons in the HYP nerve may provide a partial explanation for the transmission of pain due to provide a partial explanation for the transmission of pain due to distension of the vagina and cervix as occurs during labor. Furthermore, the present data indicate the pathways and types of fibers that may be involved in inhibition of nociceptive re-sponses during mechanical pressure applied to the vagina and cervix. Experiments are underway to assess the effects of selective nerve transection on vaginal stimulation-produced analgesia. (Supported by NIH grants NS 07022 (JLS), NS 07062 (SMC), NS 17039 (CEH,REC), NS 09743 & NS 11255 (WDW) and a grant from the Moody Foundation.) from the Moody Foundation.)

76.2 AXONAL CONDUCTION VELOCITY AND GANGLION CELL SIZE. K.H. Lee\*, K. Chung, J.M. Chung and R.E. Coggeshall. Marine Biomedical Institute and Departments of Anatomy and Physiology and Biophy

Institute and bepartments of Anatomy and Hystology and Brown sics, University of Texas Medical Branch, Galveston, Texas. Conduction velocity is generally regarded as being closely correlated with axonal and cell body size. Thus, conduction velocity and cell body size should be correlated. The use of intracellular injections of the marker enzyme horseradish peroxidase (HRP) allows this to be tested for individual dorsal root ganglion cells and axons. Dorsal root ganglia (L6-S3) and Toot gangiion cells and axons. Dorsal root gangila (Lo-SJ) and their roots were removed from adult cats, placed in an oxyge-nated, Kreb's solution until use and then put in a stimulating and recording chamber at 37°C where the oxygenated Kreb's solu-tion could be perfused over the ganglion. Cells were impaled with conventional microelectrodes filled with 5% W/V HRP. Conc Conduction velocities were calculated from conduction times and dis-tances from stimulation to recording sites and then the cell was data indicate that there is a general correlation of cell size and dorsal root axon conduction velocity, but the correlation is not close because of variability. Thus it seems that all slower conducting axons originate from small cell bodies, but some small cells have fast conducting axons.

Two other features of note were found in the morphological preparations. First it is clear that the central branch of the shaped first division of the stem process of our marked dorsal root ganglion cells is considerably smaller than the peripheral branch, a finding that is in accord with the findings re ported in classic studies but contrasts with more recent reports. ported in classic studies but contrasts with more recent reports. Second, in some cells there is axonal branching within the ganglion distal to the "T" branch. If confirmed, this will indi-cate that some dorsal root ganglion cells are multipolar neurons. Supported by NiH grants, NS18830, NS10161, NS17039 and grants from the Moody Foundation and the Pearl and Aaron Forman Research Fund.

LEVEL LOCATION AND DISTRIBUTION OF PHRENIC PRIMARY AFFERENT 76.3 NERVE FIBERS IN THE SPINAL CORD OF THE ADULT RAT. P.J. Roubal\* and H.G. Goshgarian. Dept. Anat., Sch. Med., Wayne State Univ., and H.G. Goshgarian. Detroit, MI 48201.

Previous studies from this laboratory have localized and morphologically characterized phrenic motorneurons in the rat spinal cord at light (J. Comp. Neur., 201: 441-456, 1981) and electron microscopic (J. Neurocytol., 1983 in press) levels. The purpose of this investigation was to determine at light microscopic levels the origin and distribution of phrenic microscopic levels the origin and distribution of phrenic primary afferent nerve fibers in the adult rat spinal cord. D horseradish peroxidase crystals were applied to the central stump of the transected phrenic nerve in the neck to label the phrenic spinal ganglion cells and their central processes by a modification of the TMB technique. The results showed that phrenic primary sensory neurons are found in the C3-C7 spinal ganglia. The greatest number of labeled cells occurred at C5 followed elevely by C6. Euclonements Dry followed closely by C4. Furthermore, the cell labeling seen at C6 and C7 exceeded the minimal labeling seen at C3. Our previous light microscopic study revealed that the majority of phrenic motorneurons were located at C4 (mean of 267 cells) whereas the C5 segment contained a smaller number of cells (mean of 129 cells). The study also showed that there was a rostral projection of phrenic motorneurons to C3 (20 cells) and a very small caudal tail of the nucleus projecting to C6 (mean of 2 cells). Phrenic motorneurons were never seen at C7. Thus, from the present study, it appears that phrenic primary sensory neurons tend to be more caudally disposed along the neuraxis than phrenic motorneurons. Transganglionic labeled central processes of phrenic primary afferent axons were seen entering the spinal cord from dorsal rootlets in both transverse and longitudinal sections. The axons were loosely fasciculated in the dorsolateral aspect of fasciculus cumeatus. In this region they were arranged along the longitudinal axis of the cord. A number of them were seen entering the dorsal horn. Axons entering the dorsal horn at the same level they enter the spinal cord were rarely seen. Axon collaterals were traced from their parent axons in fasciculus cuneatus through lamina I into lamina II and III. Several other axons were traced along the medial margin of the dorsal horn to enter the medial aspects of lamina IV. A few axon collaterals traversed laminas I-III and also entered into lamina IV. Supported by U.S. Public Health Service grant NS-14705.

PATTERNS OF ENTRY TO THE SPINAL CORD OF SAPHENOUS NERVE FIBRES IN 76.4 CAT AND RABBIT. S.J.W. Lisney\*, C.M. Pover\*, S.K. Heaney\* and P.J. Kendell\*. (SPON: K.W. Horch). Dept. of Physiology, The Medical School, Bristol BS8 1TD., U.K. CAT AND RABBIT.

In both the cat and the rabbit, the saphenous nerve supplies cutaneous sensory fibres to the medial surface of the hind  $\log$ between the groin and the ankle. To a lesser extent it also supplies some cutaneous sensory fibres to the anterior and post-erior parts of the lateral surface of the leg. In both animals, saphenous fibres enter the spinal cord via the dorsal rootlets of segments L5, 6 and 7. We wanted to know whether saphenous nerve fibres were distributed amongst these dorsal rootlets in an orderly, somatotopic way.

Experiments were carried out on pentobarbitone anaesthetized cats and rabbits. After routine preparative surgery the left leg was shaved and then a lumbar laminectomy was carried out so that electrophysiological recordings could be made from the L5-L7 dorsal rootlets on the left side. The left sciatic nerve was cut in the sciatic notch to eliminate most of the non-saphenous afferent input carried by the L5-L7 dorsal roots. Starting with the most caudal dorsal rootlet of L7, the individual rootlets of each root were sectioned close to the cord and then split into 4 or 5 smaller multifibre strands. Each strand was placed in turn on a pair of platinum hook electrodes and the part of the saphenous nerve field supplied by saphenous fibres in the strand determined by brushing and stroking the skin. Only light, tactile stimulation was used. The areas supplied by the strands of each individual rootlet were drawn onto a figurine of the leg. In this way a picture of the areas of skin supplied by saphenous fibres in each of the L5-L7 rootlets was built up. The identity of the

rootlets was confirmed by post mortem dissection. There were more rootlets per root in cats than in rabbits and the area of skin supplied by individual root task that in rabbits and generally smaller than in rabbits. The area of skin supplied by a rootlet was not always continuous. With both animals there was extensive overlap of the areas supplied by neighbouring rootlets and even between rootlets which were several ones apart. In both species fibres supplying the distal parts of the saphenous nerve field travelled via the more caudal rootlets of all those carrying saphenous fibres and fibres innervating the proximal parts of the field travelled via the more rostral rootlets. A gradual distal to proximal shift in the areas supplied by rootlets was evident if every third or fourth rootlet, passing from caudal to rostral, was considered.

SPINAL CORD PROCESSING OF FEMORAL VENOUS AFFERENT INPUT. <u>B. J.</u> Yates and <u>F. J. Thompson</u>. Dept. Neuroscience, Univ. Florida CoT. of Med., Gainesville, FL 32610. Electrical and mechanical stimulation of the femoral-saphenous vein elicits field potentials recordable from cord segments L-3 through S-1 in cord-transcende othe superscript that beca 76.5 SPINAL CORD PROCESSING OF FEMORAL VENOUS AFFERENT INPUT.

through S-1 in cord-transected cats, suggesting that these seg-ments contain neurons which are activated by femoral venous affer-ent input. These field potentials were comprised of a series of negative waves and a slow positive wave; those potentials recorded from L-6 also had an initial triphasic spike. In most preparatrom L-b also had an initial triphasic spike. In most prepara-tions the evoked potentials were abolished by transection of the caudal L-6 and the rostral L-7 dorsal rootlets, regardless of stimulation site along the vein. Thus, femoral venous afferents appear to enter the spinal cord focally in the caudalmost portion of the femoral nerve input zone, which includes all of the L-5 and L-6 cord segments.

Recordings of evoked compound action potentials from dorsal Recordings of evoked compound action potentials from dorsal rootlets or the femoral nerve following electrical stimulation of the femoral-saphenous vein have revealed that the activated affer-ents include both A- $\alpha$  and A- $\delta$  fibers; the most prominent compo-nents of the compound action potential had conduction velocities of 58.4 m/sec (S.D. = 6.6, n = 8) and 44.5 m/sec (S.D. = 3.8, n =

of 58.4 m/sec (S.D. = 6.6, n = 8) and 44.5 m/sec (S.D. = 3.8, n = 8). Minimal spinal cord processing time (measured by comparing the latency of evoked action potentials recorded from the dorsal roots and ventral roots of the input segment) for femoral venous afferent input is 6.3 msec (S.D. = 2.1 msec). In addition, intraspinal recordings have suggested the presence of multiple pools of interneurons activated by femoral venous afferent input. These data suggest that a multi-interneuronal circuit is involved in processing the input. ing this input.

Ing this input. Thus, the feline spinal cord appears to receive a focal input from afferents, including large-diameter afferents, innervating the femoral-saphenous vein; this input activates interneurons found in a large number of cord segments. A multisynaptic interneuronal network appears to lie between the primary venous afferents and *a*-motoneurons.

IMMUNOCYTOCHEMICAL LOCALIZATION OF TRANSPORTED WHEAT GERM AGGLUTININ IN THE SPINAL CORD OF THE RAT. K.E. McKenna and I. Nadelhaft, VA Medical Center and Depts. of Pharmacol. and Neurosurg., Univ. of Pitt., Pittsburgh, PA 15240 Experiments were performed on female Sprague-Dawley rats weighing 300-400 gm. The L6 dorsal root ganglia were exposed and injected with 1 to 2  $\mu$ l of 1% or .25% wheat germ agglutinin (WGA). After survival times of 1 to 3 days, rats were perfused and the spinal cords were processed by immunocytochemistry using the peroxidase-anti-peroxidase (PAP) technique. Labelled primary afferent fibers were visualized in segments

peroxidase-anti-peroxidase (PAP) technique. Labelled primary afferent fibers were visualized in segments L3 to S2, although the number of labelled fibers diminished greatly after one segment. Rostral to L6, fibers were labelled most heavily in the lateral portions of Lissauer's tract and marginal zone. Caudal to L6, labelled fibers were concentrated in the medial portion of Lissauer's tract and marginal zone. Labelled fibers were visualized in cross section in Lissauer's tract, in a dense plexus in the marginal zone, and extending into the substantia gelatinosa and the deeper layers of the dorsal horn. Fibers were seen extending down the medial edge of the dor-sal horn into the dorsal gray commissure. Few labelled fibers were seen in the ventral horn or the dorsal columns. It is possible that large afferent fibers are not labelled with WGA.

were seen in the ventral horn or the dorsal columns. It is possible that large afferent fibers are not labelled with WGA. A strong pattern of transynaptic labelling was seen in neurons innervated by primary afferents, as previously observed. (Ruda and Coulter, BR 249, P. 237, 1982). Small round cells were labelled in the marginal zone and substantia gelatinosa. Medium and large cells in the N. proprius were labelled as well as the large cells of the lateral spinal nucleus. Clusters of medium sized neurons were labelled in the dorsal gray commissure. All labelled neurons were observed ipsilaterally. Efferent neurons (both motoneurons and parasympathetic pre-candionics) were retrogradely labelled by spread of WGA into the

ganglionics) were retrogradely labelled by spread of WGA into the ventral root at the injection site. The reaction product in all labelled neurons was clearly within the cytoplasm and not on the labelled neurons was clearly within the cytoplasm and not on the cell surface. No staining was seen in the cell nucleus. The reaction product consisted of large  $(> l_{\perp})$  dark clumps distribu-ted throughout the soma and proximal dendrites. It was easily distinguished from non-specific staining which was a diffuse, homogeneous or very finely granular darkening of the neuron. The transynaptic labelling was observed even with survival times as short as l day. Transport distances were about 40 mm, indicating a minimum transport velocity of 1.3 mm/r. These experiments demonstrate that WGA can be used to study both efferent and afferent projections. In addition, WGA is

transported across synapses, labelling secondary afferent neurons.

ELECTRON MICROSCOPIC ANALYSIS OF PRIMARY AFFERENT FIBER TERMINALS FROM RAPIDLY ADAPTING CUTANEOUS MECHANORECEPTORS. M. D. Egger, K. Semba, P. Masarachia, S. Malamed\*, M. Jacquin, S. Harris\* and G. Yang\*, Dept. of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854 76.7

The glabrous skin of the hindlimb in the cat contains three types of low-threshold mechanoreceptors: Pacinian corpuscles (PAC), slowly adapting (SA) and rapidly adapting (RA) receptors.

types of low-threshold mechanoreceptors: Pacinian corpuscles (PAC), slowly adapting (SA) and rapidly adapting (RA) receptors. Following our previous electron microscopic studies on the ter-minals in the dorsal horn of primary afferent fibers from PAC and SA receptors, we have begun to analyze the terminals of afferent fibers from RA receptors. RA afferent fibers were physiologically identified, and injected intraaxonally with horseradish peroxidase (HRP) in the spinal cord. At the light microscopic level, HRP-labelled swellings, corre-sponding to synaptic boutons, were located in laminae II-VI with heaviest concentrations around laminae III-V. Compared with the swellings of PAC or SA afferents, those of RA afferents displayed less tendency to cluster. A tendency, seen in PAC and SA af-ferent swellings, for rostral swellings to be located dorsally and caudal swellings ventrally was not observed in the RA af-ferent swellings. At the electron microscopic level, we recon-structed serial sections of 7 boutons labelled with reaction product in laminae III-IV. The analysis of the reconstructed boutons indicated the following: (1) Labelled boutons contained clear, round synaptic vesicles, about 40 nm in diameter. (2) Labelled boutons, sometimes appearing 'scalloped' in shape, ranged from 1.1 to 2.5 ym in longest dimension; in average, smaller than PAC but larger than SA afferent boutons. (3) Individual labelled boutons appeared to form synaptic con-tacts, mostly of the asymmetric type, with one to four dendritic shafts or spines. (4) In addition, each of these RA boutons appeared to be in apposition to one to four unlabelled struc-tures, all containing clear, flattened or pleomorphic synaptic vesicles. Usually synaptic vesicles were concentrated on both sides of the cleft. Some of the unlabelled vesicle-containing structures also appeared to be presynaptic to some dendritic spines that were postsynaptic to labelled boutons. (5) The

sides of the cleft. Some of the unlabelled vesicle-containing structures also appeared to be presynaptic to some dendritic spines that were postsynaptic to labelled boutons. (5) The complexity of synaptic organization displayed by RA afferent terminals seems to be intermediate between that of SA and PAC afferent terminals, with the PAC terminals the most complex. In conclusion, the presence of clear, round vesicles and the predominance of axodendritic synapses provide morphological support for strong excitatory input from RA afferents to dorsal horn cells. Combined with our previous studies, the present study also suggests that various cutaneous afferent fibers may be distinguishable to some extent on the basis of ultrastructural features of their terminals in the dorsal horn.

INTERMEDIATE NUCLEUS INTERNEURONS MEDIATING SYNAPTIC ACTIONS ON PRIMARY AFFERENTS AND SPINAL MOTONEURONS. P. Rudomín, I. Jiménez\*, and M. Solodkin\*. Centro de Investigación del Instituto Politéc-

nico Nacional. México 14, D.F. An important question pertaining the functional organization of spinal reflexes is the identification of the interneurons medi-ating presynaptic inhibition and of their axonal projections. In other words, do these neurons belong to private pathways, or are they shared with others which produce postsynaptic excitation or inhibition of motoneurons? This can be approached by recording the dorsal (DRP) and ventral (VRP) root potentials produced by single interneurons as indicators of synaptic actions ocurring on primary afferents and on spinal motoneurons, respectively. In cats anesthetized with pentobarbital, paralized and artificially re-spired, extracellular recordings were made from interneurons in splitch, external recording were and row intermediate in the intermediate nucleus. Their spontaneous discharges were used for spike triggering averaging of DRPs and VRPs simultaneously recorded from the central ends of  $S_1$  dorsal and ventral rootlets respectively, the latter with the sucrose gap technique. Although the available sample is still relatively small, it is already possible to identify distinct groups of interneurons mediating positive to interview of primary afferents, on motoneurons, or in both of them. 11 neurons produced negative DRPs of .33-3.6  $\mu$ V and of 4.3-23 ms latency, and inhibitory VRPs of .40-4.5  $\mu$ V and .5-13.7 ms latency. Peak values were attained between 40-50 ms and total durations were between 100-200 ms. Two of these neurons were activated bi- or trisynaptically by gr. I volleys in the posterior biceps semitendinosus (PBSt); three, mono- or bisynaptically by gr. I gastrocnemius soleus (CS) fibers, and nine polyspartically by cutaneous volleys, 1.3-3 xT strength. These interneurons appear to mediate FRA and Ib inhibitory actions on motoneurons and also the PAD of Ib fibers. Three other interneurons produced negative DRPs and biphasic (excitatory-inhibitory) VRPs with the inhibition lasting as long as the DRPs. They were activated by gr. I GS but not by PBSt afferents, and polysynaptically by cutaneous fibers. Only one interneuron produced a short latency negative DRP (6.5 ms) without any VRP. This neuron was only activated bisynaptically by gr. I GS fibers and may mediate PAD of gr. Ia fibers. Four neu-rons produced no DRPs but only inhibitory VRPs with amplitudes of  $1.444 \ \mu$ V and latencies ranging from 0.6 to 16.3 ms (mean 7.645.9 ms) which lasted 60-140 ms. Three of them were polysynaptically activated by gr. I PBSt, two by gr. I GS volleys, an all by low threshold (1.2-2xT) cutaneous fibers. Finally, 7 cells produced no DRPs or VRPs; they were bisynaptically activated by gr. I GS but not by PBSt or sural afferents, and polysynaptically by super-ficial peroneus volleys (3.13±1.48 xT strength). Partly supported by NIH grant NS 09196 and CONACyT grant 012008.

A TECHNIQUE FOR RECORDING EXTRACELLULAR SINGLE UNIT ACTIVITY 76.8

FROM NEURONS IN THE LUMBAR ENLARGEMENT OF PHYSIOLOGICALLY INTACT, AWAKE, DRUG FREE, RESTRAINED CATS. J.G. Collins. Dept. of Anesthesiology, Yale Univ. Sch. of Med., New Haven, CT 06510 Introduction. Most current techniques for the study of spinal cord neurophysiology require that animals be

or Anesthesiology, fale Univ. Sch. Or Med., New Haven, CI Obilo Introduction. Most current techniques for the study of spinal cord neurophysiology require that animals be anesthetized or have CNS lesions which will produce a pain free preparation. While humane considerations demand that the animals be pain free, the presence of either anesthesia or CNS lesions introduces an uncontrolled variable which may significantly influence our understanding of the spinal cord. This new technique was developed in order to provide a way of studying spinal cord physiology and pharmacology in pain free, physiologically intact, awake, drug free, restrained cats. <u>Methods</u>. The success of this new recording technique centers on the surgical implantation, under general anesthesia, of a stainless steel recording chamber which has a central, rectangular opening (7 mm x 12 mm). The chamber is attached to the vertebral column such that the opening in the chamber is positioned over a similar sized opening in the vertebral column over the lumbar enlargement. Following several weeks of recovery from surgical implantation, the animals, which have been adapted to restraint, are placed in a plexiglas restraint box, and a microdrive assembly is attached to the recording chamber. On a daily basis, tungsten microelectrodes (Frederick Haer & Co.) are advanced through the intact dura into the dorsal horn of the spinal cord, and electrical activity from individual neurons is recorded. The microdrive assembly can be moved in the x, y and z planes, thus permitting electrode penetration anywhere within the window. <u>Results and Discussion</u>. The recordings obtained using this new technique are extremely stable. It has been possible to record for long periods of time from individual neurons. There has been no evidence of change in signal to noise ratios due either to respiratory or cardiovascular movement. In addition, it is possible to record activity from single neurons during either animal or experimenter-induced movement of hindlimbs, movement of

musculature of the back. This technique promises to provide us with a means of evaluating both the physiology and pharmacology of the spinal cord in pain free, physiologically intact, awake, drug free, restrained cats. Such studies should enable us to determine not only the influence of previous preparations on our understanding of the nervous system, but should also provide us with a way of evaluating questions about spinal cord function which could not be addressed in the acute preparation. Supported by NIH Grant GM29065

FUNCTIONAL CONNECTIONS OF INTERMEDIATE NUCLEUS INTERNEURONS MEDI-ATING SYNAPTIC ACTIONS OF PRIMARY AFFERENTS DISCLOSED BY MEANS OF ATING STMAPPIC ACTIONS OF PRIMARY AFFERENTS DISCLOSED BY MEANS OF SPIKE TRIGGERED AVERAGING OF DORSAL ROOT POTENTIALS. M. Solodkin\*, I. Jiménez\* and P. Rudomín (SPON: G. Meza) Centro de Investiga-ción del Instituto Politécnico Nacional, México 14, D.F. The purpose of these studies was to identify the interneurons

in the spinal cord which produce primary afferent depolarization (PAD) and to characterize their activation patterns. The experi-(PAD) and to characterize their activation patterns. The experi-ments were done in anesthetized cats, paralyzed and artificially respired. PAD was disclosed by using the spontaneous spike activ-ity of intermediate nucleus interneurons to trigger the averaging of dorsal root potentials (DRPs), recorded from fine S1 and L7 dorsal rootlets. Of 113 interneurons, 43 produced DRPs with a peak amplitude in the range of 0.4-4 µV (meants.D.=1.58±.32µV), and a time course similar to that of the DRPs produced by electri-eal ctimulation of cr. I would nerve (the target of the target of target of the target of the target of the target of targe and a time to be solved as the solution of the birls produced by electric cal stimulation of gr. I muscle nerves (time to peak  $53.6\pm22.5 \text{ ms}$ , duration 100-200 ms). Type I neurons produced DRPs with a mean latency of  $7.58\pm2.55 \text{ ms}$  (n=23) and responded mono-, bi- or trisynaptically to gr. I volleys in the posterior biceps and semitendi nosus (PBSt) and gastrocnemius soleus (GS) nerves. Ten of these internetrons were polysynaptically activated by low threshold (2.08±.08xT) sural (SU) fibers. <u>Type II and III</u> neurons produced DRPs with longer latencies (means 21.49±2.2 ms,n=9 and 34.1±1.84 ms, n=5 respectively) and were monosynaptically activated by gr.I PBSt and GS volleys. It thus appears that type I neurons form part of the shortest pathways producing PAD. Since Ia fibers are not depolarized by stimulation of cutaneous nerves, interneurons were further classified in types b and a depending on whether or not they responded to these inputs. Type Ia neurons (n=4) were activated by PBSt and GS gr. I volleys (below 2xT threshold) and inhibited by stimulation of the brain stem (BS) ipsilateral reti Inflotted by Stimulation of the brain stem (b), ipsilateral istr-cular formation (with 600 Hz trains). Type Ib interneurons (n=10) were excited by PBSt stimuli with mean strengths of 2.28±1.0xT and also by gr. I GS fibers (below 2xT threshold). 70% of these cells were inhibited and 20% excited by BS stimulation. It is suggested, as a working hypothesis, that type Ia interneurons mediate the PAD of gr. Ia fibers. The type Ib neurons, which are excited by BS stimulation, have the requirements expected for the interneurons mediating the PAD of Ib fibers. Partly supported by NIH grant NS 09196 and CONACyT grant 002008.

CORRELATION OF RESPONSES TO NATURAL STIMULATION OF THE SKIN 76.11 WITH RESPONSES TO SURAL NERVE STIMULATION OF THE SKIN WITH RESPONSES TO SURAL NERVE STIMULATION: THE NATURE OF LATENT SYNAPSES. Lillian M. Pubols. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97210. Latent projections to dorsal horn neurons have been demon-

strated by electrical stimulation of skin, nerves, or dorsal roots not supplying the natural receptive fields of those neurons. Mendell et al. (J. Physiol., 285:299, 1978) have shown that a small percentage (1.4%) of L7 dorsal horn neurons, responsive to natural stimulation of hindlimb skin in the responsive to natural stimulation of hindlimb skin in the intact cat, can discharge with monosynaptic latencies to electrical stimulation of flank skin, supplied by distant dorsal roots. A larger percentage of these neurons (31%) discharge with polysynaptic latencies, the remainder being unresponsive to distant stimulation. In view of the fact that discharge with polysynaptic latencies, the remainder being unresponsive to distant stimulation. In view of the fact that latent synapses can be demonstrated from afferents projecting via dorsal roots 4-5 segments from the recording site, one might expect there to be a much higher proportion of neurons receiving latent projections from nearer dorsal roots. To test this hypothesis the responses of L6 and L7 dorsal horn neurons to stimulation of the sural nerve were compared for neurons having receptive fields within the region of skin innervated by the sural nerve, i.e., the lateral foot and toes, versus those having receptive fields on other parts of the foot. Extra-cellular action potentials were recorded in response to low and high threshold cutaneous stimuli, and to electrical stimulation of A fibers in the sural nerve. Neurons with natural cutaneous receptive fields outside the sural nerve territory never gave short, fixed latency (<5 msec), presumably monosynaptic, responses to sural nerve stimulation. Four out of 5 neurons with receptive fields on the lateral foot and toes gave short latency excitatory responses to sural nerve stimu-lation, and the fifth had longer, more variable latencies. These data are very similar to the results of Mendell et al., and demonstrate that the proportion of neurons exhibiting monosynaptic latent inputs in the intact cat is very small, regardless of the proximily of the roots supplying the effec-tive and latent projections. (Support: NIH, NS16634, NS19523)

## EXCITATORY AMINO ACIDS I

- 77.1 CHARACTERISATION OF THE LOW AFFINITY KAINIC ACID BINDING SITE SOLUBILIZED FROM PIGEON CEREBELLUM. <u>A. Dilber\*, H. Henke\*, M. Cuénod and K. Winterhalter\*</u> Brain Res. Inst., Univ. of Zürich, Switzerlandand and Dep. of Biochem., Swiss Federal Institute of Technolo-gy, Zürich, Switzerland). The pigeon cerebellum contains a large number of kainic acid binding sites (B<sub>max</sub> = 118 pmol/mg pro-tein). Isotopic dilution experiments indicate the presence of a high (K. = 30 mM) and a low affinity (K. tein). Isotopic dilution experiments indicate the presence of a high ( $K_d = 30$  nM) and a low affinity ( $K_d = 330$  nM) binding site. In crude membrane preparations binding to the low affinity site shows positive cooperativity (n = 2.2). The low affinity site is specifically localized in the molecular layer of the cerebellar cortex (Henke H. et al., 1981, Brain Res., 219, 95-105). At a concentration of 0.25% the non-ionic 95-105). At a concentration of 0.25% the non-ionic detergent Triton X-100 solubilizes preferentially the low affinity binding site, whereas 1% Triton X-100 solubilizes also the high affinity site. Both sites were in an active form after solubilization. The affinity for kainic acid  $(K_d)$  in solution was 20 nM and 440 nM respectively for the high and low affinity binding site. Again binding with positive cooperativity (n = 1.5-2) was seen for the low affinity binding site. However, in contrast to the observations with vity ( $\bar{n} = 1.5-2$ ) was seen for the low affinity binding site. However, in contrast to the observations with membrane bound sites no paradoxical increment of bound <sup>3</sup>H-kainic acid (hook effect) was present in solubili-zed material. Kainic acid and L-glutamic acid showed similar displacing potencies in the membrane bound (IC<sub>50</sub>: 2 and 170 µM) and the solubilized (IC<sub>50</sub>: 6 and 250 µM) low affinity binding site. Kainic acid dime-thyl ester (IC<sub>50</sub> = 200 µM) and gamma-methylene-L-glutamic acid (IC<sub>50</sub> = 200 µM) had a more potent dis-placing activity than L-glutamic acid. Dihydrokainic acid, a kainic acid derivative (obtained by catalyti-cal reduction of the double bond in the isorpopylene cal reduction of the double bond in the isopropylene side chain), shows very little displacing activity  $(IC_{50} > 1 \text{ mM})$ . These two facts confirm the importance of the unsaturated side chain in kainic acid for its binding. Gel filtration chromatography resulted in a four to give field correspondence of the low of figure to fix the low of figure to the low of the lo four to six-fold enrichment of the low affinity site, indicating a molecular weight of about 440'000, in keeping with the sedimentation coefficient of 12S obtained by density gradient centrifugation. Isoe-lectric focusing experiments in thin layer agarose and polyacrylamide gels gave a pI of 4.8-5.5 for the low affinity kainic acid binding site.
- 77.2 ANTAGONISM OF N-METHYL-D-ASPARTIC ACID EXCITATION OF RAT HIPPOCAM-PYRAMIDAL NEURONES IN VITRO BY PHENCYCLIDINE APPLIED IN KNOWN

CONCENTRATIONS. No. Lacey\* and G. Henderson\* (SPON: Paul A. Fuchs.) (Dept. of Pharmacology, University of Cambridge, U.K.) The dissociative anaesthetic and psychotomimetic agent phency-clidine (PCP) has been reported to reduce the action of the excit-atory amino acid analogue N-methyl-D-aspartic acid (NMDA) on spinal interneurones in vivo (Lodge and Anis, Eur.).Pharmacol., <u>77</u>; 203, 1982). The action of PCP on NMDA-evoked excitation of rat hippocampal neurones has been investigated by means of intra-

cellular recording from pyramidal cells in the CA1 region of the submerged in vitro brain slice preparation. NMDA ( $100 \text{ } \mu\text{M}$ ) or glutamic acid (10 mM) was pressure ejected from a micropipette positioned close to the site of recording for 1-5 sec at 1-10 psi, producing rapid, transient depolarising responses which frequently resulted in the firing of action potentials. Application of PCP in the bathing fluid at known concen-

points which includently footnets in the firing of definition of the response to NMDA after a 10 minute exposure. Complete recovery of the response to NMDA was rarely seen and when it was, a washout of at least 2 hr for PCP was required. Responses to NMDA were reversibly inhibited by the selective NMDA receptor antagonist DL-2-amino-5-phosphonovaleric acid (2APV) (3-100 µM). In contrast, responses evoked by glutamate were unaffected by both PCP and 2APV. Responses to NMDA were also abolished by 5 mM cohalt choide; this and other evidence (Dingledine, J.Physiol.; in press, 1983) indicates a major role for calcium entry in the ionic mechanism of NMDA. The calcium channel blockers D600 and verapamil have been shown to be potent displacers of [<sup>3</sup>H]PCP binding on rat brain membranes (Quirion and Pert, Eur.J.Pharmacol., 83; 155, 1982) and it may be that a close association of the PCP binding site with calcium channels underlies its antagonism of NMDA. At present it is unclear whether PCP antagonises NMDA by an action at the NMDA is unclear whether PCP antagonises NMDA by an action at the NMDA receptor or by acting at a stage in the depolarizing mechanism subsequent to that of receptor activation.

- ACTIVITY OF ANALOGUES OF QUINOLINIC ACID ON RAT 77.3 CORTICAL NEURONES. <u>Trevor W. Stone</u>, Dept. of Physiology, St. George's Hospital Medical School, University of London, London SW 17, UK. Quinolinic acid, a rigid analogue of N-methyl-aspartate (NMA) which exists endogenously in N-methyl-aspartate (NMA) which exists endogenously in mammals has been shown to be excitatory when applied to neurones in the mammalian CNS (Europ J. Pharmacol. 72, 411 - 412; Brain Res. 259, 172-176). That excitation appears due to the selective activation of NMA receptors. We have now examined the effects of a number of methyl derivatives of quinolinate as potential selective agonists or netargoists. antagonists. Compounds were applied by microiontophoresis to neurones in the cerebral cortex of male rats anaesthetised with urethane. of male rats anaesthetised with urethane. The 2-methylester of quinolinic acid showed some tendency to reduce responses to NMDA, causing a mean reduction of 26% (± 9, s.e.m) on 10 of 26 neurones when applied with currents of less than 30 nA. However, this action was complicated by agonist activity especially at higher currents, with a marked increase of neuronal firing occurring on 16 of the 26 cells. The N-methyl-2, 3-dimethylester analogue also showed weak agonist activity but no antagonist properties. The higher homologue of quinolinic acid, homoquinolinic acid (2-carboxy-pyridine-3-acetic acid) which is the rigid <u>glutamate</u> analogue of quinolinic acid proved to be as active analogue of quinolinic acid proved to be as active an excitant as NMDA on the basis of nanocoulombs an excitant as NMDA on the basis of nanocoulombs required for equivalent excitation. Homoquinolinate was thus about 5 times more potent an excitant than quinolinate. Furthermore homoquinolinic excitations could be blocked completely by the 'NMDA' antagonists aminophosphonovaleric (APV) and aminophosphonoheptanoic (APH) acids, while glutamate responses were unchanged. This implies that activation of the APH sensitive receptor is more dependent on the rigidly extended conformation of the activating molecule than merely on the length of carbon chain separating the carboxyl groups. carboxyl groups.
- LESIONING EFFECTS OF IBOTENATE IN THE IMMATURE RAT BRAIN AND 77.4
  - LESIONING EFFECTS OF IBDTEMATE IN THE IMMATURE RAT BRAIN AND PROTECTION BY 2-AMINO-7-PHOSPHONOHEPTANOIC ACID, <u>P.J. Roberts</u><sup>1</sup>, <u>Gethin J. McBean\*</u><sup>1</sup>, <u>H.X.Steiner\*</u><sup>2</sup>, <u>C. Kohler\*</u><sup>3</sup>, <u>and R.Schwarcz</u><sup>2</sup>. <sup>1</sup> Dept. of Physiol. & Pharmacol., Univ. of Southampton, U.K., <sup>2</sup> Maryland Psychiatric Research Center, Baltimore, MD 21228, <sup>3</sup> Dept. of Pharmacology, ASTRA Research Labs, Södertälje, Sweden. Ibotenate (ibo) like kainate (KA) will cause "axon-sparing" lesions following injection into the CNS of the adult rat. In the davalapia ctrictivere corbolium buckurg. lesions following injection into the CNS of the adult rat. In the developing striatum or cerebellum however, KA fails to exhibit this property, possibly due to immaturity of receptor numbers or an undeveloped mechanism mediating KA-toxicity. Because of a num-ber of dissimilarities between the neurotoxic actions of ibo and VA is equilated to intervent intervention of the second second KA in adult animals, we have investigated the neurochemical and morphological sequelae of ibo injection into the immature rat

striatum, hippocampus and cerebellum. 7-day old rats were anaesthetised with ether and injections /-day old rats were anaesthetised with ether and injections of ibo (10  $\mu$ g) made stereotaxically into one of the brain areas defined above, utilising coordinates established from pilot dyeinjection experiments. Pups were allowed to survive for 2 days, after which time they were decapitated and brains processed for

after which time they were decapitated and brains processed for light microscopic examination, or neurochemical analyses. Injections of ibo into striatum or hippocampus resulted in the complete loss of neuronal cell bodies. Catecholamine histofluor-escence in the striatum was abolished, indicating loss of afferent terminals. In contrast with KA, "distant" damage was not observed. Injections of ibo into cerebellum, produced no detectable damage. Neurochemical analysis showed brace docraces in the uptake of

Injections of ibo into cerebellum , produced no detectable damage. Neurochemical analysis showed large decreases in the uptake of labelled GABA, glu and DA into a striatal P<sub>2</sub> preparation, although glu uptake was least affected. In hippocampus, major reductions were seen in GABA and glu uptake. CAT activity was reduced by 31%. Co-injection of 10 µg ibo with equimolar (13.6 µg) (-)-2-amino-7-phosphonoheptanoate (APH) into the striatum, resulted in protect-ion of both striatal cell bodies and DA nerve terminals. Thus, in contrast to the effects seen with KA, intrastriatal injection of ibo in 7-day old rats resulted in extensive loss of neurones. Furthermore, unlike the effects seen with ibo in the adult rat, there was a striking lack of axon-sparing properties. Finally, excitotoxicity is believed to be mediated through spe-cific membrane receptors, and, in the case of ibo, probably via

clic membrane receptors, and, in the case of ibo, probably via those activated preferentially by NMOA. The ability of APH to provide protection of both intrinsic neurones and DA terminals, indicates the presence of neurotoxicity-mediating receptors on these cellular elements (including afferent fibres) in the immature rat striatum. Thus, it is clear from this study that the development of KA and ibo receptors, and the associated mechanisms for excitotoxicity follow different ontogenetic patterns. This work is supported by grants from The Wellcome Trust to P.J.R. and by a NATO Research Grant to P.J.R. and R.S.

77.5 STRIATAL NEURODEGENERATION CAUSED BY LOCAL INJECTION OF DL-THREO-3-HYDROXYASPARTATE AND BY LONG TERM ADMINISTRATION OF L-GLUTAMATE, <u>Gethin J. McBean\*and P.J. Roberts</u>, Dept. Physiology & Pharmacology Univ. of Southampton, Southampton, S09 3TU, U.K. (SPON: A. Nistri ).

The low efficacy of the endogenous excitatory amino acid Lglutamate as a neurotoxic agent, when compared with kainate and ibotenate, may be attributed to its rapid removal from the site of injection by efficient reuptake mechanisms. We have tested the

of injection by efficient reuptake mechanisms. We have tested the ability of the potent glu uptake inhibitor, DL-threo-3hydroxyasp, to cause degeneration of striatal cells following a single, local injection. We have also tested whether continuous infusion of a high dose of glu will result in similar degenerative changes. DL-threo-3-hydroxyasp (170nmol in  $\mu$ l PBS, pH 7.4) was injected stereotaxically into the left striatum of female Wistar rats, and assays were performed 2 weeks later. There was a significant reduction in both CAT activity (30%) and Na<sup>+</sup>-dependent 3H-GABA uptake (40%) in the lesioned, compared with the contralateral striatum. For histological analysis by light microscopy, brains were performed. usion-fixed in glutaraldehyde-paraformaldehyde, embedded in wax, and 6 µm coronal sections stained with thionin. An area of pronounced neuronal degeneration surrounding the site of injection was evident.

To enable long-term administration of glutamate, rats were planted with left striatal cannulae and, one week later, Alzet osmotic minipumps containing IM L-glutamate in 0.1M PBS, pH 7.4 Osmotic minipumps containing im L-glutamate in 0.1M PBs, pH /.4 were fitted. Control rats received 0.1M PBs only. Glutamate inf-usion (flow rate approx= 0.5µ1/h) was continued for a period of 1 week. Na<sup>+</sup>-dependent <sup>3</sup>H-GABA uptake and CAT activity were determ-ined in triplicate, in both the lesioned and control striata. Both these indices of striatal function fell by 35-38% in the lesioned side, whereas infusion of 0.1M PBS alone for one week did not result in any significant changes. Examination of striata by light microscopy indicated in the glu-treated animals, a wide area of neuronal degeneration, extending on either side of the cannula tract, wherein the neurones were dark and misshapen. In the control striatum, the cannula tract was easily identifiable, yet there was no evidence of damage to the surrounding cells.

These results indicate that prolonged exposure to a sufficiently high concentration of glu, will cause degeneration of striatal neurones, as will a single dose of a potent glu uptake inhibitor.

This work highlights the important role played by the high-and low-affinity uptake systems in the prevention of striatal neurodegeneration by potentially toxic levels of glutamate. This work was supported by a grant from the Wellcome Trust to P.J.R.

GLUTAMINASE AND ASPARTATE AMINOTRANSFERASE AS MARKERS FOR GLUTAMERGIC / ASPARTATERGIC NEURONS IN RODENT AND MONKEY CEREBRAL CORTEX R.A. Altschuler, M. Parakkal, W.G. Haser, R.J. Wenthold and J.P. Donoghue, Lab. Neuro-otolaryngology, NIH, and Lab. Neurophysiology, NIMH, Bethesda, MD, Dept. Biochem., Univ. Pittsburgh, Pittsburgh, PA, and Lab. Neuro-NIH, and Lab. Neurophysics. Biochem., Univ. Pittsburgh, Pittsburgh, PA, and Lab. Neuro-physiol., Univ. Wisc., Madison, WI. It has been proposed that glutaminase and/or aspartate

aminotransferase, enzymes involved in the routine metabolism of glutamate and aspartate, may have an additional function in the regulation and replenishment of neurotransmitter pools of excitatory amino acids. These enzymes would then be present in increased levels in such neurons and be able to serve as markers in immunocytochemical studies. In this study antisera to glutaminase (GLNase) and antisera to aspartate aminotransferase (AATase) were used in an immunocyto-

artate aminotransferase (AATase) were used in an immunocyto-chemical examination of the cerebral neocortex of the rat, guinea pig, and monkey (M. fascicularis). In the rat and guinea pig neocortex dense GLNase-like immunoreactivity (ir) is present in pyramidal cells located mainly in layers V (the origin of most descending cortico-fugal pathways) and VI (the origin of corticothalamic fibers), and to a lesser extent in layer III. Layers I, II and IV contain very few well-labeled cells. A similar pattern is evident in monkey neocortex in the primary visual cortex (area 17) and in area 3b of the primary somatic sensory cortex, but in areas 1,2,5 and 7 labeled cells are also common in the deeper part of layer III. In areas 2, 5 and 7 the large, deep layer III pyramids are densely labeled. The large, deep layer III pyramids are densely labeled. The motor cortex (area 4) contains numerous labeled cells throughout layers III-VI. However, the giant layer V pyramidal (Betz) cells, are not labeled.

Antisera to AATase produces an entirely different pattern In total, fewer neurons are labeled than with antisera to GLNase. AAT-ir is present mainly in non-pyramidal neurons, but some pyramidal cells also appear to be labeled. All cortical laminae contain some AATase-ir neurons but they are more common in layers II and III throughout the neocortex

and in layer IVc of the monkey primary visual cortex. The localization of GLNase-ir neurons to layers V and VI supports the hypothesis that corticothalamic and many other supports the hypothesis that control the main order and main order transmit-ter. Some cortico-cortical neurons, especially those in layer III of non-primary sensory areas of monkey cortex may also use such a transmitter. The lack of GLNase-ir in many layer II-III pyramidal cells suggests that some cortico-cortical neurons either use a different transmitter or a different combeting orthogy different synthetic pathway.

DESENSITIZATION TO GLUTAMATE AND ASPARTATE IN RAT 77.7 PREPYRIFORM CORTEX SLICES. D. J. Braitman. Physiology Depart-ment, Armed Forces Radiobiology Research Institute, Bethesda, Maryland 20814.

In a previous report (Hori et al., <u>J. Neurophysiol.</u>, 48: 1289, 1982) my colleagues and I presented electrophysiological and pharmacological evidence that neither L-glutamate (GLU) nor L-aspartate (ASP) appeared to be the excitatory neurotransmitter from lateral olfactory tract to prepyriform cortex (PPC) pyramidal neurons. However, kainic acid (KA) and N-methyl-dl-aspartate (NMA) exhibited pharmacological profiles similar to that of the endogenous transmitter. In the present study I investigated the ability of repeated applications of these amino acid receptor agonists to desensitize the endogenous synaptic receptors in the in vitro prepyriform cortex slice preparation.

Double shock orthodromic stimulation to the LOT delivered every 4 sec throughout the experiment evoked field potentials that were recorded from the pial surface of the submerged, constantly perfused, tangential silee of rat PPC ( $350 \mu$ - $450 \mu$  thick). To quantify the action of amino acids added to the perfusate, the amplitude of the slow wave component acids added to the perfusate, the amplitude of the slow wave component of the field, representing the population excitatory postsynaptic potential, was measured and compared to control values. Initial application of 2 x  $10^{-5}$  M GLU for 5 min resulted in a significant decrease in the amplitude of the field potential due to the depolarizing action of GLU. The ampli-tude of the field potential returned to control, i.e., pre-drug values, 10 to 15 min after termination of the drug application. A second perfusion of 2 x  $10^{-5}$  M GLU was less effective; i.e., the amplitude of the field potential decreased lose them it did office the first ponlimition of CLL eucential decreased less than it did after the first application of GLU, suggesting desensitization of the receptor-mediated glutamate depolarization. Successive application had even smaller effects. However, the amplitude of the field potential continued to return to control value after termina-tion of the GLU perfusion even though the GLU receptors were still desensitized. The response to repeated application of ASP desensitized in a fashion similar to GLU while the responses to repeated applications of KA and NMA did not desensitize. The responses to D-glutamate, which is not taken up by the high-affinity uptake system, also desensitized after repeated applications. This indicates that the phenomena seen in these

experiments did not involve the facilitation of an inactivation mechanism. Thus, although exogenously applied L-glutamate and L-aspartate desensitize their postsynaptic receptor sites, they do so without affecting the receptors to the endogenous neurotransmitter. On the other hand, the responses to KA and NMA, which have a pharmacological sensitivity to the antagonist 2-amino-4-phosphonobutyric acid similar to that of the endogenous transmitter, did not desensitize. The failure to find cross-desensitization between L-glutamate and L-aspartate receptors and the receptors at the terminal synapses of the lateral olfactory tract is further evidence that neither glutamate nor aspartate is the excitatory transmitter on prepyriform pyramidal neurons.

ONTOGENESIS OF KAINIC ACID INDUCED SEIZURES AND BRAIN DAMAGE: THE CRUCIAL ROLE OF HIGH AFFINITY ["H KAINIC ACID RECEPTORS IN THE AMYGDALA. <u>M.Berger</u>", <u>E.Tremblay</u>", <u>L.Nitecka</u> & <u>Y.Ben-Ari</u>. Lab.Physiol.Nerveuse, CNRS, F-91190 Gif-sur-Yvette, France. 77.9

Systemic and intracerebral injections of kainic acid (KA) into Systemic and intracerebral injections of kainic acid (KA) into adult rats produce a typical limbic seizure - brain damage syn-drome which is a useful model for human temporal lobe epilepsy (Ben-Ari et al., Neuroscience 6/7,1361-1391, 1981). The involve-ment of the entire limbic circuity (hippocampus, amygdala, septum, limbic cortex etc.) is clearly revealed by <sup>1</sup>C 2-desoxyglucose (2-DG) studies (ibid.). In contrast, in immature rats (<18d), KA i.p. produces tonico-clonic generalized seizures without limbic signs, with the exclusive metabolic activation of the hippocampus (Tremblay et al., Neurosci.Abstr. 287/8, 1982). and no clearcut (Tremblay et al., Neurosci.Abstr. 287/8, 1982), and no clearcut brain damage (Nitecka et al., submitted). We have now investigated the ontogenetic appearance of [<sup>3</sup>H] KA

We have now investigated the ontogenetic appearance of  $[\frac{3}{H}]$  KA receptors in rat brain, differentiating between low and high on-off rate receptors, and found both populations to be heterogeneous. In particular, we discovered 3 types of low on-off rate KA receptors, with low (K\_D=20nM), high (K\_D=6nM), and very high (K\_C<1 nM) affinities for the ligand. In rats younger than 16d, we found high affinity receptors in the hippocampus, but not in the amyg-dala, where this receptor type appeared after the 18<sup>th</sup> day of life. This is exactly the time point when 1) the animals first display limbic motor seizures, 2) the 2-DG maps reveal an activation of most of the limbic circuity, including the amygdala, 3) irreversible brain damage occurs in vulnerable structures (in genetic vulnerability to limbic seizures eliciting mechanisms when the animal has become adult (Nitecka et al., submitted). Our results add further evidence for the crucial role of the first time a correlation of one of the most prominent actions of KA with a well defined subpopulation of KA receptors. The physio-logic ligand for these receptors remains to be identified.

logic ligand for these receptors remains to be identified.

PHENYLALANYL-L-GLUTAMATE ENHANCES SPECIFIC [ $^{3}$ H]-2-AMINO-7-PHOS-PHONO HEPTANOIC ACID AND [ $^{3}$ H]-L-GLUTAMATE BINDING AND INHIBITS SPECIFIC [ $^{3}$ H]-KAINIC ACID BINDING TO RAT BRAIN MEMBRANES IN <u>virro</u> J. Ferkany, R. Zaczek\*, A. Markl\*, and J.T. Coyle, Depts of Psych-iatry, Neuroscience, Pharmacology, Div. Child Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. Electrophysiological and in <u>vitro</u> binding studies have iden-tified 3 classes of excitatory amino acid receptors in brain which are preferentially activated by N-methyl-D-aspartate (NMDA), glutamate (Glu) or kainic acid (KA). In the present study, we have investigated the effects of a number of dipeptides on the specific binding of [ $^{2}$ H]-L-Glu, [ $^{2}$ H]-APH, a reputed NMDA antago-nist, and [ $^{3}$ H]-KA to rat brain membranes in <u>vitro</u>. For assay, a previously frozen buffy-coat preparation from brain was washed 4 times by centrifugation and preincubated for 30 min at 37°C in previously recent purty-coat preparation from brain was washed 4 times by centrifugation and preincubated for 30 min at  $37^{\circ}C$  in Tris citrate buffer (0.05mM pH 7.2). One ml of the tissue (0.4 mg/ml) was added to 1 ml of buffer containing the ligand and compounds of interest; and the incubation continued for 90 min. The reaction was terminated by centrifugation; and radioactivity was

pounds of interest; and the incubation continued for 90 min. The reaction was terminated by centrifugation; and radioactivity was measured in the solubulized pellets. Phenylalanyl-L-glutamate (PG) (EC50 4.9 uM) enhanced the specific binding of both [<sup>3</sup>H]-L-Glu and [<sup>3</sup>H]-APH to brain membranes in a dose dependent manner. Specific binding of [<sup>3</sup>H]-strychnine and [<sup>3</sup>H]-spiroperidol were unaffected by PG. The maximal increase in [<sup>3</sup>H]-APH binding (+445±19%) was greater than for [<sup>3</sup>H]-L-Glu (+292±25%); but in both instances, the increase in binding was due exclusively to alterations in the apparent B<sub>max</sub> of the ligands. The action of PG(50 uM) on [<sup>3</sup>H]-APH binding (+425±19%) was greater than for [<sup>3</sup>H]-APH binding (+950±100%) and least on cerebellar (+320±10%) membranes. PG failed to alter the non-specific binding of [<sup>3</sup>H]-APH to peripheral organs or heat treated brain sonicates. The pharmacological profile of [<sup>3</sup>H]-APH binding in the presence and absence of PG was identical and consistent with binding of the ligand at a Glu-type receptor. The action of PG was minicked by Tryn-Glu (EC50=11.3uM). Binding of [<sup>3</sup>H]-APH was also enhanced by Tryn-Glu (EL50=10.4u), Leu-Glu >Try-Glu (100uM) on [<sup>3</sup>H]-APH binding the presence and absence of PG was identical and consistent with binding of the ligand at a Glu-type receptor. The action of PG was minicked by Tryn-Glu (EL50=10.4u), Binding of [<sup>3</sup>H]-APH was also enhanced by Tryn-Glu (EL50=11.3uM). Binding of [<sup>3</sup>H]-APH was also enhanced by Tryn-Glu (EL50=10.4u) and Meth-Glu (EC50=29.5.5.5) although these compounds were less efficacious than PG or Tyr-Glu. The order of potency of the compounds to inhibit specific [<sup>3</sup>H]-APH binding the presence of PG (50uM) suggesting that Meth-Glu may be a partial antagonist at the PG site. The results of the present study demonstrate an interaction of a class of Glu-containing peptides with both Glu and KA type receptors in brain and suggest that alterations in one receptor may influence the other.

CONTENT AND IN VITRO RELEASE OF ENDOGENOUS AMINO ACIDS IN THE AREA OF THE NUCLEUS TRACTUS SOLITARIUS (NTS). <u>M.P.</u> 77.10 Meeley, M.D. Underwood\*, W.T. Talman and D.J. Reis. Laboratory of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.
 We sought to determine potential amino acid (AA) neurotransmitter

candidates in the area of the NTS in rats. Twenty AAs were analyzed by reverse-phase HPLC with fluorescence detection (100 fmol limit). by reverse-phase HPLC with fluorescence detection (100 fmol limit). Rats were decapitated, brains removed and sliced (1mm), and micropunches (1mm) taken of NTS and, for comparison, Caudate Nucleus (CN) and Ventrolateral Medulla (VLM). Micropunches of NTS, extracted with 0.4N perchlorate, contained notably high amounts of Glu (446+32 nmol/mg prot., n=7), Gly (375+50) GABA (359+35) and Gln (214714), and moderate to low leveIs (170-5 nmol/mg) of Tau, Asp Ser- Arg > Ala > Thr > His > Tyr > Trp > Met > Asn, Val, Phe, Ile, Leu, but no B-Ala. Glu levels in NTS were intermediate to those measured in CN (691+56, n=6), a glutamatergic area, and VLM (249+24), which has no known Glu input. The GABA content of NTS was which has no known Glu input. The GABA content of NTS was significantly higher than that of CN (235±18, p<.05) or VLM (119±13, p<.001). Gly content was greatest in NTS~VLM>CN; Asp, NTS~CN>VLM. NTS  $\sim$  CN > VLM. To examine non-selective release, bilateral micropunches of NTS (CN or VLM) from 3 rats were pooled and superfused (200uL/min) with normal and high K+ (56mM, 4 min) media without Ca2+. Basal release values in NTS were highest for ClavClu X draw Area Tanue CAPA. Gly>Glu>Asp>Tau>GABA. Stimulation with K+ resulted in release of GlySGly Asp 5 rad dependent, , with only moderate release of GABA, Gly, and Asp. A slight response to K+(+calcium) was noted for Glu and GABA in VLM. We conclude: (a) the abundance of Glu and its Ca2+-dependent release in NTS is strong additional support for the transmitter role of Glu in this area; (b) high GABA pools and dramatic releasability of GABA in NTS is compelling evidence for transmitter function of this AA in the region; and, (e) Gly may also act as a transmitter in NTS, given its substantial content, though modest Ca2+-dependent release. (Supported by Grant HL 18974 and HL 07378.)

RECEPTOR-MEDIATED EXCITOTOXIN-INDUCED LYSIS OF NEUROBLASTOMA 77.11 CELLS IN CULTURE. A.T. Malouf, R.L. Schnaar and J.T. Coyle. Depts of Neuroscience, Psychiatry, and Pharmacology and Experi-mental Therapeutics, Div. of Child Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205. The N18-RE-105 neuroblastoma x embryonic retina hybrid cell

The N18-RE-105 neuroblastoma x embryonic retina hybrid cell line was previously shown to have a high density of specific binding sites for  $[^3H]$ -L-glutamate (GLU) in washed membranes with a  $B_{max}$  of 15.5 pmoles/mg protein and a  $K_D$  of 654 nM (Malouf, A.T., et al,(1982) Soc. Neurosci. Abstr. 8,878). Pharmacological stu-dies revealed a high correlation (re0.92) of the  $K_1$ 's of several drugs which bind with high affinity to the  $[^3H]$ -GLU receptor in rat brain membranes when compared to their  $K_1$ 's of binding to the neuroblastoma hybrid cell membranes. In both cases,  $[^3H]$ -L-GLU appears to label a quisqualate-preferring receptor. To determine if the binding sites labelled by  $[^3H]$ -GLU on N18-RE-105 neuroblastoma

The determine if the binding sites labelled by [<sup>3</sup>H]-CuU on appears to label a quisqualate-preferring receptor. To determine if the binding sites labelled by [<sup>3</sup>H]-GLU on N18-RE-105 neuroblastoma membranes could mediate the cytotoxic effects of acidic amino acids on intact cells, neuroblastoma were grown in the presence of various concentrations of neuroactive amino acids and their analogs. Cell viability was assessed by lysing the cells firmly attached to the culture dish in phosphate buffer containing 0.5% Triton X-100, and measuring the activity of the cytosolic enzyme lactate dehydrogenase (LDH). In addition, LDH activity released into the growth medium by cell lysis during culture was also determined. After 24 hours of cell culture in the presence of 10 mM L-GLU, the cell associated LDH activity was decreased by 25+1% (p<0.025) whereas LDH activity in the media was increased 415+17% (p<0.025) whereas LDH activity in the media was increased 145+17% (p<0.025) whereas LDH activity in the media was increased at by reduction in cell number of viable neuroblastoma cells continues to decline for up to 3 days in the presence of GLU, resulting in a 90% reduction in cell number compared to control cultures. Microscopic inspection of the cultures grown in 10 mM GLU revealed a predominance of distended cells filled with vacuoles. As assessed by the reduction of cellular LDH, the increase in media LDH and morphological alterations, quisqualate was the most potent cytotoxin (ImM) followed by L-6LU and ibotenate (10mM); D,L-2-amino-4-phosphono butyrate (10mM), a mixed antagonist, was only partially effective. In contrast, kainate, N-methyl-D,L-aspartate and GABA, which do not compete at the [<sup>3</sup>H]-GLU receptor site, exhibited no cytotoxic effects on the N18-RE-105 cells at 10mM. The results indicate a correlation between cytotoxic potency and affinity for the [<sup>3</sup>H]-GLU receptor of excitatory GLU analogs; furthermore, the cytologic alterations accompanied by NIH NS13584, and MOD grant #5-302.

IONIC MECHANISMS UNDERLYING THE ACTION OF PUTATIVE TRANSMITTERS ON ENZYMATICALLY DISSOCIATED HORIZONTAL CELLS. R. Shingai\* and 77.13 N. Christensen. Dept. of Physiology & Biophysics, University Texas Medical Branch, Galveston, TX 77550. of Texas Medical Branch, Galveston, TX

Glutamate is one suggested candidate for the excitatory ansmitter that is released from photoreceptors at synapses transmitter transmitter that is released from photoreceptors at sympaces made with horizontal cells in the fish retina (Laster, E.M. & Dowling, J.E., Proc. Natl. Acad. Sci., 1982). The action of this substance is to depolarize the cell membrane of both horizontal cells in the intact retina as well as horizontal cells enzymatically isolated from intact retina. A prevalent hypothesis that explains the modulation of horizontal cell membrane potential during changes in luminosity is that the excitations potential uniting continuously released from the photo-receptors. It would therefore be expected that transmitter activated receptors do not desensitize in the continuous presence of the transmitter. Furthermore, the reversal presence of the transmitter. Furthermore, the reversal potential of the transmitter should be at a minimum near zero mV potential of the transmitter should be at a minimum near zero mV in order to explain the low resting potential recorded from horizontal cells in the intact dark adapted retina. We investigated the ionic basis of the physiological responses produced by the application of glutamate to horizontal cells enzymatically isolated from the catfish retina. Experiments using both current and voltage clamp were done to examine the changes in membrane potential and ionic currents during application of the acconic application of the agonist.

The putative neurotransmitter l-glutamate was pressure ejected onto isolated horizontal cells under both current and voltage clamp conditions. Pulses of the transmitter (500 uM in the pipette) produced a depolarizing potential and an inward going current. Inward currents of up to 1 nA could be elicited. going current. Inward currents of up to 1 nA could be elicited. The drug response did not inactivate over a period of time lasting up to 20 sec. This current reversed at a membrane potential of about +5 mV. Above this potential the current became outward and the amplitude of the current was linearly related to the holding potential. The reversal potential shifted to about -5 mV when the external sodium was replaced with choline suggesting a small contribution of sodium to the clutamate activated current. Under current clarm conditions glutamate activated current. Under current clamp conditions, application of the transmitter evoked an action potential which was similar in every respect to one produced by direct application of current to the intracellular electrode. The action of the transmitter appeared to have little effect on the voltage sensitive sodium and calcium currents. Because glutamate receptors do not desensitize in the presence of the agonist and because of its positive reversal potential, glutamate appears to be a good candidate for the excitatory transmitter at these cells. Supported by grant EY-01897.

EFFECTS OF KYNURENATE ON ROOT POTENTIALS EVOKED BY SYNAPTIC 77.12

EFFECTS OF KYNOREMATE ON ROOT POTENTIALS EVOKED BY SYNAPTIC ACTIVITY AND AMINO ACIDS IN THE FROG SPINAL CORD. <u>Keith S.</u> Elmslie\* and Doju Yoshikami. Dept. of Biology, University of Utah, Salt Lake City, Utah 84112. Perkins & Stone (<u>Brain Res. 247</u>: 184, 1982) have reported that kynurenate (Kyn) inhibits the effects of certain excitatory amino acids in mouse cortical cells. We report here our findings of the effects of Kyn on dorsal and ventral root potentials evoked by synaptic activity and by bath application of amino acids in isolated hemiserted spinal cords of from <u>Kyn</u> (0.5 mW) rapidly of the synaptic activity and by bath application of amino acids in isolated, hemisected spinal cords of frog. Kyn (0.5 mM) rapidly and reversibly blocked at least 90% of the synaptically mediated ventral root potential produced by stimulation of the dorsal root. Spontaneous activity recorded from both ventral and dorsal roots was also abolished by Kyn. Kyn is not, however, a general inhibitor of synaptic transmission since Kyn concentrations as high as 2.5 mM had no effect on synaptically mediated dorsal root

high as 2.5 mM had no effect on synaptically mediated dorsal roo potentials produced by stimulation of the ventral root. In addition, Kyn had no effect on synaptic transmission in sympathetic ganglia of frog. In spinal cords treated with TTX, ventral root potentials (VRPs) induced by N-methyl-D,L-aspartate, quisqualate, kainate, aspartate, and glutamate were all significantly reduced by 2.5 mM Kyn. In contrast, GABA-induced depolarizations measured from the dorsal root were not antagonized by Kyn. Kyn itself, when applied to a TTX-treated spinal cord. did not produce any when applied to a TTX-treated spinal cord, did not produce any ventral root response.

ventral root response. The dose-response curve to quisqualate was shifted to the right in 2.5 mM Kyn. Furthermore, when Kyn is washed out, the rate of recovery from Kyn block appears to be accelerated by the presence of quisqualate. These results suggest that quisqualate and Kyn compete for common binding sites. However, although concentrations of Kyn in range of 1 mM or greater generally reduced quisqualate-induced VRPs, lower concentrations of Kyn of the presence of the presence to estumine (e.g. 0.1 mM) potentiated the peak of the response to saturating concentrations of quisqualate by as much as 30%. Interestingly, the duration of the potentiated quisqualate responses were . Thus, Kyn significantly shorter than the unpotentiated responses. does not act simply as a competitive inhibitor of quisqualate. These results, taken together, raise the possibility that there is more than a single class of binding sites for quisqualate and Kyn in the cord.

Detailed experiments on the action of Kyn on the responses to other amino acids remain to be performed.

IN VITRO AUTORADIOGRAPHY\_FAILS TO DEMONSTRATE A PATTERN OF SPECI-FIC NEURONAL BINDING OF <sup>3</sup>H FOLIC ACID IN RAT BRAIN. <u>T.A. Fuller</u>, Washington Univ. Sch. Med., Dept. Psychiatry, St. Louis, MO. Direct injection of folic acid (pteroyl-L-glutamic acid, PGG) into rat striatum, amygdala or substantia inominata induces a syndrome of limbic convulsions and neuropathology distant from the injection site quite similar to that induced by the glutamate analog kainic acid (Olney et al., Nature 292, 165-167, 1981; McGeer et al., Brain Res 260, 107, 1983). The PGA metabolites N-5-formyltetrahydrofolate (FTHF) and methyltetrahydrofolate (MTHF) also produce this neurotoxic syndrome following intraamygdaloid iniection, MTHF being 20-30 fold less potent than either PGA or 77 14 also produce this neuroboxic syndrome following intrading galoud injection, MTHF being 20-30 fold less potent than either PGA or FTHF. Despite an initial report that MTHF is a potent competitor for KA binding sites on rat cerebellar membranes, it now appears unlikely that kainate preferring receptors underlie the folate induced toxic syndrome because significant folate competition for Available toxic syndrome because significant folate Competition for kainate binding has not been found in striatal membranes (Ferkany et al., Neurobehav Toxicol Teratol 4, 573-579, 1982) or telen-cephalic homogenates (M. Price, unpublished). In order to determine if specific folate binding might underlie the folate toxicity, in vitro autoradiography of H-PGA was undertaken.

toxicity, in vitro autoradiography of <sup>3</sup>H-PGA was undertaken. In brief, thaw-mounted 15  $\mu$ m frozen sections of lightly fixed brains of adult male Sprague-Dawley rats were incubated in the dark in either a 4 or 8 nm solution of <sup>3</sup>H-PGA (35 Cu/nmol, Amer-sham) in Tris HCl buffer (0.17 M, pH 7.4) or in an identical solu-tion which also contained a 1000-fold excess of unlabeled PGA for 30-60 min at 4° or 25°C. After incubation, the sections were rinsed twice in cold Tris buffer for 30 sec or 5 min. Slide-mount-ed tissue sections were placed in cassettes and tritium-sensitive ultrafilm (LKB) was directly apposed to the tissue. The film was

ed tissue sections were placed in cassettes and tritium-sensitive ultrafilm (LK3) was directly apposed to the tissue. The film was exposed for 3 or 4 weeks at -70° C and developed in Kodak D19. The sections were stained with thionine for microscopic viewing. The various incubation gonditions resulted in variable amounts of nonspecific binding of "H-PGA seen in those sections incubated with the solution containing excess unlabeled PGA. The only significant specific accumulation of label was localized in choroid plexus at all levels of brain, probably attributable to the folate-binding protein known to reside in the plasma membranes of that strycture. There was no pattern of specific neuronal binding of "H-Folate discernible in any of the sections. These preliminary studies neither support the contention that PGA significantly binds to the kainate-preferring receptors which have significantly binds to the kainate-preferring receptors which have been demonstrated by similar in vitro autoradiography (Monaghan & Cotman, Brain Res 252, 91-100, 1982) nor demonstrate a neuronal binding site for PGA. The mechanism underlying the folates' excitatory and toxic abilities remains to be clarified. These experiments were supported by RSDA MH-00330.

ANTAGONISTIC ACTIVITY OF ω-PHOSPHORUS-CONTAINING GLUTAMATE ANALOGUES IN THE PERFORANT PATH. <u>R.K. Freund, S.L. Crooks\*, J.F.</u> Koerner, and R.L. Johnson\*. Depts. of Biochemistry and Medicinal Chemistry, Univ. of Minnesota, Minneapolis, MN 55455. The finding that the glutamate analogue L-2-amino-4-phosphonobutanoic acid (L-APB) antagonizes excitatory responses in the perforant path of rat hippocampal slices [Koerner and Cotman, Brain Research, 216 (1981) 192] has prompted an investigation of the structural features required for antagonism at these synapses. On the basis of published extracellular criteria, [Koerner and Cotman, Brain Research, 251 (1982) 105], the pharmacology of several Y-substituted glutamate analogues was compared on dentate granule cells [Koerner et al., Brain Research, in press]. OnlyL-APB and 0-phospho-L-serine (0-PLS) [Fagg et al., Neurosci. Lett., 31 (1982) 59] exhibited antagonism. Planar vs. tetrahedral geometry of the Y-substituent could not explain agonist vs. antagonist activity differences. The only obvious differences are: (1) that L-APB and 0-PLS can bear a side chain dianion, while side chains of the known agonists are obligatory monoanions at physiological pH, and (2) that these antagonists contain a phosphorus atom at the &-position. In order to explore the influence of side chain charge on antagonism, we have synthesized and tested the activities of two additional Y-substituted glutamate analogues, DL-2-amino-4-(methylphosphino)-butanoic acid (DL-AMPB) and 0methylphosphonyl-L-serine (0-MPLS). The compounds were classified as antagonists by their pathway selectivity and other criteria, which indicates that a dianionic side chain is not a strict requirement for antagonistic (vs. agonistic) activity. DL-AMPB and L-APB And 0-PLS (Y = 0H) were more potent than their methyl-substituted (Y = CH3) analogues DL-AMPB and 0-MPLS. Although methyl substitution may have a variety of deleterious effects (e.g., steric, hydrophobic, etc.), the lower potencies of DL-AMPB

77.17 KYNURENATE ANTAGONISM OF HIPPOCAMPAL SYNAPTIC FIELD POTENTIALS. M.B. Robinson, K.D. Anderson\*, and J.F. Koerner. Dept. of Biochemistry, Univ. of Minnesota, Minneapolis, MN 55455. Kynurenate, a tryptophan metabolite, is an antagonist of excitatory amino acids in the cerebral cortex [Perkins and Stone, Brain Research, 247 (1982) 184], but the extent of the antagonist action in the CNS is unknown. We have previously shown that antagonists can be distinguished from agonists by extracellular recording of synaptic field potentials [Koerner and Cotman, Brain Research, 251 (1982) 105]. A slice of rat hippocampus, submerged in superfusing medium, was exposed to bath-applied kynurenate at threshold concentration for inhibiting the stimulus-evoked extracellular synaptic field potential. The drug concentration was doubled every four minutes until two doublings of the bath concentration no longer reduced the synaptic field potential or until the response was reduced >70%. Inputs to CA3 pyramidal cells were measured by stimulating in the hilus of the dentate and recording in the stratum lucidum of the regio inferior (containing mossy fiber inputs to CA3 pyramidal cells) or in the stratum radiatum of the regio inferior (containing commissural inputs to CA3 pyramidal cells). The mossy fiber inputs are (-)-baclofen insensitive; the commissural inputs are (-)-baclofen sensitive [Ault and Nadler, J. Pharmacol. Exp. Ther., 223 (1982) 291]. This differential sensitivity to (-)-baclofen was used to verify electrode placement. Inputs to granule cells were measured in the midle or outer one-thind of the molecular layer, the medial or lateral perforant paths respectively, and electrode placement was verified by the differential sensitivity to the two pathways to DL-APB [Koerner and Cotman, Brain Research, 216 (1981) 192]. Inputs to CA1 pyramidal cells were measured by stimulating and recording in the stratum radiatum of the regio superior. Kynurenate was identified as an antagonist by its sigmoidal

pyramidal cells were measured by stimulating and recording in the stratum radiatum of the regio superior. Kynurenate was identified as an antagonist by its sigmoidal concentration-response curve, the differential pathway sensitivity of different inputs to the same neuron type, and absence of the spiking induced by agonists. As an antagonist, it was found to be approximately equipotent for the medial perforant pathway, the Schaffer collateral inputs to CA1 pyramidal cells (K<sub>d</sub> = 200-300µM). It appears to be slightly more potent in the lateral perforant pathway but by no more than a factor of two. This is the most potent compound known to non-selectively antagonize these four pathways which putatively utilize acidic amino acid transmitters. In contrast, synaptic field potentials of the mossy fiber-CA3 synapses, for which no known transmitters have been implicated, were inhibited less than 20% by 8mM kynurenate. [Supported by PHS NS17944] 77.16 VALPROIC ACID AND HUMAN PLASMA AMINO ACIDS, G.N. Ko, E.R. Korpi, L.B. Bigelow, S.J. Zalcman, R.J. Wyatt. Adult Psychiatry Branch, NIMH, Saint Elizabeth Hospital, Washington, D.C. 20032

Introduction: Valproic acid is an anticonvulsant that has been administered to individuals with the schizophrenic syndrome. It has little or no beneficial effect. The purpose of the present study was to examine its effects on plasma amino acid concentrations.

Its effects on plasma amino acid concentrations. <u>Methods</u>: Morning plasma from six schizophrenic subjects was obtained and stored at -50°C until assayed by an automated HPLC amino acid analyzer. Plasma was obtained while patients were valproate free and again after receiving valproate for four weeks.

Results: Plasma glutamete and aspartate were decreased by valproate (two-tailed, T=3.36; p<0.05; T=2.75; p<0.05, respectively). Taurine was elevated (T=4.84; p<0.05). Eleven other plasma amino acid concentrations were unaltered during valproate treatment. No improvement in schizophrenic symptoms was noted during the valproic acid treatment period.

**Discussion:** Sodium valproate may confer its anticonvulsant properties by its action on these excitatory (glutamate and aspartate) and inhibitory (taurine) amino acid concentrations, as well as its well known ability to raise GABA concentrations.

The changes in amino acid metabolism apparently do not coincide with any improvement in the clinical state of patients with the chronic schizophrenic syndrome.

REGIONAL DISTRIBUTION OF L-[<sup>3</sup>H]GLUTAMATE BINDING SITES AS DETERMINED BY QUANTITATIVE AUTORADIOGRAPHY. J. T. Greenamyre, J. B. Penney and A. B. Young, Neuroscience Program and Neurology Dept. University of Michigan, 1103 East Huron, Ann Arbor, MI 48109. Electrophysiological and biochemical evidence suggest glutamate as a putative excitatory neurotransmitter in the mammalian CNS. High affinity binding of L-[<sup>3</sup>H]glutamate to CNS membranes has been demonstrated by several groups. L-[<sup>3</sup>H]Glutamate binding is saturable, reversible, highest in synaptic-enriched fractions, inhibited by various glutamate analogues and is apparently related to synaptic glutamate been limited by available dissection methods and results have been contradictory. We report the use of quantitative autoradiography to study the regional distribution of [<sup>3</sup>H]glutamate binding in rat brain. Rat brains were quickly removed, blocked, cooled in ice-cold buffered 0.32 M sucrose and frozen on microtome chucks under powdered dry ice. Twenty micron brain sections were thaw-mounted

Rat brains were quickly removed, blocked, cooled in ice-cold buffered 0.32 M sucrose and frozen on microtome chucks under powdered dry ice. Twenty micron brain sections were thaw-mounted onto subbed slides, washed for 30 min in ice-cold 50 mM Tris-HC1 (pH7.4) containing 2.5 mM CaCl<sub>2</sub> and blown dry. Slides were incubated for 30 min at 37°C with 50-1000 nM [ $^{3}$ H]glutamate in 50 mM Tris-HC1 containing 2.5 mM CaCl<sub>2</sub>. Nonspecific binding was determined in the presence of 1 mM unlabelled glutamate. After incubation, sections were rinsed 3 times with cold buffer, followed by a rinse with cold 5% glutaraldehyde in acetone. Total rinse time was 10 sec. Autoradiograms were prepared and analyzed as previously described (Penney et al., <u>Science</u>, 214: 1036, 1981). Glutamate bound to a single population of sites with a  $k_D$  of about 1.0 µM. The pharmacology of binding was similar to that observed in homogenete studies; quisqualate and ibotenate had IC<sub>50</sub> of 2 µM and 16 µM, respectively. There was marked regional variation in glutamate binding.

Glutamate bound to a single population of sites with a  $K_D$  of about 1.0 µM. The pharmacology of binding was similar to that observed in homogenate studies; quisqualate and ibotenate had IC<sub>50</sub>s of 2 µM and 16 µM, respectively. There was marked regional variation in glutamate binding. Binding was greatest in stratum moleculare of the hippocampus, followed by stratum oriens and stratum radiatum. Binding was also high in cortex (layers 1 and 2), striatum, medial and lateral geniculate bodies, stratum griesum of the superior colliculus, the cerebellar molecular layer and substantia gelatinosa. Binding was intermediate in cortex (layers 5,6), other thalamic nuclei, substantia nigra, interpeducular nucleus, periaqueductal grey matter and intermediate and ventral grey zones of spinal cord. Little binding was present in globus pallidus, hypothalamus, reticular formation or pontine or medullary tegmentum. The distribution of binding correlated well with they are related to postsynaptic glutamate receptors. Supported by NSF grant BNS-8118765. United Cerebral Palsy

SPECTRAL ANALYSIS OF CORTICAL EEG EFFECTS PRODUCED BY THE REVERSIBLE CHOLINESTERASE INHIBITOR PHYSOSTIGMINE IN RATS. Marsha L. Bloodworth-Barlow\*, Christine U. Eccles and Gerald A. Young. Deot. of Pharmacology and Toxicology, Univ. of Maryland School of Pharmacy, Baltimore, MD 21201. Physostigmine is a relatively simple and reversible cholin-esterase inhibitor. Characterization of EEG and behavioral changes following physostigmine administration should serve as a foundation for the further study of central nervous system effects of other anticholinesterase agents. Cortical EEG power spectra associated with the behavioral states of sleep, REM sleep and wakefulness in the rat have been previously characterized (Young et.al., Pharmacol. Biochem. Behav. 8:89, 1978). In the present study, power spectral analysis was utilized to delineate changes in cortical EEG in the rat follow-ing acute administration of varying doses of physostigmine. Adult female Sprague-Dawley rats were implanted with chronic cortical EEG and temporalis muscle EMG electrodes and intra-venous (i.v.) cannulae for drug administration. EEG and EMG recordings were obtained with a Grass polygraph and were stored on tape with a Hewlett-Packard recorder. EEG samples were subjected to spectral analysis, utilizing a Nicolet MED-80 minicomputer. EEG was digitized at a sampling rate of 100/sec.; spectral power densities were estimated at 0.1 Hz intervals from zero to 50 Hz.

spectral power densities were estimated at 0.1 Hz intervals from zero to 50 Hz.

From zero to 50 Hz. Following i.v. administration of higher doses of physostig-mine, two predominant spectral peaks were broduced in the cortical EEG power spectra. These spectral beaks were within the 1-3 Hz and 5-6 Hz bands. At these doses of physostigmine, behavioral manifestations of physostigmine (i.e., tremor, urination, defecation) were bresent. At lower doses of bhyso-stigmine, at which no behavioral effects of physostigmine were apparent, one bredominant spectral peak occurred in the theta band (5-10 Hz). The above effects of physostigmine on EEG and behavior persisted continuously for about one hr. In contrast, control wakefulness after saline administration was associated with relatively low amplitude, high frequency cortical EEG that alternated with frequent occurrences of sleep and REM sleep. In conclusion, the data obtained so far with physostigmine indicate that our experimental model should allow the compara-tive delineation of the effects of other anticholinesterase

tive delineation of the effects of other anticholinesterase agents upon EEG and behavior.

TRIETHYLTIN-INDUCED ENCEPHALOPATHY IN PERINATALLY EXPOSED 78.2 RODENTS; BIOCHEMICAL AND MORPHOLOGICAL EVIDENCE OF NEURONAL DAMAGE. B. Veronesi\*, Health Effects Research Laboratory United States Environmental Protection Agency, RTP, NC 27711, (Northrop Services Inc.) and <u>S.C. Bondy</u>\* Laboratory of Behavioral and Neurological Toxicology, NIEHS, RTP, NC 27709 (Spon: C.F. Mactutus)

In the rat, acute exposure to triethyltin (TET) on day 5 of postnatal development (D5) results in CNS hypomyelination, edema and errors in compaction in young (D20) animals. However, these and errors in compaction in young (D20) animals. nowever, these myelin abnormalities are corrected by D60. Since behavioral and electrophysiological abnormalities persist in adult-tested, D5-treated rats, we elected to examine the CNS neuronal population. For this, Long-Evans hooded D5 pups (n=48) were injected (IP) with saline, 6 or 9 mg/kg TET-bromide and sacrificed at D20, and D60. Gross examination of the whole brain at both ages revealed a dose dependent weight loss and a graded anterior-posterior thinning, especially prominent in the entorhinal cortex. cortical In the D20 pups, examination of the posterior cortex revealed a range of cytological abnormalities, including swollen, vacuolated and hyperchromatic neurons in all layers and a marked microglial infiltration. In the adult (D60) brain, overt cellular necrosis was not seen, although the neuronal lamination pattern of the posterior cortex was poorly defined. An immunocytological stain, specific for glial acidic fibrillary protein revealed the neu ronal population of the entorhinal cortex to be largely replaced by astrocytes. Golgi-stained material indicated that the surviving macro-neurons in this region had thinner, shorter, apical dendrites and fewer, secondary and tertiary, basilar dendrites. Biochemical analyses of DNA/RNA/protein ratios derived from the anterior and posterior cortex, the hippocampus and cerebellum of 6 mg/kg, TET-D5 exposed pups sampled at D20, indicated a re duction in the number and size of cells, most evident in the posterior cortex and hippocampus. The surviving cells appeared richer in protein, reflecting the astrocyte population. selective depression of acetycholinesterase levels was seen in the posterior cortex. This study demonstrates that perinatal insult by TET results in the destruction of cortical neurons. This damage, which predomates in the entorhinal cortex, results in a smaller brain and an altered cortical cytoarchitecture in both D20 and D60 animals. Although these neuronal changes are most evident in the D20 pups, they are not transient and are clearly demonstrable histologically in the adult brain of perinatally exposed animals. Consequently, these data suggest neuronal damage rather than myelin abnormality underlies the persistent behavioral and electrophysiological abnormalities reported in adult tested, TET-D5 exposed rats.

- EFFECTS OF TRIMETHYLTIN ON NEURAL ACTIVITY OF PYRAMIDAL AND GRANULE CELLS OF MOUSE HIPPOCAMPAL SLICES. <u>D. L. Armstrong</u>, <u>M. J. Wayner and F. C. Barone</u>. Division of Life Sciences, Univ-sity of Texas at San Antonio, San Antonio, Texas 78285. The systemic administration of trimethyltin (TMT) produces 78.3 Univernecrosis of the pyramidal and granule cells of the hippocampus. The mechanism of TMT's neurotoxic action and its effect on single cell neural activity have not been determined. To study the effects of direct application of TMT on nerve cells a perfused mouse hippocampal slcie preparation was employed. Trimethyltin chloride (0.01M) was injected into the perfusion line in a volume of 0.1cc during the extracellular recording of single unit sponeffects of TMT on responses to paired pulse stimulation of the mossy fiber system and perforant path were determined. In addition, slices were prepared from mice that had been injected with a single i.p. dose of 3.0mg/kg TMT. The spontaneous activity and evoked responses of these slices were examined 6, 12, and 24 hours following the injection in an effort to detect electrophysiological changes prior to irreversible cell loss. Direct application of TMT produced irregular bursting patterns in the spontaneous activity of granule cells in the dentate gyrus and pyramidal cells in the CA1 and CA3 region. Control injections of normal perfusate had no effect on cell activity. A repetitive application of 3 injections within a 1 hour period suppressed all spontaneous activity and responses to afferent stimulation. A single application did not affect the amplitude of CA3 and granule single application and not affect the amplitude of CAS and gram cell stimulation evoked population spikes. Significant changes were not observed in slices prepared 6 and 12 hours following the systemic injection. However, after 24 hours well developed synchronous population spikes of granule and CAS cells were not observed. Individual cell spikes appeared superimposed on the population response. In conclusion, the direct application of TMT to the slice medium produces a bursting response pattern in pyramidal and granule cells that resembles the effects observed after perfusion with penicillin, which is believed to reduce inhibitory activity in the hippocampus (Schwartzkroin and Prince, Ann. Neurol. 1:463, 1977). Electrophysiological changes could be detected in slices prepared from TMT treated mice prior to significant cell loss. The results suggest that the slice preparation can be employed as a neurotoxicological screen and further tests on TMT are being carried out.
- 78.4 EFFECTS OF HALOTHANE ON DENDRITIC BRANCHES AND SYNAPTIC DENSITY,

EFFECTS OF HALOTHANE ON DENDRITIC BRANCHES AND SYNAPTIC DENSITY, E. Uemura, E. D. Levin, N. K. Laughlin and R. E. Bowman. Dept. of Vet Anat., Iowa State Univ, Ames, IA 50011, and Dept. of Psych., Univ. of Wisc., Madison, WI 53715. Halothane neurotoxicity on synaptogenesis was studied in the cerebral cortex during postnatal development. Sprague-Dawley rats were exposed to halothane in chambers during the entire gestation period. There were three exposure conditions: chamber control, 25 + 5 ppm intermittent halothane (8 hrs/day, 7 days/week), and 25 + 5 ppm continuous halothane (24 hrs/day, 7 days/week), each condition consisted of 6 rats. Rats were sacrificed at day 5 and 21 postpartum. The cerebral cortex was processed for light microscopic analysis of dendritic growth as revealed by the Golgi-Cox stain and for electron microscopic analysis of synapses stained with 1% ethanolic phosphotungstic acid. A significantly fewer number of dendritic branches (P < 0.001) and shorter dendritic lengths (P < 0.001) per neuron were found in rats exposed to halothane. Continuous halothane exposure had most severe effects on rats at both day 5 and 21 postpartum (P < 0.001). Similarly, the synaptic density in rats exposed to halothane was lower than those found in the control (P < 0.001). The difference was particularly prominent in rats which had been exposed to halothane continuously and examined at day 5 postpartum (P < 0.001). These data suggest that the initial growth of dendritic branches was affected by halothane exposure resulting in the delay of synaptic maturation. Supported by NIH Grant NS17107.

BEHAVIORAL AND NERVOUS-SYSTEM SPECIFIC PROTEIN CHANGES ASSOCIATED 78.5 WITH EARLY POSTNATAL EXPOSURE TO TRIMETHYLTIN (TMT). D.B. Miller A. D. B. O'Callaghan\*, Biol. Sci. Res. Chtr., UNC and Neurotox. Div. U.S.E.P.A., MD-74B, Research Triangle Park, NC 27711 Acute administration of TWT to the adult rat is reported to Div. produce relatively selective damage to the limbic system as in-dicated by behavioral, biochemical, and pathological alterations. Postnatal day 5 (PhD5) exposure to TMT produces adult hyperacti-vity and decreases in whole-brain and hippocampal weights (Ruppert et al., Soc. Neurosci. Abs. 8:82, 1982). The present study characterizes the neurotoxicity of early postnatal exposure to TMT using tasks related to hippocampal function (e.g., memory and learning) in the menate and juvenile rat. Because the mor-phological maturation of the CNS is characterized by ontogenetic changes in proteins associated with critical processes (e.g., synaptogenesis, myelinogenesis, neurogenesis), toxicant-induced effects on the developing nervous system may be reflected in alterations of proteins specific to the diverse cellular and subcellular elements composing nervous tissue (O'Callaghan & Miller, Trends in Pharm. Sci., 1983). Thus, behavioral evaluations were accompanied by measurements of nervous-system specific proteins. Long-Evans rats were cross-fostered and reduced to 8 pups/litter on PND1 (birth = 0). I.P. injections of 0.0, 5.0, or 6.0 mg/kg of TMT-OH were given on PND5. Behavioral changes in the neonate included a dose-related increase in trials to learn an alleyway task, as well as a decreased ability to re-tain the task over a delay period. As juveniles, TMT rats were less accurate in a radial-arm maze (RAM), and either (1) did not learn or (2) required more trials to acquire a passive avoidance task. Open-field activity during the neonatal period gradually progressed from a dose-related hypoactivity to a hyperactivity by weaning. Hyperactivity was also a concommitant of RAM be-havior. PND5 TMT produced a transient retardation in body weight and dose-related decreases in wet weights of whole brain. hippocampus, forebrain, and cerebellum, the hippocampus being the most affected on a percentage basis. The synapse-specific phosphoprotein, protein 1 (P1), was extracted from hippocampus as well as forebrain and assayed by phosphorylation with exogenous cAMP-dependent protein kinase. Although the total amount of P1 decreases as a function of TMT dosage, the percentage of total protein accounted for by P1 either increased (hippocampus) or remained the same (forebrain). In addition, the percentage of total forebrain protein accounted for by proteins specific to myelin did not vary as a function of TMT dosage. The content of myelin proteins obtained from optic tracts, however, showed a dose-related decrease. The data reported here indicate that early postnatal exposure to TMT can interfere with development of the limbic system.

78.7

RETENTION OF MOTOR DEFICITS PRODUCED BY PERINATAL EXPO-SURE TO POLYBROMINATED BIPHENYLS (PBB). J.W. Henck\*, C.L. Carlson\*, D.H. Rezabek\* and R.H. Rech. Dept. of Pharmacology/Toxico-logy, Michigan State University, East Lansing, MI 48824. Pregnant Sprague-Dawley rats received polybrominated biphenyls (0 of 6 mg/kg) daily in a peanut butter vehicle from day 6 of gestation through day 24 postpartum. Open field activity of offspring was measured from days 12-24 postpartum. Number of squares traversed, latency to move from the center squares and number of rearings ware sesses move from the center square, and number of rearings were assessed during the 3-minute test period. Control male and female rats exhibited the characteristic peak in squares traversed at 16 days of age, followed by a decline and subsequent increase to adult levels by 24 days of age. Peak number of squares traversed was delayed to day 18 for rats exposed to 6 mg/kg. The PBB-treated rats also were significantly less active than controls by postpartum day 24. Latency to move from the center square decreased with time in a comparable manner for control and treated rats. A peak in number of rearings was observed on day 14 for control rats; no peak was observed for treated rats. This parameter was significantly depressed for treated rats throughout most of the 12-day observation period. No sex-related differences were observed for control or treated

period. No sex-related differences were observed for control or treated rats with any of the parameters tested. At 5 months of age, all animals previously examined for open field activity were tested for d-amphetamine-induced stimulation of locomotor activity. Unaccommodated locomotor activity was examined for 1 hour, during which both control and treated rats exhibited habituation. Rats were then injected with 2 mg/kg d-amphetamine and monitored for 3 additional hours. Control and treated male rats exhibited comparable activity the unsure the cheven index of the distribution of the second state of activity throughout the observation period. Peak stimulation occurred within 30 minutes of injection, while offset of action occurred at 2 hours post-injection. Peak stimulation for control and treated female rats occurred within 45 minutes of injection. Control females exhibited a second peak of stimulation at 1.5 hours post-injection, while treated females did not; activity of treated females was significantly less than that of controls for the duration of the observation period. Offset for control females occurred at 3 hours, while that for treated females occurred at 2.5 hours. Because of a large variability in the activity of female rats, testing was repeated to attempt to correlate the motor activity of control and treated females with stages of the estrous cycle. Treated female rats were found to be less active than controls during estrus and proestrus (high estrogen activity), but equally active during metestrus and distrus. These data indicate that perinatal exposure to 6 mg/kg PBB

produces motor deficits in neonates which are retained in the female up to 5 months of age; these deficits appear to relate in part to the role of estrogens in locomotor activity. (Supported by NIEHS grant ES02783.)

CAT NEUROHYPOPHYSIS FINE STRUCTURE AFTER SUB LD50 SOMAN OR DFP. 78.6

K.C. Sikora-VanMeter, T. Ellenberger, J. Willetts\* and W.G. <u>VanMeter</u>. Dept. Veterinary Physiology and Pharmacology, Coll. Vet.Med., Iowa State University, Ames, Iowa 50011. Fine structural changes in male or spayed female adult mongrel cats have been studied after acute intravenous or chronic cutaneous exposure to diisopropylfluorophosphate (DFP) or SOMAN. Chronic administration was given in daily doses of 0.3mg/kg, or 0.5mg/kg for 14days (DFP), and 1.0mcgm/kg, 2.5mcgm/kg, or 5.0mcgm/kg until a total of 5.0mcgm/kg was attained (SOMAN). All animals were killed by barbiturate overdose 24h after the last injection, perfused with glutaraldehyde and prepared for conventional transmission electron microscopy.

The fine structure of axons and pituicytes in the hypophysial stalk and neural lobe of cats receiving acute doses of DFP (0.4mg/kg) is indistinguishable from that of untreated animals and changes in neurosecretory granulated vesicles (NGV's) remain unclear until morphometric analysis can be carried out. On the other hand, acute exposure to SOMAN (5mcgm/kg i.v.) causes a decrease in axon terminal NGV's, and increase in small electronlucent vesicles, and the pituicytes within the neural lobe contain a greater number of lysosomal elements. The fine structure of the cat neurohypophysis is markedly

effected by chronic low dose exposure to DFP (0.3mg/kg/day or 0.5mg/kg/day for 14days. Total dose: 4.2mg/kg and 7.0mg/kg 0.5mg/kg/day for 14days. Total dose: 4.2mg/kg and 7.0mg/kg respectively) or to SOMAN (1.0, 2.5, or 5.0mcgm/kg/day until a total dose of 5.0mcgm/kg was attained). Chronic administration of DFP results in the appearance of large multilamellar structures within the hypophysial stalk and the neural lobe. In the neural lobe, these structures may have derived from indivi-dual nerve fibers while in the hypophysial stalk, they may be axons in the process of demyelination since myelinated axons are observed in the hypophysial stalk of untreated cats. The well developed endoplasmic reticulum and Golgi complexes in the pituicytes of these animals indicate a high level of activity and a large number of axons invaginate the pituicyte cytoplasm. and a large number of axons invaginate the pituicyte cytoplasm. On the other hand, chronic exposure to SOMAN increases the number of dilated axons and evokes early signs of degeneration. The myelin of the few myelinated axons in the hypophysial stalk remains intact and no multilamellar bodies are found in the neurohypophysis.

OBSERVATIONS ON THE TOXICITY AND CHOLINERGIC DYSFUNCTION RESULT-ING FROM INTRACEREBROVENTRICULAR INJECTIONS OF CHOLINE MUSTARD AZIRIDINIUM ION (ChM Az). E. H. Colhoun\*, D. J. Brajac\*and R. J. Rylett (SPON: M. A. Cook). Department of Pharmacology, University of Western Ontario, London, Ont., Canada, N6A 5C1. In the current literature the suggestion has been made that monoethylcholine mustard aziridinium ion (MEChM Az; also AF64A), first investigated as a potent and irreversible blocker of choline transport (Rylett and Colhoun, 1980), may be the drug of choice in the selective destruction of central cholinergic neurons and thus provide an animal model for dementia of the Alzheimer type. We have investigated the toxicity and actions of a number of choline mustard analogues, ChM Az, MEChM Az and ethoxycholine mustard aziridinium ion (EChM Az). The acute toxicity of the compounds in mice in order of potency is ChM Az > MEChM Az. Utilizing rat brain synaptosomes, the order of potency of the mustard ana-logues as inhibitors of sodium-dependent, high-affinity choline transport was ChM Az> MEChM Az> EChM Az. Othine most potent inhibitor of choline acetyltransferase. ChM Az and MEChM logues as inhibitors of sodium-dependent, high-affinity choline transport was ChM Az > MEChM Az > EChM Az. ChM Az was also the most potent inhibitor of choline acetyltransferase. ChM Az and MEChM Az showed hemicholinium-like signs of toxicity in mice; EChM Az produced acute toxicity similar to that seen with acetylcholine and at a subacute dose produced delayed toxicity (10-14 days) similar to that seen with nitrogen mustard HN2. This action was not observed with ChM Az or MEChM Az. Utilizing stereotaxic placement, ChM Az (120 nmOl) was injected into the lateral ven-tricle of mature Sprague-Dawley rats. This dose was acutely toxic with 4 of 5 rats dying within 30 hours. ChM Az-treated rats (0-24 hr) vocalized, showed contralateral circling movements, hypo-kinesia, piloerection and aggression. At 24-30 hr the rats exhi-bited rigidity and paralysis leading to death. Synaptosomes, pre-pared from a rat surviving at 3 days, showed decreases in choline transport (choline=0.45  $\mu$ ) of 60% and 30% in hippocampus and cor-tex respectively; choline transport was not significantly reduced in striatum. Injections (i.c.v.) with 40 nmOl ChM Az incurred no mortality during a 7 day observation time but rats exhibited pilo-erection, hypokinesia and lethargy. High affinity choline trans-port measured in synaptosomes prepared from hippocampus, cortex and striatum showed decreases of 45%, 30% and 0% compared to controls at 3 days after ChM Az injection. Assay of choline acetyltransferase yielded similar decreases at 3 days after treat-ment, with somewhat greater inhibition observed after 7 days. ChM Az is a highly toxic substance and has apparent central cholinergic neurotoxic actions in rat brain. (Supported by the Medical Research Council of Canada). 78.9 NEURON-SPECIFIC PHOSPHOPROTEINS AS BIOCHEMICAL MARKERS OF NEURO-TOXICITY: EFFECTS OF ACUTE ADMINISTRATION OF TRIMETHVILIN (TMT) TO THE RAT. J.P. O'Callaghan\*, D.B. Miller and H. Makkawy\* (Spon: M.I. Gage). Neurotoxicology Division, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Recently, several neuron-specific phosphoproteins that serve as endogenous substrates for calcium- and cyclic nucleotidedependent protein kinases have been identified in the central nervous system (CNS) (e.g. see Greengard, Harvey Lec. 75: 277, 1981). These phosphoproteins exhibit different patterns of distribution with respect to brain region, subcellular localization and neuron type. Because of their intimate relationship to the cellular and functional heterogeneity of the CNS, we have proposed that neuron- and other cell-type specific proteins may serve as useful biochemical markers of neurotoxicity (O'Callaghan and Miller, Trends Pharmacol. Sci., 1983). In order to evaluate this hypothesis, we are assessing the effects of known neurotoxicants on cell-type specific proteins throughout the nervous system.

In the present study, neuronal phosphoproteins, including Synapsin 1 (Protein 1), were examined following the administration of TMT, a neurotoxicant that has been reported to produce pathological changes in the rat CNS that are largely restricted to limbic system neurons. Crude synaptic membrane fractions were prepared from hippocampus and frontal cortex of rats that had received TMT or saline. These fractions were then prein-cubated for the purpose of converting phosphoproteins entirely to the dephosphorylated form. Membrane proteins were subsequently phosphorylated, in vitro, by the addition of  $Mg^{++}$  - (<sup>32</sup>P) ATP, either by endogenous kinases or by acid extraction of the proteins followed by addition of exogenous cAMP-dependent protein kinase. The two procedures gave similar results. lowing resolution by SDS-PAGE, specific protein phosphorylation was detected by autoradiography and quantified by microdensitometry or liquid scintillation spectrometry. TMT (9.0 mg/kg, i.v.) caused a time-dependent decrease in several phosphoproteins, including two bands that comigrated with the synapsespecific phosphoprotein doublet, Synapsin 1 ( $M_r$  80-85K). Max-imal loss of hippocampal phosphoproteins occurred at 3 weeks and most phosphoproteins remained significantly reduced 14 weeks after TMT administration. TMT (3.0-9.0 mg/kg) caused a dose-related decrease in Synapsin 1 in the hippocampus (to 50% of control) but not in the frontal cortex. Microdissection of slices of dorsal hippocampus revealed regional differences in the extent to which TMT affected Synapsin 1. Results will be discussed in terms of the neuropathological effects of TMT. These data indicate that nervous-system specific proteins may be useful biochemical indicators of neurotoxicity.

78.11 AXOPLASMIC TRANSPORT OF NEUROTOXIC ESTERASE IN HEN SCIATIC NERVE. C.D. Carrington\* and M.B. Abou-Donia. Laboratory of Neurotoxicology, Duke University Medical Center, Durham, NC 27710.

Neurotoxic esterase (NTE) is a putative enzyme which has been postulated to be the site at which organophoshorus compounds induce delayed neurotoxicity in chickens and other animals. This hypothesis has been faulted because NTE activity returns in brain, spinal cord, and sciatic nerve long before the onset of the neuropathy. However, organophosphorus induced delayed neurotoxicity (OPIDN) has been characterized as a distal neuropathy in which the distal portions of the longest axons are the most sensitive to the neurotoxicant. Consequently, we have determined the rate at which NTE activity returns to distal and proximal portions of hen sciatic nerve following inhibition by in vivo administration of either diisopropyl phosphoroflouridate (DEFP) or phenyl methyl sulfonyl flouride (PMSF). DFP is neurotoxic whereas PMSF is not. We also measured anterograde and retrograde transport rates for NTE. NTE activity was measured by the method of Johnson (Arch. Tox. 37:113-5, 1977), except that the incubation period was extended to up to two hours; the reaction rate was found to be linear over this period. Anterograde and retrograde transport rates were calculated from measurements of enzyme accumulation distally and proximally to double ligations. NTE recovery rates in the proximal portions of the nerve were similar to those reported previously, with 50% recovery after about 7 days following inhibition with either DFP or PMSF. Recovery in the distal portions of the nerve differed in two respects: First, recovery of activity in the most distal segment lagged about two days behind the most proximal segment. Second, activity in the distal segments was significantly more inhibited 10 and 14 days following inhibition by DFP than at the same time points following PMSF administration. Anterograde transport was found to occur at a rate of 48426 mm/day, with 10.5% of the total activity moving at this rate. Retrograde transport was found to occur at a rate of 48426 mm/day, with 10.5% of the total activity moving at this rate. Retrogr

- 78.10 BEHAVIORAL AND ELECTROPHYSIOLOGICAL EFFECTS OF ASYMPTOMATIC LEAD EXPOSURE AS A FUNCTION OF DEVELOPMENTAL STAGE IN RATS.
  - J. Burdette\* and R. Goldstein\*. (SPON: L. Grant). Dept. Psychology, Washington University, St. Louis, MO 63130. Chronic behavioral and electrophysiological effects of brief low level lead exposure during development were investigated to determine whether the pattern of impairment was affected differentially by the developmental stage of poisoning. Dams were exposed to a volume of lead acetate solution calculated to deliver a daily dosage of 270 mg/kg during one of three preiods: Days 16-23 of gestation (G); Days 1-8 of nursing (1N) or Days 9-16 of nursing (2N). Control dams received an equivalent volume of distilled water. Free erythrocyte protoporphyrin (FEP), hematocrit and hemoglobin levels were monitored in female pups during Days 16-32. Open field activity and spontaneous T maze alternation behavior were measured in male offspring during Days 40-59, following which bipolar and screw electrodes were implanted in hippocampal field CA3 and visual cortex, respectively, for recording electroencephalography (EEG) and visual evoked potentials (VEPs). A decrease in FEP values, and a parallel increase in hematocrit and hemoglobin levels, were observed until 28 days of age when all measures approached asymptotic limits. FEP values of poisoned G subjects were significantly elevated above control levels at 32 days of age, the only group tested after blood parameters were stable. Temporal and spatial activity patterns were sensitive to the timing of lead exposure, as evidenced by the failure of poisoned G animals to exhibit normal decrements in peripheral field activity over time and by their increased exploration of the center field. Spontaneous alternation behavior was not observed in control or experimental groups. Power spectrum analyses indicated that lead exposure selectively depressed 6-7 Hz hippocampal signal energy, independent of the timing of exposure providing additional evidence for functional differentiation of low (5-7 Hz) and high (8-12 Hz) frequency theta. All other hippocampal and cortical frequencies were unaffected. Similar to other reports of lead poisoning effects on VEPs, early component latencies of both cortical and hippocampal waveforms were decreased significantly in all poisoned groups. Component amplitudes were not influenced reliably. The data indicate that the observed effects of lead poisoning depend on both the function assessed and the timing of lead exposure.

78.12 POSTNATAL EFFECTS OF PERINATAL EXPOSURE TO LEAD ACETATE AND CARBON MONOXIDE. Z. <u>Annau</u>. The Johns Hopkins University, Baltimore, MD. 21205

Male and female adult Long Evans Hooded rats were exposed to 0.1% lead acetate or distilled water in their drinking water for 70 days prior to mating. Females were maintained on lead acetate (Pb) or distilled water (W) through gestation and lactation. Subgroups of pregnant females were exposed to 0.1% carbon monoxide (CO) through lactation. Litters were reduced to 8 pups and behavioral testing was started on postnatal day 4. Measures of locomotor activity indicated that by day 21 control animals were more active than animals exposed to Pb or CO or both. Homing behavior and negative geotaxis were affected by treatment in more complex ways by the experimental treatments. At weaning, half the animals were either removed from the Pb in their water or placed on it to counterbalance the post weaning lead exposures. Adult animals were tested in a two way avoidance task at ages 90,91 and 120 days. Each animal was tested for 100 trials on each day. No significant differences appeared in the first two training sessions. On the third session however, animals exposed to lead made more avoidances than controls. Animals that had been exposed to Pb through their lives were

Animals that had been exposed to Pb through their lives were exposed to hypoxia or hypercapnia and cerebral blood flow measurements were taken during exposure, using the radioactive microsphere technique. Both control and Pb treated animals increased their blood flow to a  $\rm CO_2$  challenge although the Pb treated animals higher flow levels both in normocapnia and hypercapnia. The cerebral blood flow of controls increased as inspired oxygen concentration decreased, but the blood flow of Pb treated animals plateaued in mild hypoxia and did not increase further.

The results of these experiments demonstrate that low level Pb exposure has irreversible behavioral and physiological consequences, and that the potential health risks of these consequences may be severe.

LOCOMOIOR ACTIVITY AND DOPAMINE METABOLISM IN MANGANESE TREATED NEONATAL RATS. <u>P. Kontur and L.D. Fechter.</u> Div. of Toxicology, The Johns Hopkins U. Sch. of Hyg., Baltimore, MD 21205. Manganese (Mn) toxicity is thought to result from the disrup-tion of dopaminergic neuronal function. We have shown that neo-natal administration of Mn while increasing brain regional Mn levels does not change the levels of dopamine (DA), serotonin (5-HT) or their metabolites in the striatum and hypothalamus or (3-H) or their metabolites in the striatum and hypothalamus or alter the normal development of locomotor activity (Neurotox., 3, 143,1982). This surprising lack of toxicity especially in 2 major DA containing areas was further studied by using amphetamine ad-ministration to assess the ability of Mn treated rats to compen-sate for any damage not evident as disrupted normal development.

13, 17, and 21 day old control, vehicle intubated and 25 and 50 ug/g Mn intubated rats were administered saline, .5. 1, or 3 mg/kg of amphetamine and their locomotor response measured over a 1 hour amprecample and their locomotor response measured over a 1 hor session. The animals were sacrificed immediately after the ses-sion and the brains dissected for analysis of levels of DA, 5-HT and their metabolites in the striatum, nucleus accumbens, and olfactory tubercle.

Control and vehicle intubated animals showed the expected stimulation of activity by amphetamine at each age and amphetamine dose. In these groups maximal stimulation at 13 and 17 days occurred at 1 mg/kg whereas at 21 days maximal stimulation occurred at 3 mg/kg.

At all ages Mn treated animals injected with amphetamine showed enhanced levels of activity relative to that seen in vehicle intu-bated animals receiving amphetamine. Amphetamine dose response effects appeared to predominate over Mn effects. That is, at each age, the Mn groups did not differ from each other at any amphetamine dose but within each age there were amphetamine dose depen-dent effects. Thus in 13 and 21 day old Mn treated animals 1 and 3 mg/kg of amphetamine enhanced activity whereas in 17 day old animals .5 and 1 mg/kg enhanced activity above that seen in vehicle intubated rats.

Whether this differential sensitivity of 17 day old Mn treated rats to amphetamine as well as the overall enhanced locomotor response of Mn treated animals to amphetamine will be reflected in altered neurotransmitter metabolism is currently under investiga-

In addition to theanalysis concerning Mn toxicity the normative control data relating the development of locomotor activity to regional DA metabolism and the effects of amphetamine on these parameters will be presented and discussed. These relations have not been previously characterized.

DISEASES OF THE CNS

79.2 AXONAL AND MYELIN LESIONS IN &-MANNOSIDOSIS: ULTRASTRUCTURAL

AXUMAL AND MYELIN LESIONS IN F-MANNOSIDUSISE OLIAASINGUIUKAL CHARACTERISTICS. K.L. Lovell and M.Z. Jones. Pathology Dept., Michigan State Univ., E. Lansing, MI 48824. Ultrastructural characteristics of axonal and myelin abnormalities were delineated in the nervous system of goats affected with *B*-mannosidosis. This autosomal recessive defect of glycoprotein catabolism is associated with a deficiency of *B*-mannosidase and with tissue accumulation of oligosaccharides. Severe neurological deficits present at birth include an intention tremor, pendular nystagmus, ataxia and inability to stand. Previous morphological examination revealed widespread cytoplasmic vacuolation, axonal spheroids, and severe myelin paucity in the brain, but not spinal cord or peripheral nerves. The objective of the present study was to delineate ultrastructural characteristics of axonal and myelin lesions in selected regions of the central and peripheral nervous system.

Four day old and 4 week old affected goats and age-sex-matched control goats were anesthetized and perfused intracardially with a glutaraldehyde/paraformaldehyde mixture in 0.1 M phosphate buffer. Tissue was post-fixed in osmium tetroxide, stained en bloc in uranyl acetate and embedded in Epon-Araldite. Two µm sections were stained with toluidine blue and ultrathin sections were stained with uranyl acetate and lead citrate.

Contents of axonal spheroids included dense bodies, electron lucent vesicles with a double membrane, membranous whorls, mitochondria and axonal filaments. Different proportions of each component were seen in individual spheroids. The origin of the abnormal components is not clear, but the vesicles did not originate from transported cytoplasmic vacuoles, since vacuoles consistently were characterized by single membranes. In the central nervous system, many normal appearing axons without myelin sheaths were present in regions of myelin paucity. Most of the remaining myelin sheaths appeared to be of normal thickness. The presence of an internode with myelin adjacent to an internode without myelin suggested that axonal abnormalities were not the principal reason for the myelin deficit. In the peripheral portion of cranial nerves V and VIII, myelin sheaths surrounded most axons as in control animals, but there appeared to be an increased percentage of smaller axons in the affected animals. The pathogenesis of the specific types of myelin lesions in  $\beta\text{-mannosidosis remains to be established.}$

79.3 EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN MICE: ADOPTIVE TRANSFER OF DISEASE IS MODULATED BY THE PRESENCE OF NATURAL SUPPRESSOR CELLS. I. N. Montgomery\* and H. C. Rauch. Dept. of Immunol. and Microbiol.

robiol. W.S.U. Sch. of Med. Detroit, MI 48201. Experimental allergic encephalomyelitis (EAE) is primary demyelinating disease induced in mice by an intradermal inoculation of the encephalitogen emulsified in complete Freund's adjuvant (CFA) accompanied by an intravenous injection of pertussis vaccine. Direct adoptive cell transfer in mice requires treatment of the recipient or the cells prior to transfer. Only when the donor cells are cultured with basic protein prior to injection into the recipient or when the recipient is subjected to low dose irradiation prior to the injection of the donor cells is disease transfer successful. To examine the nature of the restriction observed in direct adoptive cell transfer of EAE we have undertaken celltransfer of EAE using both SJL and  $F_1(BALB/c \ x \ SJL)$  mice and using cyclophosphamide (CY) as a recipient treatment substitute for low dose irradiation. The temporal dynamics of the lymphocyte population in response to encephalitogenic challenge were then explored. Untreated recipients of EAE-donor lymphocytes did not develop EAE and do not respond to subsequent encephalitogenic challenge which suggested the presence of suppressor-like cells in the rein CY-treated cell recipients which did not display clinical EAE in CY-treated cell recipients which did not display clinical signs after receiving cells from EAE donors. Direct evidence is presented for the presence of naturally occurring suppressor (Ng) cells in the following experiment. Splenic lymphocytes (2 x  $10^8$  cells) were transferred from naive mice to untreated recipients [suppressive] or to Cy-treated recipients [permissive]. The development of EAE following encephalitogenic challenge was significantly reduced in recipients of the naive spleen cells. Further data indicate that the temporal dynamics of lymphocyte induction in EAE donor mice is such that adoptive transfer is successful 4-8 days post-challenge. That a regeneration of the N<sub>S</sub> population occurs shortly following CY-treatment was ascertained by measuring the time interval during which the CY-treated recipients remained permissive for adoptive transfer of EAE. CY treatment of donors following encephalitogenic challenge dramatically reduced disease incidence only during the early post-sensitization period. These studies indicate the presence of a naturally occurring suppressorlike cell which modulates the function of adoptively transferred T-effector lymphocytes. (Supported in part by NIH grant NS18898).

ANTI-CEREBELLAR ANTIBODY LEVELS IN THE SERA OF AUTOIMMUNE MICE. S.A. Hoffman, D.N. Arbogast\*, P.M. Ford\*, D.W. Shucard and R.J. Harbeck\*. Brain Sciences Laboratories, Department of Pediatrics, NJH/NAC Denver, CO 80206. The NZB strain of mice has been shown to develop brain reactive subscribed in the the two parts in the strain the active 79.4

The NLB strain of mice has been shown to develop brain reactive autoantibodies similar to those seen in systemic lupus erythematosus patients with CNS involvement (Hoffman, S.A., et al., <u>Brain Res.</u>, <u>142:477</u>, 1978; Harbeck, R.J. et al., <u>Clin. exp. Immunol.</u>, <u>31:313</u>, <u>1978</u>). We have recently undertaken to extend these findings by examining other autoimmune strains of mice, viz., NZB/W, BXSB & MRL/1. The objective was to assess strain differences in the development of brain-reactive antibodies during the life of these enjined. animals

Starting at two months of age, 20 mice from each of the autoimmune strains, as well as the normal MRL/mp and the non-autoimmune  $BDF_1$  strain, were bled at monthly or bimonthly intervals. Prior to their expected deaths, based upon observation and life span estimates, the animals were anesthetized and sacrificed by exsanguination. Using an indirect immunofluorescence technique the sera were examined for Indirect immunolitorescence technique the sera were examined for brain-reactive antibody against dissociated cerebellar cells from 6-10 day old  $BDF_1$  mice. The table shows the percentage of mice with "positive" sera. Positive sera were defined as those sera which immunofluorescently stained more cells than two standard deviations above the mean of cells stained by sera from the 2,4 and 6 month old BDF<sub>1</sub> mice (6.25%).

Age+	$BDF_1$	NZB/W	NZB	BXSB	MRL/1	MRL/mp
2 3	0(20)*	40(20)	18(17)	27(15) 69(13)	10(20) 53(17)	10(19)

8	15(20)	56(9)	84(19)			37(19)
10	55(20)	100(5)	33(15)			23(13)
+Months						

\*Parentheses indicate the number of animals tested

All strains of mice tested showed some degree of serum reactivity against the cerebellar cells. The data indicate, however, that there were elevated percentages of mice with positive sera among the autoimmune as compared to the normal strains of mice. There was also a general, but not absolute, increase in serum reactivity with increasing age of the mice. Thus, there is not a qualitative difference between autoimmune and normal mice with respect to the development of anti-cerebellar antibodies, but the autoimmune strains do appear to develop these antibodies more rapidly.

L-PYROGLUTAMIC ACID: A NEUROTOXIC IMINO ACID THAT PRODUCES A DRUG 79.6

L-PYROGLUTAMIC ACID: A NEUROTOXIC IMINO ACID THAT PRODUCES A DRUG INDUCED ANIMAL MODEL OF HUNTINGTON'S DISEASE AND WITH A POTENTIAL ROLE IN THE ETIOLOGY OF HUNTINGTON'S DISEASE AND WITH A POTENTIAL Scarfe\* and J.F. Hunter\*. Dept. of Anat., College of Med., and Vet. Physiol. and Pharmac., College of Vet. Med., Texas A&M Univ., College Station, Tx. 77843. Intrastriatal injections of L-Pyroglutamic acid(L-PGA) in the mouse produces an animal that presents postural asymmetries(twist-of the head and trunk), hyper- or hypoactivity, tremor, ataxia and incoordination, and possible dyskinesias(head snapping or flinging movements, body twitches). The movements of the head and body appear to be involuntary as they occur sporadically and interrupt movements, body twitches). The movements of the head and body appear to be involuntary as they occur sporadically and interrupt ongoing directed behaviors. The injected animals also rotate pre-dominantly toward the side of the injection. The turning response consists of 360° turns with a radius of turning equal to one body length of the mouse. The rates of ipsilateral rotation in the ex-perimental group(20 nmoles L-PGA) are significantly greater(Duncan  $P\leq 0.001$ ) compared to the saline-injected control group. L-PGA produces a neuropathological response similar to kainicacid; how-ever, L-PGA is approximately 200 times less potent than kainate. The neuropil in the vicinity of the injection site contains dilat-ed profiles, degenerating neurons and oligodedrogolia, and active The neuropil in the vicinity of the injection site contains dilat-ed profiles, degenerating neurons and oligodendroglia, and active microglial-like cells many of which are active phagocytes. The swollen profiles are associated with intact presynaptic boutons. L-PGA does not destroy neurons in parts of the brain at long dis-tances from the injection site, that is, L-PGA does not have the distance effect of kainic acid. L-PGA destroys neurons in the hippocampus, prepiriform cortex, nucleus accumbens septi and the swurdplay upon it is injected dimetily into these areas a PCA is bippocampus, prepiriform cortex, nucleus accumbens septi and the amygdala when it is injected directly into these areas. L-PGA is a neurotoxin with a distinct dose-response effect upon the cells of the caudatoputamen(CPU). For example, a 200 nmole dose of the toxin destroys approximately 28% of the CPU, while 20 nmoles destroys approximately 1.4% of the CPU. The saline(0.9% NaCl) vehicle injected into control animals in conjunction with the mechanically-induced lesion involved less than 0.2% of the CPU. If the neurotoxic hypothesis for HD is correct and L-PGA, as a neurotoxin, plays a possible role in the etiology of HD then an analysis of fluid levels of L-PGA in HD patients and their off-spring "at risk" might strengthen the correlation between the L-PGA-induced model of HD and the disease in man. Presently we are conducting an analysis of the plasma of HD patients, their off-spring "at-risk" and age matched nonchoretic controls by means of microcapillary gas chromatography and mass spectrometry.

- NEUROPHARMACOLOGY OF TOURETTE'S SYNDROME, R.L. Borison and B.I. 79.5
  - and Medical College of Georgia, Augusta, Georgia 30910. The spontaneous neurological disorder, Gilles de la Tourette's Syndrome (TS) involves multiple and migratory motor and vocal tics. This disorder first occurs before the age of 15 years, and runs a lifelong course. Although the tiology of TS is unknown, it appears that there is a strong genetic component to this dis-order, with a variable penetrance. The basic pharmacology of TS suggests a striatal hyperdopaminergic-hypocholinergic state, simi-lar to tardive dyskinesia. Historically, dopamine receptor block-ers, in particular haloperidol, have been used to mask the signs of TS. In a double-blind comparison of three dopamine receptor blockers- haloperidol, fluphenazine, trifluoperazine -in 10 TS patients, we found that all three neuroleptics were capable of producing equivalent tic control, yet haloperidol produced more central side-effects, including sedation, apathy, and depression. Although TS is presumed to involve a hypocholinergic striatal balance, anticholinergic drugs are often used to treat the acute extrapyramidal side-effects produced by haloperidol in TS patients. We studied the actions of a prodopaminergic drug, amantadine (100-300mg daily) versus an anticholinergic drug, benztropine mesy-late (4-6mg daily) in seven TS patients with haloperidol-induced recurrent dystonias and pseudoparkinsonism. We found that amantadine not only did not exacerbate the underlying TS, but proved to be at least as effective as benztropine in the reversal of the haloperidol-induced side-effects. More recently it has been suggested that the alpha receptor agonist/antagonist, clonidine, may be an effective agent for treating TS as shown in open label trials. We studied the efficacy of clonidine and haloperidol in TS using a double-blind placebo-controlled design. The study group consisted of 15 TS patients, and haloperidol was used in doses from 2.25 -7.5mgs daily, whereas the dosage of clonidine was between 0.35 -0.75mg daily, Both clonidine and haloperidol proved to be statis-tically significantly superior to placebo, however, no statistical significance could be found when comparing clonidine to haloperidol in efficacy. The side-effect profile of the two drugs was much dif-ferent. Haloperidol produced sedation in greater than 50% of patients, and produced extrapyramidal side-effects as well as apathy and depression. With clonidine treatment, sedation only occassional and depression. With cionidine treatment, sedation only occassional ly occured, otherwise the major side-effect was a relatively short-lived dry mouth in approximately 33% of patients. Hence, clonidine is equal to haloperidol in its therapeutic efficacy in treating TS, but has fewer side-effects, making it a preferable therapeutic agent. The efficacy of clonidine in TS also suggests either a major clinical role for norepinephrine in striatal functioning, or a nor-adrenergic neuron in series with a dopaminergic neuron as modulat-ing the signs of TS.
- STUDIES ON ACETYLCHOLINESTERASE ACTIVITY IN MANIC-DEPRESSIVE 797 NESS. J. H. Thakar\* and Y. D. Lapierre\* (SPON: J. Metuzals) The etiology of manic-depressive illness (MDI) is not known. ILLNESS. The major hypotheses on etiology indicate cell membrane abnormal-ity, cholinergic-adrenergic malfunction and biogenic amines imbalance. Acetylcholinesterase (AchE) is an important regulator of the synaptic transmission. The role of this enzyme in cell membrane function in MDI is not understood.

To study biochemical abnormality at molecular level, it is difficult to obtain the CNS tissue from patients as well as controls. However, the studies of peripheral systems such as erythrocytes, leukocytes and platelets have been well accepted as a model for CNS system (Rowland, L.P. Muscle and Nerve 3, 3-20, 1980). We have studies AChE activity in erythrocyte membranes of 28 bipolar MDI subjects, 24 well relatives and 14 normal volunteers.

Erythrocyte membranes were prepared by washing the cells with ice-cold saline and hemolyzing them in 10 mW imidazole buffer containing lmMNaCI and MgCl\_each, at pH 7.4. The membranes were washed three times and harvested at 48,000 g by centrifuging for Vashed three times and harvested at 40,000 g by centringing for 20 minutes. AChE activity was measured by the procedure of Ell-man et al (Biochem. Pharmacol. 7, 88-95, 1961). The hydrolysis of actylthiccholine was measured by coupling thiccholine forma-tion with dithicbisnitrobenzoate at 412 nm using a recording spectrophotometer.

Our preliminary data (MDI 0.84+0.14, well 0.79+ 0.13 and normal 0.63+ 0.26 expressed as mean + S.D, moles/min/ G membrane proteins) show a significant increase in the AChE activity in MDI subjects (P\$0.002) and their well relatives (P0.02) as compared to normal volunteers. These activities were inhibited by NaF (2mM), quinidine (0.4mM) and dibucane (1mM). These data will be presented and discussed to evaluate the role of AChE and membrane functions in MDI.

TREATMENT WITH FLUOSOL-DA OF SPINAL CORD INFARCTION IN THE 79.8 RABBIT. J. F. Toole and I. J. Miller, Jr., Depts. of Neurology and Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

An infarction was induced in the lumbosacral spinal cord of rabbits to test the effectiveness of a perfluorochemical preparation (Fluosol-DA) and oxygen treatment on this ischemic lesion. A balloon catheter was inserted through the femoral artery to the thoracic aorta and inflated for 20 minutes under light penobarbital anesthesia supplemented with ether. This procedure resulted in sensory and motor defecits in the inferior extremities which include analgesia and paresis as well as flaccid paralysis in more severe cases. Following release of the occlusion, animals received an intravenous injection of 20 cc of Fluosol, saline or no treatment. Some animals in each treatment group were placed in a 95% oxygen - 5% carbon dioxide mixture at atmospheric pressure during the 4 hours following the occlusion, while the remaining animals recovered in room air. Animals were sacrificed after 48 hrs, and the spinal cords were prepared for microscopic examination using paraffin sections 8 micros thick and cresyl violet staining. Cytological features were compared among ventral horn cells in lumbar segments 6 and 7, and cervical segments were examined as controls. Ten sections separated cal segments were examined as controls. Ten sections separated by 100 microns each were selected for scoring, and each section was rated with an integer from 0 - 3 as follows: 0 for normal tissue, 1 for tissue containing chromatolysis in up to 50% of ventral horn cells, 2 for chromatolysis in more than 50% of ven-tral horn cells, and 3 for cavitation and cellular degeneration. Tissue from animals without treatment (N=4) received a mean score of  $1.8 \pm 0.2$  (S.E.M.), while tissue from animals receiving intravenous saline was scored  $2.0\pm0.3$  (N=4). Animals treated with intravenous Fluosol yielded tissue which was scored 2.0  $\pm$  0.1 (N=8). Scores of the cytological lesions varied from 1 -3 among animals in all groups, but the most severe lesions were found in animals with the most profound neurological symptoms. Treatment with oxygen produced a mean score of 2.0 + 0.1 (N=8) across groups, while animals recovering in room air were scored a mean of  $1.9\pm0.1$  (N=8). In these experiments, neither Fluosol nor oxygen proved effective in the treatment of the effects of ischemia in the rabbit spinal cord.

(Fluosol-DA was supplied by Alpha Therapeutics, Inc., Los Angeles, CA. This work was supported in part by BRS Grant RR 05404.)

DISTRIBUTIONS OF TUMOR METASTASES IN HUMAN CNS. S.M. de la Monte\* G.W. Moore\* and G.M. Hutchins\* (SPON: A.W. Clark). Department of Pathology, The Johns Hopkins Medical Inst., Baltimore, MD. 21205. It is not known whether the observed distributions of CNS metas-tases are due to trophic influences or simply a mass effect of tumor dissemination. The purpose of this study was to compare pat-terns of metastases from tumors of different histogenetic origin. Data were derived from review of the clinical histories, autopsy protocols, and histologic slides of 361 patients with metastases: malignant melanoma (56 cases), small cell lung carcinoma (85), breast carcinoma (188), and neuroblasoma (32), all subjected to complete autopsy at The Johns Hopkins Hospital. Data were analyzed using standard statistical tests.

complete autopsy at The Johns Hopkins Hospital. Data were analyzed using standard statistical tests. CNS metastases from malignant melanoma occurred most frequently in cortical grey matter (64%) and leptomeninges (46%). While metastases in leptomeninges and dura mater were correlated with metastases in endocrine and mesoderm-derived organs including gonads (all p<0.05 or better), metastases in cortical grey matter occurred independent of other sites, and a strong negative correlation between cortical grey matter and hepatic metastases as observed (p<0.001). CNS metastases from small cell lung carcinoma occurred in 56% of the cases, and in 75% of those patients, cortical grey matter and nuclei were involved. Metastases to grey matter were positively correlated with metastases to the adrenal and kidney, while metastase to option the metastase to grey matter were metavely corand kidney, while metastases to white matter were negatively cor-related with metastases in bone marrow (all p<0.001). Metastases to dura or leptomeninges were not correlated with metastases to to dura or leptomeninges were not correlated with metastases to extra-CNS sites, and mainly occurred by extension of tumor from metastatic foci in adjacent CNS parenchyma. For <u>breast carcinoma</u>, progressive declines in the frequencies of CNS metastases with increasing age were observed with respect to cortical grey, grey matter nuclei, and leptomeninges, but not dura mater or white matter. Metastases to grey matter were correlated with metastases to the adrenal (p<0.001), metastases to dura and/or leptomeninges were correlated with metastases to endocrine organs (p<0.005) and extra-CNS mesoderm derived structures (p<0.001). Neuroblastoma were correlated with metastases to endocrine organs (p<0.005) and extra-CNS mesoderm derived structures (p<0.001). Neuroblastoma metastasized primarily to dura mater and/or leptomeninges; metas-tases to neuroectoderm derived structures of the CNS were uncommon. CNS metastases were correlated with metastases to endocrine and mesoderm derived structures of the head and neck (p<0.05), the pancreas (p<0.05), and gonads (p<0.05). The results show that for several different tumors, metastases to duca mater and/or leptomeninges are correlated with metastases

to dura mater and/or leptomeningese are correlated with metastases to endocrine and mesoderm-derived structures outside of the CNS. In contrast, metastases to grey matter were not uniformly correlated with metastases to particular extra-CNS tissues, and these distributions varied as a function of tumor histogenesis.

RELATIVE PRESERVATION OF FRONTAL GLUCOSE METABOLISM IN EARLY ALZ-79.10 HEIMER'S DISEASE. HEIMER'S DISEASE. N.L. Foster and T.N. Chase (SPON: H. Lansdell). Experimental Therapeutics Branch. National Institute of Neurological and Communicative Disorders and Stroke, National

Institute of Health, Bethesda, MD 20205. Alzheimer's disease causes gradual intellectual decline associated with neuronal loss. Despite the traditional view that frontal lobes are particularly susceptible to damage in this disorder, recent quantitative post-mortem neuronal counts and studies of cerebral atrophy have suggested that frontal cortex may be spared relative to temporal and parietal cortex. Using 18fluorodeoxyglucose positron emission tomography, regional glucose utilization can be determined during life relatively early in the course of the disease. Analyses of PET scans performed in 17 right-handed patients (12 men, 5 women, mean ± SEM age 61 ± 1.5 years) with clinically diagnosed Alzheimer's disease age of 1 is years) with difficulty diagnosed algebraic solutions of the same were compared with results in 5 right-handed age-matched normal volunteers (2 men, 3 women, age 57 ± 1.9 years). All indicies of general intellectual function were significantly (p < .0001) lower in the Alzheimer's group. For example, WAIS Full Scale IQ scores were depressed by 35% (130 ± 3.1 in controls vs 84 ± 3.1 in solution). patients). The Wechsler Memory Quotient by 45% (134  $\pm$  5.9 vs 74  $\pm$  3.2), and the Mattis Dementia Scale score by 30% (142  $\pm$  1.0 vs 100 4.7). Overall cerebral glucose metabolism averaged 30% lower in the Alzheimer's patients (range 3.9 to 6.7 mg/100g/min) than in control individuals (range 5.0 to 9.9 mg/100g/min). Among normal volunteers frontal glucose metabolism was approximately the same as in the temporal and parietal lobes (7.6  $\pm$  .68 mg/100 g/min vs. 7.5  $\pm$  .73 and 7.5  $\pm$  .89). By contrast, Alzheimer patients averaged a significantly higher glucose metabolism in frontal regions  $(5.7 \pm .22)$  as compared to temporal  $(4.4 \pm .21)$ and parietal  $(4.8 \pm .23)$  areas. 16 of the 17 patients showed highest absolute glucose metabolic rates in frontal regions and 15 had the least percent reduction compared to normal values in these pariets between the states and the state back and the states between the states bet these regions. On the average, Alzheimer's patients had a 25% frontal, 40% temporal and 36% parietal reduction of glucose metabolism compared to normals. Relative preservation of frontal brain activity may be due to less cortical neuron loss or less damage to its afferent projections. These findings may have implications relative to the critical participation of certain neurotransmitter systems in the pathogenesis of Alzheimer's disease.

DISPLACEMENT OF MYELIN SHEATHS BY THE NEURITIC PLAQUES OF 79.11 ALZHEIMER'S DISEASE. W.C. Mobley, C.A. Kitt, R.G. Struble and <u>D.L. Price</u>. Neuropharm. Rr., Dept. of Med. Neurosci., Div. of N.P., Walter Reed Army Inst. of Res., Washington, DC 20307, and Dept. of Neurol., The Johns Hopkins Univ. Sch. of Med., Dept. of Neurol., Baltimore, MD 21205.

Myelin sheaths within the central nervous system can be immunocytochemically stained by antibodies to the myelin basic protein (Itoyama, Y., <u>et al.</u>, <u>Ann. Neurol.</u>, <u>7</u>:157, 1980). Neuritic plaques are one of the diagnostic features of Alsheimer's disease. We have employed an antiserum to myelin Alzheimer's disease. We have employed an antiserum to myelin basic protein in an immunocytochemical examination of myelinated fibers in cortical areas containing neuritic plaques. Serial 8 um sections were prepared from formalin fixed, paraffin embedded brain tissue of three Alzheimer's disease patients. Sections were stained for myelin basic protein, for neurites and amyloid by the Sevier-Monger silver method, for amyloid by thioflavine T, or by H&E. Neuritic plaques were identified in silver stained sections by their characteristic accumulation of argentophilic rods and granules. Thioflavine T demonstrated plaque amyloid. Except for an occasional positive sheath, neuritic plaques failed to stain for myelin basic protein. This was true in neocortex and in hippocampus. The absence of staining produced, in effect, a negative image of the plaque, highlighting it in relation to the myelin sheaths of the adjacent neuropil. These negative images were confirmed as neurific plaques by staining the same section for both myelin basic protein and for amyloid (thioflavine T). for both myelin basic protein and for amyloid (thioflavine T). Myelin sheaths very near the plaque frequently followed curvilinear paths. In those instances where such myelin sheaths were visible over long distances, they appeared to be draped around the edge of the plaque and to be displaced by it. Two around the edge of the plaque and to be displaced by it. Two mechanisms can be envisioned to account for the curvilinear path followed by myelin sheaths near plaques. It may be due to regrowth of fibers to avoid plaques. Alternatively, and more likely, existing fibers may be displaced by active accretion of material within plaques. Our observations do not discriminate between these possibilities. They do demonstrate that plaques can disrupt the normal cytoarchitectural arrangement of myelinated fibers The physiological significance of this disordered fibers. arrangement is unclear.

79.12 QUANTITATION OF VASOGENIC EDEMA IN CONTUSED SPINAL CORD Thomas E. Anderson, Biomedical Science Department, Crash Injury Section, General Notors Research Laboratories, Warren, MI 48090

Spinal cord contusion initiates pathophysiologic responses including tissue edema. The developing pathology is probably responsible for much of the permanent loss of function following contusion. Therefore, a better understanding is needed of the relation between tissue responses such as edema and permanent post-contusion loss of function.

This study of experimental spinal cord injury in the ferret quantitated spinal cord edema as a function of the amount of cord compression, with velocity of compression constant. A 20% cord compression had no long-term effects on conduction through the injury site, as measured by somatosensory evoked potentials 4 hours post-injury. Compression of 50%, on the other hand, resulted in reduced amplitude and increased latency of the evoked potential at 4 hours post-contusion. In comparison between 20% and 50% compression, increased amount of compression resulted in increased clema at four hours.

The time course of edema development differed for the two levels of compression, however. Edema developed gradually after a 20% compression, continuing to increase even after apparent functional recovery of the injured region. Cn the other hand, post-contusion edema developed within 20 min of a 50% compression, and did not increase significantly over the remainder of the 4 hour monitoring period. In the clinical situation, therefore, spinal cord edema may be well-developed prior to therapeutic intervention, and may affect the viability of spinal cord tissue.

Attempts to generate local edema without cord compression were unsuccessful. Surface application of a cryogenic probe did not produce edema significantly different from laminectomy-only controls, nor were permanent changes in neuronal conduction observed. Direct application of dry ice produced edema, but long-term changes in spinal cord conduction were variable. 79.13 PERSISTENT DEPRESSION OF CALCIUM LEVELS IN CEREBRAL CORTEX FOLLOW-ING TRAUMATIC BRAIN DYSFUNCTION. D.C. Nathanson\* and O.R. <u>Hubschmann.</u> Neurosurgery Section, Veterans Administration Medical Center, East Orange, NJ 07019, and University of Medicine and Dentistry of New Jersey-New Jersey Medical School, Newark, NJ 07103.

Recently the pathogenic effects of the disruption of calcium (Ca++) homeostasis and intracellular calcium accumulation have been reported in a number of tissues including the brain. The influx of Ca++ into the cell, resulting from mechanical injury or ischemia, has a number of deleterious effects upon the cell (e.g., membrane damage and loss of mitochondrial function) and may lead to irreversible cell injury. We have studied the changes in the concentration of extracellular Ca++ following injury in order to determine whether these levels could be used as an indication of the functional state of the brain. The dynamic changes in Ca++ activity in the cortical microenvironment were monitored in 20 cats in whom either intracerebral hematoma was produced by injecting 0.5cc of autologous blood, or cerebral ischemia was produced by the injection of air into the carotid artery. The cellular response was monitored using extracellular Dotassium (K+) and Ca++ ion-specific microelectrodes, cortical DC potential and electrocorticogram.

The cortical response was characterized by a profound cellular depolarization, extracellular accumulation of K+, extracellular Ca++ depletion, and an attenuation of the ECoG. Ca++ normally maintained at 1.12 ± .14mM fell to levels ranging between 0.26 and 0.8mM in the cortex following cerebral injury. Localized or reversible injury resulted in a transient decrease in Ca++ levels which returned to near or slightly below normal levels (0.9 -1.1mM) within 20 minutes, accompanied by cellular repolarization and recovery of the ECoG. In those animals with terminal injuries the calcium levels remained low (0.26-0.48mM), accompanied by the loss of ECoG activity and, in 3 animals, the cessation of cardiac function. Finally, in one group of animals, the calcium levels recovered to levels below normal (0.68-0.8mM) with the return of an attenuated ECoG. It is believed that while these animals may be capable of survival, there is severe neuronal damage as a result of their injury.

These results suggest that Ca++ levels in the extracellular space may be indicative of the functional state of nervous tissue following cerebral injury and may give some indication of the chances for recovery.

79.14 NERVE TERMINAL AND NERVE FIBER DEGENERATION FOLLOWING SINGLE AND MULTIPLE CEREBRAL CONCUSSIONS. L. C. Parsons and M. D. Guthrie. University of Virginia, Charlottesville, VA 22903 and UTHSC, San Antonio, TX 78201.

Twenty-four adult laboratory rats, following implantation of a concussion disc, recieved either one, two, or three experimental cerebral concussions (ECC) separated by 7 day time intervals. The force of the impact(s) ranged between 26 and 42 lbs./PSI. Criteria used to identify ECCs included the presence of convulsive seizures, and loss of corneal and postural reflexes. A Nissl stain was used to identify cell somas and brain stem nuclei while contiguous brain sections were stained, using either a Fink-Heimer or cupric silver technique. The cupric silver technique was used to verify the presence and extent of nerve terminal degeneration (ntd) and nerve fiber degeneration (nfd), observed and previously reported (Parsons and Guthrie, <u>Neuroscience Letters</u>, 24:199, 1981) to occur following ECC. Both afferent and efferent fiber tracts traversing regions identified to be in the zones of coup, contrecoup and cranicocervical junction lesions, demonstrated nfd. The extent of nfd as well as ntd appeared to correlate well with one and two blows. Differentiation between two and three blows was more difficult and probably could be attributed to the brain's macrophage system. Findings suggest further verification for the accumulative effects of ECCs. 79.15 NUCLEAR MAGNETIC RESONANCE IMAGING AND SPECTROSCOPY IN EXPERIMENTAL BRAIN EDEMA. H. M. Bartkowski, L. H. Pitts, M. Nishimuray, M. Brant-Zawadzki, M. Moseley, G. Young\*. Neurosurgical Research Laboratory, University of California, San Francisco, CA 94143. Cerebral edema was produced by the classical cold-lesion technique in a canine model. A stainless steel cylinder, 2.0 cm in diameter, was cooled in liquid nitrogen (-70 degrees C) and applied to posterior frontal dura through a burr hole. Nuclear magnetic resonance (NMR) proton imaging of the animals was performed 3, 6, and 24 hours after production of the lesion, at a field strength of 0.35 Tesla utilizing a multiparametric spinecho (SE) technique. The animals were studied with NMR proton spectroscopy utilizing a Fourier-transform spectrometer at a field strength of 3.5 Tesla and a Nicolet 1180 computer to determine longitudinal (T1) and transverse (T2) relaxation values. In addition, brain samples were analyzed for water content by microgravimetric and wet/dry weighing techniques.

Data analysis of water content, NMR spectroscopy, NMR imaging, and T1 and T2 relaxation values calculated by the SE technique was performed. NMR imaging detected the cold-lesion at 3 hours. The two-second pulse interval SE technique was most sensitive in the detection of the lesion and provided optimal differentiation of the gray and white matter. Close correlation between tissue water content and T1 and T2 relaxation values was found. Representative images and data will be presented and discussed.

SEROTONIN ANTAGONISTS INCREASE RESISTANCE OF CNS TO ISCHEMIA WITHOUT ALTERING BLOOD FLOW RATE. J.A. Zivin and J.A. Venditto\* Department of Neurology, University of Massachusetts Medical Center, Worcester, MA 01605 We tested the effects of 3 serotonin antagonists, lysergic acid diethylamide, 2-bromolysergic acid diethylamide (BOL), and cinanserin on the susceptibility of rabbit spinal cord to inforction. Blood flow to the going local was obstructed by 79.16

infarction. Blood flow to the spinal cord was obstructed by occlusion of the abdominal aorta, one of the drugs was administered 5 min later, and after 15 to 60 min of ischemia, blood flow in the aorta was restored. We found that, compared with controls, each drug was able to increase the average duration of ischemia required to produce permanent neurological deficits ( $\text{ET}_{50}$ ). The most effective drug was BOL which was able to increase the  $ET_{50}$  by as much as 49%. Since serotonin is known to have potent circulatory effects,

we conducted a study to determine whether BOL produced its beneficial action by altering perfusion of the spinal cord. Five min after obstruction of the aorta, either saline or 3 Five min after obstruction of the aorta, either saline or 3 mg/kg BOL (the dose most effective for protecting the spinal cord from infarction) was injected intravenously. Twenty min after occlusion of the aorta, spinal cord blood flow was measured using  $[1^4c]$ -iodoantipyrine as a diffusible tracer. In control animals, blood flow in the normally perfused thoracic region of the spinal cord was 20.7 + 2.66 m/100g/min (mean + s.e., n = 3) and in ischemic lumbar areas flow was 0.389 + 20.27Tn S.e., n = 3) and in isonemic lumbar areas flow was 0.369 + 0.127. In treated animals, blood flow was 22.8 + 4.99ml/100g/min (n = 3) in the thoracic cord and 0.514 + 0.044 at the lumbar levels. Analysis of variance revealed no significant differences between control and treated animals. Thus, although BOL increased the resistance of spinal cord to

ischemic damage, it did not significantly alter the blood flow rates in the spinal cord during ischemia. Supported by PHS grants NS 00456 and NS 15827

HIPPOCAMPAL CELL DEATH IN AREA CA1 FOLLOWING ISCHEMIA IN THE GERBIL: ELECTROPHYSIOLOGICAL RESULTS OBTAINED <u>IN VITRO.</u> T. S. Whittingham, W. D. Lust, Y. Yasumoto\* and J. V. Passonneau. Lab. of Neurochemistry, NINCDS, NIH, Bethesda, Md. 20205. Gerbil brains made ischemic for 5 min by bilateral carotid artery occlusion exhibit cell death of CA1, but not CA3, pyrami-dal neurons within 4 days following the ischemic episode (Kirino, <u>Brain Res.</u>, 239:57, 1982). We are using the <u>in vitro</u> brain slice preparation to study possible electrophysiological changes, such as a hyperactivity of CA1 or CA3 neurons, which might lead to this cell death.

Horizontal brain slices of 300 um were prepared from control Horizontal brain slices of 300 µm were prepared from control (non-ischemic) and post-ischemic (1,2,3, or 4 days) gerbils. Evoked and spontaneous field potentials were recorded in areas CA1 and CA3 using 3MΩ glass microelectrodes. Orthodromic evoked responses in area CA1 of control slices were typically 20 msec in duration and contained a single population spike. Secondary population spikes occurred at stimulus frequencies of 2 pps or greater, with moderate ( $\sim$ 25%) fatigue of the response occurring by 10 sec of 10 pps stimulation. Spontaneous burst discharges were seldom observed. Responses obtained from animals at 1 to 3 days post-ischemia were substantially the same as in control slices. Surprisionly, the electrophysiologial responses were with thionin and exhibited no neuronal loss in area CA1.

More recent work by Kinin suggests that CAI neurons are lost only in the dorsal portion of the hippocampus. Thus, sagittal slices were prepared approximately 3 mm from the midline to include the sensitive neurons and maintain intact hippocampal cir-cuitry. CAl electrophysiological characteristics in control cuitry. CAI electrophysiological characteristics in control slices and through 2 days recovery were very similar to those obtained from horizontal slices. Two of the four animals allowed to recover for 3 days also maintained normal responses. However, the remaining 3 day, and all 4 day, post-ischemia animals exhibited no CAI activity. The slices which failed to respond electrically all showed marked neuronal degeneration in area CAI. Pyramidal cell responses in area CA3 did not vary during the 4 day recovery period in both horizontal and sagittal slices. These results indicate that if the cell death phenomenon is to be studied <u>in vitro</u>, sagittal slices should be used. Given the same animal might be used as internal controls of insensitive CAI areas. The results fail to detect any abnormal neuronal activity prior to the sudden death of CAI neurons at 3 to 4 days of post-ischemia. It is possible that the ischemia imposed by slice preparation masks any activity changes which may take place

ischemia. It is possible that the ischemia imposed by slici preparation masks any activity changes which may take place in vivo.

UNUSUAL STRUCTURAL CHANGES OF ASTROCYTES ENCOUNTERED IN A SPONGIO-79.18 UNUSUAL SINULIURAL CHANGES OF ASTROCYTES ENCOUNTERED IN A SPONGI FORM DEGENERATION OF THE MOUSE BRAIN. <u>N.A. Azzam, R.N. Azzam\*,</u> J.V. Bready\* and P.A. Cancilla\*. Dept. of Anatomy, Fac. of Med., Kuwait Univ., Kuwait and Dept. of Pathology, UCLA Sch. of Med., Los Angeles, CA. 90024.

Los Angeles, CA. 90024. A spontaneous disorder of a Charles River strain of Swiss-Webs-ter mice that is characterized by an autosomal recessive pattern of inheritance, cranial enlargement, swelling of the brain and a spongy transformation of the white matter has recently been descr-ibed by our group. The spongy state is due to a remarkable swell-ing of the cell body and processes of astrocytes associated with fluid accumulation, dispersion of organelles and appearance or me-mbranous arrays and myelin figures. Microvascular endothelium ap-pears normal. Detailed ultrastructural analysis of astrocytes in relationship to blood vessels, ependyma and pia mater has been co-nducted to document the range and diversity of alterations present in this disorder. One of the most striking changes encountered was the presence of numerous hemidesmosomes in the foot processes of the astrocyte not only in relationship to the blood vessels but of the astrocyte not only in relationship to the blood vessels but also associated with the subpial and subependymal extensions of the cells. These hemidesmosomes were regularly distributed and The cells. Inese hemidesmosomes were regularly distributed and closely spaced along the membrane always in association with an adjacent basal lamina. Often, this change was accompanied by a retraction of the cytoplasmic membrane which led to an infolding or pinching-up of the basal lamina, with concomitent streaming and contouring of adjacent glial filaments. Since these changes were also present in astroglia in non-vascular regions including ephance support for calls, underconing the groupinform change. The enhance support for cells undergoing the spongioform change. The second unusual change was found in the subependymal astroglia. The alteration consisted of vacuolar dilatation of the endoplasmic reticulum with a uniform distribution within affected cells. The vacuoles, lined by a single membrane with some associated ribosomes were filled with a uniformly dispersed granular material. The cells were otherwise characterized by folded nuclei, a well defined Golgi zone, sparcely distributed glial filaments and an asso-Ciation with vessels or ependyma. Because the vacuoles were asso-ciated with dilatation of the cisternae of rough endoplasmic reti-culum they were presumably related to a synthetic process rather than to pinocytotic uptake by the cells. Since these cells are sometimes associated with redundant basal lamina, it is possible that they are reactive and are synthesizing some components of the basal lamina. Although the changes described here are part of a genetic disorder they are regarded as secondary rather than primary features of the disease. Supported by the University of Kuwait Research Council Grant MAO14 and by NIH Grants HL-01712 and HL-14230.

ULTRASTRUCTURAL PROPERTIES OF CNS TUMOR MICROVASCULATURE. M. Miyagami\*, B. H. Smith, T. Baginski\*, M. A. Greenwood\*, P National Institutes of Health, Burgical Neurology Branch, NINC National Institutes of Health, Bethesda, Maryland 20205. CNS tumor microvasculature is important to understanding of NINCDS.

tumor biology as well as delivery of therapeutic agents. We have undertaken a systematic study of human tumor microvessel proper-Undertaken a systematic study of numan tumor microvessel proper-ties utilizing specimens obtained from selected tumor zones at surgery and examined by standard electron microscopic techniques as well as quantitative image analysis methodology. Ten cases (astrocytoma Grade IV,6; astrocytoma Grade II, 1) oligodendro-glioma, 1; meningioma, 1; and malignant meningioma, 1; have been evaluated with respect to a) vessel number per tumor zone (centrol, intermediate and peripheral tumor as well as brain adjacent to tumor (BAT)); b) endothelial cell number and organelles; and c) blood-brain barrier related properties (endothelial cell, tight junctions, fenestrations, pinocytotic activity). Vascular numbers were calculated from examination of 3 fields from each of five blocks from each tumor zone. For ultrastructural studies 10-22 vessel profiles from each zone were evaluated.

Vessel numbers were greatest in the periphery of malignant tumors and lowest in the (often necrotic) tumor centers. Thickened vascular walls (containing increased endothelial cell numbers) as well as narrowed lumens were characteristic. Benign tumors showed no such zonal variation in vessel number. Tubular bodies were common in the marginal zones of malignant, but not benign tumors. Up to 40 percent of vessels in malignant tumors had tubular bodies, whereas benign tumors and BAT, a maximum of 10 percent. Such a finding is consistent with neovascularity. The endothelial cells themselves were increased in number and thickness most prominently in the malignant tumors. Luminal microvilli were increased in the endothelial cells of malignant tumors as were mitochondria and endothelial cells of malignant tumors as were mitochondria and rough endoplasmic reticulum. Two populations of endothelial cells, one with electron-dense cytoplasm and the other with more electron-lucent cytoplasm could be distinguished. In contrast to earlier reports, endothelial cell tight junction abnormalities were not clearly different in malignant and benign tumors. In necrotic areas of malignant tumors, more open junctions could be found. Factor VIII-related antigen was increased in endothelial cells of religner to a correct to benign tumor (Mixorgi et al. unpublished malignant as compared to benign tumors (Miyagami et al., unpublished data).

These results support the notion of important zonal variation in the brain tumor vasculature of malignant, as opposed to benign, human brain tumors; question the extent of tight junction (and hence blood-brain-barrier) abnormality; and indicate the rapid neovascularization of malignant tumor marginal zones. The latter suggests the active release of one or more angiogenesis "factors" by glioma cells. In addition, the utility of quantitative image processing techniques is demonstrated.
- 79.PO NEW TREATMENT FOR MULTIPLE SCLEROSIS. <u>A. Winter</u>. Livingston, New Jersey 07039. Multiple sclerosis is a demyelinating disorder of the central
  - nervous system. The spasticity and pain prevent the patient from functioning normally. A new treatment regime is described comprising transcutaneous nerve stimulation (INS) and D-phenylalanine (DPA). The significant improvement in signs and symptoms suggest additional factors in the etiology of multiple sclerosis and treatment.
- 79.PO PROGRESSIVE DETERIORATION OF THE CEREBELLAR CIRCUITRY IN ALUMINUM ENCEPHALOMYELOPATHY. B. Ghetti, M. Goheerf and O. Bugiani,\* Indiana University School of Medicine, Indianapolis, In. and Istituto Neurologico "Besta" Milan, Italy. The injection of aluminum (AI) powder into the cerebrospinal fluic of adult rabbits induces a progressive encephalomyelopathy, characterized by postural alterations, myoclonic jerks, muscle weakness, and ataxia. The neuropathological hallmarks of this toxic encephalomyelopathy are the neurofibrillary tangles, composed of 10 nm neurofilaments. Aim of the present study was to determine the degree of susceptibility of the cerebellar neurons to aluminum toxicity, and to establish whether cerebellar neurons relost after having developed the neurofibrillary tangles. Rabbits were injected into the cysterna magna with 0.15 ml of a 1% suspension of aluminum powder and then perfused with glutaraldehyde between 1 and 85 days after injection. The cerebellar neurons to the aluminum toxicity and they developed neurofibrillary tangles. Occasionally interneurons (e.g. basket cells) showed the presence of the intracytoplasmic neurofilament bundles. No neurofibrillary tangles were observed in the granule cells nor in the neurons of the dentate nucleus. The accumulation of filaments in the Pc extended to the main dendrite. Prominent swellings were also noticed in the initial segment of the Pc axon: in addition to the extensive accumulation of neurofilaments, mitochondria were seen in large numbers, mostly in the subaxolemmal region. In the molecular layer, numerous Pc dendrites underwent degeneration: they appeared as electron dense osmiophilic debris, surrounded by hypertrophic astrocytic processes. In animals sacrificed between 1 and 2 months after injection, the number of degenerating dendrites became progressively larger; severe Pc losses could be also noticed, in the vermis and in particular at the crown of the folia. In the second and third month the loss of Pc dendrites was followed by pr

80.3 PENTAZOCINE AND TRIPELENNAMINE: EFFECTS ON BRAIN-STIMULATION REWARD. <u>E.M. Unterwald\* and C. Kornetsky</u> (SPON: L. T. Kucharski). Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Medicine, Boston, MA 02118. In recent years, the abuse of the combination of pentazocine (Talwin<sup>R</sup>) and tripelennamine (PBZ<sup>R</sup>, Pyribenzamine<sup>R</sup>) has been reported (Showalter, C.V., <u>J. Am. Med. Assoc.</u>, 244:1224-1225, 1980). This drug combination is commonly referred to as "T's and Blues" and is administered intravenously by the abuser.

The mechanism by which tripelennamine, an antihistaminic/anticholinergic, enhances the abuse liability of pentazocine, a mixed agonist/antagonist opioid, is not well understood. In order to investigate the reinforcing properties of this combination, we determined the acute effects of tripelennamine, pentazocine, and several combinations of the two on the threshold for rewarding brain stimulation to the medial forebrain bundle - lateral hypothalamic (MTB-LH) region in the rat. Many drugs of abuse including morphine, cocaine, amphetamine and phencyclidine have been shown to lower the threshold for brain-stimulation reward suggesting that this is a useful model of abuse liability and euphoria (Kornetsky, C., et al., <u>Arch. Gen. Psych.</u>, 36:289-292, 1979). Male albino rats (CDF, Charles River Laboratories) were stereotaxically implanted with bipolar electrodes aimed at the MFB-LH

Male albino rats (CDF, Charles River Laboratories) were stereotaxically implanted with bipolar electrodes aimed at the MFB-LH area. Thresholds for rewarding brain stimulation were determined using a modification of the psychophysical method of limits. Tripelennamine (1.25-20.0 mg/kg) or pentazocine (1.25-10.0 mg/kg) administered intraperitoneally cause' a dose-dependent lowering of reward thresholds for intracranial stimulation. Doses of tripelennamine and pentazocine that were ineffective alone in lowering the threshold for brain-stimulation reward, were then administered concomitantly. The threshold for rewarding brain stimulation was significantly lowered following this combination. The magnitude of this lowering effect was much greater than what was observed with either drug alone at any dose. These results suggest a marked synergistic increase in euphoria when these two drugs are concomitantly administered intravenously in man.

80.4 INTRACRANIAL SELF-ADMINISTRATION OF METHIONINE ENKEPHALIN. N.E. Goeders, D.A. Ingham, J.D. Lane and J.E. Smith, Psychiatry Research Unit, Departments of Psychiatry and Pharmacology,

Research Unit, Departments of Psychiatry and Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130. The abuse liability of opiates depends in part upon their reinforcing properties. Rats will self-administer morphine, an opiate with a high affinity for mu opiate receptors, into the ventral tegmental area (Bozarth and Wise, Life Sci. 28, 551, 1981), lateral hypothalamus (Olds, Brain Res. 168, 351, 1979) and nucleus accumbens (Olds, Brain Res. 237, 429, 1982) at concentrations generally corresponding to the in vitro affinity of the agonist for the major receptor subtype in that region. This investigation was initiated to identify the neuronal circuitry mediating the reinforcing properties of an endogenous delta opiate receptor agonist, methionine enkephalin (met-enkephalin), using intracranial self-administration (ICSA) methodologies. Experimentally naive male Fisher F-344 rats were stereotaxically implanted unilaterally with guide cannulae into the nucleus accumbens, a structure containing primarily delta opiate receptors. The animals were allowed to self-administer 100 nl microinfusions of met-enkephalin directly into the nucleus accumbens by depressing a lever located on one wall of the experimental chamber. The microinfusions were delivered by an adaptation of the electrolytic microinjection transducer (EMIT) system described by Bozarth and Wise (Life Sci. 28, 551, 1981). Concentrations of zero to 750 pmoles of the drug dissolved in artificial cerebral spinal fluid were tested for ICSA. The delivery of met-enkephalin into the nucleus accumbens initiated a reinforcing stimulus in a dose-dependent fashion, with maximal rates of ICSA observed with 500 pmoles of the drug. The reinforcing stimulus of this endogenous ligand, implying that delta opiate receptors are responsible for the initiation of the reinforcing stimulus produced by microinfusions of met-enkephalin into the nucleus accumbens. This suggests that the activation of opiate receptors outside the ventral tegmental area can resul

NALOXONE ENHANCEMENT OF NOCICEPTIVE RESPONDING. 80.5

NALOXONE ENHANCEMENT OF NOCICEPTIVE RESPONDING. K.A. O'Neill, C.W. Scott and A. Weissman (Spon: J. Heym). Pfizer Central Research, Groton, CT 06340. The highly specific and potent opiate antagonist, naloxone, has emerged as a useful tool for the study of endogenous opiates. However, investigations of naloxone's effect on re-sponsivity to painful stimuli in animals and humans have yielded ambiguous and conflicting results (cf. Goldstein, in Beers and Bassett, eds., Mechanisms of Pain and Analgesic Com-pounds, 1979). Some variability can be attributed to differing pain tests and doses of naloxone. The present studies were designed to sustamatically examine

The present studies were designed to systematically examine the effects of naloxone alone and in combination with other agents on the jump latency of mice placed on a 50°C hotplate, agents on the jump latency of mice placed on a 50°C hotplate, using an automated apparatus (0'Neill <u>et al.</u>, J. <u>Pharm. Methods</u>, in press). CD-1 male mice (Charles River) weighing 20-25 g served as subjects. Each animal was tested only once. Naloxone's time course was established using a dose of 3.2 mg/kg, s.c. Jump latencies were recorded at 7.5, 15, 30, 60, 120 and 240 min after treatment. Maximal hyperalgesia was observed at 15 and 30 min; at 1 hr after treatment, marginal hyperalgesia was observed; latencies returned to control values at 2 and 4 hrs after drug administration. There was no evidence at 2 and 4 hrs after drug administration. There was no evidence of analgesia at these times.

Treatment with the enkephalinase inhibitor, thiorphan (100 mg/kg, s.c.; cf. Chipkin <u>et al.</u>, <u>Eur. J. Pharmacol.</u>, 83:283, 1982), 15 min prior to testing at 1, 2, or 4 hr after naloxone (3.2 mg/kg, s.c.), failed to produce analgesia. Thus, naloxone administration under this protocol does not appear to rapidly upregulate an enkephalinergic system. In a dose-response study, 15-min pretreatment with naloxone

at .5-log intervals over a dose range of 0.1 through 100 mg/kg,

at .5-log intervals over a dose range of 0.1 through 100 mg/kg, s.c. yielded hyperalgesia at doses of 1 mg/kg and above. No analgesia was observed at any dose. Naloxone at low doses (<3.2 mg/kg s.c.), given in conjunc-tion with morphine sulfate at a grossly analgetic dose (5.6 mg/kg), also resulted in hyperalgesia, and not just blockade of morphine's analgetic action. The combination of acute morphine naloxone in fact appears to result in greater hyperalgesia than does naloxone alone. Similar results were observed in ancillary tests using phenylquinone-elicited writhing in mice as an endpoint.

These data suggest that in the hot-plate jump- and phenylquinone writhing-tests application of a nociceptive stimulus activates endogenous opiate systems. Blockade of opiate re-ceptors by naloxone may result in hyperalgesia by displacement of endogenous opiates from receptors.

80.7 LACK OF EFFECT OF ADRENALECTOMY ON STRESS-INDUCED ANALGESIA. Rhode Island, Kingston, RI 02882.

Recent studies have suggested that some forms of stress-induced analgesia (SIA) are mediated by opioid systems while others are mediated by nonopioid systems. MacLennon et al. (Science, 215:1530, 1982) recently reported that hypohysectomy or adrenalectomy (ADX) blocked the SIA observed after foot shock stress (FS), when the animals were tested upon reexposure shock stress (rs), when the animals were tested upon receptorie to a brief FS. By contrast, Glusan et al. (Soc. Neurosci. Abstr., 6:321, 1980) reported that ADX potentiated SIA fol-lowing cold water stress (CWS) or FS. Most investigators re-port using a 1-2 week recovery period after ADX before testing for SIA, which may result in the development of compensatory changes such as functional tolerance to the chronically high concentrations of B-endorphin observed in ADX animals. In the present study SIA was examined after only a 24-hour recovery period from surgery.

ADX, sham-ADX, and control rats were subjected to one of three treatments: CWS, CWS + naltrexone (10 mg/kg every 24 hours), or no-CWS. Each group was tested for SIA by the tailwithdrawal method (Miksec, S. and Lal H., <u>Psychopharmacology</u>, 54:217, 1977), immediately prior to, immediately after, 24 hours after, and 5 days after a single exposure to CWS (2°C, 3.5 min), in a 3 x 3 (surgery X stress) design with four repeated measures

No differences in SIA were observed among surgical treatments at any time point. However, significant differences among stress treatments occurred immediately after CWS, when the CWS group showed longer latencies than the CWS + naltrexone group, which showed longer latencies than the no-CWS group. However, even the no-CWS group exhibited a tail-withdrawal latency significantly longer than its baseline response, which indicates that SIA occurred in response to the restraint pro cedure used in the analgesia testing. Twenty-four hours and 5 days after CWS, all groups again exhibited significantly longer latencies than their respective pre-stress baselines. These results indicate that animals are capable of exhibiting SIA 24 hours after surgery, and upon reexposure to treatment asso-ciated with stress, and that this SIA may, in part, be mediated by opioid mechanisms.

BRAIN MUSCARINIC CHOLINERGIC RECEPTOR CHANGES CORRELATED WITH RAT MORPHINE-SEEKING BEHAVIORS. J.E. SMITH, C. Co and J.D. Lane. Psychiatry Research Unit, Departments of Psychiatry and Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130. 80.6

Shreveport, LA 71130. The neurobiological substrates of opiate reinforcement have been under vigorous investigation. Pharmacological animal studies have shown agents that disrupt cholinergic, dopaminergic and noradrenergic neurons to attenuate intravenous opiate self-administration. Neurotransmitter turnover rate measurements in administration. Neurocransmitter turnover rate measurements in morphine self-administering rats have implicated cholinergic innervation of the frontal and pyriform cortices, nucleus accumbens, amygdaloid complex and ventral tegmental area (Smith et al, Neurosci. Abst. 8, 591, 1982). Acetylcholine turnover rates utilize short pulse times (5 and 10 min) with only the cholinergic neuronal activity during this period determining the turnover rates. Neuronal activity related to reinforcement processes may occur throughout the interinfusion interval (approximately 2 hours), therefore, cholinergic receptor para-meters could be more representative of the total change in activity. Muscarinic cholinergic receptor binding was evaluated in membranes from seven brain regions of rats either intravenously self-administering morphine (10 mg/kg per infusion) or receiv-ing yoked-infusions of morphine or vehicle. These were the same animals used for the acetylcholine turnover rate measurements. animals used for the acetylcholine turnover rate measurements. Membranes were prepared from frozen tissue powders by homogeniza-tion in 50 mM KH<sub>2</sub>PO<sub>4</sub>/Na<sub>2</sub>HPO<sub>4</sub>, pH 7.4 buffer and centrifugation (48 K x g for 30 min). Binding was evaluated (60 min at 25°C) with five to seven concentrations of  $[^{3}H]$ -quinuclidinyl becallate (QNB) (0.375 nM to 2.4 nM) in the presence or absence of 9 uM atropine sulfate. The membranes were rapidly collected on Whatman GF/B glass fiber filters by suction filtration and the evaluating the seven concentration of the se radioactivity determined by liquid scintillation spectrometry. Rosenthal plots and Scatchard analysis were used to determine QNB wore not altered but densities (Bmax). Binding affinities were affected by morphine (yoked-morphine compared to yoked-vehicle group) and by self-administration (self-administration compared to yoked-morphine infused group). Morphine resulted in decreases in receptor densities in the cingulate and entorhinal-subicular cortices. Self-adminis-tration resulted in decreases in receptor densities in the frontal and entorhinal-subicular cortices and increases in the amygdaloid complex. The changes generally agree with turnover rate measurements but may be more indicative of overall neuronal activity. The frontal and entorhinal-subicular cortical and amygdaloid complex cholinergic neuronal innervations appear to be involved in components of opiate reinforcement processes. (Supported in part by USPHS Grant DA-01999-05).

80.8 SELECTED OPIOIDS, PRESSING FOR INTRACRANIAL STIMULATION, AND THE CONDITIONED PLACE PREFERENCE TEST. G. A. Hunter Jr., A. M. Lindsay\* and L. D. Reid, Dept. of Psychology, Rensselaer Polytechnic Institute, Troy, NY 12181. Rats, fixed with chronically indwelling bipolar electrodes for

intracranial stimulation (ICS) of the lateral hypothalamus, were given an opportunity to press a lever for a fixed intensity of ICS 30 min/day. Thirty min before some sessions, placebox (carriers of drugs) were administered. Before other sessions, injections of selected opioids were given. Doses of 10 mg/kg, as well as smaller doses, of naloxone (the prototypic antagonist of morphine and endogenous opioids' effects) reliably reduced pressing and endogenous opioids' effects) reliably reduced pressing compared to placebo. Fentanyl (FEN, a potent analgesic) increased pressing at doses of .005 to 0.4 mg/kg (at .04 mg/kg by greater than 160%). Ethylketocyclazocine (EKC, an opioid that is a prototypic agonist for the kappa opioid receptor) decreased pressing at doses greater than .08 mg/kg. The levorotatory enantiomer of EKC also depressed rates at all doses tested while the destruction agoning. the dextrorotatory enantiomer and small doses of the racemic mixture increased pressing. Diprenorphine (DIP, an antagonist to many morphine-like effects) increased pressing at doses ranging from 5 to 250 microgm/kg (250 microgm/kg increased pressing by more than 180%).

It is presumed that a drug-induced increment in pressing for ICS reflects the ability of that drug to elicit heightened activity in neural substrates of reward or positive affect. Since DIP's effect on pressing for ICS was unexpected, it was decided to assess its capacity to elicit positive affect in another procedure, the conditioned-place-preference (CPP) test. The CPP test involves placing rats in one end of an alley under the drug's influence and the other end under placebo and, subsequently, seeing which end the rats prefer. Rats, after habituation to the entire alley, received doses of either DIP, EKC or morphine before being confined to one end of the alley. On alternate days, they were given placebo and limited to the other end. On test day, rats were given access to the entire alley while tabulating the time spent in each side. DIP, as does morphine, leads to a CPP. EKC, in large doses, only leads to a CPP with more extensive testing.

FEN, EKC, and DIP differ considerably in their ability to elicit analgesia and other morphine-like effects and in their engender signs of positive affect. There is no capacity to apparent relationship among these differing capacities, i.e., they seem to vary independently across opioids. This leads to the conclusion that opioid-analgesia and opioid's capacity to elicit positive affect are products of separate systems, and, perhaps, coded by way of different opioid receptors.

80.9 CONDITIONED TASTE AVERSION PRODUCED BY MORPHINE DOES NOT INVOLVE MU-TYPE OPTATE RECEPTORS IN BRAIN. <u>M.T. Bardo, J.S. Miller\*</u>, D.F. McCoy\* and M.E. Risner\*. Dept. of Psychology, University of Kentucky, Lexington, KY 40506 and NIDA Addiction Research Center, P.O. Box 12390, Lexington, KY 40583.

The present experiments examined the involvement of  $\mu$ -type oplate receptors in conditioned taste aversions produced by morphine. In the first experiment, adult male Sprague-Dawley rats were implanted subcutaneously with a slow-release pellet containing either naloxone (10 mg free base) or placebo. After 10 days of pellet implantation, the pellets were removed and the animals were sacrificed by decapitation at 1, 2, 4, 8 or 16 days after removal of the pellet. Brain and spinal cord regions were dissected, and the tissue homogenized in Tris HCl buffer, (pH 7.4) and incubated at 0°C for one hour with <sup>3</sup>H-naloxone in the presence or absence of 100 nM levallorphan tartrate. Each sample was then washed over GF/B glass fiber filters and the radioactivity was determined by liquid scintillation spectrometry. Using this <u>in vitro</u> assay procedure, it was found that naloxone-implanted animals exhibited a significant increase in pecific binding of <sup>3</sup>H-naloxone. This increase in  $\mu$ -type opiate binding was evident for varying durations after pellet removal, depending upon which region of the central nervous system was examined. In a second experiment, animals were similarly treated with

In a second experiment, animals were similarly treated with either naloxone or placebo pellets, except that these animals were given only 15-minutes daily access to tap water during the last seven days of pellet implantation. One day after the pellets were removed, these animals were then given 15-minutes access to .1% saccharin solution followed immediately by an injection of morphine sulfate (0, 1, 3 or 10 mg/kg, s.c.). Thirty minutes after the injection of morphine, each animal was also tested for pain sensitivity using a standard 50°C hot-plate test. The saccharin-morphine pairings were repeated once every third day for five days. During the intervening days, the animals were given 15-minutes access to water. The results from this experiment demonstrated that morphine produced a dose-dependent increase in paw-lick latencies (analgesia) and a dose-dependent decrease in saccharin consumption (taste aversion). While the naloxone pellet treatment enhanced the analgesic effect of morphine, the aversive effect of morphine remained unchanged. In addition, a third experiment demonstrated that when the naloxone pellet was left implanted during behavioral testing, the analgesic effect of morphine was blocked complete-ly, whereas the aversive effect of morphine treatment duchanged. Thus, unlike analgesia, the aversive effect of morphine does not depend directly upon p-type opiate receptors in brain.

80.11 PRE-EXFOSURE TO LOW DOSES OF MORPHINE BLOCKS MORPHINE-INDUCED CONDITIONED TASTE AVERSION. <u>T.Huntx,</u> <u>K.Spivakx, and Z. Amit.</u> (SFON. M.Britt). Centre for Behavioral and Neural Biology, 1455 De Maisonneuve Elvd., Montreal, P.Q. H3G 1M7 Male Sprague-Dawley rats were placed on a 23h 40min water deprivation schedule. On days 2, 4, and 6,

Male Sprague-Dawley rats were placed on a 23h 40min water deprivation schedule. On days 2, 4, and 6, animals received pre-exposure injections of one of three doses of morphine hydrochloride (2.5, 5.0, or 15.0 mg/Kg) or saline following the 20min drinking period. On day 8, (conditioning day) animals were presented with a 0.1% saccharin solution in place of water. Within a minute after termination of the drinking period, animals in each of the four pre-exposure groups received one of the three morphine doses (2.5, 5.0, or 15.0 mg/Kg) or saline. There were thus 16 independent groups (7-8 animals per group). On ensuing days the water deprivation schedule was continued. On day 14, (conditioning day 2) saccharin presentation and drug administration were again given as before. This cycle was repeated until 5 conditioning days had been observed. On day 38 (test day), a final saccharin presentation was performed.

day), a final saccharin presentation was performed. Results showed that saline pre-exposed animals in both the 15mg/Kg and 5mg/Kg conditioning groups exhibited significant reductions from baseline saccharin consumption levels over test trials, indicative of conditioned taste aversion (CTA). In contrast, rats pre-exposed to the three morphine doses failed to exhibit CTAs at either conditioning dose. Thus, pre-exposure to the 2.5 mg/Kg morphine, a dose which in itself did not induce a CTA, was as effective as a 15mg/Kg dose in blocking a morphine CTA. Previous studies have shown that morphine at low doses comparable to the 2.5mg/Kg dose can mediate positive reinforcement. This, then, suggests that pre-exposure to a morphine dose which does not mediate a CTA but has been shown to have positive reinforcing properties may serve to block a morphine CTA induced by higher morphine doses.

In a second experiment, it was shown that pre-exposure to the 2.5mg/Kg dose did not result in tolerance as measured by a hot plate test of morphine analgesia.

These data, then, may provide significant new insights into the discriminative properties of morphine as a potentially aversive agent. 80.10 6-OHDA LESIONS OF THE VENTRAL TEGMENTAL AREA BLOCK MORPHINE FA-CILITATION OF SELF-STIMULATION. <u>T.H. Hand<sup>®</sup></u> and K.B.J. Franklin. Psychology Dept., McGill Univ., Montreal, P.Q. Canada H3A IBI The rewarding properties of morphine and related drugs have been demonstrated to depend on the dopamine (DA) cells of the ventral tegmental area (VTA). Morphine is also known to facilitate self-stimulation (SS), and there is some indication (Broekkamp et al., <u>Pharmac. Biochem. Behav.</u> 11:289, 1979) that this facilitation is due to a direct influence of the drug on opiate receptors in the VTA. To test this hypothesis, we lesioned the VTA cells with 6-hydroxydopamine (6-OHDA), and subsequently evaluated the effects of morphine on SS.

Male hooded rats received bilateral microinjections of 6-OHDA (4ug in luL each side) or .05% ascorbic acid vehicle aimed at the VTA. Noradrenalin neurons were protected with protryptiline (15 mg/kg IP). Each rat was also implanted with a bipolar electrode aimed at the lateral hypothalamus. Rats were then trained to lever press for .2 sec trains of 100 Hz .2 msec pulses of brain stimulation delivered on a random interval 5 sec schedule. When stable response rates were established at 35-65% of maximal rate, drug testing was begun. Every second day for 7 days, rats were tested during 3 twenty minute sessions: immediately before, lh after and 3h after subcutaneous injection of 10 mg/kg morphine sulfate. Morphine was administered daily.

Control animals showed the expected biphasic effect of the drug (rate suppression followed by facilitation), with gradual development of tolerance to the rate suppression. Lesioned animals showed neither the facilitation nor the tolerance to the rate suppression. These findings further substantiate the hypothesis that VTA DA cells are necessary for the facilitation of SS by morphine. This is consistent with the more general claim that the mesolimbic DA projection takes a significant part in the reinforcing properties of morphine and related drugs.

(Supported by NSERC grant A6303.)

80.12 THE CONDITIONING OF CHANGES IN LOCOMOTOR ACTIVITY INDUCED BY MOR-PHINE APPLIED TO THE VENTRAL TECMENTAL AREA OF THE RAT BRAIN. <u>P. Vezina\* and J. Stewart</u>. Center for Studies in Behavioral Neurobiology, Psychology Dept., Concordia Univ., Montreal, H3G 1M8. Two experiments were conducted to determine whether the hyperactivity obtained from bilateral administration of morphine to the ventral tegmental area (VTA) of the rat brain (Joyce and Iversen,

Neurosc. Lett., 1979) could be conditioned to the environment associated with the drug administration. In Experiment 1, locomotor activity was measured for 90 min in one group of rats immediately following a bilateral administration of morphine sulphate crystals to the VTA (18 µg tapped into the tip of 28 gauge cannulae), and sometime before morphine administration in another group. Each of these two groups was accompanied by a no-morphine control group that received a sham administration to the VTA. During a three-week period, morphine was administred daily for four days a week. A test for conditioning followed a 10day morphine-free period; all animals were given sham administrations and placed in the activity boxes. Animals that had previously received morphine in the activity boxes were significantly more active than their sham controls; animals that had received an equivalent number of morphine administrations, but never associated with the activity boxes, had activity levels similar to their sham controls. These data show that the hyperactivity was conditioned to the environment associated with morphine administration, and that the conditioned response (CR) minicked the unconditioned response (UCR) to this action of morphine and was not a compensatory CR that opposed the UCR.

In Experiment I, repeated administration of morphine to the VTA resulted in a progressive increase of the hyperactivity (see also Joyce and Iversen, 1979). Experiment II examined the possibility that this sensitization to the effect of morphine was due to conditioning. Two groups of rats were administered morphine sulphate crystals to the VTA on five occasions, once every fourth day. One group received morphine in the activity box; the other group received morphine in the home cage. A test followed on which both groups were administered morphine in the activity box. Animals that had previously received morphine in the activity box. Animals that had previously received morphine in the activity boxes were significantly more active than animals that had received an equivalent number of morphine administrations, but in their home cages. Hence, the sensitization of the hyperactivity only appeared when animals were tested in the environment previously associated with morphine administration environment and cannot be accounted for by changes brought about by the repeated exposure of opiate receivtors in the VTA to morphine.

NON-NALTREXONE REVERSABLE HEAT-STRESS INDUCED ANAL-GESIA. Z.H.Galina, F.Rogan & Z.Amit. Center for Studies in Behavioral Neurobiology, Concordia Univ.
Rm.H1013, Montreal, Canada, H3G1M7.
Using the same procedures that we have previously shown to induce a graded release of corticosterone
(B) which was related to the intensity of the heat stress (higher intensity=greater release), we now report that a transient analgesia ca be produced by heat-stress; that it is not naltrexone (NTX) reversable, but does seem to be related to the amount of B release (as determined by previous study).
The prodedure consisted of placing male Wistar rats upon one of four hot-plates for thirty sec. Each hot-plate was set at a different temperature (21 (control), 47, 52, or 57°C). Two hrs. before hot-plate testing the rats were injected with either saline or NTX (10 mg/kg). After 30 sec on the hot-plate the rat was removed and placed in a plastic baby bottle (8 oz) that had the bottom cut out so that the rats tail projected from the end. This provides an unobtrusive restraining device with easy accesss to the tail. A modified tail-flick procedure was used to measure analgesia. A hot water bath was heated to 45 C into which 5cm of the rats tail was immersed. A 30 sec cutoff time was established. Analgesia was measured at 0, 5, 10, 15, 30, 60, 120 min and 24 hrs after the 30 sec hot-plate stress.
A three-way ANOVA (temp x time x NTX) revealed a sign. effect of Temp, time, and temp x time interaction. The main effect of NTX was not sign. Post-hoc analysis (Tukey) indicated that exposure to 57 induced a transient analgesia as compared to (21) controls which lasted for 15 min. Interestingly, though 52 was not sign different than control group, the group that recieved exposure to 52 and NTX , exhibited greater analgesia than the group recieving 52 alone. This effect of time results from the slow decrease over time of the analgesia over time of the control group.

control group. This is a demonstration that another stressor (heat) can induce a transient analgesia in rats that is not effected by the NTX sensitive receptor.

THE INFLUENCE OF CONTEXTUAL CUES ON SUBSEQUENT PREFERENCE FOR 80.14 ORAL ETONITAZENE. M. R. Lynch and J. H. Porter\*. Psych Dept., Va. Commonwealth University, Richmond, VA 23284. Psychology

In order to determine facilitory effects of environmental stimuli previously paired with oral opiate availability, on subsequent drug selection in a choice test procedure, daily  $\frac{1}{2}$  hr limited access to 5  $\mathcal{A}$ g/ml etonitazene solutions was paired with a set of discrete contextual cues. Of 80 male albino rats, 40 received this 'CS-complex' with drug pairing, while 40 were exposed to drug in the home cage as their sole available drinking solution. Groups were further subdivided into control rats which were pretreated daily with 3 mg/kg naltrexone and those injected ip. with saline. An additional factor of food depriinjected 19. With saline. An additional latter of food depri-vation was introduced in an attempt to obtain maximum drug intake during sole access, with half of the above groups gradu-ally reduced to 75% ad <u>lib</u> body weight over 12 days of opiate availability. Following these drug-environment pairings, choice testing with water was conducted for all rats, both in the same environment as prior drug exposure, and in a different environ-ment (i.e., distinctive vs. home cage). Tests were conducted during the daily 1 hr limited access period, with order of testing counterbalanced over the two environments. While the predicted facilitation was not obtained, (no main

effect for place of testing), food deprived rats did show a significantly greater preference for etonitazene than those maintained at 100% body weight. This finding indicates that food deprivation may indeed increase opiate reinforcement as measured by preference in a choice test situation, and thus extends previous findings of Carroll, France & Meisch (Science, 205: 319-321, 1979) and Carroll & Meisch (Pharmac. Biochem. Behav., 10: 155-159, 1979) who reported increases in absolute ml intake with 24 hr sole access to drug solutions. Overall, animals exposed in the familiar home cage also preferred drug solutions more than distinctive environment groups, this differ-ence being significant for saline-injected but not naltrexone animals (an injection X environment interaction). Post-choice test tail-flick tests of morphine analyesia revealed cross-tolerance in all saline-injected rats, which was no longer apparent after a two-month drug free period. As contrasted with the previously reported inability to block opiate effects of oral etonitazene with naltrexone pretreatment, in a 24 hr drink-ing paradigm (Lynch, Porter & Johnson, <u>Neurosci. Abstr.</u>, <u>8</u>: 590, 1982), no signs of precipitated or spontaneous withdrawal were observed during these striking. observed during these studies.

# NEUROPEPTIDES AND BEHAVIOR: OPIATES

FACILITATION OF DEVELOPMENT OF RESISTANCE TO MORPHINE ANALGESIA 81.1 BY OXYTOCIN AND THE ROLE OF BRAIN CATECHOLAMINES IN THE RAT. <u>K. Sharifi Hossaini, and M.S. Shahid Salles</u>. Department of Phar-macology and Physiology, School of Medicine, Shiraz University, Shiraz, Iran.

Rats were prepared with permanent electrodes for recording EEG Rats were prepared with permanent electrodes for recording ELG and EMG. Morphine injections of 10 mg/Kg given S.C. were followed by the appearance of high voltage EEG slow bursts associated with stuporus behavior. This phase was suppressed by the appearance of behavioral arousal shown by EMG and behavior of rats and after-wards behavioral sleep became apparent on the EEG. Administration of 10 mg/Kg of morphine to rats pretreated with oxytocin (0.5 mg)of 10 mg/Kg of morphine to rats pretreated with oxytocin (0.5  $\mu$ ) 0.5 ml/animal) strongly increased the above mentioned behaviors. The result of tailflick-tests in another series of animals treated with oxytocin show rapid facilitation of development of resistance to morphine analgesia. Administration of a 10 mg/Kg dose of mor-phine to rats pretreated with  $\alpha$ -methylparatyrosine ( $\alpha$ -MPT)50mg/Kg was followed by a significant decrease in morphine effect. Pre-treatment with  $\alpha$ -MPT and oxytocin before morphine injection was followed by a significant of  $\alpha$ -MDT treatment. The result may followed by a reduced effect of  $\alpha$ -MPT treatment. The result may suggest an important role for neurohypophyseal hormone oxytocin in morphine analgesia. Furthermore it is suggested that the effect of oxytocin may depend on the integrity of the brain noradrenergic system.

81.2 IRON DEFICIENCY: MODIFICATION OF CIRCADIAN RHYTHM OF PAIN THRESHOLD-BRAIN DOPAMINE AND &-ENDORPHIN. <u>S. Yehuda and M. B. H.</u> Youdim.\* Dept. of Psychology, Bar-Ilan Univ., Ramat-Gan 52100, Israel, and Rappaport Medical Research Ctr., Fac. Med., Technion, Haifa, Israel.

Rats were made nutritionally iron-deficient. Experimental iron deficiency (ID) selectively modifies the binding capacity dopamine-D, receptors. Behavioral correlates of an ID state of includes reversal of the circadian cycles of dopamine-mediated behaviors, such as d-amphetamine-induced hypothermia in rats kept at  $4\,^\circ\text{C}$  , d-amphetamine- and apomorphine-induced hypermotility, and stereotyped behavior. d-Amphetamine potentiates the reversal of the cycles, but TRH and its peptidase-resistant analogue CG 3703 prevent the reversal of the cycles. Pain threshold (Hot plate,  $58\,^\circ\text{C}$ ) is also circadian cycle-dependent. In ID rats the pain threshold cycle was reversed. Peripherally injected  $\beta\text{-endorphin}$ (0.1, 1.0, 3.0 mg/kg) elevates pain threshold only in ID rats and not in control rats (no linear dose-response curve was found). Morphine (10.0 and 20.0 mg/kg) and haloperidol (2.0 mg/kg) elevate pain threshold both in ID and in control rats. This elevation was smaller than that induced by a 1.0 mg/kg dose of  $\beta$ -endorphin. No additive effect was found after the combined treatment of haloper-idol and  $\beta$ -endorphin. Naloxone (1.0 mg/kg) induces a reduction in pain threshold and blocks the effect of  $\beta$ -endorphin. Neuroleptics are also able to increase pain threshold. These results indicate that dopamine (via the endorphin system) may play an important role in modifying pain threshold.

FRACTIONATION OF POSTURAL SUPPORT MECHANISMS WITH COMBINED SYS-TEMIC ADMINISTRATION OF HALOPERIDOL AND MORPHINE. S.M. Pellis\*, F. de la Cruz\*, V.C. Pellis\* and P. Teitelbaum. Psychology Dept., University of Illinois at Urbana-Champaign, Champaign, IL 61820 Haloperidol (a dopamine antagonist) and morphine have been used to isolate two separate, but complementary, complexes of reflexes used in posture and locomotion. Haloperidol, in rats, induces a state of akinesia/catalepsy in which the rats adopt a crouched posture with broad-based support. When pushed they will resistbeing displaced or rolled over by actively pushing against the displacing force. In contrast morphine eliminates these supporting reactions. Rather than oppose a displacing force, they allow themselves to be rolled over. The limbs are rigidly arrested in phases of the step cycle, compatible with a state preparatory to locomotion. (De Ryck et al., <u>Brain Res., 201</u>:143-172, 1980). EMG recordings from antagonistic muscles of the limbs support these conclusions (De Ryck and Teitelbaum, <u>Expl</u>. Neurol., 79:54-76, 1983). 81.3

Timbs support these conclusions (De Nyck and Terterbaum, Lopi-Neurol., 79:54-76, 1983). When given haloperidol and morphine in combination, the rats adopt and actively maintain their limbs in an abducted and ex-tended posture, while their bodies lie completely flat. Althous most postural support mechanisms are abolished, some residual, for example in response to being Although most postural support mechanisms are abolished, some residual, fractionated ones remain. For example, in response to being pushed on the ground or placed on a vertical grid, the rats will grip with their digits. However, unlike when given haloperidol alone, the gripping does not involve flexion of the forearms and ventroflexion of the head, rather the body is limply held up by the flexed digits. The sensory guidance of remaining responses is also simplified. For example, while these rats do not respond to also simplified. For example, while these facs do not respond to slowly occurring postural changes, they exhibit normal limb and body movements in response to rapid postural changes. With the use of visual occluders and labyrinthectomy, it was found that for either drug alone, these movements involved both propriocep-tive and vestibular guidance. With haloperidol and morphine combined these movements were exclusively dependent on

combined these movements were exclusively dependent on vestibular guidance. The combined haloperidol and morphine preparation has proved to be useful in fractionating hitherto intact postural support reflexes. Furthermore, there appears to be an interaction between opiate and dopaminergic systems in postural and locomotor behaviour not previously described.

SELF-STIMULATION IN THE REGION OF LOCUS COERULEUS: OPIOID OR CATECHOLAMINERGIC MECHANISMS? <u>S.E. Loughlin, J.D.</u> Belluzzi, F.M. Leslie, and L. Stein. Department of Pharmacology, University of California, Irvine, Irvine, CA 92717. The catecholamine reinforcement hypothesis, and, more specifically, 81.5

the noradrenergic hypothesis, predicts that stimulation of nucleus locus coeruleus should support self-stimulation (SS). While many investigators report positive electrode sites in the locus coeruleus, some workers suggest that those electrodes located precisely in the nucleus are negative for SS. Furthermore, in many experiments, manipulation of noradrenergic transmission failed to affect SS at positive sites. Since the region surrounding the locus coeruleus contains dense opioid terminal fields, and a role of opioid systems in reinforcement has been suggested (Belluzzi and Stein, 1977), we postulated that opioid systems might play a role in SS in this area. To test this hypothesis, we examined the self-stimulation behavior of rats implanted with electrodes in dorsal pons. Animals which exhibited stable rates of self-stimulation were tested for Animals which exhibited stable rates of self-stimulation were tested for sensitivity to the opiate antagonist, naloxone (0.5 to 40 mg/kg). Localization of electrode tips was accomplished by routine histological procedures or in brains prepared by immunocytochemical staining for various opioid peptides. In addition, maps of noradrenergic cell bodies and axons were generated and electrode placements were correlated with these. The results suggested the following tentative conclusions: First, one group of electrode tips supported high rates of self-stimulation, which was blocked or greatly decreased by administration of naloxone. These were located in, or in close proximity to, regions which exhibited onjoid-like immunoreactivity. A second group of electrode tips exhibited opioid-like immunoreactivity. A second group of electrode tips supported low to medium rates of self-stimulation which was unaffected Many of these electrodes were located within or directly by naloxone. anterior to the nucleus locus coeruleus. These data may explain the results of other studies suggesting that self-stimulation in this region is unaffected by a variety of noradrenergic manipulations. Electrode tips in these studies may have been located in opioid-positive regions. These data further suggest that at least two independent systems may support CCSs in dorsal pons, an opioid system and a non-opioid, perhaps catecholaminergic, system. - 81.6 PERIPHERALLY ADMINISTERED NEUROPEPTIDES AND LATERAL HYPOTHALAMIC SELF-STIMULATION IN RATS. <u>G. Meisenberg</u>, S.A. Lorens and W.H. Simmons\*. Loyola University Medical School, Maywood, IL 60153. S.A. Horens and w.H. Shimols. Boyla only start weights and weights and weights. Boyla only on the start weights and weights and the start of the st waves (100 Hz) on a continuous reinforcement schedule. The current intensity was adjusted individually to yield response rates which were approximately 50% of the maximal response output. On drug days, the animals were tested before and 30 min after the injection. None of the peptides significantly altered LHSS responding. On the other hand, D-amphetamine (0.2-1.0mg/kg) produced a marked dose-dependent increase while halo-peridol (0.25mg/kg) was followed by a profound reduc-tion in LHSS response output. Our results to date, thus, have failed to support the view that peripheral administration of the aforementioned peptides induce a "neuroleptic-like" or "psychostimulant-like" effect on brain stimulation reward. on brain stimulation reward.
- ENDORPHIN-CATECHOLAMINE INTERACTIONS IN NUCLEUS 81.7 ENDORPHIN-CATECHAMINE INTERACTIONS IN NOCLEOS ACCUMBENS SELF-STIMULATION. K. A. Trujillo, J. D. Belluzzi, and L. Stein. Department of Pharmacology, University of California, Irvine. Evidence suggests that the catecholamine-like drugs amphetamine and cocaine (Lyness, et al, Pharmacol. Biochem. Behav. 12:781, 1980) as well as Roberts, et al, Pharmacol. Biochem. Behav. 12:781, 1980) as Weil as opiate drugs, such as heroin (Wise and Bozarth, Pharmacol. Biochem. Behav. 17:239, 1982; Spyraki, et al, Psychopharmacol. 79:278, 1983) exert their reinforcing effects by actions on mesolimbic dopamine neurons. These neurons project heavily to the nucleus accumbens, a region rich not only in dopamine, but also in enkephalins. There are at least two possible mechanisms by which catecholamine and opiate drugs might produce reinforcing effects in the mesolimbic system. The first is that they act on independent and parallel pathways-catacholaminergic drugs acting through the dopamine neurons, and opiate drugs acting through an independent set of enkephalin neurons. The alternative is that these pathways are interactive—opiates might act by affecting dopaminergic transmission. Since intracranial self-stimulation (SS) is a dopaminergic transmission. Since intracranial self-stimulation (55) is a valuable tool for studying reward mechanisms, experiments were performed examining drug effects upon barpress rates for nucleus accumbens SS. Experiment I studied the dose-related effects of naloxone (0.2, 2.0, 20 mg/kg subcutaneous) upon this behavior. Consistent with previous studies that have shown supressive effects of Consistent with previous studies that have shown supressive effects of naloxone in rats with electrodes in enkephalin-rich brain regions, nucleus accumbens SS rates were dose-dependently supressed by this opiate antagonist. This action of naloxone suggests that endogenous opioids play a role in SS behavior in the nucleus accumbens. Experiment II compared the effects of a single dose of naloxone (2.0 mg/kg subcutaneous) with those of a single dose of amphetamine (1.0 mg/kg subcutaneous) in individual rats (n=18). The supression of barpress rate subcutaneous) in individual rats (n=18), the supression of particular produced by naloxone (calculated as percent of control) correlated well (n=1, n=1, n=1) with the facilitation produced by ambetamine. This produced by national calculated as percent to control, correlated were  $(r_{e-}, s_{75}, p_{e-}, o_2)$  with the facilitation produced by ampletamine. This correlation is supportive of a common pathway for the rewarding effects of endogenous opioids and catecholamines. The results of these experiments are consistent with the hypothesis that the rewarding effects of these compounds are mediated by the mesolimbic dopamine system.

81.8 INHIBITION AND FACILITATION OF HYPOTHALAMICALLY-ELICITED HISSING BY CENTRAL GRAY STIMULATION ARE DIFFERENTIALLY SENSITIVE TO NAL-OXONE. C. B. Pott\*, S. Z. Kramer\* and A. Siegel. Dept. of Neuroscience, UMDNJ, Newark, NJ 07103 and Dept. of Biology, Seton Hall Univ., So. Orange, NJ 07079. Specific areas of feline central gray (CG) modulate intraspecific areas of feline central gray (CG) modulate intraspesectific areas of feline central gray (CG) modulate intraspesectific areas of feline central gray (CG) modulate intraspegray (CG) modulate intraspeg

Specific areas of feline central gray (CG) modulate intraspecific aggression elicited by hypothalamic stimulation. Recent studies in our laboratory (M. Brutus et al., 1982, <u>Neurosci.</u> <u>Abst.</u> 8:971) have demonstrated regional differences of modulatory sites. Stimulation of rostral-dorsal CG inhibits, while stimulation of caudal-ventral CG facilitates, attack. Central gray stimulation also produces analgesia, possibly mediated by enkephalins (Akil & Liebeskind, 1975, <u>Brain Res.</u> 94:279). The relationship between CG stimulus induced analgesia and aggressive behavior is unclear, although analgesic midbrain stimulation (rat) suppresses shock elicited target biting (Renfrew & Leroy, 1988, <u>Physiol. &</u> <u>Behav.</u> 30:169). The present study examines the possible role of endogenous opiates in CG modulation of feline intraspecific attack.

Adult cats were implanted with chronic electrodes aimed at the ventromedial hypothalamus (VM), which when used to stimulate, elicited hissing, growling, piloerection, mydriasis, and attack directed at conspecifics. Later, while restrained, control latency to hypothalamically-elicited hiss was established. Each animal was then implanted with CG cannula-electorodes. Response modulation was determined by dual stimulation of CG and VM electrodes, alternated with VM stimulation alone, in an A-B-B-A sequence. A Hamilton syringe was lowered into CC modulatory, cannula-electrodes to the tip, and 5 ul (lug) of naloxone (in saline) injected. Hypothalamically-elicited hiss latency was again determined, followed by paired trials of single and dual stimulation. To date, three electrodes aimed at caudal-ventral CG produced facilitation of VM induced hissing, not significantly affected by naloxone. In contrast, three electrodes in the rostral-dorsal CG produced inhibition of hissing which was blocked by naloxone. Moreover, two of the sites became facilitatory.

These results demonstrate that CG inhibition of VM-elicited hissing can be blocked or reversed by the opiate antagonist, naloxone, and are consistent with the premise that both analgesia and inhibition of emotional responses produced by dorsal CG stimulation are interrelated.

 81.9 ARCUATE NUCLEUS LESIONS REDUCE OPIATE-MEDIATED STRESS-INDUCED ANALCESIA (SIA) IN RATS AND ENHANCE NONOPIATE-MEDIATED SIA.
 J. E. Kelsey and L. D. Kimball III\*. Dept. Psychology, Bates College, Lewiston, ME 04240.
 If the β-endorphin system in the rat's brain is involved in

If the  $\beta$ -endorphin system in the rat's brain is involved in mediating stress-induced analgesia (SIA), then lesions of the arcuate n. of the hypothalamus, which contains the cell bodies of this  $\beta$ -endorphin system, should reduce SIA. In contrast to this expectation, Kelsey and Hoerman (1981) reported at these meetings that lesions of the arcuate n. enhanced the analgesia produced by inescapable shock (1 sec shock every 5 sec for 30 min) when the rats were tested more than 2 weeks following surgery. Indicating that this enhanced SIA represented a time-dependent compensatory change occurring within the damaged brain, we also reported that if the rats were tested within 3-7 days following surgery, the same lesions tended to reduce the SIA.

In this presentation, we report that neither the SIA observed in the control rats nor the enhanced SIA observed in the rats with arcuate n. lesions was blocked by the opiate receptor blocker, naltrexone (6 mg/kg). This finding indicates that this SIA was not produced by the release of opiates as expected, but was produced largely by the release of nonopiate substances. Furthermore, the enhanced SIA observed in the rats with arcuate n. lesions appeared to reflect enhanced activity within a nonopiate system. In contrast to these results, we found that if the mode of inescapable shock delivery was changed such that the SIA produced the SIA as originally expected.

If the ability of naTrexone to block the SIA is used as a criterion for opiate-mediation, these data suggest that arcuate n. lesions damage a  $\beta$ -endorphin system that is important for the production of opiate-mediated analgesia. In response to the loss of this opiate analgesic system, the brain apparently initiates a time-dependent compensatory (or overcompensatory) change in an undamaged nonopiate analgesic system. Hence, if the SIA is produced by the release of opiates, i.e., is opiate-mediated, arcuate n. lesions reduce the SIA. On the other hand, if the SIA is nonopiate-mediated, the compensatory nonopiate system is activated in rats with arcuate n. lesions, producing enhanced SIA.

81.10 HANDLING, ACTH, CORTICOSTERONE AND NALOXONE EFFECTS ON CHICKEN BEHAVIOR. <u>S. Williams</u>\* and <u>D. Scampoli</u>\* (SPON: L.N. Irwin). Biology Dept., Simmons College, Boston, MA 02115.

Intraventricularly administered ACTH has been associated with excessive grooming or preening behavior in cats, dogs and pigeons. The purpose of the present study was to see if handling, ACTH, ACTH<sub>1-24</sub>, corticosterone and naloxone influence the behavior of domestic chickens, <u>Gallus domesticus</u>. Chickens were fitted with intraventricular cannulae (I.V.C.) using Ketalar and Chloropent anaesthesia and stereotaxic techniques. The behavior of four birds was then observed for 15 min after one of the following procedures: 10 min of handling, 2 µl saline (I.V.C.), 1 I.U. ACTH/2 µl saline (I.V.C.), 8 µg ACTH<sub>1-24</sub>/2 µl saline (I.V.C.), 0.02 mg corticosterone/0.2 ml peanut oil (I.P.) plus handling, and no handling or other treatment. These procedures were repeated randomly five times using a double blind procedure where appropriate. Handling, ACTH, ACTH<sub>1-24</sub>, of two-tailed Mann-Whitney U tests when compared to saline-treated controls. Naloxone-treated birds showed significantly less preening and pecking than birds treated with ACTH<sub>1-24</sub> and corticosterone. 81.11 CYCLIZATION OF α-MSH FRAGMENTS MARKEDLY INCREASES BEHAVIORAL POTENCY. <u>R. Wilson<sup>\*</sup></u>, M.D. Hirsch<sup>\*</sup>, T.K. Sawyer<sup>\*</sup>, V.J. Hruby<sup>\*</sup>, <u>M.E. Hadley<sup>\*</sup></u> and T.L. O'Donohue (SPON: W. Mink). ETB, NINCDS, NIH, Bethesda, MD 20205 and Depts. of Chem. and Biol., Univ. of Arizona, Tucson, AZ 85721.

Alpha-melanocyte stimulating hormone ( $\alpha$ -MSH) is an N-acetyl linear tridecapeptide-amide secreted by opiomelanotropinergic cells of the intermediate lobe of the pituitary gland and by neurons in the central nervous system. Previous structurefunction studies have demonstrated that the 4-10 sequence is crucial for mediation of behavioral, melanotropic, steroidogenic, and lipolytic functions (Schwyzer, R. and Eberle, A., <u>Front. Horm. Res.</u>, 18, 1977). It has recently been demonstrated that cyclization of  $\alpha$ -MSH and  $\alpha$ -MSH fragments via a disulfide bridge between cystine substitutions in the 4 and 10 residue positions (half-Cys 4, half-Cys 10) results in a superagonist on melanotropic activity (Knitel, J.J. et al., J. Med. Chem., 26: 125, 1983). Present studies evaluated the behavioral potency of cyclic  $\alpha$ -MSH fragments.

Adult, male Sprague-Dawlwy rats (250-350g) received equimolar intracerebroventrioular injections of 3nmol peptide/5µl saline. Grooming activity was quantitated over a 55 min. period as described previously (Gispen, W.H. et al., <u>Life Sci.</u>, 17: 645, 1975). Excessive grooming behavior has been interpreted to be indicative of an increased state of arousal. The results of this study indicate that the linear  $\alpha$ -MSH fragments  $\alpha$ -MSHACTH4-10, Ac- $\alpha$ -MSH4-10-NH, Ac-(Nle4)- $\alpha$ -MSH4+10-NH, Ac-(Nle4)- $\alpha$ -MSH4-11-NH, Ac-(Nle4)- $\alpha$ -MSH4-12-NH, and Ac-(Nle4)- $\alpha$ -MSH4-13-NH, are inactive or weak agonists in éliciting grooming. Interestingly, whereas the linear fragments are relatively inactive, cyclization of these peptides to Ac-(half-Cys4, half-Cys10)- $\alpha$ -MSH4-13-NH, Ac-(Nle4)- $\alpha$ -MSH4-12-NH, Ac-(half-Cys4, half-Cys10)- $\alpha$ -MSH4-13-NH, results in peptides that are approximately equipotent to  $\alpha$ -MSH in inducing grooming. In addition, Ac-(half-Cys4, half-Cys10)- $\alpha$ -MSH+13-NH, was equipotent to native  $\alpha$ -MSH in eliciting grooming. Cyclization of c-MSH fragments may increase potency by decreasing susceptibility to peptidase degradation or by changing the three-dimensional conformation of the peptide.

81.12 BEHAVIORAL EFFECTS OF AN ADRENOCORTICOTROPIC HORMONE FRAGMENT ANALOGUE IN SHAM, NEOCORTICAL, AND HIPPOCAMPAL LESIONED RATS. J. H. Hannigan, Jr., and R. L. Isaacson. Center for Neurobehavioral Sciences and Department of Psychology, SUNY-Binghamton, Binghamton, NY 13901.

This research tested the ability of a potent analogue of the ACTH<sub>4-9</sub> fragment, ORG 2766 ([Met-0\_2]<sup>4</sup>[D-Lys]<sup>8</sup>[Phe]<sup>9</sup> ACTH<sub>4-9</sub>), to alter the behavioral effects of brain damage in rats. ORG 2766 (1 µg/rat) or saline was injected (s.c.) daily for 1 week after "sham," neocortical, or hippocampal ablations. Twenty-four hrs. after the last injection, the food-deprived rats were trained on a food search task for 7 consecutive daily sessions. The rats were again tested about 3 mos. later. Hippocampally lesioned rats, and shams treated with saline, easily learned to perform the task. Hippocampals showed specific deficits that suggested an impairment in attentional processes. Prior treatment with ORG 2766 attenuated behavioral changes related to these deficits; even those found 3 mos. later, but did not affect changes in lesion-induced hyperactivity. Rats with neocortical lesions were severely impaired in the food search task. The results suggest that specific behavioral deficits following hippocampal damage in rats, perhaps related to attentional processes, may be attenuated by treatment with ORG 2766. However, these results must be evaluated relative to possible deleterious effects of ORG 2766 on adaptive behavior in nominally normal animals.

# **OPIATES II**

82.1 IPSIVERSIVE TURNING IN RATS AFTER UNILATERAL MORPHINE INJECTION INTO THE VENTRAL TEGMENTAL AREA.

M.R. Szewczak\* and M.T. Spoerlein. (SPON: T. Jerussi).
 Rutgers University, P.O. Box 789, Piscataway, N.J. 08854.
 Morphine has been reported to cause contraversive turning in rats when injected unilaterally into the substantia nigra (Iwamoto and Way, J. Pharmacol. Exp. Ther. 203: 347, 1977;
 Kaakola, Acta Pharmacol. et Toxicol. 47: 385, 1980), which was naloxone, haloperidol and pilocarpine sensitive, and atropine and muscimol insensitive.

We are now reporting that morphine causes dose-dependent (12.5-50.0 mMoles) ipsiversive turning when injected unilaterally into the ventral tegmental area (VTA) in the rat. This turning is not blocked by naloxone given systemically (10 mg/Kg, sc) or by simultaneous injection (50 mMoles) with morphine into the VTA. The turning is blocked by haloperidol (0.5 mg/Kg, ip), alphamethyl-p-tyrosine (250 mg/Kg, ip), phentolamine (2 mg/Kg, ip), clonidine (0.01 mg/Kg, ip) and muscimol (1 mg/Kg, ip). Partial blockade is seen with atropine (10 mg/Kg, ip). while pilocarpine (10 mg/Kg, ip) has no effect. Neither levorphanol (50 mMoles) nor the delta receptor agonist, D-ala, D-leu enkephalin (50 nMoles) cause turning, when injected alone into the VTA; both, however, cause catalepsy.

The kappa receptor agonist, ethylketocyclazocine (10 nMoles), when injected into the VTA, shows ipsiversive turning; this is not blocked by simultaneous injection of naloxone (50 nMoles) into the VTA. The sigma receptor agonists, SKF 10,047 (50 nMoles) and phencyclidine (50 nMoles) cause no turning when injected centrally.

The VTA appears to have receptive sites which may be of the kappa opioid type.

(Supported in part by a Charles and Johanna Busch Research Grant-Rutgers University.) 82.2 CHANGES IN SPINAL AMINE METABOLISM PRODUCED BY INTRATHECAL AND PERIAQUEDUCTAL GRAY INJECTIONS OF MORPHINE. <u>T. G. Reigle</u> and <u>R. M. LoPachin\*</u>. Dept. of Pharmacology, University of Georgia, College of Pharmacy, Athens, GA 30602. This study examined the ability of intrathecal (IT) injec-

This study examined the ability of intrathccal (IT) injections of morphine to alter the concentrations of homovanillic acid (HVA) 3,4-dihydroxyhenylacetic acid (DOPAC) and 5-hydroxyindoleacetic acid (5-HIAA), major metabolites of dopamine (DA) and serotonin (5-HT), in cervical, thoracic and lumbar spinal segments of male Sprague-Dawley rats. Changes in 3-methoxy-4-hydroxyhenylathylene glycol sulfate (MOPEC-SO<sub>4</sub>), the major norepinephrine (NE) metabolite, were measured in the spinal cord after periaqueductal gray (PAC) injections of morphine as well as in the limbic system and cortex following IT morphine injections. Analgesia (tailflick latency) was 89 ± 1.4% of maximal 15 min. after 5µg IT morphine and this effect was maintained for at least an hour. This dose also produced significant (p <0.01) increases in cervical, thoracic and lumbar HVA and DOPAC which peaked 15 min. after injection and returned to control levels by 60 min. A significant (p <0.01) increase in cervical and lumbar 5-HIAA was also maximal at 15 min. In addition, IT morphine (5µg) elicited significant (p <0.01) increases in spinal MOPEG-SO, at 30 min. After injection. The increases in spinal and brain NE metabolism occurred in conjunction with significant analgesic effects and were antagonized by pretreatment (10 min.) with intraperitoneal naloxone (1mg/kg). Thus, interactions between spinal DA, 5-HT and NE systems may be involved in the mediation of opiate analgesia and both spinal and supraspinal mechanisms may contribute regardless of the initial site of opiate receptor activation. 82.3 CHANGES IN LOCOMOTOR ACTIVITY AND IN THE DISCHARGE RATES OF MIDBRAIN DOPAMINE NEURONS WITH REPEATED ADMINISTRATIONS OF LOW DOSES OF MORPHINE. <u>N.L. Ostrowski, I. Paul\*, M. Drnach\* and A.R.</u> <u>Caggiula</u>. Psychobiology Program, Psychology Department, University of Pittsburgh, Pittsburgh, PA 15260.

<u>Caggiula</u>. Psychobiology Program, Psychology Department, University of Pittsburgh, Pittsburgh, PA 15260. We previously reported (Soc. Neurosci. Abstr., vol. 8, p. 230, 1982) that 10 ug/kg of morphine (IV) increased locomotor activity in awake rats, increased the discharge rates of putative Type A dopamine neurons in the midbrain within the same time period, and, produced a long-lasting suppression of discharge rates in a population of Type B dopamine neurons.

Here, we report that morphine (10 and 200 ug/kg, IV) produces a dose-dependent increase in locomotor activity in rats, and that pre-treatment with 0.1 mg/kg of naloxone antagonizes this increase. Similarly, in electrophysiological tests in chloral hydrate anesthetized male rats, the same doses increased the discharge rates of Type A neurons and suppressed firing rates in Type B cells. While the morphine-produced increase in Type A cell firing rates was antagonized suppression of Type B neurons was not.

Across four consecutive days of morphine administration, the increases in locomotor activity during the first 10 min after drug delivery remained stable. Over repeated tests, however, morphine-treated rats showed a progressive increase in locomotor activity and stereotyped gnawing throughout the 30 min test sessions.

In electrophysiological experiments, the responses of Type A neurons to IV morphine did not change after 5 days of repeated administrations. However, the morphine-produced suppression of Type B neurons in rats previously exposed to morphine were of shorter durations than in animals receiving morphine for the first time. Specifically, Type B neurons recovered firing rates within 30 min of drug delivery and these neurons demonstrated an oscillatory pattern of discharge. These data support the idea that dopamine subsystems in the

These data support the idea that dopamine subsystems in the substantia nigra pars compacta show differential responses to acute and repeated administrations of morphine.

82.5 OPIATE SUBSTANCE RELEASED BY A WALKER-256 (W-256) DERIVED TUMOR. G.K.W. Yim, K.M. Johnson,\* M.T. Lowy,\* and P.V. Malven, Dept. of Pharmacology & Toxicology, Sch. of Pharmacy and Pharmacal Sci. and Dept. of Animal Sci., Purdue University, W. Lafayette, IN 47907.

The similarity in the feeding deficits of W-256 tumor bearing rats (TBR) and of rats treated with opiate antagonists or dexamethasone (to deplete pituitary  $\beta$ -endorphin) suggested that tumor-induced anorexia might result from depleted endogenous opioids(EO) (Neural Basis of Feeding and Reward, B. Hoebl and D. Novin, eds., p. 485, 1982). Since a depletion of EO might be expected to cause hyperalgesia, pain sensitivity (tail-flick) was tested in Sprague Dawley rats bearing Walker 256 carcinosarcoma which had been maintained in this laboratory for two years. Rather than hyperalgesia, we observed significant analgesia in TBR compared to controls. The degree of analgesia increased with tumor size, and was reduced by 1 mg/kg naloxone. Acid-ethanol extracts of the tumor, when injected i.c.v. in mice, also elevated tail-flick responses and induced Straub tail responses. Both responses were blocked by naloxone. Immunoreactive  $\beta$ -endorphin was not detected in tumor extracts nor was it elevated in plasma of anlagetic TBR. When new W-256 tumors were acquired from Mason Res. Inst., the significant tailflick analgesia was not observed. In summary, these results document the secretion by a secondary W-256 tumor line of a potent EO capable of causing analgesia. (Supported in part by grants from the Amer. Cancer Soc., IN #194, and the Elsa Pardee Fdn.)

- 82.4 MU AND KAPPA OPIOID MECHANISMS IN RAT AND TOAD. <u>D. Aleman\*</u>, <u>K. Carr, M. Holland\* and E. Simon</u> (SPON: J. Miller). Depts. of Psychiatry and Pharmacology, New York Univ. Med. Ctr., NY 10016.
  - Psychiatry and Pharmacology, New York Univ. Med. Ctr., NY 10016. We have recently shown that the predominant opiate receptor subtype in toad brain is the benzomorphan-preferring ( $\kappa/\sigma$ ) type (Simon et. al., Life Sci. <u>31</u>:1367, 1982). By contrast, rat brain is deficient in this type but has a high proportion of the morphine-preferring ( $\mu$ ) type. To examine the relation between these biochemical findings and the behavioral pharmacology of opioids we compared analgesic effects of a benzomorphan (<sup>±</sup>)ethylketocyclazocine (EKC), and morphine sulfate (MS) in rat and toad. Threshold intensity of footshock (200 msec) to elicit a loco-

Threshold intensity of footshock (200 msec) to elicit a locomotor response was determined using the method of limits. Animals were then injected (s.c.) with EKC, MS, or vehicle. Thresholds were retested 30 min later. In rat, EKC and MS elevated threshold in a dose-related manner, though EKC was 6 times as potent. Naloxone was used to evaluate whether EKC and MS analgesia are mediated by different receptor types because, in <u>vitro</u>, agonists are displaced from the  $\mu$  receptor by 4-8 fold lower concentrations than from the  $\kappa$  receptor. Separate groups of rats received EKC (1.5 mg/kg) or an equi-analgesic dose of MS (10.0 mg/kg) preceded by saline or one of four doses of naloxone (0.05-0.5 mg/kg). EKC and MS analgesia showed similar reductions as a function of naloxone dose, suggesting that EKC analgesia results from activity at the  $\mu$  receptor. A unique behavioral effect of EKC, though, was a flaccid paralysis at doses greater than 2.0 mg/kg. In toad, doses of EKC up to 50.0 mg/kg had no effect on response to footshock. Higher doses produced a flaccid paralysis as was ob-

In toad, doses of EKC up to 50.0 mg/kg had no effect on response to footshock. Higher doses produced a flaccid paralysis as was observed in rats. MS in the toad elevated threshold with no signs of motor impairment, but doses of 100.0-200.0 mg/kg were required. MS analgesia in toad is blocked by pre-treatment with naloxone (5.0 mg/kg) and is therefore receptor-mediated. The findings that EKC and MS analgesia are equi-sensitive to

The findings that EKC and MS analgesia are equi-sensitive to naloxone antagonism in rat, and that EKC at sub-paralytic doses fails to produce analgesia in toad while MS does, suggests that in both animals the locomotor response to footshock is modified by opioid activity at the preceptor.

The observation that MS is 20 times less potent (analgesia) and EKC 30 times less potent (flaccidity) in toad than rat does not seem due to differential distribution or blood-brain barrier permeability to these compounds; rats and toads were injected (s.c.) with EKC (2.0 mg/kg) containing 30  $\mu$ Ci <sup>3</sup>H-EKC/kg and sacrificed at 30 min. Brains were removed and solubilized. In both animals, approximately 500 cpm/100 mg tissue were recovered, indicating that uptake into brain is similar. The possibility that these compounds are metabolized differently or have different levels of specific binding in rat and toad brain will be discussed. (Supported by NYS HRC Award 12-073 (K.C.) and NIDA grant DA-00017 (E.S.).

82.6 RX-336W, AN EXPERIMENTAL CODEIONE, HAS CPIATE ANTAGONISTIC EFFECT IN TESTOSTERONE-TREATED FEMALE RATE. <u>C-A. Hardy and R.L. Isaacson</u>. Dep't of Fsychology and Center for Neurobehavioral Sciences, SUNY-Binghamton, Binghamton, N.Y. 13901. RX-336W, an experimental codeione with morphine-like effector here there the meduce are roleted behaviored.

RX-336W, an experimental codeione with morphine-like effects has been shown to produce sex-related behavioral effects in periadolescent rats (age: 40 days of age). In general, the drug effects are greater in young male than in young female rats. The present study was designed to asses the possible contribution that testosterone may have on the opiate-related effects of RX-366W. Female Long-Evans rats, 33 days of age at the start of the study, received daily subcutaneous injections of either 1mg testosterone benzoate in .2ml oil or .2ml of the oil vehicle for 8 days. At 40 days of age each animal received either an IP injection of 6 mg/kg/ml RX-336W or the volume equivalent of the saline vehicle. Immediately after injection each animal was placed in a plexiglass observation chamber and during the next 40 min behaviors were recorded every 15 sec. The behaviors scored included locomotion, rearing, grooming, and scratching. "Wet-dog shakes" were scored independent of the 15 sec observation time interval. The following day the testing procedure was repeated with each animal receiving the opposite treatment (i.e. RX-336W had no significant behavioral effects in the oil-treated female rats. However, in the testosterone-treated females RX-336W significantly increased grooming and "wet-dog shakes". Additionally, following RX-336W here was a tendency for decreased locomotion and increased scratching in testosteronetreated females. In conclusion, the present findings suggest a role of the sexual hormones in the opiatelike effects of RX-336W.

IN VIVO AUTORADIOGRAPHY: VISUALIZATION OF CHANGES IN OPIATE 82.7 RECEPTOR OCCUPANCY DUE TO BEHAVIORAL MANIPULATIONS. T.F. Seeger, Biological C.B. Pert and A. Pert (sponsored by R.U. Esposito). Biol Psychiatry Branch and Clinical Neuroscience Branch, NIMH, Bethesda, MD 20205

A method of in vivo autoradiography was utilized which allows the indirect visualization of functional opiate peptide release, based on the assumption that prior receptor occupation will exclude the binding of an exogenously applied, tritium-labelled, opiate ligand. Coupled with tritium-sensitive film autoradio-graphy, it allows the mapping of relative levels of behaviorspecific receptor occupancy throughout the whole brain.

We tested two types of stress manipulations which are known to release endorphins; forced swims in cold water (4°C for 3.5 min.), and prolonged intermittent footshock (1 ma. for 20 min., 1 sec. on, 5 sec. off). Both of these have been shown to Following the stress, the high affinity opiate antagonist, 3H-diprenorphine was injected via an indwelling jugular catheter (50  $\mu$ Ci/kg, 0.002 mg/kg). After twenty minutes (to allow washout from non-specific sites), the rats were decapitated and the brains frozen intact for slicing. Unstressed control rats were prepared identically and matched to stressed rats on the basis of cerebellar and liver (non-specific) binding levels. All comparisons made were between anatomically congruent sections from these matched pairs, exposed on the same sheet of film.

In the cold water swim group, this severe stress caused a greatly decreased binding to most caudal subcortical structures, while cortex, hippocampus, and more rostral structures were largely unchanged. Greatest decreases (up to 60%) were seen in brain areas such as periaqueductal gray, reticular formation, and midline-intralaminar nuclei of thalamus, reflecting opiate peptide release in areas which receive and modulate incoming pain information. Lesser decreases in binding were seen in hypothala mus and limbic areas such as amygdala, the bed nucleus, and pre-optic area. Motor areas of thalamus and the basal ganglia showed still smaller effects. In the footshock group, decreases were similar but less extreme. Periaqueductal gray, reticular formation, and the midline thalamic areas showed decreases of up to 30%, while limbic changes were slightly smaller. No changes unique to the footshock treatment were seen, suggesting similar opiatergic responses to painful stress of differing modalities. This in vivo autoradiographic technique holds great promise, both for the study of other behaviorally-induced changes in patterns of opiate release, and for adaptation to other neuro-

82.9 Methadone Effects on Dopamine and Serotonin Systems of C57BL/6J and DBA/2J Mice: Relationship to Locomotor Activity. <u>George E.</u> <u>Platt\* and Lawrence D. Middaugh</u>. Depts. of Biochemistry and of <u>Psychiatry</u> and <u>Behavioral</u> Sciences, Med. Univ. So. Car., Charleston, S.C., 29425.

transmitter systems.

Narcotics either elevate or reduce locomotor activity of C57BL/6J (C57) mice depending on dose and post-injection time, however, only reduce that of DBA/2J (DBA) mice. Limiting the availability of catecholamine neurotransmitter eliminates the narcotic induced activity elevation. Since morphine reportedly increases dopamine metabolism in C57 mice while having no effect or decreasing its metabolism in DBA mice, strain differences in dopaminergic systems have been hypothesized to account for the or decreasing its metabolism in DBA mice, strain differences in dopaminergic systems have been hypothesized to account for the different effects of the drug on locomotor activity. Support for this hypothesis is currently restricted to one time period after morphine injection. To test the generality of this hypothesis, we determined the effect of methadone in these two strains on dopamine metabolism at intervals after injection when locomotor activity was either elevated, reduced, or no different from controls. Since serotoninergic systems are involved in narcotic induced activity reductions in rats, we also determined the induced activity reductions in rats, we also determined the effect of methadone on metabolism of this transmitter. Activity was tested for five minutes beginning 15, 45, or 180

min. after subcutaneous injections of saline or methadone hydro-chloride (7.0 or 21.0 mg/Kg). Immediately following this test animals were decapitated and their brains removed and dissected for determination of dopamine (DA), dihydroxyphenylacetic acid (DOPAC), serotonin (5-HT), and 5-hydroxyindoleacetic acid (5-HIAA) in n. accumbens septi and neostriatum. Locomotor activity of C57 mice was elevated at early time periods by both doses, however, at later time periods was inversely related to dose. Activity of DBA mice was also inversely related to dose, however, was never elevated above control levels. Methadone elevated DOPAC concentration in the n. accumbens septi and the neostriatum of both mouse strains. The drug, however, decreased 5-HIAA concentrations in both structures of C57 mice and in neostriatum of DBA mice. Since similar changes in monoamine neostriatum of DBA mice. neostriatum of DBA mice. Since similar changes in monoamine metabolites occurred under conditions where locomotor activity was increased, decreased, or not effected, the relationship of drug induced changes in locomotor activity and monoamine metabolism appears to be quite restricted and may be only spurious.

- EFFECTS OF GLUTAMATE AND/OR BIPIPERIDYL MUSTARD TREATMENT ON 82.8
  - EFFECTS OF GLOTAMATE AND/OR BIPJPERIDYL MUSIARD IREAIMENT ON HYPOTHALAMIC PROOPIOMELANOCORTIN NEURONS, FOOD INTAKE, OBESITY INDEX AND BLOOD INSULIN. A.C.Scallet and J.W.Olney, Washington Univ Sch Med, Dept Pathology & Psychiatry, St. Louis, MO. 63110 Glutamate (Glu) produces neurotoxic lesions of areas immedi-ted with the second sec ately adjacent to circumventricular organs, particularly the arcuate hypothalamus (AH). Bipiperidyl mustard (BPM) produces a lesion straddling the border between AH and the ventromedial hypothalamus (VMH). Rats treated neonatally with subcutaneous nypothalamus (VMH). Kats treated neonatally with subcutaneous Glu or saline, received a subsequent intraperitoneal injection of BPM or vehicle as weanlings. Groups of such rats consisting of Glu alone, BPM alone, Glu/BPM, or controls were observed developmentally for linear growth, weight gain, food intake and plasma insulin. At 32 weeks of age some rats received intraplasma insurin. At 32 weeks of age some rats received incra-ventricular injections of colchicine and were sacrificed 48 hr later for immunohistochemical evaluation of the AH for loss of proopiomelanocortin (POMC) neurons employing an antibody to a-melanocyte stimulating hormone. There was a 77%, 70% and 92% loss of POMC neurons from the rostral 3/4 of AH in rats treated Note of PUMC neurons from the rostral 3/4 of AH in rats treated with Glu, BPM and Glu/BPM, respectively. The Glu/BPM lesion differed from the Glu lesion in deleting a larger number of POMC neurons from the lateral margins of AH. No treatment appreciably reduced the number of POMC neurons in the posterior 1/4 of the nucleus.

Glu but not BPM produced elevated fasting levels of plasma insulin (p<.01) and Glu but not BPM rats became obese as defined by elevated Lee Index scores, although both groups had lowered food intakes consistent with their shortened body statures. A subgroup of the Glu/BPM-treated rats became extremely obese and had elevated food intakes despite insulin levels no greater than for Glu alone rats. Thus hyperinsulinemia correlates with the Tor Glu alone rats. Inus hyperinsulinemia correlates with the normophagic obesity observed in Glu-treated rats but not with the more extreme hyperphagic obesity in some Glu/BPM rats which presumably stems from increased loss of neurons at the lateral border of AH. Supported in part by NIH Grants ESO7066, DA00259 and RSA MH38894 (JWO).

82.10 CHANGES IN BRAIN GLUCOSE UTILIZATION AFTER AN INJECTION OF MOR-CHANGES IN BRAIN GLUCOSE UTILIZATION AFTER AN INCLOSE PHINE OR EXPOSURE TO IONIZING RADIATION. G. Andrew Mickley, Karen E. Stevens, Gerald A. White\* and Gregory L. Gibbs\*. Depa ment of Behavioral Sciences and Leadership, USAF Academy, CO 80840 and Penrose Cancer Hospital, Colorado Springs, CO 80903. When C57BL/6J mice are exposed to ionizing radiation they ex

When C57BL/6J mice are exposed to ionizing radiation they ex-hibit a naloxone-reversible locomotor hyperactivity which is simi-lar to that observed after an injection of morphine (Mickley et. al. <u>Soc. Neurosci. Abstr.</u>, 7:166,1981). This finding, along with others, (Mickley et.al. <u>Rad. Res.</u> 93:381-387,1983) suggests that endogenous opiates may be involved in radiogenic behavioral change. The present study used the [<sup>14</sup>C] Deoxyglucose (<sup>14</sup>C-DC) method (Sokoloff et.al. <u>J. Neurochem.</u>, 28:897-916,1977) to analyze glucose utilization in the brains of both morphine-injected and irrediated rice. irradiated mice

Male C57BL/6J mice received an i.p. injection of 30mg/kg morphine sulfate or saline followed, 15 minutes later, by an i.p. injection of  $15\mu$ ci of 14C-DG. These subjects moved freely in their home cages for 45 minutes and were then sacrificed. Other mice were treated as just described but, after the morphine or saline treatment, they received an injection of gallamine(14mg/kg, i.p.) which inhibited their locomotion. Additional <sup>14</sup>C-DG-injected subjects were exposed to 1500 rads <sup>60</sup>Co or sham irradiated. After irradiation/sham half of these mice were permitted to move freely in their home cages while activity of the remaining animals was inhibited by an injection of gallamine. Brains were removed and treated as described by Sokaloff et.al. The density of brain

radiographs and standards were analyzed photometrically. Morphine enhanced glucose utilization in many brain areas. compared to controls, the radiographs of morphine-injected brains reflected significantly higher (p<.05, ANOVA) energy metabolism in the Nucleus Accumbens, Lateral Septum, Medial Caudate and several sites in the cerebral cortex. These increases were not dependent on the behavior of the mouse since akinetic (gallamine-injected) subjects showed similar (albeit reduced) effects. These data agree with others which implicate portions of the basil ganglia and limbic system as locii of morphines' central actions (Olivero. Br. Res., 83:135-141,1975; Teitelbaum et.al. J. Comp. Physiol. Psychol. 93:745-751,1979;Ebel et.al. Neuropharm.19:423-427,1980).

Although the effect was less dramatic, exposure to ionizing ra-diation also produced significant changes in the Nucleus Accum-beus, Lateral Septum and Medial Caudate. However, irradiation <u>de</u>creased (p<.05) glucose utilization in these areas. The data suggest that although both morphine and ionizing radiation may effect similar areas of the brain morphine activates these areas while 60Co inhibits energy metabolism.

82.11 ANATOMICAL, PHARMACOLOGICAL AND PHENOMENOLOGICAL CHARACTERISTICS OF MORPHINE-INDUCED CIRCLING ELICITED FROM THE VENTRAL MESENCEPH-ALON. L.J. Holmes\*, M.A. Bozarth and R.A Wise. Center for Research in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec.

cordia University, Montreal, Quebec. Crystalline morphine applied unilaterally throughout the vent-ral mesencephalon induced circling directed contralateral to the side of injection. Circling was seen after morphine application to either the ventral tegmental area or the zona compacta of the substantia nigra, however latency was shorter and rates higher following ventral tegmental stimulation. When morphine-induced circlers were placed in an open field they consistently followed the perimeter of the enclosure in a contralateral direction; the radius of the circle was determined by the size of the enclosure. Morphine induced little postural asymmetry and induced forward locomotion in all four limbs. The opiate receptor antagonists naltrexone and naloxone blocked morphine-induced circling whether given before or during the sessions. Pimoride pretrament also blocked morphine-induced circling. Thus circling following uni-lateral morphine application was dependent on both an opiate receptor mechanism and dopaminergic circuitry. In contrast to morphine-induced circling, unilateral application of muscimol at the same sites resulted in more circumscribed contralateral circling that was resistant to dopamine receptor blockade. Muscimolinduced circling was qualitatively different from morphine-induced circling. Rather than travelling over the entire test area, mus-cimol-treated animals maintained a relatively fixed position within either the small test box or the large open field, circling with a diameter of travel on the order of 12 cm. In this case, the hind limb contralateral to the side of injection was engaged in backward stepping movements while the hind limb ipsilateral to the side of injection served as a pivot. A strong postural asymmetry accompanied muscimol-induced circling. These studies demonstrate that two midbrain mechanisms can

These studies demonstrate that two midbrain mechanisms can mediate circling. Morphine-induced circling results from dopaminergic activation and results in behavior that is compatible with forward locomotion. In contrast, muscimol-induced circling activates a mechanism that is independent of, or efferent to, the dopamine pathways and appears incompatible with simple forward locomotion. Muscimol-induced circling, unlike that induced by morphine, appears relatively independent of environmental objects and events. 82.12 AN ENKEPHALIN SYSTEM IN THE CHICK RETINA:

1. PRODUCTION AND CHARACTERIZATION OF MONOCLONAL ANTIBODIES; ENKEPHALIN CONTENT AND IMMUNOCYTOCHEMICAL LOCALIZATION. <u>C. Watt\*</u>, <u>D. Tavella\*</u>, Y.Y.T. Su, Y.W. Peng\* and D.M.K. Lam. Clayton Foundation for Research, Houston and Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030.

Foundation for Research, Houston and Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030. We have produced and affinity-purified monoclonal antibodies against enkephalins (Tyr-Gly-Gly-Phe-Met and Tyr-Gly-Gly-Phe-Leu) using ovalalbumin-conjugated enkephalins, binding only slightly with Gly-Gly-Phe-Met and not at all with Tyr-Gly-Gly-Phe-Met-Arg (dynorphin), Tyr-Gly-Gly-Phe-Met-Arg-Phe or Tyr-Gly-Gly-Phe-Met-Arg (dynorphin), Tyr-Gly-Gly-Phe-Met-Arg-Phe or Tyr-Gly-Gly-Phe-Met-Arg-Gly-Leu. These results indicate the absolute requirement of a free carboxyl terminal in position 5 for binding of our monoclonal antibodies. We have used these as well as polyclonal antibodies for biochemical and immunocytochemical studies of putative enkephalinergic pathways in the chick retina.

Immunochemical assays demonstrate that the concentration of enkephalin-like immunoreactivity is about 0.2  $\mu$ M in this retina. At the light microscope level, enkephalin-immunoreactive cells are localized to a subpopulation of amacrine cells with somas in the proximal half of the inner nuclear layer and processes ramifying in sublaminas 1, 3-5 of the inner plexiform layer. This result agrees well with the findings of Brecha and others. Additionally, all our monoclonal antibodies against enkephalins stain the same americe cells as the polyclonal antibodies.

stain the same amacrine cells as the polyclonal antibodies. At the ultrastructural level, the processes of enkephalinimmunoreactive amacrine cells are found to receive input from bipolar and other amacrine cells. Immunolabeled varicosities form conventional synaptic contacts onto other vesicle-filled profiles tentatively identified as amacrine cell varicosities. Bipolar cell terminals are not found to receive synaptic input from stained varicosities of enkephalin-immunoreactive amacrine cells. Moreover, all of the above synaptic relationships were identified in each of sublamina 1, 3-5 of the inner plexiform layer. Lastly, large enkephalin-immunoreactive varicosities often contain a number of large dense core vesicles in addition to small agranular vesicles.

We thank Professor W.M. Cowan of the Salk Institute for his valuable advice and collaboration in this project.

82.13 AN ENKEPHALIN SYSTEM IN THE CHICK RETINA:

AN ENKEMALLY SIGLEM IN THE CHARMENT RELING. 2. BIOSYNTHESIS, RELEASE AND PHYSICLOGICAL STUDIES. Y.Y.T. Su and D.M.K. Lam. Clayton Foundation for Research, Houston and Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030.

Enkephalin-like immunoreactivity has been localized immunocytochemically to subpopulations of amacrine cells in both mammalian and nonmammalian retinas (Brecha et al. 1979; Stell et al. 1981; Altschuler et al. 1982). However, the localization of enkephalinlike immunoreactivity alone is clearly not sufficient to demonstrate that enkephalins are present in these neurons. In this report we present direct evidence that in the chick retina, Met<sup>5</sup>enkephalin is synthesized and released, and that exogenously applied enkephalins influence the release of certain retinal transmitters.

Isolated chick retinas were incubated in 0.2 ml of oxygenated (95%  $0_2$  and 5%  $C0_2$ ) Ringer's solution containing 40µCl of 3H-methionine and the peptidase inhibitor, trasylol, for 30 min. The tissue was rinsed three times in large volume of Ringer's solution containing trasylol and incubated in the same unlabeled solution for at least another hour. The products synthesized in the tissue were extracted in acetic acid and assayed by high performance liquid chromatography (HPLC) and immunochemical assays. In addition to Met5-enkephalin (35%), Gly-GLy-Phe-Met (12%) and Argl-Met5-enkephalin (3%) were also detected.

(12%) and Arg-Meto-enkephalin (5%) were also detected. High external K<sup>+</sup> induced <sup>3</sup>H-labeled compounds release from the labeled tissue was observed. On HPLC, the eluates contained all three Met<sup>5</sup>-enkephalin related compounds with Met<sup>5</sup>-enkephalin as the major component (95%). In the presence of 6 mM Co<sup>+2</sup>, K<sup>+</sup>-stimulated release of Met<sup>5</sup>-enkephalin was significantly inhibited, indicating that the release may be Ca<sup>+2</sup> dependent. The relationship hotpuon packobaling and taber pupurtrangittant

The relationship between enkephalins and other neurotransmitter systems were also studied. Our results show that exogenous enkephalins inhibit the  $K^+$ -stimulated release of GABA and dopamine from the chick retina and may therefore function as a presynaptic modulator to both GABAergic and dopaminergic amacrine cells.

- MOTOR EVOKED POTENTIALS VIA TRANSCRANIAL CORTEX STIMU-LATION IN CAT AND MAN. W. J. Levy, M. <u>McCaffrey\*</u>, D. H. York. Neurosurgery Div., Univ. of Mo. Sch.of Med., Columbia, MO. 63212. Evoked potentials are increasingly important in testing of the central 83.1
  - nervous system for injury. However, until now they have tested only sensory systems (visual, auditory, somatosensory). We have developed and sensory systems (visual, auditory, somatosensory). We have developed and reported a motor evoked potential based on one of two stimulation methods. During spinal cord surgery the cord is stimulated directly by placing an electrode directly on it between the intermediolateral sulcus and the dentate ligament. This stimulates the underlying motor tracts and can produce distal limb movement. The second method is non-invasive. A 3x5 cm plate is placed on the scalp over the motor cortex. Stimulation between this plate and one held against the hard plate will direct a mild current (3-15 m A, 500-1000 sec) through the cortex and produce an evoked potential in the spinal cord. This can be detected by skin recording or, more effectively, by deep or dural electrodes. This signal has the same properties as that described in the experimental literature on stimulation of the exposed motor cortex and can produce contralateral limb movement. In cats we have found with lesioning and depth electrode studies that the signal is primarily in the pyramidaldepth electrode studies that the signal is primarily in the pyramidal-rubrospinal area with some component in the anterior cord near small motor tracts there. This work has extended to man where we found a motor tracts there. This work has extended to man where we found a similar wave. It correlates in clinical conditions better with motor function than the somatosensory evoked potential. On 60 cases to date no adverse effects have occurred and patients tolerance is good. We are continuing to evaluate his test. It offers the possibility of testing the motor pathways of cortex, brainstem and spinal cord for injury. The production of movement (detected by EMG or peripheral nerve recording) could assess functional capabilities as well as electrical continuity. The recording of cranial nerve signals could aid in localizing brainstem lesions. Further more this test could aid development of investigative and therapeutic efforts for spinal cord injury. We report new experimental data on the basis of this test and supporting clinical observations.

83.3 FACTORS AFFECTING ATONIA PRODUCED BY ELECTRICAL STIMULATION OF THE MEDIAL MEDULLA IN CATS. W.J. Wilson, J.M. Siegel, K.S. Tomaszew-Ski<u>j</u> and <u>R. Nienhuis</u>\*. Sepulveda VAMC, Sepulveda, CA 91343, and Dept. of Psychiatry, School of Medicine, University of California, Los Angeles, CA 90024.

Magoun first identified a large medial medullary region which when stimulated produced nonreciprocal inhibition of muscle tone. Later studies by Sprague, Gernandt, and others disputed this con-clusion, contending that the predominant effect of medullary stimulation was excitation, or reciprocal inhibition and excitation of muscle groups. The nature of the medullary inhibition mechanism has generated increasing interest because of its presumed role in the atonia of REM sleep and narcolepsy. In the present series of experiments, we have seen both cats in which medullary stimulation generates bilateral inhibition of muscle tone, and cats in which the stimulation generates only excitation or reciprocal changes in muscle tone. We find that transection level is the variable most

strongly correlated with the amount of inhibition. Sixteen adult mongrel cats of both sexes received brainstem transections at varying levels from P 6.5 to A 8. After aspiration of the medial cerebellum, the medial medulla was stimulated electrically via a stereotaxically mounted electrode passed through at least 6 tracks in each cat, and the effects of the stimulation on the splenius muscles were noted. The proportion of sites yielding from 0 to .78. Some cats showed small amounts of bilateral inhi-bition even after transections at the lowest levels. The best predictor of the number of inhibitory sites was the transection level: r = .58, p<.05. Of various physiological variables recorded, none was correlated with the amount of inhibition observed: heart rate, r = -.01; respiration rate, r = .23; percent expired  $CO_2$ , r =-.01; blood pressure(n=4), r = -.40.

Although there is a large amount of variability, the data sug-gest that a region near AP 0 or A 1 contributes importantly to medullary inhibition. 7 of 8 cats with transections caudal to AP 0 showed atonia on 50% or less of the tracks tested, while all 8 cats transected rostral to A 1 showed inhibition on 50% or more of the tracks tested.

Rostral brainstem mechanisms could contribute to medullary atonia in a number of ways. Ascending pathways from the medulla to the pons and midbrain might be involved in a positive feedback loop the effect of which is the recruitment of medullary inhibitory neurons. Alternatively, descending projections from the rostral brainstem to medullary or spinal regions might gate interneuronal activity critical to the production of atonia.

THE VENTRAL PART OF THE CAUDAL BRAINSTEM TEGMENTIM INCLUDING THE 83.2 NUCLEUS RAPHE MAGNUS AND PALLIDUS IN THE CAT: EFFERENTS AND AFFERENTS. AN AUTORADIOGRAPHIC TRACING STUDY. Gert Holstege

AFFERENTS. AN ADDRAFHIC FRACING STOLL GET HOLSTED Linda Meiners and Kiong Tan, Dept. of Anatomy, Erasmus University Rotterdam, P.O.Box 1738, 3000 DR Rotterdam, The Netherlands. For studying the efferent connections several <sup>3</sup>H-leucine injec-tions (+ 0,5  $\mu$ L containing 50  $\mu$ Cl) were made in the ventral part of the medial tegmentum of the caudal brainstem. For studying the afferent connections many other injections were made in parts of the central nervous system.

 Efferent connections (rostralwards). The nucleus raphe magnus (NRM) and adjoining tegmentum at levels of caudal pons and upper medulla distribute fibers to the PAG, mesencephalic tegmentum, zone incerta, the intralaminar and paraventricular thalamic nuclei, the posterior, paraventricular, lateral and anterior parts of the hypothalamus and the preoptic area. Yet, an injection in the nucleus raphe pallidus (NRP) resulted in only a very restricted projection to the PAG.

II. <u>Efferent connections (caudalwards)</u>. <u>Injections in the caudal pontine medial tegmentum including</u> the rostral NRM distributes fibers to the medullary lateral and medial tegmentum, the solitary and dorsal vagal nuclei and all parts of the spinal dorsal horn and intermediate zone. After injections in the upper medullary medial tegmentum including the caudal NRM the same distribution pattern in the caudal brainstem areas could be observed but in addition labeled fibers were present in the marginal layer of the caudal trigeminal nucleus. In the spinal cord labeled fibers were distributed to laminae I and II the spinal cord labeled fibers were distributed to laminae 1 and 1 of the dorsal horn, the intermediate zone and the intermedio-lateral cell column at the thoracolumbar and sacral levels. In contrast, after injections in the NRP and in the medial tegmentum at the level of the inferior olive, labeled fibers were distri-buted to the brainstem motor nuclei V, VII and XII and to the intermediate gene and entermine and correction retoreversel areas intermediate zone and autonomic and somatic motoneuronal areas throughout the spinal cord.

III. Afferent connections. The NRP received afferents from the dorsomedial hypothalamic area, the tegmentum just caudal to the red nucleus, the PAG and the medullary lateral tegmentum at the level of the rostral pole of the hypoglossal nucleus. The NRM and the adjoining caudal pontine and medullary tegmentum received afferents from these same areas but also from the lateral hypothalamus, the dorsal and lateral PAG, the nucleus subcoeruleus and the lateral pontine tegmentum. The lateral tegmentum of caudal pons and medulla did not distribute fibers to this area. These results suggest that afferents to the ventral part of the medullary and caudal pontine medial tegmentum are mainly derived from limbic brain structures.

THE NUCLEUS TEGMENTT PEDUNCULOPONTINUS PARS COMPACTA IN THE BAT: ORGANIZATION, EFFERENT PROJECTIONS AND CHOLINERGIC ASPECTS.

T. Sugimoto and T. Hattori. Dept. Anat., Fac. Med., Univ. Toronto, Med. Sci. Bldg., Toronto, Ontario M5S 1A8 Canada. The cellular organization and efferent projections of nucleus tegmenti pedunculopontinus pars compacta (TPC) were examined in the rat. From measurements of Nissl-stained TPC sections, three neuronal populations (large, medium and small neuron groups) were seen in the TPC. Although large neurons were the least encountered population, they are occupancy rate apparently contributed to compact appearance of the nucleus. 3H-leucine injections into the TPC produced transported label in dorsally and ventrally coursing ascending fibers. The dorsally coursing fibers terminated in the centrolateral nucleus (CL) and centre median-parafascicular complex (CM-Pf) of the thalamus. The median-parafascicular complex (CM-Pf) of the thalamus. The ventrally coursing fibers formed apparent terminal fields in the substantia nigra pars compacta (SNc) and subthalamic nucleus (STN), and less significantly in the ventral tegmental area, lateral hypothalamus and zona incerta. Much less anterograde labeling was seen in the equivalent terminal sites contralateral to the injection. The contralateral thalamus was innervated by crossed TPC fibers through the posterior commissure and thalamic midline nuclei. The ventrally coursing TPC fibers crossed through the supraoptic commissure of Meinert and then descended Lurougn the supraoptic commissure of Meinert and then descended to reach the contralateral basal ganglia. Terminal sites of TPC axons in the SNc, STN, CL and CM-Pf were examined by EM auto-radiography in rats injected with 3H-leucine in the TPC and later injected with HRP in the ipsilateral striopallidum. Statistical data showed preferential radiolabeling of asymmetrical terminals in the CL, CM-Pf and STN. Termination in the SNc was not supported by this analysis. In the CL and CM-Pf, asymmetrical radiolabeled terminals making synaptic contact with HRP-labeled dendrites verified direct TPC inputs to the striatal projection neurons. 3H-choline injections in the thalamus and STN produced retrograde perikaryal labeling of large TPC neurons; these neurons remained unlabeled after 3H-choline injections in the SN. The result strongly suggests the choliner-gic nature of TPC-thalamic and TPC-STN projections. Large TPC neurons are responsible for this cholinergic innervation and probably provide the axon terminals of asymmetrical type in these target nuclei. # 83.5

BENEFICIAL EFFECT OF MEGADOSE METHYLPREDNISOLONE ON POST-INJURY SPINAL CORD ISCHEMIA. D.L.Wolf and E.D.Hall, CNS Research, The Upjohn Company, Kalamazoo, MI 49001. Previous work demonstrated that a single large 30 mg/kg i.v. dose of methylprednisolone (MP) sodium succinate (Solu-MedrolR'), administered 30 min after injury, decreased free radical-induced lipid peroxidation and increased (Na<sup>+</sup>+K<sup>+</sup>)-ATPase activity in the acutely contused cat spinal cord (Hall and Braughler, J. Neurosurg. <u>57</u>:247, 1982). The present study has investigated the effects of MP given 30 min after injury on local spinal cord blow (SCBF) and somatosensory evoked potential (SEP) conduction. conduction.

A 500 gm-cm (50 gm dropped 10 cm) contusion was applied to the exposed L3 spinal segment (dura intact) of Na pentobarbital anesthetized cats. At various times before and after injury, SEP conduction was monitored and SCBF determinations were made in the dorsolateral funiculus using the hydrogen clearance method. Blood flow values (ml/100 g/min) were derived from the exponential slope of the initial 10 min of the hydrogen washout curve. Four animals received a 30 mg/lm min of the hydrogen washout curve. Four animals received a 30 mg/kg i.v. bolus of MP at 30 min after spinal contusion while another 4 cats

i.v. bolus of MP at 30 min after spinal contusion while another 4 cats received an equivalent vehicle injection. The mean pre-injury SCBF values for all animals was  $12.33\pm1.04$  (S.E.) ml/100 g/min. Following injury, SCBF within the injured segment was reduced approximately 40% in vehicle-treated cats by 1 hr and remained at that level over the subsequent 4 hr (table). In contrast, MP administration at 30 min significantly prevented the fall in SCBF (p<0.001 by ANOVA, F=103, df=1,6). Nevertheless, SEP conduction, which was completely lost upon injury, never returned in either group over the ensuing 4.5 hr. Administration of the MP dose at 4.5 hr in vehicle-treated cats did not affect the depressed SCBF over the subsequent 30 min. subsequent 30 min.

Mean (±S.E.) SCBF in White Matter (ml/100g/min)

		Hours After Injury					
Pre-Injury		0.5	1	2	3	4	
Ŷ	11.57	7.08	6.15	6.25	6.78	6,95	
	(2.60)	(1.33)	(0.83)	(0.88)	(0.83)	(0.81)	
MP	13.09	11.68	12.75	12.90	13.80	13.55	
	(1.71)	(1.85)	(1.29)	(2.20)	(2.32)	(2.65)	

These results confirm the work of others (Young <u>et al.</u>, J. Neurosurg. <u>57</u>:667, 1982) in demonstrating the efficacy of the 30 mg/kg MP dose, if given early, to prevent post-traumatic spinal cord ischemia. Maintenance of SCBF may be important in attenuating the secondary hypoxiarelated degenerative changes which occur following spinal cord injury.

83.7 THE TERMINATIONS OF CORTICOSPINAL TRACT AXONS IN THE MACAQUE MONKEY. <u>Diane D. Ralston\*, Henry J. Ralston III and Robert</u> <u>E.W. Fyffe\*</u> Dept. of Anatomy, University of California, School of Medicine, San Francisco, CA 94143 and Depts. of Anatomy and Physiology, University of North Carolina, Chapel Hill, NC 27214 27514

of Medicine, San Francisco, CA 94143 and Depts. of Anatomy and Physiology, University of North Carolina, Chapel Hill, NC 27514 The corticospinal tract (CST) projections of the motor and somatosensory cortices have been examined in monkeys using orthograde transport methods, or intraaxonal staining of single, physiologically chacacterized axons. Following injections of <sup>3</sup>H-leucine or horseradish peroxidase conjugated to wheat germ agglutinin (HRP-WGA) into either the sensory or motor cortex, terminal fields could be identified with the dominant projection to the cervical enlargement. There are more labeled large diameter axons from motor than from sensory cortex. Motor cortex projects widely to the spinal gray, from laminae V through IX, the heaviest projections being to the mid regions of laminae VI and VII. Some axons cross the midline to reach contralateral VI, VII and VIII. Sensory cortex has its chief projections to the dorsal horn, with significant numbers of terminal fibers to II (substantia gelatinosa), and a few fibers as dorsally as lamina I. Ventrally, the sensory cortex projections are dense in laminae III-VI, with some into dorsal VII. Electron microscopic autoradiography reveals a heterogenous synaptic population labeled following cortical injection. CST axons make axodendritic contacts upon dendrites of all sizes. No axosomatic or axoaxonal contacts involving CST terminals have been found. The CST synaptic profiles usually contain pleomorphic vesicles, but some contain pleomorphic vesicles, suggesting different types of transmitters being utilized. The terminals vary in size, and some in the dorsal horn make multiple contacts with postsynaptic dendrites, thus resembling the "C" type terminals of dorsal root afferents. Individual CST axons were impaled with micropipettes in the lateral column white matter at lumbar levels. Bipolar stimulus trains with fixed latency were judged to be CST axons. Intraaxonal labeling with HRP reveals that single CST axons. Intraaxonal labeling with HRP reveals that s

- ANATOMICAL EVIDENCE OF A POSSIBLE GLYCINERGIC RETICULOSPINAL PATHWAY, <u>H. Nauta and D. A. Carter</u>\*. Playfair Neuroscience Unit, Univ. of Toronto, Toronto, Ontario, Canada and Div. of Neuro-surgery, Univ. of Texas Medical Branch, Galveston, Texas 77550. 83.6
  - An autoradiographic study was carried out in rat comparing the retrograde cell labeling in the brain resulting from <u>in vivo</u> spinal cord injections of radiolabeled glycine and three other

putative transmitter substances. Following in vivo injections of  ${}^{3}$ H-glycine into the lower cervical spinal cord, retrogradely labeled cells were consistently observed in the medullary gizantocellular reticular formation (GCRF). When the spinal injection locus was predomi-nantly unilateral the labeled neurons were found predominantly contralateral in the GCRF. Injections of <sup>3</sup>H-glycine into the lumbar cord enlargement failed to produce such retrograde cell Labeling. No retrogradely labeled cells were observed in the brains of rats receiving spinal injections of either  ${}^{3}$ H-GABA or  ${}^{3}$ H-D-aspartate. However, following injections of  ${}^{3}$ H-serotonin, almost universal retrograde labeling of spinal cord afferents resulted.

Bearing in mind the many reservations to be discussed, the findings may provide anatomical evidence of a glycinergic reticulospinal pathway previously postulated on physiologic and pharmacologic grounds.

A DOUBLE LABELLING STUDY DEMONSTRATING THAT MOST SPINALLY PRO-JECTING NEURONS OF THE NUCLEUS RETICULARIS GIGANTOCELLULARIS DO NOT PROVIDE COLLATERAL INNERVATION TO THE DIENCEPHALON IN THE RAT. NOT PROVIDE COLLATERAL INNERVATION TO THE DIENCEPHALON IN THE RAT. <u>R.P. Waltzer\*</u> and <u>G.F. Martin</u>, Dept. of Anat., Coll. of Med., The Ohio State Univ., Columbus, Ohio 43210. (Spon: A.O. Humbertson) The interest of our laboratory in descending systems had led us to investigate the extent to which reticulospinal neurons provide

collateral innervation to other targets in the brain. HRP injections into either the spinal cord or diencephalon label neurons in the nucleus reticularis gigantocellularis (Gi) in the rat. the nucleus reticularis gigantocellularis (Gi) in the rat. In light of observations made from Golgi studies of the reticular formation in young animals (Scheibel, '58), it is often assumed that many spinally projecting neurons of the Gi provide collateral innervation to the diencephalon. In order to determine whether that is the case we have employed fluorescent markers in double labelling experiments. Multiple injections of True Blue (TB) were made into the cervical spinal cord of adult rats, followed oir daws later by injections of Multiple (NV) into the six days later by injections of Nuclear Yellow (NY) into the diencephalon. The latter injections were centered in the medial forebrain bundle (MFB) and adjacent areas, but also included reticular targets of the dorsal thalamus. The animals were sacrificed 24 hours or less after the second injection by intracardiac perfusion with 30% formalin in cacodylate buffer. Sections were cut at 32um on a freezing microtome and viewed with a fluorescence microscope using an excitation wavelength of 360mm. Spinally projecting neurons i.e. those containing TB, as well as neurons projecting to the MFB, which contain NY, were found inter-mingled in the Gi. Less than 3% of the neurons in the Gi were double labelled. Similar results were obtained when the NY injections were made into the midbrain reticular formation.

In a previous communication (Waltzer and Martin, Soc. for Neurosc., Abst. Vol. 8, 1982) we presented evidence that Gi neurons projecting to the spinal cord are intermixed with those projecting to the cerebellum but that few neurons provide collaterals to both targets. Such results, plus those reported herein, lead us to the hypothesis that spinally projecting neurons of the Gi (and other nuclei of the reticular formation, unpublished observations), are for the most part a separate population of cells within a nucleus which is connectionally heterogeneous. (Supported by BNS-80-08675)

THE ORIGINS AND TRAJECTORIES OF DESCENDING PATHWAYS IN THE SPINAL 83.9 CORD OF THE STINGRAY, DASYATIS SABINA. <u>C.A. Livingston, B.J.</u> <u>Williams, T.C. Ritchie and R.B. Leonard</u>. Marine Biomedical Insti-tute and the Department of Physiology & Biophysics, University of tute and the Department of ruysiology a prophysics, online, Texas Medical Branch, Galveston, Texas. Cells of origin and funicular trajectories of descending sys-

tems have been studied in vertebrates. We are interested in identifying the pathways capable of initiating locomotor activity. used a combination of whole cord HRP injections caudal to spinal lesions and small injections into the white matter. Large injections of HRP were made several segments caudal to subtotal spinal cord lesions while small injections were made by inserting an HRP Coated insect pin into the white matter. Cells were labeled in the reticular formation from the spino-

medullary junction to the rostral rhombencephalon by pathways in the dorsolateral (DLF), lateral (LF) and ventrolateral (VLF) fun-niculi. Cells of the reticulospinal system are predominantly lo-cated ipsilateral to the injections at all levels except the spinomedullary junction. Here labelled cells are located bilaterally along the midline and in the medial and lateral portions of the reticular formation. Cells labelled through the DLF are located mostly within the medial reticular formation and include many larger cells. LF pathways labeled cells within both the medial and lateral reticular formation. Injections of the VLF labeled a large reticulospinal component in the raphe as well as in the medial and lateral zones. Large cells located in the ventrolate-ral margins of the medulla are labeled through the VLF.

Injections of the DLF or LF occassionally result in labeled cells in the vestibular complex. With involvement of more ventral pathways, larger numbers of vestibulospinal cells are found in the ipsilateral magnocellular vestibular nucleus. With larger injec-tions involving portions of the ventral gray matter, cells located medially within this nucleus are labeled. These cells may be projecting through the ventromedial portions of the cord. A band of cells extending across the base of the cerebellar peduncle is observed following large ventral injections. This may also be a vestibulospinal component.

In the caudalmost portions of the mesencephalon cells wer occassionally observed along the lateral boundary of the PAG following DLF injections. Ventral pathways labeled occassional cells in the tegmentum of the caudal mesencephalon. A contralateral Tubrospinal pathway can be demonstrated projecting through the DLF. Injections of either the DLF or VLF labeled cells of the interstiliospinal pathway. These were located predominantly on the ipsilateral side. Labeled cells are only rarely observed the tectum following spinal cord injections of HRP. Supported by grant NS11255.

83.11 EFFECT OF SARIN AND SOMAN ON SPINAL REFLEXES IN THE CAT. <u>Qin Zhao</u> EFFECT OF SARIN AND SOMAN ON SPINAL REFLEXES IN THE CAT. <u>Qin Zhao</u> Yang and Jordan E. Warnick. Dept. of Pharmacol. & Exp. Ther., Univ. of Maryland School of Medicine., Baltimore, MD 21201. The effects of sarin and soman were investigated on spinal reflexes of cats anesthetized with orchloralose (70 mg/kg,

reflexes of cats anesthetized with a-chloralose (70 mg/kg, i.v.). Stimulation of either the peroneal or tibial nerves evoked an afferent volley in the intact  $L_7$  dorsal root, a monosynaptic reflex (MSR) in the cut  $L_7$  ventral root and dorsal root reflex (DRR; polysynaptic reflex) in the cut  $L_6$  dorsal root. The afferent volley, MSR and DRR were each evoked at 0.2 to 10 Hz and the input/output (1/0) relationship of the MSR determined at 0.2 Hz. From 30 min to 5 hr after injection of sarin (10 µg/kg, i.v.), the MSR gradually effective in producing facilitation while the DRR decreased to 85% of control with no change in blood pressure. Sarin was equally effective in producing facilitation pressure. Sarin was equally effective in producing facilitation after high cervical ( $C_1$ ) transection as in cats with intact neuraxes. Atropine (1 mg/kg) reduced the facilitatory effect of neuraxes. Atropine (1 mg/kg) reduced the facilitatory effect of sarin in the intact cat but had little or no effect on sarin-induced facilitation of the MSR in spinal transected cats. At higher doses sarin caused hypotension and anoxia which, despite artificial respiration, led to a rapid loss of the reflexes that could be reversed with atropine. Sarin reduced the frequency-dependent depression of the MSR elicited by peroneal or tibial nerve stimulation at 0.2, 2 and 5 Hz by 20 to 24% such that the ratios of the 10th/lst potentials in the train are increased from 0.9, 0.18 and 0.03 to 1.1, 0.5 and 0.27. respectively. Changes in 0.9, 0.18 and 0.03 to 1.1, 0.5 and 0.27, respectively. Changes in the I/O relationship of the MSR with sarin suggest a possible alteration in motoneuron threshold. The plasma levels of alteration in motoneuron threshold. The plasma levels of cholinesterase after injection of sarin were reduced by 30 to 70% within 3 min and this lasted for at least 4 h. The time course and degree of inhibition of cholinesterase by sarin did not correlate with the effects on the MSR and DRR. In the intact cat, soman (5 µg/kg) depressed the MSR and DRR after a brief (< 20 min) period of potentiation. At 10 µg/kg, soman rapidly depressed the spinal reflexes but atropine (1 mg/kg) allowed gradual recovery of spinal reflexes but atropine (1 mg/kg) allowed gradual recovery of the spinal reflexes which remained smaller than (70% of) control. Atropine pretreatment (1 mg/kg) prevented the usual depressant effect of soman. The plasma levels of cholineseterase were reduced by 50% with 5  $\mu$ g/kg. Soman and sarin have different effects on the MSR which do not appear to be directly related to an inhibition of cholinesterase but the alteration induced by atropine suggests that some muscarinic component is involved in their effects. their effects. Additionally, these agents may have a direct action on neurons of the lumbar spinal cord as indicated by the persistance of sarin's effect in the transected cat. (Supported by U.S. Army Medical Research and Development Command contract DAMD17-81-C-1279.)

TRIGEMINO-HYPOGLOSSAL PROJECTIONS IN THE RAT.T.B. Boone\* and L.D. 83.10

IRIGEMINO-HTPOGLOSSAL PROJECTIONS IN THE RAT.1.B. Boone\* and L.D. Aldes\*. Dept. of Neurobiology and Anatomy, University of Texas Medical School, Houston, Texas 77025 (SPON: R. Wiggins) Secondary trigeminal afferent projections to the hypoglossal nucleus (XII) in the rat were investigated with retrograde and anterograde labeling methods. The significant finding in this study was that only the rostral trigeminal nuclear complex, con-sisting of the principal trigeminal nucleus, supratrigeminal nu-cleus and subnucleus oralis of the spinal trigeminal nucleus, was found to send avone to XII. found to send axons to XII.

Microiontophoretic injections of horseradish peroxidase Microiontophoretic injections of horseradish peroxidase into XII resulted in retrograde labeling of large neurons (35-40u) in the dorsal one-third of the principal trigeminal nucleus. The den-sity of labeling was greater in the caudal two-thirds of the nu-cleus, and labeled neurons were found equally in both medial and lateral regions. The supratrigeminal nucleus, located dorsal to the motor nucleus of V, contained small (15-20u), fusiform shaped labeled neurons. Similarly shaped, labeled neurons occasionally were seen in the reticular formation medial, lateral and ventral to the motor nucleus of V, and in two animals, a single labeled, small neuron was identified within the motor nucleus of V. Medium to the motor nucleus of V, and in two animals, a single labeled, small neuron was identified within the motor nucleus of V. Medium and small sized neurons (25-30u) were found labeled in the dorsal and rostral one-half of the subnucleus oralis. The greatest number of labeled neurons was found near the level of the exting facial nerve. In all components of the rostral triggminal complex, labeled neurons were found bilaterally, although a clear prepon-derance for ipsilateral distribution was evident.

derance for ipsilateral distribution was evident. Each of the projections observed in the retrograde labeling experiments was confirmed autoradiographically. Small microionto-phoretic injections of tritiated amino acids into the dorsal re-gions of the principal trigeminal nucleus, subnucleus oralis, and the supratrigeminal nucleus, resulted in predominately ipsilateral terminal fields within XII. The density of silver grains over XII, however, consistently was greater following injections into the supratrigeminal nucleus than into the principal trigeminal nucleus or subnucleus oralis. Additional injections into the ventral por-tion of the principal trigeminal nucleus and subnucleus oralis, as well as into the subnucleus internolaris and caudalis, did not well as into the subnucleus interpolaris and caudalis, did not result in labeling in XII. However, following a large injection into the dorsal subnucleus caudalis that included the parvicellular component of the lateral reticular formation, bilateral la-beling of XII was observed.

The significance of these projections are discussed in rela-tionship to the reflex and central control of the tongue. This research supported, in part, by NIH grant MH36814-01 and a University of Texas Biomedical Research Support Grant.

83.12 ULTRASTRUCTURAL DEMONSTRATION OF NORADRENERGIC SYNAPSES IN THE RAT SPINAL CORD BY DOPAMINE-B-HYDROXYLASE IMMUNOCYTOCHEMISTRY. Akeyson\*, M.S. Lewis\*, M.E. Molliver and R. Grzanna. of Cell Biology and Anatomy, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Noradrenergic (NA) varicosities have been demonstrated throughout the spinal cord gray matter and descending NA projections have been implicated in the control of visceral, somatomotor and sensory spinal cord functions. To understand the function of these NA projections it is necessary to identify the neuronal elements within the spinal cord which are influenced by these NA axons and to characterize the fine structure of the appositional In this study we have employed antibodies to dopamine- $\beta$ hydroxylase (DBH) to determine the ultrastructural features of NA terminals in the dorsal horn, the intermediate zone and the ven-tral horn of the rat thoracic spinal cord. DBH is a specific marker for NA neurons and their processes, but does not distin-guish them from epinephrine containing neurons. DBH varicosities toor misulized using the accounting neurons. were visualized using the peroxidase-anti-peroxidase immunocyto-chemical method with pre-embedding staining.

Light microscopic inspection reveals three regions exhibiting a high density of DBH varicosities: the outermost portion of the dorsal horn, the region containing the preganglionic sympathetic neurons and the ventral horn. All other regions of the spinal gray contain a lower density of DBH varicosities. In the ventral horn, DBH varicosities were found in close apposition to large multipolar neurons, their proximal dendrites and the surrounding neuropil.

At the ultrastructural level, DBH immunoreactive varicosities At the ultrastructural level, bbh immunoreactive valicosities are seen in the three regions described above, and inter-varicose segments are rarely stained. The diameter of DBH-positive boutons varies from 0.4  $\mu$ m to 1.9  $\mu$ m ( $\bar{x} = 0.91 \ \mu$ m ± 0.25  $\mu$ m). In indi-vidual thin sections, more than half of all DBH-positive vari-The cosities exhibit distinct synaptic membrane specializations. Th majority of contacts are axo-dendritic on medium sized dendrites and are typically asymmetric with a moderate but varied amount of post-synaptic specialization. Axo-somatic contacts are infrequent and have symmetric membrane specializations.

The finding that DBH terminals in the spinal cord make synaptic contacts indicates that NA neurons have a precisely targeted and restricted influence on spinal cord neurons via specialized and discrete junctions. Additionally, the existence of morpholog-ically heterogeneous DBH synapses in all major subdivisions of the spinal cord indicates multiple types of synaptically mediated influences of NA neurons on diverse spinal cord functions. ELECTROPHYSIOLOGICAL CHARACTERIZATION OF THE IN VITRO SPINAL CORD OF DASYATIS SABINA, AN ELASMOBRANCH FISH. <u>B.J. Williams and R.B.</u> Leonard. Marine Biomedical Institute and the Dept. of Physiol. 83.13 and Biophy., Univ. Tex. Med. Branch, Galveston, Texas.

We have been studying the spinal cord of an elasmobranch fish, the Atlantic stingray, as a comparative model of spinal cord organization. Isolated portions of the nervous system maintained in vitro have several advantages for neurophysiological analysis. We now report the development of an in vitro preparation of the stingray spinal cord. Small stingrays (15 cm fin span) were stingray spinal cord. anesthetized in tricaine methanesulfonate. The peripheral nerves innervating one pectoral fin were exposed and a laminectomy was performed. A length of spinal cord (7-10 segments) in the vertebral column, along with the peripheral nerves to one fin, was re-moved and placed in cold elasmobranch Ringer's solution. The moved and placed in cold elasmobranch kinger's solution. Ine composition of the Ringer's solutions was (in mM): 280 NaCl, 4.5 KCl, 8.5 CaCl<sub>2</sub>, 1.4 MgCl<sub>2</sub>, 25 NaHCO<sub>3</sub>, 11 glucose, containing 28g/1 urea and bubbled with 95%  $O_2$ - 5%CO<sub>2</sub>. In most experiments, most of the cord contralateral to the intact nerves was removed. After completing the dissection the cord was superfused with the same Ringer's solution and allowed to come to room temperature.

Isopotential contours were computed from signal-averaged rec-ords of field potentials which were recorded with NaCl filled electrodes and evoked by stimulation of the separated motor and sensory nerves. The evoked volleys were monitored with suction electrodes on the sensory or motor nerves close to the spinal cord. As in the in vivo preparation (Leonard, Rudomin & Willis, J. Neurophysiol., 41: 108, 1978), late negative field potentials were recorded in the substantia gelatinosa. These field poten-tials are attributed to activation of second order neurons in this area by the small myelinated fiber population in the sensory nerves. In addition, an Nl wave was recorded in the nucleus proprius, and is attributable to activation of interneurons by the proprius, and is attributable to activation of interneurons by the large myelinated sensory fibers. This field potential inverts in the ventral horn in both the  $\underline{in}$  vitro and  $\underline{in}$  vivo preparations. Antidromic stimulation of the motor nerves evokes a small negative field potential in the ventral horn with a maximum negativity at the level of the motoneuron somata. This negativity is delayed and appears rounded when the electrode is dorsal and dorsolateral to the motoneurons, which suggests electrotonic conduction along the dendritic trees. Intersegmental interactions are also viable in the isolated spinal cord. Conditioning stimuli applied to adjacent sensory nerves depress the segmental field potentials with a time course similar to the depression seen in vivo which with a time course similar to the depression seen <u>in vivo</u> which is attributed to PAD (Rudomin, Leonard & Willis, J. Neurophysiol., 41: 126, 1978). Supported by NIH grants, NS11255 and NS16093.

THE RELATIONSHIP OF THE HYPOGLOSSAL NUCLEUS AND ITS ADJACENT 83.15 ENVIRONMENT. M.H. Cooper and <u>T.G. Spangler\*</u>. Depts. of Otolaryngology and Anatomy. St. Louis Univ. Sch. of Med., St. Louis, MO. 63104.

The hypoglossal nucleus (XII Nu) and its relationship to The hypoglossal nucleus (XII Nu) and its relationship to surrounding structures has been studied in the laboratory rat (Rattus norvegicus albinus). A variety of techniques were used including the horseradish peroxidase (HRP) intraaxonal transport technique of Mesulam (J. <u>Histochem</u>. Cytochem. 26:106-117, 1978), the autoradiographic anterograde transport technique of Cowan <u>et al</u>. (Br. Res. 37:21-51, 1972), the degeneration technique of Fink and Heimer (Br. Res. 4:369-374, 1967) and the Golgi technique of Adams (<u>Stain Technol. 54</u>:225-226, 1979). Tetramethylbenzidine (TMB) was used as the chromagen for the HRP technique and tritiated leucine was used in the autoradiographic technique. tritiated leucine was used in the autoradiographic technique. The most striking feature of the XII Nu and its surrounding

environment is the intricate relationship of the XII Nu and the adjacent reticular formation (RF). This is most remarkable at the ventro-lateral aspect of the nucleus. Following an iontophoretic injection of tritiated leucine or an electrolytic lesion in the Injection of tritiated feature of an electrosyste resion at the RF either silver grains or fragments of degenerating axons were observed bilaterally in this area. Ejections or electrolytic lesions in the medial part of the RF caused the greatest amount of input to occur. This included the RF from medullary through mid-pontine levels. The amount of grains or fragments was becaution or the includer side heaviest on the ipsilateral side.

heaviest on the ipsilateral side. Following injections of HRP into the musculature of the tongue, numerous dendrites of HRP positive neurons of the XII Nu were observed to extend into the adjacent RP laterally and ventro-laterally. These dendrites extended into the same portion of the RF in which the input from the RF, previously described, was observed. Similar dendritic extension was observed in Golgi preparations.

HRP injections in the musculature of the tongue resulted in  ${\tt HRP-positive}$  neurons not only within the XII Nu, but also neurons outside the nucleus. In the area ventral and somewhat lateral to the XII Nu and possibly in one of the perihypoglossal nuclei (nucleus of Roller) large multipolar neurons were observed to be HRP-positive. Dendrites of these neurons were occasionally observed to extend into the XII Nu proper. Similar neurons including the dendritic extensions were observed in Golgi preparations. Frequently in HRP preparations an axon of one of these neurons was observed to enter fascicles of the hypoglossal nerve.

LIGHT MICROSCOPIC STUDY OF THE INFERIOR OLIVARY COMPLEX IN 83.14 NORMAL MICE AND REELER AND WEAVER MUTANT MICE. G.J. Blatt\* and L.M. Eisenman (Spon: D. Goldowitz). Daniel Baugh Institute,

Link Lisenman (spon: U. Goldowitz). Daniel baugn institute, Jefferson Medical College, Philadelphia, PA 19107. This is a preliminary report of a study of the inferior olivary complex (IO) in normal  $(+/+: +/r_1)$ , reeler  $(r_1/r_1)$  and weaver (wv/+: wv/wv) mouse strains. We have begun our analysis by looking at serial sections through the IO, cut in the coronal and parasagittal planes and stained with cresyl violet. The rostrocaudal and mediolateral extent of the inferior olive as well as the morphology of its three major subdivisions, the principal olive (PO), dorsal accessory olive (DAO) and medial accessory olive (MAO) were examined at the light microscopic level.

The organization of the IO of the neurologic mutant mice remains remarkably preserved, despite gross cerebellar abnormalities including reduced numbers of Purkinje cells in the cerebellar cortex.

The inferior olive of the normal mouse (+/+) and heterozygous reeler (+/r), which has no known mutant phenotype, possess reeler (+/r\_\_), which has no known mutant phenotype, possess well defined olivary subdivisions with distinct borders. Subtle differences in the homozygous mutant mice were found suggesting some minor alterations in olivary structure. This is especially appent in reeler (r/rl) where it is difficult to distinguish PO from DAO in mid-rostral sections of the to distinguish PD from DAD in mid-rostral sections of the olivery collies. There is also an approximate 20-25% reduction of olivary cells in this animal. Preliminary counts of the IO suggest that there are similar numbers of olivary cells in  $+/r_{1}$ , wv/+ and wv/ww mice. We plan to do Purkinje cell counts in these same strains to determine the ratio of Purkinje cells to olivary cells which in the normal mouse is approximately 6:1 (Caddy and Biscoe, 1978).

83.16 COERULOSPINAL EFFECTS ON THE RHEOBASE OF CAT SPINAL MOTONEURONS.

**COERULOSPINAL EFFECTS ON THE RHEOBASE OF CAT SPINAL MOTONEURONS.** <u>S. J. Fung and C. D. Barnes</u>, Department of Physiology, Texas Tech Univ. Health Sci. Ctr., Lubbock, TX 79430. Previous investigations from our laboratory have demonstra-ted an excitatory coerulospinal action on lumbar monosynaptic reflexes as well as on afferent impulse transmission. The present study on precollicularly decerebrate cats examined the excitability change of the motoneuron membrane evoked by locus coeruleus stimulation. The excitability of motoneuron membrane was tested by measuring the threshold current to induce a discharge 90% of the time with long (20-50 ms) depolarizing current pulses. Single units of locus coeruleus demonstrating the typical firing response to pinch stimuli were searched for discharge 90% of the time with long (20-50 ms) depolarizing current pulses. Single units of locus coeruleus demonstrating the typical firing response to pinch stimuli were searched for with either glass micropipettes filled with 0.5 M sodium acetate and 8% Alcian Blue or stainless steel microelectrodes. These sites were subsequently stimulated with cathodal volleys at low intensities (100-500  $\mu$ A). These recording/stimulation sites were subsequently shown with fluorescent techniques to be located in close proximity to noradrenergic neurons. With the locus coeruleus electrode in place intracellular recordings were made with 3 M KCl or 4 M K acetate-filled micropipettes from ipsilateral hindlimb motoneurons. A total of 25 motoneurons Ipstiateral hindlimb motoneurons. A total of 25 motoneurons (both flexors and extensors) with antidromic spike heights above 60 mV were used for the present analysis. A majority of motoneurons (20/25) exhibited a lowering of rheobase (up to 40%) upon locus coeruleus stimulation. This could explain the findings that activation of noradrenergic locus coeruleus neurons resulted in an augmented somatomotor outflow at the level of spinal cord. This work was supported by NIH grant NS 170017040.

83.17 INDOLEAMINERGIC PROJECTIONS FROM LOCUS COERULEUS TO THE LUMBAR CORD IN THE CAT. Y.-Y. Lai and C. D. Barnes, Department of Physiology, Texas Tech Univ. Health Sci. Ctr., Lubbock, TX 79430. In the cat, the nucleus locus coeruleus is a loosely arranged group of neurons in the pons. Although the majority of neurons are, as in the rat, noradrenergic, a number of them are serotonergic. Several studies using a retrograde and anterograde axonal transport have demonstrated a projection of noradrenergic neurons to lumbar cord from locus coeruleus in rat and cat. The question of whether the serotonin cells project into the cord remains unanswerad. The present study was designed to answer that question. Descending projections from the locus coeruleus were studied by using retrograde fluorescence labeling combined with monoamine fluorescence histochemically. Under pentobarbital anesthesia, 0.5 µl of Evans blue (10% w/v) was injected into the L<sub>7</sub> ventral horn of adult cats. After 4 days, the cats received 50 mg/kg of nialamide and were given 20 mg/kg of L-tryptophan I hr later. After another I hr the cats were perfused with Ringer-Locke solution (pH 7.4) followed by a solution of 4% formaldehyde and 0.5% glutaraldehyde in 0.1 M phosphate buffer solution (pH 7.0) at room temperature. The brainstems and spinal cords were then removed and stored separately in 30% sucrose Faglu solution overnight at 4°C. The tissues were cut into 12 µm slices on a cryostat. The sections were placed in Faglu solution and then transferred to precoated microslides. Wet sections were photographed under the light microscope, dried over phosphorus pentoxide for 1 hr, and mounted in mineral oil. Fluorescence was examined under a fluorescence microscope system equipped with V/Y475 (420/480 nm) filter combination for visualizing indelemine, and G/R610 (500/590 nm) filter combination for visualizing for the lowed be seen in both catecholamine and serotonin neurons. Thus, this study demonstrates both catecholamine figurescence of the lumbar spina

# OPIATES, ENDORPHINS, AND ENKEPHALINS: PHYSIOLOGICAL EFFECTS I

84.1 MEASUREMENT OF ENKEPHALINS IN BIOLOGICAL TISSUE EXTRACTS WITH UNAMBIGUOUS MOLECULAR SPECIFICITY BY MEANS OF MASS SPECTROMETRY, D.M. Desiderio, F.S. Tanzer\*, and M. Kai\*, Charles B. Stout Neuroscience Mass Spectrometry Laboratory, University of Tennessee Center for Health Sciences, Memphis, Tennessee, 38163.

Center for Health Sciences, Memphis, Tennessee, 38163. This research program aims to elucidate molecular processes involved in pain. This study is based on peptide measurement with an off-line combination of reverse phase high performance liquid chromatography (HPLC) and fast atom bombardment mass spectrometry (FAB-MS) to determine antagonism between methionine enkephalin (ME), leucine enkephalin (LE), and prostaglandins (PGE<sub>2</sub>) in control (untreated) and stimulated (treated) tooth pulp tissue. The hypothesis to be tested is: in control (untreated) tissue, neuropeptide (ME and/or LE) levels are elevated while PGE<sub>2</sub> levels are lowered whereas in stimulated (treated) tissue, the converse is true.

is true. In the first phase of this study, the two opioid pentapeptides, methionine enkephalin (YGGFM) and leucine enkephalin (YGGFL), are measured in tissue extracts from canine tooth pulp and brain regions. The peptides are separated using acidified acetone for protein precipitation, low resolution mini-column (sep-pak) chromatography, and high resolution analytic reverse phase HPLC utilizing acetonitrile as organic modifier and 0.04 M triethylamine formate as volatile buffer. While ultraviolet detection at 200 nanometers is used as a preliminary screen for peptides, the detector for this system is a fast atom bombardment (FAB) mass spectrometer. A Finnigan MAT 731 double focusing mass spectrometer is utilized in the fast atom bombardment mode to produce a protonated molecular ion of each individual peptide. While increased molecular specificity is achieved for quantification utilizing the protonated molecular ion and an O-incorporated enkephalin internal standard, a much higher level of molecular specificity is achieved to reported here. The protonated molecular ion of the peptide is subjected to collision activated dissociation processes to be reported here. By alternatively jumping between two linked field scan mode. By alternatively jumping between two linked field scan walues, B/E corresponding to the amino acid sequence-determining carboxy-terminus tripeptide ion GCM from the peptide of interest and B'/E' for the corresponding fragment for the internal standard, we achieve for the first time an extraordinarily high level of molecular specificity, notectior that analytical measurement. Measurements will be presented for canine tissue extracts - anterior pltuitary, posterior pituitary, and that and that measurement. Measurements will be presented for canine tissue extracts - anterior pltuitary, posterior pituitary, and that and the other pup. This work is supported by NIH (GM 28611 and 26666). 84.2 COMPARISON OF RAT HIPPOCAMPAL TISSUE CONTENTS AND IN VITRO RELEASE OF PRO-DYNORPHIN-RELATED OPIOIDS. <u>C. Chavkin</u>, <u>C.</u> Bakhit, <u>E. Weber\*</u>, and <u>F.E. Bloom</u>. A.V. Davis Center, The Salk Institute, P.O. Box 85800, San Diego, CA 92138 and Department of Psychiatry, Stanford University, Palo Alto, CA 94305.

The pro-dynorphin molecule can potentially be cleaved to yield several active opioids: dynorphin-A-(1-17) [dynA], dynorphin-A-(1-8) [dynB], dynorphin-B [dynB], dynorphin [dneo], bendorphin [fineo], and possibly leucine-enkephalin [LE]. Since these products differ in opioid receptor selectivites and potencies, the determination of which peptides are naturally present and released at nerve terminals is important for understanding the physiological role of the pro-dynorphin containing neurons.

Previous immunohistochemical and radioimmunoassay (RIA) studies have demonstrated that the pro-dynorphin-derived opioids are present in rat hippocampus. Using separate, selective RIAs for each of the six opioids listed above, we have measured their contents in IM acetic acid extracts of rat hippocampus. Tissue contents were found to be (proles immunoequivalents/gm protein): dynA, 250; dynB, 100; dynB, 925; oneo, 200; ßneo, 20; and LE, 290. DynB immunoreactivity (IR) had the highest concentration and ßneo the lowest.

In order to determine the molecular forms of the IR, hippocampal extracts were resolved on C18 HPLC columns and then eluate fractions were assayed using selective RIAs. Dyn8, oneo, Bneo and LE-IR present in hippocampal extracts were each homogeneous and coeluted with appropriate synthetic standards. DynA-IR and dynB-IR however, were both hetereogenous with roughly 20-40% of each coeluting with synthetic standards and the remainder of each eluting as higher molecular weight material.

Calcium-dependent release of each peptide-IR listed above from fresh hippocampal tissue slices was stimulated by 50 mM K+ induced depolarization. The rates of stimulated release from 200 mgs of tissue were found to be (fnoles/min): dynA, 1.6; dynB, 16.6; dynB, 23; oneo, 9.6;  $\beta$ neo, 6.1; and LE, 84. The release of each opioid is not strictly consonant with their relative tissue contents; dynB,  $\beta$ neo and LE were each released at a ten fold higher fraction of their contents than dynA, dynB or oneo. Potential differences in peptide recoveries from the release chambers needs to be considered. Taken at face value however, our results not only reflect the relative peptide abundances at nerve terminals but may provide the means to determine the sequential steps by which the pro-dynorphin molecule is processed to its agonist products in the hippocampus. (Supported by NIAAA Grants 03504 and 07273.) 84.3 DISSOCIATION OF MORPHINE'S ANALGESIC AND RESPIRATORY DEPRESSANT ACTIONS. <u>G.S.F. Ling</u>, <u>K. Spiegel</u>, <u>S.L. Nishimura\*</u> and <u>G.W.</u> <u>Pasternak</u>. The George C. Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021 USA

USA The high affinity (mu<sub>1</sub>) opioid binding site plays a role in opiate and opioid peptide analgesia, as well as prolactin release and catalepsy but not lethality, growth hormone release or sedation. To further explore the relationship between morphine induced respiratory depression and analgesia, we examined the effect of naloxonazine, a selective mu<sub>1</sub> antagonist, on both of morphine's actions. Arterial and venous cannulae were placed and the rats treated with either saline or naloxonazine (10 mg/kg i.v) 24 hours prior to receiving morphine (i.v.). Respiratory function was evaluated in serial arterial blood samples (100 µl) and analgesia by radiant heat tail-flick. Morphine (3.5 mg/kg) elevated the mean control tail-flick latencies from 3.4  $\pm$  0.2 sec to 9.2  $\pm$  0.8 sec (pc0.001) while depressing the DQ about 17 mm Hg and raising pCO<sub>2</sub> approximately 12 mm Hg. Naloxonazine pretreatment had virtually no effect on morphine's respiratory depression, with a 23.8 mHg drop in DQ and a 10 mm Hg rise in pCO<sub>2</sub>. However, naloxonazine treatment effectively blocked morphine's analgesic actions with a peak latency of 3.4  $\pm$  0.4 sec compared to a 3.0  $\pm$  0.1 sec baseline. Full dose response curves for both respiratory effects and analgesia using four morphine sulfate doses (3.5,5,10, and 15 mg/kg) have been studied. In contrast to analgesia whose dose-response curves shifted to the right, no significant change in respiratory parameters was observed following naloxonazine treatment. These results suggest that morphine's affect on respiration can be dissociated from it's analgesia activity. Although these results confirmed earlier claims regarding the role of mu<sub>1</sub> Sites in morphine analgesia, it is as yet unclear which opiate receptor subtype mediated morphine's respiratory depressant actions. 84.4 POSSIBLE PARTICIPATION OF ENDOGENOUS CHOLECYSTOKININ 8 (CCK) IN THE TOLERANCE TO MORPHINE ANALGESIA IN THE RAT. J. Tang\*, J. Chou\*, M. J. Idaarola, H.-Y.T. Yang and E. Costa (SPON: An-Zhong Zhang). Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Numerous axons containing cholecystokinin (CCK)-like immunoreactivity are located in laminae I and II of the posterior horn of the spinal cord (Brain Res. 165:201, 1979). Intrathecal injections of CCK-8 antagonize opiate analgesia (Science 219:310, 1983) but the molecular events and physiological mechanisms underlying this action are unclear. In rats, we have replicated the CCK-8 (15 pmol) antagonism of morphine analgesia (30 ug) by injecting the two compounds intrathecally and estimating analgesia by measuring the tail flick latency in response to radiant heat. Moreover, the CCK-8 antagonism of morphine analgesia was inhibited by pretreatment with proglumide (25 mg/kg s.c.), a blocker of CCK-8 action at CCK receptors. Using a push-pull pump we infused (1 ml/10 min) the subarachnoid spaces of the rat spinal cord with artificial spinal fluid containing captopril (10<sup>-6</sup>M) and bestatin (10<sup>-6</sup>M). The addition of morphine (10<sup>-6</sup>M) to the artificial spinal fluid releases endogenous CCK-8-like immuoreactivity into the perfusion fluid. This effect of morphine was curtailed or abolished by naloxone (2x10<sup>-6</sup>M). Rats receiving one injection of morphine sulfate (10 mg/kg s.c.), repeated every two hours exhibited a progressive decrease of morphine-elicited analgesia. Complete morphine analgesia usually appeared after the 7th or 8th injection. If morphine injections were given concurrently with injections of proglumide (15 mg/kg s.c.), the morphine tolerance was greatly reduced and usually failed to occur. These results suggest that release of endogenous cholecystokinin may participate in the onset of

84.5 ACUTE AND CHRONIC MORPHINE MODIFIES THE IN VIVO RELEASE OF METHIONINE ENKEPHALIN-LIKE IMMUNOREACTIVITY FROM THE CAT SPINAL CORD AND BRAIN. K. Jhamandas\*, T.L. Yaksh and V.L.W. Go\* (SPON: R.J. Boegman). Department of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada; Departments of Neurological Research and Gastroenterology, Mayo Clinic, Recepter. Singasco, 55001

Rochester, Minnesota, 55901. Interaction between exogenous and endogenous opioids has been proposed as the basis for narcotic dependence. Occupation of opiate receptors by morphine is hypothesized to trigger a negative feedback mechanism which leads to reduced biosynthesis or release of the endogenous opioids. This study was performed to test whether the release of methionine enkephalin-like immunoreactivity (MELI) in vivo is modified by acute or chronic morphine treatment.

Release of MELI from the spinal cord and the brain of chloralose-urethane anesthetized cat was investigated using the technique of spinal superfusion and ventrocisternal perfusion. To evoke release of MELI bilateral sciatic nerve stimulation was applied at intensities known to activate small diameter fibers. The released material was identified as methonine enkephalin by radioimmunoassay with two different anti-sera, parallel displacement with serial dilucions of perfusates and co-migration with authentic methonine enkephalin in a Sephadex G-25 column. In control experiments release of MELI occurred spontaneously

In control experiments release of MELI occurred spontaneously from the spinal cord and the brain; bilateral sciatic stimulation significantly increased this release. Local application of morphine ( $5 \times 10^{-6}$  M) to the spinal cord decreased evoked release of MELI from the spinal cord and the brain. Naloxone (2 mg/kg i.v.) administered during morphine treatment increased both the spontaneous and the evoked release of MELI. In morphine naive animals naloxone did not modify MELI release. In cats chronically exposed to morphine by implantation of morphine pellets ( $2 \times 75$  mg) the spontaneous release of spinal and brain MELI was higher than that seen in control animals. Naloxone treatment resulted in a large and sustained increase in spontaneous and evoked release of MELI.

spontaneous and evoked release of MELI. The results show that acute morphine suppresses MELI release. Chronic treatment does not produce this effect. The enhanced release of MELI in chronically morphine treated animals may be due to a loss of an autoinhibitory mechanism or an excessive drive in enkephalinergic neurons by other excitatory systems.

[Supported by the MRC (Canada) and NS Grant 16541.]

84.6 THE EFFECTS OF EXERCISE TRAINING ON BRAIN ENDOCENOUS OPIOID SYSTEMS. M. J. Blake, E. A. Stein and A. J. Vomachka\*. Dept. of Biology, Marquette University, Milwaukee, WI 53233. It has been postulated that endogenous opioid peptide (EOP)

It has been postulated that endogenous opioid peptide (EOP) systems are involved in reproductive functions since: 1) exogenous morphine can inhibit ovulation in rats, 2) Naloxone (Nx) reverses this drug effect, and 3) Nx also elevates serum luteinizing hormone (LH) levels in rats. The observations that trained female athletes are often amenorrheic, and that treadmill running increases plasma  $\beta$ -endorphin ( $\beta$ E) levels, led us to investigate the role of the EOPs in exercise training using a rat animal model. We report here the effects of treadmill running on serum gonadotropin and EOP levels in several discrete brain nuclei.

Thirty-two female Holtzman rats were randomly divided into two identical groups. One group received daily exercise training consisting of running on a treadmill on an 8° incline at 28 m/min for 60 min/day. The other group received no exercise training, serving as controls. Following 8 weeks of training and just prior to sacrifice each group was subdivided such that  $\frac{1}{2}$  of each group received a final fatiguing bout of exercise. Thus, the final four groups consisted of a trained-fatigued (TF), trained-nonfatigued (TN), control-fatigued (CF), and control-nonfatigued (CN). Animals were sacrificed on diestrus based on vaginal smears. Serum was collected and brains removed. Citrate synthase was assayed in plantaris muscle to determine the level of training. The nucleus accumbens (NA), cortex, caudate putamen, septum, amygdala (AMY), anterior and posterior hypothalamus, substantia nigra, and ventral tegmentum (VT) were microdissected according to the method of Heffner et al. Levels of  $\beta E$  and leucine enkephalin (LE) in all nine brain areas and serum levels of LH and follicle stimulating hormone (FSH) were determined using standard radio-immunoassay procedures.

Two-factor ANOVAs were performed with significance at  $p \le 0.5$ . Fatigued rats showed an increase of GE in the NA which may have resulted from either an increase of GE in the NA which may have cells of origin or a decrease in release from this terminal field. Fatigued rats also showed an increase of LE in VT which may be due to local synthesis and accumulation in this intrinsic system. In addition, TF rats had less LE than TN rats in the AMY. This again may be due to intrinsic accumulation. Finally, serum RIA results showed a reduction of LH in fatigued vs. nonfatigued rats which may reflect an inhibition of LHRN. It thus appears that acute exercise (or stress) may influence brain EOP system. Supported in part by grants from Marquette University, Committee on Research, and the Dr. William Scholl Foundation.

GROWTH-INDUCED CHANGES IN THE PULSATILE PATTERN OF GROWTH HORMONE (GH) SECRETION IN THE HAMSTER : THE INVOLVEMENT OF ENDOGENOUS OPIATES. D.R.Nicoski<sup>\*</sup> and K.T.Borer,Dept.Kinesiology,Univ.Mich., 84.7 Ann Arbor,MI 48109.

Mature golden hamsters can be induced to grow rapidly by exposure to voluntary running (Borer,K.T. & Kelch,R.P.Am.J.Physiol. 1978,234:E611) or by lesions of rostromedial septum (Borer,K.T.et al.<u>Neuroendoc</u>.1977,23:133), and such acceleration of growth is accompanied by increases in serum GH concentration.

To determine whether acceleration of growth is accompanied To determine whether acceleration of growth is accompanied by changes in the pulsatile pattern of GH secretion, mature fema-le hamsters were induced to grow rapidly by exposure to voluntary running (n=18) or septal lesions (n=9). Sedentary and sham-opera-ted hamsters (n=16) served as slowly-growing controls. Two to 3 weeks after the onset of exercise and 7 to 13 days after neuroweeks after the onset of exercise and / to 13 days after neuro-surgery, hamsters were implanted with a jugular cannula and were subjected to sequential blood sampling every 20 minutes for 6 hr the next day.The 0.5-ml blood samples provided serum for measure-ment of hamster GH and prolactin (PRL) by homologous radioimmuno-assays (Borer, K.T. et al.,<u>Neuroendoc.,1982,35</u>:349 and 13). To determine whether the possible changes in the pattern of GH and PRL secretion was due to the release of endogenous opiates, 20 mg/kg of naloxone was administered I.P. to half of the animals in each of the experimental groups while the remaining hamsters

20 mg/kg of naloxone was administered I.P. to half of the animals in each of the experimental groups, while the remaining hamsters received an equal volume of saline. Both exercise (0.8+0.1 g/day,p<0.001) and septal lesions (3.4+0.4 g/day,p<0.001) accelerated growth relative to control groups (0.4+0.04 and 0.2+0.2 g/day). In rapidly-growing hamsters, there was a reduction in CH pulse frequency from a pulse every 63 to 68 minutes to a pulse every 92 minutes. Naloxone administra-tion normalized pulse frequency in all rapidly growing animals (p=0.05). Rapidly-growing hamsters displayed increased amplitude of CH pulses (28.5+6.2 vs 13.4+3.6 ng/ml,p<0.05).Naloxone sup-pressed GH amplitude only in neurologically intact animals (p< 0.05). Basal CH levels were elevated in rapidly-growing exercising 0.05). Basal GH levels were elevated in rapidly-growing exercising (17.6+1.3 ng/ml) and septal-lesioned hamsters (21.6-23.4 ng/ml) relative to controls (12.6+1.5, p<0.05). Naloxone was effective in relative to controls (12.071.3.9. $\times$ 0.03). National was effective f suppressing basal GH levels in neurologically-intact, but not in septal -lesioned animals (p<0.05). No changes were noted in the pattern of PRL secretion as a function of growth or naloxone. Thus in the hamster, endogenous opiates control frequency, amplitude, and baseline levels of circulating GH.Furthermore, ros-

tromedial septum may be the site of inhibitory input over opiate release directed toward facilitation of GH secretion.

Supported in part by the National Science Foundation grant PCM 81-04375.

INCREASED BRAIN AND CEREBELLAR GROWTH IN INFANT RATS TREATED WITH 84.8 AN OPIATE ANTAGONIST. P.J. McLaughlin and I.S. Zagon. Departm of Anatomy, The M.S. Hershey Medical Center, Hershey, PA 17033. Department

Exposure to exogenous opioids such as heroin and methadone in perinatal life inhibits somatic and neurobiological development. This interference in growth by opioids is stereospecific and reversed by narcotic antagonists, with the locus of opioid action postulated to reside at the opiate receptor (see review by Zagon and McLaughlin, <u>Neurobehavioral Teratology</u>, J. Yanai, ed., in press). The present study was designed to explore the relationship of endogenous opioids and opiate receptors to brain development. Waltrexone, a long-acting narcotic antagonist, was given to pre-weaning rats in order to examine the neuro-ontogenetic effects of blocking the opiate receptor from interaction with endorphins. Newborn Sprague-Dawley rats (8/litter) were injected (SC) daily

with high dosages of naltrexone or sterile water until 21 days of age. At 21 days of age, rats were perfused with formalin, brains and cerebella removed, weighed, and macroscopic dimensions recorded. Brain weight, width, length, and height of naltrexone-treated pups were increased 2-11% over control levels. Cerebellar weight and width were elevated 7% and 5%, respectively, above con trol values. Morphometric analyses of hematoxylin-eosin stained sections from the somatosensory cortex (coronal sections) and cerebellum (sagittal sections) showed an enlargement of both regions for naltrexone-treated offspring in contrast to control animals. Cerebral area, cortical thickness, and cerebral width of naltrexone rats were 17%, 18%, and 9%, respectively, greater than control levels. Areal measurements of total, molecular, internal Control levels. Areal measurements of total, molecular, inclemating granule, and medullary layers were increased 41-45% in naltrexone-treated rats relative to controls. Analysis of cellular content in the pyramidal lobe of the cerebellum indicated 30% more inter-nal granule neurons/section and 70% more glial cells/section (oligodendrocytes and astrocytes) in the medullary layer from paltrecomportented rate relation to controls. The total popular naltrexone-treated rats relative to controls. The total popu-lation of neural cells, including glia, basket and stellate neurons in the molecular layer was increased 169% above control levels in the naltrexone-injected animals. These results indicate that an opiate antagonist, administered at dosages known to block the opiate receptor for 24 hr, stimulates brain and cerebellar development in young rats. Moreover, these data suggest that endorphins and opiate receptors are involved in cellular events such as cell proliferation, migration, and differentiation. This research was supported by NIDA grant DA-01618.

84.9 PROGRESSIVE DECREASE IN SEIZURE SEVERITY PRODUCED WITH PROGRESSIVE DECREASE IN SEIZURE SEVERITY PRODUCED WITH INTERMITTENT ELECTROCONVULSIVE SHOCK: INVOLVEMENT OF ENDOGENOUS OPIOID SYSTEMS. F.C. Tortella, J.B. Long, L. Robles\*, and J.W. Holaday. Neuropharmacology Branch, Department of Medical Neurosciences, Division of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, D.C. 20307. Given the recent findings that a) electroconvulsive shock (ECS) elicits a spectrum of opiate-like effects, b) ECS increases brain opioid peptide

content and receptor numbers, c) opioid peptides protect against a variety of experimentally-induced seizures, it was proposed that central opioid peptide systems may function postictally as endogenous anticonvulsants (Tortella, et. al., <u>Eur. J. Pharmacol., 1981</u>). It has since been demonstrated that endogenous opioid systems play a selective role in the rise in seizure threshold occurring after ECS (Tortella and Cowan, <u>Life</u> <u>Sci., 1982</u>). Additional studies on opioid peptides as endogenous

Fise in servere uncounter that is a provided by the server of the ser was also recorded. A single ECS resulted in a tonic-clonic seizure characterized by tonic extension of forelimbs and hindlimbs (duration = characterized by tonic extension of forelimbs and hindlimbs (duration =  $14.58 \pm 0.45$  sec), a seizure pattern score of 2.9 (on a scale of 0 to 3), and a PID lasting 2586  $\pm$  211 sec. Naloxone (NX,10 mg/kg,sc) given 10 minutes prior to ECS did not affect seizure severity, but markedly decreased the duration of PID (1386  $\pm$  294 sec). I-ECS caused a progressive decrease in seizure severity. Following 6 I-ECS treatments the duration of tonic extension and the seizure pattern score declined from 13.8  $\pm$  0.6 to 4.7  $\pm$  0.8 seconds and from 2.2 to 0.78, respectively. It is interesting to note that, despite the decrease in seizure severity. I-ECS was associated with an enhanced duration of PID (4032  $\pm$  507 sec). NX, administered 10 minutes prior to the sixth ECS, partially reversed the decline in seizure severity (duration of tonic extension =  $9.91 \pm 1.36$  sec, and seizure pattern score of 1.45) as well as the duration of PID (1536  $\pm$  305 sec) produced by I-ECS.

These data support the premise that following a seizure there exists a refractory period during which time the activation of a subsequent seizure becomes increasingly more difficult. Alteration by naloxone of the decrease in seizure severity and PID associated with I-ECS suggests that activation of enkephalin and/or endorphin systems contributes to these theorem is enjoying support. changes in seizure susceptibility. Additionally, it was assumed that the duration of PID was a direct function of seizure severity; the above findings indicate that these phenomena are not interdependent. The possible role of endogenous opioid systems in the self-regulation of seizure activity during postictal states will be discussed.

84.10 DISCRIMINATIVE STIMULUS EFFECTS OF RECEPTOR-SELECTIVE OPIOID PEP-TIDES IN THE RAT. K. W. Locke\* and S. G. Holtzman\*, (SPON: B.A. Faraj). Dept. of Pharmacology, Emory Univ. Sch. of Med., Atlanta, Cardon Concerning, Cardon Concerning GA 30322.

The morphine-like discriminative stimulus effects of  $\mu$ - and  $\delta$ receptor selective opioid peptides were evaluated following in-tracerebroventricular (ICV) administration. Rats were trained to discriminate between SC injections of morphine (M) (3.0 mg/kg) and saline in a two-choice discrete-trial avoidance paradigm. Behavior was considered to be under stimulus control when the rats could reliably complete at least 18 trials of a 20-trial session on the appropriate choice lever. ICV administration of the relatively selective  $\delta$ -receptor agonist D-Ala<sup>2</sup>-D-Leu<sup>5</sup> enkep alin (DADL) produced dose-related increases in the number of enkephtrials completed on the M-appropriate lever, and 1.0-3.0 µg DADL produced M-appropriate responding comparable to the training dose of M.  $\beta$ -endorphin, which has equal affinity for  $\mu$ - and  $\delta$ -recepof M.  $\beta$ -endorphin, which has equal affinity for  $\mu$ - and  $\delta$ -recep-tors, also engendered M-appropriate responding over the dose range of 0.01-10  $\mu$ g. Complete generalization to ICV  $\beta$ -endorphin occurred at 1.0-10  $\mu$ g. We have shown previously that the dis-criminative stimulus effects of 1.0-3.0  $\mu$ g ICV M are comparable to the systemic M training dose (Locke, K.W. and Holtzman, S.G., <u>Pharmacologist</u> 24: 230, 1982). Thus, DADL and  $\beta$ -endorphin ap-pear to be equipotent or more potent than M on a molar basis in remains an adjustion patient of the systemic of the systemic force of serving as a discriminative stimulus. The stimulus effects of both DADL and  $\beta-endorphin$  were blocked by low doses of SC naltrexone (0.1 mg/kg). In contrast, the relatively selective  $\mu\text{-}$  receptor agonist D-Ala<sup>2</sup>-NMePhe<sup>4</sup>-Gly<sup>5</sup>(ol) enkephalin (DAGO) engendered almost exclusively saline-appropriate responding even though behaviorally active doses (0.1-3.0 µg) were tested. Although M is considered to be a relatively selective  $\mu$ -receptor agonist, these data suggest that 6 receptors are involved in mediating the discriminative stimulus effects of M in the rat. (Supported by US-PHS Grants 5T32-GM07594, DA 00541, and by KO2DA 00008.)

84.11 FACILITATION OF ENKEPHALINERGIC RECEPTOR FUNCTION BY THIORPHAN, AN ENKEPHALINASE INHIBITOR, <u>K. Blum, L. DeLallo\*, and A. H.</u> <u>Briggs\*</u>. Div. Subs. and Alc. Mis. University of TX, Health Sci. Ctr., San Antonio, TX 78284.

It is well established opioid-like compounds act through their interaction at opiate receptors. There is strong evidence for a multiple opioid receptor system and consensus of the literature indicates the endogenous enkephalins preferentially bind to the  $\delta$ -receptor. Enkephalinas as neurotransmitters are catabolized in vivo by enkephalinase which is inhibited by thiorphan (TH), a high affinity thiopeptide. In this study, a comparison was made\_between normorphine (NM), methionine enkephalin (ME) and D-ala<sup>2</sup>-met<sup>2</sup>-enkephalinamide(DAMEA) and the ability of TH to potentiate their in vitro activity to inhibit the electrically induced contractions of mouse vas deferens. Pretreatment with (TH) (N10<sup>-</sup> M) for 15 minutes did not significantly effect the twitch inhibition of NM (5X10<sup>-</sup> M), but did significantly (P<0.05) facilitate\_the twitch inhibition of ME (7X10<sup>-</sup> M) as well as 1.7X10<sup>-</sup> M DAMEA. Since the decay profile of TH - ME treated tissue was not different than the ME control it was inferred this potentiation was not the result of enkephalinase inhibition but through a direct  $\delta$ -receptor mechanism. This is the first report showing that TH (or any other agent) facilitates enkephalinergic receptor function via a direct mechanism independent of enkephalinase inhibition. Analogs of thiopeptides may become potent useful therapeutic agents for the treatment of addictive diseases. (This research is supported in part by the Raleigh Hills Foundation.)

## PEPTIDES: ANATOMICAL LOCALIZATION I

85.1 DISTRIBUTION OF NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY IN RAT BRAIN. T.L. O'Donohue, B.M. Chronwall\*, D.A. DiMaggio\*. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205.

mental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205. Neuropeptide Y (NPY) was recently discovered and sequenced from extracts of porcine brain (Tatemoto, <u>Proc Natl Acad Aci, USA</u> 79:5485, 1982). The peptide is part of a family of peptides that include pancreatic polypeptide (PP) and peptide YY (PYY). Recent results demonstrated a system of neurons in brain that stains with bovine PP antisera (Olschowka et al, <u>Peptides</u> 2:309-331, 1981), yet the peptide was found to be distinct from PP (DiMaggio et al, <u>Soc Neurosc Abst</u>, 1983).

(s) Soc Neurosci Abst, 1983). In this study, antisera were raised to NPY by conjugating synthetic peptide to bovine serum albumin. The indirect immuno-fluorescence method was used on 20 μM cryostat sections from colchicine treated adult Sprague-Dawley rats perfused with 0.5% sodium nitrite in phosphate buffered saline, pH 7.4, (PBS) followed by 4% formaldehyde in PBS (pH 7.4) which was, in some cases, followed by 4% formaldehyde in borate buffer (pH 10).

cases, followed by 4% formaldehyde in hos to buffer (pH 10). An extensive system of intensely staining NPY immunoreactive neurons were observed throughout the rat telencephalon. Regions containing highest densities of NPY-positive terminals were the lateral septum, nucleus (n.) of the stria terminalis, suprachiasmatic n., paraventricular n. and the dorsomedial n. Moderate densities were observed in cortical regions, n. tractus diagonalis, medial preoptic n., dorsomedial n. and amygdala centralis. Lower densities were observed in the striatum, hippocampus and most thalamic n. A large number of perikarya containing NPY immunoreactivity were observed in the arcuate n., periventricular n. and in the septum. The staining pattern seems identical to that of PP. Preabsorption of the NPY antisera with 1 µg/ml of NPY completely blocks staining, as does preabsorption with 1 µg/ml of bovine PP. Because PP immunostaining is also blocked by both PP and NPY, the identity of the peptide is unclear. Further studies are in progress to characterize this peptide in brain. 85.2 NEUROTENSIN AND DOPAMINE ARE NOT CO-LOCALIZED IN RAT BRAIN. G. Bissette, L. Jennes\*, A.J. Prange, Jr., G.R. Breese, and C.B. Nemeroff. Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med. Chapel Hill, NC 27514. Neurotensin (NT) localization in the central nervous system

has been extensively studied by radioimmunoassay (RIA) and immuno-histochemical (IHC) techniques. Many brain areas that contain high concentrations of NT are known to contain dopamine (DA) cell bodies or nerve terminals. In an attempt to determine if NT and DA are co-localized, DA neurons were chemically lesioned with 6-hydroxydopamine (6-OHDA). Adult, male Sprague-Dawley rats (200 g, n=16) were injected with desmethylimipramine (30 mg/kg, IP) one hour prior to injection with 6-OHDA (240  $\mu g$ , IC). Desmethylimi-pramine (DMI) is used to protect norepinephrine-containing cells from 6-OHDA-induced neuronal destruction. Controls (n=16) received DMI and 6-OHDA vehicle (ascorbic acid). Three weeks later, animals were killed by decapitation and their brains quickly removed and placed on an ice-cooled petri dish. The following brain regions were rapidly dissected: nucleus accumbens, septum amygdala, ventral tegmental area of Tsai (VTA)-substantia nigra, hypothalamus, striatum, dorsal hippocampus, and olfactory tubercles. Brain samples from control (n=8) and 6-OHDA-treated rats (n=8) were homogenized in 1 N HCl, centrifuged, and duplicate supernatant aliquots were frozen and lyophilized for measurement of NT by RIA. An additional set of brain samples from control of NT by RIA. An additional set of brain samples from control (n=8) and 6-OHDA-treated (n=8) rats were homogenized in 0.1 N perchloric acid and extracted with alumina for determination of DA concentration by HPLC with electrochemical detection. Protein concentration was measured with the Folin reagent. Data are expressed as pg NT/mg protein or ng DA/mg protein, and the degree of statistical significance (p < .05) was assessed with Student's t-test (two-tailed). Animals treated with 6-OHDA exhibited a 99% deplection of DA, as compared to controls in the septum, amygdala, VTA-substantia nigra, and olfactory tubercles, and an 89% and 83% depletion in the striatum and nucleus accumbens. Hypothalamic DA was reduced approximately 50% in the 6-OHDA-treated rats. The concentration of NT was not significantly reduced by 6-OHDA treatment in any brain region; in fact, small but significant increases in NT levels in septum and olfactory tubercles (p < .01) were Immunohistochemical studies using an antiserum to observed. tyrosine hydroxylase (as a marker of DA neurons) and an antiserum to NT confirmed the findings obtained with the neurochemical methods described above. These data demonstrate that DA and NT are not co-localized in rat brain. (Supported by NIMH MH-34121, MH-33127, MH-22536, and NICHHD HD-03110.)

85.3 SECRETIN LIKE IMMUNOREACTIVITY IN THE CEREBROSPINAL FLUID OF RAT AND HUMAN. C.G. Charlton', R.L. Miller\*, P.A. LeWitt\*, T.N. Chase and T.L. O'Donohue (SPON: M.E. Goldman). Experimental Therapeutics Branch, National Institute of Neurological and Communicative Disorders and Stroke, National Institute of Health, Bethesda, MD 20205 and Division of Clinical Pharmacology, Howard University, Washington, DC 20059.

University, Washington, DC 20059. Secretin like bioactivity and immunoreactivity (SLI) in extracts of rat and pig brain have been reported (Mutt et al. Life Sci 25: 1073, 1979; Charlton, et al. Peptides 2: Suppl. 1, 45, 1981 and 0'Donohue, et al. <u>Proc Nath Acad Sci USA</u> 78:5221, 1981). This report describes the identification and characterization of SLI in the cerebrospinal fluid (CSF) of rat and human.

CSF was obtained by lumbar tap from normal human and by ventricular perfusion in rats. A stainless steel cannula was stereotaxically placed in the lateral ventricle of each rat. Another cannula was placed in the cisterna magna. Artificial CSF (o'Donohue et al., 1981) was infused into the lateral ventricle while withdrawn through the cisterna magna at 15 ul/min for 20 min periods. CSF was acidified to 0.5 M acetic acid and analyzed utilizing reverse phase high pressure liquid chromatography (HPLC) with a µBondapak C<sub>18</sub> column and a specific radioimmunoassay for secretin. Aliquots of rat CSF perfusate and synthetic porcine secretin

showed similar HPLC retention pharacteristic and superimposable curves for the inhibition of  $^{125}$ I-secretin binding to secretin antibody. The concentration of SLI in human CSF was 0.72  $^+$  0.05 ng/ml. In the rats the mean SLI for each 20 min collection period was 3.6 - 0.48 ng/ml.

85.5 IMMUNOCYTOCHEMICAL LOCALIZATION OF NEUROPEPTIDE Y (NPY) IN THE RAT BRAIN. J. Guy\*, Y.S. Allen\*, J.M. Polak\* and G. Pelletier. MRC Group in Molecular Endocrinology, CHUL, Quebec, Canada and Canada and Dept. of Histochemistry, Royal Postgraduate Medical School, London, U.K.

Recently, a 36 amino acid residue peptide, named neuropeptide Y (NPY) has been purified from porcine brain and fully character-ized (Tatemoto, K., <u>Proc. Natl. Acad. Sci. USA</u> 79: 5485, 1982). In order to identify the nervous structures containing NPY, we performed the immunocytochemical localization of this peptide in the rat brain. For this purpose, adult rat brains were perfused with 4% paraformaldehyde or a mixture of 4% paraformaldehyde and 0.2% glutaraldehyde. Immunocytochemistry involving use of the peroxidase-antiperodixase complex was performed on both 30  $\mu$ m thick Vibratome and ultrathin plastic sections (post-embedding technique). The Vibratome sections were used for light micro-scopic observations and also embedded for subsequent ultra-structural studies (pre-embedding technique). Antibodies against porcine NPY, raised in rabbits, did not show any significant crossreactivity with related peptides including peptide YY (PYY) and pancreatic polypeptide. Light microscopic immunocytochemistry revealed that immunostaining was widely distributed throughout the brain. Positive cell bodies and fibers were found in large number in the cortex, caudate-putamen nucleus, hypo-thalamic arcuate nucleus and hippocampus. High concentrations of fibers were also observed in the paraventricular and suprachiasmatic nuclei of the hypothalamus, the paraventricular nucleus of the thalamus and the periaqueductal gray. All these regions were examined for ultrastructural localization of NPY immunoreactivity. With the pre-embedding technique, immunotatining could be detected in axon profiles and endings. In these structures, the reaction product was located within the large dense core vesicles (70-100 nm in diameter) and also to some extent throughout the axoplasm. With the post-embedding technique, the staining was restricted to the large dense core vesicles in axons and endings. Only a small proportion of positive endings were seen making synaptic contacts with other neural elements. These results indicate that NPY could act as a neuromodulator or neurotransmitter of which the role remains to be clarified.

IMMUNOHISTOCHEMISTRY OF RAT INTERPEDUNCULAR NUCLEUS(IPN): 85.4 SUBNUCLEAR DISTRIBUTION. G.S.Hamill, J.A.Olschowka, N.J.Lenn & D.M. Jacobowitz. Dept.of Neurol.and Clinical Neurosci.Research Center, Charlottesville, VA 22908 and Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

The distribution of cell bodies and processes within the IPN, containing substance P(SP), vasoactive intestinal polypeptide(VIP), cholecystokinin(CCK), somatostatin(SST), leu-enkephalin(L-ENK) serotonin(5HT) and dopamine beta hydroxylase(DBH) was determined in male rats treated with colchicine 48 hrs prior to perfusion. Serial 16µm frozen sections cut coronally, were examined for immunofluorescence. Variations in the density of terminal fluor-escence were rated 1+(sparse) to 4+(intense).

Rostral subnucleus contained SP,SST, and L-ENK reactive somata. SP and VIP varicosities(2+) were present throughout Rostral, but were concentrated in 2 ovoid areas located dorsally in the caudal vere concentrated in 2 ovoid areas located dotsarily in the caudar region of this subnucleus. CCK(2+) and L-ENK(3+) varicosities were also present, but were absent from these ovoid areas. 5HT(1+) SST(1+) and DBH(2+) processes were present diffusely. Central subnucleus contained SST reactive somata distributed in

a narrow band at its dorsal margin. Fine SP(1+) varicose processes extended as 2 vertically oriented bands adjacent to the lateral margins of the subnucleus, and in horizontal bands across its width. SHT(1+) varicose processes were evenly distributed. Fine DBH(3+) varicose processes were evenly distributed, except for 2 laterally placed, vertical bands of decreased density. VIP(2+) and SST(1+) processes were observed only in the dorsal margin of Central. A very fine L-ENK(2+) terminal plexus was distributed throughout the Central subnucleus.

Intermediate subnuclei contained fine 5HT(1+) and DBH(3+)

varicose processes, which were evenly distributed. Lateral subnuclei contained evenly distributed fine SP(4+) varicosities that extended medially, ventral to the Intermediate subnuclei. 5HT varicosities(1+) were present but concentrated(3+) in the ventral lateral corners, which also contained 5HT somata. Fine VIP(3+),CCK(3+),and L-ENK(1+) varicose processes were concentrated along the medial edge of the subnuclei. A narrow,horizontal band without staining for SP,VIP,and CCK was observed in the Lateral subnuclei.

Dorsal subnucleus contained 5HT and L-ENK reactive somata. SP (2+),5HT(3+),CCK(2+),L-ENK(3+),VIP(2+) and DBH(1+) varicosities were present. Dorsal lateral subnuclei contained SP(2+),L-ENK(2+), DBH(2+) and SST(1+) varicosities. Interstitial subnuclei contained SP(4+),5HT(1+), and DBH(1+) varicosities.

The data demonstrate precise localization for various peptides, noradrenergic and 5HT systems within the IPN whose distribution and density of somata, and processes differ amongst the subnuclei of TPN.

85.6 CO-LOCALIZATION OF CYCLIC GMP IN SUPERIOR CERVICAL GANGLION WITH PEPTIDE NEUROTRANSMITTERS. M.A. Ariano & E.L. Tress.\* Anatomy & Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

Synaptic activation of ganglionic afferents produces significant elevations in cyclic nucleotide concentrations in rat superior cervical ganglion (Briggs, et al, <u>Cell Molec. Neurobiol</u>. 2: 129-142, 1982). Immunofluorescent localization of cyclic AMP after stimulation is greatly augmented within satellite cells of the ganglion, while cyclic GMP immunofluorescence is increased within postganglionic neurons (Ariano, et al, Cell Molec. Neurobiol. 2: 143-156, 1982). This investigation has examined the co-incidence of immunofluorescence of the peptide neurotransmitters, substance P, somatostatin, and met-enkephalin with cyclic GMP in rat superior cervical ganglion.

Pairs of ganglia were isolated from 17 Sprague-Dawley rats and maintained in oxygenated Locke's solution for 30 min at  $23 c_0$ , then frozen at  $-25^{\circ}C$  in a cryostat and sectioned at 8 µm. Serial Serial then trozen at -25°C in a cryostat and sectioned at 8 um. Serial sections were mounted sequentially onto chrom alum-coated glass slides, and processed for neuropeptide and cyclic GMP immunore-activity. Substance P, somatostatin, and met-enkephalin (Immuno-Tech, Inc., Chapel Hill, NC), and cyclic GMP antisera, synthesized in our lab and extensively characterized, were used at 1:500 to 1:1000 dilution in PBS, incubated overnight at 4°C in a moisture box. Unbound primary antisera were removed with PBS washes, and coardery fourced reminered actions of the NC for the state of the second state of the se secondary, fluorescein-conjugated antisera (Cappel Labs, W. Chester, PA) was applied at 1:50 to 1:100 dilution in PBS for 1 hour. Following a final wash, sections were examined with ultraviolet optics, using a 485 nm/520 nm FITC filter combination. Photo-micrographs of serially-identified regions of ganglia were studied and tabulation of all cyclic GMP-staining cells were compared to substance P, or somatostatin, or met-enkephalin immunofluorescent neurons. The percentage of peptide neurotransmitter-reactive cells versus the cyclic nucleotide was also determined. Cyclic GMP-immunofluorescent postganglionic neurons were evenly

distributed among the neuropeptide-reactive cells. 36.9% of the cyclic GMP-positive cells demonstrated co-localization with sub-stance P, 36% of cyclic GMP-stained cells exhibited somatostatin reactivity, and 37.7% of the cyclic GMP-fluorescent elements also contained met-enkephalin reaction. 43% of the substance P-posi-tive neurons demonstrate cyclic GMP-staining. 41% of somatostatin and met-enkephalin fluorescent neurons also demonstrate co-local-ization of cyclic GMP immunofluorescence. The results suggest cyclic GMP is not preferentially associated with one of the three peptide neurotransmitters studied. This work also suggests that ome 60% of the neuropeptide-staining neurons utilize non-cyclic GMP mechanisms

Supported by NSF grant BNS 81-02648.

85.7 INCREASE IN IMMUNOREACTIVE VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN THE MAJOR PELVIC GANGLION FOLLOWING INTERRUPTION OF THE PELVIC NERVE. W.G. Dail, M.A. Moll\* and R.A. Dziurzynski\*. Department of Anatomy. University of New Mexico School of Medicine, Albuquerque, New Mexico 87131.

Albuquerque, New Mexico 87131. Postganglionic autonomic neurons are subject to a variety of influences mediated by their presynaptic input. For example, the appearance of certain enzymes in the postganglionic neuron during development depends upon the acquisition of functional connections by preganglionic cells. Preganglionic nerve activity is also known to elevate the activity of synthetic enzymes in adrenergic neurons. The effect of removal of the preganglionic input on the level of neurotransmitter in the postganglionic neuron is less clear, but the majority of studies indicate a slow, but significant, rise in catecholamines. In contrast, a very rapid and pronounced rise in peptides may occur in autonomic neurons following deafferentation (Schultzberg, et al. Neurosci. 3, 1978; Lewis, et al. J. Neurosci. 1, 1981; Kessler and Black, Brain Res. 234, 1982). In a series of studies to define the VIPergic innervation of male pelvic viscera, we have noted a rapid rise in immunoreactive VIP in the major pelvic ganglion of the rat after surgical section of the pelvic incrve, the presumed preganglionic parasympathetic input to this ganglion. In the intact ganglion, most of the neurons are VIP positive, as determined by immunofluorescent and immunoperoxidase methods (Dail, et al. in press, Neuroscience 1983). VIP staining appears as anuclear halo in the Golgi zone. Only a few VIP-IR fibers are present in the neuropil of control ganglia. However, at three days following surgical interruption of the pelvic nerve, a rich plexus of VIP fibers appeared in the ganglion in close relationship to neurons. The plexus of fibers was notably sparse in the region of the ganglion known to contain adrenergic neurons. Some neurons stained intensely and evenly throughout their cytoplasm. This staining pattern was rarely seen in control tissue. Although no quantitative study was performed, the number of neurons which stained for VIP did not seem to increase after deafferentation. The changes we have de

85.9 LOCALIZATION OF GASTRIN, CHOLECYSTOKININ, SRIF, INSULIN, AND GLUCAGON IN FELINE NERVOUS SYSTEM. <u>L. Eldridge\*, T. Yamada\*,</u> and W.F.H.M. Mommaerts. Department of Physiology, University of California at Los Angeles, CA 90024. The distributions of five peptides in the nervous system of the cat

The distributions of five peptides in the nervous system of the cat were studied with previously published radioimmunoassay techniques. In thirteen normal adult cats of both sexes, gastrin, cholecystokinin (CCK), somatostatin (SRIF), insulin, and glucagon were assayed in spinal cord, dorsal root ganglia, and brain. The cord and ganglia tissues were divided into cervical, thoracic, lumbar, and sacral sections, and the cord sections were then split into dorsal and ventral portions. The brain tissues analyzed were cerebellum, brainstem, thalamus, cortex, hypothalamus, and pituitary. In the spinal cord as well as the dorsal root ganglia, the peptides were found in the greatest concentrations in the sacral tissue. The dorsal portions of the spinal cord usually were higher than the ventral. For all peptides, highest levels were found in the brain, but certain regions of the brain had much lower levels than were observed in many cord and ganglia tissues. Of the brain tissues, the cerebellum, brainstem, and thalamus were relatively low in peptides, while cortex, hypothalamus, and pituitary were moderate to high, depending on the peptides.

85.8 Hippocampal Cholecystokinin-like Neurons - A Fluorescence Retrograde Labeling Study, <u>R. S. Greenwood and K. K. Winstead\*</u>. Dept. of Neurology and Neurobiology Program. U.N.C. Sch. of Med., Chapel Hill, N.C. 27514. The hippocampal formation contains numerous intensely the hippocampal formation contains numerous intensely

The hippocampal formation contains numerous intensely cholecystokinin-like (CCK-L) immunoreactive neurons. These neurons are found in most layers and subdivisions of the hippocampal formation. It is not known if these CCK-L neurons are only short-axon cells or if they have connections outside the hippocampal formation or to another subdivision of the hippocampal formation. In this study retrograde fluorescent dye tracing was combined with the indirect immunofluorescence technique to label hippocampal neurons and determine the course of axons of CCK-L immunoreactive neurons.

True Blue (5%, wwt/vol) was injected into the lateral septal nucleus, the medial septal nucleus, the subiculum, or the entorhinal cortex of pentobarbital anesthetized rats. After four to six days for dye transport and after colchicine injection the brain was sectioned. The sections were examined for True Blue distribution and processed for cholecystokinin immunocytochemistry by the indirect immunofluorescence technique (Coons 1958) using an antiserum to the C-terminal octapeptide of cholecystokinin. Previously described features of the efferent and

Previously described features of the efferent and intrahippocampal pathways of the hippocampal formation were observed. No definite CCK-L immunoreactive hippocampal neurons were labeled with True Blue following lateral septal nucleus, medial septal nucleus or entorhinal cortex injections. True Blue injections in the dorsal subiculum, however, did result in retrograde labeling of CCK-L immunoreactive neurons in <u>regio</u> <u>superior</u> and subiculum. These CCK-L immunoreactive neurons were located in <u>stratum pyramidale</u> of <u>regio superior</u> and layer III of the subiculum. The CCK-L immunoreactive neurons labeled with True Blue constituted a minority of the CCK-L immunoreactive neurons in <u>regio superior</u> and the subiculum. Adjacent to the sites of True Blue injection, CCK-L immunoreactive cells were frequently found to contain True Blue.

We conclude that the majority of CCK-L immunoreactive neurons in the hippocampal formation are short axon neurons. However, some CCK-L immunoreactive neurons in septal  $\underline{\text{regio}}$  superior and the dorsal subiculum have axons that extend caudally to the subiculum.

85.10 CCK NEURONS OF THE HIPPOCAMPUS AND SUBICULUM: POSSIBLE EXTRA-HIPPOCAMPAL PROJECTIONS. J.B. Nelson\*, G.E. Handelmann\*, M.C. Beinfeld, and T.L. O'Donohue. (SPON: D. Symmes). Lab. Cell Biology, NIMH, Bethesda, Md.; Dept. of Pharmacology, St. Louis Univ., St. Louis, Mo.; Experimental Therapeutics Branch, NINCDS, Bethesda, Md. 20205.

Cholecystokinin (CCK), a peptide hormone originally identified in the gut, is also contained in neurons in the brains of a number of vertebrate species and appears to act as a neurotransmitter. In the rat brain, the hippocampus contains a high concentration of CCK. Neuronal cell bodies containing CCK-immunoreactive material were identified in the hippocampus, dentate gyrus, and subiculum [1,2]. These polymorphic cells were located subjacent to the pyramidal cells in stratum radiatum in both regio superior and inferior of the hippocampus. A small number were located in other cell layers. In the dentate gyrus, they were located subjacent to the granule cells. CCK-positive terminals were visible in the hippocampal pyramidal layer and dentate granule layer. Destruction of the major hippocampal afferents had no effect on the CCK content of the hippocampus, indicating that the intrinsic cells are responsible for the hippocampal CCK content. Destruction of the septo-

Destruction of the major hippocampal afferents had no effect on the CCK content of the hippocampus, indicating that the intrinsic cells are responsible for the hippocampal pathway, however, produced decreases in CCK content of the septum and hypothalamus of 59% and 24%, respectively. A microdissection analysis indicated that the loss of CCK occurred only in regions receiving direct projections from the hippocampus and subiculum: lateral septum, nucleus of the stria terminalis, mammillary bodies, and anteroventral nucleus of the thalamus. These results suggest that CCK-containing neurons of the hippocampus and subiculum project to extrahippocampal regions. CCK may therefore be important in mediating neural function in the limbic system.

THE PREFERENTIAL DISTRIBUTION OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN THE SACRAL SPINAL CORD OF THE RHESUS MONKEY. J.R. Roppolo, I. Nadelhaft, W.C. deGroat. Depts. of Pharmacology and Neurosurgery, Univ. of Pittsburgh and V.A. Hosp., Pittsburgh, PA Immunchistochemical (IHC) studies have localized VIP containing 85.11 neural processes in various peripheral structures including the GI tract, gentiourinary tract, and in spinal and autonomic ganglia. In addition recent IHC studies in the cat spinal cord revealed that the distribution of VIP is restricted to the sacral segments of the cord. This distribution of VIP resembles closely the dis-The distribution of pelvic nerve afferents in the cat sacral spinal cord. The present study was undertaken to determine whether VIP has similar localized distribution in the monkey spinal cord. The distribution of neuronal processes containing VIP-immunore-activity (VIPIR) was studied in five rhesps monkeys using standard

immunchistochemical techniques (either PAP or FITC methods). In two monkeys the sacral dorsal roots on one side were transected 10-14 days prior to sacrifice. VIPIR neuronal processes were localized primarily in the sacral segments of the spinal cord and in the sacral dorsal root ganglia

segments of the spinal cord and in the sacral dorsal root ganglia (DRG). VIPIR processes within the DRGs were seen as single fibers or thick bundles leaving the DRG and passing into the dorsal root. VIPIR cell bodies in the DRGs were not seen in the present study since visualization of cells usually requires pretreatment with an axonal transport inhibitor. Labelled fibers were seen projecting from the sacral dorsal rootlets, to their spinal entry zone and into Lissauer's tract (LT). The VIPIR in LT was arranged in thick bundles (5-20 µm) and in the sacral segments was distributed throughout LT. In horizontal sections these thick bundles could be seen as groups of long rostrocaudal projecting fibers. From LT fibers projected in the superficial laminae of the dorsal horn be seen as groups of long rostrocaudal projecting fibers. From LT fibers projected in the superficial laminae of the dorsal horn (DH). The projection along the lateral edge of the DH reached lamina V. Here some of the fibers ended abruptly near the sacral parasympathetic nucleus (identified by AchE stain) while a few fibers could be seen directed medially in laminae V and VI to the dorsal commissure (DC). A much less dense projection was seen a-long the dorsomedial border of the DH to DC. In lumbar and coccylong the dorsomedial border of the DH to DC. In lumbar and coccy. geal spinal segments, the VIPIR in the DH disappeared. However, the VIPIR in LT could be detected as far rostral as T<sub>13</sub>. The fi-bers in LT at the more rostral segments of the spinal Cord occu-pied a more medial position. Section of the sacral dorsal roots markedly reduced the VIPIR fibers in the ipsilateral cord while ventral root section had no effect. These results suggest that the majority of VIP fibers seen in the lumbosacral spinal cord are afferent fibers entering at the sacral level and that the distribution of these fibers resembles very closely the distribution of pelvic nerve afferents reported previously in the rhesus monkey.

previously in the rhesus monkey.

EDINGER-WESTPHAL NUCLEUS: IMMUNOCYTOCHEMISTRY AND DESCENDING PROJECTIONS IN THE CAT. B.S. Phipps, R. Maciewicz, B.B. Sandrew<sup>#</sup>, and J.B. Martin, The Stanley Cobb Lab. for Psychiatric Res. and Depts. of Neurology, Neurosurgery, and Psychiatry Mass, General Hospital and Harvard Med. Sch., Boston MA 02114. 85.13

The Edinger-Westphal nucleus (EW) is a well-defined collec-tion of medium-sized neurons lying dorsal and anterior to the oculomotor nucleus. Although classically thought to principally contain preganglionic parasympathetic neurons that innervate the orbit, axoplasmic transport studies demonstrate that the projections of EW are considerably more complex. In the cat, EW has descending projections to spinal dorsal horn and several brain descending projections to spinal dorsal horn and several brain stem nuclei, including the superficial layer of the spinal tri-geminal nucleus (nV). Recent studies also show that the majori-ty of neurons in EW demonstrate substance P-like immunoreactiv-ity (SP-LI). Since SP and cholecystokinin (CCK) are found toge-ther in some central and peripheral neurons, we examined EW cells for CCK-like immunoreactivity (CCK-LI) and compared the distribution of EW neurons with CCK-LI to the pattern of cells in the same region that stain for SP-LI. Immunoperoxidase meth-ods in colchicite pretreated animals demonstrated cells with In the same region that stain for SPLI. Immunoperoxidase meth-ods in colchicine pretreated animals demonstrated cells with CCK-LI throughout the length of EW. The frequency, appearance and distribution of cells stained for CCK-LI was similar to that of EW cells that demonstrated SP-LI. The pattern of cells with CCK-LI also closely corresponded to the distribution of EW neurons that project to spinal cord, but was quite different from the pattern of preganglionic cells that project to the orbit. A combined retrograde transport-immunocytochemical method was next used to determine whether EW neurons that project to spinal cord also demonstrate CCK-LI. Simultaneous co-localiza-tion of retrogradely transported horseradish peroxidase (HRP) and CCK was accomplished by using 3,3'-diaminobenzidine (DAB) for the HRP histochemistry and alpha-napthol/pyronin B for the peroxidase-antiperoxidase (PAP) immunocytochemistry. In sections exposed to CCK antibody, cells showing CCK-LI were found throughout the rostrocaudal extent of EW, and many CCK-LI posi-tive neurons throughout EW also contained retrogradely transported HRP.

In companion experiments, HRP was injected into spinal cord In companion experiments, HAR was injected into spinal cord and either nuclear yellow or DAPI was injected into NV on either side. In these studies numerous EW neurons were retrogradely labeled with both HRP and a fluorochrome, evidence that some EW cells project to both NV and spinal cord. These findings demon-strate a direct pathway from midbrain to dorsal horn that contains CCK and probably also SP. As many EW neurons project to both nV and spinal levels, this system may have a widespread rather than regional effect on somatosensory transmission. 85.12 THE DISTRIBUTION OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN THE LUMBOSACRAL SPINAL CORD OF THE RAT. I. Nadelhaft, V.A.Med. Centr. and Dept. of Neurosurg., Univ. of Pittsburgh, Pittsburgh, PA 15261 Recent immunohistochemical studies of the location of VIP immuno-reactivity (VIPIR) in cat, monkey and human spinal cord have demonstrated a rather unique and restricted distribution for this polypeptide; 1) VIP was relegated to afferent fibers entering the cord via the sacral roots. 2) In the sacral cord, VIPIR was found in Lissauer's tract (LT), the superficial layers (I and II) of the dorsal horn, and characteristically in a prominent collateral projection around the lateral border of the dorsal horn into the area containing preganglionic neurons forming the sacral parasympathetic us(SPN). 3) Outside the sacral region VIPIR was located mainly in LT. In contrast to these findings, the present study in the rat exhibits a quite different VIPIR (S1-L6). VIPIR was found in LT and dorsal horn laminae I and II (outer) in all these segments. The reaction was intense in LI and appeared to be contained in fibers running parallel to the boundaries of the lamina. In LII a less intense reaction was noted organized in varicosities along short fiber fragments in a random fashion characteristic of a terminal field. In LII a less intense reaction was noted organized in various te-along short fiber fragments in a random fashion characteristic of a terminal field. The intensities of VIPIR did not vary greatly from segment to segment. In segments L6 and L1 a collateral afferent projection extended along the lateral margin of the dor-sal horn and into the area containing SPN neurons. This is homosal horn and into the area containing SPN neurons. This is homo-logous to the sacral lateral projection noted in cat, monkey and human. A prominent but small (diameter 20 microns) longitudinal fiber bundle was located on the midline just beneath the central canal in all segments. Other studies in the rat have revealed Substance P immunoreactivity in this same location and experiments Substance P immunoreactivity in this same location and experiments in which horseradish peroxidiase was applied to the rat pelvic nerve have shown that this fiber bundle contains visceral afferent projections from that nerve. Radially oriented strings of VIPIR varicosities were located in the lateral and ventral funiculi and a few fragments were noted in the dorsal columns. VIPIR fibers with varicosities were also found sparsely distributed throughout the gray matter.

In summary, this study has shown that although there is some specialization of the distribution of VIP in the region of the sacral parasympathetic nucleus in the rat as in the cat, monkey and human, the intensity and location of VIP within the cord out-side this area is quite different from those other mammals. Thus VID is there or even and have be excepted with pathways and Thus, VIP in the rat spinal cord may be associated with pathways and functions other than those of the pelvic viscera.

THE DISTRIBUTION OF MET-ENKEPHALIN (ME), SEROTONIN (5HT) AND SUBSTANCE P (SP) IMMUNOREACTIVITIES IN THE AREA POSTREMA (AP) OF 85.14 THE RAT AND CAT. B. W. Newton\*, B. Maley and H. H. Traurig\*. Dept. of Anatomy, Univ. Kentucky Med. Ctr., Lexington, KY 40536.

The area postrema, the proposed emetic center, lies on the dorsal surface of the brainstem at the level of the obex. It is a midline structure in the rat, but is bilateral in the cat. Using the peroxidase, antiperoxidase technique, ME, 5HT, and SP immunoreactivities were localized in the AP of the two species. Eight cats and eight rats were sacrificed by vascular perfusion transcardially with 4% paraformaldehyde in 0.1 M Sorenson's phosphate buffer, pH 7.2. In both the rat and the cat, ME had the greatest accumulation of immunoreactive fibers, followed by SHT and SP. The rat AP contained ME and SHT immunostained neurons, while the cat AP possessed only ME immunostained cell bodies. ME immunostained fibers, in the rat, were present along the ventrolateral border The area postrema, the proposed emetic center, lies on the

fibers, in the rat, were present along the ventrolateral border and the dorsal surface of the AP. ME immunoreactive cell bodies were found mainly along the ventrolateral and ventral borders. The cat's AP had the majority of ME immunoreactive fibers at its periphery in caudal sections with fewer fibers more rostrally, while the central region of the AP contained few immunoreactive fibers. ME immunostained cell bodies were located principally in central portions of AP with the cat having fewer cell bodies than the rat. For the rat, 5HT immunoreactive fibers were present along the AP's ventral and ventrolateral borders, with the fibers becoming more dense rostrally. 5HT immunoreactive cell bodies were seen centrally throughout the entire extent of the AP. In the cat, 5HT immunostained fibers were most prominent along the lateral border. The medial border contained fewer fibers which decreased in number from a caudal to rostral direction. In the rat the heaviest concentration of SP immunoreactive fibers was along the ventrolateral border in caudal sections, while the fiber numbers decreased rostrally. SP immunoreactive fibers, which increased in more rostral sections, were found mainly along the lateral border. There was consistent but low immunstaining along the medial border with some central AP regions lacking SP immunoreactivity. For all of the neuropeptides examined, in both species, the central region throughout the AP had the least numbers of immunostained fibers. The heterogeneous distribution of immunoreactive fibers and neurons in the AP suggests possible functional divisions within the region. Differences between the cat and the rat may be due

to species differences in their respective emetic and non-emetic behavior.

85.15

VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IS LOCALIZED TO THE LUMBOSACRAL SEGMENTS OF THE HUMAN SPINAL CORD. <u>M. Kawatani\*,</u> <u>I. Lowe, J. Moossy\*, J. Martinez\*, I. Nadelhaft, R. Eskay\* and</u> <u>W.C. deGroat.</u> (Spon: B. Dixit). Depts.of Pharmacol.,Pathol.and Neurosurg.,Univ. Pittsburgh and V.A. Hosp.,Pittsburgh, PA 15261 Recent immunohistochemical (IHC) studies of the cat spinal cord revealed that VIP is located primarily in the sacral seg-ments where it is contained in afferent projections to Lissauer's tract (LT) and lamina I on the lateral edge of the dorsal horn (DH). Dye tracing combined with IHC showed that VIP was present in sacral afferent pathways from the pelvic viscera. The present experiments were undertaken to determine whether VIP has a simi-lar localized distribution in the human spinal cord.

in sacral afferent pathways from the pelvic viscera. The present experiments were undertaken to determine whether VIP has a simi-lar localized distribution in the human spinal cord. Spinal cords were removed at autopsy (8 hrs post mortem) and fixed by immersion in Zamboni's solution. The tissue was sec-tioned in a cryostat and processed by indirect immunofluorescence or the PAP method. VIP-immunoreactivity (VIPIR) exhibited a very restricted segmental distribution in the human spinal cord being localized primarily to the sacral region, where the highest con-centrations were present in LT and the superficial layers of the DH. Smaller amounts of VIPIR were detected in LT as far rostral as L<sub>2</sub> and caudally into the coccygeal segments, however, rela-tively few VIP terminals were present in the DH of the lower thoracic, lumbar and coccygeal segments. In LT at the sacral level VIPIR was present in thick (6-25  $\mu$ m) bundles of rostrocaudally oriented axons. In lamina I of the sacral dorsal horn fine VIP axons and varicosities were heavily concentrated at the apex and lateral edge of DH, with relatively small numbers on the medial side of the DH. This contrasts with the distribution of substance P (SP) terminals which were located throughout laminae I-III of the DH. Some of the VIP and SP ter-minals were present in the sacral parasympathetic nucleus which was identified by AchE stain in S<sub>3</sub> and S<sub>4</sub> segments. Large num-bers of L-Enk terminals were also present in this area. In addi-tion, a few VIP axons projected from lateral lamina I through lamina V to end in the region of the dorsal commissue and cen-tral canal. Horizontal sections showed that VIP terminals at the ventral end of lateral lamina I exhibited a periodic organi-zation in which clusters of terminals corred at regular interthe ventral end of lateral lamina I exhibited a periodic organization in which clusters of terminals occurred at regular intervals  $(300 \,\mu\text{m})$  along the length of the cord. In horizontal sections VIP was also detected in rostrocaudally oriented axons in the desclutance lateral terminals the dorsolateral funiculus.

In summary the present study has shown that in the lumbosacral and coccygeal segments of the human spinal cord VIP is localized primarily in LT and on the lateral edge of the dorsal horn. This distribution suggests that VIP may be associated with pelvic visceral afferent pathways as demonstrated previously in the cat.

85.17 THE IDENTIFICATION OF LEUCINE ENKEPHALIN AND SOMATOSTATIN IN THE SACRAL PARASYMPATHETIC PREGANGLIONIC OUTFLOW TO THE COLON OF THE CAT. I.P.Lowe, M.Kawatani\*, W.C.deGroat, Dept. of Pharmacology, Medical School, University of Pittsburgh, Pittsburgh, PA 15261 The presence of leucine-enkephalin (L-Enk) and somatostatin (SS) in neurons in the region of the sacral parasympathetic nucleus has raised the possibility that these peptides may be co-transmitters with acetylcholine in the sacral preganglionic out-flow to the pelvic viscera. Support for this view was obtained

flow to the pelvic viscera. Support for this view was obtained in recent studies on the innervation of the cat urinary bladder where it was shown that L-Enk is localized in vesical preganglio-nic pathways and may function as an inhibitory transmitter in bladder ganglia. The present experiments were undertaken to examine the relationship of SS and L-Enk with the sacral pregang-lionic outflow to the colon of the cat. Ganglia on the surface of the distal colon were removed from normal animals and from animals in which the sacral ventral roots had been transected unilaterally for 4-8 weeks to produce degen-eration of the preganglionic input to one side of the colon. Frozen sections of ganglia were processed by indirect immunohis-tochemical methods to identify SS, L-Enk, substance P and vaso-active intestinal polypeptide (VIP). Colon ganglia were characterized by dense networks of SS and

Colon ganglia were characterized by dense networks of SS and L-Enk terminals surrounding the ganglion cells. Axons and axonal varicosities containing SS and L-Enk were also present between the ganglion cells and in nerves outside the ganglia. Pericellu-lar L-Enk terminals occurred in a greater density than SS-terto the transection but were normal in the contralateral ganglia.

to the transection but were normal in the contralateral ganglia. Axons containing SS were also eliminated on the transected side, however, some axons containing L-Enk remained. Axons and varicosities exhibiting VIP and substance P immuno-reactivity were distributed throughout colon ganglia, although not in pericellular networks similar to L-Enk and SS. VIP was also present in some ganglion cells. The distribution of VIP and substance P immunoreactivity was not changed by ventral root transection.

In summary, the present findings indicate that SS and L-Enk In summary, the present findings indicate that as and L-Enk terminals in extramural colon ganglia are of central origin, and most likely are a component of the parasympathetic pregang-lionic pathway arising in the sacral parasympathetic nucleus. Further studies will be necessary to determine whether SS and L-Enk have synaptic modulatory functions in colon ganglia as previously demonstrated for L-Enk in bladder ganglia. 85.16 SUBSTANCE P-CONTAINING SENSORY NERVES OF THE RAT IRIS: NORMAL DISTRIBUTION, ONTOGENY, REINNERVATION OF INTRAOCULAR IRIS GRAFTS AND DENERVATION BY CAPSAICIN. A. Seiger\*, C. Ayer-LeLievre\*, U.-B. Selin\*, I. Black and J. Kessler. Karolinska Institute, Stockholm, Sweden, Cornell Univ. Med. Coll., New York, U.S.A., and Albert Einstein Coll. Med., New York, U.S.A. Substance P (SP) in sensory nerves of iris stretch prepara-

tions was visualized using immunohistochemical fluorescence. innervation exhibited a characteristic 2-dimensional pattern with irregular plexuses and scattered arcades of non-terminal axons. Both sphincter and dilator areas were invested by SP nerves, whereas blood vessels were not associated with such fibers

During ontogeny, scattered SP nerves were already present in wborn irides. Density of the fiber plexuses increased by 4 newborn irides. and 8 days postnatally, and approximated adult levels by 14 days. To study re-innervation, iris grafts were placed in oculo: no SP was detectable 5 days post-operatively, however, reinnervation occurred rapidly. Scattered ingrowing fibers were apparent at 2 weeks; slightly irregular plexuses and axons of apparent at 2 weeks; slightly irregular plexuses and axons of normal density were present after 4 weeks and remained unchanged for 2 and 3 months. In host irides, SP fibers were initially normal, but moderate hyperinnervation developed 4-8 weeks after grafting. Capsaicin (C) treatment (50mg/Kg s.c.) of adults resulted in total disappearance of iris SP fibers within 3 days, and no reappearance for at least 12 weeks. After identical treatment of neonates, normal numbers and patterns of SP fibers were present at 4 and 8 weeks. However, administration X 4 at weekly intervals caused disappearance of all SP fibers by x 4 at weekly intervals caused disappearance of all SP fibers by 4 and 8 weeks of age. Moreover, single intraocular injections of  $(5\,\mu, 2.5\text{mg/ml})$  caused a 70-80% decrease in iris SP fibers at 10 days. After 8 weeks SP fibers had reappeared with a normal distribution. Our results suggest that SP may be used to examine normal sensory innervation of targets as well as ontogenesis and regeneration.

85.18 SUBSTANCE P-CONTAINING FIBERS IN MIDDLE CEREBRAL ARTERIES ORIGIN AND ULTRASTRUCTURE. L.Y. Liu-Chen, T. Liszczak, S.A. Gillespie<sup>\*</sup>, M.R. Mayberg<sup>\*</sup>, & M.A. Moskowitz. Neurosurgery and Neurology Services, Massachusetts General Hospital, Boston, MA. 02114 U.S.A.

Direct evidence for a substance P (SP)-containing trigeminovascular pathway was found in cats using the techniques of labeling two antigens both within a single section and in adsections. Wheat germ agglutinin (WGA), a retrogradely jacent Jacent sections. Wheat germ agglutinin (WGA), a retrogracily transported marker, was applied to the proximal segment of the right middle cerebral artery. Forty eight to sixty four hours after the above application, cats were treated with colchicine intracisternally, and 6 hours later perfused with buffered 4% paraformaldehyde. Successive immunocytochemical localization of WGA and SP on single sections was performed using avidin-biotin-peroxidase (ABC method) and dual color reactions. Diaminobenzidine was used to identify immunoreactivity attributed to WGA (brown); 4-chloro-1-naphthol was used to identify cells containing immunoreactive SP (ISP) (blue). Cells containing blue were found in all three trigeminal divisions; small numbers of cells containing brown or brown and blue were found in the ipsilateral first division only. Results of the immuno-cytochemical experiments using alternate adjacent thin sections confirmed the coexistence of WGA and SP immunoreactivities in the same neuron.

Immuno-electron microscopy of ISP-containing afferent immuno-electron microscopy of IS-containing afterent pro-cesses were performed in rat and cat cerebral atteries combining pre-embedding and ABC methods. Preliminary results indicated that fibers containing electron dense reaction product were associated with Schwann cells and were unnye-linated; axons contained neurotubules (24nm), microfilaments Indiced; axons contained neurotubules (24nm), microfilaments (10nm), mitochondria and vesicles; varicosities contained numerous clear vesicles (40-60 nm) and some dense core vesicles (60-120 nm), but few, if any, neurotubules. No membrane spe-cializations were observed within varicosities. Control tissues incubated either with normal rabbit serum, or SP antiserum preadsorbed with SP did not contain reaction product within nerve processes.

In summary, trigemino-vascular projections to middle cerebral artery contain ISP in vesicle-containing small unmyelinated fibers.

85.19 EVIDENCE FOR THE PRESENCE OF NEUROTENSIN-LIKE IMMUNOREACTIVITY IN A SCHWANNOMA CELL LINE. A. Nath\*, B. Haber, G. Bissette, L. Jennes\*, P.J. Manberg\*, and C.B. Nemeroff. Marine Biomed. Inst., Univ. Tex. Med. Branch, Galveston, TX 77550 and Biol. Sci. Res. Ctr., Univ. North Carolina Sch. Med., Chapel Hill, NC 27514. Neurotensin (NT) is an endogenous tridecapetide that is heterogenously distributed in the mammalian CNS and gastrointestinal (GI) tract. It is believed to be present in neurons of the CNS and in endocrine-like cells in the GI-tract. The purpose of the present study was to determine whether NT is present in a variety of glial and neural cell lines. To this end, NT-like immunoreactivity (NTLI) was determined by radioimmunoasay (RIA) as previously described (Manberg et al., J. Neurochem. 38:1777-1780, 1982) using an antiserum directed toward the mid-portion of the molecule. In addition, a C-terminally directed antiserum to NT, as previously described (Jennes et al., J. Comp. Neurol. 210: 211-224, 1982), was utilized to immunohistochemically (IHC) visualizet NTLI in the cell lines. Using the RIA, NTLI was found to be present in the RN-22 Schwannona cell line but not in several neuroblastoma cell lines (BN41A, SEY and NAA), a C6 glioma line or Bil0, a rat glioma line. The immuncytochemical method, for visualization of NT was conducted after the cell lines were fixed in acetone: methanol (1:2) and incubated with NT antiserum (1:500 dilution) for 16 hrs. Using an indirect immunohistofluorescent method (fluoroscein isothiotyanate or thodamine), NTLI was visualized in the cytoplasm of the RN-22 Schwannona cells but not in a variety of other cell lines including the SKY human neuroblastoma, C6 glioma and bovine aortic endothelial and fibroblast cells. The staining of NTLI was abolished by addition of exogenous NT. Although the molecular nature of the NTLI is unknown, these findings raise the question as to whether NT occurs in the nervous system in cells other than neurons.

## METABOLISM OF TRANSMITTERS AND MODULATORS

86.1 FORMATION AND METABOLIC DISPOSITION OF NE METABOLITES IN MOUSE BRAIN. P.P.LI, J.J. Warsh and D.D. Godse\*, Dept. of Biochemical Psychiatry, Clarke Institute of Psychiatry, University of Toronto, Toronto, Ontario. Although 3,4-dihydroxyphenylethyleneglycol (DHPG) and 3-methoxy-4- hydroxyphenylethyleneglycol (MHPG) are the major back of the state of

Although 3,4-dihydroxyphenylethyleneglycol (DHPG) and 3-methoxy-4- hydroxyphenylethyleneglycol (MHPG) are the major brain NE metabolites, the metabolic interrelationship between these metabolites has not been completely clarified. In this study we have examined the kinetics of formation and disappearance of brain DHPG and MHPG to estimate the degree of conversion of DHPG to MHPG and the amount of DHPG eliminated unchanged from the brain. Studies were undertaken in the mouse, a species in which these brain metabolites occur principally in unconjugated form, as in humans. Turnover estimations were obtained with the technique of synthesis inhibition following monoamine oxidase (MAO) and/or catechol-O-methyltransferase (COMT) inhibition. Quantitation of DHPG and MHPG was performed simultaneously by GC-MS.

Preliminary studies indicated immediate and maximal inhibition of MAO-A and COMT following clorgyline (10 mg/kg i.p.) and tropolone (75 mg/kg i.p.), respectively. During the first 30 min following tropolone, brain DHPC levels accumulated linearly at a rate of 1340 pmol/g/h, whereas MHPG disappeared exponentially at a rate of 411 pmol/g/h, with an estimated fractional rate of elimination (k) of 1.5/h. Following clorgyline administration, brain DHPC declined exponentially at a rate of 1200 pmol/g/h (k = 10.9/h). In contrast, the elimination of MHPG followed first-order kinetics only when COMT was also inhibited in addition to MAO. Thus combined clorgyline and tropolone treatment resulted in an exponential decline of MHPC levels at a rate of 520 pmol/g/h (k = 1.8/h), whereas DHPC levels were slightly but significantly elevated compared to control values. As it was possible that a small but significant amount of NE might be deaminated through MAO-B in the presence of MAO-A and COMT inhibition, the animals were treated with a combination of clorgyline, tropolone and pargyline (75 mg/kg). Under this condition, brain DHPC and MHPC disappeared at rates of 40 and 660 pmol/g/h (k = 0.4 and 2.0/h), respectively. The results suggest that mouse brain DHPC is cleared primarily

The results suggest that mouse brain DHPG is cleared primarily through O-methylation with minimal direct elimination from the brain. Assuming the disposition of NE metabolites are similar in mouse and human brain, then peripherally measured DHPG in humans is likely derived principally from extracerebral sources and more likely reflects peripheral sympathetic function.

This work has been supported in part by the Medical Research Council of Canada.

86.2 TRYPTOPHAN AND SEROTONIN METABOLISM AFTER SUSTAINED INFUSION OF TRYPTOPHAN BY MINI-OSMOTIC PUMP. <u>R. I. Peters and B. R. Buhr\*</u>. Dept. of Biological Sciences, Wichita State University, Wichita, KS 67208.

In an attempt to further delineate the regulatory role of tryptophan in serotonin synthesis and turnover, mini-osmotic pumps charged with L-tryptophan or vehicle were implanted subcutaneously in albino mice. After 24 or 96 hours of infusion, plasma and brain tryptophan concentrations, brain serotonin and 5-hydroxyindoleacetic acid concentrations, and hepatic tryptophan pyrrolase activities were measured. After 24 hr of infusion there was little difference in plasma tryptophan values of treated and control animals, presumably because of the elevated activity of the hepatic degradative enzyme seen in the treated animals. At this time serotonin concentrations were elevated in treated animals, although there were no apparent differences in brain tryptophan or 5-hydroxyindoleacetic acid concentrations. After 96 hours of infusion the activity of hepatic tryptophan concentrations were elevated. Despite the elevated brain tryptophan at this time, serotonin and 5-hydroxyindoleacetic acid concentrations were not significantly elevated in treated animals. Thus, although even a very low dose of tryptophan (c.a. 0.47 mg/Kg-hr) infused for 24 hr was sufficient to elevate brain serotonin concentrations, sustained infusion of tryptophan at this rate resulted in a dissociation of serotonin synthesis from precursor availability.

EFFECT OF LOW pH ON CHATECHOLAMINES (CA)SYNTHESIS AND 86.3 EFFECT OF LOW PH ON CHATECHOLAMINES (CA)SINIHESIS AND RELEASE IN THE CAT CAROTID BODY. (c.b.)R.Rigual\*,E.Gon-zález\*,S.Fidone and C.González. Dept. of Physiol Fac. de Med. Valladolid,Spain, and Dpt. of Physiol. Sch. of Med.Univ. of Utah, Utah. U.S.A. The c.b. is a CA containing organ, being dopamine (DA) the most abundant. DA has been suggested to play some role as medulator of chemosensory activity. Be-

some role as modulator of chemosensory activity. Re-cently, Fidone et al (J.Physiol.333:69-110) have shown a close relationship among hypoxic stimulations, syn-thesis and release of DA and activity in the carotid sinus nerve (c.s.n). In order to define the precise ro le of DA in the chemoreception it is necessary to know if the relationship found for hypoxia exits for other natural stimuli. The present data show that it is also the case for acidic stimuli.

The c.bs. were isolated and cleaned of surrounding tissues. To study the effect of low pH on CA synthesis, the c.bs. were incubated for 3h in a modified Tyrode the c.bs. were incubated for 3h in a modified Tyrode (pH 7.4 controls, pH 7 experimentals) equilibrated with 100% O<sub>2</sub> and containing 5mM glucose,1mM ascorbic acid 0.1 mM 6-MPH<sub>4</sub> and 0.04 mM <sup>3</sup>H-Tyr. To study the relation-ship among the intensity of acidic stimulation, the c.s.n. activity and <sup>3</sup>H-DA release, the c.bs. were incu-bated with <sup>3</sup>H-Tyr and then superfused (Fidone, 333:69-110) with 100% O<sub>2</sub> equilibrated Tyrode at different pH. The effluents were collected for <sup>3</sup>H-DA nallisis and the electrical activity was simultaneously monitored. The c.bs. incubated at low pH showed a 190% increase in total synthesis of CA, most of these being <sup>3</sup>H-DA. Superfusion of the c.bs. with Tyrode of increasing acid ity (pH 7.4 to 6.6) promotes a progresive increase in both c.s.n. activity and <sup>3</sup>H-DA release. The acidosis-induced release showed a marked Ca<sup>++</sup> dependence. In chronically deafferented c.b.s. the acidosis-induced

chronically deafferented c.b.s. the acidosis-induced release was moderately reduced. Our data, as a whole, are consistent with a role for DA in the response to are consistent with a role for DA in the response to acid. Specifically our data suggest that low pH acti-vates tyrosine hydroxylase and explain previous find-ings of increased stores of DA in acidotic animals. The released data show a direct effect of acidosis on type I cells and, consequently, the assumption that the acidic stimuli acts only on the chemosensory nerve endings seems untenable. This work was supported by a Grant from the C.A.I.

86.4 SENSITIVITY OF MITOCHONDRIAL MAO-A AND RESISTANCE OF MAO-B TO INHIBITION BY TRYPSIN AND OTHER PROTEASES: COMPARISONS ACROSS TISSUES AND SPECIES. Helen L. White\* and Deborah K. Stine\* (SPON: R.M. Ferris). Dept. of Pharmacology, Wellcome Research Labs,

Research Triangle Park, NC 27709. A selective inhibition of MAO-A (monoamine oxidase-A) activity A selective infinition of Audo-A (moloaline oxidase-A) activity by trypsin has been observed in human brain or liver extracts [White & Tansik (1979) in Monoamine Oxidase: Structure, Function, and Altered Functions (eds. T.P. Singer, <u>et al.</u>) Academic Press, 129-144]. This inhibition occurs in both crude mitochondrial extracts and in solubilized preparations of the enzyme. In the present study the protease sensitivities of MAO-A and B in dif-ferent tissues and species (rat, rabbit, dog, man) have been compared in an effort to explore factors that may influence the wide variations in MAO-A and B activities that are found in brain and peripheral tissues of different species. MAO-A/B ratios in mitochondrial extracts from brain, heart, and liver were estimated by determination of substrate affinities and selective inhibitions at low concentrations of clorgyline or deprenyl. Effects of incubations with trypsin, chymotrypsin, thermolysin or papain on MAO-A/B activities were interpreted in terms of known specificities of these proteases. Trypsin, which tends to attack basic peptide residues, was the most effective in causing loss of MAO-A activity, while MAO-B was remarkably resistant to the action of activity, while MAO-b was remarkably resistant to the action of this protease in all MAO extracts studied except those from rabbit. For example, MAO-A of human brain, human liver, and dog heart were inhibited 76 - 86% after incubation at  $37^{0}$ C with 10 U/ml of trypsin, while MAO-B activity was unaffected. MAO-A of rat mitochondria was somewhat less sensitive to trypsin than were human and dog enzymes. On the other hand, MAO-B in mitochondrial preparations from rabbit was also sensitive to trypsin. MAO inhibition by trypsin was prevented by soybean trypsin inhibitor and was diminished in the presence of MAO substrates at concentrations that can protect enzyme active sites and, indirectly,

enzyme conformation. Although species differences were observed in the responses to various proteases, the sensitivity to trypsin hydrolysis of MAO-A from all sources examined leads to a conclusion that MAO-A may contain basic residues that are important for enzyme activity either as part of the enzyme protein sequence or in an associated regulatory protein. The resistance of MAO-B in most extracts may indicate a lack or inaccessability of such basic residues. No interconversion of A and B activities was observed. In general, the results of this study support the concept that MAO-A and B are the distributed in the concept that may be embedded two distinctly different independent enzymes that may be embedded in the same mitochondrial membranes.

- 86.5 ESTRADIOL OR 2-OH-ESTRADIOL TREATMENT ALTERS SEROTONIN UPTAKE AND METABOLISM IN RAT BRAIN. S. Kowalik\* and A.I. Barkai\* (SPON: M. Baron) N.Y.S. Psychiatric Inst. and Dept of Psychiatry Columbia University Coll. of Physicians & Surgeons, N.Y. 10032. The influence of the steroid sex hormone estradiol (E) on brain function and behavior is presumably mediated by E receptor sites which are located in certain brain areas of either females or males. Variations in circulating E levels which affect behavior are associated with changes in monoamines. Because of Because of behavior are associated with charges if monoanties. Because of the apparent antidepressive effects of E and because the avail-ability of serotonin (5-HT) has been implicated as an important factor in depression, the effects of chronic E and its catechol metabolite 2-OH-estradiol (2-OH-E) on the metabolism or uptake of 5-HT were studied. Male rats (180-220g) were treated with of S-Hi were studied. While rats (180-220g) were treated with E or 2-04-E (5 µg/kg) daily for 5 days. For 5-HT uptake studies animals were sacrificed 30 min. after the last injection and the hypothalamus or cortex homogenized in Krebs-phosphate buffer. Homogenate aliquotes were incubated for 5 min. at 37° C with  $1^{14}C-SHT$  concentrations ranging from 0.2 - 2 µM. Vmax and Km were determined using the Wolfe-Augustinson-Hofstee method. Changes in 5-HT metabolism in the intact brain were estimated from the concentrations of 5-Hydroxyindoleacetic acid (5-HIAA) in the cerebrospinal fluid (CSF). Cisternal CSF was withdrawn from the urethane-anesthesized animal at a rate of 2  $\mu$ l/min. and 5-HIAA concentrations were determined using LCEC. In the uptake studies, treatment with either E or 2-OH-E significantly decreased Vmax values in the hypothalamus (2.1  $\pm$  0.4 or 2.9  $\pm$ 0.3~pmol/5~min/mg tissue, respectively) compared to controls (3.7  $\pm$  0.2) whereas no significant change was seen for cortex The level of 5-HIAA in the CSF was significantly higher The set of sumably by increasing its availability in the synapse. Supported by NIH Grant MH-33690.
- 86.6 ENZYMATIC DEACETYLATION OF N-ACETYLHISTAMINE IN RAT BRAIN. L.R. ENCYMAILC DEACEIVLATION OF N-ACEIVLHISIAMINE IN RAI BRAIN. LIX. Hegstrand, T. Kalinke\*, R. J. Hine\* and C. Barksdale\*. Univ. of Wisconsin and Middleton Vet. Admin. Hospital, Madison, WI 53706. There is substaatial evidence supporting a neurotransmitter role for histamine (HA) in brain. However, the mechanisms involved in the regulation of the biosynthesis of HA are poorly understood. Possible points of regulation are histidine uptake, histidine decodevalues (UC) and Neoretulitations. histidine decarboxylase (HDC) and N-acetylhistamine decarboxylase (NAcHAD). Chudomelka and Murrin (J. Neurochem. 40, 830, 1982) concluded from their studies on synaptosomal histidine uptake that this probably is not an important regulatory step in HA synthesis. Although the conversion of histidine to HA via the specific HDC is the most important biosynthetic pathway for HA formation, maximal in vivo doses of 2 HDC inhibitors, brocresine and  $\alpha$ -hydrazinomai in vivo doses of 2 HDC inhibitors, brocresine and canyofazino-histidine, cause less than a 50% HA depletion in brain (Dismukes and Snyder, Brain Res. 78, 467, 1974), whereas in vitro these compounds inhibit HDC 100% (Schwartz et al., J. Neurochem. 21, 1301, 1973). Perhaps when HDC is inhibited in vivo, the activity of NACHAD prevents HA from being depleted further. Endo and Ogura first described the enzymatic deacetylation of N-acetylhistamine (NAcHA) in rat brain (Jap. J. Pharmacol. 25, 161, 1975). They determined NAcHAD activity by measuring the HA formed fluorometrically after a column separation. This method is very insensitive and time-consuming. We have modified the assay by coupling it to and time-consuming. We have modified the assay by coupling it to a radioenzymatic assay for HA. This results in an assay for NACHAD that is at least 1000 times more sensitive as well as 5 to 10 times faster. Our results confirm their basic observations, but some of our findings differ. The source of our enzyme is fresh or frozen whole rat brain which has been homogenized on ice in 25 mM HEPES at pH 8.0, and 1 mM GSH in a glass homogenizer with a Teflon pestle that is motor driven. The homogenate is centrifuged for 15 min at 16,000xg. The supernatant is then assayed immediately or stored frozen at  $-80^\circ$ C. NACHAD activity is linear with time for 60 min and with tissue up to 10 mg in 200 µl. All enzyme activity is destroyed by boiling for 3 min. NACHAD activity is maximal at pH 8.0 in HEPES buffer. This activ NACHAD activity is maximal at pH 8.0 in HEPES buffer. This activity is dependent on the buffer as well as its pH. MnCl<sub>2</sub> more than doubles NACHAD activity. For brain NACHAD, the K<sub>m</sub> for NACHA is 140 µM and the V<sub>max</sub> is 13.2 pmoles/h/mg tissue. We synthesized and tested iodo-NACHA for substrate and inhibitor activity. It sin elither a substrate nor an inhibitor of NACHAO. We have synthesized <sup>3</sup>H-NACHA and are in the process of developing a direct radioenzymatic assay. Future studies will include additional biochemical characterizations, more complete kinetic studies, on-togenetic, regional and subcellular distribution of brain NACHAD activity, as well as purification of the enzyme to generate anti-bodies which will be used to do immunocytochemical localizations.

HPLC ASSAY FOR 3,4 DIHYDROXYPHENYLGLYCOL (DOPEG) AND 3-METHOXY-4 86.7 HIDE ADSHITCK 5,4 DIRKOTTHEKIGHTCH (DOED) AND STMIT HYDROXYPHENYLGLYCOL (MOPEG) IN GUINEA PIG. <u>G.A. Davis & R</u> <u>Goy</u> (Spon: P. Lipton). Wisconsin Regional Primate Research Center, University of Wisconsin, Madison, WI 53715-1299. We have been engaged in studies on the role of norepinephrine (NE) in controlling sexual receptivity in the guinea pig. In or der to gain an estimate of the rate of release of NE  $\underline{in}$   $\underline{vivo}$  we In orhave developed an HPLC assay for the NE metabolites, DOPEG and The method also provides values for the bioamines and MOPEG. their acidic metabolites.

Brain tissue is homogenized in 20 vol of acetone/IN formic acid (v/v:85/15) and centrifuged. 0.5 ml of the supernatant is extracted with 0.2 ml of heptane/chloroform (v/v:8/1), then dried under  $N_2$ . To obtain free MOPEG and DOPEG, the residue is reconstituted in 0.2 ml of 0.2M citrate-phosphate buffer (pH 3.6) and extracted 3X with 0.2 ml of water-saturated ethyl acetate/nand extracted 3X with 0.2 ml or water-saturated ethyl acetate/h-butanol (v/v:1/1). To obtain the total metabolites (free plus sulfate conjugated), the residue from the tissue supernatant is first digested for 5 h at 37<sup>0</sup> with 1.8 units of sulfatase (Sigma Type H-1) in 0.1 ml of 0.2M acetate buffer (pH 5.0). Before ex-traction, the pH is adjusted by adding 0.1 ml of 0.2M citratephosphate buffer (pH 2.5). The dried organic phase is reconsti-tuted in 0.1 ml of HPLC mobile phase and 0.02 ml of it is inject-ed onto a µBondapak C18 column, which is run at 1.9 ml/min with a buffer of pH 4.7 (1% acetic acid adjusted with NaOH, IMM EDTA). For the assay of NE, the dried tissue supernatant is reconstitu-(J) the askay of NC, the drived risks apprindum is reconstruct ted and analyzed under the conditions described by Mayer & Shoup (J. Chrom. 255: 533, 1983).
 Recoveries range from 68% for DOPEG to 85-90% for the acidic

metabolites. The sulfatase treatment produces no significant change in recoveries of internal standards. As a check on the method, whole rat brain was assayed and values for amines and metabolites were found which were very close to those reported in the literature. Further, clonidine (0.3 mg 3 h before sacrifice) was found to reduce total DOPEG and MOPEG in rat hypothalamus by Was found to reduce total DOPEG and MOPEG in rat hypothalamis by 40% and 28% respectively. In the guinea pig, as in the rat, a significant proportion of brain DOPEG and MOPEG was found to be conjugated with sulfate (SO<sub>4</sub>). For guinea pig hindbrain the following values were obtained (in ng/g tissue): free DOPEG, 22  $\pm$  2; DOPEG-SO<sub>4</sub>, 73  $\pm$  4; free MOPEG, 87  $\pm$  3; MOPEG-SO<sub>4</sub>, 34  $\pm$  3. Supported by NIH grant HD14821.

86.9 DIRECT FEEDBACK CONTROL OF GLUTAMATE DECARBOXYLASE BY GABA. T. G. Porter\* and D. L. Martin. Center for Labs and Research, NYS Dept. of Health, Albany, NY 12201. Studies from this laboratory have shown that glutamate decar-

boxylase (GAD), the enzyme responsible for GABA synthesis, is regulated by a cycle of inactivation and reactivation which is regulated by a cycle of inactivation and reactivation which is influenced by a number of regulatory factors including ATP, inorganic phosphate (Pi), the cofactor, pyridoxal 5'-phosphate (PLP), and the substrate, glutamate. Evidence is now presented that GABA, at concentrations within the range reportedly occur-ring in nerve endings, promotes inactivation of GAD by direct interaction with this cycle, thereby providing a potentially important molecular mechanism for negative feedback control of presynaptic GABA biosynthesis. Inactivation proceeds by an alternative transamination reaction catalyzed by GAD in which the active holoenzyme containing bound PLP is converted to anoenzyme with the release of pyridoxamine phosphate (PMP) and apoenzyme with the release of pyridoxamine phosphate (PMP) and succinic semialdehyde. Subsequent reactivation of the apoenzyme by PLP completes the cycle.

Inactivation experiments were performed with purified rat-brain GAD. To measure inactivation, GAD was preincubated with GABA for various lengths of time after which the remaining GAD activity was measured in a short (5 min) radiometric assay with 10 mM glutamate as substrate. The effect of PLP, Pi and ATP were determined by their inclusion in the preincubation mixture. The results showed that in the absence of added PLP, GAD was rapidly inactivated by GABA in a first-order process. The rate of inactivation depended strongly on the concentration of GABA. The concentration of GABA giving a half-maximal rate of inactiva-tion (Ki) was 16 mM. The half-time for inactivation increased from about 8.5 min at saturating GABA concentrations to more than 120 min at GABA concentrations well below Ki (1mM). GABA-Inactivation experiments were performed with purified ratthan 120 min at GABA concentrations well below Ki (1mM). GABA-dependent inactivation was prevented by the presence of 10  $\mu M$ PLP and 1 mM Pi, indicating that inactivation occurs by formation of apoenzyme in a manner similar to glutamate-dependent inactivation. The effect of ATP on the inactivation of GAD by GABA was also similar to that previously observed with glutamate-promoted inactivation. In the absence of added PLP, 100 µM ATP slightly accelerated inactivation (half-time = 7 min). In the presence of PLP, ATP strongly accelerated inactivation. Although the GABA concentration in the GAD compartment is

unknown, the GABA concentration in nerve endings is reportedly exceedingly high (>100 mM). Even if the GABA concentration in the GAD compartment were an order of magnitude lower, GABA would still have a strong inactivating influence on GAD. Supported by grant MH-35664 from the USPHS/DHHS.

HALOPERIDOL INDUCES HIGHER HOMOVANILLIC ACID CONCENTRATIONS IN 86.8 CEREBROSPINAL FLUID IN FEMALE THAN MALE NON-HUMAN PRIMATES. F. Seegal and K. O. Brosch.\*. Ctr. for Labs. & Res., New York State Dept. of Health, Albany, NY 12201. Evidence suggesting sexually dimorphic responsiveness to

agents that modify central dopaminergic (DA-ergic) function in-cludes: (1) male/female differences in dextro-amphetamine induced relase of DA from in-vitro perfused rat striata (Becker & Ramirez, <u>Brain Res. 204</u>, 361, 1981); (2) alterations in stri-atal DA receptor density with estrogen treatment (Hruska & Silbergeld, <u>Science</u>, 208, 1466, 1980); and (3) sexual differ-ences in the development of haloperidol-induced catalepsy in the Jpn. J. Pharm. 32, 247, 1982).
 The following study was undertaken to determine if sexually-

dimorphic changes in lumbar cerebrospinal fluid (CSF) concentrations of homovanillic acid (HVA) (3-methoxy-4-hydroxy-phenylacetic acid) would occur in adult male and female Macaca Neme-strina (pig-tailed Macaques) following acute exposure to haloperidol.

Lumbar CSF concentrations of HVA were determined by high-performance liquid chromatography with electrochemical detection under no-drug (baseline), probenecid only (50 mg/kg IP, to inhi-bit transport of HVA from CSF), or probenecid + haloperidol (.25 and .5 mg/kg). The drug administrations and CSF collections occurred under the following schedule:

ΙP	Probenecid	IM	Haloperidol	CSF	TAP
0			+2	+5	;
			HOURS		

Baseline CSF-HVA levels were higher in the females than in the males (X=43 ng/ml vs 20 ng/ml). Probenecid led to a large increase in HVA concentrations in both sexes due to inhibition of a probenecid sensitive acid-metabolite transport system. Treatment with probenecid and haloperidol elevated CSF-HVA con-

Treatment with probenecid and haloperidol elevated CSF-HVA con-centrations, with a significantly greater response seen in the females ( $\bar{X}$ =196 ng/ml vs. 66 ng/ml) than in the males. These results demonstrate, in a species closely related to man, that adult female monkeys are hyper-responsive to a widely used anti-psychotic DA-receptor blocking agent. The sexually dimorphic differences in CSF-HVA concentrations induced by pro-benecid-haloperidol might be due to differences in drug distribu-tion or motherlier. but outdows in redevice descentering is a specific but outdows in the second tion or metabolism, but evidence in rodents demonstrating in-creased DA-receptor density in striata following estrogen treatment and greater sensitivity in females to haloperidol-induced catalepsy suggests that the observed differences may be due to the influence of gonadal or pituitary hormones on central DAergic processes.

FORMATION, STORAGE AND, RELEASE OF GABA FORMED FROM [<sup>4</sup>H] GLUTAMINE AND [<sup>14</sup>C] GLUCOSE IN HIPPOCAMPAL SLICES: EFFECT OF DEPOLARIZATION. J. C. Szerb, Dept. of Physiol. and Biophys., Dalhousie U., Halifax, N.S., Canada, B3H 4H7 To study the off 86.10 FORMATION, [<sup>3</sup>H] GLUT

of Physiol. and Biophys., Dalhousie  $\overline{U}$ . Halifax, N.S., Canada, B3H 4H7 To study the effect of depolarization on the synthesis, storage and release of GABA, rat hippocampal slices were first incubated in 5 ml Krebs containing 0.25 mM glutamine, 2.5 mM gluçose and 3 or 50 mM K<sub>1</sub> followed by 15 min exposure to [<sup>+</sup>H] glutamine and [U<sup>-1</sup>C] glucose. Total and labelled glutamine, glutamate and GABA content and GABA release were measured by high-performance liquid chromatography. After incubation with 3 mM K<sup>+</sup> [<sup>+</sup>H] and [<sup>+</sup>C] glutamate contents were equal but there was twice as much [<sup>+</sup>C] than [<sup>+</sup>H] GABA present. After incubation with 50 mM K<sup>+</sup> labelled glutamate content doubled and labelled GABA content increased 3 fold as compared with incubation in 3 mM K<sup>+</sup> but there was no change in total glutamate and GABA content. When slices were incubated in 0 Ca<sup>2+</sup> and 10 mM Mg<sup>2+</sup> 50 mM K<sup>+</sup> no longer increased labelled glutamate content and increased labelled GABA content by only 30%. Slices, which after incubation in 50 mM K<sup>+</sup>, were superfused for 40 min with unlabelled 0.25 mM glutamine and 2.5 mM glucose maintained their higher labelled glutamate and GABA contents as compared to those incubated in 5 mM GABA contents as compared to those incubated in 3 mM GABA contents as compared to those incubated in 3 mM K<sup>+</sup>. Furthermore, slices that had been incubated in 50 mM K<sup>+</sup> released twice as much labelled GABA upon a second depolarization than those that were incubated in 3 mM K<sup>+</sup>. The specific activity of released [<sup>+</sup>C] GABA was 50%, that of [<sup>+</sup>H] GABA 100% higher than of GABA contained in the slices. Superfusion with 1 mM AOAA, after incubation arrested the synthesis of GABA but even in the presence of AOA slices incubated in the slices. AOAA, after incubation arrested the synthesis of GABA but even in the presence of AOAA slices incubated in 50 mM K' released twice as much labelled GABA than those which had been incubated in 3 mM K<sup>+</sup>. This indicates that most of the released labelled GABA originated from stores formed during incubation and not during superfusion. Results suggest that depolarization increases in a Ca<sup>2+</sup>-dependent manner the turnover of releasable GABA stores the same way as it increases the turnover of acetylcholine and the turnover of acetylcholine and increases norepinephrine in peripheral terminals.

86.PO ACTIONS OF CLASSICAL AND ATYPICAL NEUROLEPTICS ON DOPAMINE METAB-OLISM AND RELEASE IN VIVO. P. L. Wood, P. McQuade\* and N. P. V. NAIR. Research Lab., Douglas Hospital Research Centre, Verdun, Qué. H4H 1R3.

The neurochemical differentiation of classical and atypical neuroleptics until recently has focussed on possible differential actions in the extrapyramidal and mesolimbic dopaminergic (DA) projections. However, these studies have not revealed consistant preferential action of neuroleptics in either DA system. We have reinvestigated in more detail the actions of these drugs on DA metabolism and release <u>in vivo</u> in the mouse striatum. With classical drugs (haloperidol, perphenezine and chlorpromazine) dramatic increases in both DA metabolism and release vere meassured with a gas chromatographic-mass fragmentographic assay for dihydroxyphenylacetic acid, homovanillic acid, DA and 3-methoxy-tyramine. In marked contrast to the classical neuroleptics, the atypical agents (clozapine and thioridazine) increased DA metabolism with no concomitant increase in DA release. Sulpiride had similar actions except at high doses where increases in DA release were also noted. These data indicate the atypical neuroleptics differ from classical agents in their actions on DA release and suggest possible presynaptic actions in addition to their postsynaptic blockade.

## STAINING AND TRACING TECHNIQUES

87.1 ULTRASTRUCTURAL LOCALIZATION OF GLYCOGEN AND GLUCOSE-6-PHOSPHATASE (G6Pase) IN CELLS RELATED TO THE CNS. <u>A.M. Cataldo<sup>\*</sup> and R.D. Broadwell</u>. (SPON: G. Samaras) Department of Pathology (Neuropathology), University of Maryland School of Medicine, Baltimore, Maryland 21201

Glycogen and cytochemical activity for G6Pase were identified in neurons, glia, ependyma, choroid plexus epithelia, cerebral endothelia, and cells of the anterior and intermediate lobes of the pituitary gland in mice. Glycogen appeared as electron-dense aggregates scattered throughout the cells, including all portions of the neuron. Glycogen was preserved best by perfusion fixation with 2% glutaraldehyde-2% formaldehyde followed by a 2 hr. post-fixation in 1.5% ferrocyanide-2% aqueous osmium tetroxide. X-ray microanalysis has indicated that the electron-dense aggregates are representative of glycogen (de Bruijn, W.C., J. Histochem. Cytochem. 28:1242, 1980). G6Pase activity was preserved in all cells with a 5 min. perfusion fixation with 2% gluataraldehyde. Tissue sections were incubated in a modified Wachstein-Meisel medium (J. Histochem. Cytochem. 4:592, 1956) using the lead capture technique of Gomori. Glucose-6-phosphate, mannose-6phosphate, sodium and thiamine pyrophosphates, and B-glycerophosphate served as substrates. Only tissue incubated with glucose-6-phosphate and mannose-6-phosphate exhibited G6Pase activity consistently in the nuclear envelope and rough endoplasmic reticulum (ER) of all cells. G6Pase activity was negligible in axons and terminals. The cytochemical reaction involves the liberation of phosphate ions from the substrate and their subsequent capture by lead ions to form electrondense lead phosphate. This reaction indicates that G6Pase functions as a phosphohydrolase for converting glucose-6-phosphate to glucose. Absence of reaction product with inorganic pyrophosphate as a substrate suggests that G6Pase does not act as a phosphotransferase to supplement hexokinase activity for converting glucose to glucose-6-phosphate. In neurons and pituitary cells, localization of G6Pase activity was present frequently in the outer (cis) Gogi saccule and less so in the saccule subjacent to it. This latter saccule porfile of ER. Neither the trans Golgi saccules nor GERL (an acid phosphatase reacti 87.2 SELECTIVE DESTRUCTION OF SCIATIC NEURONS USING THE SUICIDE TRANS-PORT TECHNIQUE, R.G. Wiley and J. Wall, Lab of Experimental Neurology-VAMC, Vanderbilt University Medical School, Nashville, TN 37203.

Electrophysiological studies of the S-l cortex after sciatic nerve transection in rats have characterized changes in the cortical representations of the sciatic and saphenous nerves which develop within 1-2 d following sciatic transection. Such transec-tions produce inconsistent and incomplete loss of dorsal root ganglion (DRG) neurons after several days to weeks. In order to study the electrophysiological changes in central representation resulting from destruction of DRG neurons, and presumably their central processes, we sought to develop a technique for selective-ly destroying the DRG neurons projecting through the sciatic nerve. We chose to employ the suicide transport technique (Wiley, et.al., <u>Science</u>, <u>216</u>:889, 1982) using the toxic lectin, ricin, by intraneural injection (5 µl of 2-5 mg/ml on 2 separate occasions) of the sciatic nerve at mid-thigh level in adult rats. Additionally, similar injections of wheat germ agglutinin-horse radish peroxidase conjugate (WGA-HRP: 5 µl of 10 mg/ml) were made either contralateral to the ricin injections or in normal animals for the purpose of mapping the distribution of DRG neurons projecting through the sciatic nerve. WGA-HRP transport was dem-onstrated using TMB as the chromagen and darkfield optics. WGA-HRP retrogradely labelled 90-92% of neurons in the L5 DRG and a wariable, but somewhat smaller proportion of neurons in L4 and L6. Retrogradely transported ricin similarly destroyed 994% of neurons in the L5 DRG and smaller proportions of the L4 and L6 neuron populations demonstrating that it can be used to remove firstorder sensory neurons. At short survival times, ricin produced a complete loss of Nissl substance followed by progressive disintegration of the affected neurons. WGA-HRP also produced robust labelling of sciatic motor neurons in the mid-lateral ventral horn of the spinal cord, of central terminals of sciatic DRG neurons in the dorsal horn of the spinal cord, and of central terminals of sciatic DRG neurons in the nucleus gracilis. Ricin destroyed the appropriate motor neurons but had no detectable effect on dorsal horn or nucleus gracilis neurons. In summary, retrograde ('suicide') transport of ricin can be used to selectively destroy the motor and sensory neurons projecting through the sciatic nerve, but the doses are much larger than those that have been found effective in the vagus, presumably due to the presence of many heavily myelinated fibers in the sciatic nerve. Animals prepared in this fashion should prove useful in studying the CNS reponse to loss of first-order sensory neurons (This work supported by VA Merit Review Award.)

FURTHER STUDIES ON THE NATURE OF THE CARBONIC 87.3

ANHYDRASE POSITIVE NEURONS IN THE DORSAL ROOT GANGLION OF THE RAT. <u>V. W. Wong, C. P. Barrett, L. Guth and E. J. Donati\*</u> (SPON: F. D. Anderson). Dept. of Anatomy, University of Maryland Sch. of Med., Baltimore, MD 21201.

We have recently demonstrated histochemically that carbonic anhydrase activity is present in the perikaryon as well as the peripheral and central processes of some neurons of the dorsal root ganglion. These neurons are large in diameter (100 um) and have large processes (20 um) suggesting that they might represent muscle spindle afferents. To examine this possibility, we injected horseradish peroxidase (or bisbenzimide fluorescent dye) into the soleus muscle of adult rats. The horseradish peroxidase frozen sections of L4 and L5 spinal ganglia were reacted with fluorescein-conjugated-anti-peroxidase 48 hours later; after this procedure the carbonic anhydrase histochemical reaction was performed on the same sections. Fluorescent labeling was found to be performed on the same sections. Fluorescent labeling was found to be present only in those neurons which reacted positively for carbonic anhydrase We next sought to determine if the carbonic anhydrase positive neurons arose at the same developmental time (viz., the 12th day of gestation) as do la neurons. Pregnant rats were injected intraperitoneally with tritiated thymidine (5 uCi/g) at days 10, 11, 12, 13, and 15 of gestation. The L4 and L5 spinal ganglia of the offspring were removed at 33 day postnatally and frozen sections prepared. After being incubated for carbonic anhydrase histochemistry the slides were coated with llford emulsion for autoradiography. The amount of radioactive labeling in the carbonic anhydrase positive neurons was greatest after injection at 12th day of gestation, indicating that terminal mitosis occurs in these cells mainly on that day. These results show that carbonic anhydrase positive neurons in the rat dorsal root ganglion have the same anatomical distribution and embryological birthdate as the la afferent neurons. We conclude that carbonic anhydrase activity is found in la afferent neurons and that the carbonic anhydrase histochemical reaction serves as a useful marker for this neuronal population of the dorsal root ganglion. Supported by a grant from the NIH (NS 12847).

IMMUNOCYTOCHEMICAL CHARACTERIZATION OF GROWTH HORMONE, PROLACTIN, AND ACTH CONTAINING CELLS IN THE CETACEAN ANTERIOR PITUITARY. A. Schneyer and D. Odell\*. School of Marine and Atmospheric Science, Univ. of Miami, Miami FL 33149.

In order to assess the applicability of various immunochemical techniques to the study of reproductive physiology in the bottle-nosed dolphin, we attempted to identify cells in the anterior pituitary using the PAP immunocytochemical technique. Pituitaries were obtained from several species of stranded cetaceans, fixed in Were obtained from several species of standard clauses, the 2% glutaraldehyde for 1.5 hours, rinsed in buffer for 1 hour, de-hydrated, and embedded in Epon 812. Sections of 1-2w were affixe to glass slides and exposed to NaOH/EtOH solution to remove the Epon. Antisera to ovine and human pituitary hormones were Sections of 1-2u were affixed obtained from the National Pituitary Agency (NIAMDD) and applied at the following dilutions for 48 hours (4°C): prolactin (PRL), at the following dilutions for 48 hours (4°C): prolactin (PRL), 1:5,000; growth hormone (CH), 1:5,000; and adrenocorticotrophic hormone (ACTH), 1:10,000 (human only). Antisera to both human and ovine hormones cross reacted sufficiently with cetacean hormones to produce specific staining in all 3 cell types. Control exper-iments consisted of pre-incubation of antisera with homologous antigen to eliminate staining, pre-incubation of antisera with other hormones to check for non-precific staining of related cell other hormones to check for non-specific staining of related cell types, and deletion of various steps of the protocol to eliminate possible non-specific staining in subsequent steps. PRL cells were less numerous and more variable in shape than

GH cells and contained large, pleomorphic granules typical of this cell type. GH cells tended to occur in groups near capillaries and usually contained more granules per cell than lactotrophs. The cross reactivity of antisera demonstrated in this study is important in that cetacean pituitaries are relatively scarce,

hence purified hormone and cetacean-specific antisera are not available. Furthermore, this is the first report where immunocy tochemical techniques have been applied to research on any marine mammal. These results can also be applied to the development of heterologous RIAs for circulating levels of pituitary hormones in cetaceans.

IS THERE A SPECIES-SPECIFIC MONOCLONAL ANTIBODY WHICH HISTOCHEM-ICALLY VISUALIZES MOUSE CNS? J.K. Daniloff & M.A. Ariano. Anatomy & Neurobiology, Univ. Vermont College of Medicine, Burlington, VT. In our search for a species-specific monoclonal antibody (McAb) to mouse CNS, we have utilized two commercially available IgG: 1) species specific rat anti-mouse H-2 (MI/42, Hybridtech), and 2) strain-specific mouse anti-mouse Thy 1.2 (Accurate Chem. Co.). Neither McAb has been characterized immunohistochemically. Our aim was to locate McAb which would a) bind strictly to perfusion-fixed sections of C57B1 mouse brain with no crossreaction to rat brain, and b) permit robust visualization of labeled cells.

brain, and b) permit robust visualization of labeled cells. Anti H-2 is new to the commercial market and binds to antigens of a variety of haplotypes (J. <u>Immunol</u>. 127: 923, 1981) on C5781 mice. These cell surface antigens are recognized by T lymphocytes which lyse allogenic virus-infected or chemically-modified cells (<u>Transp. Rev. 29: 89, 1976</u>). Because biochemical assays have re-vealed H-2 antigens on mouse cerebellum (J. <u>Neuroimmunol</u>. 1: 429, 1981) we attempted to visualize H-2 antigens immunohistochemically. H-2 is best preserved through transcardial perfusion with 4% paraformaldehyde-0.05% glutaraldehyde in cacodylate buffer (pH 7.4). 50  $\mu m$  vibratome-sections were incubated overnight in the primary So has vibrations seen to be included overlaght in the primary McAb, 1:100, using the indirect percoxidase method with DAB as the chromagen. Reaction product was intensified using the Co-Ni meth. (J. <u>Histo. Cyto.</u> 29: 775, 1981). Results indicated robust and widespread labeling of neurons throughout the forebrain of <u>both</u> rat and mouse, including all layers of cortex and hippocampus,

rat and mouse, including all layers of cortex and hippocampus, thalamus, and striatum. Glial components were rarely visualized. There are two forms of the allelic Thy-1, 1.1 and 1.2. Only the 1.1 form is found in rat (J. Exp. Med. 136: 1054, 1972) and 1.2 is strain specific to C57BI mice, among others. Thy-1.2 anti-genicity is difficult to maintain (J. Histo. Cyto. 31: 263, 1983). The lightly-fixed brains were friable, and the 50 µm-vibratome sections were incubated overnight with McAb, 1:100. Darkly labeled neurons were apparent throughout comparable neocortical and hippocampal regions of both rat and mouse brain. We found it was necessary to use an affinity purified goat anti-mouse peroxidase conjugate that had been specifically adsorbed against rat (E-Y Lab oratories; American Qualex) to eliminate non-specific staining resulting from the application of the secondary antibody.

The present investigation indicated: 1) both H-2 and Thy-1.2 antigens can be preserved for immunohistochemistry, 2) both McAb recognized determinants in rat CNS, despite claims of mouse species specificity, and 3) anti-mouse and anti-rat peroxidase conjugates crossreact widely. Although the crossreactivity of various anti-bodies is rarely discussed and less frequently tested, it has widespread implications in the production of false-positive immuno histochemical staining. Supported by NSF grant BNS 81-02648.

A PREEMBEDDING COLLOIDAL GOLD STAINING PROCEDURE FOR THE ELECTRON 87.6 MICROSCOPIC LOCALIZATION OF STRAINING INCOLDENT IN RAT HYPOTHALAMIC MICROSCOPIC LOCALIZATION OF STRAINING INCOLDENT IN RAT HYPOTHALAMIC NEURONS. <u>R. Lamberts\* and P.C. Goldsmith</u>. Dept. Ob/Gyn and Repro. Sci. & Repro. Endo. Ctr., Univ. of Calif., San Francisco, CA 94143. Colloidal gold has primarily been used as an immunolabel for the electron microscopic demonstration of intracellular antigens in electron microscopic demonstration of intracellular antigens in postembedding grid staining, and for the localization of cell sur-face receptors by preembedding staining. In order to use this ver-satile marker for both light and electron microscopy, we applied it in the preembedding staining of vibratome sections of brain tissue. Following perfusion fixation with Nakane's PLP, SO-75 µm vibratome sections of rat hypothalamus were processed for immunocytochemistry (ICC). Incubation in primary antisera against  $\beta$ -endorphin or ACTH for 72 h use followed hu cert anti-rabht LoC counled to 20 µm for 72 hr was followed by goat anti-rabbit IgG coupled to 20 nm colloidal gold (GaRbIgG-Au) for 2 hr. The optimal pH and protein concentrations for coupling were determined according to the method of Frens. In some cases, colour intensification was attained by incubation in a second gold-labeled immunoreagent (RbIgC-Au or protein A-Au). The development of pink to light red cell bodies was monitored under the light microscope. Immunoreactive perikarya exreports using the PAP or immunofluorescence techniques. Positive cell bodies occurred predominantly in the arcuate nucleus, sometimes cell bodies occurred predominantly in the arcuate nucleus, sometimes extending dorsally in the periventricular zone, or laterally, near the ventral hypothalamic surface. Only the proximal portions of neuronal processes were labeled, whether or not the animals were pretreated with colchicine. At the electron microscopic level, positive staining was confined to the periphery of 90-110 nm dense neurosecretory granules. Clusters of colloidal gold particles that seemed to lie free in the cytoplasm in one sections were actually asso-cieted with concretery granules in diagont certions. No other cell seemed to he tree in the cytoplasm in one section were actually asso-ciated with secretory granules in adjacent sections. No other cell organelle was consistently labeled; the ergastoplasm and all Golgi elements were routinely negative. Non-specific staining was ob-served in large blod vessels, along the ventricular surface, and in the contact zone of the median eminence.

This ultrastructural localization of  $\beta$ -endorphin/ACTH in hypo-thalamic neurons correlates well with biochemical data on the intracellular processing of the peptide precursor in pituitary tumor cells. Our results demonstrate the usefulness of colloidal gold as an ICC label for staining intracellular antigens in vibratome sections. While reliable immunostaining may be restricted to the re-gions close to section surfaces, the method does not produce the diffuse reaction product obtained with many enzymatic ICC techni-ques. The specificity and distinctiveness of colloidal gold makes it an important tracer for double staining of neuronal systems in central nervous tissue.

Supported by NIH Grants HD 10907, HD 11979, and Deutsche Forschungsgemeinschaft.

DIFFERENTIAL BACKFILLING OF INTERNEURON POPULATIONS IN A LOBSTER 87.7 ABDOMINAL GANGLION USING RUBEANIC ACID PRECIPITATES OF Co<sup>++</sup> AND Ni<sup>++</sup>. <u>K. A. Jones<sup>\*</sup> and C. H. Page</u>. Dept. of Biological Sciences, Rutgers University, Piscataway, NJ 08854. Cobalt or nickel ions when used as intracellular markers form

different colored precipitates with rubeanic acid (dithiooxamide -Quicke and Brace, <u>J. Microscopy</u> 115: 161-163, 1979; Delcomyn, <u>J.</u> <u>Neurobiol.</u> 12: 623-627, 1981). Since mixtures of Co<sup>++</sup> and Ni<sup>++</sup> form colored precipitates distinct from either ion alone, doubly labelled neurons can be distinguished from those containing only labelled neurons can be distinguished from those containing each one ion type. We employed this differential staining technique to quantitate and locate the somata of the ascending, descending and bidirectional populations of projecting interneurons in the second abdominal ganglion.

The left ascending and descending hemiconnectives, that carry the axons of interneurons projecting from the ganglion, were the same of the interface of projecting from the gauginon, we can be simultaneously backfilled with separate solutions of NiCl<sub>2</sub> and CoCl<sub>2</sub>. Two sets of differential backfills were prepared. In the first the ascending hemiconnective was filled with  $Co^{++}$  and the posterior with Ni<sup>++</sup>, while in the second set the two ion solutions posterior with Ni<sup>++</sup>, while in the second set the two ion solutions were reversed. In the anterior-Ni/posterior-Co set 56 descending interneurons stained yellow (Co<sup>++</sup> presence), 55 ascending inter-neurons stained blue (Ni<sup>++</sup> presence) and 25 bidirectional interneurons stained red (Ni<sup>++</sup> and Co<sup>++</sup> presence). Although the other set of backfills (anterior-Co/posterior-Ni) stained a similar number of total interneurons a smaller proportion of these appeared red. More specifically, identifiable groups of somata stained red only in the anterior-Ni/posterior-Co set of backfills. These observations suggest the differential backfill-ing technique is sensitive to caudal-rostral asymmetries in the structure of the bidirectional interneurons. structure of the bidirectional interneurons.

HISTOCHEMICAL DETECTION OF ADENYLATE CYCLASE ACTIVITY WITH 87.8

FORSKOLIN. G. Szumanska\*, J. Bembry\* and M. Spatz (SPON: W. D. Lust). Lab. of Neuropathology and Neuroanatomical Sciences, National Institutes of Health, Bethesda, Maryland 20205. So far the available histochemical techniques for the visualization of adenylate cyclase (AC) activity in various tissues have been based on hormonal and 5-guanylylimidodiphosphate (CppNp) been based on hormonal and 5-guanylylimidodiphosphate (GppNp) stimulation of the enzyme activity irrespective of the type of agent (lead or strontium) used as a capturing ion. Recently, forskolin, a known hypotensive and antispasmotic drug, was shown to be a unique stimulator of cAWP-generating systems. This sub-strate in contrast to isoproterenol and GppNp increases the level of cAWP formation apparently through the direct stimulation of the catalytic unit of the AC without requiring the presence of guanine nucleotide binding subunit (Seamon and Daly, J. Cycl. Nucl. Boc. 7, 201, 1081) Nucl. Res. 7: 201, 1981).

In this communication we will demonstrate a histochemical method for the detection of AC activity using various concentrations of forskolin instead of isoproterenol and OppNp as sub-strate. The essential procedures of the technique were based on those described by Palkama et al. (J. Histochem. Cytochem. 29: 898, 1981) for light and electron microscopy. The AC reaction product formed with each substrate was evaluated in cerebrovascular endothelial cultures derived from brain microvessels and brain sections of rats.

The comparative studies showed that AC reactivity is greater to forskolin than to isoproterenol and GppNp. The histochemical demonstration of AC activity in these tissues was already possible with 0.2  $\mu M$  of forskolin while 100  $\mu M$  of isoproterenol and 10 mM of GppNp were needed to visualize this enzyme with the previously reported method.

These findings indicate that forskolin is not only a suitable As stimulatory agent but it represents a far superior substrate as compared to the other substrates for the demonstration of AC activity histochemically.

87.9 A NEW METHOD FOR STABILIZATION OF THE TETRAMETHYLBENZIDINE (TMB) REACTION PRODUCT FOR USE IN THE VISUALIZATION OF RETROGRADELY TRANSPORTED THE VISUALIZATION OF RETROGRADELY TRANSPORTED HORSERADISH PEROXIDASE-WHEAT GERM AGGLUTININ (HRP-WGA). T.M. Perney<sup>8,4</sup>, D.B. Rye<sup>8,4</sup>, B.H. Wainer<sup>4</sup>, and C.B. Saper<sup>b</sup>. Departments of Pathology and Pediatrics, The University of Chicago, Chicago, IL., 60637<sup>4</sup>, and Department of Neurology, Washington University School of Medicine, St. Louis, Mo., 63110<sup>b</sup>. The sensitivity of TMB makes it an ideal chromogen for tracing neural pathways (Mesulam, M.-M., and Rosene, D.L., J. Histochem. Cytochem., <u>27</u>: 763-773, 1979). The instability of the TMB reaction product in aqueous solutions, however, discourages its use for combined retrograde and immuno- staining methods, and makes EM applications difficult. This study presents a method for stabilizing the TMB reaction product. makes EM applications difficult. This study presents a method for stabilizing the TMB reaction product. Following development of TMB by the procedure of DeOlmos et. al. (J. Comp. Neurol., <u>181</u>: 213-244, 1977), tissue sections were incubated in the presence of DAB and  $H_2O_2$  at 4°C for 10 min. This procedure resulted in a stable brown-colored reaction product at sites of TMB accumulation. Addition of cobalt to the DAB- $H_2O_2$ TMB accumulation. Addition of cobalt to the DAB- $H_2O_2$ solution resulted in a black reaction product. Both procedures were as sensitive as TMB alone. Following cortical injections of HRP-WGA in rats, retrogradely-labeled cells in the basal forebrain were counted, and the following parameters affecting the sensitivity of this stabilization procedure were sensitivity of this stabilization procedure were studied: DAB concentration, temperature, and the requirement for  $H_2O_2$ . The reaction was stable at DAB concentrations of 0.1-0.01%, it appeared to require the presence of  $H_2O_2$ , and it was more stable when performed at low temperatures. This reaction product was stable when subjected to standard clochelaryloso was stable when subjected to standard alcohol-xylene was stable when subjected to standard alcohol-xylene dehydration. Finally the color and physical appearance of the reaction product when developed in the presence of cobalt, made it suitable for combinations using PAP immunohistochemistry. This h This has been confirmed by staining retrogradely labeled cells in the basal forebrain with a monoclonal antibody against choline acetyltransfersase. This work was supported in part by research grants from the Whitehall, McKnight, and American Parkinson Dis. Assoc. foundations, and USPHS NS-17661, HD-04583, NS-18669, NS-0631, 5-T32GM07281, and GM07839.

PROTEIN PHOSPHORYLATION IN A SINGLE, IDENTIFIABLE MOLLUSCAN NEURON. 88.1 J.T. Neary, J. Acosta-Urquidi, L.A. Tengelsen\*, A.M. Kuzirian\*, and D.L. Alkon. Section on Neural Systems, Lab. of Biophysics, NINCDS-

<u>D.L. Alkon</u>. Section on Neural Systems, Lab. of Biophysics, NINCDS-NIH, Marine Biological Laboratory, Woods Hole, MA 02543. Protein phosphorylation may play a role in associative learn-ing<sup>1</sup> and in the modulation<sup>2,3</sup> of a transient, voltage-dependent K<sup>+</sup> current, I<sub>A</sub>, which is reduced<sup>4</sup> following associative learning in <u>Hermissenda crassicornis</u>. Previously we found that intracellu-lar injection of Ca<sup>4+</sup>-dependent<sup>5</sup> or cAMP-dependent<sup>2</sup> protein kinase leads to a reduction in I<sub>A</sub>. To define the relationship of protein phosphorylation to the modulation of ionic conductance, it is necessary to identify and characterize the proteins which are phosphorylated by the injected kinases. With this goal in mind, we have developed to protein to chosphorylation in

phosphorylated by the injected kinases. With this goal in mind, we have developed a protocol to study protein phosphorylation in a single, identifiable neuron in <u>Hermissenda</u>. The cell selected for study, LP-1, is located in the left pedal ganglion<sup>6</sup> and has a diameter of  $\sim 150 \ \mu$ . <sup>32</sup>P-phosphoproteins from LP-1 are detected by labeling ganglia in carrier-free <sup>32</sup>Pi (125 µCi/200 µL incubation solution), dissecting and homogenizing LP-1 following freeze substitution of the ganglia<sup>7</sup>, and separating the proteins by CS coll characterization and contracterization LP-1 following freeze substitution of the ganglia', and separating the proteins by SDS gel electrophoresis and autoradiography<sup>1</sup>. Histological examination of the dissected cell reveals minimal contamination by glial cells or connective tissue. Time course studies indicate that <sup>32</sup>Pi uptake, <sup>32</sup>P-ATP, <sup>32</sup>P-lipids, and <sup>32</sup>P-proteins in LP-1 reach a plateau in 8 to 12 hr. <sup>32</sup>P-proteins and <sup>32</sup>P-lipids from one LP-1 cell can be detected by autoradiography after 2-3 day exposure using intensification techniques. The LP-1 phosphoprotein pattern is similar to that previously observed in <u>Hermissenda</u> circumesophageal ganglia and eyes<sup>1,3</sup>. Based on these studies, it should now be possible to conduct parallel biophysical and biochemical experiments in a single neu-

ron in Hermissenda and to investigate the proteins that are phosphorylated by protein kinases injected into LP-1 and by pharmaco-logical agents that affect Ca<sup>++</sup> and cAMP levels. LP-1 may also serve as a model cell for investigating biochemical processes which underlie associative learning since LP-1 contains a voltage-dependent I<sub>A</sub> current which exhibits  $Ca^{++}$ -mediated inactivation<sup>8</sup> and which is similar to that previously observed to change in Hermissenda Type B photoreceptors following associative learning4.

88.3 DEMONSTRATION OF PHYSIOLOGICAL RELEASE OF THE PUTATIVE NEUROMODU-LATOR GLYCINE FROM APLYSIA NEURON R14. A.R. Rittenhouse<sup>\*</sup> and C.H. Price (SPON: M.C. Nelson). Department of Biology, Boston University, Boston, MA 02215.

sity, Boston, MA 02215. Identified neuron R14, located on the dorsal surface of the parietovisceral ganglion (PVG) of <u>Aplysia</u> contains two possible chemical messengers, the free amino acid glycine and a small peptide. Previous studies indicate that R14 innervates the anterior aorta (AA) where it plays a neuromodulatory role (Sawada et al., <u>Brain Res.</u>, 207: 486, 1981). Both bath and iontophoreti-cally applied glycine and stimulation of R14 potentiate sero-toninergic-induced contractions of AA longitudinal muscle (AALM) without any apparent changes in muscle membrane electrical parawithout any apparent changes in muscle membrane electrical para-meters. However, the release of free glycine in this preparation has not been demonstrated. In this study, we report that stimula-tion of the axons or soma of Rl4 preloaded with <sup>3</sup>H-glycine (3H-G) results in a corresponding increase of 3H-G released from R14

axons that terminate in AALM. The PVG, vulvar nerve (VN), and AA were dissected out and The PVG, vulvar nerve (VN), and AA were dissected out and pinned such that the AA occupied one chamber and the PVG another. The VN (which contains R14 axons) projected from the PVG to the AA through a water-tight barrier. The AA chamber was superfused with seawater medium and the PVG was bathed for 8-14 h in medium containing 100  $\mu$ Ci/ml of 3H-G. The incubation period allowed time for R14 to take up the 3H-G and actively transport it to terminal regions in the AA. Both chambers were then repeatedly rinsed to wash off extracellular 3H-G and reincubated in plain medium. A sampling schedule was established so that the medium bathing the AA was removed every 5-10 minutes for scintillation counting.

There is tonic and occasional increases in release (or other efflux) of label from the AA when artificial stimulation is absent. Both bath application of 5 mM histidine (which stimulates R14 to approximately 1 Hz) and direct VN stimulation caused a several-fold increase in 3H-G release above baseline. TCA pre-cipitation of AA medium samples indicates that little of the 3H-label is present in protein. Autoradiographic studies show that only the identifiable axons of Rl4 in the VN and AA are heavily labelled. Experiments involving intracellular stimulation of Rl4 above spontaneous levels (0.7 Hz) were difficult (due to membrane accommodation) and were inconclusive. Experiments to test Ca++ dependency of this presumed release are underway but this preliminary data suggest that R14 releases free glycine during pro-longed spontaneous and induced electrical activity.

88.2

INCREASED AGE DECREASED RC1 MODULATION OF R15 BURSTING IN APLYSIA. T. L. SKINNER\* and B. PERETZ, Dept. of Physiology, Univ. of Ky. Med. Ctr., Lexington, KY 40536 R15 is a bursting pacemaker in the abdominal ganglion of Aplysia, whose activity can be modulated by the RC1 input via the right connective. Repetitive firing of the RC1-R15 pathway for several minutes has been shown to have a prolonged effect on bursting such that the number of spikes per burst increases as well as the interburst interval (Parnas et al., JNP 37:609, 1974). We found that the efficacy of RC1 modulation of R15 activity is decreased with age. Our study examined pre- and post-synaptic characteristics of the RC1-R15 pathway at different ages: mature (MAT) and old (OLD) Aplysia, 121 + 5 and 214 + 6 days post-metamorphosis, respectively. A suction electrode was used to stimulate the right connective. The following parameters were measured, with an intracellular electrode in R15, both before (C) and after (E) a four minute stimulation of RC1 at rates of 2 and 10/sec: spikes per burst, amplitude of bursting pacemaker potential (BPP), membrane potential (Em, at the trough of the BPP), and membrane input resistance (R1, at the trough of the BPP). Results for the two age groups at a stimulation, spikes per burst, Em, and BPP amplitude all increase for MAT R15's but remain relatively unchanged for OLD R15's. These data show that RC1 modulation of bursting pattern was present in MAT animals and was significantly less in OLD animals. With increased age, decreased modulation by the RC1 input may result from pre-synaptic and post-synaptic changes. A pre-synaptic change is decreased R1 R00 at 100 ms increased, which possibly is related to decreased EPSP size. Post-synaptic changes involved decreased R1 which could contribute in part to the decreased EPSP size. These results show that a central

changes involved decreased  $R_{in}$  which could contribute in part to the decreased EPSP size. These results show that a central synapse in <u>Aplysia</u> is affected by increased age.

MOTORNEURON SIGNALING PROPERTIES AND MOTORNEURON-MOTORNEURON SYNAPTIC INTERACTIONS IN THE NEMATODE ASCARIS. Ralph E. Davis\* and Antony O.W. Stretton. Neurosciences Training Program and Department of Zoology, University of Wisconsin, Madison, WI 53706.

We have been investigating the physiological properties of Ascaris commissural motorneurons and of their synapses. We reported previously that these cells have high resistance membranes, and that they propogate graded (non-action potential) signals. However, voltage-sensitive channels are present since graded anode-break responses can be elicited (Soc. Neurosci. Abstr. 8, 685). Both electrically evoked depo-larizations and anode-break responses are reversibly Co<sup>2+</sup>-senlarizations and anode-preak responses are reversibly Co<sup>--</sup>-sensitive. No change in commissural input resistance (steady state or early transient) occurs when  $Ca^{2+}$  is replaced by  $Co^{2+}$ . The lack of all-or-none action potentials in the presence of 50-100  $\mu$ M veratridine suggests that masked veratridinesensitive channels are not present in the commissures.

We also previously reported that neuromuscular transmission is graded and there is tonic transmitter release in the un-stimulated neuron. We have now demonstrated that the motorneuron to motorneuron synapses share these same properties. The spontaneous EPSPs and IPSPs seen in the five classes of commissural motorneurons are chemically mediated, since they can be reversed with current injection of the appropriate amplitude and polarity. These PSPs persist when the commissure is cut between the recording site (in the commissure) and the dorsal nerve cord, showing that these signals originate in the ventral nerve cord.

Ventral nerve cord. Previous anatomical studies have provided a description of the synapses between motorneurons. To examine the physiologi-cal properties of these synapses, we have made simultaneous microelectrode penetrations of pairs of motorneurons. Stimulating the presynaptic fiber produces post-synaptic poten-tials for most of the anatomically-defined synapses. Paradoxically, however, the synapse that is anatomically most common gives the weakest of physiological responses. We are currently investigating whether this is due to the properties of the synapse itself, or due to membrane properties and/or the geometrical relationship of the recording site (in the commissure) and the synapse (in the nerve cord).

Supported by USPHS Grant #AI 15429.

INTRACELLULAR RECORDINGS AND LUCIFER VELLOW-FILLS OF 88.5 INTERNELIDBERR RECORDINGS AND LOCITER TELLOWFILLS OF INTERNEURONS IN THE NEMATODE ASCARTS. James D. Angstadt and Antony O.W. Stretton (SPON: A. LeVin). Neurosciences Training Program and Department of Zoology, University of Wisconsin, Madison, WI 53706.

The motornervous system of the nematode Ascaris lumbricoides contains about 20 interneurons. There are six large interneurons that are identifiable anatomically and about 14 small interneurons that have so far not been individually identified. Anatomical studies have shown that the interneurons make synapses onto motorneurons, as well as among themselves. In order both to investigate the role of the interneurons in controlling the motorneurons, and to develop criteria for identifying the small interneurons, intracellular microelectrode penetrations and Lucifer-yellow dye injections have been performed. We find that like the motorneurons and large interneurons, the morpho-logy of the small interneurons is simple. One bipolar neuron, however, exhibits a somewhat unusual morphology. Its anterior-going process abruptly changes direction 180° within the ventral cord and travels posteriorly.

Electrophysiological recordings have shown that the largest ventral cord interneuron (int. A) makes excitatory synapses onto type DE1 motorneurons. In addition, some of the inter-neurons exhibit rhythmic voltage changes. In some cases the phase of the rhythm can be reset with short current pulses, suggesting that the cell is involved in the generation of the rhythm.

Supported by USPHS Neuroscience Training Grant 5T32 GM 7507 and Grant #AI 15429.

MONOCLONAL ANTIBODIES TO NEURONS OF THE NEMATODE ASCARIS. Carl D. Johnson\* and Antony O.W. Stretton (SPON: Philippa 88.6 Claude). Department of Zoology, University of Wisconsin, Madison, WI 53706.

With the ultimate goal of generating specific labels that can be used to identify neurons and synapses in light micrographs, we are generating monoclonal antibodies to Ascaris nervous tissue. Using collagenase-treated Ascaris as a source of enriched nervous tissue for immunization, we have generated hybridomas by fusing spleen cells with NS-1 myeloma cells. Screening for interesting antibody-secreting hybridomas was carried out by ELISA using homogenates of nerve cord and collagenase dissociated head pieces (back to, but not including, the retrovesicular ganglion). Specific cellular localization of antibody binding was determined anatomically using the anterior 20-30 mm of collagenase-dissociated worms that had been fixed with formaldehyde, and permeabilized with 1% Triton X-100.

We have found some antibodies that bind to neuronal pro-cesses, including commissures, sensory neurons and processes in the nerve cords and nerve ring. A second commonly occurring class of antibodies bind to fibrils in the hypodermis; comparison with electron micrographs suggests that these antibodies react with intermediate filaments. Some of these anti-bodies selectively stain elements within the sensory system. A balance of the sensory accessory cells, and to subsets of neuronal cell bodies. In particular, the cell bodies of excitatory motorneurons in the ventral nerve cord (Stretton et al., PNAS <u>75</u>, 3493 [1978]) are differentially stained: type DE2 neurons stain intensely whereas types DE1 and DE3 neurons stain weakly; similarly, among the putative ventral excitatory motorneurons, type V-2 neurons stain intensely and type V-1 neurons stain weakly. It is interesting that types DE2 and V-2 neurons are thought to be involved in posteriorly propagating locomotory waves, while types DE1, DE3 and V-1 neurons are thought to mediate anteriorly-propagating waves. We are currently investigating the chemical basis for these differences

88.7 SYNAPSES OF THE THICK ACCESSORY NEURON ON THE STRETCH RECEPTOR NEURON OF THE CRAYFISH, <u>PROCAMBARUS CLARKII</u>. <u>Kazuo Ikeda</u>, Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010. The distribution of the synapses on the fast adapting and slowly adapting stretch receptor neurons in the first to the fifth abdominal segments and the eighth thoracic segment was investigated with light- and electronmicroscopy. The thick accessory neuron was found to make synaptic contacts on the soma of the recentor neuron as well as the previously known dendritic of the receptor neuron as well as the previously known dendritic contacts.

contacts. Whole mount specimens of the receptor neuron and related nerves stained with methylene blue or impregnated with silver revealed that fine axonal branches of the thick accessory neuron forms a basket-like network covering the surface of the soma. The fine branch was accompanied by serially connected bulbs. The fast adapting receptor neurons were more densely covered by this net-work than the slowly adapting receptor neurons. Electronmicroscopy revealed that these fine branches on the soma were indeed making en passant type synaptic contacts on the

soma were indeed making en passant type synaptic contacts on the somal membrane. Thus the somal membrane receives numerous synapsomal membrane. Thus the somal membrane receives numerous synapses. Synapses were also found at the axon hillock region as well as on the axonal membrane as far as 50  $\mu$ m from the axon hillock. Although the quantitative analysis of the distribution of the synapses on the entire receptor neuron has not been completed, the density of the synapse on the somal membrane appeared to be higher than that on the dendrites. The present result is in accord with the finding of somal synapses reported by Peterson and Pepe (1961). Furthermore, the fine branches on the soma were traced to the thick accessory neuron in the present study. Since the receptor neuron and the x-fiber, the branching of those axons were carefully examined and found to make synapses on the dendrites of the receptor neuron but not on the somal membrane. Thus these somal synapses are identified to be those of the thick accessory neuron. The implication of this distribution for the inhibitory mechanism The implication of this distribution for the inhibitory mechanism must be investigated physiologically. (Supported by USPHS NIH Grant NS18858).

DYE COUPLING AND GAP JUNCTIONS BETWEEN CRUSTACEAN NEUROSECRETORY CELLS. H. Aréchiga<sup>+</sup>, B. Chávez<sup>\*+</sup> and R. M. Glantz++. +Depts. of Physiology and Cell Biology, CINVESTAV, IPM, Apdo. Postal 14-740, México, D.F. 07000. ++ Dept. of Biology, Rice University, Houston, Texas. 77001. The X organ in the crustacean eyestalk is a cluster of 100-200 processor of the sector of the secto 88.8

The X organ in the crustacean eyestalk is a cluster of 100-200 neurosecretory elements mostly located at the medial part of the medulla terminalis. They are known to project to a neurohaemal organ, the sinus gland, and to secrete a host of neurohomones of peptidic nature. There is electrophysiolo-gical data suggesting a possible coupling among these elements (Iwasaki & Satow, J. Gen. Physiol., 57:216, 1972). In the present report we describe morphological evidences compatible with such coupling. The experiments were conducted in adult cravits Pacifastacus

The experiments were conducted in adult crayfish Pacifastacus leniusculus or Procambarus clarki, of either sex. The animals were left one hour in advance in cold, oxygenated saline solution once the dorsal carapace was excised and the heart removed. The eyestalk was glued to the carapace and the removed. The eyestatic was glied to the cardiace and the eyestalk dorsal exoskeleton removed. For the dye-coupling experiments, glass micropipettes filled with 3% lucifer yellow were used. Their tip resistance was 50-100 m%. After the implement and characterization of the electrophysiological properties of the recorded neuron, the dye was introduced with 400 Acc huerenclaring relate of current for 40 02 with 10 n Amp hyperpolarizing pulses of current for 10-30 min. The eyestalk was removed and treated for wholemount

With 16 H when hyperpolarizing pusses of current volument observation. For a number of cells, the dye passed from the injected one to other elements, showing different patterns. Some neurons appear to be coupled only to one or two neighbour cells, others, to several cells. Still, a number of them did not show any evidence of dye-coupling. The possible presence of gap junctions was explored by subjecting the isolated eyestalks to freeze-fracture. The X organ-sinus gland system was divided in segments. At the level of cell bodies and proximal branches in the neuropil typical formations containing gap-junctions were observed. None were detected in the axons beyond the neuropil, and some again were seen in the nerve-endings at the sinus pland. These observations lend support to the notion of a functional coupling between neurosceretory cells in the X organ-sinus gland system. The physiological significance of these connections remains to be studied. remains to be studied.

IMMUNOHISTOCHEMICAL IDENTIFICATION OF DEVELOPING PURKINJE NEURONS 88.9 IN CULTURES OF RAT CEREBELLUM. <u>C.F. Franklin\*</u> and <u>D.L. Gruol</u> (SPON: R. Anderson). A V. Davis Center for Behavioral Neurobiology, The Salk Institute P O. Box 85800, San Diego, CA 92138.

The well-detailed organization of the cerebellum, the limited The well-detailed organization of the cerebelium, the limited number of neuronal types present and known synaptic organization make this brain region ideal for studies of the intrinsic electrical characteristics of identified CNS neuronal types and their function within a known circuitry We have developed a culture preparation of rat cerebellum to facilitate such studies, focusing initially on anatomical methods to identify developing Purkinje neurons in culture. The cultures are prepared from 20 day rat embryos a ago at which the carabellum is small Purkinge neurons in culture. The cultures are prepared from 20 day rat embryos, an age at which the cerebellum is quite small and morphologically immature. By 1 week in culture. extensive development has occured as indicated by the morphological characteristics of the cells and the presence of numerous synapses, identified by immunostaining for Protein I, a protein localized to synapses (Bloom et al, PNAS 76, 1979). Prior to 2 characteristics of the cells and the presence of numerous synapses, identified by immunostaining for Protein I, a protein localized to synapses (Bloom et al, PNAS 76, 1979). Prior to 2 weeks in vitro, morphological identification of cell types in unstained cultures is difficult, but in mature cultures (4 weeks in vitro; Gruol, Brain Res. 263, 1983) three classes of neurons can be identified: Purkinje neurons (PNs) granule cells and inhibitory interneurons. To obtain a more definitive identification of the PNs, immunohistochemical techniques were applied. Mature cultures were examined with an antibody against cGMP-dependent protein kinase, previously shown to stain PNs selectively in histological sections of rat cerebellum (Lohmann et al. PNAS 78, 1981). In the cultures, cells identified as PNs based on their unique morphology were also immunoreactive but all other cells (granule cells, inhibitory interneurons and non-neuronal cells) remained unstained. This antibody was then used to identify developing PNs in 1, 2, and 3 week cultures. The morphological maturation of PNs in the cultures was remarkably similar to that previously described in vivo (Altman, J. Comp. Neur., 145, 1972). As for PNs in vivo, three stages in NM maturation could be identified: (1) fusiform and apical cone stage (1 week cultures), (2) dendritic maturation (2 week cultures) and (3) somatic maturation (3 week cultures). Only minor changes in the morphology of PNs were observed at older culture ages. Electrophysiological studies are now in progress to identify the electric and properties of the PNs during the culture ages. Electrophysiological studies are now in progress to identify the electrical properties of the PNs during the maturation process in culture. All antibodies were gifts from Dr. Paul Greengard and are gratefully acknowledge. (Supported by NIAAA 03504)

CARTWHEEL AND STELLATE NEURONS IN THE DORSAL COCHLEAR NUCLEUS OF THE RAT: ELECTRON MICROSCOPY OF GOLGI IMPREGNATED CELLS. F. G. Mouterlood\* and E. Mugnaini. Laboratory of Neuromorphology, University of Connecticut, Storrs, Connecticut 06268. Of the five types of neuron which can be observed in Golgi sections of the outer two layers of the dorsal cochlear nucleus (DCN), three types, namely bipolar cells, cochlear granule cells and cochlear Golgi cells have been correlated previously with neuronal perikarya and profiles observed in thin sections of standard EM material. Although in the Golgi sections rapid and unequivocal distinction can be made between the two other types of neuron, called "cartwheel" and "stellate" cells, identification in standard EM material of their perikarya, dendritic and axonal profiles has not been resolved satisfactorily. By the present Golgi-EM approach we studied in the electron microscope thin sections of neurons classi 88 11 studied in the electron microscope thin sections of neurons classified by their light microscopic Golgi features as either carthwheel or stellate. Slices of rat brainstem containing the DCN were impregnated according to the Golgi-Del Rio Hortega procedure. Soliwith either D 19 or Kodalith developers, embedded in epoxy resin, thin sectioned and examined in an electron microscope. Both cartthin sectioned and examined in an electron microscope. Both Cart-wheel and stellate perikarya have smooth contours and contain an indented nucleus with an eccentric nucleolus. The nuclei of cart-wheel cells contain evenly dispersed chromatin, whereas the nuclei of stellate cells display small peripheral clumps of heterochroma-tin. In contrast to stellate cells, perikarya of cartwheel cells contain small Nissl bodies and large numbers of subsurface cis-terns associated with mitochondria. Axo-somatic synapses on cart-wheel cells are oulgoingly of the type true wheels cells terns associated with mitochondria. Axo-somatic synapses on cart-wheel cells are exclusively of the symmetric type, whereas stel-late cells receive axo-somatic synaptic contacts of both the sym-metric and asymmetric types. In addition, perikarya of stellate cells are apposed by dendrites of other stellate cells. These ap-positions include <u>puncta adherentia</u> and gap junctions. Cartwheel cells have thick, <u>smooth primary dendrites</u> and uniformly sized, densely spinous, curved secondary and tertiary dendrites which receive synaptic contacts of the symmetric (predominantly on shafts) and asymmetric (predominantly on spines) types. Stellate cells possess thin smooth dendrites with occasional pleomorphic spines. In addition to synaptic contacts of the same types as on cells possess thin smooth dendrites with occasional pleomorphic spines. In addition to synaptic contacts of the same types as on cartwheel dendrites, these dendrites are also engaged in numerous dendro-dendritic and dendro-somatic appositions, featuring <u>puncta</u> <u>adherentia</u> and gap junctions, with profiles of stellate cells. Both the axons of cartwheel cells and of stellate cells were ob-served to acquire a thin myelin sheath. FLUORESCENCE-LABELLED HYPOTHALAMIC ISOLATION OF 88 10 NEURONS. D.C.D. Rohrer\*, D.M. Gash, M.F.D. Notter\*, J.F. Leary\* (SPON: F.C. Barone) Departments of Anatomy and Pathology, University of Rochester, Rochester, N.Y. 14642. A major advance in neuroscience would be to have the capacity to

isolate pure populations of viable neuronal types for in vitro and in vivo study. One possible method under current investigation is utilizing retrograde transport of fluorescent tracers followed by fluorescent-

activated cell sorting of the dispersed tissue. This model is presently being tested using the hypothalamic neurosecretory system (HNS). A promising retrograde tracer for these studies is fluorescein isothiocyanate labelled wheat-germ agglutinin (FITC-WGA), a fluorescence-labelled plant lectin which demonstrates limited diffusion from injection sties, fast retrograde transport, packaging into lysosomes, and brilliant fluorescence. Through a parapharyngeal, infrahyoid, trans-sphenoidal approach, the neural lobes of 20 day post-natal and older Long-Evans rats have been exposed and injected with 1.5 ul of 2% FITC-WGA (Sigma).

WGA (Sigma). Time studies show that FITC-WGA is retrogradely transported to magnocellular neurons of the HNS within 10 hours. These cells remain brightly fluorescent for 48 hours in vivo and then gradually lose their fluorescence by 4 to 5 days post-injection. After a 24 hour survival period, the animals are decapitated, supraoptic and paraventricular nuclei quickly microdissected-out into cold calcium-magnesium-free media with 1% glucose, and then trypsinized. The dispersed cell preparation is run through a fine-grade Sweeney filter, 5 fetal calf serum washes and a bovine serum albumin density gradient to remove debris. Cell viability after this treatment remains greater than 85% in age groups tested. Most importantly, these remains greater than 85% in age groups tested. Most importantly, these single cells retain their internal fluorescent marker.

Single-cell preparations containing fluorescence-labelled hypothalamic cells are being examined and sorted by a multiparameter laser flow cytometer-cell sorter (EPICS V, Coulter Electronics). Cells can be sorted viably and sterilely on fluorescence and light scatter at rates of approximately 1000 cells/second, having pre-examined populations at more than 100,000 cells/minute up to 6 parameters/cell.

This presentation will review the properties of labelled and unlabelled cells in dispersed preparations on the parameters of fluorescence and light scatter. In addition, the viability of sorted cells maintained both in vitro and in vivo will be reviewed.

SYMPOSIUM. LESIONS OF THE VISUAL SYSTEM DURING INFANCY OR ADULTHOOD: EFFECTS ON MORPHOLOGY, PHYSIOLOGY AND BEHAVIOR. <u>R.E.</u> Kalil, Univ. of Wisconsin (Chairman); <u>J. Dineen</u>\*, Univ. of Wash-ington; <u>D.E. Mitchell</u>, Dalhousie Univ.; <u>E.H. Murphy</u>, Medical College of Pennsylvania; <u>V.H. Perry</u>\*, Univ. of Oxford; <u>P.D. Spear</u>, Univ. of Wisconsin 90 Univ. of Wisconsin.

It is well known that the infant brain may respond to damage It is well known that the infant brain may respond to damage differently from the adult. For example, the developing brain often appears to compensate for damage, using mechanisms that are apparently not available to the adult. As a result, brain damage during infancy frequently, but not always, leads to milder defi-cits than comparable damage to the mature brain. This symposium will focus on the consequences of damage to the

ints symposium will focus on the consequences of damage to visual system during development and adulthood. The effects o early versus late damage of the visual cortex or superior col-liculus in several species will be reviewed. When possible, behavioral results will be correlated with recent information The effects of

liculus in several species will be reviewed. When possible, behavioral results will be correlated with recent information concerning changes in the underlying anatomy and physiology. V. Hugh Perry will describe the effects of superior colliculus lesions in the neonatal rat on ganglion cells of the retina and their central projections. Visual acuity deficits will be re-lated to the anatomical consequences of lesions made at different stages of development. E. Hazel Murphy will compare the morpho-logical consequences of early cortical ablation in cats and rab-bits, especially with respect to retinal ganglion cells and the retino-thalamic projection. Differences between these species will be discussed in relation to the timing of central visual system development and the role of sustaining collaterals in ganglion cell survival. <u>Ronald Kalil</u> will review the morphologi-cal changes that occur in the retina, thalamus, and cortex fol-lowing removal of visual cortex in newborn and adult cats. <u>Peter</u> <u>Spear</u> will discuss the neurophysiological effects of visual cor-tex damage in neonatal or adult cats. Particular attention will be paid to the functional compensation that occurs in the lateral suprasylvian visual area following removal of visual cortex in young cats but not in adults. <u>John Dimeen</u> will contrast the ef-fects of striate cortex ablation in infant and adult macaque monkeys. Anatomical results in retina, thalamus and cortex will be described, and related to behavioral measurements of visual acuity. <u>Donald Mitchell</u> will report behavioral evidence regard-ing the visual acuity and depth perception of cats with lesions of visual cortex made during infancy or adulthood. The superior performance of infant operated animals will be discussed in re-lation to the anatomy and physiology of extrastriate visual areas. The session will conclude with an open discussion of questions from the audience.

from the audience.

WORKSHOP. NEW APPROACHES TO THE STUDY OF THE MECHANISM OF FAST 91 WORSHOF. New AFRONCHES TO THE STORY OF TH

Ever since the discovery of fast axonal transport there has been speculation about the molecular mechanisms that drive fast transport. However, until recently the experimental evidence about the molecular mechanism has been rather limited, and has been mainly pharmacological. In the last few years new techni-cal approaches have been used to provide new information about the biochemical and morphological substrates of fast transport. In this workshop, some of these new methods and new findings will be presented. <u>Tom Reese</u> will describe the new picture of the ultrastructure of axoplasm that is emerging from studies of specimens prepared by ultra-rapid freezing, followed by freeze-substitution or freeze-etching. <u>Daniel Goldberg</u> will present the results of experiments in which experimental probes were microinjection technique it has been possible to study the microinjected into single identified axons of Aplysia. By usin the microinjection technique it has been possible to study the effects on fast transport of probes that would not normally enter intact axons. Another method for introducing impermeant probes into cells is to permeabilize the plasma membrane with detergents and reactivate movement with exogenous ATP. <u>David Forman</u> will describe studies using lobster axons permeabilized by treatment with saponin. <u>Mark Willard</u> will present immuno-cytochemical and radiolabeling studies of the structure of the axonal cytoskeleton. <u>Scott Brady</u> will describe fast transport in isolated squid axoplasm studied with the AVEC-DIC micro-scopic technique. The speakers will discuss their current views of the molecular mechanism of fast axonal transport.

## DEVELOPMENT: ENDOCRINE CONTROL AND TRANSMITTER PLASTICITY

92.1 CONDITIONED MEDIUM ALTERS DISTRIBUTION OF PEPTIDES IN ENTERIC

CONDITIONED MEDIUM ALIERS DISTRIBUTION OF PEPITIDES IN ENTERIC NEURONS IN CELL CULTURE, <u>R. Nishi and A. Willard</u>, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115. We have previously shown that cultures of neurons dissociated from small intestines of newborn rats express many of the differ-entiated properties of enteric neurons <u>in vivo</u>. We are inter-ested in how these differentiated properties can be altered by changing the environment in which the neurons are growing. We have the object of medium conditioned by a programmer we have tested the effect of medium conditioned by a monolayer of heart cells. Previous work by our collaborators has shown that such conditioned medium (CM) contains a factor that induces

such conditioned medium (CM) contains a factor that induces cholinergic properties in cultured rat sympathetic neurons (see P. Patterson, 1982, Mol. Genetic Neurosci, pp 437-443). CM concentrated 10x by ammonium sulfate precipitation was resuspended in standard growth medium for enteric neurons (MEM with 25mM K<sup>+</sup> + 5% rat serum). All enteric neurons were initially plated in standard growth medium. Three days after plating half the cultures were switched to CM-containing medium. Cultures

the cultures were switched to CM-containing medium. Cultures were assayed 3-4 weeks after plating. CM caused little change in the number of neurons surviving. Cell bodies in CM were larger overall, with a range in diameter of 10-50um, versus 10-25um in control medium. Synthesis and storage of 3H-ACh from 3H-choline in a <math>3 hr. period was 2-4xhigher in CM neurons. This might be accounted for by the larger size of the somata. Neurons grown under either condition could not be distinguished electrophysiologically on the basis of electrical excitability or the frequency of occurrence of sponta-neous or evoked synaptic potentials. The most dramatic effect of CM was on the levels of pentides

The most dramatic effect of CM was on the levels of peptides in the enteric neurons. Processes of cells grown in CM lacked the usual high levels of peptide-like immunoreactivity as demon-strated by PAP immunohistochemistry. Antisera tested were those specific for met-enkephalin, somatostatin, substance P, and VIP. No apparent differences in immunoreactivity of the somata + CM were detected. In contrast, 5-HT-like immunoreactivity in both processes and somata were enhanced by CM. The decrease in pep-tide-like immunoreactivity was correlated with a change at the ultrastructural level. Enteric neurons grown under control conditions normally contain a heterogeneous population of synaptic vesicles, of which 100-150mm opaque core vesicles pre-dominate. Processes of CM neurons contained many clusters of 200dominate. Processes of CM neurons contained many clusters of 200-400nm vesicles that either lacked the opaque core or contained one that was considerably reduced in size. These were very rarely seen in control cultures. We are currently investigating the mechanism(s) of this effect of CM on the levels of peptides. This study was funded by NINCDS, the Muscular Dystrophy Association, and the American Heart Association.

92.2

EXPRESSION OF CATECHOLAMINE ENZYMES IN CHICK EMBRYO CILIARY GANGLIA IN VIVO AND IN VITRO. L. Iacovitti, G. Teitelman, L. Grayson\*, T.H. Joh and D.J. Reis. Laboratory of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021. Neurons of the cholinergic ciliary ganglia (CG) of chick embryo are able to express the catecholamine biosynthetic enzyme tyrosine hydroxylase (TH) when grown in vitro in the presence of notochord (36 out of 43, 83%) (Teitelman et al., Neurosci. Abstr. 8:257, 1983). To further evaluate the capacity of CG neurons to express a CA phenotype, we examined CG neurons for the appearance of CA enzymes during development in vivo. CGs were removed from chick at during development in vivo. CGs were removed from chick at embryonic day E 5 to  $\overline{E}$  14, fixed, sectioned, and processed for immunocytochemical localization of the CA enzymes TH and phenylethanolamine N-methyltransferase (PNMT) according to the PAP technique. A few cells containing TH were found in each 16 um section of CG from E 5 to E 14. These cells ranged in size from 18 to 22 um and had long stained processes. Fine varicose terminals containing TH and had long stained processes. Fine varicose terminals containing TH were also throughout the ganglion. At no time were cells containing PNMT found in the CG. This finding raised the possibility that CG neurons may also express CA enzymes in vitro in the absence of notochord. To test this, CG's from stage 30 to 35 chick embryos (E 7-E 9) were dissociated and plated onto collagen-coated dishes at a density of 1 CG/dish. After 5 to 8 days in vitro, cultures were processed for immunocytochemical detection of TH or PNMT. To test for the presence of aromatic L-amino acid decarboxylase (AADC), another CA enzyme, cultures were incubated with L-DOPA (60 min at 370) and processed for detection of CA histofluorescence. We found that in 50%enzyme, cultures were incubated with L-DOPA (60 min at 370) and processed for detection of CA histofluorescence. We found that in 50% of the experiments (n=135 cultures) all CG cultures stained for TH while in the remaining experiments only an occassional culture was stained. In those experiments where staining was observed, it was seen in the majority of neurons in the dish. In general, stained cultures contained widely distributed neurons with numerous branching processes and few non-neuronal cells. Cultures of this morphology also expressed PNMT. Similar results were obtained when the neuronal density was increased up to 5 CG/dish. In contrast, donamine histofluorescence was increased up to 5 CG/dish. In contrast, dopamine histofluorescence was present in all cultures preincubated with L-DOPA irrespective of morphology, suggesting that the expression of AADC and that of TH

and PNMT are differentially regulated. We conclude that at least a small population of CG neurons have the intrinsic ability to express CA traits during development in vivo and that this number increases when CGs are grown under certain tissue culture conditions. These findings suggest that the expression of CA traits is elicited in CG neurons by a number of environmental cues including, possibly, notochord. (Supported by Grant NS03346.)

92.3 TRANSMITTER PHENOTYPIC PLASTICITY IN HUMAN PHEOCHROMOCYTOMA CELL CULTURES, A.S. Tischler, Y.C. Lee, R.L. Perlman, J.E. Jumblatt<sup>\*</sup>, and S.R. Bloom<sup>\*</sup>. Dept. of Pathol., Thirs Univ. Sch. of Med., Boston, MA 02111; Dept. of Med., Hammersmith Hospital, London W120HS, England; Dept. of Physiol. and

Biophys., Univ. of Illinois Coll. of Med., Chicago, IL 60680. It has been known for some time that chromaffin cells from human pheochromocytomas exhibit spontaneous and nerve growth factor (NGF)-induced neurite outgrowth in culture (A.S. Tischler et al, Science 192:902, 1976). In the present investigation transmitter phenotype was studied in freshly dissociated cells and in 21-day old monolayer cultures from human pheochromocytomas to determine whether neurite outgrowth is accompanied by functional alterations. In 6 tumors studied, production of vasoactive intestinal peptide (VIP)-like immunoreactivity, whether measured per culture dish or per mg cell protein, was consistently enhanced by culturing in McCoy's 5A medium with 20% fetal bovine serum, rising from levels undetectable in four of the cases at day 0 to as much as 3.5 undetectable in four of the cases at day 0 to as much as 3.5 pmol/mg protein at day 21. This effect was consistently magnified by 2.5S NGF(100 ng/ml), resulting in levels as high as 9 pmol/mg protein. In one of the 6 tumors, neurotensin-like immunoreactivity was detected at day 0 (0.2 pmol/mg protein) and rose along with VIP (0.9 pmol/mg protein at day 21 in control medium, >1 pmol/mg with NGF). In one of 3 tumors studied, somatostatin-like immunoreactivity rose from undetectable levels at day 0 to as much as 0.8 pmol/mg protein at day 21, but this increase was not affected by NGF. Choline acetyltransferase (CAT) activity was studied in one of the six tumors and was also found to increase markedly in culture (16±13 pmol/min/mg protein at day 0, 188±7 pmol/min/mg at day 21 in control medium, 295±24 pmol/min/mg with NGF).

In contrast to the large increases in immunoreactive peptides and in CAT activity, catecholamine content in the same culture and in CAT activity, catecholamine content in the same culture dishes decreased to approximately 1/8 to 1/80 of initial levels per mg of cell protein and to 1/150 to 1/250 per dish, and was either unaffected or slightly decreased by NGF. We conclude that capacity for VIP production is a characteristic which is latent in many human pheochromocytomas, and is expressed in response to environmental signals which also favor neurite outgrowth in monolayer cultures. At least some human pheochromocytomas can also express cholinergic traits. Studies of human pheochromocytoma cultures may provide insights into molecular and cellular mechanisms in the regulation of a number

of human neuroendocrine genes. Suported by ACS Grant PDT-171, NIH grants R23CA27808 and HL 29025, and the Medical Research Council.

92.5 TARGET REGULATION OF ADULT SENSORY NEUROTRANSMITTER PLASTICITY. D.M. Katz, K.A. Markey, J.E. Adler and I.B. Black. Division of Developmental Neurology, Cornell Univ. Med. Coll., NY, NY 10021.

Studies in this laboratory have recently documented expression Studies in this laboratory have recently documented expression of functional catecholaminergic (CA) characteristics by primary sensory neurons in the nodose (NG) and petrosal (PG) ganglia of the normal adult rat, in vivo (Katz et al, PNAS, in press; Katz et al, 1982, Soc. Neurosci. Abs. 8:8). These characteristics include catalytically active tyrosine hydroxylase (TOH), the rate-limiting enzyme in CA biosynthesis, formaldehyde-induced catecholamine fluorescence, and sensitivity of intraneuronal catecholamine levels to pargyline, a specific inhibitor of monoamine oxidase. These findings demonstrated that adult expression of CA phenotypic characteristics, in the periphery, is not restricted to cells of the symmathor-adrenal axis, and indicrestricted to cells of the sympatho-adrenal axis, and indicated that catecholamines may serve autonomic sensory, as well as To define the mechanisms regulating CA metabolism in sensory

neurons, we examined the acute effects of axotomy on petrosal neurons, we examined the acute effects of axocomy on petrosal TOH. Peripheral axotomy dramatically reduced TOH catalytic activity and immunoreactivity in adult PG neurons within one week after surgery. However, enzyme activity and immunocyto-chemical staining returned to control levels within one month. These data suggest that PG neurons do not die following peri-These data suggest that PG neurons do not die following peri-pheral axotomy, but rather remain viable, expressing reduced levels of TOH activity. Consequently, target factors may regulate TOH levels in the innervating PG neurons. Moreover, colchicine blockade of axonal transport in PG axons appears to reproduce the effects of axotomy, indicating that transport mechanisms may mediate target influences on sensory TOH. To further characterize target effects on sensory CA charac-teristics, we have begun to examine TOH expression by PG neurons in tissue culture. Preliminary studies indicate that PG neurons in tissue culture. Preliminary studies indicate that PG neurons, grown for one week in the presence of their normal carotid body arget, exhibit TOH immunocytochemical staining. Definition of factors regulating sensory TOH <u>in vitro</u> is currently in progress. Supported by NIH post-doctoral fellowship NS 06623 to D.M.K. and NIH grants NS 10259 and HD 12108.

- 92.4 NEUROPEPTIDE DEVELOPMENT IN CULTURED EMBRYONIC RAT DORSAL ROOT GANGLIA. J.E. Adler, J.A. Kessler, I.B. Black. Division of Developmental Neurology, Cornell Univ. Med. Coll., NY, NY 10021.
  - Substance P (SP) and somatostatin (SS), putative peptide neurotransmitters, are localized to non-overlapping populations of small sensory neurons in the dorsal root ganglion (DRG). We have previously reported that the SP content of neonatal DRG sensory neurons increases markedly in culture. To further investigate the expression and ontogeny of neuropeptides, we have extended our observations to embryonic ganglia.

Cervical dorsal root ganglia from rat embryos were explanted onto reconstituted collagen and grown in medium supplemented with 10% fetal calf serum and nerve growth factor (10u/ml). To characterize developmental potentials at different ages, ganglia were explanted at different gestational stages. At embryonic day were explanted at different gestational stages. At embryonic day 13 (E13) ganglia contained low but detectable amounts of SP, which remained constant for up to 7 days in culture. In con-trast, explanted E14 ganglia initially contained similar quanti-ties of SP, but exhibited a 3-fold rise after a 3 day lag. Further, E15 ganglia exhibited a 10-fold increase of SP from the same baseline levels. Consequently, from E13 to E15 there is a progressive increase in the apparent potential for SP development in culture the same baseline levels. in vitro, suggesting that critical regulatory events occur during this period.

determine whether development of other sensory peptides To determine whether development of other endows personal paralleled that of SP, we examined SS. The EIS DRG contrast detectable levels of SS. However, in contrast to SP, SS de-creased significantly during the 7-day culture period. Since SS Τo and SP appear to be localized to different DRG neuronal popula-tions, these peptides may be useful markers for differential developmental requirements of different neurons in the same ganglion.

In summary, our observations suggest that (a) there is

critical period in the development of SP in the DRC, and (b) SP and SS development are differentially regulated. (Supported by Fellowship from Committee to Combat Hunting-ton's Disease and NIH Grants NS10259 and HD12108).

NOT ALL TRANSIENTLY CATECHOLAMINERGIC CELLS OF THE RAT EMBRYO POSSESS NOREPINEPHRINE UPTAKE. <u>G. M. Jonakait, K. Markey, M.</u> <u>Goldstein, and I.B. Black</u>. Div. Develop. Neurol., Cornell 926 Goldstein, and I.B. Black. Div. Develop. Neurol., Cornell Univ. Med. Coll., New York, N.Y., and Dept. of Psychiatry, NYU Med. Center, New York, N.Y.

We have been working with several cellular populations in the rat embryo which have in common the transient expression of tyrosine hydroxylase (T-OH), the rate-limiting enzyme in of tyrosine hydroxylase (T-OH), the rate-limiting enzyme in catcholamine (CA) biosynthesis. We wondered whether these populations, located in gut mesenchyme (Cochard et al., 1978; Teitelman, et al., 1979) and in several cranial sensory and dorsal root ganglia (Jonakait, et al., 1983) possessed, in addition to their other CA traits, the specific, high-affinity uptake of H-norepinephrine (H-NE). While high-affinity uptake of NE has already been demonstrated for a population of cells in embryonic rat gut (Jonakait et al., 1979), the coincidence of uptake and T-OH in the same cells has not been established (Jonakait, et al., 1979; Gershon et al., 1982). Utilizing simultaneous immunocytochemical and radiouatographic localization of T-OH and H-NE respectively, we found no T-OH-positive gut cells at 11.5 days of gestation (E11.5) which also exhibited uptake of H-NE. However, by E12.5 20% of T-OH-positive gut cell profiles had overlying silver

E12.5 20% of T-OH-positive gut cell profiles had overlying silver grains, and by E13.5, this percentage had increased to almost 60% for T-OH-positive cells throughout the gut, and attained almost 95% for T-OH-positive cells oral to the umbilical flexure. A few 95% for T-OH-positive cells oral to the umbilical flexure. A few cells, negative for T-OH, exhibited silver grains, but these were sparse. By El4.5 T-OH immunoreactivity was fading, but even faintly stained cells continued to exhibit NE-uptake, though increasing numbers of cells negative for T-OH took up H-NE. By El5.5, though only a few cells were positive for T-OH, radioautography revealed that gut cells continued to take up H-NE. At all ages examined, uptake was blocked by des-methylimiramine methylimipramine.

In contrast to cells of the gut, uptake of  ${}^{3}$ H-NE was never

In contrast to cells of the gut, uptake of H-NE was never exhibited by cells in the trigeminal, nodose, or petrosal ganglia, even though these cells, too, exhibit transient ex-pression of CA traits (Jonakait, <u>et al.</u>, 1983). We conclude, therefore, 1) that embryonic cells which tran-siently express aspects of the CA phenotype do not necessarily exhibit specific, high-affinity uptake of NE; and 2) that the population of cells responsible for uptake in the embryonic gut is coincident with the population of transiently CA cells pre-viously described, and that uptake remains a feature of these cells after their loss of other CA traits. This research has been supported by NIH grants NS17814.

92.7 TRANS-SYNAPTIC REGULATION OF ADRENAL LEU-ENKEPHALIN BY IMPULSE ACTIVITY. E.F. LaCamma\*, J.E. Adler and I.B. Black (SPON: E.M. Bloom). Division of Developmental Neurology & Perinatology Center, N.Y. Hospital-Cornell Medical Center, N.Y. 10021. Trans-synaptic impulse activity has long been known to increase catecholamine (CA) biosynthesis and CA synthetic enzymes in the adrenal medulla. Since opiate peptides are co-stored and co-released with CA's in medullary cells, and since medullary opiate peptides may be important modulators of the sympatho-adrenal stress response, we examined trans-synaptic regulation of the putative peptide neurohumour, leucine-enkephalin (L-enk). Adrenals were unilaterally denervated in adult rats and L-enk was determined using a sensitive and specific radioimmunoassay. Four days postoperatively L-enk increased by 250% compared to shamoperated or contralateral control adrenals. Further, treatment with chlorisondamine, a long-acting nicotinic receptor antagonist, also significantly increased L-enk, suggesting that impulse activity and medullary depolarization per se decreased L-enk. To define underlying molecular mechanisms, medullary explants were grown in culture. 4 days after explantation the (now denervated) medullae exhibited a 100-fold increase in L-enk. Tetrodotoxin (Ttx) which blocks the Na flux effects of V, prevented the effect of V on L-enk. Moreover, depolarization with 50mM KCL also prevented the rise in L-enk. Neither Ttx alone or 50mM NaCL controls affected the increases medullary L-enk through postsynaptic simulation decreases medullary L-enk through postsynaptic simulation the anoty increase of L-enk. Tetrodotoxin (Ttx) which blocks the Na flux effects of V is prevented the frise in L-enk. Neither Ttx alone or 50mM NaCL controls affected the increases medullary L-enk through postsynaptic simulation decreases Ma influx. Thus, trans-synaptic impulses simultaneously regulate opiate peptides and biogenic amines in the adrenal medulla.

92.8 ORIGIN OF ENTERIC SEROTONERGIC NEURONS FROM THE NEURAL CREST AND DETERMINATION OF THE SEROTONERGIC PHENOTYPE BY THE ENTERIC MICRO-ENVIRONMENT: A STUDY USING QUAIL-CHICK INTERSPECIES CHIMERAS. <u>M.D. Gershon, P. Cochard\*, D. Sherman\* and T.P. Rothman, Dept.</u> Anatomy and Cell Biol., Columbia Univ., P&S, New York, NY and Institut d'Embryologie du CNRS et du Collège de France, Nogentsur-Marne, France.

The enteric nervous system (ENS) differs structurally, neurochemically, and physiologically from other regions of the PNS. particular, the phenotypic diversity of its component neurons exceeds that of any other group of peripheral ganglia. Amongst the neurons intrinsic to the bowel are enteric serotonergic neurons. These neurons constitute about 2-3% of the enteric neuronal population and project widely as interneurons throughout the enteric plexuses. Through the use of quail-chick interspecies chimeras, LeDouarin and co-workers have established that enteric ganglia arise from the vagal (somites 1-7) and sacral (caudal to somite 28) levels of the neural crest and have proposed that phenotypic expression by enteric neuroblasts may be determined by the microenvironment of the bowel rather than by the level of origin of these neuroblasts in the neural crest. The current experiments were done: (1) to determine whether enteric serotonergic neurons are derivatives of the neural crest and (2) to test the hypothesis that the serotonergic phenotype is dependent upon a microenvironmental-neural precursor interaction within the bowel. Interspecies chimeras were constructed in which neural tube and crest were grafted from donor quail embryos into chick recipients. crest were grafted from donor quail embryos into chick recipients. The vagal neuraxis was removed from the hosts prior to stage 10, before the onset of neural crest migration. Either the vagal or the truncal neuraxis was grafted from the quail to the vagal region of the chick. Grafts were allowed to survive until day 8 to 15 of incubation, after which the gut was removed and exposed to  $^{3}$ H-serotonin ( $^{3}$ H-S-HT; 0.5 uM) in the presence of pargyline (0.1mM). The developing ENS in the resulting chimeras was examined by light (LM) and electron microscopic (EM) radioautography. The quail nuclear marker was identified for LM by specific DNA stain-ing and for EM by selective extraction of stain from DNA with quali nuclear marker was identified for LM by specific DNA staining and for EM by selective extraction of stain from DNA with EDTA. Enteric serotonergic neurons of quail origin were identified as doubly marked with the quail nucleus and  $H_{\rm DS}-HT$ . Grafts of vagal and even truncal neural crest gave rise to these neurons. It is concluded that enteric serotonergic neurons are of neural crest origin. Since truncal neural crest (somites 8-15) does not ordinarily give rise to serotonergic neurons, the observation that it will do so when grafted so as to migrate to the gut, supports the view that the enteric microenvironment, through induction or selection, plays a role in serotonergic phenotypic expression. 92.9 DEVELOPMENTAL PLASTICITY OF SYMPATHETIC NEURONS INDUCED BY GONADAL STEROIDS. L. L. Wright, P. Beaston-Wimmer\* and A. J. Smolen. Dept. of Anatomy, Med. Coll. of Penn., Philadelphia, PA 19129. We have found that adult male rats have 20% more neurons in the superior cervical ganglion (SCG) than females. This difference is

We have found that adult male rats have 20% more neurons in the superior cervical ganglion (SCG) than females. This difference is not present at birth, and the number of SCG neurons in adult males can be significantly reduced by neonatal castration. These results show that the normal low levels of endogenous testosterone in neonatal male rats alter the final number of SCG neurons.

To determine whether the gonadal steroids increased the numbers of neurons by enhancing proliferation or reducing neuron degeneration, pregnant females were injected with (3H)-thymidine on gestational day 16. The pups were then treated with 17-beta-estradiol (E2) or vehicle on alternate days from the day of birth until postnatal day 15 (P15), when they were sacrificed. Significantly more labeled neurons were present on P15 in the E2 treated animals. Other animals were injected with (3H)-thymidine on P3 and sacrificed 2 hours later. Although many non-neuronal cells were labeled, there was no evidence of postnatal neuron proliferation in SCGs of either vehicle or E2 treated animals. There is a temporal correspondence between animals treated with E2 or vehicle from birth were found at 3 days of age, prior to the onset of developmental neuron death. However, after the period of cell death, at P15, the number of neurons had not declined in animals treated with E2 from birth, as it had in vehicle treated littermates. These studies indicate that the increase in neuron numbers seen after neonatal gonadal steroid treatment neuron between strong the result of enhanced survival of sympathetic neurons through the period of developmental neuron death.

Treating neonatal rats with testosterone or E2 almost doubles the number of synapses found in the SCG. This treatment difference seen on day 15 is eliminated by cutting the preganglionic cervical sympathetic trunk (CST) on postnatal day 13 and allowing the extrinsically derived synapses to degenerate. This indicates that the additional synapses formed in the SCG as a result of gonadal steroid treatment arise from the axons of the CST, and not from the intrinsic postganglionic neurons or SIF cells.

The modification of gonadal steroids of neuron and synapse numbers in the SCG is an example of neuronal plasticity during development. It is of particular developmental interest because physiological levels of these hormones initiate a sequence of highly specific developmental alterations that are likely to be relevant to the function of sympathetic target tissues.

92.10 DEVELOPMENT OF THE ADRENERGIC PHENOTYPE IN RAT BRAIN: CHAR-ACTERIZATION OF A GLUCCOCRTICOID RESPONSIVE PERIOD. M.C. Bohn and I.B. Black. Division of Developmental Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

The adrenergic phenotypic character, <u>PNMT</u>, (phenylethanolamine N-methyltransferase), the epinephrine-forming enzyme, is expressed in both the peripheral and central nervous systems. To compare factors involved in phenotypic expression in brain and periphery, we have studied the initial expression, development and hormonal regulation of PNMT in adrenal medulla, superior cervical ganglion (SCG) and medulla oblongata MO). We have previously reported that PNMT is initially observed in brain on embryonic day 14 (El4), whereas PNMT does not appear in the periphery until El7. These observations suggest that the <u>initial expression</u> of PNMT is differentially regulated in brain and periphery. In the periphery, PNMT development and regulation during adulthood are glucocorticoid-dependent. To determine whether central PNMT is similarly regulated, we have now studied the effects of perturbations of the pituitary-adrenal axis and various steriod treatments on PNMT in MO. <u>Prenatally</u>, PNMT was increased in fetal adrenal and SCG following dexamethasone (DEX) treatment of late gestation preg-

<u>Prenatally</u>, PNMT was increased in fetal adrenal and SCG following dexamethasone (DEX) treatment of late gestation pregnant rats. As in the periphery, treatment of pregnant rats from E18 to E21 at doses of 1 or 4 mg/kg increased PNMT activity in MO at E22 45% and 60%, respectively. In both the periphery and brain, DEX treatment prior to E18 was without effect. <u>Postnatally</u>, we have previously observed that an increase in glucocorticoid levels on days 0-6 increases PNMT levels in SCG. In contrast treatment of rate on postnatal was 0-2 6-9

Postnatally, we have previously observed that an increase in glucocorticoid levels on days 0-6 increases PNMT levels in SCG. In contrast, treatment of rats on postnatal days 0-2, 6-9, or 7-13 with DEX (0.1µg/g) or cortisol (200µg/day) did not affect PNMT activity in MO at 3, 10 or 14 days. Adrenalectomy (ADX) on postnatal day 7 also did not affect development of PNMT in MO. In <u>adult</u> rat, decreased levels of glucocorticoids following ADX or hypophysectomy (HPX) had no effect on PNMT activity in MO during the postoperative month. In contrast, PNMT activity in the adrenal fell following HPX as observed previously (R. Wurtman & J. Axelrod, J. Biol. Chem. <u>241</u>, 2301, 1966).

6 J. Axelrod, J. Biol. Chem. <u>241</u>, 2301, 1966). Our experiments demonstrate striking differences in glucocorticoid regulation of PNMT in brain and periphery. In adrenal, the developmental increase in PNMT as well as the maintenance of PNMT in adult are steroid-dependent. In contrast, brain PNMT is not affected during development or adulthood by glucocorticoid deficiency. Nevertheless, prenatal DEX treatment during late gestation increases PNMT in both periphery and brain. Consequently, all adrenergic cells may be responsive to glucocorticoids during specific development al phases.

TESTOSTERONE-INDUCED ENHANCEMENT OF MALE MEDIAL PREOPTIC TISSUE 92.11 TRANSPLANT VOLUMES IN FEMALE RECIPTENTS: A "NEURONOTOPHIC" ACTION OF TESTOSTERONE. <u>C. W. Arendash and R. A. Gorski</u>. Dept. of Biology, College of Natural Sciences, University of South Florida, Tampa, Florida 33620 and Lab. of Neuroendocrinology, UCLA Brain Research Institute, Los Angeles, CA 90024.

The critical importance of the medial prooptic area (MPOA) for the expression of masculine sexual behavior in the rat has been well established. Through the use of a new intraparenchymal transplantation technique, we have recently reported that im-mature brain tissue from male neonates not only survives trans mature brain tissue from male neonates not only survives trans-plantation into the MPOA of female neonates, but that male MPOA tissue transplants can apparently develop <u>functional</u> connectivity with the female recipient's brain to enhance dramatically her dis-play of masculine sexual behavior during adulthood (Science 217: 1276-78, 1982). To gain some insight into the mechanisms(s) by which gonadal hormones "organize" or alter the development of the mammalian brain to bring about its sexual and neuroanatomical difmammalian brain to bring about its sexual and neuroanatomical all-ferentiation, the present study tested the ability of testosterone treatment to modify the volume of male brain tissue transplants in female recipients. 1-day old females, in addition to having either male MPOA or Caudate nucleus (CN) tissue bilaterally im-planted into their MPOA's, also received either 200 ug testosterone propionate (TP) or oil (sc) concurrently, and 200 ug TP or oil for the following four days. All recipients were sacrificed at 30 days of age, their brains serially sectioned at 50 um and at 30 days of age, their brains serially sectioned at 50 um and stained with Thionine. An analysis of male transplant volumes indicated that MPOA transplants in oil-treated recipients were substantially reduced in size  $(0.06 \pm .01 \text{ mm}^3)$  compared with the initial transplant volume of  $0.19 \text{ mm}^3$ . However, MPOA transplants in recipients treated with TP showed a 79% increase above the initial transplant volume (to  $0.34 \pm .05 \text{ mm}^3$ ). This 5- to 6-fold enhancement in MPOA transplant volume induced by TP treatment was highly significant (p < .001). In sharp contrast, the same TP treatment to recipients receiving male CN transplants resulted in no such enhancement. Therefore, transplants involving a brain area known to concentrate  ${}^{3}\text{H-labeled}$  testosterone neonatally (i.e., the MPOA) responded to TP treatment with an enhancement of volume which was not observed for transplants consisting of brain tissue not known to concentrate  ${}^{3}H$ -labeled testosterone (i.e., The above results suggest that testosterone is a "neuronotrophic" agent during development that acts specifically on cells within steroid-sensitive brain areas to prevent neuronal death within these areas. Such a CNS mechanism of steroidal action may be involved with the development of sexual dimorphisms in behavior, hormonal secretory patterns, and CN9 neuroanatomical structure. (Supported by NIH Grant HD-01182 and USF FRCS Grant #19-2702-005).

THE SPECIFICITY OF MOTONEURON TO MUSCLE INNERVATION CAN BE MANIPULATED HORMONALLY IN THE RAT. <u>S. Marc Breedlove</u>, Department of Psychology, University of California, Berkeley, CA 94720. Motoneurons of the spinal nucleus of the bulbocavernosus (SNB) inner-vate the perineal muscles bulbocavernosus (BC) and levator ani in male rats. These muscles are present in female rats at birth, but disappear shortly thereafter. Thus adult females possess neither the SNB nor its target muscles. Neonatal treatment of female rats with either testoster-one projugate (TP) or dibudratestosterone projugate ((DHTP) results in 92.13 one propionate (TP) or dihydrotestosterone propionate (DHTP) results in adult females which, like males, have an SNB and its target muscles. However, these two androgens exert disparate effects on this neuromuscoular system when they are administered just before birth. Prenatal TP causes the muscles and the SNB to persist into adulthood, but prenatal DHTP treatment paradoxically causes the muscles to persist without in-creasing the number of SNB cells. This condition is the result of either: a) muscles without innervation, b) muscles innervated by cells in the SNB region which do not morphologically resemble motoneurons, c) muscles in-nervated by a very few SNB cells, each innervating many muscle fibers, or d) muscles intervated by motoneurons with a normal morphology, but which are outside their normal anatomical locus in the SNB. The present results of horseradish peroxidase (HRP) injections into the muscles of androgenized females indicates that the last alternative is correct.

Pregnant Sprague-Dawley rats were injected with 2 mg/day of either TP or DHTP from the 17th - 22nd days of gestation. Upon delivery (day 23), the female pups were toe-marked and cross-fostered to untreated dams. The androgenized females were implanted with silastic capsules of testosterone in adulthood in order to increase the size of the perineal muscles. At least 2 weeks after capsule implantation the androgenized females were anesthetized and their BC muscles were injected with either 0.5 or 1.0 µL of 30% HPC in saline via a microsyringe guided under a dissection microscope. The rats were sacrificed 24-48 hrs later and the spinal cords were horizontally sectioned and stained for HRP by a tetra-methylbenzidine method. The experiments were done in five yoked pairs consisting of 1 prenatal DHTP and 1 prenatal TP female injected, stained and analyzed together.

and analyzed together. In females given TP prenatally, most motoneurons innervating the BC were found in the same location as in normal males: the medial moto-neuronal column normally occupied by the SNB. However, the BC of fe-males prenatally treated with DHTP was innervated by motoneurons in an anomalous location: the lateral motoneuronal column more than 600  $\mu m$  away. In prenatal TP females 71% of the labeled motoneurons were in the (normal) medial column, while in prenatal DHTP females only 18% of the motoneurons were in this medial position. These results represent a unique example of an alteration in the pattern of motoneuron to muscle innervation using normally relevant hormonal cues. An understanding of how this anomalous pattern comes about may elucidate mechanisms by which "proper" innervation patterns are normally achieved. Supported by NIH BRSG grant 2-S07-RR07006.

92.12 SEXUAL DIMORPHISM AND PERSISTENCE OF THE SYNAPTOGENIC EFFECT OF ESTROGEN IN PREPUBERAL RATS

Richard W. Clough and Jorge F. Rodriguez-Sierra, Department of my, Univ. of Nebr. Medical Center, Omaha, NE 68105. We have previously reported that treatment of 25-day-old We have previously reported that treatment of 25-day-old female Sprague-Dawley female rats with estradiol benzoate (EB) results in an acute induction of synaptogenesis in the hypothala-mic arcuate (ARC) region two days later (Clough and Rodriguez-Sierra, Am. J. Anat., in press). The present studies were con-ducted to determine if (1) this acute induction of synapse formation in prepuberal female rats is also manifest in EB-treated male rats and (2) if the increased number of ARC synapse after EB in female rats on day 27 persists beyond this 2 day period. Twentyfive day old Sprague Dawley female and male rats were administered 10 µg of EB or oil vehicle subcutaneously at 1200 hours. Male of age by jugular venipuncture at 1600 hours. Plasma was assayed for LH by radioimmunoassay. After bleeding, all rats were perfor the by radio multiple star in the bleeding, all table were per-fused transcardially with a paraformaldehyde-glutaraldehyde fixa-tive in phosphate buffer. The ARC, preoptic area (POA) and medial septal area (MSA) were dissected out and processed for electron microscopic analysis of synaptic area density.

	ARC	Area Density
Group (N)	<u>27 day</u>	<u>31 day</u>
oil-male (4)	10.06 + .46	
EB-male (4)	10.05 ∓ .48	
oil-female (6)	10.75 🖡 .42	14.35 + .44
EB-female (6)	18.51 + .46*	17.47 <del>-</del> .66*
( <b>*</b> p<0.05;	$\bar{x}$ + S.E.M./100 $\mu^2$ ,	compared to oil controls)

Results (table above) indicated that EB treatment does not induce an increase in all synaptic area density in prepuberal male rats. In contrast, prepuberal female rats show a significant inrats. In contrast, prepuderal remain rats show a significant in-crease in synaptic area density in the ARC on day 27. The increase in synaptic area density of the ARC, induced by EB, was found to persist in 31 day old female rats. We found no significant effect of EB on synaptogenesis in the POA or MS in either sex. We conclude from these studies that there is a dramatic

sexually dimorphic neural, as well as endocrine, response to EB administration in prepuberal rats. Females respond with a precocious surge of plasma LH and associated induction of ARC synaptogenesis; while males show neither an LH surge or increased synapse formation following EB administration. Furthermore, the acute induction of synaptogenesis seen on day 27 remains through at least day 31 in the prepuberal period suggesting the relative permanency of this maturational effect of EB in prepuberal female rats (Supported by NIH grant, HD 13219).

92.14

THE MORPHOLOGIC DEVELOPMENT OF SEROTONERGIC NEURONS IN THE CHICK EMBRYO: NEW FINDINGS OF LATE DEVELOPING NEURONAL SYSTEMS. J.A. Wallace, Department of Anatomy, University of New Mexico School of Medicine, Albuquerque, New Mexico 87131. As a continuation of earlier morphologic studies of the develop-ment of serotonergic systems in the chick embryo (Wallace <u>et al</u>. Neurosci. Abs. #255.2, 1981) the present investigation extends the findings of immunocytochemical staining patterns for serotonin (F. HT) in ordpriver, form 3 to 12 days of incubation (53 to F12). Be-

henosati. Action in the present interference of the end of the section of the sec 25%) in the innermost lamina of the three layers present in the optic tectum at this age. This latter finding of cells containing 5-HT (or a related indoleamine) in the optic lobes is particularly novel (or a related indoleamine) in the optic lobes is particularly novel since monoaminergic neurons have not previously been reported at this location in adult or developing chickens. 5-HT neurons were also initially detected at E7 to E9 in the lateral portion of the medulla at the point of entrance of cranial nerves VII and VIII. These spindle shaped cells were oriented with the cranial nerve fascicles as they entered the medulla. The possibility that these 5-HT neurons project axons peripherally into these sensory nerve roots is currently under study. Cells immunocytochemically stained for 5-HT were also noted for the first time outside the CNS in sympa-thetic chain ganglia and in the anterior pituitary. Large numbers of cells in the sympathetic ganglia were stained as early as E5, however the proportion of these cells in the ganglia at later stages is un-known. The immunostaining of cells at all the locations mentioned Alown. The immunosation of the artiserum with 10µM 6-hydroxy-tetrahydro-B-carboline, a condensation product of 5-HT formed during tissue fixation with formaldehyde (Schipper and Tilders, J. Histochem. Cytochem. 31: 12, 1983). The possibility that these later formed 5-HT cells occur transient-by during dural organization to a medanized from colle that begin their direct

ly during development or are derived from cells that begin their dif-ferentiation expressing another neurotransmitter phenotype is cur-rently under investigation. Supported by NSF BNS 82-08433.

93.1 NEW OBSERVATIONS ON THE TOPOGRAPHIC ORGANIZATION OF THE THALAMO-CORTICAL PROJECTIONS TO THE MOTOR CORTEX IN THE CAT. <u>A. Morán<sup>\*</sup> and F. Reinoso-Suárez</u>. Departamento de Morfologia, Fac. de Medicina, Univ. Autónoma, Madrid 34 (Spain).

The absence of systematic anatomical studies of the talamo-cortical connections of areas 4 and 6 of the cat motor cortex (MC), including those which end in its hidden parts situated in both banks and the bottom of the cruciate sulcus, suggested the value of an HRP retrograde technique study in which all levels of the thalamus could be analyzed serially. For this purpose, systematic small injections of HRP aqueous solution (sigma type VI) were made in 24 adult cats with careful avoidance of enzyme contamination of the surrounding cortical areas. Our results contribute greater detail to the description of the sites of origin in thalamic nuclei of projections to the MC (rostral part of ventral anterior, ventral anterior-ventral lateral complex, principal and basal ventral medial, rostral dorsolateral part of ventral posterolateral, medial subdivision of the posterior nuclear group, ventral posteroinferior, central lateral-paracentral, centromedian-parafascicular and midline nuclei). In addition we describe new thalamic regions which also project to MC, such as the lateral subdivision of the posterior nuclear group (to area 4), medial dorsal (not only medially to area 6 in the proximity of area 8 but also in the most lateral part of area 6), lateral intermediate coral, lateral anterior, lateral intermediate caudal and lateral medial nuclei (to areas 4 and 6) and the suprageniculate nucleus (also to both areas 4 and 6). We suggest an overall topography of these thalamo-cortical connections, which in spite of their overlapping show a sequential arrangement proceeding from zones which are partially aligned in a band-like fashion in the thalamus and send projections which are also aligned in bands in the cortex. This thalamocortical relationship generally extends beyond the borders of the thalamic nuclei and the cortical subareas and is arranged along latero-medial coordinates. This topographic organization also shows that the arrangement in the thalamus from ventral to dorsal may be reflected in

93.3 MOTOR PROGRAMMING AND THE PREMOTOR CORTEX OF THE RHESUS MONKEY Karl-Heinz Mauritz and Steven P. Wise. Laboratory of Neuro-

physiology, NIMH, Bethesda, MD 20205 The premotor cortex has been suggested to subserve motor programming, and class of directionally specific and "set-related" neurons could be involved in such programming (Weinrich and Wise, J. Neurosci. 2: 1329). These set-related neurons are activated or inhibited during a delay period between the presentation of a visual or auditory instruction stimulus (IS) and a subsequent trigger stimulus. Most set-related cells show qualitatively different changes in activity for impending limb movements in opposite directions, e.g. an increase in neuronal discharge before flexions and a decrease before extensions. In order to see how a change in the visuospatial instruction influences neuronal activity, several visuomotor tasks were presented randomly to an operantly conditioned rhesus monkey.

Target-On Condition: When the monkey pressed a center key for 1 s, either a left or a right target key was illuminated to serve as the IS. After a randomly varied delay period (1.5, 2.25, or 3 s) a light above the target was turned on to serve as a trigger signal for a reaction time movement. <u>Target-Off</u> <u>Condition</u>: The IS was turned off (after 1 s) during the delay period and the monkey had to remember the direction of the next required movement for the remainder of the randomly varied delay period. <u>Target-Change Condition</u>: The IS was switched, after 1 s, from one side to the opposite side.

Directional set-related unit activity was profoundly affected by the target-change condition. After a change of the IS from one side to the other, the sustained activity changed from activation to inhibition or vice versa with a mean latency of 143 + 37 ms to reflect the new impending movement direction. All 31 directionally specific set-cells that have been observed to date have displayed this behavior. In the target-off condition, the sustained activity pattern is comparable to that shown when the target remains on. Additionally, about 24% of the set-related neurons showed either transient bursts or inhibitions 169 + 42 ms after the target light was turned off. There was almost no modulation in the neuronal activity during repetitive, self-paced, and slower movements between the left and right targets.

and slower movements between the left and right targets. The results are consistent with the hypothesis that directionally specific set-related premotor cortex neurons reflect the motor preparations of the animal. Furthermore, these results indicate that the directionally specific set-related cells are activated or inhibited when changed targeting necessitates a rapid reprogramming of the next motor act. 93.2 MODIFICATION OF CORTICO-CORTICAL PROJECTION AFTER ELIMINATION OF THALAMOCORTICAL PROJECTION IN THE CAT. <u>H. Asanuma, E. Kosar, N.</u> <u>Tsukahara and H. Robinson</u><sup>\*</sup> The Rockefeller University, New York New York, 10021

We have reported (Kosar et al., 1982, Neurosci. Abstr.) that in normal cats association fibers arising from area 2 of the sensory cortex (S-Cx) terminate in the superficial layers (II and III) of the motor cortex (M-Cx), area 4 $\delta$ . The neurons receiving this input were primarily stellate interneurons. In the present study, we have examined the changes of projection from area 2 to area  $4\delta$ after ablation of neurons in the ventro-lateral (VL) nucleus of the the thalamus.

Cats were anesthetized with Nembutal and 2.5  $\mu$ g of kainic acid was injected into VL nouleus stereotaxically. After one month survival time the cats were re-anesthetized (Nembutal 35 mg/kg) and a double chamber was installed over the motor and sensory cortices. 3-5 stimulating electrodes were implanted in area 2 of S-Cx and a stimulating pulse of 0.2 ms duration, 30  $\mu$ A intensity was delivered at 2/sec through each electrode. Intracellular recordings were made from motor cortical neurons through a pipette electrode filled with 10% HRP in 0.5 M KCl. In several animals, depth reversal of evoked potentials in the motor cortex elicited by stimulation of S-Cx was examined. At the end of the experiments, animals were deeply anesthetized, perfused, and sections were cut and reacted with TMB method.

A total of 49 M-Cx cells was successfully impaled and their EPSFs were compared to those in the control animals. The major changes were 1) EPSFs beared multiple notches whereas in the control animals the majority was monophasic. 2) The time from the beginning to the peak of EPSP became longer. 3) Some of the neurons receiving S-Cx input were located in layer V. 4) The surface positive evoked potential showed a negative focus in the depth whereas in the control group no such focus was present. 5) Some of the neurons stained with HRP were not typical stellate cells.

It is concluded that elimination of one input produced significant changes to the other input which might explain the recovery of motor function after deprivation of thalamic input to the motor cortex.

93.4 MICROSTIMULATION MAPS OF THE ARM AREA OF THE MONKEY'S MOTOR COR-TEX BEFORE, IMMEDIATELY AND TWO MONTHS AFTER MEDULLARY PYRAMIDO-TOMY. A.R. Mitz\* and D.R. Humphrey. Lab. Neurophysiology, Emory Sch. Med., Atlanta, GA 30322. Recent mapping studies of the motor cortex of the cat have

Recent mapping studies of the motor cortex of the cat have shown that two major outputs emerge from the zone assumed previously to control only distal forelimb muscles: (i) a low-threshold pyramidal tract outflow which affects principally distal forelimb muscles, and (ii) a higher-threshold, extrapyamidal outflow which affects proximal limb and trunk muscles (Asanuma et al, J. Neurophysiol., 46: 694-703). Similar spatial overlap has been observed in the motor cortex zones which control wrist, elbow and shoulder muscles in the monkey, but it is not known whether distal and proximal arm muscles are effected principally by separate corticofugal systems. To obtain such information, we used intracortical microstimulation methods  $(2-60 \ \mu A, 0.2 \ msec$  biphasic pulses, 10-30 pulse trains, 300 pps) to map the precentral arm area in two lightly tranquilized monkeys before, 3-7 days after, and 42-60 days after unilateral medullary pyramidotomy. Evoked movements were carefully recorded, and chronically implanted EMG leads were used to continuously monitor evoked activity in five major muscle groups of the arm. Our major results were as follows. (1) Before pyramidotomy, low-threshold  $(3-20 \ \mu A)$  stimulation at various cortical loci evoked any one of the major forms of fundamental movements observed about finger, wrist, elbow or shoulder joints in the alert animal. In particular, isolated movements of the thumb, the index finger (digit 2), and of digits 3-5 were easily evoked. (2) 3-7 days after medullary pyramidotomy, the cortical map was drastically reduced in spatial extent, with only 'in-concert' movements, remaining. No evoked activity was observed in biceps or triceps EMGs, and only questionable responses were seen from two cortical loci in shoulder girdle muscles, even with the most intense stimuli and the longest cortical trains used. (3) 42-60 days after pyramidotomy, however, the map returned partially toward the pre-lesion configuration, with shoulder, wrist and, to a lesser extent, elbow move

Thus, movements of proximal limb muscles evoked by motor cortex stimulation in the monkey appear to depend upon the integrity of pyramidal tract fibers, a situation unlike that in the cat. Moreover, the only functional outflow from the arm area immediately after pyramidotomy seems to be one for controlling crude movements of the hand. Those movements of more proximal muscles that are recovered later appear to depend upon adaptive changes in other extrapyramidal systems. (Supported by NIH Grant NS 10183)
- CORTEX I
- THE RELATION OF CALLOSAL CONNECTIONS TO MICROSTIMULATION MAPS OF 93 5

THE RELATION OF CALLOSAL CONNECTIONS TO MICROSTIMULATION MAPS OF PRECENTRAL MOTOR CORTEX IN OWL MONKEYS. H. J. Gould, III, C. G. Cusick, T. P. Pons and J. H. Kaas. Dept. of Anatomy, LSU Medical Center, New Orleans, LA 70112 and Dept. of Psychology, Vanderbilt Univ., Nashville, TN 37240 Microstimulation mapping procedures were combined with injec-tions of horseradish peroxidase (HRP) in the same animals to re-late the functional organization of motor cortex to patterns of corpus callosum connections in adult owl monkeys. A typical pro-cedure was to label callosal pathways in anesthetized animals by making multiple injections of HRP into the entire somatomotor cortex of one cerebral hemisphere, and then explore motor cortex of the uninjected hemisphere for a remaining 24-48 hour survival period. In order to obtain extensive and detailed mass of motor of the uninjected hemisphere for a remaining 24-48 hour survival period. In order to obtain extensive and detailed maps of motor cortex, 200-600 sites were stimulated in each animal. At the end of mapping, reference lesions were made at known sites, and the brains were removed, flattened, and cut parallel to the cortical surface so that the areal pattern of callosal connections could be readily appreciated in sections reacted using tetramethyl benzidine or benzidine dihydrochloride. Movements to  $0.5-10 \ \mu A$  levels of current were obtained over a 6 mm wide strip of cortex bordering Area 3a and including Area 4 and parts of Area 6. Stimulation sites near the medial wall related to tail movements, and bindlimb, foot, trunk, forelimb, hand, face, and finally tongue bordering Area 3a and including Area 4 and parts of Area 5. Stim-ulation sites near the medial wall related to tail movements, and hindlimb, foot, trunk, forelimb, hand, face, and finally tongue movements were elicited by successively more lateral sites. In cortex rostral to the tail motor representation, there was a re-representation of the head and forelimb in what appears to be the supplementary motor region. Rostral to the motor representation of the shoulder, face and eyelids, stimulation of a restricted region of cortex resulted in eye movements (frontal eye fields). Within the low threshold motor field, some body movements appeared to be represented both rostrally and caudally. Zones of callosally projecting cells and zones of callosal terminations within the motor field were quite similar. Densities of connections varied considerably. In particular, two 2-3 mm wide patches of dense callosal connections, one rostral to the other, were noted. The caudal patch included motor representation of parts of the trunk, shoulder, and neck, and it also extended somewhat out of motor cortex into Area 3a. Stimulation of the rostral patch also re-sulted in movements of the trunk, hips, and shoulder. Cortex devoted to movements of the trunk, hips, and shoulder. Cortex callosal connections. callosal connections.

MOVEMENT DEPENDENT MODULATION OF FORELIMB PERTURBATION RESPONSES IN 93.6 MONKEY PARIETAL CORTEX. <u>D.J.Crammond\*</u>, <u>W.A.MacKay and J.T.Murphy.</u> Department of Physiology, University of Toronto, Toronto. Ontario. Canada, M5S 1A8.

Late myotatic reflex responses have been shown to be modifiable under many conditions and are known to be modulated during a movement uncer many conditions and are known to be modulated during a movement cycle (W.A.MacKay et al; Electroenceph, Clin, Neurophysiol.,1983. In press). The aim of the present research was to similarly examine the proprioceptive input to somatosensory cortex at different times during a movement cycle, to see if at the cortical level the responses are constant and if not investigate the relationship between the motor program and the responsiveness of individual neurones. Single unit recordings were undertaken in the nariatal cortex of such are been to be recordings were undertaken in the parietal cortex of awake monkey (Macaca arctoides). The animal was highly trained to sequentially flex and extend his elbow in order to track a line on a video monitor with a cursor corresponding to the elbow position. Movement amplitude was 15°, At 5 phases during both movement directions a torque perturbation (70 msec ramp) was applied to either flex or extend the elbow. Brachialis msec ramp) was applied to either flex or extend the elbow. Brachialis and triceps EMG was rectified and integrated to record active and reflex activity. Standard transdural unit recording techniques were used. Both isolated single units (bandpass 450 to 3K Hz) and evoked field potentials (DC to 100Hz) were simultaneously recorded from a single glass insulated platinum/iridium microelectrode. The peripheral input to all cells was examined by passive manipulation of joints and touch to the skin to localise receptive fields and to classify modelity or either the peripheral field in the peripheral as either cutaneous or 'deep'. Single unit responses to the perturba-tion were collected at each phase of both movements for comparison of raster histograms. Analysis of responsive cells indicated that there was clear modulation at the cortical level. Generally, for units with proprioceptive input from an elbow muscle, torque responses were maximal just prior to or at the onset of stretch in the muscle from which the proprioceptive information arose and could be totally absent when the same muscle was actively contracting. Although for some units a 'positional dependence' may be the reason for sensory gating, others showed a true phasic modulation. Measurement of the consistancy of the snowed a true phasic modulation, measurement of the consistancy of the imposed perturbation makes a mechanical basis for modulation unlikely. Units with cutaneous receptive fields on the forearm were also stimul-ated by the perturbation. Although also modulated, responses were not consistantly related to any phase of movement. The field responses also showed clear modulation but unlike single unit data they were maximal prior to movement, diminished during and recovered after movement ended. Standardised comparisons were made by recording fields only in large cell layer V and on this basis modulated responses are localised to small foci. It is postulated that proprioceptive sensory information originating from muscles involved in a motor program is utilised particularly when required most (ie at movement onset and termination) and may be gated out when less relevant. Supported by the MRC of Canada.

DORSAL COLUMN PROJECTION TO THE THALAMIC RELAY TO THE MOTOR CORTEX 93 7 IN CAT: AN ANATOMICAL AND PHYSIOLOGICAL DEMONSTRATION. Waters, Y. Tamai\* and H. Asanuma. The Rockefeller University, The motor cortex of the cat receives a direct projection from

a border region in the thalamus between n. ventralis lateralis and n. ventralis posteriolateralis. Neurons in this thalamic region are responsive to cutaneous and deep structure stimulation and project to cells in the motor cortex having similar receptive fields. However, there is still an ambiguity about the input to this thalamic region. Therefore, we set out to determine whether this region receives an input from the dorsal column nuclei, using a combination of anatomical and physiological techniques

Under inhalation anesthesia the motor cortex was exposed and a recording chamber was installed over the skull. Through the chamber 1id 7 tungsten-in-glass stimulating electrodes were inserted to a depth of 1.2 mm around the cruciate sulcus. A second chamber was stereotaxically placed to provide access to the thalamic border region and a microelectrode, filled with 0.2M KCl and a 20% solution of HRP, was driven into the thalamus while stimulating pulses (0.2ms duration, 30µA) were delivered simultaneously through the 7 electrodes in motor cortex. When an activated neuron was encountered the responsible motor cortex When an electrode was identified, the latency and threshold were measured and the collision test employed. If the antidromically activated neuron responded to somatosensory stimulation, then HRP was iontophoretically injected (5µA x 10min) through the same electrode. After a 48 hr survival time, the subject was sacrificed, and the tissue processed using the TMB method. In the second part of the study the procedures were identical to the above with the exception that the recording electrode was replaced by a tungsten microelectrode. When an antidromically activated thalamic neuron was identified the receptive field was measured. The recording electrode was then used to deliver single stimulating pulses, while a third microelectrode was inserted in the contralateral cuneate nucleus to record antidromically activated neurons. The receptive field of the activated neuron was examined and compared to the receptive field(s) of neurons around the thalamic stimulating electrode.

Using these procedures the following results were obtained: (1) Short latency antidromically activated neurons having clear recep-tive fields were located in the thalamic border region, (2) HRP delivered into the physiologically identified thalamic site labelled neurons in the ventro-caudal parts of the contralateral caudal cuneate nucleus, and (3) This result was corroborated in the second part of the study, i.e., antidromically activated neurons were found in a narrow region of the ventro-caudal cuneate Supported by NIH # NS-10705 nucleus.

CORTICAL EFFERENTS IN THE MACAQUE: THE DENSITY OF 93.8 PONTINE PROJECTIONS FROM SUBDIVISIONS OF THE CEREBRAL CORTEX. M. Glickstein and B. Mercier\* M.R.C. Unit on Neural Mechanisms of Behaviour, 3 Malet Place, London WC1E7JG, U.K.

The pontine nuclei are one of the main targets of efferent fibers from the cerebral cortex. Orthograde tracing methods clarify the spatial organization of this pathway but they are less appropriate for determining the number of corticopontine fibers contributed by different cortical areas. We injected horseradish peroxidase into the pontine nuclei of eleven monkeys. In cases in which the pontine nuclei were filled on one or both sides. we counted the number of labeled cortical neurons. The linear extent of each cortical area was measured planimetrically, and the number of filled cells was divided by the length to yield the number of labelled cells per millimeter of cortex. We describe here the results of these counts for the dorsal aspects of cortex including all or part of Brodmann's Areas 17,18,19,7,5,2,1,3,4,6,8 and 9. Note that these are linear measurements; the density per unit area would be approximately equal to the square of these number. Area 4 had the highest density of filled cells (Mdn = 18.8/ mm). Surprisingly, areas 6 (Mdn = 14.1/mm) and 8 (Mdn = 16.7/mm) contribute nearly as many corticopontine fibers per unit length of cortex. Areas 5 (Mdn  $\approx$  14.3/mm) and 7 (Mdn = 11.1/mm are also well represented. The primary somatosensory areas contribute rather fewer fibers than previous studies had suggested (areas 3, and 2 combined Mdn = 8.1/mm). In addition to area 7 the principal visual contribution is from Area 19 (Mdn = 4.9/mm). There was an occasional filled cell in area 18 (Mdn = .4/mm) and no filled cells in dorsolateral area 17. The dorsal aspect of Area 9 had a small (Mdn 2.2/mm) number of filled cells adjacent to area 8. These data emhasize the contribution to the cortico-pontocerebellar system from cortical regions outside the primary motor and sensory areas.

SENSORY PROPERTIES OF MOTOR CORTEX NEURONS IN THE AWAKE RAT. 93.9 C.F. Sievert\* and E.J. Neafsey. Dept. of Anatomy, Loyola Univ. Med. Cntr., Maywood, IL 60153.

Although the sensory properties of neurons in rat somatosensory cortex have been described by several laboratories, there is little information available on how neurons in rat <u>motor</u> cortex respond to peripheral sensory stimulation. One reason for this lack of information is that in the anesthetized rat it is very lack of information is that in the anesthetized rat it is very difficult to find any motor cortical neurons that respond to sensory stimulation. The present experiments have, therefore, in-vestigated this question in awake, head-restrained rats. To pre-pare the animal for recording, he was first habituated to handling and mild restraint, and then, under anesthesia, a head-restraint-recording chamber device was implanted on the skull using screws and dental corrulio. When the animal hed recovered from surgery he and dental acrylic. When the animal had recovered from surgery he required several days to become accustomed to having his head rigidly fixed for several hours; recording sessions were then begun. (The animals showed no signs of pain during this procedure). During each recording session a single transdural penetration was made using a glass-insulated tungsten microelectrode. The depth of each cell from the surface (defined by encountering neuronal activity) was noted as was the depth where the white matter appeared to begin. On most tracks intracortical microstimulation was also done and the movements evoked were noted. Small marking lesions (10  $\mu \, \text{amps}$  DC for 10 sec) were made at the end of a number of penetrations. After 10-15 recording sessions the animal was sacrificed by perfusion and the brain sectioned. The electrode tracks were reconstructed.

Thus far 2 rats have been studied. From 26 penetrations histologically located in motor cortex, 138 neurons were recorded; 27 (20%) of these had peripheral receptive fields. Of these 27 cells, ment or pressure around a joint while 12 (45%) responded to cuttaneous inputs such as hair deflection or light touch. Special attention was devoted to the sensory responsiveness of neurons located in the caudal and rostral forelimb areas we have previously described (BR 232,1982). In the caudal forelimb area 51 neurons were recorded and 18 (35%) had peripheral sensory input, primarily (72%) deep. In contrast, in the rostral forelimb area 24 neurons have been recorded and none responded to peripheral sensory input. This lack of sensory inputs to the rostral forelimb area is consistent with the notion that this region is part of the rat's supplementary motor cortex. Loyola University).

93.11 CONTRALATERAL, MID-LINE AND WHITE MATTER MOTONEURONS OF DORSAL NECK MUSCLES. V.C. Abrahams and J. Keane\*, Department of Physiology, Queen's University, Kingston, Ontario, Canada. K7L 3N6

Older anatomical descriptions have suggested that neck motoneurons are not confined to lamina IX, but are also found in more dorsomedial regions of the ventral horn. Previous HRP experiments using DAB as a chromogen confirmed this observation and also showed that some motoneurons may be located in commissural structures. Using the more sensitive TMB method for the demonstration of retrogradely transported HRP, it has now been found that neck motoneurons are not only present in the ipsilateral lamina IX, the ipsilateral dorsomedial and commissural nuclei, but they are also present at some contralateral ventral horn sites. Up to 19% of retrogradely filled cells in cats whose C2 and C3 biventer cervicis and complexus muscle nerves were dipped in HRP were found in laminae VII and VIII of the contralateral ventral horn and up to 12% of retrogradely filled cells were present in the commissural nuclei close to the mid-line.

Measurements of equivalent cell soma diameter have shown that neck motoneuron somas are generally somewhat smaller than those supplying hind legs. All the contralateral and mid-line motoneurons were small, with equivalent soma diameters less than 40  $\mu m$ . Thus the possibility is raised that mid-line and contralateral motoneurons are fusimotor. Supported by the Medical Research Council of Canada.

93.10 A MICROELECTRODE STUDY OF THE TOPOGRAPHICAL PROJECTION OF THE SENSORI-MOTOR CORTEX TO THE ROSTRAL TRIGEMINAL SENSORY NUCLEI OF THE RABBIT. K.A. Olsson\*, K. Sasamoto\* and J.P. Lund. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal (Ouébec), Canada.

As a part of studies on the modulation of sensory transmission during jaw movements, we have examined in detail the effects of electrical stimulation of a wide area of the anterior and lateral cerebral cortex on the trigeminal sensory nuclei. The experiments were carried out on rabbits anesthetized with urethane. The uncut inferior alveolar, infraorbital and lingual nerves trunks were directly stimulated. Nerves in the upper lips, fore- and hind-paws were stimulated by electrodes inserted through the skin. The electromyographic activity of jaw opening

In the first part of the study, evoked potentials and/or in the first part of the study, evoked potentials and/or single unit activity were recorded on the surface or within the cerebral cortex. After sensory maps had been drawn, bipolar stimulating electrodes were inserted and fixed in the centers of the receiving areas of the various nerves and also into sites known to give jaw movements at lowest threshold. The focal potentials and unit activity were recorded in the main sensory triggminal nucleus, the bordering dorsal, medial and ventral areas and the rostral parts of the nucleus of the spinal triggminal tract, while stimulating peripheral nerves and cortical sites.

The distribution of peripheral receptive fields in the nucleus agrees with previous observations in the cat: the mandibular dermatome is represented dorsally, with the maxilla deeper and more laterally situated. The ophthalmic division is ventrolateral. In general, stimulation of the corresponding cortical Sensori-motor area evoked potentials in the same regions of the main sensory nucleus and rostral parts of the nucleus of the spinal trigeminal tract as the peripheral input. However, the maximum amplitude of the cortically-evoked poten-tials occurred ventral to that of the corresponding peripheral potential. The maximum effects of stimulation of the region of the Motor-sensory cortex that causes short latency effects on jaw muscles were found in more medial parts of the sensory nuclei and in the medio-ventral bordering areas that are known to contain interneurons projecting to the trigeminal motor nucleus.

The majority of neurons that were excited by sensory inputs were also excited by stimulation of more than one cortical electrode. However, the point with lowest threshold was usually in a topographically-related region of the sensory or motor cortex. (Supported by the Canadian Medical Research Council).

93.12 GENERATION & MODIFICATION OF NEURONAL NETWORKS ACTING AS METRIC TENSORS: A COMPUTER DEMONSTRATION OF THE PROCESS OF ORGANIZING SENSORIMOTOR TRANSFORMATIONS. A. Pellionisz, G. Os R. Llinas. Department of Physiology and Biophysics, A. Pellionisz, G. Ostriker and New York University Medical Center, 550 First Avenue, New York, NY 10016. Tensor network theory assumes that, globally, the function of the CNS is that of matching relationships of the external invariants with internal multidimensional geometries, comprised in neuronal networks acting as metric tensors. Sensorimotor coordination, described by other theories as transformations of vectors via matrices expressed in external Cartesian frames, can be generalized via tensor network theory. Since tensorial models can use generalized natural coordinates intrinsic to sensorimotor systems rather than being restricted to Cartesian description, the problem of coordination may be solved in a reference-frame independent manner as a covariant embedding followed by covariant-contravariant metric-type transformation. The question of how such CNS networks may be generated and modified then remains the

> publication) where

sensorimotor scheme (Fig), modeling the emergence of covariant embedding and cerebellar metric tensor-type matrices (1-3) and in a tensorial computer gaze-control, involving vestibulo-ocular reflex and neck muscle coordination. Here, the procedure of generating a network acting as an oculomotor metric tensor, necessary for transforming a vestibular vector to a higher dimensional gaze vector, accounts for Listings' law, which confines movements of the 6D eye muscle system into 2D. The general concept of metric network metaorganization leads to experimentally testable paradigms of the genesis and functional maturation of such networks, eg. in the emergence of the cerebellar metric via the climbing fiber system. --- Supported by USPHS grant NS13742.

- ACTIVATION OF A PEPTIDE-ACTIVATED NEURON BY CYCLIC AMP RELEVANT 94.1
  - ACTIVATION OF A PEPTIDE-ACTIVATED NEURON BY CYCLIC AMP RELEVANT AGENTS. <u>Jeffrey L. Ram and Kurt A. Haller.</u>\* Dept. of Physiology, Wayne State University, Detroit, MI 48201. In <u>Aplysia</u>, the neuropeptide egg laying hormone (ELH) activates buccal ganglion motoneuron B16, which innervates buccal muscle I5 (Ram, <u>Soc. Neurosci. Abs</u>. 8:285; <u>Br. Res.</u>, in press, 1983). Since peptide actions are often mediated by cyclic AMP, experiments were initiated to test the involvement of cyclic AMP in this electrophysiological response. We tested whether the peptide response could be mimicked by 8-bromo cyclic AMP, an analog of cyclic AMP; isobutylmethylxanthine and theophylline, inhibitors of cyclic AMP degradation; and forskolin. an activator of adenvlate cyclase which reversibly forskolin, an activator of adenylate cyclase which reversibly activates the enzyme <u>in vivo</u> independently of specific agonist activates the enzyme in vivo independently of specific agonist receptors. In most experiments, these agents were applied in artificial sea water containing 150 mM Mg++ and 1 mM Ca++, which blocks chemical synapses in the ganglion but does not block activation of B16 by ELH. Under these conditions all four agents produced a response similar to ELH: a slow depolarization, leading to tonic activation of action patential.

agents produced a response similar to ELH: a slow depolarization, leading to tonic activation of action potentials. Depending on the agent and concentration used, latency until the first action potential was generally 2-10 min. Threshold concentrations to activate action potentials were  $10^{-4}$  to  $6 \times 10^{-4}$  M 8-bromo cyclic AMP (4 preparations),  $2 \times 10^{-4}$ to  $10^{-3}$  M isobutylmethylxanthine (4 preparations),  $10^{-3}$  and  $3 \times 10^{-3}$  M theophylline (2 preparations), and  $3 \times 10^{-5}$  to  $10^{-4}$  M  $3^{-5}$  move concentrations, these agents produced subthreshold depolarization from a resting potential averaging 10 mV below threshold in this medium. The ability of forsholin to raise cyclic AMP content of buccal ganglia was tested. Cyclic AMP in buccal ganglia, extracted by 6% TCA and washed with ethyl ether, was measured by radioreceptor assay. Cyclic AMP content in the presence of various concentrations of forskolin (FSK) was 24 + 10 pmole cAMP/mg protein, 0 FSK; 318 + 152 pmole/mg,  $5 \times 10^{-5}$  M FSK; and 473 + 285 pmole/mg,  $10^{-4}$  M FSK; an 3 ganglia each. These data are consistent with the possible mediation of the response to ELH by cyclic AMP. Further experiments to test this hypothesis would include measurement of cyclic AMP changes in B16 in response to ELH and testing the effect of injection of protein kinase inhibitor into the cell. The present data do not exclude the possibility that cyclic AMP may be mediating the response to other physiological depolarizing substances that affect the cell. affect the cell.

94.3 Analysis of inhibition produced by the candidate neurotransmit-

Karen Sigvardt<sup>†</sup>, Barry S. Rothman<sup>†</sup>, and Earl Mayeri<sup>††</sup>. <sup>†</sup>Department of Physiology, Univ. of Calif., San Francisco, CA 94143, and <sup>†</sup>Department of Basic Sciences, California College of Podiatric Medicine, San Francisco, CA 94115.

A burst discharge of the neuroendocrine bag cells produces several types of excitatory and inhibitory responses in specific identified neurons of the abdominal ganglion. Two neuropeptides, egg-laying hormone and  $\alpha$ -bag cell peptide ( $\alpha$ -BCP), are candidate neurotransmitters for mediating different subsets of these responses (Branton et al., PNAS 75: 5732; Rothman et al., PNAS, in press). The two peptides as well

Notimate to a single gene, which encodes the ELH/ $\alpha$ -BCP precursor molecule (Scheller et al., Cell 32:7). In the present study we focused on the role of  $\alpha$ -BCP as a possible

the present study we focused on the role of  $\alpha$ -BCP as a possible transmitter mediating bag-cell-induced inhibition of left upper quadrant (LUQ) cells, L<sub>3</sub> and L<sub>6</sub>.  $\alpha$ -BCP(1-7) acts directly on LUQs. The presence of protease inhibitors in the perfusion medium increased the potency of the peptide by 5-10 fold, suggesting that the peptide is rapidly degraded in vascular and interstitial spaces of the ganglion. LUQ cells were unaffected by arterial perfusion of 4 other other peptides present on the EHA-G-BCP precursor, acidic peptide, ind  $\beta$ -,  $\gamma$ -, &  $\delta$ -BCP. The inhibition caused by  $\alpha$ -BCP was unaffected by coapplication of  $\alpha$ -BCP and the other peptides at equimolar concentration. When  $\alpha$ -BCP meen surfuged at high

at equimolar concentration. When  $\alpha$ -BCP was perfused at high concentration (1 mM) for prolonged periods (30 min), the

response desensitized and a subsequent electrically triggered discharge of the bag cells produced little or no inhibition, suggesting that cross desensitization had occurred.

Suggesting that cross desensitization had occurred. Remorate conductance was measured by periodic injection of a 3-step current pulse. Arterial perfusion of a-BCP produced a conductance increase that appeared to be voltage-sensitive. A similar conductance change occurred during inhibition produced by a bac soll discharge organities that the transformed

Similar conductance charge suggesting that the two ionic mechanisms of inhibition are identical. The combined data provide further evidence that  $\alpha$ -BCP is an inhibitory

neurotransmitter.

ALL THE BAG CELL NEURONS OF APLYSIA PRODUCE BOTH ELH AND AP.

ALL THE BAG CELL NEURONS OF APLYSIA PRODUCE BOTH ELH AND AP. G. Whitney\* and S. Arch (SPON: G. F. Gwilliam). Biological Laboratories, Reed College, Portland, OR 97202. The bag cell neurons of <u>Aplysia californica</u> are organized in two clusters of about 400 cells each. The cell population appears to be homogeneous upon morphologic, cytochemical, and physiologic investigation. It is known that the principal secretory products of the cells are synthesized as parts of a common precursor mole-cule. Thus, it could be anticipated that each cell produces the same proportions of these products. Alternatively, individual same proportions of these products. Alternatively, individual cells could process the common precursor differently as has been seen to be the case for PONC in the rat pituitary. Moreover, molecular studies have disclosed the possibility that there may be several genes coding for closely similar precursor sequences. We therefore attempted to determine if differential precursor proces-sing and/or multiple precursor expression is occurring in individual bag cells by assaying single cells for their relative contents of newly synthesized egg-laying hormone (ELH) and acidic peptide (AP). From kinetic studies on cell clusters it is known that these peptides appear with a fixed stoichiometry. Since the sequence for each appears in tandem on the best characterized sequence for each appears in tandem on the best characterizes an index for differential expression in the cells. Bag cell clusters were, therefore, labeled in vitro by exposure to  ${}^{3}$ H-leucine and then rinsed in a low-Ca<sup>++</sup> saline. After the rinse they were transferred to a low-Ca<sup>++</sup> solution containing collagenase. The collagenase treatment was terminated with an ice-coll low-Ca<sup>++</sup> saline and the clusters were dissected with glass needles into individual cells. These were taken up in a minimum of medium and frozen on dry ice. Isoelectric focusing electrophoresis was performed on the freeze-thaw disrupted cells and scintillation performed on the freeze-thaw disrupted cells and scintillation counting of sequential gel slices performed to determine radio-label content. In 64 cells assayed from 10 clusters both ELH and AP were present at their native pI's. Thus bag cells are not specialized for production of either of these peptides to the exclusion of the other. There is, on the other hand, evidence of variability in relative quantities of the two species present in the gels. While this would appear to suggest variability in the excrusion or processing of precursor species, variation in the recovery of such small mounts of protein cannot be excluded at recovery of such small amounts of protein cannot be excluded at present.

APLYSIA EGG-LAYING HORMONE: PRECURSOR PROCESSING ACTIVITY IN 94.4 BAG CELL EXTRACTS. M.E. Yates and R.W. Berry. Dept. Cell Biol. and Anat. Northwestern Univ. Sch. of Med. Chicago, IL 60611

The bag cells of <u>Aplysia</u> produce a peptide egg-laying hor-mone, ELH, along with other neurosecretory products, by promone, ELH, along with other neurosecretory products, by pro-teolytic cleavage of ca. 29,000 dalton precursor. Since the primary structure of this precursor is known, and since the processing sequence leading to the secretory products has been established, it is of interest to identify and characterize the enzyme or enzymes responsible for processing. We have begun to do so by studying processing in bag cell homogenates. Bag cells homogenized in low ionic strength buffer retain the Bag cells homogenized in low ionic strength buffer retain th capacity to cleave previously-synthesized precursor, and to produce products which are indistinguishable from those pro-duced by intact cells, as judged by sequential SDS-PAGE and isofocusing. There is no evidence of non-specific degradation. The processing activity is recovered in the superna-tant of homogenates which have been frozen and thawed and centrifuged at 1000xg for 30 min. The pH optimum for processing is 5.5-6.5, similar to that of the proopiomelanocortin and proinsulin converting enzymes (P.N.A.S. 79:108-112, 1982: P.N.A.S. 79: 4613-4617, 1982). Processing activity is not inhibited by monensin or chloroquine, nor by inhibitors of trypsin or cathepsin B, and its inhibitor spectrum is dis-tinct from that of either of the converting enzymes cited above. This suggests that, even though each precursor is cleaved at sites consisting of pairs of basic amino acids, the cleavage enzymes are not identical. Supported by NIH NS-16756.

94.5 FURTHER CHARACTERIZATION OF BIOLOGICALLY ACTIVE ATRIAL GLAND PEPTIDES IN APLYSIA. C. T. Nagle, S. D. Painter and J. E. Blankenship. Marine Biomedical Institute, Univ. Tx. Med. Br., Galveston, TX 77550.

When the neuroendocrine bag cells of <u>Aplysia</u> are triggered to fire, they release an egg laying hormone (ELH) into the blood; ELH directly causes egg release from the ovotestis and results in egg laying. The atrial gland, an exorine organ in the reproductive tract, contains two peptides, A and B, structurally similar to each other but unrelated to ELH. These peptides cause a bag cell discharge which leads to egg laying; they do not cause egg laying in bag cell-less animals. The atrial gland also contains another peptide, egg releasing hormone (ERH), that has strong sequence homologies to the N-terminal half of ELH and to the C-terminal half of peptides A and B. In keeping with these sequence homologies, ERH is able to directly induce egg laying in intact or bag cell-less animals (like ELH), as well as trigger bag cell discharges <u>in vitro</u> (like peptides A and B). By using two bioassays, we can distinguish between ELH-like peptides (egg laying in bag cell-less animals) and A/B-like peptides (induction of bag cell discharge <u>in vitro</u>). We have used these bioassays in conjunction with gel filtration, isoelectric focusing (IEF) and HPLC purification procedures to further investigate and characterize peptides from the atrial gland.

Atrial glands were homogenized in an acid medium and fractionated by Sephadex G-50 chromatography. Three fractions (C,D and E) in the 3-15 k daltons MW range induced egg laying in intact and bag cell-less animals. Two of these, D and E, were subjected to IEF (pH 3.5 to 10) on gels containing 6M urea and 1% Triton. Peptides were eluted from gel slices and bioassayed in bag cellless animals and in an <u>in vitro</u> neuroassay. Several basic peptides with ELH-like activity were found in

Several basic peptides with ELH-like activity were found in both D and E, but these were not further characterized. Peptides with A/B-like activity were found at pI 7.9-8.1 and 9.0-9.2 in peak E; presumably these correspond to peptides A and B, respectively. Two hybrid peptides were found at pI 5.9-6.1 and 7.8-8.1 in fraction D. The pI of the more basic species presumably corresponds to that of ERH. Traces of the more acidic species were detected in fraction E, but only on the more sensitive neuroasay. This molecule is a hybrid, like ERH, but is presumably not ERH. These biologically active peptides are being further purified by HPLC. Supported by NIH NS 07025 (G.T.N.), NS 07010 (S.D.P.), NS 11255 and NSF PCM 82-15185 (J.E.B.). 94.6 A NEWLY SEQUENCED NEUROPEPTIDE (SCP<sub>B</sub>) IS A PHYSID-LOGICAL MODULATOR OF SOMATIC MUSCLE IN APLYSIA. Philip E. Lloyd\*, Irving Kupfermann, Klaudiusz R. Weiss. Center for Neurobiology and Behavior, New York State Psychiatric Institute, and Departments of Physiology, Anatomy and Cell Biology, and Psychiatry, Columbia PsS, and School of Dental and Oral Surgery, New York, N.Y. 10032.

Small cardioactive peptide B (SCP<sub>B</sub>) has recently been purified from <u>Aplysia</u> neural tissue and sequenced (Morris et al., Nature 1982). SCP<sub>B</sub> levels in tissues were determined by means of reverse phase HPLC and bioassay on an isolated snail heart (Lloyd, J. Comp. Physiol., 1978). SCP<sub>B</sub> was found in a variety of tissues, including the accessory radula closer (ARC), a somatic muscle involved in feeding. SCP<sub>B</sub> is also present in the nerve and ganglion which innervates the ARC, and preliminary immunocytochemical analysis suggests that the peptide is localized to axonal fibers and varicosities in the muscle.

Low doses of SCP<sub>B</sub> (threshold:  $10^{-9}$ M) applied to the ARC do not directly cause contractions but do enhance the amplitude of contractions produced by stimulating identified cholineryic motorneurons. SCP<sub>B</sub> appears to function in a manner similar to that previously shown for serotonin (Weiss et al., J. Neurophysiol. 1978). It enhances contractions produced by pulsed applications of ACh suggesting that its action is post-synaptic. Furthermore it was as effective as serotonin in increasing cAMP levels in the muscle. High Mg<sup>++</sup>, low Ca<sup>++</sup> solutions did not inhibit this action of SCP<sub>B</sub> indicating that it does not increase cAMP levels indirectly by releasing serotonin from nerve terminals in the muscle. SCP<sub>B</sub> ( $10^{-5}$ M) causes a significant additional elevation of cAMP in the ARC when the serotonin. This suggests that SCP<sub>B</sub> acts via a different receptor than serotonin. These results suggest that SCP<sub>B</sub> is a physiological modulator of the ARC. Because serotonin acts in this muscle to mediate an aspect of food induced behavioral arousal, it is possble that SCP<sub>B</sub> is also involved in this arousal. (1 ROI MH36730, 5 ROI MH 35564).

94.7 THE PRESENCE, DISTRIBUTION, AND EFFECTS OF FMRFamide-LIKE PEPTIDES IN THE HORSESHOE CRAB, <u>LIMULUS POLYPHEMUS</u>. <u>W.H. Watson, III, J. Groome\*, B. Cromwell\*, J. Bishop\*, and <u>T. O'Donohue</u>. Dept. of Zoology, UNH, Durham, NH 03824 and Exp. Ther. Branch, NINCDS, Bethesda, MD 20205. The tetrapeptide FMRFamide was first discovered in the</u>

The tetrapeptide FMRFamide was first discovered in the sunray venus clam, <u>Macrocallista nimbosa</u> (Greenberg, M., Price, D., <u>Science</u>, <u>197</u>:670, 1977). Subsequent immunocytochemical and radioimmunological studies have demonstrated that FMRFamidelike peptides are present in a wide variety of animals including humans (reviewed in Greenberg, M., Price, D., <u>Ann. <u>Rev. Physiol.</u>, <u>45</u>:271, 1983). We now present evidence that a FMRFamide-like peptide is also present in the nervous system of the horseshoe crab and that it has direct actions on the neurogenic <u>Limulus</u> heart. Regions of the Limulus nervous system were assayed for</u>

Regions of the <u>Limulus</u> nervous system were assayed for FMRFamide using radioimmunoassay (RIA). The antibody used in these studies did not cross-react with any known FMRFamide-like peptides (CCK 1-4, Met-enkephalin, BPP) or proctolin. The highest concentration of FMRFamide immunoreactivity was found in the brain, but substantial quantities were also detected in abdominal and cardiac ganglia. These observations were confirmed with immunocytochemical studies. FMRFamide-like immunoreactivity was observed throughout the CNS and cardiac ganglion. It was located primarily in the neuropile, and cell bodies were stained in abdominal and circumesophageal ganglia. A few immunoreactive axons were observed on the surface of cardiac muscle. No fluorescence was observed in sections after preabsorbing the antisera with synthetic FMRFamide.

In order to determine if the peptide recognized by our antibody was authentic clam FMRFamide, we fractionated <u>Limulus</u> brain homogenates using reversed phase high pressure liquid chromatography on a <u>ABondapak Cl8</u> column. We then measured FMRFamide levels in each fraction using RIA and a FMRFamide bioassay (the <u>Busycon</u> radula protractor muscle). Some of the immunoreactive and bioactive material coeluted with authentic FMRFamide. However, the major immunoreactive peaks of activity did not coelute with FMRFamide. One of the major immunoreactive peaks corresponded with fractions containing most of the bioactivity. Thus, it appears as if there are several FMRFamide-like peptides in <u>Limulus</u>.

peaks corresponded with fractions containing most of the bioactivity. Thus, it appears as if there are several FMRFamide-like peptides in <u>Limulus</u>. In order to examine the physiological role of FMRFamide in <u>Limulus</u> we examined the effects of synthetic <u>FMRFamide</u> on the <u>Limulus</u> heart. At a concentration of 5 x 10<sup>-5</sup>M it caused a 100% increase in both the rate and strength of heart contractions. These effects were due to a direct action of FMRFamide on both the cardiac ganglion neurons and the heart muscle. 94.8 NEUROPEPTIDE PROCTOLIN IN THREE IDENTIFIED POSTURAL MOTONEURONS OF THE CRAFFISH. C.A. Bishop, J.J. Wine and M. O'Shea. Dept. of Psychol., Stanford Univ., CA 94305 and Dept of Pharm. Physiol. Sci., Univ. of Chicago, Chicago, Il 60637.

Physicl. Sci., Univ. of Chicago, Chicago, Il 60037. Using reverse phase liquid chromatography and a sensitive bicassay, we have purified, from extracts of the crayfish central nervous system (CNS), a component indistinguishable from proctolin (H-Arg-Try-Leu-Pro-Thr-OH). The distribution of proctolin in the nervous system of the crayfish was investigated using a specific polyclonal rabbit antiserum. Proctolin-like immunoreactivity (PLI) in the crayfish CNS was widely distributed; immunoreactive cell bodies were stained in every ganglion.

Among the cell bodies that stain in the crayfish, we have found that three are identified excitatory motoneurons of the tonic flexor muscles which help control abdominal posture. PLI containing cell bodies appropriate in size and position to motoneurons fl, f3 and f4 were seen in the abdominal ganglia. Prominent PLI was visualized in up to three axons in the tonic flexor motor root, which contains just six axons distinguishable on the basis of relative diameters. Stained axon diameters were consistent with these being fl, f3 and f4. We could not trace stained axons to the cell body of f3 by double labelling with Lucifer yellow and the proctolin antiserum, using the PAP procedure. PLI was seen in the axons as they branch onto the muscle and terminals were stained over the entire muscle. Cutting the nerve two months prior to immunohistochemical processing eliminated all PLI from the muscle.

A sensitive and specific bioassay (O'Shea, M. and Bishop, C., J. <u>Neurosci.</u>, 2:1242-1251, 1982) detected bioactivity equivalent to about 370 fmole proctolin per tonic flexor muscle. All bioactivity was eliminated in muscles denervated for two months and in muscle homogenates pre-incubated with proctolin antiserum.

These results indicate that proctolin is present in three excitatory motoneurons that are thought to use either L-glutamate or acetylcholine as their transmitter. A precedent for our findings is the proctolin-containing postural motoneuron of the cockroach (Adams, M. and O'Shea, M., Sci., in press, 1983). We are currently investigating the role of proctolin in modulating tension generation in the tonic flexor muscles.

Supported by NIH grant NS-06684 (C.A.B.), NSF grants BNS 82-02515 (M.O.) and BNS 81-12431 (J.J.W.).

PROCTOLIN IN LOBSTERS: GENERAL DISTRIBUTION AND CO-LOCALIZATION WITH SEROTONIN. <u>K. King Siwicki\* and E. A. Kravitz</u>. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115 Radioimmunoassay with an antiserum raised against the penta-peptide proctolin (Arg-Tyr-Leu-Pro-Thr) has demonstrated 94.9

proctolin-like material to be widespread in the lobster nervous system. The highest concentrations were found in the pericar-dial organs and proximal portions of the second roots of thoracic ganglia: both of these are neurosecretory regions that also contain high concentrations of monoamines.

To bring the analysis of the role of proctolin in lobsters to a cellular level we have used immunohistochemical techniques to a cellular level we have used immunohistochemical techniques to map the distribution of proctolin-like immunoreactivity. The specificity of our antibody preparation was demonstrated by (1) a complete block of the staining by pre-absorbing the anti-serum with a proctolin-BSA conjugate, or with free proctolin, (2) the failure to eliminate the staining by pre-absorbing with FMRF-amide, Substance P, leu-enkephalin, serotonin, or octop-amine, and (3) the failure to detect, by radioimmunoassay, cross-reactivity of the antiserum with these substances or 7 other perides other peptides

The pericardial organs are covered with a dense network of fine varicose processes that stain with the artiserum. We have not seen immunoreactive cell bodies in pericardial organs, but 1-2 stained axons are found in each of the thoracic roots that We have project to pericardial organs. Every central ganglion contains stained fibers and varicosities. After colchicine treatment, many small immunoreactive cell bodies are seen in the nerve cord: the greatest numbers are in the subesophogeal and fifth thoracic ganglia. In addition, the fifth thoracic and first thoracic ganglia. In addition, the fifth thoracic and first abdominal ganglia each contain a pair of large immunoreactive cell bodies. These are identical to the paired cells in these ganglia that show serotonin-like immunoreactivity (Beltz & Kravitz, J. Neurosci. 3:585, 1983). In 25  $\mu$ m alternate serial sections of the ganglia, the same cells showed staining with an anti-serotonin antiserum and an anti-proctolin antiserum. These two pairs of cells project anteriorly and are thought to branch into the thoracic second roots, where the neurosecretory regions described above are found. Thus it is possible that some neurosecretory endings release both proctolin and serotonin. In addition. in each of the paired circumesonbogeal ganglia, a neurosecretory endings release both proctolin and serotonin. In addition, in each of the paired circumesophogeal ganglia, a single, large anterior cell shows proctolin-like immunoreactivity. These cells may correspond to the dopamine cells in these ganglia described by Barker, et.al. (Br. Res. 161:99, 1979). At present we are exploring the chemical and physiological properties of these large cells to define their roles in the lobster nervous system. (Supported by NIH)

- 94.10 CO-LOCALIZATION OF BURSICON BIOACTIVITY AND PROCTOLIN IN
  - DENTIFIED NEURONS. Michael E. Adams and Mary N. Phelps.
     Research Laboratories, Zoecon Corp., Palo Alto, CA 94304.
     The proctolin-containing lateral white (LW) neurons occur as individual pairs in cockroach (Periplaneta americana) abdominal ganglia (0'Shea and Adams, <u>Science</u> 213:567-569, 1981). Axon projections from these neurons extend to the heart and to the perivisceral organs, which are specialized neurohaemal release sites. We now report that both proctolin and bursicon, a neuro-peptide involved in cuticular tanning, are localized in cell bodies of LW neurons.

LW somata were isolated from adult cockroach ganglia by dissection in ice-cold physiological saline, disrupted by sonication and freeze-thaw treatments, and centrifuged at An equal number of octopaminergic dorsal unpaired 12,000 x g. median (DUM) somata were collected from metathoracic ganglia as control cells. Supernatants were assaved for bursicon bioactivity on isolated wings from pharate adult <u>Manduca sexta</u> (Reynolds, <u>J. Exp. Biol</u> 70:17-39, 1977). Bursicon levels were quantified on a relative basis by serial dilution of samples until tanning activity disappeared. Bursicon bioactivity was detected in LW somata extracts at

threshold doses of 0.6 cell equivalents. A single LW cell body pair accounted for about one-fifth the bioactivity measured in an entire abdominal ganglion. Control cells showed no bursicon bioactivity at doses up to 2.5 cell equivalents. The co-existence of proctolin and bursicon in LW neurons may indicate a common precursor relationship as well as co-release from nerve endings at neurohaemal release sites. These hypotheses are currently under investigation.

The distribution patterns of bursicon and proctolin were compared in the central nervous system and gut. Substantial compared in the central nervous system and gut. Substantial bursicon bioactivity was detected in all ganglia of the CNS. Thoracic ganglia and terminal abdominal ganglia consistantly showed the highest levels, which were approximately twice the amounts found in brain, subesophageal and abdominal ganglia. In contrast, proctolin levels in the terminal abdominal ganglion as contrast, proceeding levels in the terminal abdominal ganglion as measured by RIA (Bishop, et al., PNAS, 78:5899-5902, 1981) were 4 to 20 times those found in all other ganglia. Therefore, the relative amounts of the two peptides depend on their location in the CNS. Both proctolin and bursicon occur in the fore- and hindgut, where proctolin has been suggested to function as a neurotransmitter. Although the function of bursicon in the gut is not known, local release from nerve endings may play a role in the dynamics of the inner cuticular lining which is not directly exposed to hemolymph.

94.11 STRUCTURE AND BIOLOGY OF TWO NEW RELATED NEUROPEPTIDES FROM INSECT: FURTHER EVIDENCE FOR A PEPTIDE FAMILY. J. Witten, M. Schaffer\* and M. O'Shea. Dept. Pharmac. and Physiol. Sci., The University of Chicago, IL 60637. We have isolated two neuropeptides from the corpora cardiaca or

cc ( a major neurosecretory structure in insects) and CNS of the American cockroach Periplaneta <u>americana</u>. Three biological actions are identified: contraction of skeletal muscle, accel-eration of an accessory heart and elevation of blood lipid levels. We call these peptides MI and MII.

The cc contains about 50pmol MI and 20pmol MII. They have been purified to homogeneity by reverse-phase HPLC and subjected to amino acid and FAB-Mass Spec. analysis. Compositions are - <u>MI</u>: GLX-1, ASX-2, SER-1, VAL-1, PHE-1, PRO-1; <u>MII</u>: GLX-1, ASX-1, THR-2, LEU-1, PHE-1, PRO-1. Fluorescence at 280nm indicated the presence of TRP or TYR but TYR was excluded by amino acid anpresence of the for fir but the was excluded by amino acid an-alysis. We confirmed the presence of TRP by the incorporation of 3H-TRP by <u>in vitro</u> synthesis. Molecular weights are 972 (MI) and 987 (MII), consistent with one TRP, GLX = pGLU, ASX = ASN, and carboxy terminal amides for both peptides. Incorporation of  $^{3}$ H-TRP established the cc as the site of synthesis as well as stor-age for both. MI and MII are released into the blood from the cc by a calcium-dependent mechanism. During a ten minute evosure by a calcium-dependent mechanism. During a ten minute exposure to 50mM-K<sup>+</sup> saline we have purified about 10% of the total store of MI and MII from the superfusate. Reverse-phase HPLC confirms the presence of both peptides in the CNS and gut. Hormonal and transmitter functions are therefore indicated in the cockroach. A survey in other species suggests MI and MII are present in the moth <u>Manduca</u> <u>sexta</u>, both may be present in crayfish and neither were found in the rat brain.

The grasshopper cc does not contain MI or MII in abundance, but does contain a related peptide - locust adipokinetic hormone or AKH (Stone, et al. <u>Nature</u>, 1976). MI and MII produce AKH-like activity in the locust as does another arthropod peptide called red pigment concentrating hormone or RPCH (Carlson et al. Insect Biochem., 1979). The sequences of AKH and RPCH are homologous and both are pGLU and  $-NH_2$  terminally blocked. This data plus our structure and activity studies suggest MI, MII, AKH, and RPCH are members of a family of homologous peptides. We therefore suggest the following tentative sequences. MI: CULLWALASNEE

are memoers of a family of homologous peptides. We therefore suggest the following tentative sequences; MI: pGLU-VAL-ASN-PHE-SER-PRO-ASN-TRP-NH, and MII: pGLU-LEU-THR-PHE-THR-PRO-ASN-TRP-NH, Supported by grants NIH 5T32CM-07151, NIMH RSDA 5K01 MH00325, NSF BNS-8202515, The Brain Research Foundation and E.I. du Pont de Nemours & Company. We thank Dr. K.L. Rinehart (Dept. Chemistry, Univ. of Illinois) for doing mass spec. measurements and Dr. R. Heinrickson (Dept. Biochem., Univ. of Chicago) for the use of an amino acid analyser. amino acid analyser.

94.12 REGULATION OF PEPTIDE RELEASE BY NEUROTRANSMITTERS IN THE ISO-LATED EYESTALK OF THE FIDDLER CRAB, UCA PUGILATOR. L. S. Quackenbush\* AND M. Fingerman. Dept. of Biology, Tulane Univ., New Orleans, LA 70118.

The neuroendocrine complex within the eyestalk of crustaceans The neuroendocrine complex within the eyestalk of crustaceans releases at least two pairs of antagonistic peptidergic neuro-hormones which regulate pigment migration in integumentary chro-matophores in the fiddler crab, <u>Uca pugilator</u>. The pigment within the chromatophores disperses or concentrates in response to a specific peptide. Melanophores, containing black pigment are regulated by black pigment dispersing hormone (BPDH), and black pigment concentrating hormone (BPCH). Erythrophores, containing red nigment are regulated by red pigment dispersion containing red pigment, are regulated by red pigment dispersing hormone (RPDH) and red pigment concentrating hormone (RPCH). The isolated eyestalk remains viable when perfused with saline, and releases these four peptides (BPDH, BPCH, RPDH and RPCH) in a voltage dependent manner upon stimulation. They can be separated from each other subsequently on a Sephadex G-25 column. Previous in vivo experiments demonstrated that norepinephrine (NE) induces BPDH release, and dopamine (DA) induces RPCH release, and 5-hydroxytryptamine (5-HT) induces RPDH release. rease, and phydroxytyptamene (S-II) had to be release. In yitro preparations supported the previous findings with NE and  $\overline{5-HT}$ , and also revealed that DA releases BPCH as well as RPCH. The crustacean eyestalk contains 0.6 µg/g octopamine with no previously demonstrated role in the crustacean color change system. We now report octopamine (10<sup>-8</sup>M) inhibits the release system. We now report octopamine  $(10^{-0}M)$  inhibits the release of BPDH, but not RPCH or BPCH, <u>in vitro</u>, in a dose dependent manner. Octopamine has no direct activity in the bioassay used. A preliminary report (Kirk and Glantz, 1982, Neurosci. Ab-stracts, 8:532) demonstrated GABA produces IPSP's in neuroendo-crine cells in the eyestalk of a crayfish. We found that GABA, inhibits release of BPCH and RPCH release <u>in vitro</u> (10<sup>-7</sup>M), in a dose dependent manner. This inhibition of endocrine output is consistent with the role of GABA controlling neurohormone release in the crayfish proposed by Kirk and neurohormone release in the crayfish proposed by Kirk and Glantz.

Recent preliminary immunocytochemical studies demonstrated the presence of Met-enkephalin-like and Leu-enkephalin-like immunoreactivity in the eyestalk complex of Uca pugilator Immunoreactivity in the eyestalk complex of Uca pugliator (Fingerman et al., 1983, Neurosci. Abstracts). Met-enkephalin ( $10^{-6}$ M), but not Leu-enkephalin, induces RPCH and BPCH release in a dose dependent manner in vitro. Naloxone ( $10^{-6}$ M) blocks both this response to Met-Enkephalin and the voltage stimulated release of RPCH and BPCH. The release of the chromatophorotropic hormones from the crustacean eyestalk is controlled not only by stimulatory neurotransmitters but by inhibitory ones as well.

MONOCLONAL ANTIBODIES TO INSECT PEPTIDERGIC NEURONS. PH Taghert, 94.13 NJ Tublitz, JW Truman and CS Goodman Dept. of Biol. Sciences, Stanford Univ., Stanford CA 98305 and Dept. Zoology, Univ. of WA Seattle, WA 98195.

We are interested in the expression and regulation of insect we are interested in the expression and regulation of inSect neuropeptides. There are to date only two insect peptides -proctolin and the adipokinetic hormone - that have been purified, sequenced and for which immunological probes are available. Tn sequenced and for which immunological proces are available. In an effort to create probes to as yet unpurified neuropeptides, we have made monoclonal antibodies against a neurohaemal organ, the transverse nerve, from the moth <u>Manduca sexta</u>. The transverse nerve is a segmentally repeated structure that contains 2 motor axons and the axons and terminals of 18 identified neuroendocrine axons and the axons and terminals of 10 identified neuroendocrine neurons (including 8 bursicon-containing and at least 2 cardio-active peptide-containing neurons). 3000 nerves were used to hy-perimmunize a single mouse. Fusion of the spleen cells with NS-1 myeloma cells produced 382 hybrid-containing wells, each of which was screened histologically on serial frozen sections of single abdominal ganglia. 31 positive wells were identified and and hybrids cloned according to the criterion that subsets of abdomi-nal ganglion neurons were stained.

29/31 monoclonal antibodies (mabs) appear to stain cytoplasmic antigens. 10 mabs appear to stain a similar pattern: some to many granular inclusions in approximately 5% of the 700 neurons in the ganglion. 5 mabs specifically stain two pairs of neurons that extend throughout the entire CNS. 1 mab intensely stains two of the four bursicon-containing neurons, 1 mab stains all four and 3 mabs stain all four plus four unpaired neurons at the mid-line of the ganglion. 3 other mabs intensely stain unpaired neurons exclusively.

Thus we have generated a set of monoclonal antibodies that exhibit diverse patterns of specific staining among the 18 neuro-endocrine neurons in the moth abdominal ganglion. We are currently testing the ability of these antibodies to recognize known insect neurohormones. These antibodies and this technique may prove useful in the localization and purification of new biologically active neuropeptides.

Supported by grants from the NSF, NIH and McKnight Foundation.

#### VESTIBULAR REFLEXES: FUNCTIONAL ORGANIZATION

FUNCTIONAL SEMICIRCULAR CANAL (SCC) GEOMETRY REFLECTED IN VESTIBU-LAR MYSTAGMUS AND SINGLE UNIT ACTIVITY IN THE ALERT RHESUS MONKEY. H. Reisine, V. Henn\*, A. Böhmer\*, and J.I. Suzuki\*. Dept. of Neurology, University Hospital, 8091 Zürich, Switz. and Dept. of Otolaryngology, Teikio University, Tokyo, Japan. The general question how an applied angular acceleration (AAA) to the head in any plane results in the vestibulo-ocular reflex (VOR) is addressed. Specifically, Rhesus monkeys were chronically prepared with Ag-AgCl electrodes for EOG monitor-ing of eye position, bolts for head fixation, and a device for recording single unit activity with varnished tungsten microelec-trodes. Turntable and gimbal equipment permitted application of angular acceleration in any desired head plane. Finally, results from normal monkeys were compared with those of animals with various combinations of SCCs plugged. In normal monkeys horizontal slow phase eye velocity (HSPEV) is maximal when the AAA is in the plane of the HSCCs (170 nose down) and decreases as a cosine function of the angle

nose down) and decreases as a cosine function of the angle between the AAA and HSCC planes. The plane of the HSCCs does not coincide with the functional null plane of the vertical canals (330 nose down). VSPEV is maximal when the AAA is in the sagittal plane and also decreases as a cosine function of the angle between the AAA and sagittal planes. In canal plugged animals HSPEV can be generated without HSCC function and almost normal VSPEV can be generated in animals with different combinations of VSCCs plugged. Single unit activity in the vestibular nuclei modulated by AAA

Single unit activity in the vestibular nuclei modulated by AAA can be nulled in two rotational planes and is maximal in a third, defining a functional SCC plane. As the AAA plane is rotated out of the functional SCC plane the modulation of the single unit activity decreases as a cosine function. In an animal with all SCCs plugged on one side single unit responses did not grossly differ from those of the normal situation. In general, most units sensitive to the AAA did not respond to static head tilt. Units sensitive to HAAA responded to horizontal optokinetic stimulation, whereas VAAA units did not. Vertical optokinetic responses could not be tested. Unit activity also reflected various strenghts of

an eye position signal. Thus, AAA to the head in a specific plane can be resolved into components lying within each SCC plane. Neural coding of these components has been found in the peripheral nerve and, in this report, in the vestibular nuclei. Central generation of patterns of vestibular nystagmus, induced in any rotational plane, in normal and canal plugged animals can thereby be analyzed in terms of the distribution of a head velocity signal in the vestibular nuclei that is organized in head coordinates. Supported by Swiss National Foundation for Scientific Research 3.718.80. 95.2 THE VALIDITY OF MATRIX ANALYSIS FOR THE DESCRIPTION OF SPATIAL VESTIBULO-OCULAR COORDINATION IN CAT AND RABBIT. <u>W. Graf and K. Ezure\*</u>. The Rockefeller University, New York, <u>NY 10021</u> <u>K. EJUTE\*</u>. The Kockefeller University, New York, NY 10021 The spatial coordination of the vestibulo-ocular reflexes in cat and rabbit was evaluated by taking into account the geometri-cal arrangement of semicircular canals and extraocular muscles (from our own measurements and those of Blanks, Curthoys & Mark-ham, 1972) in the form of sensitivity and action vectors. The canal (C) and extraocular muscle matrices (M) then read:

с	Rabbit=	ARPL PRAL HRHL	X (.748 .748 .000	¥ •615 •.615 •000	Z 221 221 977/	)м	Rabbit	X = Y Z	1050 (657 (670 .303	IRSR 825 .482 .294	LRMR .188 208 .959	
с	Cat =	ARPL PRAL HRHL	(.711 .711 .000	.687 687 .000	.079 .079 990/	)м	Cat	X = Y Z	(813 (539 .210	470 .872 .133	$\begin{pmatrix} .129 \\059 \\ .989 \end{pmatrix}$	

IOSO, IRSR, LRMR of the left eve are obtained by averaging the antagonists IO and SO (IO:inferior oblique, SO:superior oblique etc.),similarly ARPL, PRAL, HRHL stand for averages of two coplanar canals (AR:right anterior, PL:left posterior, etc.) in Cartesian coordinates. From these matrices the brain stem matrix(T)of the underlying neuronal network was calculated for a symmetric or an asymmetric VOR gain(in the latter, the torsional gain was set to one half of the horizontal or vertical gains).

Principal VOR connections are indicated by an asterisk(\*).From the above matrices we observe that e.g. the averaged muscle IOSO not only is linked to ARPL, the principal reflex connectivity, but also receives accessory input from PRAL and even the horizontal canals, RRHL. Comparing calculated pathways to experimentally obtained data we find good agreement between the two in the cat, but not in the rabbit. For an asymmetric gain, the situation is improved in the rabbit. The functional role of the accessory (non-principal)VOR connections is interpreted to equalize the incongruences between semicircular canal and extraocular muscle planes. This statement is certainly justified for the cat. From the com-parison between theoretical and experimental data, we also conclude that largely three-neuron-arc connections are responsible for the spatial coordination of the vestibulo-ocular reflexes. Supported by NIH grants EY04613 and NS02619.

VISUAL FIELD MOTION RELEVANT TO OPTOKINETIC EYE MOVEMENTS PREDICT-95.3 ED FROM THE PLANES OF EACH OF THE SEMICIRCULAR CANALS IN RABBIT. Barbara J. Winterson, Department of Physiology, New England College of Osteopathic Medicine, Biddeford, Maine 04005.

Optokinetic eye movements and the vestibulo-ocular reflex work in a synergistic manner to produce compensatory eve movements. Recently, it has been proposed that the preferred directions of visual neurons in the retina, accessory optic system, and floccu-lus are aligned with the visual field motion induced by rotation

lus are aligned with the visual field motion induced by rotation of the head such that a particular semicircular canal is maximally stimulated (Simpson, et al, 1979, Prog. Brain Nes. 50, 715-724). In order to assess this hypothesis, semicircular canals (surgi-cally exposed) had points along them measured. These points were used to compute best-fit planes using a least square method. Mean planes were computed for 7 rabbits (4 Dutch and 3 New Zealand White). The mean planes were used to predict mathematically the visual field motion paths at infinity for each of the mean semi-circular canals and plotted on a Mercator projection of that porcircular canals and plotted on a Mercator projection of that por-tion of the left visual field that corresponds to the optokinetic sensitive area (Dubois & Collewijn, 1979, Vis. Res. 9-17). These motions are shown in the figure below.

(d=dorsal, t=temporal, n=nasal)

Comparison of the predicted motion to preferred directions of visual neurons presumed to be in optokinetic pathways showed mod-erate to good correspondence to selected semicircular canals. Open-loop optokinetic slow phase direction (Dubois & Collewin 1979) corresponded excellently to motion induced by the left hori-zontal canal and quite well to that of the left posterior canal and the right posterior canal.

95.**5** VESTIBULAR NUCLEI ACTIVITY IN THE ALERT MONKEY DURING CONSTANT VELOCITY AND SINUSOIDAL OPTOKINETIC STIMULATION. <u>U. Büttner\*, R. Boyle\* and U.Schreiter\*</u> STIMULATION. U. (SPON: V. Matsuo).

(SPON; V. Matsub).
Dept. of Neurology, Univ. of Düsseldorf, D-4000
Düsseldorf (Germany)
During sinusoidal rotation of large field optokinetic stimuli the sensation of circularvection can be induced in humans up to frequencies of 2 Hz
(Büttner and Henn, <u>Ann.N.Y.Acad.Sci.</u>, <u>374</u>:274-283, 1981). Furthermore such stimuli also lead to compensatory eye movements. The aim of this study was to determine a possible involvement of the vestibular nuclei in these responses.

Prior to experiments monkeys (Macaca fascicularis) were chronically prepared for single unit and eye position recordings. During the experiment the monkey sat upright in a primate chair with his head fixed on a turntable. For vestibular stimulation the monkey was rotated about a vertical axis in complete dark-ness at 0.1-0.2 Hz. During optokinetic stimulation a large striped cylinder completely surrounding the monkey was rotated at constant velocity (5-100 deg/s)or sinusoidally (0,02-2 Hz, 5-100 deg/s) around the stationary monkey. For each neuron initially the or sinusoidally (0,02-2 Hz, 5-100 deg/s) around the stationary monkey. For each neuron initially the responses to vestibular and constant velocity opto-kinetic stimuli were obtained. For the responses during sinusoidal optokinetic stimulation gain and phase relative to cylinder velocity was determined. Results indicate, that most vestibular nuclei neurons do not respond to optokinetic stimuli above 0,2 Hz. However, a few neurons still responded strongly at 1 Hz. These results will discussed in relation to the psychophysical and oculomotor effects observed at higher frequencies of optokinetic stimulation.

- TRANSFORMATIONS OF COORDINATES INTRINSIC TO THE VESTIBULO-95.4
  - OCULAR REFLEX. John I. Simpson, Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Avenue, New York, N.Y. 10016 Intrinsic coordinate systems of sensorimotor integration for the vestibulo-ocular reflex can be identified in the periphery and the transformations properly interpreted (Pellionisz & Llinas, 1980; Simpson & Graf, 1981; Robinson, 1982). The principal response axes of the semicircular canals constitute a sensory coordinate system while the eye rotation axes of the extraocular muscles constitute a motor coordinate system. From in situ measurements of plastic casts of the rabbit labyrinth, In situ measurements or plastic casts of the rabbit labyrinth, the direction cosines of the canal axes are expressed relative to a right handed Cartesian reference frame fixed to the head after elevating the nasal bone 57° from earth horizontal, as in the freeze position (Hughes, 1971). The z = 0 plane is horizontal, the y = 0 plane is the midsagittal plane. Anterior, left and dorsal are positive. The average (n=4) direction cosines (x,y,z coordinates) of the rotation axes for best exciting the left canals are: horizontal, -.122, .018, .992; anterior, -.712, .702, .026; posterior, -.794, -.605, -.062. This set of unit vectors, along with the mirror symmetric set, establishes an intrinsic coordinate system for detection of rotational head movement. With the eye in primary position (assumed to be its position in the freeze state), the orientation of the eye rotation axis for each muscle is computed from measurements of the location of the insertion and computed from measurements of the location of the insertion and origin and the eye rotation center, under the assumption that the sclera is part of a spherical surface and that the muscle courses over the globe along a great circle route to its point of departure from the globe. From preliminary measurements in two rabbits, the direction cosines (x,y,z coordinates) of the rotation axis for contraction of each of the muscles of the left eye are as follows: medial rectus, .006, .155, -.988; left eye are as follows: medial rectus, .006, .155, -.965; lateral rectus, -.412, .050, .910; superior rectus; 802, -.579, .147; inferior rectus, -.883, .470, -.013, superior oblique, .702, .563, .435, inferior oblique, -.656, -.717, .236. This set of unit vectors establishes an intrinsic coordinate system for execution of eye movements. With both the peripheral sensory and motor coordinate systems known, the central transformations of intrinsic coordinates can be explored. transformations of intrinsic coordinates can be explored theoretically using matrix and tensor operations. From a From among the possible theoretical predictions, those relating to the sign of the net connectivity between canals and muscles are presently amenable to comparison with existing anatomical and physiological observations. Supported by USPHS Grant 13742.
- CONVERGENCE OF CANAL INPUTS TO SECONDARY NEURONS IN CAT VESTIBULAR NUCLEI. J. Baker, J. Goldberg, G. Hermann\*, and B. Peterson. Northwestern Univ. Med. School, Chicago, TL 60611 The organization of vestibular reflexes requires convergence of

vestibular inputs to muscles. For example, spatial orientations of semicircular canals and eye muscles dictate that to produce proper compensatory vestibulo- ocular movements each eye muscle must receive input from all three pairs of canals. We studied input convergence to secondary vestibular neurons in awake cats. Secondary neurons were identified by short latency responses (<1.3 msec.) to labyrinth stimulation via electrodes on round and oval msec.) to labyrinth stimulation via electrodes on round and oval windows. We applied sinusoidal rotations successively in 12 or more vertical and horizontal planes to determine spatial response properties of each neuron. Rotation with sum of sinusoid waveforms determined a cell's frequency response; rotation of the body with the head fixed in space tested for neck afferent inputs; and many cells were tested for eye position sensitivity. We subdivided our sample of 76 sufficiently well studied neurons

into two groups, 50 cells that we believe received vestibular input primarily from semicircular canals, and 26 "STC" cells with complex response properties which suggest they received canal and otolith inputs. An accompanying abstract describes STC cells. Canal cells had responses related to head velocity during sum of defined planes of rotation in which their response was maximal or null. The figure below shows a canal cell's responses to rotation in several vertical planes at 0.5 Hz. Canal cell data were well fitted by sine functions based on the assumption that responses fitted by sine functions based on the assumption that responses were the result of a linear sum of inputs from the three canal pairs. We calculated the angles between a cell's maximum response plane and the canal planes. Assuming an angle <75 deg. indicated significant input, 22 cells had input primarily from a single canal pair, 20 cells significant input from two canal pairs, and 8 cells input from all six canals. In addition, we found that many secondary neurons received neck and/or eye position input. Thus, extensive convergence occurs as early as the first central vestibular relaw. Supported by grants EV04058. EV00231. vestibular relay. Supported by grants EY04058, EY00231.

95.7 SPATIO-TEMPORAL CONVERGENCE ONTO SECOND ORDER VESTIBULAR NEURONS. J. <u>Goldberg</u>, J. <u>Baker</u>, <u>G. Hermann<sup>\*</sup></u>, <u>B. Peterson</u>. Department of Physiology, Northwestern Univ. Med. Sch., Chicago, II 60611. This abstract continues the description of identified second order neurons in the alert cat studied by the methods described in the preceding abstract by J. Baker et al.

the preceding abstract by J. Baker et al. The figures below show responses of a second order neuron to vertical rotation as the animal is positioned at different angles around its yaw axis. Note that the gain does not have a null and the phase is a continuous function of the orientation angle, unlike the responses of 'canal cells' described in the preceding abstract. Of the 76 neurons studied, 26 exhibited the above properties during sequences of rotations in vertical planes. These spatio-temporal response patterns cannot be produced by summation of inputs differing only in their spatial orientation and not in the phase of their response during sinusoidal rotation. Instead, inputs differing both in <u>spatial and temporal</u> properties must converge on these second order vestibular neurons, which we therefore call spatio-temporal convergent (STC) neurons. Comparisons of responses to horizontal and vertical plane rotations and the presence of responses to low-frequency (0.01-0.05 Hz) and static vertical notation suggest that many of these cells receive convergent canal and otolith inputs. In some cases STC behavior may also be produced by convergent canal inputs with different dynamic (temporal) properties. STC neurons, with rotational response phase dependent on the

STC neurons, with rotational response phase dependent on the plane of head rotation, may be suitable for controlling neck muscles during vestibulocollic reflex, since moving the head in different planes requires inputs with different dynamics to these muscles. Convergent canal neurons that receive inputs with different spatial but the same temporal characteristics may be hypothesized to drive muscles that encounter relatively constant dynamic loads regardless of the plane of motion, such as the extraocular muscles. Supported by grants EY04058 and EY00231.

95.9 DIRECTIONAL SELECTIVITY OF TILT-SENSITIVE CENTRAL VESTIBULAR NEURONS IN THE CAT. R. H. Schor, A.D. Miller and D.L. Tomko. Lab. of Neurophysiology, Rockefeller Univ., New York, NY 10021 and Dept. Physiology, Univ. of Pittsburgh, Pittsburgh,PA 15261. Responses to head tilt were recorded from vestibular neurons in and around the lateral vestibular nucleus (LVN) of the decerebrate cat. Each animal had all six semicircular canals rendered nonfunctional by a plugging procedure. Each cell was studied by slowly tilting the cat using one or both of two paradigms. The first method employed sinusoidal tilts (0.05 or 0.1 Hz, up to 20 degrees) about earth-horizontal axes, oriented in up to 12 directions including longitudinal (roll) and transverse (pitch) tilt. The second method imposed a constant 10-degree tilt; the direction of the tilt was rotated with a 10 or 20 second period around the animal by an appropriate combination of roll and pitch motions.

Neurons responded by maximally increasing their discharge frequency in a particular direction of head tilt from the horizontal. Each cell's response could be described by a vector in the animal's horizontal plane whose orientation was given by the direction of the most effective stimulus, and whose length represented the neuron's sensitivity to tilt. The two methods of stimulation yielded equivalent response vectors.

Response vectors have been obtained for more than 100 neurons. The distribution of vector directions for these vestibular neurons was not uniform; there was a conspicuous absence of neurons with fore/aft-directed vectors. The median sensitivity of these cells (length of the response vector) was 50 impulses/ sec/g. Neurons whose vectors lay in the ipsilateral half-plane (which would be excited by ear down tilt) tended to be less sensitive than those with contralateral vectors. Neurons excited by ear up tilt tended to be located ventrally in the LVN while those excited by ear down tilt were more evenly distributed. There was no other obvious correlation of vector orientation with the anatomical locus of the cell in the brainstem.

A subset of these neurons was also tested with a broad frequency bandwidth of tilt stimuli. The response vectors determined at higher frequencies (e.g. 0.5Hz) often pointed in the opposite direction, since responses which developed a phase lag of more than 90 degrees (Schor and Miller, EBR 47: 137-144, (1982) reversed the apparent excitatory and inhibitory directions of tilt. (Partially supported by NASA grants NSG-2380 and NAG2-155, and PHS grants NSI7808, NS02619 and RR07065). 95.8 EYE MOVEMENTS OF THE ALERT CAT DURING OTOLITH AND OPTOKINETIC STIMULATION. J. H. Anderson and M. Le Taillanter\*. Depts. of Otolaryngology and Physiology, University of Minnesota Medical School, Minneapolis, MN 55455. When an animal is in his normal upright position and is

subjected to a disturbance such as pitch rotation, otolith and semicircular canal inputs interact to produce a symmetrical vestibulo-ocular reflex response (cf., Barmack, J. Physiol., 314:547-564, 1981). In contrast, when an animal is on its side, which causes a change in the gravity bias on otolith organs, the which causes a change in the gravity black of birth organs, the vertical VOR and vertical optokinetic reflex are asymmetric (cf., Anderson, <u>Dev. Neuro.</u>, 12:395-401, 1981; Matsuo et al., <u>Brain</u> <u>Res.</u>, 176: 159-164, 1979; Darlot et al., <u>Exp. Br. Res.</u>, 41: 420-426, 1981; Matsuo, Ph.D. Thesis, 1981). The present work focused on some characteristics of this asymmetry and the responses due to otolith stimulation alone or in combination with optokinetic stimulation. Alert, restrained cats were subjected to sinusoidal linear accelerations in the horizontal plane they were stationary and viewed a rotating optokinetic pattern. For linear motion, the frequencies used covered the range 0.05 to 0.25 Hz and the peak accelerations were 0.029 to 0.75 m/s<sup>2</sup>. Eye movements were recorded with the magnetic search coil technique. When the animal was positioned in a normal upright manner and subjected to accelerations along its longitudinal (X) axis, there were no significant vertical eye movement responses in the dark. Also, when the animal was positioned laterally on its side and subjected to accelerations along its X- or vertical (Z) axis, there were no responses in the dark. However, when viewing an optokinetic pattern during movement along the Z-axis, there were responses. The vertical eye movements were very asymmetric. T velocity of the downward slow eye movements was small, compared The velocity of the downward slow eye movements was small, compared to that of upward eye movements, and the ratio of downward to upward eye velocities was less than 1/4. These results indicate that small amplitude linear accelerations (less than 0.75 m/s<sup>2</sup>) do not cause a measurable otolith-ocular response in the cat. However, when there is an optokinetic input in addition to the otolith input, there is a vertical eye movement response which is asymmetric. This may be due to the static change in head orientation relative to gravity (Matsuo, Ph.D. Thesis, 1981) and the modulated otolith input interacting with the optokinetic system (Buizza et al., Exp. Br. Res., 39:165-176, 1980).

95.10 GRAVITATIONAL EFFECTS ON VISUAL-VESTIBULO-OCULOMOTOR COORDINATE TRANSFORMATIONS GENERATING COMPENSATORY EYE MOVEMENTS. T. Raphan and B. Cohen. Departments of Computer and Information Science, Brooklyn College and Neurology, Mount Sinai School of Medicine, New York, N.Y. Rotation of the visual surround that induces horizontal

Botation of the visual surround that induces horizontal optokinetic nystammus (OKN) excites the velocity storage mechanism and induces horizontal obtokinetic after-nystammus (OKAN). If horizontal OKN is induced while monkeys are tilted with regard to gravity, then the OKAN which follows has a vertical commonent. The direction of the vertical commonent is gravity specific. When the slow phases of OKN are directed away from gravity, the OKAN is oblique with the vertical commonent of the slow phases in the downward direction. If the slow phases of OKN are toward the direction of gravity, the OKAN has an upward slow phase commonent. The vertical component of the nystagmus does not appear immediately but builds up and decays to zero as if excited by an exponential function. This suggests that under appropriate circumstances stored information associated with horizontal nystagmus can excite a mode of the storage mechanism that generates vertical nystagmus. Such cross coupling is also demonstrated in other ways. Pure vertical OKAN with the animal upright is associated with little vertical OKAN. Consistent with this, if monkeys are upright when they receive an oblique optokinetic stimulus, only horizontal OKAN is induced and the vertical component. The vertical component is also dwith regard to gravity and are given an oblique optokinetic stimulus, oblique OKAN is now induced with a strong vertical component. The vertical component is symmetrical regardless of whether the slow phases are up or down. This is in contrast to vertical OKAN induced in a 90° roll position which is stronger when the slow phases are up. To incorporate the effects of gravity, we posit that velocity storage is best represented by a multidimensional system, with specific states of that system establishing a coordinate basis for interpreting head movement and movements of the visual surround. Gravity appears to reorient the basis vectors for the state space of the system by modifying the coupling from the visual and vestibular systems to the stor

EFFECT OF ABNORMAL VESTIBULAR-VISUAL INTERACTIONS UPON POSTURE CONTROL IN TWO DIFFERENT TYPES OF VESTIBULAR DEFICIT PATIENTS. L.M. Nashner and F.O. Black. Neurological Sciences Institute and Department of Neuro-otology, Portland, OR 97209. A group of 48 vestibular deficit patients was assessed on the moving platform and independently by standard clinical means. Patients were selected based upon two clinical cri-teria: complaints of postural instability not adequately categorized by standard clinical tests, and/or benign parox-ysmal positional nystagmus (BPPN). Platform tests exposed patients to six sensory conditions: normal support surface and visual surrounds (S<sub>N</sub>V<sub>N</sub>), normal support with eyes closed (S<sub>N</sub>V<sub>C</sub>) and with visual surrounds rotated to precisely follow the patient's A-P sway motions (S<sub>N</sub>V<sub>S</sub>), then repeating in the same order the three visual conditions but not with the support rotated to precisely follow A-P sway motions (S<sub>S</sub>V<sub>N</sub>, S<sub>S</sub>V<sub>C</sub>, S<sub>S</sub>V<sub>S</sub>) (see Nashner, et al, J. Neuroscience 2, 1982). Based upon the configuration of normal and abnormal per-formance under the six conditions, 38 of the 48 fell into one of three categories (5 tested normal and 5 too impaired to characterize).

of three categories (s tested normal incomparison of abnormality identical characterize). Category 1: 18 showed a configuration of abnormality identical to that described previously for symmetric and/or asymmetric reduced vestibular function; i.e., within normal range (<1 S.D.) in all  $S_N$  and the  $S_SV_N$  tests (Nashner, et al, ibid), abnormal in the  $S_SV_S$  test (>2 S.D.), and inconsistent in the CMM test

Syc test. <u>Category 2</u>: 6 patients were distinguished from the previous 18 by abnormal performance in the  $S_NV_S$  test (>2 S.D.) and consistently normal performance on the  $S_SV_C$  (<1 S.D.) (i.e., a relatively normal vestibular inertial gravitational reference to conturn

to posture). <u>Category 3</u>: 14 patients were significantly abnormal (>2 S.D.) under those test conditions representing an overlap of categories 1 and 2.

gories 1 and 2. Category 2 and 3 patients presented symptoms consistent with one or both posterior canals being sensitive to linear as well as angular accelerations (i.e., BPPN). Category 2 patients experienced motion sickness symptoms under the V<sub>S</sub> conditions. Apparently, a perceptually undetectable "distortion" of vestibular space (in contrast to reduced or asymmetrical vestibular output) leads to very different visual-vestibular interactions. Those with distorted vestibular posterior canal function could not ignore the inappropriate visual reference, even when provided correct somatosensory information and what appeared to be a relatively normal vestibular upright reference to posture.

- 95.12 GEOMETRICAL ANALYSIS OF POSTURAL INSTABILITY IN BPPN (VES-TIBULAR) PATIENTS. G. McCollum and L.M. Nashner. Neurological Sciences Inst., 1120 N.W. 20th Avenue, Portland, Oregon 97209. The postural behavior of the BPPN patients described in the previous abstract varied with sensory modality and with mix of sensory modalities. Stabilized ankle angle input was appro-priately ignored when the eyes were closed. But stabilized provide the sensory and the sensory back and the sensory visual input inappropriately overrode even correct ankle angle information in the presence of the distorted BPPN vestibular signal.

Signal. Since the BPPN patients were able to use ankle angle information appropriately in the absence of vision, the purest measure of their direct vestibular input to posture was stance upon the stabilized support surface with eyes closed. In that case, they oscillated forward and backward with a charac-

This finding is consistent with BPPN canals sensing not pure rotation but a combination of rotational and linear motions. In the diagrams below, radius gives response amplitude for motions of constant instantaneous acceleration of the canal.

of constant instantaneous acceleration of the canal. Postural motions, about axes outside the canals, include movements of the head both rotational and linear to the canals. Also, visual sensation of head movement includes both rotation and translation. Sensation of linear motion, indistinguishable for the canals from rotational, gives the axis of canal sensation the freedom to wander in both postural and visual spaces. When normal visual response superimposes on distorted BPPN canal response to leave an area of overlapping responses of opposite sign, there is sensory conflict. That is, canal response to postural motion is inappropriate and disagrees with visual response. visual response.

This sensory conflict, rather than lack of vestibular input, causes BPPN patients to follow visual cues even when they are inappropriate.

FUNCTIONAL INTERRELATIONSHIPS BETWEEN ANDROGEN RECEPTOR 96.1 FUNCTIONAL INTERRELATIONSHIPS BETWEEN ANDROGEN RECEPTOR OCCUPATION IN BRAIN AND PITUITARY AND SERUM TESTOSTERONE (T) AND LITEINIZING HORMONE (LL) LEVELS IN MALE RATS. M.Y.McGinnis and L.C.Krey (SPON:P. Anderson). Dept. Anatomy, Mount Sinai School of Medicine, New York, N.Y. 10029 and Rockefeller University, New York, N.Y. 10021. We have characterized the dynamics of cell nuclear androgen receptor binding, and serum T and LH levels associated with the insertion and removal of two x 10 mm T-filled Silastic capsules implanted ca into proferred open Flork proveds of survey

insertion and removal of two x 10 mm T-filled Silastic capsules implanted sc into preformed, open flank pouches of awake, castrated (2-3 wks), male rats. Rats were sacrificed at 1/2,2,4,8 or 24h after capsule insertion. Additional groups of rats were sacrificed prior to T insertion, or 2,4, or 8h after capsule removal (24h T exposure). Cell nuclear androgen receptor binding was measured in combined hypothalamus, preoptic area, amygdala and septum (HPAS) and pituitary (PIT) using an exchange assay (McGinnis et al.Brain Res.1983). In no-T castrates serum T and cell nuclear androgen receptor levels were barely detectable, while serum IH levels were elevated. Serum T rose to 2-4 ng/ml during the 1/2 to 24h of T exposure. Nuclear androgen receptor levels during the first 1/2 to 8h increased dramatically in the HPAS (12-23 fold) and PIT (18-24 fold). Further slight increases occured at 24h. Serum IH levels began to decline 4h after capsule insertion, and reached undetectable levels only after 24h T exposure. and reached undetectable levels only after 24h T exposure. Following capsule removal, serum T and nuclear androgen receptor levels in HPAS and PIT fell precipitously. Serum T was undetectable at 2h; androgen receptor levels fell by one half at 2h and approached castrate values at 4h. Serum LH half at 2h and approached castrate values at 4h. Serum IH levels began to rise at 4h and approached castrate levels by 8h. These results suggest relatively rapid association and dissociation rates of androgens to their receptors in brain and pituitary. Results further indicate that T must be present for >2h for suppression of IH secretion, and that complete suppression of IH requires >8h of T exposure. Moreover, feedback actions of T are retained following androgen receptor clearance from the cell nucleus. Presently we are examining the influences of these T treatments on frequency:amplitude characteristics of episodic IH release in male rats. Supported by grants from The Mount Sinai Medical Center and Supported by grants from The Mount Sinai Medical Center and The Rockefeller Foundation.

**96.2** PATTERN OF SYNAPSES ON VENTROMEDIAL HYPOTHALAMIC NEURONS IN THE FEMALE RAT: AN ELECTRON MICROSCOPIC STUDY. <u>M. Nishizuka\* and D.</u> Pfaff (SPON: L.-M. Kow). Laboratory of Neurobiology & Behavior,

Rockefeller University, New York, NY 10021. Ultrastructural observations of synaptic types in limbic and hypothalamic structures have been useful in neuroendocrine studies. for example in the demonstration of sex differences (Nishizuka & Arai, <u>Brain Res. 212</u>:31, 1981). Synapses impinging on ventromedi-al hypothalamic (VMH) neurons must be described in the analysis of inputs controlling cell bodies important for lordosis and other behaviors. In this analysis, the existence of intrinsic synapses can be tested by looking for those which remain after transections that circumscribe VMH.

Ovariectomized female rats were used. Some were given 2 weeks exposure to systemic estrogen. Also, some rats were subjected to surgery in which the VMH was isolated by a circumscribing knife cut; these were perfused 5 days after surgery. Perfusion with 2%paraformaldehyde-2% glutaraldehyde, osmification, embedding in epon, sectioning and staining followed standard electron microscopic procedures.

In unoperated animals, normal axodendritic synapses were seen. with a predominance of synapses on dendritic shafts as opposed to spines. Axosomatic synapses were also detected. Dense-cored vesicles could be seen in some synaptic terminals. Notable we Notable were large clear-centered vesicles (maximum diameter 130 nm) in a small percent of terminals. Also, in a few terminals in individual sec-tions multiple contact zones could be visualized. In these respects, estrogen-treated rats were qualitatively similar to ovari-ectomized controls.

Synapses on VMH neurons survived total VMH isolation, proving that some VMH somas give rise to axons with intrinsic synapses. Axodendritic intrinsic synapses were detected on both shafts and spines, and intrinsic axosomatic synapses were also seen. These intrinsic synapses comprised a substantial proportion of the total synapses on VMH neurons. Overall, the synaptic patterns observed allow for a variety of types of physiological controls over VMH neurons, including possible effects of "local circuit neurons"

Supported by NIH grant HD-05751.

LOCALIZATION OF LH-RH-LIKE IMMUNOREACTIVITY IN THE OVINE BRAIN. 96.3 Juan Pablo Advis\* and Rodrigo O. Kuljis. Dept. of Animal Sciences, Cook College, Rutgers University, New Brunswick, N.J. 08907 and Depts. of Neurology and Neurobiology and Behavior, S.U.N.Y. at Stony Brook, N.Y. 11794.

Immunocytochemical techniques for the localization of LH-RH have been employed in a variety of mammalian species, including the rat (Baker et al., '74), the guinea pig (Krey and Silverman, '78) and primates (Barry and Carette, '75). The present study analyzes the distribution of LH-RH-like immunoreactivity in the brain of the sheep.

Two 10-month old female sheep were anesthetized and decapitated The heads were perfused with 0.9% saline followed by periodate-lysine-paraformaldehyde fixative (McLean & Nakane, '74) via the carotid arteries. The brains were freeze-sectioned coronally at 30 µm in a sliding microtome, and the sections processed for LH-30 µm in a sliding microtome, and the sections processed for LH-RH-like imminoreactivity by means of the peroxidase-anti-peroxi-dase (Sternberger, '74) and indirect fluorescence (Coons, '58) methods. The primary antibody was raised in rabbits and generously supplied by Dr. V.D. Ramirez from the University of Illinois. LH-RH-like immunoreactivity is present in cell bodies located in the medial proptic area, lamina terminalis, dorsal aspect of the procedia pertia of the supractic publics.

In the medial proptic area, lamina terminalis, dorsal aspect of the preoptic portion of the supraoptic nucleus, arcuate nucleus, retrochiasmatic area, medial septal nucleus, triangular septal nucleus, diagonal band of Broca and anterior perforated substance. LH-RH-like immunoreactivity is present in fibers located in the paraventricular portion of the hypothalamus, forming rather loose bundles between LH-RH-containing cell groups in the preoptic area and the ventro-basal hypothalamus. A dense fiber system descends from the security nuclus into the median emisance Loose fiber from the arcuate nucelus into the median eminence. Loose fiber bundles appear to extend from the preoptic area and adjacent limbic structures into the ventral tegmental and basal area of the midbrain, after traversing through the hypothalamus in the medial forebrain bundle.

These observations suggest that LH-RH is present in discrete cell groups and fiber systems in the ovine basal forebrain, in agreement with LH-RH determinations by radioimmunoassay (Advis & Kuljis, in progress).

IMMUNOCYTOCHEMICAL LOCALIZATION OF LHRH IN THE INFUNDIBULAR STALK AND NEUROHYPOPHYSIS: A COMPARATIVE STUDY. <u>E.L.P. Anthony# and</u> J.C. King (SPON: D.A. Damassa). Dept. of Anatomy and Cellular 96.4 logy, Tufts University Schools of Medicine, Boston, MA 02111. Complex vascular relationships have recently been demonstrated Biology, between these regions and the basal hypothalamus. These interactions suggest re-examination of the routes whereby hypothalamic hormones may reach the anterior pituitary. The distribution of the hypothalamic hormone LHRH was studied using light microscopic the hypothalamic hormone LHRH was studied using light microscopic immunocytochemistry in the hypothalamic-pituitary complex of several mammals. Primary antisera employed included 1) IJ29 (I.M.D. Jackson), 2) R422 (A. Arimura), and 3) CRR11B73 (V. Ramirez); each of these antisera binds a different portion of the LHRH molecule. In humans, rhesus monkeys, cynomolgos monkeys, little brown bats and ferrets, LHRH-immunoreactive fibers were observed in both the internal and external zones of the median observed in both the internal and external zones of the median eminence. Additionally, substantial numbers of immunoreactive fibers traversed the infundibular stalk and entered the neural lobe of the pituitary. In all of these species, the majority of fibers entering the neural lobe coursed along the posterior border of the adenohypophysis, although individual fibers commonly diverged from this region and entered deeper portions of the neural lobe. In addition to immunoreactive fibers LHRH-immunoreactive neuronal perikarya were observed within the median eminence in bats and within the infundibular stalk in rhesus monkeys and ferrets. This distribution of LHRH cells and fibers bears little resemblance to that demonstrated in the rat by equivalent immunocytochemical procedures. In rats, immunoreactive fibers were numerous in the external, but not the internal, zone of the median eminence. Only occasional fibers and no perikarya were associated with the infundibular stalk and and no perikarya were associated with the infundioual stark neural lobe in this species. These striking interspecific variations suggest that multiple routes may exist in the tuberoinfundibular region for the delivery of LHRH to the pituitary. In addition, some neurovascular endings of LHRH neurons in this region may distribute the peptide to distant sites via systemic circulation or return it to the hypothalamus via retrograde flow. This study was supported by grants HD00352 from NIH and PCM 8103243 from NSF to JCK.

96.5 THE INFLUENCE OF DIFFERENT LIGHT WAVE LENGTHS ON THE SHORT PHOTOPERIOD-INDUCED COLLAPSE OF THE MALE SYRIAN HAMSTER REPRODUCTIVE SYSTEM. <u>George C. Brainard, Mary K. Vaughan, and</u> <u>REPRODUCTIVE SYSTEM. George C. Brainard, Mary K. Vaughan, and</u> <u>Russel J. Reiter.</u> Department of Anatomy, The University of Texas Health Science Center, San Antonio, Texas 78284 and Department of Neurology, Thomas Jefferson Medical College, Philadelphia, Pensylvania 19107.

Neurology, Thomas Jefferson Medical College, Philadelphia, Pennsylvania 19107. Environmental light perceived by the retina is responsible for entraining circadian rhythms, regulating reproductive cycles, and influencing a variety of endocrine and metabolic functions. Specifically, hamsters exposed to short photoperiods (12.5 hours of light or less) undergo an inhibition of the neuroendocrine-reproductive axis. The following study was designed to determine which light wavelengths are capable of blocking this suppression of the reproductive system. Groups of 10 hamsters each were exposed to short photoperiods (11 hours) of bright white light at 400  $\mu$ /cm<sup>2</sup>, extended by 3 hours of either white light, rear-ultraviolet light, blue light, green light, yellow light, red light or darkness. The white light was produced by cool white fluorescent light sources. The restricted wavelength sources had half-peak bandwidths of 330-371 nm (near-ultraviolet), 435-500 nm (blue), 515-550 nm (green), 558-636 nm (yellow), 635-770 nm (red). The lights used in the additional 3 hour period were adjusted to produce an irradiance of 0.2  $\mu$ W/cm<sup>2</sup>. After 12 weeks of exposure to these different photoperiodic conditions, paired testes, accessory sex organs, and pituitary glands were weighed. Blood samples and pituitary glands were assayed for prolactin by radioimmunoassay. Animals exposed to short photo-periods extended by white, near-ultraviolet, blue or green light had testicular weights which were typical of reproductively competent hamsters. Animals exposed to short photoperiods extended by 3 hours of yellow light, red light, or darkness had significantly suppressed testicular weights (P<0.001). This reproductive suppression was also observed in the accessory sex organs. Interestingly, hamsters exposed to near-ultraviolet, blue, and green lights had significantly higher pituitary PRL levels than all other groups (P<0.01). These data demonstrate that the neuroendocrine reproductive axis is differentially responsive to different responsive to different wavelengths of visible light. However, it appears that not all aspects of the reproductive axis respond (Supported by NSF Grant No. PCM 8003441. The experimental light sources were generously supplied by the Durotest Corporation, North Bergen, New Jersey.)

96.6 LESIONS OF THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS BLOCK THE

LESIONS OF THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS BLOCK THE INFLUENCE OF PHOTOPERIOD ON CONADAL REGRESSION AND PINEAL MELATONIN IN MALE HAMSTERS. E.L. Bittman, M.N. Lehman, and Dept. Anatomy, Univ. Mich., Ann Arbor, MI 48109. The pineal gland mediates photoperiodic control of hamster neuroendocrine function. Retinal input to the suprachiasmatic nucleus (SCN) and sympathetic innervation of the pineal are critical to the inhibition of reproduction by short days. Intervening structures are unidentified. In the rat, the hypothalamic paraventricular nucleus (PVN) receives extensive input from the SCN (Berk & Finkelstein, <u>Brain Res., 226</u>:1), and may influence autonomic function via its brainstem and spinal may influence autonomic function via its brainstem and spinal may influence autonomic function via its brainstem and spinal cord projections (Swanson & Sawchenko, <u>Neuroendo.</u>, <u>31</u>:410). We therefore studied the role of the PVN in photoperiodically-induced testicular regression in the golden hamster. Initially, Il males housed in long days (14L:10D) received either bilateral PVN lesions (n=7) or sham lesions (n=4). After 3 weeks all males were blinded by bilateral enucleation. When inspected Il weeks later the gonads of sham-lessioned males were uniformly regressed. Six hamsters with complete destruction of the PVN had large testes similar to those of sighted males in long days. One lessioned male exhibited substantial but incomplete testicular regression; in this animal the lesion spared a large dorsocaudal portion of the PVN.

In a second experiment, 25 males housed in long days either received bilateral PVN lesions (n=7), SCN lesions (n=9), sham lesions (n=7), or served as normal controls (n=5). Three weeks later all males were transferred to short days (10L:14D). After later all males were transferred to short days (101:140). After 11 weeks animals were decapitated under dim red illumination 3-5 h prior to lights on, and pineal melatonin content was determined by radioimmunoassay (Tamarkin et al., <u>Endo.</u>, 104:385). Sham-lesioned and normal control hamsters all had regressed, spermatogenically inactive testes (combined weight, x=0.53) while hamsters bearing complete bilateral lesions of the PVN or SCN had large, spermatogenically active testes (x=3.81). As expected, control animals exhibited high nocturnal levels of pineal melatonin, while the pineals of PVN-lesioned males contained significantly lower levels. Effective PVN lesions were restricted to the caudal portion of this nucleus and completely spared the SCN. The PVN may therefore be an important relay for photoperiodic information from the SCN to spinal structures responsible for rhythmic autonomic control of pineal melatonin synthesis and gonadal function.

96.7 ACTIVITY IN THE MEDIAL BASAL HYPOTHALAMUS AND LH RELEASE IN FE-MALE RHESUS MONKEYS. <u>R.R. Yeoman & E. Terasawa</u>. Wis. Reg. Pri-mate Res. Ctr. University of Wisconsin, Madison, WI 53715-1299. The hypothalamus is involved in the progesterone (P) induced It surge in ovariectomized and estrogen primed rhesus monkeys since pentobarbital blocks this release (J. <u>Endocrinol. 92</u>; 327, 1982). Single unit activity (SUA) in the ventral part of the med-ial basal hypothalamus (MBH) increased during LH release after P injection (<u>Endocrinol. 112</u>; Suppl. 156, 1983). However, the ex-Information number and the second sec chronically implanted with a pedestal on their crania using X-ray ventriculography under halothane anesthesia. Small capsules containing estradiol-17 $\beta$  (EB) were implanted subcutaneously 2 wks be fore the experiments. SUA was recorded during 2 different steroid treatments: 1) 22-36h and 40-50h after  $15-25\mu g$  EB injection, and 2) 1-2h after 2.5 mg P injection which was administered 24h following 15-25µg EB. The animals were chaired up to 14h only during the recording periods under minimal sedation (3mg ketamine/h). For SUA recording, a sheathed 50µm dia. stainless steel electrode with a 2-5µm tip was used and the position of electrode was veri-fied by X-ray each time. The units sampled were within a stereo-taxically defined area of 2.0mm lateral, 1.5mm anterior and 2.0mm posterior to the infundibular recess of the 3rd ventricle. The posterior to the infundibular recess of the 3rd ventricle. The firing frequency was calculated by a programmed data analyzer. Serum samples were obtained periodically for LH analysis. The frequency of unit firing of the ventral and dorsal MBH before EB administration was 1.6  $\pm$  0.4 Hz, (n=28), (mean  $\pm$  SE) and 3.8  $\pm$  0.9 Hz, (n=24), respectively. Twenty to 30h after the priming dose of EB neither firing rate of SUA (ventral: 1.5  $\pm$  0.1 Hz, n=65; dorsal: 5.9  $\pm$  0.7 Hz, n=96) nor LH level changed. Similarly 40 to 50h after EB the SUA (ventral: 1.7  $\pm$  0.3 Hz, n=15; dorsal: 5.5  $\pm$  1.6 Hz, n=18) did not change although LH increased slightly at this Hz, n=18) did not change although LH increased slightly at  $\bar{t}his$  time. In contrast, 2h after P the SUA of the ventral MBH started to increase and 6-10h after P it reached maximum firing rate (5.7 + 1.4 Hz, n=24). An increase in LH release occurred in a similar time course significant at 3h and peaking at 9h after P. Mean firing rate 2-12h post P was 4.7  $\pm$  0.5 Hz, n=101 (p < 0.001). Dorsal MBH activity was not changed significantly (5.2  $\pm$  0.7 Hz, n=61). In summary a small dose of EB alone did not change hypothalamic SUA nor circulating LH, while additional P increased the SUA of the ventral MBH coincident with the LH surge. Therefore, P but not the priming dose of EB, activates the neural substrate in-fluencing LH release. (Supported by NIH grants RR-00167, HD-15433 and HD-11355).

EFFECTS OF SMALL DOSE OF ESTROGEN AND PROGESTERONE ON SINGLE UNIT

96.9 DIFFERENTIAL EFFECTS OF PROLACTIN ON THE UPTAKE AND RAPID RELEASE OF DOPAMINE (DA) FROM MEDIAN EMINENCE (ME) AND STRIATAL (S) SYN-APTOSOMES. <u>Karen A. Gregerson\* and Michael K. Selmanoff</u> (SPON: D. Ruchkin). Department of Physiology, University of Maryland, School of Medicine, Baltimore, Maryland 21201.

The effects of hyperprolactinemia on the uptake and release of The effects of hyperprolactinemia on the uptake and release of  $^{3}H-DA$  was studied in crude synaptosomal preparations (P<sub>2</sub> fraction) from rat ME and S using a rapid filtration technique. Synaptosomes were prepared from intact male rats treated with ovine prolactin (oPRL) for 48h (4mg/kg, sc, every 8h) and from vehicle-treated controls. ME and S synaptosomes were prepared from comparable masses of tissue (10-15mg) and were run simultaneously. The synaptosomes were preloaded by incubation in 0.1µM  $^{3}H-DA$  for  $^{20}$ 30 min at 30°C, then stimulated with 75mM K<sup>+</sup> or 75µM veratridine, and the effluents obtained by rapid filtration were analyzed for <sup>3</sup>H-DA content. <sup>3</sup>H-DA release under basal (5mM K<sup>+</sup>) and depolarizing

conditions was determined over 5 sec intervals. In synaptosomes from vehicle-treated controls, uptake of <sup>3</sup>H-DA In synapcosomes from venicle-treated controls, uptake of 3-54 was about 2-fold greater into S than into ME synaptosomes. The majority of depolarization-evoked release of 3H-DA from both ME and S synaptosomes was Ca<sup>++</sup>-dependent, although a component existed which was not dependent on externally added Ca<sup>+++</sup>. The latter represented a greater fraction of the stimulated release from the  $10^{-10}$  German state of the stimulated release from the state of the stimulated release from the stimulated r ME (32%) than from the S (14%). In addition, the rate constant for the calculated initial phase of release from S was much greater than that for ME synaptosomes, suggesting that the apparent kinet-ics of DA release are markedly different in the ME as compared to the S.

 $^{3}\mathrm{H}\text{-}\mathrm{DA}$  incorporation into S synaptosomes was enhanced following exposure to oPRL, whereas the hormone treatment did not affect the percent of preaccumulated  $^3\mathrm{H-DA}$  released from S synaptosomes under either basal or depolarizing conditions. In contrast, hyperprolactinemia did not alter the amount of <sup>3</sup>H-DA taken up by ME synaptosomes but did selectively increase the evoked release of  $^{3}\mathrm{H}{-}\mathrm{DA}$  from ME. Basal efflux was unchanged from controls. The difference in evoked release between oPRL-treated and control ME The occurred when depolarization was induced with either high external  $K^+$  or veratridine. Since the enhanced <sup>3</sup>H-DA efflux from ME synapto some sfrom hyperprolactinemic rats was also evident during depolarization over a wide range of external Ca<sup>++</sup> concentrations (0.01-3.0mM), the data suggest that this effect of oPRL is on a

(0.1) Simply, the data suggest that this effect of orke is on a Catt-independent release mechanism in the ME. In conclusion, the apparent kinetics of DA release differ be-tween the ME and S. Moreover, oPRL in vivo has differential ef-fects on the in vitro release of DA from these two dopaminergic terminal projection fields.

EFFECTS OF PHOTOPERIOD ON ESTROGEN RECEPTOR IN HAMSTER BRAIN. Ρ. 96.8 Mak\* and G.V. Callard\*. (SPON: Boston Univ., Boston, MA 02215 A. Miller). Biology Dept.,

Exposure of hamsters to short days (8:16 LD) in contrast to those maintained in long days (16:8 LD) leads to increased sensi-tivity to the negative feedback effects of androgen (A) but decreased responsiveness to the behavioral effects of the hormone. Aromatization of A to estrogen (E) in situ is known to mediate many central A actions, and we previously observed decreased aro-matase in brain tissues of short day (Solomon and Callard, Biol. Reprod. 22:85A, 1980) and blinded (Callard <u>et al.</u>, <u>Biol Reprod.</u> 21:33, 1979) hamsters. In order to determine whether changes in the quantity of E formed locally might be reflected in the uptake, the quantity of L formed locally might be reflected in the uptake binding, and translocation of receptors (ER), hamster brain was examined for specific E binding activity. Using a protocol similar to that for measuring ER in hamster uterus (Evans et al., <u>Endocrinology</u> 107:383, 1980) and LH 20 column chromatography an E binding macromolecule having the characteristics of a receptor was detected in crude cytosolic and nuclear extracts of brain tissues. These binding proteins exhibited high affinity (K<sub>d</sub> = 10.8 x  $10^{-10}$ M for cytosol; 11.5 x  $10^{-10}$ M for nuclear) and limited binding capacity (20 - 50 fmol/g tissue). Binding was specific for E (estradiol > estrone > estriol) but not for A (testosterone,  $5\alpha$  -dihydrotestosterone) or progesterone. Cytosolic ER had a sedimentation coefficient of 7-8S in a 5-20% linear sucrose gradient (no salt), whereas nuclear ER sedimented in the 5S region of a high salt gradient. Intact and castrated hamsters showed a similar neuroanatomic distribution of ER (limbic hamsters showed a similar neuroanatomic distribution of ER (limbic > remaining forebrain = mid/hindbrain), and 2 h after a single in-jection of E, ER was depleted in limbic regions with a concomitant increase in nuclear ER. ER was measurable in nuclear extracts from brain of intact males, but values were lower or non-detec-table following castration or when testes were regressed as a con-sequence of short day exposure. This suggests that the hamster gonad normally secretes estrogen or aromatizable androgen which is responsible for ER translocation. When nuclear ER was measured in limbic tissues after E injection, values were similar in animals exposed to long days or short days whether or not the testes were present. Thus, photoperiod does not affect FR or FR translocation. Thus, photoperiod does not affect ER or ER translocation present. present. In this, photoperiod does not a first law of law transforation of and transformed and a commatizable androgen, nuclear ER was lower in short day groups (intact and castrate) compared to the corresponding long day comtrols. These results support the view that aromatization is important of the second paired in the brain of hamsters maintained on short daily photoperiods, and that changes in the quantity of estrogen formed in close proximity to ER can regulate a critical step leading to biological activation in the central nervous system. (HD 16714)

**96.10** DOSAGE AND TEMPORAL EFFECTS OF ESTROGEN ON AUDITORY EVOKED POTEN-TIALS RECORDED FROM THE FROG'S AUDITORY MIDBRAIN. K. F. Ramey\* (SPON: A. S. Feng). Dept. of Physiol. Biophysics., Univ. of

TALS RECORDED FRAM THE FRAG'S AUDITORY MIDRATIN. K. F. Ramey\* (SPON: A. S. Feng). Dept. of Physiol. Biophysics., Univ. of Illinois, Urbana, IL 61801. Acoustic communication plays an important role in the repro-ductive behaviors of frogs and toads. Such behaviors are gov-erned by both extrensic environmental as well as intrinsic physiological factors including sex hormones. Hormones have been shown to be taken up in and act directly upon the neurons in the anuran central nervous system. A recent study in our laboratory (Yovanof and Feng, 1983) showed that intraventricular injections of a small amount of 17-B-estradiol hemisuccinate, but not vehicle injections, significantly increased the auditory evoked potentials (AEP) recorded from the torus semicircularis of female northern leopard frogs (Rana p. pipiens). Increase in AEP was observed only after the second hormone injection made several hours after the first one. In this study, the dosage and hours after the first one. In this study, the dosage and temporal effects of estrogen were investigated.

Temporal effects of estrogen were investigated. Female northern leopard frogs were ovariectomized two weeks prior to the recording session in order to achieve a uniform estrogen background level among animals and thus obtain a more accurate estimate of the estrogen dose effect on AEP. Each frog was anesthetized and surgically prepared for AEP recordings from the torus semicircularis with a sharpened tungsten microelecrode. Acoustic stimuli consisted of isointensity (80 dB SPL) bursts of pure tones at four frequencies comprising the four dominant spec-tral components of the conspecific mating calls. Following an initial control recording period for establishing the baseline AEP, a varying amount of 17-8-estradiol hemisuccinate dissolved in 50% ethanol was injected into the third ventricle via a 1- $\mu$ L microsyringe and the AEP observed for a period of 2-5 hours. Then a second hormone injection (same amount as in the first injection) was made and the AEP observed for up to 5 hours. Pilot studies have shown that when the time between injections

injection) was made and the AEP observed for up to 5 hours. Pilot studies have shown that when the time between injections was 5 hr, a dual injection of 0.4  $\mu$ L would cause a significant increase in the recorded AEP. In contrast, injection dosages of 0.2  $\mu$ L showed no change in the AEP. When this time was decreased to 2 hr, no increase in the AEP was observed even at dosages as high as 0.5  $\mu$ L. The results of additional experimentation will be presented and discussed to conclusively establish this trend. This study indicates that the effects of estrogen on the auditory responses of female frogs is both dosage and time dependent. This concept is not only important in analysis of seasonal behaviors of these frogs but may also lend to future theories of hormonal mechanisms in neural tissue.

THE INFLUENCE OF OLFACTORY BULBECTOMY (ANOS), BLINDING (BLD) AND 96.11 PHREALECTOMY (PK) ON 24-HOUR PLASMA PROLACTIN (PRL) LEVELS IN NORMAL AND NEONATALLY ANDROGENIZED (NA) FEMALE RATS. <u>R.R. Gala</u>, <u>D.R. Pieper,\* Jenn-Tser Pan,\* W.P. Clarke\* and D.J. Haisenleder.\*</u> (SPON: J. Benjamins). Dept. of Physiol., Wayne State Univ. Sch. of Med., Detroit, MI 48201.

Female Sprague-Dawley rats were purchased pregnant and placed in a room with controlled lighting (14L-10D; lights on 0600 h) and temperature (24°C). The day of parturition was day 0 of life. On day 3 of life the litters were sexed, adjusted to ten pups/litter favoring females whenever possible and injected subcu with 1.25 mg testosterone propionate/0.1 ml of sesame oil. Normal female rat testosterone propionate/0.1 ml of sesame oil. Normal female rat pups received no injection. Litters were weaned at 21 days of age. Between 22 and 26 days of age the following surgical procedures were performed on both NA and normal animals: Sham ANOS and PX, BLD + ANOS and BLD + ANOS + PX. At 10 wks of age all animals were vaginally smeared for a week to determine their estrous cycle pattern. At 15 wks of age the animals were ovariectomized, im-planted with an atrial catheter and injected subcu with 0.5 mg of only stradiol phosphate. Ovarian and ovidictal weights were repolyestradiol phosphate. Ovarian and oviductal weights were re-corded. At 16 wks of age the animals were attached to a catheter extension at 0800 h and 0.3 ml of blood was obtained at 0900, 1100, 1400, 1700, 2000, 2300, 0200, 0500 and 0900 h replacing the fluid removed each time with sterile, warm (37°C) heparinized (50 units/ ml) saline. Animals were sacrificed after sampling and uterine weights were recorded. Animals with incomplete surgery were removed from the experiment.

Sham NA animals had constant vaginal estrus while BLD + ANOS animals had constant vaginal diestrus. PX returned the BLD + ANOS animals to a constant estrous smear. Normal BLD + ANOS animals animals had constant estrous smear. Normal BLD + ANOS animals could be divided into two groups: one group had constant diestrus smear while the other group cycled normally. Ovarian and uterine wts were decreased by BLD + ANOS in both NA and in normal rats with diestrus smears. Normal BLD + ANOS animals that cycled had signi-ficantly larger organ weights. BLD + ANOS + PX animals had organ weights comparable to those of sham animals. Normal sham animals had elevated morning basal values and an attenuated afternoon surge. Both normal and NA BLD + ANOS animals had a marked decrease in 24-hour plasma PRL levels and the surge exhibited a free-running rhythm. In BLD + ANOS + PX animals the plasma PRL levels were re-turned to values comparable to those of sham animals and PRL surges were again observed to have a free running rhythm. The results indicated that the NA animals respond similarily to BLD + ANOS as do normal animals and that PX eliminates the suppressing effect of BLD + ANOS on endocrine organ weights and plasma PRL levels. (Supported in part by NIH Research Grant #HD 14671). 96.12 EFFECT OF THE SEROTONIN RELEASER FENFLURAMINE ON RENIN, PROLACTIN AND CORTICOSTERONE SECRETION. L.D. Van de Kar and Cynthia L Bethea. Loyola Univ., Stritch Sch. of Med., Maywood, IL and

Oregon Regional Primate Res. Ctr., Beaverton, OR. The serotonin releasing drug fenfluramine caused a dose depen-dent stimulation of renin and prolactin secretion in male rats. The effect on renin, however was different in that the initial (30 minute) stimulatory effect was followed by an inhibiting effect after 2 hours. At 4 hours plasma renin activity was a low as the detection limit of the assay whereas plasma prolactin levels were detection limit of the assay whereas plasma prolactin levels were still slightly higher than saline level. This inhibitory effect of fenfluramine on renin secretion is also dose dependent and is maximal at 10 mg/kg (i.p.). Pretreatment of the rats with the serotonin uptake inhibitor fluoxetine (10 mg/kg i.p.) caused an inhibition but not complete blockade of the effect of fenfluramine on renin secretion at 30 min. and 4 hours. These results suggest that the effect of fenfluramine on renin correction are partly. that the effects of fenfluramine on renin secretion are partly mediated by brain serotonin but that other mechanisms may also be involved.

## SYNAPSE ELIMINATION, COMPETITION, AND NEURON DEATH I

97.1 THE RELATIONSHIP OF CONVERGENCE AND POSTSYNAPTIC GEOMETRY IN MAMMALIAN SYMPATHETIC GANGLIA. Dale Purves and Jeff Lichtman, Washington University School of Medicine, Department of Physiology, St. Louis, MO. 63110.

Recent studies have shown a striking relationship between the Recent scules have snown a striking relationship between the geometrical complexity of individual parasympathetic ganglion cells and the number of axons that innervate each neuron in maturity. Thus in the rabbit ciliary ganglion, neurons that lack dendrites are innervated by a single preganglionic axon, whereas neurons that have dendrites are innervated by a number of different axons which increases in proportion to the of complexity of the dendritic arbor (Purves and Hume, 1981). The purpose of the work reported here was to assess this relationship in a mammalian sympathetic ganglion, the superior cervical, in which the geometry of neurons is considerably more complex than in parasympathetic ganglia. Superior cervical ganglia from adult guinea-pigs, hamsters

and rats were dissected in continuity with the sympathetic chain and the upper thoracic ventral roots. Individual neurons in the the ganglia were impaled with microelectrodes <u>in vitro</u> and the average number of inputs received by each ganglion cell was determined by monitoring the increments in the postsynaptic response while individually stimulating different ventral roots. In semarate expression roots. In separate experiments superior cervical neurons were impaled with microelectrodes filled with 5% horseradish peroxidase and labeled by iontophoresis. After a suitable diffusion time the morphology of the cells was demonstrated in whole mounts by application of the Hanker-Yates method.

whole mounts by application of the Hanker-Yates method. Guinea-pig ganglion cells had, on average, 11-12 primary dendrites arising from the neuronal soma, whereas hamster ganglion cells had an average of only 6-7. In accord with this morpholgoical difference, guinea-pig neurons had an average of about 11 inputs measured electrophysiologically, whereas hamster ganglion cells had an average of only 6-7 different preganglionic inputs (about 100 neurons were examined in each species). Both the geometry and the number of inputs to rat "Umering cervical ganglion cells had an average of a second the species." superior cervical ganglion cells lay between the values in guinea-pig and hamster.

We conclude that, as in the parasympathetic nervous system, We conclude that, as in the parasympathetic nervous system, the convergence of preganglionic axons onto target neurons in sympathetic ganglia is closely tied to the geometry of the postsynaptic cells. The possible ways in which postsynaptic geometry might regulate the number of different axons that converge upon individual ganglion cells will be discussed. <u>Reference:</u> Purves, D. and Hume, R.I. J. Neurosci. <u>1</u>: 441-452. Supported by NIH Grants NS 18629 and 11699. 97.2 REGIONAL INNERVATION OF RABBIT CILIARY GANGLION CELLS BY THE TERMINALS OF INDIVIDUAL PREGANGLIONIC AXONS. Forehand and Dale Purves. Department of Cynthia J. and Physiology Medicine, Biophysics, Washington University School of St. Louis, MO. 63110.

In the rabbit ciliary ganglion neurons with dendrites maintain inputs from several different axons during the period of synaptic rearrangement that occurs in early postnatal life. Neurons without dendrites, on the other hand, lose most of their initial inputs during this time and are innervated in maturity by the terminals of only one or two axons (Purves and Hume, 1981; Hume and Purves, 1981). We have explored the basis of this phenomenon by intracellularly staining both pregan-glionic axons and the neurons they innervate with horseradish peroxidase (HRP).

general, the innervation of geometrically complex (multiply innervated) neurons by individual preganglionic axons is regional. That is, the synaptic contacts made by an axon onto such neurons are limited to a portion of the postsynaptic surface that usually includes the cell body and some, but not all, of the dendrites. Moreover, an individual preganglionic axon can follow a particular dendrite for 100 microns or more, elaborating boutons along its course while ignoring the surfaces of adjacent postsynaptic cells.

Electron microscopical examination of multiply innervated HRP-labeled ganglion cells shows that each of their several dendrites receives innervation. Therefore, the dendrites of a labeled ganglion cell which are not contacted by one labeled preganglionic axon are likely to be innervated by another input.

This regional innervation of target neurons is consistent with the view that dendrites allow multiple innervation to persist by providing relatively separate postsynaptic domains for individual preganglionic axons. Such regional innervation may mitigate competitive interactions between the several axons which initially innervate the same neuron. References:

97.3 DENDRITIC SPINES MAY REDUCE SYNAPTIC COMPETITION. <u>Barry Horwitz</u>. (SPON: John Rinzel). Laboratory of Neurosciences, NIA, NIH, Bethesda, MD 20205. Evidence suggests that during development there is a competition among axons for synaptic sites, and as a result, only some of the innervating axons become stabilized. Electrical activity seems to play an important role in this competition. There are many who feel that synaptic competition also occurs during learning. Because dendritic spines are the primary locus of synapses for spiny neurons in the cerebral cortex, it is important to investigate the role spines play in synaptic competition.

I previously proposed (Soc. Neurosci. Abstr 8:709, 1982) an electrophoretic mechanism by which electrical activity at a synapse increases the probability for structural change near the synapse. The electrophoretic attenuation of a postsynaptic potential, as it spreads electrotonically from the site of synaptic activation, generates an intraneuronal electric field which permits the electrophoretic migration of charged molecules, both along the inner surface of the cell membrane and in the cytoplasm. These fields thus may locally organize the distribution of charged metabolites, allowing differential biochemical activity at different synaptic locations.

Here, this mechanism is applied to dendritic spines. Theoretical calculations are presented which show that synaptic activity at a spine head can establish large electrical fields along the spine, whereas synaptic activity at the base of the spine generates very small electrical fields in the spine. The thinner the spine, the stronger the fields. It is show that the strong electric fields can be several times larger than those which have been used to produce measurable rearrangements of membrane-bound molecules (Poo, Ann. Rev. Biophys. Bioengn. 10: 245-276, 1982). If one assumes that these electric fields can lead to electrophoretic migration of charged metabolites necessary for either synaptic stabilization or enhancement, significant accumulation should occur within spines. Because the electric fields are small along the spine when electrical activity is generated elsewhere in the neuron, charged metabolites should not easily be drawn out of a spine. As a result, it is proposed that dendritic spines provide an anatomical means to reduce the competition between neighboring afferent inputs. 97.4 HISTOCHEMISTRY OF SINGLE MOTOR UNITS DURING SYNAPSE ELIMINATION IN RAT SOLEUS MUSCLE. <u>V.J. Thompson, L. Sutton\* and D.A. Riley</u>. Dept. of Zoology, Univ. of Texas, Austin, TX 78712 and Dept. of Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226.

Motor units in adult mammals each contain muscle fibers of a single histochemical type. How these uniform motor units arise during development is incompletely understood. We have investigated the fiber type composition of single motor units during the period of synapse elimination in neonatal rat soleus muscle.

Soleus undergoes a postnatal synapse elimination in which each soleus motor neuron reduces the number of fibers it innervates in the muscle. The time course of this process is such that up until postnatal day 10 every muscle fiber is polyneuronally innervated and it is only at day 16 that the process is nearly complete and most fibers are singly innervated (Brown et al., J. Physiol. 261: 387). As early as day 8, staining for myofibrillar ATPase after alkaline preincubation reveals that there are two distinct muscle fiber types present in soleus: ca. 55% of the fibers are darkly stained and 45% lightly stained (Riley, Exp. Neurol. 56: 400). The proportion of each fiber types are present in soleus prior to the establishment of the final pattern of innervation.

Using the technique of glycogen depletion we have identified muscle fibers belonging to a single motor unit. At the conclusion of most synapse elimination at 16 days, motor units are composed almost exclusively of one of the two fiber types. At 8 days, motor units contain, as expected, many more muscle fibers. However, even at 8 days these units are still greater than 70% homogeneous in fiber type. Thus, even at 8 days when motor neurons innervate at least two times their adult complement of fibers, this innervation is non-random, being largely confined to one of the two types of fibers present in the muscle. This non-random innervation might be present from the very earliest stages of muscle innervation or alternatively it could arise from an earlier random pattern by selective synapse loss.

97.5 THE PREVENTION OF SPINAL MOTONEURON DEATH IS ASSOCIATED WITH AN INCREASE IN ACETYLCHOLINE RECEPTORS IN SKELETAL MUSCLE. R. W. Oppenheim and S. Bursztajn. Department of Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103 and Department of Neurology, Baylor University, Houston, TX 77030. The suppression of neuromuscular transmission during the period of naturally-occurring motoneuron death in the chick embryo results in the survival of virtually all of the neurons that would have died. Previously. we suggested that the

The suppression of neuromuscular transmission during the period of naturally-occurring motoneuron death in the chick embryo results in the survival of virtually all of the neurons that would have died. Previously, we suggested that the sequence of events leading to the prevention of motoneuron death may include an alteration in the number and/or distribution of acetylcholine receptors (AChR) in the target muscles (J. Comp. Neurol. 1979 v. 187). Chick embryos were injected once daily on embryonic days (E) 6-10 with 2.0 mg of curare. Embryos were sacrificed on either E11 or E16. Brachial (Br) and lumbo-sacral (L-S) spinal cords were processed for the determination of motoneuron numbers in the lateral motor columns (LMC); several different fore- and hindlimb muscles (slow and fast) were dissected from the same embryos. Muscles were washed with saline and fixed in 2% paraformaldehyde for 1 hr. After an overnight wash in phosphate buffered saline, muscles were incubated in 20 mM of  $^{1251}$ -a-bungarotoxin (ABTX) (10-18  $_{\rm UC}$ /ug). For light microscopic autoradiography muscles were processed by two different procedures: 1) half were mechanically dissociated into individual muscle fibers and placed on glycerinated slides; 2) the other half were dehydrated, embedded in Epon and sectioned. Computer-aided analysis of the autoradiographs revealed a significant increase (p < 0.05) in the number of AChR clusters in all muscles from curare-treated embryos (E11 and E16). There was also a highly significant increase (p < 0.001) in the number of motoneurons in the LMC of Br and L-S cords from curare-treated embryos (E11 and E16) had significantly more (p < 0.05) AChR sites per mg of wet weight than those from curare-treated embryos (E11 and E16) had significantly more (p < 0.05) AChR sites per mg of wet weight than those from curare-treated embryos; there were no differences in AChR number per mg of protein between muscles from curare and control embryos; there were no differences in AChR number per mg of protein between m

97.6 THE FINE STRUCTURAL CHANGES IN FETAL PYRIFORM CORTEX FOLLOWING DEAFFERENTATION. <u>H. Newman-Gage\* and L.E. Westrum</u>. Depts. of Biological Structure and Neurological Surgery, University of Washington, Seattle, WA 98195. The ultrastructural patterns of degenerative change in fetal

The ultrastructural patterns of degenerative change in fetal animals has been little studied in contrast to the well-described degenerative patterns in adult systems. Evidence from studies in pyriform cortex of early postnatal rats suggests a markedly different sequence of events in developing brain from that in the mature brain (Westrum, L.E., <u>Anat. Embryol.</u>, 160:153-172, 1980). Clearly, these observations are of importance in understanding the increased capacity for plastic rearrangement in developing systems. The present study investigates deafferentation-induced degeneration during the period of initial synaptogenesis in fetal pyriform cortex. Earlier studies of normal development in this area show that synapse development begins on embryonic day 17 (E17 of 21.5) and is increasing rapidly by E19 (Newman, H. and Westrum, L.E., <u>Neurosci.</u>, 8:866, 1982). Transuterine unilateral olfactory bulb lesions are made via needle aspiration in pups aged E17 or E19 with acute survival times of 6, 12, and 18 hours.

At 6 hour survival in both ages, the lateral olfactory tract (LOT) is characterized by marked swelling of growth cones and axons accompanied by disorganization and disappearance of organelles leaving a pale homogeneous cytoplasmic matrix. In addition two other forms of degenerating profiles are commonly seen: swollen profiles with flocculent aggregations of matrix and nonswollen profiles filled with a dense homogeneous granular cytoplasm. Normal appearing axons often contain organelles that appear to be degenerating. The superficial portion of layer I (Ia) contains expanded profiles similar to those described above. Many may be identified as growth cone processes. Occasionally, degenerating Type I synapses are seen in addition to apparently unaffected developing synapses of both Types I and II. Deep layer I (Ib) contains relatively fewer swollen profiles and many more developing synapses. From 12-18 hours all of these changes are progressively advanced. In addition, many profiles now have ruptured membranes and are being phagocytosed resulting in an exaggerated extracellular space. In conclusion the study shows the extreme rapidity of degeneration in fetal brain as compared to postnatal or adult tissue and describes the nature of degeneration in growing processes. NEURONAL DEATH IN THE CHICK EMBRYO'S ISTHMO-OPTIC NUCLEUS (ION): SUSTAINING ROLE OF AFFERENTS FROM THE TECTUM. <u>P.G.H. Clarke\*</u> (SPON: C. Marchand). Anatomy Institute, Lausanne University Medical School, 1001 Lausanne, Switzerland. 97.7

More than half the neurons in the ION are known to die be-tween stage 38 (embryonic day 12 - E12) and stage 42 (E16). There is strong evidence that the survival of ION neurons during tween stage 38 (embryonic day 12 - E12) and stage 42 (E16). There is strong evidence that the survival of ION neurons during this period depends on their receiving some kind of maintenance from their axonal terminal field in the retina, but it has been less clear whether their afferents help to maintain them. The largest source of afferents to the ION is the ipsilateral optic tectum, and damaging the tectum is known to increase the ION neuronal death, but to interpret this result it was necessary to perform a series of control experiments, as reported below. 1) The lesions were restricted to the lateral and ventral parts of the tectum, since the isthmo-optic tract runs at its dorsomedial edge, but even with this precaution early (e.g. stage 25, E4) tectal lesions led to severe nonspecific effects, e.g. collapsed ventricles, failure of isthmo-optic fibres to reach the eye; but late (e.g. stage 38, E12) lesions avoided these difficulties. 2) The late lesions led to increased neuro-nal loss in the ipsilateral ION from stage 40 (E14) onwards. This might have been due to: 3) the shrinkage and subsequent misidentification of neurons, or to 4) migration of neurons out of the ION. I eliminated these possibilities: 3) all the ION neurons were labeled selectively with H-thymidine applied at stage 27 (E5), whereas even in embryos fixed after the cell loss period the small (glial?) cells were unlabeled, so none of them can have been shrunken neurons. 4) Retrograde tracers were injected into an eye just before the period of cell loss, and the labeled neurons <u>outside</u> the ION were counted after short or long survival times; the numbers were similar in each case, so there cannot have been outward migration. 5A) The additional ION cell loss was probably not due to multistage retrograde in-fluences, since the only retinal cells to degenerate in response to the tectal lesions were the retinal ganglion cells, and the amacrine sublayer (which contains the ION's target cells) was unaffected. 5B) Furthermore, ION neurons whose d amacrine sublayer (which contains the ION's target cells) was unaffected. 5B) Furthermore, ION neurons whose death was induced by a tectal lesion behaved differently from those which died following selective destruction of the amacrine cells by intra-ocularly injected kainic acid, since only in the latter case did the dying ION neurons phagocytoze extracellular HRP. Hence, receiving tectal afferents is important for the sur-vival of ION neurons during the latter half of the neuronal death period.

death period.

NATURALLY OCCURRING GANGLION CELL DEATH IN THE POSTNATAL CAT 97.8 RETINA. <u>H. E. Pearson, B. R. Payne and T. J. Cunningham</u>. Dept. of Anatomy, The Med. Coll. of Pennsylvania, Phila., PA 19129.

The visual system of the cat shows protracted development during postnatal life, as evidenced by continued synaptogenesis, maturation of physiological response properties and the existence of a lengthy critical period for the influence of visual experience. In other mammalian species, postnatal development has been shown to include naturally occurring neuron death and there is suggesto include hardnary occurring metrom death and there is sugges-tive evidence that this phenomenon may contribute to the matura-tion of the retina in the cat (Stone <u>et al.</u> '82; Williams <u>et al.</u> '83). We have investigated this possibility directly by examining the retinae of kittens between the ages of 2 and 10 days postnatal for the presence of degenerating neurons.

Retinae were taken from kittens at ages 2,4,5,8 and 10 days postnatal. Following perfusion with aldehyde fixative, whole mounts of the retinae were made and drawn in outline. From each retina, a sample area was taken from the periphery of superior retina centered along the vertical meridian. The tissue samples were processed for plastic embedding.

Degenerating neurons were observed in all three cellular layers of the retina at all ages studied and early stages of neuron de-generation were characterized by marked condensation of nuclear chromatin. The morphology of degenerating cat retinal ganglion cells is therefore similar to that described for retinal ganglion cells of neonatal rats and embryonic chicks. Counts of degenera-ting profiles were made in the ganglion cell and inner nuclear layers from regularly spaced one-micron sections. Calculation of the surface areal density of degenerating neurons was made following measurement of the retinal area sampled. In the ganglion cell Ing measurement of the Fernar area sampled. In the gangiton cert layer, we also expressed the numbers of degenerating neurons as a proportion of live cells present in that layer. The results from these analyses show that considerable numbers of neurons die naturally during early postnatal development in both the ganglion cell and inner nuclear layers of the cat retina. Thus far, we have observed maximal numbers of degenerating cells on postnatal days 5 and 8.

This documentation of naturally occurring neuron death by counts of actual degenerating cells shows that the final numbers of ganglion cells in the cat retina are determined after birth. Data obtained after target manipulation in cats and other species. including our previous results on ganglion cell death following visual cortex ablation, suggest that the survival of ganglion cells is dependent in part on the availability of target space. The regulation of neuron numbers in cat retina during normal postnatal development may depend, therefore, on interactions with appropriate targets. 97.9 TRANSIENT CEREBRO-CEREBELLAR PROJECTIONS IN KITTENS. IS THEIR TRANSIENCE DUE TO NEURONAL DEATH? <u>D.L. Tolbert\* and W.M.</u> <u>Panneton</u>. (SPON: L.C. Massopust). Murphy Neuroanatomy Research Laboratory, Depts. Anat. and Surg. (Neurosurg.), St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Direct projections from the cerebral cortex to the cerebellum have been observed in neonatal kittens. Cerebro-cerebellar axons arise from pyramidal neurons in layer V and project bilaterally to the internal granule cell layer of the cerebellar cortex as well as to the underlying deep nuclei. These projections are also and the correct for the cerebellar cortex days of the cerebellar cortex. clearly transient in nature. Cerebro-cerebellar axons develop late in the 1st postnatal week, reach their maximum density in the 2nd postnatal week, and then quickly regress and disappear.

Since we have shown using fluorescent dye techniques that some cerebro-cerebellar axons are collaterals of cortical projections to the caudal medulla, experiments were carried out to determine if the transient nature of cerebro-cerebellar projections was due to selective elimination of collaterals or to neuronal death. Unilateral injections of 1% True Blue (TB) were made into the cerebellum of kittens 8-11 postnatal days old. At 12-85 postmatal days of age, injections of 1% Nuclear Yellow (NY) were made into the brain stem on the opposite side, after which the animals were sacrificed and then processed for fluorescent microscopy

In all of these experiments only neurons labeled with NY, identifying a projection to the brain stem, were observed in the cerebral cortex. There were no cells labeled with TB present in the cortex. This lack of TB labeling of neurons in the cortex contrasted sharply to labeling of numerous neurons with TB in precerebellar nuclei of the brain stem which fluoresced brightly with this dye, even following long post-injection survival periods. Thus the absence of TB labeling in the cerebral cortex following injection into the cerebellum would indicate that cerebro-cerebellar projections arise from a population of neurons which subsequently degenerate with cortical maturation. Other possibilities which may account for the above findings are possibilities which may account for the above findings are currently being explored. However, if the transient nature of cerebro-cerebellar projections is indeed due to neuronal death, then this pathway is different from those described in other studies using similar fluorescent dye techniques which showed that most of the loss of transient projections descending to medullary logicle form the entry when due techniques the ideatorie of any levels from the cortex was due to selective elimination of axon collaterals rather than to neuronal death (Stanfield, et al., Nature 298:317-373, 1982). (Partially supported by grant PHS 5 S07 RR05388-20.)

97.10 CELL DEATH IN THE NEOCORTEX OF THE NORMAL MOUSE AND THE REELER MUTANT. A.L. Pearlman, J.O. Bautista, and J.P. Cohen. Depts. of Physiology of Physiology and Neurology, Wash Medicine, St. Louis, Missouri 63110. Washington University School

Naturally occurring neuronal death is an important feature in the developmental history of many neural structures, but its role in the development of the mammalian neocortex has only recently been established. This study was undertaken to analyze the extent and time course of cell death in the neocortex of neonatal mice. In addition, we have studied cell death in the necortex of the reeler mutant mouse, in which a developmental abnormality results in a disruption of the normal laminar pattern of neocortex and a striking anomaly in the relative positions of cortical neurons. Our prior electrophysiological positions of cortical neurons. Our prior electrophysiological and neuroanatomical studies and those of other laboratories have shown that the connections of reeler neocortex are established appropriately despite the abnormality in neuronal position. appropriately despite the abnormality in heritonal position. We wondered whether cell death might be responsible for eliminating neurons that were unsuccessful in establishing their proper connections in reeler with the result that only normally connected neurons remain. If that were the case, cell death ought to be present to a greater extent in the neocortex of reeler than it is in normal cortex.

We examined thionin stained serial sections (10µm) of the neocortex of newborn mice from the first postnatal day (P0) through P25, identifying dying cells by the presence of a very densely stained, homogeneous and sometimes fragmented nucleus. In normal neocortex cell death occurs primarily in the first 8-10 postnatal days, peaking on P5-6. It appears to spread in a broad wave from anterior to posterior and from medial to lateral, and to involve the deep cortical layers before the superficial layers. Cell death occurs in the same temporal and spatial pattern in the reeler neocortex, except that it involves neurons scattered at the depths of the cortex at the time when the most superficial neurons are dying in normal cortex. We also determined the ratio of dying to living cells from PO through P25 in the sections that contained the posterior end of the corpus callosum and found no difference between reeler and normal. These findings indicate that cell death is an event that occurs at a particular time in the maturational history of selected cortical neurons, even though the cells may be abnormally positioned. The normal pattern of connections seen in the reeler neocortex can not be attributed to the elimination of an excess number of abnormally connected neurons by the process of cell death.

97.11 STRAIN DIFFERENCES IN DOPAMINE NEURON NUMBER DEVELOP POSTNATALLY. H. Baker, S. Alden\*, T.H. Joh and D.J. Reis. Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 Differences in tyrosine hydroxylase (TH) activity in the substantia nigra-A10 area in adults of two inbred mouse strains are attributable to

Differences in tyrosine hydroxylase (TH) activity in the substantia nigra-A10 area in adults of two inbred mouse strains are attributable to greater numbers of dopamine (DA) neurons in adult BALB/cJ than CBA/J mice. During development the strain differences in nigral TH activity are not present at birth but appear postnatally (Baker et al., Dev. Br. Res. 4: 157, 1982). Since neurogenesis of dopamine neurons is completed by the second week of embryogenesis, the postnatal appearance of the TH activity differences suggests that the differences in neuron number also appear after birth. To determine the age at which strain differences in neuron number could be detected within the substantia nigra, mice at 5, 10, 15 and 30 days postnatal age were perfused, the brains embedded in paraffin, and 10µ sections stained by the peroxidase anti-peroxidase technique using specific antibodies directed against tyrosine hydroxylase. Approximately 5-10 animals per strain per age were analyzed, but large numbers of mice were processed to insure that parameters such as sex, weight, and staining intensity were closely matched across strains.

were closely matched across strains. In agreement with the biochemical findings at 5 days, there were no strain differences in the number of immunocytochemically demonstrable DA neurons. Similarly, by postnatal day 30, BALB/cJ mice had significantly greater numbers of immunocytochemically stained neurons than CBA/J mice, although the adult level of strain differences had not yet been reached. At postnatal day 10, however, although small but significant differences in TH activity exist, no differences in the number of DA neurons were detectable. At 15 days, there was a trend towards greater numbers of DA neurons in BALB/cJ than CBA/J mice; however, the data did not reach the significance level and contrasted with the biochemical findings where TH activity at 15 days is significantly greater in BALB/cJ mice. The disparity between the biochemical and neuron number data at this age may be attributable to the rapid changes in TH activity, and perhaps in neuron number, occurring at this time and resulting in a higher variability in the cell counts at this developmental stage. We conclude that the difference in DA neuron number in these two mouse strains develops postnatally. (Supported by NIMH Grant 33190.)

# SENSORY SYSTEMS IN INVERTEBRATES II

98.1 AN INVESTIGATION OF THE ROLE OF MICROTUBULES IN SENSORY TRANSDUCTION BY AN INSECT MECHANORECEPTOR. J.E. Kuster\* and A.S. French, Department of Physiology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Microtubules are prominent cellular components of mechanosensitive and chemo-sensitive sensilla associated with the insect cuticle, and they have been suggested to play several important roles in sensory transduction. Microtubule dissociating agents such as colchicine and vinblastine have been shown to interfere with transduction in these sensilla and this has been attributed to their anti-microtubule activity. We have now studied the effects of colchicine, vinblastine and lumicolchicine on the dynamic properties of sensory transduction in the cockroach femoral tactile spine and have simultaneously examined the effects of the drugs upon the ultrastructure of the sensory ending.

All of the agents reduced the sensitivity of the mechanoreceptor and in the cases of colchicine and vinblastine this was accomplished without any effect on the dynamic properties of transduction. In the case of lumicolchicine there was a shift in the relative sensitivity toward rapid movements. All of the drugs also caused a reduction in the conduction velocity of the afferent action potentials in the axon arising from the sensillum

In the relative sensitivity toward rapid movements. All of the drugs also caused a reduction in the conduction velocity of the afferent action potentials in the axon arising from the sensillum. The actions of the drugs on the ultrastructure of the sensory ending were quite disparate. In the case of colchicine there was a complete loss of microtubules in the tubular body and sensory dendrite before the cessation of mechanical sensitivity. Vinblastine was less effective in eliminating the microtubules although more effective in interfering with transduction. Lumicolchicine, which is produced by ultra-violet irradiation of colchicine, is known to be less effective than colchicine in dissociating microtubules. Its major morphological effect was a significant disruption of the dendritic membrane.

These results show that the microtubules are not essential for mechanotransduction in this receptor and that the effects of the chemical agents used are more likely to arise from their actions on the cell membrane than upon the microtubules.

on the cell membrane than upon the microtubules. Supported by the Canadian Medical Research Council and the Alberta Heritage Foundation for Medical Research. 98.2 SENSORY INTERNEURONS IN THE LOCUST FLIGHT CONTROL SYSTEM: <u>H. Reichert and C. H. F. Rowell</u>\*. Department of Zoology, University of Basel, Basel, Switzerland.

We study the integration of descending sensory information with the rhythm generating elements of the flight motor in the locust. We record with Lucifer filled electrodes from the neuropil of the thoracic ganglia during fictive flight. The effects of ocelli, windhair and compound eyes on impaled neurons are determined as are the interconnections among the neurons. These sense organs in nature report deviations from the flight path and elicit correctional steering maneuvers.

Second order interneurons convey processed ocellar information to the thoracic ganglia. Several of these phasic off units are also excited by the windhairs. These neurons make only weak and variable direct connections to flight motoneurons. However, they elicit large, short latency PSPs in at least 2 different populations of thoracic interneurons. One of these populations receives similar synaptic input from stimulation of any of the ocelli. It therefore seems unlikely, that they play a role in correctional steering during flight. During flight no phasic modulation of these interneurons occurs.

A second population of thoracic interneurons receives asymmetric ocellar input, being excited by stimulation of one lateral ocellus or of one lateral and the medial ocellus and often receiving inhibition from stimulation of the remaining lateral ocellus. The response properties of these neurons are appropriate for a role in roll/pitch correctional steering. Some of these interneurons make strong, short latency connections to flight motoneurons. Additionally, they are phasically modulated at flight frequency during flight. Depending on phase relationships, EPSPs caused in these neurons by ocellar stimulation are either augmented or shunted by this subthreshold modulation. Descending sensory information thus seems to be gated by the flight rhythm generator and can influence flight motoneurons only in specific, presumably appropriate, phases of the flight cycle.

THERMOGRAPHIC IMAGING OF THE SENSORY DERMATOME. S. Uematsu\* (SPON: D. ZEE). Johns Hopkins Hospital, School of Medicine, 98.3 (SPON: D. ZEE). Johns Hopkins Hopkins Hospital, School of Medicine, Baltimore, MD 21205. Sensory examination of the skin is based on the patient's

subjective expression of the skin is based on the batient's subjective expression of sensation; therefore, results of the examination are difficult to objectify. However, it is generally believed that cutaneous temperature alters in the vicinity of the peripheral nerve impairment. If this is true, then thermographic imaging of the sensory dermatome may be of practical clinical use.

In this study, all measurements were made using a telethermograph with a built-in computer for data compilation and analysis. Cutaneous temperature was measured in 37 segmental areas of the body on 32 controls (12 to 65 years old) and in selected areas on 38 patients with peripheral nerve impairment. Average temperatures were obtained in corresponding areas of interest on each side of the body and then compared. In normal controls, the average temperature differences between sides of the body were extremely small: on the trunk, the difference was  $0.17 \pm 0.042^{\circ}$ C; on the extremities,  $0.20 \pm 0.073^{\circ}$ C; and on fingers and toes,  $0.45 \pm 0.129^{\circ}$ C. The temperature difference between the median and unar side was  $0.37 \pm 0.28^{\circ}$ C in the forearm and the palm. The difference between the fifth lumbar and first sacral dermatome was 0.53+ 0.42°C. In contrast, in nerve-damaged patients, skin temperature on the side with impaired nerve was 1.63 + 1.002°C different from the corresponding normal site on the body. difference is approximately ten times that of the normal control (P<0.0001).

Outlines of the sensory dermatome obtained by pin pricks, neurological examinations, and thermogram matched very well in all 38 cases. In cases of completely sectioned nerve (neuronotmessis), the anesthetic area was 2 to  $4^{\circ}\mathrm{C}$  warmer than surrounding skin. In irritative lesion (e.g. lumbar disc herniation), the hypesthetic area was colder then surrounding area.

These results indicate that computerized color telethermography makes thermographic imaging of the sensory dermatome practical for use in clinical examination.

PESPONSES OF VIPRATION RECEPTORS IN THE MEDICINAL LEECH TO NEAR-FIELD STIMULATION. <u>P.D. Brodfuehrer and W.O. Friesen</u>. Dept. of Biology, University of Virginia, Charlottesville, VA 98.4 22901

Dept. Of Blobdy, Onlyersity of Virginia, Chariottesville, VA Water-wave stimulation can elicit swimming in intact medicinal leeches. This same stimulus will also initiate swimming activity in dissected leeches via activation of segmental vibration receptors (SMRs), provided that serotonin is added to the saline (Brodfuehrer and Friesen, Neurosci. Abstr. 8:529, 1982). To study the responses of the SMRs to vibratory stimulate individual sensilla in a precisely controlled manner. Suction electrode recordings from segmental dorsal posterior (DP) nerves of isolated body wall flaps give the following results. (1) A single vibratory probe stimulus near a sensillum evokes a long duration (8-12 ms), graded compound action potential (CAP). As the stimulus intensity (i.e. probe displacement) increases, the amplitude of this SMR response increases and the latency decreases. (2) The conduction velocity of the sensory units in the DP nerve is 0.34 m/s (S.D.=0.09, N=9). This value is approximately one-third of the conduction velocity of touch cell axons. (3) The SMR Methed the DP nerve is not eliminated by high Mg++ (40 mM) saline. However, the neuronal responses evoked response recorded from the DP nerve is not eliminated by high Mg++ (40 mM) saline. However, the neuronal responses evoked in nerve cord connectives by near-field stimulation are reversibly eliminated by high Mg++ saline. Thus no chemical synapse occurs between the peripherally situated SMRs and the segmental ganglia, but a synapse is interposed between the SMRs and intersegmental neurons. (4) At stimulation frequencies of less than 1 Hz the SMR response is constant, while at frequencies greater than 25 Hz the response exhibits a reduced amplitude and an increased duration. At intermediate frequencies greater than 25 Hz the response exhibits a reduced amplitude and an increased duration. At intermediate frequencies only the shape of the CAP fluctuates. Thus at high stimulus frequencies not all of the sensory units are activated by each stimulus, perhaps due to receptor adaptation. (5) Finally, the SMR response can be elicited with sinusoidal stimulation at frequencies as low as 1 Hz. This suggests that the SMRs could be activated by the swimming movements of the looph leech.

In conclusion, the SMRs are able to faithfully follow near-field stimulation at rates up to 10 Hz. Water-wave stimulation also provides vibratory stimulation at about 10 Hz (Friesen, J. exp. Biol., <u>92</u>:255-275, 1981). Thus the SMRs are probably not adapting during water-wave stimulation that elicits swimming. Furthermore, the SMRs could provide sensory feedback by NSF grant ENS 81-0243.

98.5 SENSORY INPUT TO MOTOR NEURONS AND INTERNEURONS GENERATING THE

SEASON INFOID NOTOR REDERONS AND INTERNEDRONS GENERATING THE HEARTBEAT RHYTHM OF THE LEECH. R. Davis and J.G. Nicholls, Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305. The rhythmical activity of the leech heart is produced by the activity of endogenously active interneurons (HN cells) within the CNS that periodically inhibit the motor neurons (HE cells) supplying the cardiac musculature (Thompson, W.J. and Stent, G.S., J. Comp. Physiol. 111: 309-333, 1976). The connections that make up this circuit have been studied in detail but no input from the periphery has as yet been described. Presumably such sensory information could allow the circulation to respond to needs of the animal under various circumstances.

In the present experiments the activity of motor neurons and interneurons has been measured with intracellular microelectrodes while peripheral nerves were stimulated electrically. In ganglia towards the head (that contain HN interneurons) stimulation of the peripheral nerve roots leads to ipsp's in the inter-neurons and large epsp's in the motor neurons. In HE motor cells of midbody segments, peripheral root stimulation leads to both inhibitory and excitatory synaptic potentials. The course, amplitude and sign of the response depend on the particular peripheral root that is stimulated. The time

The specific modalities and receptive fields of the sensory inputs have not yet been identified. Nevertheless, it is clear that mechanical stimuli applied to regions of the periphery can also evoke synaptic potentials in the motor neurons that dramatically alter their pattern of firing. 98.6 DENDRITIC STRUCTURE PREDICTS THE RECEPTIVE FIELDS OF IDENTIFIED INTERNEURONS <u>G.A. Jacobs and R.K. Murphey</u> Dept. of Biology, SUNY Albany, Albany, New York, 12222

The response properties of a neuron are a function of the inputs it receives and how those inputs are distributed over its dendritic surface. We are studying how the structure of wind sensitive interneurons (INs) in crickets determines their sensitive fields. Different INs respond preferentially to wind stimuli from different directions around the animal's body. Wi Wind direction is encoded by four groups of afferents on each cercus which respond to four different wind directions. Each group of afferents arborizes in a separate neuropil region of the hemiganglion it innervates (Bacon and Murphey, this vol.). an IN could obtain its receptive field by virtue of the position of its dendrites with respect to distinct populations of afferents

In order to assess the role of structure in determining receptive fields we have studied an identified neuron with dendrites in three discrete regions of neuropil representing three different wind directions. This neuron is maximally sensitive to wind from one side of the animals body yet it has dendrites on both sides of the ganglion. To break this response down into its component parts we first determined the receptive field for the neuron on one side of the ganglion by blocking all the afferents which terminate on the other side. We have shown that the response of the neuron is oriented differently to inputs from the two different sides.

In order to assess these various inputs we created patches of hairs of known directional sensitivity. If we chose a group of hairs of known directional sensitivity. If we chose a group of hairs known to overlap a particular dendrite the cell was now tuned exclusively to this direction. In order to determine how the neuron sums inputs from various directions we are creating patches of hairs of equal numbers known to overlap two different dendrites and then examining the response to each patch independently and finally to both patches simultaneously. Thus the directional preference of this neuron can be thought of as the sum of three different wind directions each of which is detected by a separate dendritic region.

These experiments do not provide a definitive test concerning These experiments do not provide a definitive test concerning the location of the various inputs on a given cell. In order to precisely localize the inputs in a more dynamic way we are trying to ablate a specific dendrite and determine the effect of its absence on the receptive field of this neuron. In collaboration with Dr. J.P. Miller we will try to selectively photoinactivate a specific dendrite on a living neuron to answer this question. Supported by NSF Grant # BNS 81 19799 98.7 ALTERATIONS IN THE VISUAL SYSTEM OF A "REDUCED EYE" MUTANT CRASSHOPPER. J.D. Steeves, D.J. Emery\* and K.A. Bell\*. Dept. of Zoology, UBC, Vancouver, B.C. V6T 2A9. The "reduced eye" mutant grasshopper of the species <u>Melanoplus sanguinipes</u> is characterized by small flat compound eyes, which lack facets (Chapco, 1980, Can. J. Genet. Cytol. 22:439-441). Our examination of this mutant indicates normal motor capabilities in terms of walking, jumping, flying and feeding. Escape responses normally elicited by visual and auditory inputs are absent, however jumping can be evoked with tactile stimulation.

Scanning electron micrographs reveal that the "reduced eye" mutant does not have lateral ocelli, and the median ocellus appears only as a small convex thickening of the cuticle in the center of the frons. Extracellular recordings from the ventral nerve cord, as well as electroretinograms, indicate that neither the compound eyes nor the dorsal ocelli function in this mutant. Attempted cobalt backfills of the compound eyes and median ocellus, in addition to gross dissections of the "reduced eye" mutant brain, show that the compound eyes and median ocellus fail to innervate the CNS. The optic lobes are substantially reduced in size and there is no evidence of any ocellar nerves.

Histological examination confirms these findings, and further reveals the incomplete differentiation of the retina in the compound eyes and the accompanying absence of the underlying optic lamina. The optic medulla and lobula are present, however the medulla lacks the characteristic neuronal projection patterns found in wild type animals. Similarly, there are only a few poorly differentiated cells underlying the cuticlar thickening of the "vestigial" median ocellus in the mutant. The development of the lateral ocelli is completely suppressed.

It is hoped that this "reduced eye" mutant grasshopper will be useful in the analysis of behaviors which are usually dependent on visual input. (Supported by NSERC) 98.8 NARROW YELLOW ELECTRORETINOGRAPHIC SPECTRAL SENSITIVITIES AND IN SITU MSP OF A VISUAL PIGMENT AND OF A RED SCREENING PIGMENT FROM THE RHABDOMERIC REGION IN TWILIGHT ACTIVE FIREFLIES. Abner B. Lall\*, G.K.Strother\*, H.H.Seliger\*, J.E.Lloyd\*and W.H.BiggTey\* (SPON: B. L. Partridge). McCollum-Pratt Institute and Dept. of Biology, The Johns Hopkins University, Baltimore.MD. 21218. North American fireflies which restrict their activity periods to twilight possess narrow yellow visual spectral sensitivity, VSS, (1/2 bandwidth about 50 nm) as determined by electroretinography. 98.9 POSSIBLE TRICHROMACY IN A CRUSTACEAN VISUAL SYSTEM. <u>Robert Schehr\* and E. Macagno.</u> Department of Biological Sciences, <u>Columbia University</u>, New York, N.Y. 10027

We have examined photoreceptors in the single compound eye of <u>Daphnia magna</u> with intracellular electrodes; some of these cells were injected with horseradish peroxidase.

of <u>Daphnia magna</u> with intracellular electrodes; some of these cells were injected with horseradish peroxidase. Results of recordings in many of the 22 ommatidia that comprise the bilaterally symmetric compound eye show that there are, probably, three major classes of photoreceptor spectral sensitivities with maxima at about 450, 510 and 590nm. There is however considerable spread in the distribution of maximum sensitivities. These sensitivities were calculated from measurements of the maximum depolarizing displacement of the membrane potential after a stepwise change in illumination. If other features of the different in some cases, suggesting the possibility of interactions between photoreceptors of different spectral sensitivity type.

We also classed cells at a given location in the eye according to spectral sensitivity. Each ommatidium has eight photoreceptors and they may be numbered according to their position around the rhahdom (Flaster et al, in Neuronal Development, N. Spitzer, ed., 1982). By examining serial one micron and occasional thin sections made perpendicular to the optical axis of an ommatidium we could identify cells filled with horseradish peroxidase reaction product with respect to position around the rhahdom and identify the ommatidium by virtue of the arrangement of lenses in the eye. It is our impression that all three classes of spectral sensitivities occur in all ommatidia, although the sample is small. Whenever cells in the same relative position in different ommatidia were filled they were of the same type. The synaptic connections that these identified photorecep-

The synaptic connections that these identified photoreceptors make with the cells of the laminar cartridges (Macagno et al. PNAS 70: 57, 1973) show that channels containing only information from  $\overline{a}$  single spectral sensitivity class are maintained at this level. 98.10 <u>DROSOPHILA</u> MUTATION THAT DISRUPTS THE RHABDOMERE STRUCTURE AND <u>DISPLAVS</u> A DOSAGE EFFECT ON A RETINA SPECIFIC POLYPEPTIDE. Hiroyuki Matsumoto\*, Quentin Pye\*, Kunio Isono\*, and W. L. Pak. Dept. of Biol. Sciences, Purdue Univ., W. Lafayette, IN 47907. The <u>ninaC</u> locus, mapping at 24 map units on the second chromosome, was identified by mutations that decrease the amplitude of the prolonged depolarizing afterpotential (PDA) and reduce the rhodopsin content. Cytogenetic localization placed the gene between 26F and 28B. Ultrastructural studies of several allelic mutants of <u>ninaC</u> revealed that the rhabdomeres of both the peripheral and central photoreceptors are markedly decreased in size. To determine if there are any alterations in photoreceptor layer specific proteins in <u>ninaC</u> mutants, SDS polyacrylamide gel electrophoresis was carried out on the <u>ninaC</u> mutants and on wild type.

polyacrylamide gel electrophoresis was carried out on the <u>ninaC</u> mutants and on wild type. Polypeptides specific for the photoreceptor layer were identified by comparing electrophoretic patterns obtained from (1) compound eye samples, (2) samples of heads with the eyes removed, (3) samples of compound eyes with the corneas removed, and (4) cornea samples. Results showed that five polypeptide bands, labeled B1 to B5, ranging in molecular weights from 170K (B1) to 120K (B5) are specific for the photoreceptor layer. This layer contains primarily photoreceptor cell bodies and pigment cells and does not contain photoreceptor layer suggests that they are neither the components of enzyme systems involved in general metabolism nor the elements of synaptic functions.

The provide a metabolism nor the elements of synaptic functions. Results of the electrophoretic analysis showed that the B1 polypeptide is missing in all mutants homozygous for any of the nine <u>minad</u> alleles. The other four polypeptides, B2 - B5, were also present in these <u>minac</u> homozygotes in amounts different from that in wild type. The amounts present depended on the particular <u>minac</u> region was constructed to carry out the following analysis. Flies carrying 0 and 1 copy of the amount of B1 in wild-type flies, suggesting that the <u>minac</u> locus codes for the structural gene for the polypeptide B1. The results to date are consistent with the working hypethesis that the <u>minac</u> gene encodes the 170K B1 polypeptide and that this polypeptide may be involved in the formation and/or maintenance of the rhabdomeric membrane structure.

CIRCADIAN CLOCK IN LIMULUS BRAIN GENERATES SYNCHRONOUS EFFERENT 98.11

CIRCADIAN CLOCK IN <u>LIMULUS</u> BRAIN GENERATES SYNCHRONOUS EFFERENT OPTIC NERVE ACTIVITY TO ALL EYES. Leonard Kass, <u>Leslie E. Eisele</u>, and <u>Robert B. Barlow</u>, Jr. Institute for Sensory Research, Syracuse University, Syracuse, New York 13210. A circadian clock in <u>Limulus</u> brain <u>in situ</u> generates efferent lateral optic nerve (LOR) activity at night, leading to numerous changes in retinal structure and function (<u>Science</u> 197:86-89, 1977; <u>Science</u> 210:1037-1039, 1980). We developed an excised brain preparation to further characterize the efferent and afferent con-nections to this circadian clock. The <u>Limulus</u> brain and optic nerves were removed by dissection and were placed in a temperature controlled chamber filled with organ culture solution. Glass suction electrodes were positioned along the various desheathed optic nerve stumps, allowing us to record from or to electrically stimulate the nerves.

Efferent optic nerve activity can be recorded for up to three days in the excised brain of Limulus. Like efferent activity re-corded in situ, the discrete bursts of efferent activity recorded from the excised brain were first detected in the early evening, continued throughout the night, and stopped at dawn. The general rate of bursting activity was greater at night than during day. The bursts of efferent activity recorded from one LON were synchronous with those recorded from the opposite LON, the median optic nerve (MON), and the ventral eye nerve. Electrically stimulating the MON induced efferent activity in both LONs. T1luminating the excised brain can inhibit the efferent activity. We have not detected efferent activity in other nerve trunks (non-optic) leading to the protocerebrum; nor have we succeeded in modulating the efferent activity in LONs by electrically stimu-lating other nerves leading to the protocerebrum. Thus, with regard to sensory systems, the circadian clock appears to primarily mediate functional changes in the visual system that occur from day to night.

Bisecting the isolated protocerebrum desynchronizes the bursts Bisecting the isolated protocerebrum desynchronizes the burst: of efferent activity in opposite LONs, indicating that efferent cell bodies are located in both sides of the protocerebrum. Fur-ther lesions of the brain suggest that the location of the cell bodies may be limited to the lamina or medulla. Various studies are currently underway to identify the precise location of the efferent cell bodies and the associated circadian clock.

98.12 RECEPTOR POTENTIALS OF IDENTIFIED MECHANORECEPTOR NEURONS IN THE COCKROACH LEG BEFORE AND AFTER THE FINAL MOLT. J.B.Zuckerman\* and D.-W.Shin\* . Neuroscience S K.M. Chapman. Neuroscience Sect., Brown rovidence, RI 02912.

In the final days before the immature cockroach molts, the bipolar neuron of each proprioceptive campaniform sensillum on bipolar neuron of each proprioceptive campaniform sensillum on the legs remains attached to the old exoskeleton, but its dendritic sensory process elongates roughly tenfold as molting fluid erodes the old cuticle and separates the epithelial.cell layer from it (Moran et al, 1976). Behavior suggests that sensory function persists until the moment the outer sensory process is shed with the exoskeleton, and resumes immediately afterward. To study this process electrophysiologically, we have recorded receptor potentials noninvasively from the same sensillum in individual cockroaches (<u>Blaberus discoidalis</u>) during the weeks before, and shortly after their final molt in previous work on amputated legs, individual campaniform sensilla of Group 6 at the knee were stimulated with a fine tungsten compliance probe (Chapman, Mosinger & Duckrow, 1979) tungsten compliance probe (Chapman, Mosinger & Duckrow, 1979) and transcuticular receptor potentials were recorded from the sensillar cap with a gel-filled pipet (Mann & Chapman, 1975; Swearingen & Chapman, in prep.). Trans-cap resistances were high () I Gohm) on initial contact, but after gentle stimulation with 10-100 uN punctate force, fell to 50-500 Mohm, as in amputated legs, and remained so during subsequent weeks of observation. Until several days before the molt, receptor potentials were virtually identical to those found in amputated legs, with typically: (1) 0 to -20 mV "standing potential" in the unstimulated state. unlike the +20 to +70 mV found in many insect sensilla (Thurm & Wessel, 1979); (2) mechanically modulated negative-going 1-10 mV receptor potentials, with transfer functions on the 0.1-130 Hz range which remained reproducible for weeks; (3) evoked spikes superimposed on the receptor potential. About a week before molting, positive-going the sensil of the superimposed on the reproducible for weeks; (3) evoked spikes superimposed on the receptor potential. About a week before molting, positive-going receptor potential modulations became common, with "irregular" changes in the transfer functions. In the final 2-3 days, receptor potentials became too small to measure, but modulated spike trains remained. Within a week the typical non-molting pattern reappeared. These findings suggest that the "irregular" transfer functions reflect elongation of the dendritic cable until molting fluid finally attenuates the generator current immediately before the molt. We are grateful for a gift from the Grass Foundation.

IDENTIFIED INTERNEURONS STEER FLIGHT IN THE DRAGONFLY. 9813 R. Olberg, Dept. of Biological Sciences, Union College, Schenectady, NY 12308 Schenectady, NY

In the ventral nerve cord of the dragonfly, 7 giant interneurons have been identified, each of which produces asymmetrical wing movements when stimulated intracellularly. The interneurons fall into two distinct classes, (1) rotation-sensitive and (2) object-movement sensitive. Lucifer Yellow and/or cobalt sulfide staining revealed that the cell bodies and dendritic arborizations of rotation sensitive interneurons are located in the prothoracic ganglion. Here they receive inputs from the compound eyes, antennae, wind-sensitive hair fields on the head and prothorax, cervical proprioceptors, and in some cases the ocelli and/or abdomen. Each input is directionally selective, and all code for rotation in a given direction within the same plane in space. The wing movements produced by individual rotation-sensitive neurons are small, but appear to be components of reflex movements elicited by the rotation of the visual surround, rotation of the head, or directed puffs of air. Object-movement sensitive neurons are purely visual and descend from the brain. They are directionally selective for small-object (8° or less, visual angle) movement within their receptive fields. Intracellular stimulation revealed that they produce much larger wing movements. The two groups of interneurons appear to exert potent influence on flight direction, at least during gliding flight.

THE MAJOR PRODUCTS OF THE DYNORPHIN GENE ARE  $\kappa$  OPIOID LIGANDS. 99.1 I.F. James\*, W. Fischli and A. Goldstein. Addiction Research Foundation, 701 Welch Rd., Palo Alto, CA 94304.

The precursor for dynorphin contains at least five active opioid peptides, dynorphin A, dynorphin A-(1-8), dynorphin B,  $\alpha$ -neo-endorphin and  $\beta$ -neo-endorphin, all of which have been found in mammalian tissue. There is strong evidence that dynorphin A is highly selective for  $\kappa$  opioid receptors; one of three well known types of opioid receptor. We have now assessed opioid receptor selectivity of the other main products from the dynorphin preselectivity of the other main products from the dynorphin pre-cursor using the guinea pig ileum myenteric plexus-longitudinal muscle preparation (GPI). In GPI there are two types of opioid receptor,  $\mu$  and  $\kappa$ , which are distinguished by their sensitivity to the antagonist naloxone. Agonists acting at K receptors are 10 times less sensitive to naloxone than those acting at µ receptors.

Dynorphin A, dynorphin B and  $\alpha$ -neo-endorphin were all equally Dynorphin A, dynorphin B and  $\alpha$ -neo-endorphin were all equally insensitive to naloxone (K<sub>e</sub> values of 29±3, 33±9 and 22±3, re-spectively), compared to the prototypical  $\mu$  agonist normorphine (K<sub>e</sub>=3.1±0.3). Furthermore, all three of these peptides protected K but not  $\mu$  receptors from inactivation by the opioid site directed alkylating agent  $\beta$ -chlornaltrexamine, suggesting that they act exclusively through K receptors in this tissue. Dynorphin A-(1-8) and  $\beta$ -neo-endorphin (K<sub>e</sub> values 15±1.5 and 14±1, respec-tively) were more sensitive to naloxone than dynorphin A but less sensitive than normorphine. Values of Ke for these peptides were still intermediate between values for dynorphin A and normorphine when peptidase inhibitors were present in the bathing medium, indicating that the intermediate naloxone sensitivity was not caused by degradation to products with different receptor selec-tivity from the parent compounds. We propose therefore that dyntivity from the parent compounds. We propose interefore that dynorphin A-(1-8) and  $\beta$ -neo-endorphin act predominatly at  $\kappa$  receptors but partially at  $\mu$  receptors in GPI. Members of two different families of endogenous opioid peptides have now been associated with different opioid receptor

types -- dynorphins with  $\kappa$  receptors and enkephalins with  $\delta$  recycles - Gynorphins with K feedpoirs and encepharins with of pied ceptors. Perhaps each opioid gene, coding for a family of opioid peptides constitutes a cognate pair with a single receptor type. Hence in vivo dynorphins may always act at K receptors and enkephalins always at  $\delta$  receptors. It is not known what endog-enous ligand may be selective for  $\mu$  receptors.

MULTIPLE OPIOID RECEPTORS IN THE GUINEA PIG ENTERIC NERVOUS SYS-99.2 TEM: UNMASKING OF RECEPTOR SUBTYPES, A.R. Gintzler\* and D. Hyde\* (Spon: F. Kao). Dept. of Biochemistry, Downstate Med. Ctr., Brooklyn, New York 11203. The presence of  $\delta$  opioid receptors have been demonstrated in

the myenteric plexus of the guinea pig by radioligand binding experiments but their functional significance is not clear. The naloxone Ke for the  $\delta$  preferring agonist D-ala<sup>2</sup>-D-leu5-enkephalin (DADLE) indicates that the u and not the  $\delta$  receptor mediates the inhibitory action of these peptides on responses to 0.1 Hz electrical stimulation. However, the demonstration in the guinea pig trical stimulation. However, the demonstration in the guinea pig ileum of differential tolerance to normorphine and DADLE suggests that myenteric & receptors mediate at least a portion of this effect in tolerant/dependent preparations (Gintzler and Scalisi, Brain Research 238:254-259, 1982). The present experiments were performed in order to clarify this apparent discrepancy and to demonstrate the presence of functional  $\boldsymbol{\delta}$  receptors in naive preparations.

The population(s) of receptor mediating responses of the naive gut (0.1 Hz contractions) to u and  $\delta$  agonists were compared on the basis of their reactivity with the nonequilibrium opidia antagon-ists, B-chlornaltrexamine (B-CNA) and B-funaltrexamine (B-FNA), ists, B-chlornaltrexamine (B-CNA) and B-funaltrexamine (B-FNA), (q" value). The "q" value for normorphine and DADLE calculated following pretreatment with B-CNA was  $0.12 \pm 0.02$  and  $0.43 \pm 0.06$ respectively. After incubation with B-FNA, (selective for u re-ceptors), the "q" value for normorphine was 0.24+0.046 while that for the highly selective  $\delta$  agonist Tyr-D-Ser-Gly-Phe-Leu-Thr (DSLET) was  $0.1 \pm 0.037$ . These results indicate that the above agonists do not act via identical populations of receptor in the naive ileum despite the similarity of their naloxone K<sub>e</sub> value (1-2nM). In addition, the naloxone K<sub>e</sub> for DSLET was determined 10 fold approximating the value observed in the mouse vas deferens. These results indicate that the delta preferring agonists acts

via two populations of myenteric opioid receptor to inhibit the 0.1 Hz contraction height. Following the elimination of the u opioid receptor the DSLET-induced inhibition that remains results option receptor the DSLEI-Induced inhibition that remains results from the occupation of another opioid receptor subtype. The mark-ed lack of cross-reactivity between DSLET and K receptors would suggest that this subclass is of the & type. These data also in-dicate that naloxone Ke values by themselves may not be sufficient criteria for concluding that a particular receptor subtype is not present in a given tissue or not associated with a particular function. Supported by NIDA Grant DA02893.

DIFFERENTIAL PROPERTIES OF MU RECEPTORS IN THE GUINEA-PIG ILEUM (GPI) AND MOUSE VAS DEFERENS (MVD) PREPARA-TIONS. <u>Susan J. Ward</u>\*. (SPON: T. Truscott). Sterling-Winthrop Research Institute, Rensselaer, NY 99.3 12144.

Incubation of the GPI with the highly selective non-equilibrium antagonist B-funaltrexamine (B-FNA), in-activates those mu receptors at which normorphine interequilibrium antagonist B-Hunaltrexamine (B-FNA), in-activates those mu receptors at which normorphine inter-acts, such that, following pretreatment with B-FNA (500 nM), the pA, value for the interaction of nor-morphine (NM) and naloxone is similar to that for the interaction of ethylketazocine and naloxone, but different from that for the interaction of NM and naloxone in control preparations incubated with nalorphine (500 nM). Similarly, those mu receptors at which morphine and methadone interact are also blocked by B-FNA, and the pA, values for the interactions of these agonists with fialoxone are lowered by pretreatment of tissues with B-FNA. In contrast, the pA, values for the interactions of naloxone with D-Ala<sup>2</sup>D-Leu<sup>5</sup>-enkeph-alin, D-Ala<sup>2</sup>met-enkephalin, D-Ala<sup>2</sup>met-enkephalimide, D-Ser<sup>2</sup>, Thr<sup>0</sup>, Leu-enkephalin, D-Ala<sup>2</sup>met-enkephalimide, D-Ser<sup>2</sup>, Thr<sup>0</sup>, (CH<sub>2</sub>)<sub>2</sub> (Rx 78, 3030) were not altered by pretreatment of itsues with B-FNA, despite the fact that B-FNA did antagonise the agonist actions of these compounds. compounds.

compounds. In contrast to the effects of B-FNA on the GPI, on the MVD, pretreatment of tissues with B-FNA resulted in the lowering of pA, values for the interactions of naloxone with both NM-like and Rx 78,3030-like agonists.

Similar experiments using the non-equilibrium mu antagonist naloxonazine instead of B-FNA (0.2 or 1 uM) demonstrated that the pA<sub>2</sub> values for the interactions of naloxone with NM-like and Rx 78,3030-like were lowered by pretreatment with naloxonazine in both the GPI and the MVD.

GPI and the MVD. In experiments using the non-equilibrium antagonist B-chlornaltrexamine (B-CNA), B-CNA was a more potent non-equilibrium antagonist of NM than of Rx 78,3030 on the GPI, and 'q', the proportion of receptors not occupied by B-CNA (100 nM) was greater when Rx 78,3030 was the agonist in the GPI. These experiments suggest that NM-like and Rx 78,30-30-like agonists interact with mu receptors in the GPI in a different manner, or that these two groups of compounds interact with different populations of receptors that are equally sensitive to naloxone in the GPI. GPI.

OPIATE RECEPTOR UPREGULATION IN EXPLANTS OF SPINAL CORD-DORSAL 00 4 ROOT GANGLIA. A. Tempel, S. Crain, E.J. Simon and R.S. Zukin Department of Biochemistry and Neuroscience, Albert Einstein Coll. Med., Bronx, N.Y. 10461, (E.J.S.) Dept. of Psychiatry,

New York University Medical Center, New York, NY 10016 High-affinity stereospecific opiate receptors have been demon-strated in explant cultures of fetal mouse spinal cord with attached dorsal root ganglia (DRG). We have used this system to examine the mechanisms underlying the regulation of opiate to examine the mechanisms underlying the regulation of opiate receptors in response to chronic antagonists. Cultures were grown in standard growth medium for two weeks, and then in this medium containing naloxone (10  $\mu$ M) for an additional 7 days. For opiate binding assays, 7-9 cultures were pooled, and homogenates prepared. Aliquots of homogenate were incubated with 3H-dihydromorphine (DHM, 5 nM) in the absence and presence of levorphanol (10  $\mu$ M). Analyses of cultures exposed to naloxone for 7 days revealed a 50% increase in  $^{3}$ H-DH binding relative to that in control cultures exposed to medium only or to short-term naloxone (1 hour prior to assay). In order to answer the question as to whether antagonist-induced receptor upregulation term naloxone (1 hour prior to assay). In order to answer the question as to whether antagonist-induced receptor upregulation requires the synthesis of new receptors, cultures were co-exposed to naloxone (10  $\mu$ M) and cycloheximide (1  $\mu$ M), a potent and relatively selective inhibitor cf protein synthesis, for 5 days at 37°. These conditions have been shown to block protein synthesis by greater than 90%, as measured by incorporation of <sup>14</sup>C-leucine into total protein. Upregulation was observed in cultures so exposed. This result suggests that upregulation may be due to an unmasking of previously-existing receptors. The time-course of upmasking of previously-existing receptors. The time-course of upregulation was also determined. No significant change in re-ceptor density was observed following I day of naloxone treat-ment; a modest increase was observed after 2 days; and maximal upregulation was observed after 5 days of chronic exposure. The upregulation was observed after 5 days of chronic exposure. The maximal increase of 50% was quite comparable to the 52% increase observed in assays of spinal cord after chronic naltrexone in <u>situ</u> (Tempel and Zukin, in preparation). These data demonstrate the feasibility of utilizing cord-drog explants as an in <u>vitro</u> model system for further analyses of cellular mechanisms underlying opiate supersensitivity and tolerance. KAPPA RECEPTOR ANTAGONISTS REVERSE "NON OPIOID" STRESS INDUCED ANALGESIA. A.E.Panerai, A.Martini<sup>+</sup>, P.Sacerdote<sup>+</sup>, L.Vicentini, P. Mantegazza<sup>+</sup>. Dept. Pharmacology, School of Medicine, University of 99.5 Milano, Milano, Italy The opiate receptor antagonist Naloxone reverses stress

induced analgesia when this is induced by a long, intermittent stress (1 sec every 5 sec for 20 min), but is ineffective on analgesia induced by a short, continuous stress (3 min). This observation suggested the definition of this stress-induced analgesia as "non opioid dependent". We show that two specific analgesia as "non opioid dependent". We show that two specific antagonists of the kappa opiate receptor: NR-2266 and NR-1452 MS completely reverse the "non-opioid" stress induced analgesia. We confirm that the two antagonists of the receptor: Naloxone and Naltrexone are ineffective in reversing the 3 min stress-induced analgesia, and show that also the mixed and delta receptor interpent because the stress of the stress antagonist Diprenorphine and the delta receptor antagonist ICI 154129 are ineffective. Moreover, only the receptor antagonists Naloxone and Naltrexone can completely reverse the long, inter-mittent stress "opiod dependent" analgesia, while Diprenorphine is only partially effective. Both kappa receptor antagonists and the delta receptor antagonist are ineffective in reversing the "opioid-dependent" stress-induced analgesia.

Our results indicate that "opioid dependent" analgesia is inhibited by an endogenous opiate active on the receptor, e.g B-endorphin, while the "non opioid" stress induced analgesia is receptor, e.g. mediated by an endogenous opiate active on the kappa receptor, e.g. Dynorphin. Endogenous opiates active on the delta receptor, e.g. Leu-enkephalin, do not seem to be involved in stress induced analgesia.

BINDING OF <sup>3</sup>H-DIHYDROMORPHINE IN NEWBORN RAT BRAIN MEMBRANES: 99.6

BINDING OF <sup>3</sup>H-DIHYDROMORPHINE IN NEWBORN RAT BRAIN MEMBRANES: CORRELATION WITH ENDOGRNOUS OPIOID PEPTIDE LEVELS. William J. Shoemaker, R. Suzane Zukin-, Lynne Randolph\*, and F.E. Bloom. Albert Einstein College of Medicine, Bronx, New York 10461 and The Salk Institute, La Jolla, CA 92037. Both high and low affinity opiate binding sites have been described in newborn rat brain membranes using H-dihydrognorphine (DHM), as well as several other opioid ligands. We use H-DHM to quantitate high and low affinity opiate binding sites in newborn rat pups that have been treated in a way that alters their brain B-endorphin levels. Liquid diets that contain alcobol are fed to For pupe that have been treated in a way that inters their brain  $\beta$ -endorphin levels. Liquid diets that contain alcohol are fed to timed-pregnant female Sprague-Dawley rats in a model of the Fetal Alcohol Syndrome (FAS). The offspring of these alcohol treated mothers and their controls have previously been reported by us to have greatly increased levels of  $\beta$ -endorphin in two regions of their brains at birth (Shoemaker et al. Soc. Neurosci. Abstr. 7:349, 1981). The increase in  $\beta$ -endorphin levels is proportional to the blood alcohol levels of mother during gestation. The brain homogenates from these treated offspring are the subject of H-dihydromorphine binding in homogenates at birth. Five brains from each treatment type were pooled for Scatchard analysis over 12 concentrations of "H-dihydromorphine (range 0.1 nM to 10 nM). 12 concentrations of H-dihydromorphine (range 0.1 nM to 10 M). The four treatment groups are as follows: (C) = mothers receive high quality lab chow; (BSA) = a liquid diet with low protein and 5% alcohol; (BSP) = the same diet as BSA with alcohol cmitted, pair-fed to BSA; (RA) = a higher protein liquid diet containing 5% ethanol. In general, neonate brains bind only a small fraction of the adult level of DHM binding; however, the affinities for the two sites do not change. The effect of alcohol treatment to the fetuses (BSA) was to decrease the number alcohol leadmark to be refuses (BA) was to decrease the Scatchard analysis. This effect was not due to the undernutrition since the BSP (pair-fed control) did not show such alterations. The results from the RA group were difficult to interpret. However, there appears to be an inverse correlation between the level of brain  $\beta$ -endorphin and the number of high and low affinity DHM binding sites. (Supported by NIAAA 03504.) binding sites.

99 7 EVIDENCE FOR K-RECEPTOR MEDIATED ANALGESIA IN THE DEVELOPING RAT Gordon A. Barr\*, William Paredes\*, Karen L. Erickson\* & R. Suzanne Zukin (SPON: E.L. Gardner). Albert Einstein College of Medicine, Bronx, NY 10461 and Biopsychology Program, Hunter College, CUNY, New York, NY 10021

Mu, delta, and kappa opiate receptors are distinguished on the basis of: 1) differing physiological and behavioral profiles of different opiates; 2) differing sensitivities of opiate agonists to naloxone antagonism; and 3) differences in binding characteristics and selective protection (for a review see Zukin & Zukin, 1981). The question arises as to whether mu and kappa opiates elicit analgesia by an interaction with the same or with different opiate receptors. Evidence for separate receptors has been provided by findings that ketocyclazocine (KC) and morphine (M) have different anatomical sites of action and do not produce cross-tolerance. Data in support of a common receptor are the similar pA<sub>2</sub>'s for naloxone antagonism, and the ability of naloxazone to block KC- and M- induced analgesia. The present study azone to block KC- and M- induced analgesia. The present study examined the development of  $\mu$  and  $\kappa$  binding sites and correlat-ed these with the onset of M- and KC- analgesia. For receptor assays, high affinity <sup>3</sup>H-dihydromorphine binding was measured using homogenates of whole brain of rat pups of various ages. For  $\kappa$  receptor assays, <sup>3</sup>H-ethylketocyclazocine (<sup>3</sup>H-EKC) binding was measured in the presence of  $\mu$  and  $\delta$  receptor blocking agents. For analgesia studies, tail flick nociception thresholds were determined by immersing the pups' tails in water (50°C) and recording tail flick latencies. M and KC were injected 30 minutes prior to testing. At birth  $\kappa$  receptor density, determined by Scatchard analysis, was ca. 65% of adult levels. K site density remained nearly constant until 10 days of age, at which time it increased to adult levels. In contrast, high affinity 3H-DHM stilleressed to adult levels. In contrast, high affinity 3H-DHM stilleressed gradually until about 13 days of age, at which time they increas-ed markedly to nearly adult levels. In analgesia testing, KC was modestly active at very high doses from 3 to 9 days of age, but increased markedly in potency at 10 days of age. M was without any detectable effect until 12 days of age, at which time it pro-duced analgesia at adult potency. Thus, the onset of KC-induced analgesia correlates with the observed increase in  $\kappa$  binding sites, and that of M- induced analgesia with the rise in  $\mu$ receptors. The appearance of functionally-active  $\kappa$  receptors precedes the onset of  $\boldsymbol{\mu}$  receptors by approximately 3 days. In summary, the present study assigns a role for the K binding sites in analgesia and differentiates its ontogenetic pattern from that the  $\mu$  receptor. We thank NIH Grants DA01843 and DA00069 (to R. Suzanne Zukin).

Phencyclidine Displaceable Binding of  $[{}^{3}H]$  Dextrorphan in Rat Brain Membranes. <u>T.F. Murray and M.E. Leid\*</u>. Washington State University, College of Pharmacy, Pullman, WA 99164-6510. State University, College of Pharmacy, Pullman, WA 99164-6510. Dextrorphan and certain psychotomimetic opioids have been reported to share discriminative stimulus properties with phencyclidine (PCP) in numerous behavioral studies. Moreover, we have previously demonstrated that dextrogphan is a competitive inhibitor of the specific binding of ["4] PCP in rat brain membranes (Murray et al., <u>Soc. Neurosci. Abstr.</u> 8, 388, 1982). The purpose of the present, investigation was to characterize the specific binding of ["4] dextromghan to crude synaptic membranes from the rat cortex. ["4]-Dextrorphan (19 Ci/mmole, NEN) binding was measured by rapid filtration using glass fiber filters which had been presoaked in a 0.1% w/v poly-L-lysine solution. This treatment of filters completely eliminated PCP displaceable binding of ["4] dextrorphan to filters in the absence of brain homogenate. Specific binding was defined as the total binding minus that occurring in the presence of a 10.M nonradioactive PCP. The specific binding of ["4] dextromphan to synaptic membrane preparations was routinely determined binding minus that occurring in the presence of a 10LM nonradioactive PCP. The specific binding of [<sup>3</sup>H] dextrorphan to synaptic membrane preparations was routinely determined after 2 hr. incubations at 0-4°C. Under these conditions the specific binding of [<sup>3</sup>H] dextrorphan displayed tissue linearity between 200-800 µg protein per assay tube. The ratio of specific to nonspecific binding was enhanced in a medium of low ionic strength. The PCP displaceable component of binding ranged from 50 to 70% of the total in a 10MM HEPES buffer. The IC<sub>50</sub> for PCP determined from logit-log analysis of competition data was 0.34 µM. The rank order potencies as displacing agents for [<sup>3</sup>H] dextrorphan binding to cortical membranes was phencyclidine > (±) cyclazocine > (±) N-allyl-normetazocine which is compatible with behavioral data for these compounds. These relative potencies are also similar to those reported for the binding of these compounds to the sigma opiate/PCP recognition site (Zukin et al., Brain Res. 258, 277, 1983). Thus, our results suggest that [<sup>4</sup>H]-dextrorphan may be a useful probe to investigate the recognition site which mediates the unique psychotominetic effects of drugs such as PCP, dextrorotatary opioids, and N-allylnormetazocine. N-allylnormetazocine.

SIGMA OPIATE/PCP BINDING SITES IN DEVELOPING RAT BRAIN. Ratna 99 9 Sircar\* and Stephen R. Zukin, Dept. of Psychiatry, Albert Einstein College of Medicine, 1300 Morris Park Ave., Bronx, NY 10461 Stereospecific binding sites selective for phencyclidine (PCP), derivatives dioxalans and sigma opiates, with characteristics suggesting that these sites mediate the unique psychotomimetic effects of these agents, have been demonstrated in rat brain (Vincent et al., <u>Proc. Natl. Acad. Sci. USA</u> 76:4678, 1979; Zukin and Zukin, <u>Proc. Natl. Acad. Sci. USA</u> 76:5372, 1979; Quirion et al., <u>Proc. Natl. Acad. Sci. USA</u> 78:5881, 1981; Vignon et al., Eur. J. Pharmacol. 81:531, 1982; Hampton et al., Life Sci. 30: 2147, 1982; Zukin, Life Sci. 31:1307, 1982). In order to further the understanding of the functional roles of these receptors in the CNS, we have examined the time course of their development in the brain of the developing fetal and neonatal rat.

Brain homogenates from Blue Spruce hooled rats were incubated in 5 mM Tris-HCl, pH 7.4,  $4^{\circ}$ C, 45 min. with [<sup>3</sup>H]PCP alone or with 10  $\mu$ M PCP or varying concentrations of PCP or other drugs. Free ligand was separated from bound by rapid filtration over vacuum through GF/B filters (Whatman) pretreated with 0.01% poly-Llysine. Apparent K and B values were obtained by Scatchard analysis. IC  $_{50}$  values for displacement of 10 nM [3H]PCP by other drugs were calculated by linear regression. In each experiment,

an adult brain was run in parallel as control. Displaceable [<sup>3</sup>H]PCP binding was detected at low levels in fetal brain homogenates on gestational day 13, increased gradual-If until day I7, then increased rapidly to adult levels by gestational day 21. The increased represents a change in B , no change in K coccurred. As has been reported for adult adult is homogenetes, Scatchard plots of  $[{}^{3}H]PCP$  binding in fetal brain Managenates, Scatchard prots of a lifer binding in retain brain were linear, indicating a single case of binding sites throughout the developmental period examined. Stereospecific [<sup>3</sup>H]PCP binding, defined as [<sup>3</sup>H]PCP binding dis-

placed about 100 fold more potently derived as which binding de-adrol, appeared suddenly at gestational day 20. Such stereospe-cific [<sup>3</sup>H]PCP binding has been shown to be characteristic of pharmacologically-relevant CNS PCP binding sites, but not to be found in peripheral tissues, nonbiological materials or denatured CNS tissue (Hampton et al., Life Sci. 30:2147, 1982; Zukin, Life Sci., 31:1307, 1982). These results suggest differential development of membrane components responsible for non-stereospecific and stereospecific [<sup>3</sup>H]PCP binding, and predict that the rat CNS becomes capable of response to the unique pharmacological effects of PCP-like or sigma opiate drugs just prior to parturition.

EVIDENCE THAT [3H]DADL LABELS TWO CLASSES OF DELTA RECEPTORS IN SLIDE-MOUNTED SECTIONS OF RAT CAUDATE. <u>R.B. Rothman\*, W.D. Bowen\*,</u> and C.B. Pert. (SPON: C.B. Pert) Section on Brain Biochemistry, NSB, NIMH, Bethesda MD 20205. Previous work has shown that [3H]D-Ala<sup>2</sup>-D-Leu<sup>5</sup>-enkephalin (DADL) labels two anatomically distinct binding sites in rat cau-date which differ in their sensitivity to ionic conditions (Bowen et al., <u>PNAS</u>, 78:4818, 1981). Further, Rothman and Westfall (Mol. Pharmacol., 21:538, 1982) demonstrated noncompetitive inter-actions between mu and delta receptors. A concept consistent with both sets of data is that [3H]DADL labels two types of delta receptors, the class of delta receptor on competitively inhibited

both sets of data is that  $[^{3}H]DADL$  labels two types of delta receptors, the class of delta receptor noncompetitively inhibited by morphine being the Type I opiate receptor. To explore this idea, the displacement of  $[^{3}H]DADL$  binding to slide-mounted sections of rat caudate (90 min incubation at 25°C in 50 mM TRIS pH 7.4, 100 mM NaCl, 3 mM MnAc, and 2 uM GTP) by mor-phine, oxymorphone (0X), and leucine enkephalin (LE) were analyzed simultaneously with a  $[^{3}H]DADL$  binding isotherm according to a two-site competitive model and a two-site allosteric model. The allosteric model fit the data better than did the two-site competi-tive model. Further, only the allosteric model correctly predicted the noncompetitive interaction of 0X with  $[^{3}H]DADL$  binding. We conclude that 0X is a noncompetitive inhibitor of  $[^{3}H]DADL$ binding. Our working hypothesis is that the population of delta

We conclude that 0X is a noncompetitive inhibitor of  $[^{3}H]DADL$  binding. Our working hypothesis is that the population of delta receptors noncompetitively inhibited by 0X is the Type I receptor. The population of delta receptors competitively inhibited by 0X is the Type II receptor. These data are consistent with the idea that the Type I receptor is a conformationally malleable receptor complex, with distinct mu and delta binding sites, which can assume mu and delta conformational states.

QUANTIFICATION OF RECEPTOR DENSITIES BY AUTORADIOGRAPHY: TISSUE DEFATTING MINIMIZES DIFFERENTIAL ABSORBANCE OF TRITIUM BY GRAY AND WHITE MATTER. Miles Herkenham and Louis Sokoloff. Lab. Neurophysiol. and Lab. Cerebral Metabolism, NINH, Bethesda, MD 20205. A newly-developed means for quantifying neurotransmitter and drug receptor densities in discrete brain regions is densitometry of film autoradiographs previously exposed to tissue sections con-taining tritiated ligand bound to receptors. The technology for autoradiographic receptor localization and quantification has fol-lowed the developments in the field of local brain glucose metabo-lism mapped by [<sup>14</sup>C]2-deoxy-D-glucose (2DG) uptake. In that field, recent attempts to increase the autoradiographic resolution by the use of  $[^{3}\mathrm{H}]2DG$  resulted in the observation that gray matter and white matter differentially absorb low-energy tritium emissions (Alexander et al., Br. Res., '81, 223: 59-67). In fact, as much as 30-50% of emissions from white matter are absorbed relative to as 50-50% of emissions from white matter are absorbed relative to gray matter. Consequently, circulating methyl glucose, when label-ed with  $^{14}$ C, produces a homogeneous autoradiograph because of its uniform distribution; but when it is labeled with  $^{3}$ H, it produces autoradiographs in which gray and white matter are clearly distinguished (Orzi et al., J. Cereb. Blood Flow Metab., in press)

This artifact can be minimized by defatting the sections in xylene prior to autoradiographic exposure (Herkenham and Pert, J. Neurosci., '82, 2: 1129-1149). To demonstrate this, adjacent slide-mounted sections, cut frozen from unfixed brains, were incubated in either 2.5nM [ $^{3}$ Il]- or [ $^{125}$ I]DAGO-enkephalin (a selective mu opiate ligand), washed, dried and film exposed. Some sections were first fixed in formaldehyde vapors and defatted. The results show that fixation and defatting did not alter the relative densities of  $[^{12}5]$  DAGO binding in myelin-rich and myelin-poor regions. In contrast, the  $[^{3}\text{H}]$  DAGO labeling matched the pattern of  $[^{12}5]$  DAGO labeling only after the sections were defatted. Sections that were not defatted produced autoradiographs with exaggerated density differences at gray/white matter borders, resulting in a "contrast enhancement." In addition, receptor-dense fiber tracts appeared

less optically dense, as did most of the reticular formation. Even though 50% of the bound [<sup>125</sup>]DAGO is lost in the defatting process, the relative densities and distributions across structures are unaltered, indicating a non-selective loss of ligand. With  ${}^{3}\text{H}$  as the isotope, the image after defatting is "corrected" for the as the isotope, the image after defatting is corrected for the differential quenching, even in autoradiographs of other opiate lig-ands which are lost in varying amounts (15-80%) during the defat-ting process. These results suggest the general applicability of tissue defatting to all  $[^{3}H]$  ligand-receptor binding studies, in-cluding those that report quantitative results as well as those that require the higher resolution and improved counterstaining achieved by the course defatting and liquid any union particle. achieved by tissue defatting and liquid emulsion coating.

HIGH RESOLUTION RADIOAUTOGRAPHIC VISUALIZATION OF OPIATE BINDING 99.12 SITES IN RAT CENTRAL NERVOUS SYSTEM. <u>E. Hamel and A. Beaudet</u>, Lab. of Neuroanatomy, Montreal Neurological Inst., McGill University, Montreal, Quebec H3A 2B4.

The distribution of specifically labeled opiate binding sites was studied by light and electron microscopic radioautography in sections of rat striatum labeled <u>in vitro</u> with the met-enkephalin analog FK 33-824 (Sandoz). Brains were lightly fixed by intraaortic perfusion of an ice-cold phosphate buffered solution containing weak concentrations of aldehydes, rapidly dissected out of the skull and sectioned on a vibratome. Fifty or 100 µm-thick slices were collected across the striatum and incubated at room temperature in Tris-sucrose buffer (pH 7.4) with lnM  $^{125}\mathrm{I-FK}.$ After rinsing, the tissue slices were immersion-fixed in 4 to 6% glutaraldehyde, post-fixed in 2% osmium tetroxide, dehydrated in ethanols and flat embedded in Epon. Semi-thin (1  $\mu$ m) and thin sections were then cut from the surface of each slice and pro-cessed for radioautography. Radioactivity measurements indicated that 50-70% of specifically bound FK molecules had been retained in the tissue during histological processing. Film radioauto-graphs of whole incubated slices showed similar topographical distributions of specific FK binding sites before and after fix-ation and dehydration, consistent with the observed stabilization of receptor-ligand complexes by glutaraldehyde (Hamel and Beaudet, in press). In light microscope radioautographs, 85% of silver grains appeared scattered over the neuropil as compared to 15% over neuronal cell bodies. A significant proportion of the former (15%) was clearly associated with large dendritic profiles. However, in the majority of cases, underlying structures could not be identified by light microscopy. Of the grains localized over nerve cell bodies, 42% were associated with the cytoplasmic membrane. Tissue slices incubated in the presence of 1  $\mu M$  non-radio-active FK or naloxone exhibited 75% fewer grains than those incubated with  $^{125}\mathrm{I-FK}$  alone. Most of these were detected over nuclei, nuclear membranes and unidentified structures of the neuropil. Electron microscope radioautography revealed that a large number of silver grains in the neuropil were located in the vicinity of axo-dendritic synaptic junctions involving mainly small axonic and dendritic shaping junctions incoming maring small axonic and dendritic processes. It also confirmed the as-sociation of silver grains with plasma membranes of neuronal perikarya and proximal dendrites. Some of these grains, however, did not appear to be associated with synaptic specializations. These preliminary results suggest that opiatergic terminals are extent, the some and proximal dendrites of certain striatal neurons. Supported by fellowship (EH) and grant from the Medical Research Council of Canada.

EFFECTS OF L-GLUTAMATE AND L-GLUTAMIC ACID DIETHYL ESTER (GDEE) ON THE RESPONSE OF CORTICAL UNITS TO HYPOTHALAMIC STIMULATION. 100.1 H. Cooper and C. D. Woody. Department of Anatomy and Psychiatry, UCLA Medical Center, Los Angeles, CA 90024. Extracellular recordings of unit activity were made from twenty eight cells of the motor cortex of awake cats during extracellular iontophoresis of 1 M monosodium glutamate (buffered extracellular ioncophoresis of 1 A monosodium glutamate (Differed to pH 8.0) with push-pull currents ranging between 2 and 100 nA. Twenty four of the cells (86%) showed an increased firing rate in response to application of glutamate. Eight cells that demonstrated short latency (less than 20 msec) activation in response to hypothalamic electrical stimulation were tested with iontophoretic application of glutamate. Seven of these cells showed an increased firing rate in response to glutamate. Six of these cells were then tested with hypothalamic stimulation after extracellular iontophoretic application of 0.5 N GDEE (a glutamate blocker). The short latency response to hypothalamic stimulation was suppressed in four and reduced in one of these cells.

Other studies (Kim, E.H.-J., Woody, C.D. and Berthier, N.E. J. <u>Neurophysiol.</u>, <u>49</u>:767-779, 1983; Woody, C.D., Kim, E.H.-J. and Berthier, N.E., <u>J. Neurophysiol.</u>, <u>49</u>:780-791, 1983) have shown that hypothalamic stimulation, when added to presentations of a conventional CS and US, accelerates the rate of acquisition of a classically conditioned eyeblink reflex. Short latency activation of neurons of the motor cortex by hypothalamic stimulation is predictive of loci of stimulation within the hypothalamus that will produce this effect. It was also shown that hypothalamic stimulation had to be presented in an associative manner in order for this acceleration of conditioning to occur. The present findings indicate that cells of the motor cortex that respond to hypothalamic stimulation can also be activated by glutamate and, further, that the short latency response of neurons of the motor cortex to hypothalamic stimulation can be suppressed by extracellular application of GDEE, a glutamate blocker. (Supported by DNS 78-24146 and AFOSR F49620-83-C-0077.)

PATTERNS OF RESPONSE TO A BEHAVIORAL US AMONG NEURONS OF THE 100.2 SENSORIMOTOR CORTEX OF AWAKE AND ANESTHETIZED CATS. D. Birt and C. D. Hoody. Depts. Anatomy & Psychiatry, UCLA Med. Ctr., Los Angeles, CA 90024.

The temporal patterns of response to glabella tap were studied with intracellular recordings from 33 cortical units in awake and barbiturate anesthetized cats. Glabella tap is a satisfactory unconditioned stimulus (US) for the development of associative eyeblink conditioning. Unconditioned eyeblink responses to tap were recorded electromyographically from the levator oris and orbicularis oculi muscles.

The responses of most cortical units to tap-US fit one of two patterns. Half of the units responded with a sequence of increased activity (E), followed by a period of decreased activity (I), and then by a later period of increased activity (E). This pat-tern was termed E-I-E. Another fourth of the units showed early activation followed in many cases by inhibition, but without the later period of increased activity. This pattern was termed E-I.

Previous studies have shown that glabella tap elicits a two-component unconditioned eveblink response, the first occurring 7by soil, 32:704-716, 1969). The time course of the E-I-E and the E-I unit responses resembled the time course of the two components of the unconditioned eveblink response. However, the unit responses were not due to sensory feedback from the blink movement since similar response patterns were observed in awake ani-mals (in which ENG identified blink responses occurred) as in anesthetized animals (during sequences of trials when no blink re-sponses occurred). The blink movement in response to glabella tap is itself uncessary for blink conditioning to occur (Crow, T.J. and Woody, C.D., <u>Brain Res</u>., 64:414-418, 1973). A variety of stimuli that can serve as effective USs for

classical conditioning produce response patterns in neurons of the sensorimotor cortex which resemble that of the E-I (or E-I-E) reported here. These include stimulation of the pyramidal tract reported here. These include stimulation of the pyramidal tract (0'Brien, J.H. et al., J. Comp. Physiol. Psychol., 91:915-929, 1977; Bindman, L.J. et al., <u>Soc. Heurosci. Abstr.</u>, 6:540, 1982), stimulation of the reticular formation (Segundo, J.P. et al., <u>EEG Clin. Heurophysiol</u>., 11:471-484, 1979; Kumar et al., <u>Brain <u>Res.</u>, 163:156-160, 1979), and stimulation of the hypothalamus (Voody, C.D. et al., <u>J. Heurophysiol</u>, 49:780-791, 1983). Weak clicks used as auditory conditioned stimuli (CSS) elicit the corbs F supersent clare. The reachility crices that the Yel</u> early E component alone. The possibility arises that the E-I pattern of response to the US may serve to distinguish USs from CSs and thereby play a critical role in the development of conditioned responses. (Supported by BNS 78-24146.)

SUBSTANTIA NIGRA LESIONS AND PAVLOVIAN CONDITIONING OF EYEBLINK AND HEART RATE RESPONSES IN THE RABBIT. K. T. Kao\* and D. A. Powell (SPON: N.S. Shah). Neuroscience Laboratory, VA Hospital 100.3

AND HEART RATE RESPONSES IN THE RABBIT. K. T. Kao\* and D. A. Powell (SPON: N.S. Shah). Neuroscience Laboratory, VA Hospital and University of South Carolina, Columbia, S.C. Bilateral radio frequency lesions were made in the substantia nigra (SN) of New Zealand albino rabbits. A group of sham operate rabbits served as a control group. Following a 2-4 week recovery period, all animals were trained on delayed classical conditioning in which eyeblink (EB) and heart rate (HR) responses were concurrently assessed. Each session consisted of 100 trials. A 500 msec, 1216 Hz, 75 db (SPL) tone conditioned stimulus (CS) was followed immediately by a 250 msec, 3 mA paraorbital shock train as the unconditioned stimulus (UCS). The intertrial interval was 60 sec. The animals were trained to a criterion of 10 consecutive EB conditioned responses. responses

The lesioned group showed a deficit in EB acquisition compared to sham-lesioned animals. However, conditioned brady-cardia appeared to be unaffected by the lesions. Furthermore, SN lesions did not affect unconditioned EB or HR thresholds to paraorbital electric shock, suggesting that lesion-induced motor and/or sensory deficits could not account for the conditioning deficits in the lesioned animals.

deficits in the lesioned animals. A previous report from our laboratory suggested the involve-ment of the caudate nucleus in Pavlovian somatomotor but not HR conditioning (Powell et al., Physiol. Behav., 1978, 20, 143-150). The present data suggest that the nigrostriatal system may also be important in mediating acquisition of somatomotor conditioning. Other extrapyramidal motor structures have also been implicated in simple Pavlovian somatomotor conditioning (lavond et al. Physiol. 1981 - 9, 335-339; Moore. been implicated in simple Pavlovian somatomotor conditioning (Lavond et al., Physiol. Psychol., 1981, 9, 335-339; Moore, Desmond & Berthier, In: <u>Conditioning: Representation of</u> <u>Involved Neural Functions</u>, C. D. Woody (Ed.), 1983). However, the occurrence of conditioned bradycardia in the lesioned animals of the present study is inconsistent with the suggestion that the nigrostriatal system is a part of a "general learning system" (Thompson, Robert, <u>Physiol. Psychol., 1982, 10</u>, 186-198). 186-198).

ROLE OF THE ACCESSORY ABDUCENS NUCLEUS IN THE NICTITATING MEMBRANE 100.4

ROLE OF THE ACCESSORY ABDUCENS NUCLEUS IN THE NICTITATING MEMBRANE RESPONSE OF THE RABBIT. J.A. Harvey, G.J. Marek\*, A.M. Johannsen\*, S.E. McMaster\*, T. Land\* and I. Gormezano\* (SPON: M.S. Stewart). Dpt. Psychology and Pharmacology, Univ. Iowa, Iowa City, IA 52242. The corneal reflex of the rabbit, involving retraction of the eyeball by the retractor bulbi muscle and the correlated extension f the nictitating membrane, is being increasingly used as a model for examining the neuronal substrates of associative learning. The anterograde and retrograde transport of HRP was used to map the pathways of this reflex from cornea to the accessory (ACC) and abducens (ABD) nuclei which contain retractor bulbi motoneurons. Injection of HRP into ACC resulted in retrograde labeling of cells in ventral pars oralis of the spinal trigeminal nucleus, while HRP injected into ABD did not. Application of HRP to the cornea resulted in anterograde labeling of fibers in the ventral part of the trigeminal spinal tract and labeled fibers could be seen to enter the ventral pars oralis. These results suggested a disynaptic pathway for the nictitating membrane response (NMR) elicited by corneal stimulation and a primary role of motoneurons in ACC for mediating this defensive reflex. We, therefore, employed electrolytic and knife-cut lesions to examine the role of the VIth cranial nerve, and of the motoneurons in ACC and ABD that supply the Vith nerve, and of the motoneorons in AcC and AbD that supply the Vith nerve, in the conditioned and unconditioned MMR. The amplitude of the unconditioned NMR, elicited by three intensities of air puff delivered to the cornea, was measured before and after these surgeries. Total destruction of the Vith nerve, with the resultant loss of all motoneurons in ACC and ABD, or interruption of all ACC inputs to the VIth nerve, while leaving the ABD and its projections into the VIth nerve intact, produced a large reduction projections into the VIth nerve intact, produced a large reduction in the magnitude of the NMR, though a small residual response to the air puff (less than 1 mm) could still be detected. This re-sidual NMR was not affected by removal of all extraocular muscles while leaving the retractor bulbi intact. In contrast, severing the VIIth (facial) nerve, which alone had no effect on the NMR, eliminated this small residual responding. Therefore, a small com-ponent of the NMR elicited by air puff results from contraction of the obicularis oculi muscle. Interruption of all ABD inputs to the VIIth nerve while leaving ACC inputs intact had no effect on the VIth nerve, while leaving ACC inputs intact, had no effect on the NMR elicited by air puff. Isolation of ACC inputs to the VIth nerve in animals that had acquired conditioned NMRs to a tone conditioned stimulus, that had been paired with corneal air puff as the unconditioned stimulus, produced a large and equivalent reduction in both the conditioned and unconditioned NMR. These re-sults indicate that both the unconditioned NMR elicited by air puff delivered to the cornea and the conditioned NMR elicited by an auditory conditioned stimulus are mediated by motoneurons in the ACC, but not by motoneurons in the ABD. Supported by NIMH grant MH16841 and NSF grant BNS 80-05907.

100.5 RED NUCLEUS AND SUPRATRIGEMINAL RETICULAR FORMATION: BRATN STEM COMPONENTS OF THE CONDITIONED NICTITATING MEMBRANE RESPONSE. J. E. Desmond\*, M. E. Rosenfield\* and J. W. Moore. Department of Psychology, Univ. of Mass., Amherst, MA 01003. Crystalline HRP (Boehringer Mannheim Grade 1) was implanted into the region of the accessory abducens nucleus (AAN) of 3 rabbits. This brain region contains motoneurons involved in defensive eye reflexes and extension of the nictitating mem-brane (NM). Following 24-48 hr survival time, the animals were perfused under deep nembutal anesthesia. Two 1 of 0.9% saline was followed by 2 1 of 10% formalin, and then 2 1 of 12% sucrose in 0.1M phosphate buffer. Brain stem and cerebellar tissue, cut at 40-60 um thickness, were reacted with the TMB procedure of Mesulam (J. Histochem. Cytochem., 26: 106, 1978) with the stabilization step omitted. Labeled cells and a network of fibers and apparent terminations were observed throughout the brainstem. Most relevant from the standpoint of current research into the anatomical substrates of the classically conditioned NM response is the observation of extensive bilateral labelling of small diameter cells of the supratrigeminal region (SR, i.e., the reticular formation located dorsal to N.V): SR has been implicated in the conditioned WM response (Desmond et al., <u>Physiol. Behav.</u>, 28: 1029, 1982; Moore et al., <u>Soc. Neurosci. Abstr.</u>, 7: 358, 1981). Labelling of cerebellar nuclei was mostly confined to contra-lateral fastigial nucleus. Many labeled cells were observed

in contralateral magnocellular red nucleus (RN). Sixteen rabbits received classical conditioning of the right NM response using a tone CS and electrostimulation of the right eye as the US. Single RF lesions of the medial portion of the left previously acquired conditioned response. This finding is not only consistent with the HRP data described above, but is also consistent with the idea that an essential anatomical substrate of the conditioned response includes a circuit from the cerebellum (McCormick et al., <u>Proc. Nat.</u> Acad. Sci. USA, 79: 2731, 1982) to the contralateral RN which projects contralaterally in turn to pontine motoneurons medi-ating the NM response.

CONDITIONED STIMULUS DURATION INFLUENCES LONG LATENCY HIPPOCAMPAL 100.6 ACTIVITY DURING SHORT-DELAY CLASSICAL CONDITIONING OF THE RABBIT'S NICTITATING MEMBRANE RESPONSE. A. G. Romano\* and M. M. Patterson. Dept. of Psychology, Ohio Univ., Athens, OH 45701.

Previous research has demonstrated that multiple unit activity (MUA) in the pyramidal cell layer of the hippocampus exhibits a learning-dependent increase in frequency during short-delay classical conditioning of the rabbit's nictitating membrane (NM) response.

One training variable known to have an effect on rate of shortdelay NM conditioned stimulus (US) offset. This study examined the efunconditioned stimulus (US) offset. Inis study examined the er-fect of post-US CS duration on rate of NM conditioning and condi-tioned hippocampal MUA. Rabbits were chronically implanted with electrodes in the pyramidal cell layer of the hippocampus one week prior to classical conditioning of the NM response. For one group of animals, a standard short-delay conditioning procedure was employed; a 350 msec tone CS overlapped and terminated with the offset of a 100 msec corneal airpuff US yielding a CS-US interval of 250 msec. For a second group of animals, a similar training procedure was employed except that CS duration was ex-tended to 2.1 sec. During each trial, hippocampal MUA was bandpass filtered at 500-5000 Hz and recorded on magnetic tape. Off-line analysis of hippocampal MUA consisted of the creation of poststimulus histograms and the computation of standard scores of MUA for the 250 msec CS-US interval and 8 consecutive 500 msec periods following the onset of the US.

Animals trained with the short CS conditioned faster and ex-hibited more conditioned responses than animals trained with the long CS. Similarly, standard scores of hippocampal MUA during long CS. Similarly, standard scores of hippocampal MUA during the CS-US interval and first post-US period increased faster for the short CS animals. Moreover, the poststimulus histograms for the short CS animals showed a pattern of activity resembling the topography of the NM response. The poststimulus histograms for long CS animals also bore a resemblance to the topography of the NM response but only up until the second or third post-US period. At this point during the trial, although there was no evidence of At this point during the triat, although there was no evidence of NM movement, hippocampal MUA showed a pronounced and long-lasting increase which did not decline to baseline levels until 1-2 sec after the offset of the CS. In most instances, the standard scores of the long CS group were several orders of magnitude greater during the later post-US periods than during the first post-US period when the NM response was being executed. Given that the hippocampus has often been implicated in short-term memory processes, it is possible that a short-term memory for a CS-US pairing is being expressed in the hippocampus as a result of cueing by the continued presence of the CS.

EFFECTS OF LESIONING CEREBELLAR NUCLEI ON CONDITIONED LEG-FLEXION RESPONSES. N. H. Donegan\*, R. W. Lowery\*, and R. F. Thompson (SPON. S. Levine). Dept. of Psychology, Stanford Univ., Stanford, CA. 94305. 100.7

Stanford, CA. 94305. McConmick et al. (1981, 1982) have shown that the cerebellum is an essential element of the neuronal circuitry responsible for the generation of conditioned NM/eyeblink responses in the rabbit --lesions of the dentate and interpositus cerebellar nuclei ipsi-lateral to the side of training selectively abolish the NM con-ditioned response (CR), leaving the unconditioned response (UR) unaffected. Here we report that lesioning the cerebellar nuclei produces a similar effect on conditioned leg-flexion responses. Initial training involved presentation of a 350 msec tone con-ditioned stimulus (CS) that overlapped and coterminated with a 100 msec. 2 mA shock unconditioned stimulus (US) to the rabbits'

Initial training involved presentation of a 350 msec tone con-ditioned stimulus (CS) that overlapped and coterminated with a 100 msec, 2 mA shock unconditioned stimulus (US) to the rabbits' left hindpaw. Subjects (N=7) received 45 trials per session (30 paired, 10 tone-alone, and 5 US-alone), one session per day for six days. Over the course of training, both hindlimbs de-veloped substantial, equivalent conditioned flexion responses, measured as increased PMG activity to the tone CS. (Additional subjects (N=4) given unpaired presentations of the CS and US showed little or no change in EMG activity to the tone over ses-sions.) Subjects then received lesions of the left cerebellar nuclei and/or overlying cortex, were allowed seven days of re-covery, and then received six days of retraining on the left side. Lesions of the dentate and interpositus nuclei (N=4) resulted in an abolition or substantial impairment of the leg-flexion CRs in both hindlimbs. Cortical lesions (N=3) re-sulted in an initial reduction of CR amplitude followed by a recovery approaching prelesion levels. When training was switched to the right hindlimb, both hindlimbs developed condi-tioned responses similar to prelesion training. This finding, that normal CRs can be generated by the left hindlimb hen training is given on the side contralateral to the lesion (right), and the fact that leg-flexion use to the pawshock US training is given on the side contralateral to the lesion (right), and the fact that leg-flexion URs to the pawshock US (measured by a stabilimiter device) were unaffected by the lesions, indicate that the lesions did not produce an overall performance deficit, but rather, a selective deficit in the expression of the learned behavior. When training was shifted back to the left side, conditioned responding in both hindlimbs returned to near zero levels in the nuclear lesioned animals. These results (a) indicate that the lesion effects of McComnick et al. (1981; 1982) are not peculiar to the NM/eye-blink response systems and (b) suggest that the cerebellum is an essential part of the circuitry for classical conditioning of discrete striated muscle response, at least with aver-

of discrete striated muscle responses, at least with aversive USs.

THE CLAIRE-BISHOP AREA IN THE CAT AS A REPOSITORY OF VISUAL EXPERIENCE. <u>D. N. Spinelli</u>. Dept. of Computer and Information Science, University of Massachusetts, Amherst, MA 01003. To further our understanding of how visual experience is re-corded in the brain we trained cats to perform a visual experi-ence which has unique identifying properties. Normally reared cats are shown a "danger" signal (i.e. two vertical bars) to one eye only and required to flex one of their forelegs (within one second) to avoid a mild negative reinforcer. Correct performance causes the danger stimulus to disappear and the appearance of a "safe" signal (i.e. two horizontal bars) which are shown to the other eye. This experience is unique in that animals with frontally located eyes always see the same things with both eyes. We have shown previously that a percentage of cells in area 17 become tuned to vertical bars for one eye and horizontal bars for the other: a class of cells which is not present in cats not so trained. In this study we find that the receptive fields of single cells in the Claire-Bishop area of cats which had been trained <u>up to two years ago</u> are extremely large, binocular, and primarily responsive (60% of the total) to horizontal or vertical bars. Most interestingly we find that a percentage of cells have receptive fields of 30° of visual arc or more and that, when bi-nocularly activated, these cells respond best to vertical bars for one eye and horizontal bars for one eye and horizontal or sertical bars. 100.8 receptive fields of 30° of visual arc or more and that, when bi-nocularly activated, these cells respond best to vertical bars for one eye and horizontal bars for the other, as seen during training. Furthermore, the shape of these receptive fields con-sists of two excitatory areas whose shape and separation are strikingly similar to the one used in the stimuli. These unique properties clearly reflect the unique aspects of the experience. The genesis of receptive field properties under guidance of visual experience, will be discussed. visual experience will be discussed.

DISRUPTION OF SHORT AND LONG-TERM MEMORY FOLLOWING REVERSIBLE 100.9 DISKOFILON OF SHORI AND LONG-IEN MEMORI FOLLOWING REVERSIBLE INACTIVATION OF THE HIPPOCAMPUS. <u>Douglas C. Smith,</u> <u>Robert A. Jensen and T. M. Reeves</u>, Developmental Biopsychology Program and School of Medicine, Southern Illinois University-Carbondale, IL 62901.

Using a passive avoidance paradigm, Kesner and Conner (1972) demonstrated that electrical stimulation of the hippocampus (HC) demonstrated that certected standards of the memory (STM). In outrast, stimulation of the midbrain reticular formation dis-rupted STM, but not LTM. While these and similar results have been taken to indicate that two separate neural pathways mediate STM and LTM, the lack of a localized effect of electrical stimulation makes these conclusions tenuous. We now report that dis-crete injections of lidocaine, a local anesthetic which completely and reversibly inactivates all neural activity in the area affected, into the HC produce both STM and LTM deficits.

In a one-trial inhibitory avoidance task, 20 Long Evans rats received a 1.5 ma, 1.0 sec shock immediately upon entering the dark compartment from the light side of a two compartment alley. For the experimental group, 1.0 µl of lidocaine was bilaterally injected into each HC through implanted cannulae within 5 sec following termination of the shock and were then tested for retention 60 sec and 24 hrs later. Control rats (C) received the same training and testing procedure but no lidocaine. Data were analyzed using a mixed design analysis of variance with repeated analysed being a mixed design unitypic of the measures on one factor. Mean post-learning-trial latency to enter the dark at 60 sec was 290 sec (ceiling 300 sec) for C rats, and 171 sec for HC injected rats  $(\underline{r}_{-1,18}^{=7}, 19, \underline{p}^{<}, 025)$ . 24 hrs, mean latency was 292 sec in C rats and 120 sec for HC-injected rats ( $\underline{F}_{1,18}$ = 17.94,  $\underline{p}$ <.001). For HC-injected rats, 60 sec and 24 hr latencies to enter the dark did not differ  $(\frac{F}{1.9})$ 1.4, p>.20). Preliminary electrophysiological investigations indicate that 1 µl of lidocaine affects a brain area approximately 2 mm in diameter.

We conclude that when highly discrete regions of the hippocampus are inactivated for a short period of time following a learning trial, deficits in both STM and LTM are produced. However, the memory deficit was not complete, i.e., there was some retention evident in those animals that received a lidosome referition evident in those animals that received a linear call and the second se of Research and Development of Southern Illinois University-Carbondale to D.C.S.

DISSOCIATION BETWEEN 'PROCEDURAL' AND 'DECLARATIVE' ASPECTS OF SPATIAL MEMORY AFTER RECOVERY FROM RETROHIPPOCAMPAL 100.11 USIONS BY RATS. R. G.M. Morris\*and F.Schenk\* (Spon:W.Heitler). Psychol.Lab.Univ.St.Andrews, SCOTLAND & Institute de Physiol., Univ.de Lausanne, SWITZERLAND.

This study examined whether retrohippocampal lesions would cause a comparable deficit in place-navigation as that after hippocampal damage (Morris <u>et al.</u>, <u>Nature</u>, 1982,<u>297</u>,681-683) and whether extensive pre- and/or postoperative training could ameliorate any deficit observed. Rats with bilateral RHC lesions (including entorhinal cortex, pre/para subiculum RHC lesions (including entorhinal cortex, pre/para subiculum and the tip of the angular bundle), sham surgery (SH) or no treatment (C) (Ns=11, 12 & 8) were allowed to escape from opaque water onto a small platform hidden (lcm below water) at a fixed position in a large (132cm diam) pool. Spatial room cues were readily visible but no local cues marked the position of the platform. RHC lesion rats were slower to escape than SH and C rats throughout training (pr0.0001). This deficit disappeared when these, and other rats (RHC, SH & C; Ns=8, 4 & 4) which had received pre-op training also, were then trained with a visible platform (lcm above water). Finally, the rats were returned to the hidden platform task (the RHC lesion deficit reappeared) and then given a 60 sec transfer test during which the hidden platform was removed 

failed to <u>search</u> near the now absent platform, but often passed through its exact former location during semi-stereotyped traverses of the entire pool. The

groups differed with respect to time spent in the training groups differed with respect to time spent in the training quadrant (p<0.0001) but not crossings of the correct location (p>0.10). Thus rats with RHC lesions can learn the <u>procedural</u> rule of going to a particular place, but do not recognise it or initiate localised search upon failing to find it. This lack of <u>declarative</u> spatial knowledge (Squire and Cohen, 1983) was also reflected in the failure of "recovered RHC" rats to discriminate two visible platforms by their spatial location in a later emperiment. Datailed biotelogical conviction (CM and a later experiment. Detailed histological examination (CV and Fink-Heimer) has shown the lesions to be complete.

PLACE NAVIGATION IN RATS AS A FUNCTION OF AGE. F. Schenk 100.10 F. Inglin and R.G.M. Morris. Institute of Physiology, University of Lausanne, 1011 Switzerland and Physiological Laboratory, University of St. Andrews, Scotland.

Hippocampal damage have been shown to cause a significant defi-cit in place but not in cue guided navigation (Morris et al., Nature, 297: 681-3, 1982; Morris & Schenk, in prep.). This study examined whether the maturation of the hippocampus in young Rodents would be accompanied by significant changes in place navigation.

Young hooded rats were trained to escape from opaque water onto small platform (Ø 8.0 cm) at a fixed position in a circular swimming pool (Ø 100 cm). Only spatial room cues were available for locating the platform position in the condition "place only"; a small piece of wood (5 cm height) was placed onto the platform as an additionnal local cue in the condition "place + cue". Five litters (8-10 pups) were weaned at 20 days. Training consisted in four daily sessions of resp. 4, 4, 8 and 8 trials, beginning when the individuals were either 21 (n=24) or 35 days old (n=23).

The young rats (n=17) were slower to escape than their 35-dayold littermates (n=16) (p<0.01), and showed longer path length (p<0.05) throughout training in the condition "place only". On a subsequent "transfer test" during which the hidden platform was removed from the pool, young rats were less accurate than older subjects in passing through its exact former location (p < 0.05). The behaviour of the 21-day-old rats (n=7) was more similar to that of the 35-day-old subjects (n=7) at the end of "cue + place" training. However, removal of the wooden cue for the subsequent 15 trials "place only" condition) strongly impaired the performance (path length and latency,  $p \le 0.001$ ) of the young but not of the older rats.

Complementary data from 28 and 42-day-old subjects help discussing critical days for the maturation of place navigation in young rats. Detailed analysis of the pathways suggests that onset of searching behaviour impairs performance between 26 and 32 days of age.

100.12 LESIONS OF THE NUCLEUS BASALIS MAGNOCELLULARIS IMPAIR LONG-TERM MEMORY IN RATS. H.C. Fibiger, C.L. Murray\* and A.G. Phillips, Div. Neurological Sciences, Dept. Psychiatry; Dept. Psychology, University of British Columbia, Vancouver, B.C., Canada, V&T LWS. It has been demonstrated that there is a loss of cholinergic neurons in the basal forebrain of patients dying with Alzheimer's disease and this appears to be the basis of the consistent decrease in cortical choline acetyltransferase (ChAT) activity that is observed in this syndrome. At the present time, the functional consequences of the loss of this cholinergic innervation of the cortex are not known. Inasmuch as there is a profound impairment of certain types of memory in Alzheimer's patients, the present experiments were designed to investigate spatial memory in rats that received bilateral ibotenic acid lesions of the nucleus basalis magnocellularis (nBM), the origin of a major cholinergic projection to the cortex in this species. Under halothane anesthesia, male Long-Evans rats (300-350 gm) received bilateral injections of ibotenic acid (5 µg in 1 µL) or vehicle at co-ordinates APT.2, Lt2.4, and DV+2.7 rm from stereotaxic zero with the animal's head held in the horizontal plane. Six weeks postoperatively the animals were food deprived to 85% of free-feeding weights and received training in a 16 arm radial maze in which 9 of the arms contained food. The animals were trained to run this maze for food reinforcement over a period of 36 days, during which measures of working or short term memory (defined as the number of entries into previously unentered baited arms) and reference or long term memory (defined as the tote or long

memory (defined as the number of entries into previously un-entered baited arms) and reference or long term memory (defined as the total number of entries into the baited arms) were ob-tained (Olton, D.S. and Samuelson, R.J., J.exp.Psych., 2:97,1976; Olton, D.S. and Papas, B.C., <u>Neuropsychologia</u>, <u>17</u>:669,1979). Unlike the control group, animals with lesions of the nBM failed to show evidence of spatial reference memory over the 5 week training period. On the other hand, working memory was not disrupted by these lesions. At the end of the 5 week training period, the nBM lesioned group received intraperitoneal injec-tions of physostigmine sulfate (0.5 mg/kg) 30 min before each daily session. The reference memory performance of the physostions of physostigmine sulfate (0.5 mg/kg) 30 min before each daily session. The reference memory performance of the physostigmine treated animals improved rapidly and significantly to approach that of the control group. Cortical ChAT activity was found to be reduced by approximately 50 percent whereas hippocampal ChAT activity was not affected by the lesions. The data indicate that the cholinergic innervation of the cortex is an important neuronal substrate for long term spatial memory and suggest that the loss of cortical ChAT activity in Alzheimer's patients may be responsible for some of the memory deficits associated with this disease.

THE ROLE OF THE POSTERIOR PARIETAL ASSOCIATION CORTEX IN THE 100.13 RCCESSING OF SPATIAL EVENT INFORMATION. B. V. DiMattia\* and R. P. Kesner. Dept. of Psychology, University of Utah, Lake City, UT 84112. -Salt

Damage to the posterior parietal association cortex (PPC) in humans results in deficits for information concerning spatial aspects of their environment. These patients typically exhibit an inability to discriminate near from far objects, an inability to read or draw maps or diagrams of familiar spatial locations,

an induitive to discriminate hear from far objects, an inhority to read or draw maps or diagrams of familiar spatial locations, an impaired recent spatial memory and a general loss of "topographic sense". In addition, there is a deficit in attention to spatial stimuli, which appears to be a function of lesion size and level of difficulty of the task. In order to test whether there might be a correspondence between rats and humans regarding the role of PPC in the processing of spatial event information, the effect of PPC lesions in the rat on memory for a list of five spatial events (arms on an Olton eight-arm radial maze) was examined. Animals were trained to employ either a win-stay or a win-shift rule on the maze and serial position functions were generated for each group of animals. These tasks were chosen because it is assumed that they have differential attention requirements, because (a) the win-shift rule is considerably easier for the rat to learn than the win-stay rule show a serial position curve which includes significant primacy and recency effects, whereas only recency effects are seen with animals that have learned the win-shift rule. rule

rule. Half of the win-stay and half of the win-shift animals were given bilateral aspiration lesions of PPC while the remaining animals from each group received sham operations. In the win-stay task, rats' ability to perform was deleteriously affected by bilateral removal of PPC, i.e., there was a disruption of memory performance for every position on the list, including both primacy and recency positions. However, comparable lesions of PPC did not produce any post-operative impairment of memory in the win-shift task. Sham operated control animals did not show a deficit in either task. Thus. the PPC lesions only affected memory for spatial events

Control animals did not show a deficit in either task. Thus, the PPC lesions only affected memory for spatial events in the task that is assumed to have greater attentional requirements for spatial information. An alternative possibility is that the win-stay task requires the utilization of more spatial information than the win-shift task. The results of the present study provide support for an equivalency of mnemonic function of the PPC in both rats and humans.

DISSOCIATION OF ITEM AND ORDER MEMORY IN RATS FOLLOWING MEDIAL PREFRONTAL CORTEX LESIONS. R. P. Kesner and T. H. Holbrook\* (SPON: M. E. ELLIS). Dept. of Psychology, University of Utah, 100.14 Salt Lake City, UT 84112.

Humans with prefrontal lobe damage have difficulty in remembering the temporal ordering of events. When these patients are tested for item and order memory for a list of events, they show poor memory for order information, but have normal memory for item information. In order to test whether there is a correspondence in function of prefrontal cortex in rats and humans, rats were tested for item and order memory for a list of items (places on a maze). Rats were trained on an eight arm radial maze for Froot Loop

Rats were trained on an eight arm radial maze for Froot Loop reinforcement. After extensive training each animal was allowed on each trial (one per day) to visit four arms in an order that was randomly selected for that trial (study phase). The sequencing of the four arms was accomplished by sequentially opening of Plexiglas doors (one at a time) located at the entrance of each arm. Immediately after the animal had received reinforcement from the last of the four arms, the test phase began. The test for order memory consisted of opening of either the first and second, second and third, or third and fourth door that occurred in the sequence. The rule to be learned leading to an additional reinforcement was to choose the arm that occurred earlier in the sequence. The test for item memory consisted of opening of a door that was previously visited for to an additional reinforcement was to choose the arm that occurred earlier in the sequence. The test for item memory consisted of opening of a door that was previously visited for that trial and a door that was not. The rule to be learned resulting in an additional reinforcement was to choose the arm previously visited during the study phase of the trial (win-stay rule). The order of presentation of the two tests was varied randomly randomly.

randomly. Following extensive training, animals performed better than chance for each item position for both tests. The animals then received medial prefrontal cortex aspiration lesions. Results indicated a complete loss for order memory. This order deficit appeared even when (a) the list length was only two items, (b) the items presented during the study phase of a 5-item list were constant from trial to trial and, (c) the animal was allowed to colf order during the study phase.

self-order during the study phase. In contrast, there was excellent memory for the first item of the list with a deficit for the remaining items on the item memory test. In addition, memory was excellent for all items of a 5-item list when the study phase was constant from trial to trial.

Thus, rats can remember the occurrence, but not the temporal ordering of spatial events. This suggests that there is a correspondence between rats and humans with respect to the mnemonic functions of prefrontal cortex.

**BIOGENIC AMINES I** 

A NEW RECEPTOR FOR 5-HT: CHARACTERIZATION AND LOCATION IN THE 101.1 NERVOUS SYSTEM OF THE GUT. <u>Theresa Branchek, Mandes Kates</u> <u>Michael D. Gershon</u>, Dept. Anatomy and Cell Biology, Co Univ., P&S, New York, NY 10032. Columbia

Although the existence of enteric serotonergic neurons is now well established, relatively little is known about enteric sero-tonin (5-HT) receptors. We have therefore sought to characterize these receptors utilizing a filtration assay and radioautography with  ${}^{3}H{}^{-5}$ -HT as a radioligand. Satyrable, reversible, specific, high affinity (K<sub>D</sub> = 5nM) binding of  ${}^{3}H{}^{-5}$ -HT was found to membranes isolated from the submucosa-mucosa of the gut and from the longitudinal smooth muscle with attached myenteric plexus. Specific  $^{4}$ H-5-HT binding sites were localized by radioautography to discrete patches in the gut wall corresponding to the location of the myenteric plexus and to non-epithelial components of the submu-cosa-mucosa. The binding of  ${}^{3}$ H-5-HT was not inhibited by antagonists active at the following of  $H_2$ -fit was not initiated by antegorists active at the following receptors: a- and B-adrenoceptors (phentolamine, propranolol),  $H_1$  histamine (diphenhydramine, mianserin, cyproheptadine),  $H_2$  histamine (cimetadine), or dopamine (butaclamol, domperidone, metoclopramide, spiroperidol).  $H_2$ -HT was also resistant to displacement by agents known to be active at the two 5-HT receptors that have been identified in the CNS, the S2 (LSD, spiroperidol, ketanserin, mianserin, cyproheptadine) and S1 (LSD, methysergide, trazodone, cinanserin, metergoline, quipazine, 6-nitroquipazine, 5-methoxytryptamine) sites respectively. The enteric <sup>3</sup>H-5-HT binding sites are thus specific to 5-HT but unique to the bowel.

unique to the bowel. Structure-activity requirements for binding to the enteric 5-HT site were studied by analyzing the ability of analogues to compete with  ${}^{3}\text{H}$ -5-HT. Tryptamine, 5-aminotryptamine, and 5-methoxytrypt-amine all failed to displace  ${}^{3}\text{H}$ -5-HT at 10,000 times the 5-HT concentration, whereas 6-HT, 5,6-dihydroxytryptamine, and 5,6,7-trihydroxytryptamine were nearly as potent as 5-HT itself. Dis-placement of the hydroxyl group to the 4 or 7 positions decreased activity. A hydrowyleted index activity. A hydroxylated indole ring, preferably at the 5 or 6 position, thus seems to be necessary for binding to the 5-HT site. In contrast, the aliphatic side chain of 5-HT appeared to be relatively unimportant in determining binding to the enteric 5-HT site and could be deleted. These requirements are similar to those needed for pharmacological activation of enteric neurons but dissimilar to those needed for activation of smooth muscle. It is concluded from the effects of antagonists, the correlation of structure-activity requirements for 5-HT binding with the pharma-cological activation of enteric neurons by 5-HT, and the radio-gutographic localization of  $^{-2}H-5-HT$  binding, that the enteric  $^{-2}H-5-HT$  binding site is a unique neural 5-HT receptor. Supported by NIH grants NS12969 and 5T32 NS07062.

<sup>3</sup>H-TRYPTAMINE BINDING IN THE BRAIN AND SPINAL CORD: IN VITRO 101.2

H-IRYPIAMINE BINDING IN THE BRAIN AND STINAL CORD: IN VIIKO AUTORADIOGRAPHY. J.K. McCormack\*, A.J. Beitz and A.A. Larson. Dept. of Vet. Biology, Univ. of Minnesota, St. Paul, MN 55108. Tryptamine, an endogenous trace amine, is currently postu-lated to be a neuromodulator or neurotransmitter in the mammal-ian CNS. Both electrophysiological and pharmacological studies have demonstrated differential responses of tryptamine and serotonin (5-HT). Recently, a high affinity binding site has been described for tryptamine in the rat brain homogenate by Kellar and Cascio (Eur. J. Pharmacol. 78:475, 1982). The pre-sent study further characterizes tryptamine binding throughout the CNS and delineates its distribution using autoradiographic techniques.

Saturation studies on 20 µ thick brain sections suggest a single class of binding sites (Hill plot coefficient  $\sim 1.00$ ) with a high affinity (K<sub>D</sub>  $\sim 13.00$  nM). In a competition study, 5-HT failed to significantly inhibit tryptamine binding (K<sub>I</sub> = 1.37  $\mu$ M). Maximum specific to non-specific binding was achieved using a 30 min incubation period at 25 °C in a solution containing 0.1 M Tris citrate (pH = 7.4), 5 mM ascobic acid, 20  $\mu$ M pargyline and 2 nM <sup>3</sup>H-tryptamine. Tissue sections were processed for <u>in vitro</u> autoradiography using sections from rat brain and brain stem and from dog brain stem and spinal cord. Highest binding occurred in limbic structures: the anterior olfactory nucleus, olfactory tubercle, septal area, amygdaloid complex, anterior cingulate gyrus and hippocampus. Binding was also evident in the nucleus accumbens and medial hypothalamus. In the brain stem, binding was most notable in the interpedun-cular nucleus, superficial layer of the superior colliculus. cutar nucleus, superiscal layer of the superior collicuus, periaqueductal gray, substantia nigral region, spinal trigeminal nucleus, inferior olivary nucleus and the region of the nucleus solitarius. Binding was evident in both the dorsal and ventral horns of the spinal cord. These results demonstrate that try-ptamine binding sites are predominant in limbic structures and also are found throughout the spinal cord and selective brain stem sites.

GUANINE NUCLEOTIDES MODULATE CORTICAL S2 SEROTONIN RECEPTORS, 101.3 M. Titeler, G. Battaglia and M. Shannon<sup>\*</sup> Department of Pharma-cology, University of Toronto, Toronto, Ontario M5S 1A8.  $S_2$  serotonin receptors appear to mediate several important CNS and peripheral effects of serotonergic drugs (1,2). It has been

reported that guanine nucleotides do not regulate cortical S2 serotonin receptors (1). Contrary to these findings we find a pronounced agonist-

specific effect of guarine nucleotides in modulating "H-ketan-serin-labelled cortical S2 serotonin receptors (see Table). Agonist interactions, in the absence of nucleotides, display high and low affinity components in inhibition of  $^{3}\mathrm{H}\xspace$  ketanserin binding. GTP apparently converts the high affinity receptor population to low affinity (3). Antagonist interactions are not affected (see Table). Computer-assisted analysis of a two-state model for the  $S_{2}$ 

Computer-assisted analysis of a two-state model for the  $S_{2_1}$  serotonin receptor will be presented. These results are similar to results from radioligand studies of adenylate cyclase coupled receptors, which are modulated by GTP through a guanine nucleotide binding protein. Therefore, we have undertaken studies to determine whether there is an  $S_2$  serotonin receptor coupled to adenylate cyclase activity through a guanine-nucleotide binding protein.

<sup>125</sup>I-LSD: A SELECTIVE, HIGH SENSITIVITY LIGAND FOR SEROTONIN SHt, RECEPTORS. <u>P. Hartiz. M. Kadan. A. Krohn. M. Evans.</u> and R. Waltz<sup>\*</sup>. Dept. of Biology, Johns Hopkins University, Baltimore, MD 2128. We synthesized unlabeled 2I-LSD by the method of Troxler and Hofmann (Helv. Chim. Acta. 60, 2160 (57)). 2I-LSD was over 98% pure by HPLC analysis. This ligand displays a high affinity for serotonin SHt<sub>2</sub> (S<sub>2</sub>) receptor sites in rat frontal cortex (IC<sub>20</sub> = 6.4 mM for <sup>3</sup>H-spiroperidol) and a moderate affinity for dopamine D<sub>2</sub> receptor sites in bovine caudate (IC<sub>20</sub> = 16 nM for <sup>3</sup>H-spiroperidol and 24 mM for <sup>3</sup>H-domperidone). In contrast to the parent compound d-LSD, the iodinated ligand is selective for these sites, showing only a weak affinity for SHt, receptor sites (IC<sub>20</sub> = 99 nM for <sup>3</sup>H-ADTN in bovine caudate). We synthesized <sup>325</sup>I-LSD using N-<sup>125</sup>I-succinimida in c (anobi

Sit, receptor sites (IC<sub>1</sub>, = 99 nM for <sup>3</sup>H-5Ht in frontal cortex) or D, dopamine receptors' (IC<sub>10</sub> = 110 nM for <sup>3</sup>H-ADIN in bovine caudate). We synthesized <sup>123</sup>I-LSD using N-<sup>123</sup>I-succinimide in a modification of the method of TroxIer and Hofmann. It comigrates with 2I-LSD in a high resolution 2D-HPTLC system and has been synthesized carrier free (2175 Ci/mmol). It is stable for over 2 months under the proper conditions. In rat frontal corter homogenates, <sup>123</sup>I-LSD binding erhibits a linear Scatchard behavior with K<sub>d</sub> = 5.6 nM and B<sub>max</sub> = 37 fmol/mg tissue. The binding is reversible, stereoregic if and is destroyed by boiling the membranes. The binding is potently displaced by the 5Ht, ligands spiroperidol. mianserin and cinanserin (IC<sub>2</sub>, values of 3.1, 15.4 and 19 nM respectively) and serotonin is the most potent neurotransmitter in displacing this binding represents 75-85% of tal binding it both tissues. Displacement of <sup>123</sup>I-LSD binds primarily to a single class of sites with K<sub>d</sub> = 3.6 nM and B<sub>max</sub> = 24 fmol/mg it soue. Specific binding represents 75-85% of moltal cortex, indicating that <sup>123</sup>I-LSD preferentially labels 5Ht, receptors in bovine caudate. If this 5Ht, binding is inhibited by the inclusion of 0.3 µM Minnserin, a second component of <sup>123</sup>I-LSD binding is revealed with a K<sub>d</sub> = 27 nM and B<sub>max</sub> = 37 fmol/mg itssue. This secondary binding is most potently inhibited by dopaminergic ligands with a rank order of potency for agonists of: apomorphine > dopamine > pinephrine > norepinephrine, serotonin. The rank order of antagonist inhibition resembles that for <sup>3</sup>H-SD appears to label either serotonergic SHt, or dopaminergic D, sites in bovine caudate. <sup>124</sup>I-LSD is the first iodinated ligand available for sensitive than other available [<sup>3</sup>H] ligands for these receptor sites. <sup>124</sup>I-LSD displays an excellent ratio of specific to nonspecific binding, a high affinity for SHt, receptor sites, and a high degree of selectivity in its binding. (Supported by NSF grant BNS 81-08080.)

McBride\*, J.J. Mann, B. McEwen and A. Biegon. Psychopharmacology Lab., Cornell University Medical College, NY, NY 10021. In recent years the platelet has been increasingly utilized as a model for the serotonergic neuron. The following study was undertaken to identify the types of serotonin binding sites on the human platelet membrane, and compare their binding characteristics to serotonin receptors found in human brain. A high affinity, saturable <sup>3</sup>H-spiroperidol binding site was demonstrated on the intact human platelet with a  $K_D$  of 2.7  $\pm$  0.8 nM and a Bmax of 1.4  $\pm$  0.5 pmoles/10<sup>8</sup> platelets. Binding was preferentially displaced by serotonin-2 (S-2) receptor

101.5 CHARACTERIZATION OF SEROTONIN BINDING SITES ON HUMAN PLATELETS: METHODS FOR STUDYING SEROTONIN RECEPTOR FUNCTION IN VIVO. P.A.

preferentially displaced by serotonin-2 (S-2) receptor antagonists such as ketanserin and cinanserin (IC<sub>50</sub> approximately 80nM), in contrast to 5-hydroxytryptamine (IC<sub>50</sub> = 2.3uM), the serotonin uptake inhibitors imipramine (IC<sub>50</sub> > 10uM) and fluoxetime (IC<sub>50</sub> = 1.3uM), and the dopamine antagonist sulpiride (IC<sub>50</sub> 10uM). Comparison of the IC<sub>50s</sub> of a range of drugs for displace-ment of <sup>3</sup>H-spiroperidol binding to human platelets and frontal cortex showed a correlation of 0.95,  $p \leq 0.001$  (Pearson Product Memory). These studies provide attempt of a subscience that a 5.3 Roment). These studies provide strong evidence that an S-2 receptor is present on the human platelet. A single population of <sup>3</sup>H-serotonin binding sites was also

A single population of <sup>3</sup>H-serotonin binding sites was also located on the intact human platelet, which appears to represent the 5-hydroxytriptamine uptake site. The Kp of this site was  $42 \pm 18n$ M. Serotonin uptake inhibitors were the only effective displacing agents found ( $1C_{508} = 10-800$ M) and 1.0uM fluoxetine totally abolished detectable specific binding of <sup>3</sup>H-serotonin. A highly significant correlation (r = 0.99,  $p \leq 0.001$ ) between the potencies of drugs as <sup>3</sup>H-serotonin displacing agents and serotonin uptake inhibitors of interval alcoholet paraete stores entities of the second uptake inhibitors in intact platelets presents strong evidence that  ${}^{3}\text{H}\text{-serotonin}$  is bound to the uptake site. No  ${}^{3}\text{H}\text{-serotonin}$ binding site with features of the serotonin-1 (S-1) receptor in brain was located on the platelet. Contrast of the  $\rm IC_{50s}$  of multiple agents for displacement of  $^{3}\rm H-serotonin$  binding to platelets and frontal cortex was nonsignificant (r = 0.31, p)0.2).

The results described above suggest that specific <sup>3</sup>H-spiroperidol binding to the intact human platelet could be used as a model to explore potential defects in central S-2 receptor model to explore potential defects in central 5-2 receptor activity in a number of psychiatric and neurologic illnesses where alterations of serotonergic function have been reported. These include, in particular, depression, autism, and mental re-tardation. Furthermore, assay of 3H-serotonin binding to the platelet uptake site might supplement studies of the kinetics of altered platelet serotonin uptake reported in depressed patients. **101.6** THE USE OF [<sup>3</sup>H] RO 11-2465 IN THE SOLUBILIZATION, PARTIAL PURIFICATION AND RECONSTITUTION OF PLATELET IMIPRAMINE BINDING

SITES. <u>Alan Davis</u>, Psychopharmacology, Clarke Institute of Psychiatry, 250 College St., Toronto, Ontario, CANADA, M5T 1R8. [<sup>3</sup>H] Ro 11-2465 is a structural analogue of chlorimipramine which has high affinity for the imipramine binding site. These binding sites are believed to control serotonin transport into both platelets and CNS serotonergic neurons. In an attempt to

both platelets and CNS serotonergic neurons. In an attempt to elucidate the exact molecular relationship between the binding sites and the transporter protein, I have developed a procedure to solubilize and reconstitute the imipramine binding site. Outdated human platelets were incubated with  $[^{3}H]$  Ro 11-2465 at 4° C. in Tris-ions buffer (50mM Tris, 120mM NaCl, 5mM KCl, pH 7.4). Under these conditions this ligand becomes effectively irreversibly bound. The platelets were solubilized with 2% sodium cholate (containing tracer amounts of  $^{14}$ C detergent). Gel permeation chromatography of cholate-solubilized  $[^{3}H]$  Ro 11-2465 bound sites implied a Stokes radius of 4.1mm. Azolectin (Assoc. Conc's) (1 vol at 10 mg/ml) was added to 2 vol of cholate-solubilized material and the mixture dialysed overnight. Essentially no sodium cholate was associated with the cloudy dialysate obtained. Reconstituted  $[^3{\rm H}]$  Ro ll-2465 binding sites could be retained on filters (0.45 µm pure size) and showed vesicular-like structure under electron microscopy. Table 1 shows the recoveries of the binding sites and protein into the reconstituted vesicles.

Future studies will focus on whether or not true vesicles are formed and the ability of such vesicles to transport serotonin. By such an experimental approach, it is hoped to show whether the imipramine binding site and the serotonin transporter protein reside on the same molecule, or are separate entities.

DISCRIMINATIVE CUE PROPERTIES OF QUIPAZINE: MEDIATION 101.7 BY SEROTONIN-2 BINDING SITES. R.L. Friedman\*, R.J. Barrett\* and E. Sanders-Bush. Dept. Pharmacol., Vanderbilt University, Tennessee Neuropsychiatric Nashville, TN 37232.

Nashville, TN 37232. Distinct serotonin (5HT) receptor subtypes have been defined in previous radioligand binding studies. Although the value of such <u>in vitro</u> binding studies in identifying and characterizing 5HT-related sites is unquestionable, other approaches are required to determine the relevance of these binding sites to re-ceptors operating <u>in vivo</u>. Our laboratory has focused on the development of behavioral models of 5HT binding sites using the drug discrimination paradigm

The relative abilities of ten possible 5HT binding The relative abilities of ten possible 5HT antago-nists to block the discrimination of the interoceptive effects of the 5HT agonist, quipazine (Q), were assessed. Male Sprague-Dawley rats were trained to assessed. Male Sprague-Dawley rats were trained to discriminate 2.5 mg/kg of Q from saline. Following acquisition of the discrimination, different antagonists were administered 90 minutes prior to a 5 minute test with 1 mg/kg of Q (which gave 75% Q-lever responding). At least 3 doses of each antagonists were tested. All of the antagonists were able to block completely the Q-cue and none substituted for Q when given alone. ID values for antagonism of the Q-cue were estimated by linear regression analyses of loglogi plots. logit plots.

The binding of <sup>3</sup>H-5HT (5HT-1 site) and of <sup>3</sup>H-spi-perone (5HT-2 site) was determined in crude membranes prepared from frontal cortex of naive rats as described previously (Naunyn-Schmeideberg's Arch. Phar-macol. 321: 165-170, 1982). IC<sub>5</sub> values for the antagonists were determined in competition binding studies. These were compared to the ID<sub>50</sub> values derived from the Q discrimination studies. A signi-ficant correlation (r = 0.87, r < 0.01) was found derived from the Q discrimination studies. A significant correlation (r = 0.87; p < 0.01) was found between the relative antagonists' affinities for the 5HT-2 site and their inhibition of Q discrimination. In contrast, no correlation existed between the Q discrimination and the 5HT-1 site (r = 0.15). These results suggest that the discriminative cue properties of Q may be mediated by central 5HT-2 sites. VASCULAR PREPARATIONS: USE IN THE DEVELOPMENT SEROTONERGIC AGENTS SPECIFIC FOR RECEPTOR SUBTYPES. E.W. Taylor<sup>\*</sup>, <u>S.P.Duck</u>les and D.L.Nelson Debt. of Pharmacol. & Taylor<sup>\*</sup> 101.8

Jaylor<sup>\*</sup>, S.P.Duckles and D.L.Nelson, Dept. of Pharmacol. & Toxicol., Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ 85721. Ligand-binding studies using (<sup>3</sup>H)serotonin ((<sup>3</sup>H)5HT) have shown that some tryptamine analogs can discriminate between subgroups of 5HT-1 binding sites, suggesting that some of these compounds may be useful in the development of selective agonists and/or antagonists for specific 5HT receptor subtypes. Confirmation of this has been difficult due to the lack of tests of functional 5HT-1 receptors. Recently, however, Peroutka et al. (Brain Res. <u>259</u>: 327-330, 1983) reported that 5HT-induced contractions of canine basilar artery correlate with 5HT-1 as opposed to 5HT-2 binding sites. Therefore, to test the tryptamines synthesized in our laboratory for activity at functional receptors two systems were examined, the canine basilar artery as a model tissue containing 5HT-1 receptors and the rabbit femoral artery as a hole fissue containing  $\beta HT-1$  receptors. Preliminary experiments compared these tissues using metergoline, an antagonist with high affinity (Ki = 0.3-5.0 nM) for both  $\beta HT-1$  and  $\beta HT-2$  sites, and ketanserin, a relatively selective  $\beta HT-2$ antagonist having low affinity (Ki = 3  $\mu$ M) for 5HT-1 binding sites. pA<sub>2</sub> analogons having low animity (K) = 5 km/ 10 5 m<sup>-1</sup> binding sites.  $PA_2$  measurements indicated that metergoline was essentially equipotent in the two tissues with K<sub>B</sub>'s of 1-2 nM. Ketanserin, however, showed a nanomolar K<sub>B</sub> value in the femoral artery and a micromolar K<sub>B</sub> value in the basilar artery. This was consistent with the existence of 5/HT-2 receptors in the rabbit femoral artery and 5/HT-1 receptors in the canine basilar artery. The canine middle cerebral arteries were also examined and their responses to these antagonists and various tryptamines were found to be essentially identical to those of the basilar, though the maximal contractions were weaker. Thus, in addition to the basilar, other maximal contractions were weaker. Thus, in addition to the basilar, other parts of the canine cerebral circulation may also show 5HT-1 receptor pharmacology. Two series of tryptamines were selected for study in the vascular systems because ligand binding studies of the parent compounds, N,N-diisopropyltryptamine (DIPT) and morpholinyltryptamine (4-(2-(3-indoly))ethyl)-morpholine, MLT), indicated that they could discriminate between two different 5HT-1 binding sites. Computer analysis with a two site model suggested circs with Kd values of approximately 40 pM and 4.5 site model suggested sites with Kd values of approximately 40 nM and 4.5  $\mu$ M for both compounds. 5-Benzyloxy, 5-methoxy and 5-OH analogues of DIPT and MLT were subsequently synthesized, and they all showed this discriminative ability to varying extents. Compounds from each series discriminative ability to varying extents. Compounds from each series were tested in the vascular preparations, and it was found that the DIPT analogues acted as agonists while the MLT series were generally antagonists. 5-MethyoxyMLT and 5-OHMLT were moderately potent antagonists (Kg (1  $\mu$ M), especially in the basilar artery preparation; however, MLT itself was almost inactive. The ED<sub>50</sub> of the agonist DIPT in the basilar artery was in the micromolar range, suggesting that the 5HT-1 receptors in this tissue more likely correspond to the lower affinity sites identified using the ligand-binding technique. (Supported by NIH Grant NS16605).

CHARACTERIZATION OF SEROTONIN RECEPTOR SUBTYPES IN CANINE VASCULATURE. S.J. Peroutka, S.B. Banghart\* and G.S. Allen\*. Departments of Neurology and Neurosurgery, Johns Hopkins Hospital Baltimore, Maryland 21205.

Serotonin is a potent vasoconstrictor in many vascular smooth muscle systems. However, both drug potencies and the requirement for extracellular calcium vary greatly depending on the specific vessel studied. For example, serotonergic drug interactions with canine basilar arteries are mediated via 5-HT<sub>1</sub> receptors as defined by brain membrane studies (Peroutka et al, <u>Brain Research</u>, <u>259</u>:327-331, 1983). In addition, serotonin induced contractions of canine basilar artery segments are dependent on the entrance of extracellular calcium via calcium ion channels. Serotonin induced contractions are therefore potently blocked by specific calcium channel antagonists. Analysis of canine basilar artery contractions allows the site of drug antagonism to be localized

to either the serotonin receptor or calcium channel binding site. In marked contrast, significantly higher doses of serotonin are needed to contract the canine femoral artery. Similar con-tractions are elicited in the presence or absence of extracellular calcium, suggesting that serotonin activates internal stores of calcium that lead to the initiation of the contractile mechanism. As a result, calcium channel antagonists have a minimal effect on serotonin induced contractions of the canine femoral artery. Drug antagonism studies suggest that serotonin induced contractions of the canine femoral artery are mediated via 5-HT2 receptors.

In summary, 5-HT1 receptors mediate contraction of canine basilar artery segments via the opening of specific calcium ion channels. By contrast, serotonin induced contractions of the canine femoral artery appear to be mediated by 5-HT2 receptors and are not dependent on the entrance of extracellular calcium. Canine artery contractions provide a physiologic model for the analysis of  $5-\mathrm{HT}_1$  and  $5-\mathrm{HT}_2$  receptor subtypes that have previously been biochemically identified in brain membranes.

# 101.10 PHARMACOLOGIC CORRELATES OF 5HT-LESION SYNDROMES. <u>M.Pranzatelli</u>, <u>G. Rubin</u>, and <u>S.R. Snodgrass</u>. Neurology Research, Childrens Hos-pital of Los Angeles, CA 90054. The effects of 5-HTP, fenfluramine (FF), and p-chloroampheta-

The effects of 5-HTP, fenfluramine (FF), and p-chloroampheta-mine (PCA) on brain regional amine concentration (DA, NE, and SHT by HPLC), 5HT-S1 binding ( $^{3}$ H-5HT with 5HT as displacer), loco-motor activity (photocell activity cage) and videotaped behaviors (rearing, pivoting/circling, hindlimb abduction, forepaw tremor, lateral head weaving, backing up-- as scored by "blind" observer) were evaluated in 45 adult male rats. Prior treatment included multiple intracisternal injections of 5,7-DHT or vehicle, and be-havioral testing began two weeks after making the lesions. 5-HTP (65 mg/kg) IP, after DHT lesioning) and FF (15 mg/kg), alone or in combination, reduced or eliminated rearing. Backing up behavior was specific to PCA (25 mg/kg) and FF. Forepaw tremor was evoked by all the drugs, but FF had a slight effect. Suppres-sion of locomotor activity decreased in the order of FF, 5-HTP, and PCA. Neither morphine sulfate (8 mg/kg) or naloxone (3 mg/kg) prevented the FF or 5-HTP induced syndromes. Four DHT injections caused a 90-100% depletion of 5HT concur-

Four DHT injections caused a 90-100% depletion of 5HT concur-Four DHT injections caused a 90-100% depletion of 5HT concur-rently in neocortex, hippocampus, striatum, septum, pons, cere-bellum, and cervical spinal cord, yet did not correspondingly de-plete midbrain or diencephalon more than single injections. 5HT depletions following PCA were greater in the thalamus and mid-brain than those of DHT, but were similar, though lesser in mag-nitude, in other regions. FF induced the least depletion, and when given after DHT lesioning, did not alter the pattern or de-gree of 5HT depletion. Significant catecholamine depletion oc-curred only with FF and PCA in the midbrain. Although the different drugs resulted in disparate patterns of regional 5HT depletion, they were able to cause similar behavior-al syndromes. However, abnormal responses to 5HTP were seen only

regional Sni depiction, they were able to cause similar depiction-al syndromes. However, abnormal responses to SHTP were seen only after previous treatment with DHT. The degree of 5HT depletion correlated directly with behavioral score and inversely with loco-motor activity, but did not correlate with Kp or  $B_{max}$  of 5HT-S<sub>1</sub> binding, studied two and one-half weeks after lesioning.

101.11 HISTAMINE- AND CIMETIDINE-INDUCED DEPRESSION OF SEROTONERGIC HISTAMINE- AND CIMETIDINE-INDUCED DEPRESSION OF SERGIORERGIC NEURONS IN THE DORSAL RAPHE: INVOLVEMENT OF H<sub>2</sub> AND GABA RECEPTORS J.M. Lakoski, D.W. Gallager and G.K. Aghajanian, Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508 Histamine and the H<sub>2</sub>-antagonist cimetidine have potent inhibitory effects when applied iontophoretically onto serotonin (5-HT)-containing cells in the dorsal raphe (DR)

serotonin (5-HT)-containing cells in the dorsal raphe (DR) nucleus; this response to histamine appears not to be mediated by either a typical H<sub>1</sub> or H<sub>2</sub> receptor type (Lakoski and Aghajanian, Soc. Neurosci. Abstr., <u>8</u>: 276, 1982). Both the histamine- and cimetidine-induced inhibition of cell firing were found to be selectively attenuated by the iontophoretically applied GABA antagonists bicuculline and picrotoxin, indicating these physiological effects may be mediated directly or indirectly at a GABA receptor complex. Therefore, we investigated the ability of histamine and cimetidine to displace radioligands specific for GABA (<sup>3</sup>H-FLU) binding sites in membranes (P2 fraction) prepared from several brain regions in adult male rats. several brain regions in adult male rats.

Therefore brain regions in adult male rats. As in previous studies, histamine was unable to displace <sup>3</sup>H-MUS binding ( $10^{-8}$ M to  $10^{-3}$ M) in membranes prepared from cortex, hypothalamus, cerebellum and DR; likewise, <sup>3</sup>H-FLU binding was not altered by histamine. In contrast, the imidazole-derived H<sub>2</sub> antagonists, including cimetidine, produced GABA agonist-like inhibition of <sup>3</sup>H-MUS binding and enhancement of <sup>3</sup>H-FLU binding (DR: IC<sub>50</sub> GABA = 0.20 µm, IC<sub>50</sub> CIMET = 0.46 µm and EC<sub>50</sub> GABA = 0.22 µm, EC<sub>50</sub> CIMET = 2.20 µm, respectively). On the other hand, the non-imidazole-derived H<sub>2</sub>-antagonist ranitidine did not significantly alter <sup>3</sup>H-MUS or <sup>3</sup>H-FLU binding. Since ranitidine did not have GABA-like binding, properties we tested its ability to block the histamine-induced depression of 5-HT cell firing in the DR. Iontophoretically applied ranitidine selectively attenuated the histamine-induced but not the cimetidine- or GABA-Induced inhibition of cell firing. These data indicate that the response to histamine in the DR can be blocked by at least one type of H<sub>2</sub>-receptor antagonist,

can be blocked by at least one type of H2-receptor antagonist, ranitidine. The data also suggest that histamine's effect may ranitidine. The data also suggest that histamine's effect may be mediated by an indirect action at a GABA receptor complex. In contrast, cimetidine acts directly as a GABAmimetic at the GABA receptor complex in DR neurons. Further studies are needed to elucidate the ionic mechanisms underlying the GABA-, histamine- and cimetidine-induced depression of serotonergic DR neurons. (Supported by USPHS Grants MH-17871, MH-14276, Klingenstein Fund, and the State of Connecticut).

- 101.12 ULTRASTRUCTURAL LOCALIZATION OF HISTAMINE-LIKE IMMUNOREACTIVITY IN THE RAT BRAIN. B.J. Wilcox<sup>§</sup>, B. Maley<sup>†</sup> and V.S.Seybold<sup>§</sup>. <sup>§</sup>Department of Anatomy, University of Minnesota Medical School, Minneapolis, MN 55455 and <sup>†</sup>Department of Anatomy, University of Kentucky, Lexington, KY 40506. Histamine is believed to function as a neurotransmitter in memalian brain and has been immunohistochemically localized at

Histamine is believed to function as a neuroransmitter in mammalian brain and has been immunohistochemically localized at the light microscopic level in neuronal elements throughout the rat brain (Wilcox and Seybold,Neuroscience Lett.,29:105,1982). In the present study, immunohistochemical methods were employed to visualize histaminergic neuronal components at the ultrastructural level.

Colchicine treated female rats were sacrificed by vascular Colchicine treated female rats were sacrificed by vascular perfusion with buffered 4.0% paraformaldehyde containing 0.2% glutaraldehyde. Each brain was removed and the hypothalamus was sectioned on a vibratome. Tissue sections one hundred microme-ters thick were processed for histamine-like immunoreactivity by the PAP technique of Sternberger using the primary antiserum at a dilution of 1:1000 in phosphate buffered saline containing 0.3% Triton X-100. The secondary and tertiary antisera were both used at a dilution of 1:100 in phosphate buffered saline containing 0.3% Triton X-100. After reacting the tissue with 3,3-diaminobenzidine, the sections were osmicated, dehydrated and embedded in Spurr's resin. When thin sections were examined under the electron

When thin sections were When thin sections were examined under the electron microscope, staining was observed in neuronal elements located adjacent to the dorsal limit of the third ventricle near the paraventricular nucleus. This histamine-like immunoreactivity was located in neuronal structures including unmyelinated fibers, varicosities and terminals containing both small clear vesicles and large granular vesicles. The diaminobenzidine reaction pro-duct was distributed over the large granular vesicles and the cytoplasmic space. Apparent synaptic contacts were observed bet-ween histamine immunoreactive terminals and unlabeled dendrites. The localization of histamine-like immunoreactivity in neuro-nal structures by electron microscopy not only provide further examined under the electron

In a localization of histamine-like immunoreactivity in heuro-nal structures by electron microscopy not only provides further confirmation of a role for histamine in neuronal transmission but also suggests a possible physiological function. Its location in terminals which form apparent synaptic contacts with other neuro-nal structures is consistent with a possible role for histamine in regulation of some hypothalamic neuroendocrine secretions via neuronal circuitry. neuronal circuitry. ### MORPHOLOGY OF NEURONS AND GLIA

EARLY APPEARANCE OF MACROPHAGE-LIKE CELLS IN THE PRESUMPTIVE DORSAL FUNICULUS OF EMBRYONIC MICE. L.E. Wentworth. Department of Anatomy, School of Medicine, University of California, San Francisco, CA 94143 and Basic Science Department, California College of Podiatric Medicine, San 102.1 Francisco, CA.

Cells are observed in the dorsolateral spinal cord as early as embryonic day 11 (E11, where E0 = vaginal plug) which do not have the appearance of young neurons. The majority of these cells occur in the presumptive dorsal funiculus with only an occasional cell encountered in the dorsal mantle layer. Some of these cells have numerous and extensive projections of various sizes and shapes. The nuclei are often irregular and sometimes quite elongated. The cytoplasm is dense and contains source of different sizes, the contents of which vary from electron lucent similar to that of extracellular space, to debris ranging from pale amorphous material to electron-dense whorled membranes. Some of these cells are found near the entrance of the incoming dorsal roots. On examining serial sections containing dorsal roots occasionally cells have been observed in the ventral root close to the spinal cord with a

observed in the ventral root close to the spinal cord with a process extending into the presumptive dorsal funiculus. Microglia have been described as originating from neuroectoderm, mesenchymal elements, cells of leptomeninges, vascular adventitia or blood vessels. Cells with the ultrastructural appearance of macrophages have been described within ventral nerve roots in immature rats (Fraher, J.P. and R.D. MoDougall, J. Anat., 120:537, 1975). Stensaas and Reichert (Z. Zellforsch. Bd., 119:147, 1971) described round and amoeboid microglial cells in the white matter of neonatal rabbits. Some investigators have suggested that macrophages in the CNS can transform into microglia (Immoto. K. and C.P. Tables. Some investigators have suggested that macrophage in the CNS can transform into microglia (Imamoto, K. and C.P. Leblond, <u>J. Comp. Neur.</u>, <u>174</u>:255, 1977) and vice versa (Konigsmark, B.W. and R.L. Sidman, <u>J. Neuropath. exp. Neurol.</u>, <u>22</u>:643, 1963). Blood vessels are not observed in the area in which the macrophage-like cells are found. Additional cells in which the macrophage-like cells are found. Additional cells in the presumptive dorsal functulus and in and around the entering dorsal roots from E11-E14 are being serially reconstructed to see if the cells change shape with age and location and to attempt to shed some light on the origin of these cells. Supported by NIH NS17268.

102.2 AN ANATOMICAL ANALYSIS OF A CERVICAL DENDRITE BUNDLE IN THE RAT SPINAL CORD. D. Lorton and W.J. Anderson. Indiana Univ. Sch. of Med., Terre Haute Ctr. for Med. Ed., Terre Haute, IN 47809. In the cervical enlargement of the cat spinal cord, dendritic bundles have been described by the Scheibels (1971), which occur in the ventromedial and ventrolateral aspect of the ventral horn. Recently a survey of the cervical region revealed a similar bun-dle in the rat which has not been thoroughly described. This dendritic bundle organization appears to be more extensive than that described by the Scheibels. Transverse and longitudinal paraffin sections revealed three discrete dendrite bundles which parallin sections revealed three discrete dendrite buildies with traversed cervical segments. A midline bundle running from C2-C6 in the ventromedial gray matter had a diameter of  $40\mu$  and length of 5.5mm. The central bundle, in the medial aspect of the ventral born of C3-C5, was  $60\mu$  in diameter and 2.5mm in length. The lateral bundle traversed C2-C4 in the ventrolateral gray The lateral bundle traversed C2-C4 in the ventrolateral gray matter and was  $60\mu$  in diameter and 4.0mm long. Alpha and gamma motoneurons, ranging from  $20-70\mu$ , were present among the den-drites as was capillaries and glial cells. Using acetylcholin-esterase-positive staining, indicating these were most probably motoneurons. Golgi analysis revealed that the majority of the dendrites were longitudinally-oriented. However, the central and lateral bundles also contained small dendritic subunits that projected transversely and appeared to connect the central with the lateral and to a lesser extent with the midline bundle. the lateral and to a lesser extent with the midline bundle. Electron microscopy of these dendrite bundles has shown the pre-sence of dendrodendritic and dendrosomatic contacts of the des-mosomal type. It has been hypothesized that the dendrite bundle in the cat is involved in respiratory function (Roney, 1979). In support of this hypothesis, Cameron (1982) has found electro-physiological evidence that this dendrite bundle is highly asso-ciated with the phrenic nucleus and nerve in the cat. Perhaps the dendritic bundle organization in the rat is also involved in respiratory function. respiratory function.

EVIDENCE FOR CONTINUITY OF MICROTUBULES IN DENDRITES. 102.3 D.E. Hillman and S. Cuccio\*. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016 A number of studies analyzing microtubules from axons and

dendrites by 3-dimensional reconstruction suggest that neurotubules occur as interrupted, overlapping segments from 0.4 to 800 microns in length. One study supports earlier hypotheses that tubules can extend the entire length of processes. An answer to this question is important in understanding the role of microtubules in the cytoskeleton of neuronal processes. Dendrites of pyramidal and Purkinje cells have an orderly arrangement of microtubules and were analyzed by reconstruction for continuity along their course. Rat brains were rapidly fixed by perfusion with warm, 9%

glutaraldehyde in potassium phosphate buffer for chelating calcium. All microtubule appearing structures were followed in serially sectioned segments of dendrites. The results showed that profiles of microtubules begin in or near the soma and only a small percentage end along non-terminal segments. A much higher ending rate was found in segments judged to be terminals. For example in a reconstructed pyramidal cell dendritic segment, 13 µm long, one tubule of 320 was lost distally. In comparison, a small dendrite, having a diameter of 0.3 µm and sectional series extending over 7.5 µm, lost three tubules distally. Microtubules did not start for extension distally along the course of six reconstructed series that ranged in length from 5 - 13 µm.

Occasional structures in cross section had similar diameters to tubules and, when followed for one or two microns in either direction, always enlarged as endoplasmic reticular profiles. Longitudinally cut dendrites confirmed that endoplasmic reticulum frequently acquired the same size as tubules and extended for distances of up to 3 or 4 microns before returning to the larger Microtubules passed through sheets of endoplasmic reticusize. lum within a closed perforation but were separated from the membrane by 20 nm. Comparison of reconstructions from conventions from the second tional fixatives revealed frequent breakdown of tubules into short segments. This most often occurred in the periphery of the cross section. These results show that fixation can result in breakdown of tubules and that endoplasmic reticulum can con-strict in diameter to the size of tubules. This study indicates that further analysis is needed in order to determine whether or not microtubules of the axonal cytoskeleton begin at the soma and end at or near terminals. Supported by USPHS Grants NS-13742 and HD-10934.

MAP2 IS SPECIFICALLY ASSOCIATED WITH DENDRITIC MICRO-102.4 TUBLIES IN CEREBELLAR NEURONS. R. Bernhardt\* and A. Matus (SPON: W.B. Adams). F. Miescher-Institut,

P.O. Box 2543, CH - 4002 Basel, Switzerland. A number of high molecular weight microtubule-associated proteins (MAPs) have previously been shown to occur only in Purkinje cell dendrites and not in axons (Matus, Bernhardt, Hugh-Jones, <u>PNAS,78</u>:3010,1981). In the present study we have used immunohistoche-mical techniques with a rabbit antiserum which reacts specifically with MAP2 (MW 280 000 to 320 000) and some of its degradation products (as shown on microtubule protein gel blots) to study the distribution of the MAP2 antigen in the adult rat cerebellum.

At the light microscopic level MAP2 is detected in Purkinje cell dendrites, extending into the fine den-dritic arborization. In addition, there is staining of other processes in the molecular layer which often can be identified as dendrites of basket, stellate and Golgi interneurons. A lower level of immunoreactivity is generally observed in neuronal cell bodies, but in no case is there evidence of axonal staining. For example parallel fiber axons and myelinated tracts are white matter and the axons and myerinated tracts all antiserum. Similarly, an antiserum directed against neurofilament proteins (which stains axons in the white matter and the axons of the basket cells) shows a completely different staining pattern. Non-neuronal cells are unstained by anti-MAP2.

Studies at the electron microscopic level confirm the results of the light microscopic examination. Thus, immunoreactivity is associated with dendritic micro-tubules of Purkinje, basket, stellate, Golgi and granular cells. There is no staining in any axon, including the readily identified parallel fibers and myelinated axons. Electron microscopic examination of neuronal perikarya shows that the somal staining observed on the light microscope is associated primarily with ribosomes, possibly suggesting that even in the adult animal MAP2 is continually synthesized. This data suggests a specific role of MAP2 in dendritic maintenance and function.

MONOCLONAL ANTIBODIES THAT STAIN NEURONAL SOMATA IN THE RAT 102.5 MUNOLUMAL ANIHOULS THAT STAIN NEUROMAL SOMALA IN THE KAT CEREBRAL CORTEX AND IN PRIMARY CULTURES OF DISSOCIATED CORTEX. J.P. Horn, R. Hofstein\* and C.J. Bernstable. Department of Neurobiology, Harvard Medical School, Boston, MA 02115. To study neuronal differentiation in the cerebral cortex, we have initiated a search for monoclonal antibodies against cell-specific markers. Antibody 4G9 was raised against synapcell-specific markers. Antibody 409 was raised against sy tosomal membranes of adult rat brain. Antibody E15.1 was raised against membranes from cortices of embryonic day 15 raise against memoranes from cortices of embryonic day is rats. Antibodies were screened using a solid phase binding as-say and indirect immunofluorescent staining of tissue sections. Cortical cultures were made by mechanically dissociating the cortices of E15 rats. Neurons were defined as cells with phase bright cell bodies(8-25u) and extended processes that stained with anti-neurofilament antibodies. Upon impalement, larger cells having this morphology exhibited action potentials and synaptic potentials.

In adult cortex, 469 produced a bright perinuclear staining of all neuronal somata that sometimes extended into large proximal dendrites. In layer 1, which contains mainly axons and glia, faint staining of processes suggested that 4G9 also stains glia. Double labelling with 4G9 and an anti-GFA antibody showed that some of the lighter staining of processes in layer 1 was due to binding of 4G9 to astrocytes. In E15 cor-tex, 4G9 labelled all cells brightly. In young cultures(< 1 week), in which non-neuronal cells had not reached confluency, 4G9 produced very bright staining of neurons and their processes and weaker staining of all non-neuronal cells. As non-neuronal cells became confluent(1-3weeks), the bright neuweaker and in some cells disappeared. Thus it appears that 409 recognizes an antigen(s) that is expressed by all cells in em-

bryonic cortex and preferentially by neurons in the adult. Similar to 4G9, E15.1 stained the perinuclear region of neurons in the adult cortex. However, in addition E15.1 stained radial processes, that grouped into regularly spaced bundles of increasing sizes as they coursed through layers 2 + 3 and then broke up in layer 1. Some of the radial fibers could be traced back to pyramids. In cultures (1-2 weeks) E15.1 stained neu-rons, their processes and non-neuronal cells. The non-neuronal rons, their processes and non-neuronal cells. The non-neuronal staining had a fibrillar appearance that was distinct from that seen using 4G9. At present we cannot say how the staining of non-neuronal cells by E15.1 contributes to the staining of adult cortex. Further studies will be targeted to resolving this question and to charactering the antigens recognized by 4G9 and E15.1. (Supported by EY 07042-0551, EY 03735, NS 17309 and the Hereditary Disease Foundation.) 102.6 A SUBSET OF AXONS IN THE CHICK CILIARY GANGLION IDENTIFIED WITH

A SUBSET OF AXONS IN THE CHICK CILIARY GANGLION IDENTIFIED WITH A MONOCLONAL ANTIBODY AGAINST A MICROTUBULE-ASSOCIATED PROTEIN. J.P. Tremblay, C. Gravel\* and R. Hawkes\* (Spon: L.J. Poirier). Lab. Neurobiology, Laval Univ., Que., Canada, GlJ 124. We are using monoclonal antibodies to investigate synaptic physiology in the chick ciliary ganglion. One antibody we have studied, PS2, was raised in mice against rat brain postsynaptic densities, and has been shown to recognize a microtubule-asso-ciated polypeptide antigen (Hawkes, Huber, Matus in prepara-tion). We have used electron microscope immunocytochemistry to study the distribution of the PS2 antigen in the chick ciliary ganglion. The fixative (0.1% glutaraldehyde, 2% formaldehyde in 0.12M cacodylate buffer) was injected in the orbital cavity. The ganglion was dissected out and left in the same fixative for 45 min and transferred overnight to a fixative without glutaral-dehyde. The ganglion was cut in 80um thick sections with a tis-sue chopper. These slices were incubated with the PS2 antibody Such object. The gaugiton was cut in order three sections with a tra-source object. These slices were inclusted with the PS2 antibody (undiluted culture medium) for 20h at  $20^{\circ}$ C, rinsed 3 times for 10 min in buffer, inclusted 2h at  $20^{\circ}$ C with a rabbit antimouse antibody coupled with horseradish peroxidase and rinsed. The peroxidase was revealed by a modified Graham and Karnovsky (J. Histochem, Cytoch. 14, 291, 1966) reaction. The tissue was then dehydrated and embedded in epon. The antibody reveals a highly selective antigen distribution,

with stain deposits restricted to the cytoplasm of a minor sub-set of axons, comprising less than 10% of the observed axon set of axons, comprising less than 10% of the observed axon cross sections. Most of the antigen-positive axons are charac-teristically narrow and are unmyelinated but a few larger myeli-nated axons have also been observed. Seen in transverse scc-tion, the staining is punctate and distributed throughout the cytosol. Glancing sections through axons reveal the punctate staining to reflect a longitudinally arranged set of long fibers, probably microtubules. The cytoplasm of a few neurons is also labelled by PS2. Since the labelled processes are more abundant in the vicinity of these labelled aurons, they may well be the cells of origin of the labelled axons. We conclude that in the chick ciliary ganglion, as in the rat brain, anti-genically-distinct microtubules are present in different cellu-lar populations. (Supported by MRC awards DG 285, DG 286, DG 287 (RH) and MT5977 (JT).

IMMUNOCYTOCHEMICAL LOCALIZATION OF NEUROFILAMENTS AND RELATED 102.7 PROTEINS IN THE CENTRAL NERVOUS SYSTEM. R. Hofstein<sup>1\*</sup>, R.E. Majocha<sup>2\*</sup>, C.J. Barnstable<sup>1</sup> and C.A. Marotta<sup>2</sup>. Departments of <sup>1</sup>Neurobiology and <sup>2</sup>Psychiatry, Harvard Medical School, Boston, MA 02115, and <sup>4</sup>Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Intermediate filaments are characteristic marker molecules of various cell types in the mammalian nervous system. In order to extend our understanding of both the molecular heterogeneity of these proteins and their role in cytoskeletal architecture, we have produced monoclonal antibodies against the 200,000 dalton and 145,000 dalton neurofilament polyperides (NF 200 and NF 145). A subcellular fraction enriched for those proteins was prepared from subcellular fraction enriched for those proteins was prepared from white matter of rat or human brain. The proteins were purified by polyacrylamide gel electrophoresis (PAGE), and gel strips corresponding to 200K and 145K protein bands were excised, crushed, mixed with Freund's adjuvant and used for immunization of mice. A final injection with proteins eluted from corresponding mice. A final injection with proteins eluted from corresponding gels was performed four days prior to fusion of the spleen cells with P3-NS1 myeloma cells. Hybrid cultures derived from the fusions were screened by a solid phase radioactive binding assay using NF fractions as the target, by immunoblots of PAGE-separated NF proteins attached to nitrocellulose membranes, and by indirect immunofluorescence on 10µ fixed frozen sections of retina and brain. Fusion of spleen cells sensitized with NF 200 gave rise to two classes of monoclonal antibodies. The first was the expected one against NF 200 which did not cross-react with the other NF proteins on blots. These gave a characteristic staining of neurofilaments in fibers of brain and retina. The second class of antibodies reacted with two proteins of approximately 240K and 160K and in retina stained primarily astrocytes and Muller cells, 160K and in retina stained primarily astrocytes and Muller cells, particularly the endfeet in the ganglion cell layer. Whether these antibodies arose as a result of some cross-reaction with NF 200 or because of a contaminating protein in the immunogen is currently being investigated. Both antisera and antibodies against NF 145 showed staining of retinal sections similar to that of NF 200 except that ganglion cell bodies and dendritic processes were clearly labeled. In addition, two unexpected classes of antibodies were produced in these fusions. The first reacted with a 160K protein and stained all nuclei in retina and also gave weak labeling of optic nerve fibers. The second reacted with a 240K protein and stained what apoeared to be a membrane-associated because of a contaminating protein in the immunogen is currently protein and stained what appeared to be a membrane-associated antigen of all retinal cells.

RADIAL GLIA OF MATURE TURTLE CEREBELLUM: MORPHOLOGY AND 102.9 PHYSIOLOGY. C. Nicholson, M. Chesler, P. Thompson\* and R. Du Carmo\*. Dept. Physiol., New York Univ. Med. Ctr., 550 First Do Avenue, New York, N.Y. 10016

Golgi studies show that the adult turtle cerebellum possesses no true astrocytes (Stensaas & Stensaas: Z Zellforsch 91: 315, 1968) but instead has a system of radial glia (RG) with cell bodies at the ventricular surface and processes that reach to the pia.

Using fine micropipettes and an isolated, superfused whole cerebellar preparation, we iontophoresed HRP into the cell bodies of RG (typical diameter 10 um). We confirmed the radial structure of the cells and showed that the processes usually branch several times. This classifies the cells as ependymal astrocytes (Tennyson & Pappas; Z Zellforsch 56: 595, 1962). The cell processes were adorned with numerous leaf-like appen dages that made them similar to those of Bergmann fibers found in mammals. Using cobalt intensification, we showed also that HRP injected into one RG sometimes transfered to Purkinje, and other, cells close to the RG processes.

As with other glia, RG depolarized when  $[K^+]_O$  was increased. We changed  $[K^+]_O$  in 3 ways: a) superfusing the preparation with physiological salines containing different [K<sup>+</sup>] and sampling many cells at each concentration; b) changing  $[K^+]_0$  while recording from one cell; c) recording the membrane potential during a spreading depression, while  $[K^+]_0$  was monitored with a  $K^+$  ion-selective microelec-trode immediately outside the cell. In all cases we found that the slope (range 41-47 mV/decade) of the membrane potential versus log  $([{\tt K^+}]_{\rm O})$  was below that predicted by the Nernst equation. This may show that these RG accumulate  ${\tt K^+}$  when  $[K^+]_O$  is elevated (Kettenmann et al: J. Neurosci. 3: 500, 1983). Comparison of the transient glial depolarization during spreading depression with the change in  $[K^+]_0$  showed that the RG act as a very localized  $K^+$  electrodes. Evidence for the continuity of the radial glial cables was obtained by passing current across the cerebellum and measuring laminar profiles of  $[K^+]_O$  (Gardner-Medwin & Nicholson; J. Physiol. 335; 375, 1983). The profiles showed a complete reversal of the current-induced changes in  $[K^+]_O$  from one cerebellar surface to the other.

We conclude that the radial glia of the turtle cerebellum have many of the morphological and physiological properties presently associated with astrocytes in other species Supported by USPHS Grants NS-13742, 5-T32-GM-07308 and NSF Grant INT-8202685.

NEURONS MODIFY THE SHAPE OF CEREBELLAR ASTROGLIA IN VITRO 102.8 M.E. Hatten Dept. Pharmacology, New York Univ. Sch. of Med., New York, N.Y. 10016

In the embryonic mouse cerebellum, proliferating precursors of granule neurons move across the rhombic lip and form the external granular layer (EGL); radial glia transform into Bergmann glia beneath the layer of proliferating young neurons. During the first two postnatal weeks, postmitotic granule neurons leave the EGL and descend into the cortex by consisting with the presence of Postner postnatalia associating with the processes of Bergmann astroglia. The present study explores whether granule neurons influence the expression of the astroglial cell shape required for neuronal migration and positioning.

Cerebellar cells harvested from C57B1/6J mouse cerebellum at postnatal day 3 were dissociated into a single cell suspension with trypsin, passed through a 33  $\mu m$  filter to remove cellular

with trypsin, passed through a 33  $\mu$ m filter to remove cellular aggregates, applied to a step gradient of Percoll and enriched glial (G) and neuronal (N) fractions were collected at the three resulting interfaces. Complete separation was achieved by preplating the fractions on a polylysine-coated substratum. In the absence of cerebellar neurons, astroglia assumed a flattened morphology and underwent cell division. Their identity was confirmed by staining with antiserum raised against purified glial filament protein (AbGF). In the absence of cerebellar astroglia, granule neurons formed cellular reaggregates which did not attach to a culture substratum coated with  $10-25 \mu g/ml$  polylysine. Their identity was confirmed by staining with antiser astrogliated by staining with NILE glycoprotein and by electron microscopy.

confirmed by staining with antisera raised against the NLE glycoprotein and by electron microscopy. When purified astroglia were plated in the presence of increasing numbers of granule neurons (0-90% of the total cell population), the flattened shape expressed in the absence of neurons transformed into "Bergmann-like" or "astrocyte-like" shapes and specific glial-neuronal interactions were observed. These results raise the possibility that neurons influence

the differentiation of astroglia.

102.10 MONOCLONAL ANTIBODIES REVEAL THE CYTOARCHITECTURE OF THE BERGMANN GLIA FIBERS IN THE CEREBELLUM, Angel L. De Blas and Holly M. Cherwinski\*. Department of Neurobiology and Behavior, SUNY at Stony Brook, NY 11794.

The cytoarchitecture of the cerebellar Bergmann glia fibers in the adult rat was investigated. Two monoclonal antibodies, one specific for the Bergmann fibers and astrocyte processes and the other specific for the cell bodies and dendrites of the Purkinje cells, as well as an antiserum to the glial fibrillary acidic protein (GFA), were used in immunocytochemical peroxidase-anti-peroxidase assays.

The Bergmann fibers are revealed as columns organized in long vertical palisades parallel to the longitudinal plane of the fol-ium. The palisades are not continuous; instead they are formed by sets of two to six aligned Bergmann fibers. Each of these sets of Bergmann fibers is separated from its longitudinally aligned neighbors by gaps. Each Bergmann fiber is formed by a bundle of two to four Bergmann glia strands which frequently show a helical organization.

These results help to reconcile the different views on the organization of the Bergmann fibers derived from the studies done with the light microscope versus the electron microscope. The Bergmann glia may play a fundamental role in directing the geo-metrical organization of the cerebellar constituents. Supported by NIH grant NS-17708 and by a Basil O'Connor starter research grant from the National Foundation - March of Dimes.

A CHARACTERIZATION OF HYPEKTROTHLED, HOLLANDER, CONTOR FOLLOWING A CEREBRAL CORTICAL LESION. James R. Connor. Dept. of Anatomy, Boston Univ. Sch. of Med. Boston MA 02118 CHARACTERIZATION OF HYPERTROPHIED, MULTIVACUOLATED ASTROCYTES 102.11 Following a stab wound to the parietal cortex of 3 month old rats, a large (12 um diameter) astrocyte appears by 8-days later. This large cell is seen by reacting the tissue with glial filament acidic protein antisera (generously provided by Dr. L.F. Eng) and visualization of the binding sites by the peroxidase-anti-peroxidase method of Sternberger. From the light micrographs, this cell appears to contain many nonimmunoreacted areas or vacuoles. These vacuoles range in size from one to four microns. After reconstruction from one micron sections and counterstaining with thionin, the vacuoles have a basophilic nature, staining similarly to the nuclei of neighboring astrocytes. Electron microscopic examination of the immunohistochemically prepared material reveals that the multivacuolated cell is an astrocyte frequently containing large lipid droplets. The nucleus of this cell is so grossly lobulated that as many as five distinct nuclear profiles are seen in a given section. As many as three of these profiles can contain nucleoli. Serial reconstruction at the EM level shows strands of nucleoplasm can bridge between each lobulated nuclear portion. Thus rather than portions of the nu-cleus budding off, perhaps in an aborted attempt to divide, it is apparent the nucleus is grossly lobulated and the many nuclear regions result in the vacuolar appearance of this cell at the light microscopic level.

Rats have been injected with <sup>3</sup>H-thymidine to determine if the convoluted nucleus of this cell is synthesizing DNA. Also tissue From lesioned animals that have been perfused for straight electron microscopy will be used to compare the hypertrophied astrocytes with the astrocytes that have multilobulated nuclei. Whether or not this multivacuolated astrocyte is functional or

whether or not this multivacuolated astrocyte is functional of in an agonal state is presently unclear. It is of interest that the multivacuolated cell is preferentially located in layer VI, the white matter, and the hippocampal sulcus. It has not been observed contacting the lesion site. In addition, the multivac-uolated astrocyte does not appear until after at least 2-days uolated astrocyte does not appear until after at least 2-days post-lesion. It is present by 8-days post-lesion in 3 month old rats, but it is not seen until 16-days post-lesion in 2 year old rats. In conclusion, the multivacuolated astrocyte may be the Monsterzellen described by Penfield to occur following "chronic pathological conditions" and if so, it is also present in high numbers in multiform glioblastoma.

102.13 TRANSITIONS IN FORM AND CYTOSKELETAL CONTENT OF CEREBELLAR

TRANSITIONS IN FORM AND CYTOSKELETAL CONTENT OF CEREBELLAR ASTROGLIA. P. Bovolenta\*, R.K.H. Liem\*, C.A. Mason, Dept. of Pharmacology, New York Univ. Sch. of Med., New York, NY 10016. There is increasing evidence that glial cells form templates for neuronal migration and axon outgrowth, but the identity and transitional forms of glia during normal development are not well understood. We have been studying the morphology of devel-oping astroglia in embryonic and postnatal mouse cerebellum, particularly in relation to axon outgrowth. Monospecific anti-bodies to intermediate filaments found in glia - glial filament protein (GF, 51 K) and Vimentin (Vim, 58 K) - and in neurons (the 150 K component of the neurofilament triplet, NF) were applied to fixed cryostat and vibratome sections of embryos and applied to fixed cryostat and vibratome sections of embryos and applied to fixed cryostat and vibratome sections of embryos and postnatal cerebellum and visualized by peroxidase-anti-peroxidase (PAP) and fluorescence techniques at the light microscope level. Antisera to NF reveal that axons are present in the cerebellar anlage as early as embryonic day (E)15. From E15 to postnatal day (P)2 Vim-positive cells are ubiquitous and include radial forms, cells with amorphous shapes and 2-3 irregular processes, and thick longitudinal elements oriented evention to prove the provide the irregular processes, and thick longitudinal elements oriented parallel to axons within axon tracts. GF-positive cells do not appear in the cerebellum until P3-4 and by P7 there is a sudden and dramatic increase of GF-positive cells in the developing white matter with stellate shapes and long processes. These cells are more numeroùs and more darkly stained than at any time thereafter. Bergmann fibers begin to stain with GF by P7. Between P7 and P14 Vim and GF coexist in both astrocytes and Bergmann fibers but after this age Vim expression is progres-sively rarer in all astrocytes excent for Bergmann fibers. From sively rarer in all astrocytes except for Bergmann fibers. From P10 onwards, GF-containing cells become more common in the granule cell layer and fewer are found in the developing white matter. This trend continues until P21 when the distribution of GF-positive astrocytes is more even throughout the cerebellum, but more sparse than at P7.

inese results demonstrate that the form, disposition and cytoskeletal components of astroglia change considerably during embryonic and postnatal development. Two issues are raised: (1) The lineage and relationship of cells expressing Vim and GF. This is currently under investigation by means of doubles These results demonstrate that the form, disposition (1) the integer and treatforming of certs expressing vin and GF. This is currently under investigation by means of double-labelling experiments with  ${}^{3}\text{H-Thymidine}$  and antisers to intermediate filaments. (2) Since the appearance of GF-positive cells corresponds to the cessation of axon ingrowth and onset of myelination, axon outgrowth must occur in a terrain comprised of Vim-positive cells, thus having different cytoskeletal compos-ition and shape than mature astrocytes, or the GF-rich astrocytes that proliferate after injury. (Supported by NHH Grants NS-16951 (CAM) and NS15182 (RKHL).

A LIGHT AND ELECTRON MICROSCOPIC ANALYSIS OF THE DEVELOPMENT OF RADIAL GLIAL CELLS IN THE RAT DENTATE GYRUS. M. Rickmann\* and D.G. Amaral, (SPON: JAMES W. PATRICK) The Salk Institute, P.O. Box 85800, San Diego, CA 92138. 102.12

To determine the possible role of radial glial cells in guiding dentate granule cell precursors as they migrate from the ventricular zone to their secondary proliferative zone, we have examined the development and distribution of glial cells using standard immunocytochemical procedures for localization of the glial fibrillary acidic protein (GFAP) and routine EM preparations. At the EM level the first indication of radial glial cells (as judged by the presence of numerous glycogen particles) was on day E14. GFAP-positive radial alial fibers were first observed in the dentate gurve on day E17. glial fibers were first observed in the dentate gyrus on day E17. At these stages, the cells extend from the neuroepithelium lining the ventricular surface of the fimbria to the pia overlying the presumptive dentate gyrus. The proximal processes of the cells are radially oriented but they become increasingly tangential in orientation as they approach the pia. At later stages, when the dentate gyrus begins to enlarge and take on its characteristic C-shape, the glial cells retain enlarge and take on its characteristic C-shape, the glial cells retain their radial orientation with respect to the granule cell layer. It is likely, therefore, that the radial glial cells serve to guide the precursors from the ventricular layer to the secondary proliferative zone in which most of the granule neurons are generated. In support of this notion we have observed a class of immature cells that are closely apposed to the radial glial processes from day E17 onwards which are characterized by their electron dense cytoplasm and their high contact of frae riberomes and eal/infeasome. high content of free ribosomes and polyribosomes.

By day PI a second form of GFAP-positive cell is observed. These cells do not have a ventricular process and their perikarya are preferentially located just beneath the developing granule cell layer of the suprapyramidal blade. Both forms of radial glial cells coexist until about day P7, but thereafter only those within the hilar zone persist into adulthood. Although it is possible that the original radial glial cells become transformed into the persistent radial glia by withdrawing their ventricular processes, it seems more likely that most of the secondary cells are generated <u>de novo</u>, since we have observed numerous GFAP-labeled mitotic figures during the late fetal and early neonatal periods.

Supported by NIH Grant NS-16980, the German Science Foundation, and the McKnight Foundation.

102.14 GLIAL-SPECIFIC MARKERS IN THE HORIZONTAL NEURONS OF TELEOST NEURAL RETINA. P. J. Linser\* (SPON: D. Price). C. V. Whitney Laboratory of the University of Florida, St. Augustine, FL 32084

> The horizontal cells of the vertebrate retina are a morphologically diverse and perhaps functionally unique class of neuron. Early histological studies of lower vertebrates raised questions concerning whether these cells are neuronal or glial in character. However, synaptic activity of horizontal cells in most vertebrates has been demonstrated and it is generally accepted that these cells are true neurons.

> neurons. The focus of attention in our lab is the expression and compartmentalization of the proteins glutamine synthetase (CS), carbonic anhydrase-C (CA-C) and glial fibrilary acidic protein (GFA), all of which have been demonstrated to be glial-specific in higher vertebrate nervous tissues (Roots, B. I. J. Exp. Biol. <u>95</u>: 167, 1982). Recent immunohistochemical analyses of teleost retina show that horizontal cells do indeed share certain characteristics with neuroglia. Histological vertices of formeldebude fixed actions from the continent floander sections of formaldehyde-fixed retinas from the southern flounder (Paralichthys lethostigma) were immunohistochemically stained to localize GS, CA-C and GFA. We have previously shown that GS and CA-C are found in high concentration only in the Müller glial cells of chicken retina (Linser, P. J. and Moscona, A. P.N.A.S. <u>78</u>: 7190, 1981). This observation was mimicked in the flounder except that in addition to the glial cells, intense staining for CA-C was also evident in the horizontal neurons. In addition, antisera to GFA obtained from two independant sources gave marginally detectable staining of Müller cell end feet, particularly near the ciliary margin of the retina, mimicking previous observations in other vertebrate retinas (Bignami, A. and Dahl, D. Exp. Eye Res. 28: 63, 1979). However, very intense staining with anti-GFA sera was seen in the horizontal cells and their processes in the flounder retina. The presence of GFA in synaptically active neurons has not been previously described. The specificity of all antisera used in this study was verified by standard tests including immunodiffusion, immunoabsorption and immunostaining of Western blots of SDS polyaerylamide gel electrophoretograms of retina extracts. Further ongoing studies indicate that glial characteristics are likewise found in horizontal cells of other teleost and elasmobranch retinas.

> Our observations thus serve to enforce the tantalizing suggestion that horizontal cells may represent a bifunctional cell type combining both neuronal and glial characteristics. Indeed, it is tempting to speculate that perhaps the horizontal cells of lower vertebrates actually represent a transitional element in the evolution of the neuronal-glial dichotomy.

102.15 HETEROGENEITY OF 50kd IMMUNOREACTIVE SITES IN THE GLIAL CYTOSKELETON, REVEALED BY MONOCLONAL ANTIBODIES <u>A. L. Gard, J.</u> L. Eastburn and G. R. Dutton. Department of Pharmacology, University of Iowa, Iowa City, IA 52242. Using immunocytochemical methods we have reported that rabbit

Using immunocytochemical methods we have reported that rabbit antisera to glial fibrillary acidic protein (GFAP) specifically label rat liver Kupffer cells (Soc. Neurosci. Absts. <u>8</u>: 240, 1982, in press). To authenticate the localization of GFAP to these cells, a panel of monoclonal antibodies (MCA's) was raised using C3H/OuJ mice immunized with GFAP isolated and partially purified from normal human brain (gift of Dr. L. Lapham). Hybridoma supernatants were screened by an immunoperoxidase dot binding assay on 80 ng of antigen spotted onto nitrocellulose. Positive supernatants were then incubated on frozen parasagittal sections of rat cerebellar vermis and their binding immunoperoxidase specificities es visualized by indirect immunoperoxidase Those MCA's that specifically bound Bergmann glial staining. and/or astrocytes in the granule layer and white matter fibers were then incubated on Western blots of fresh cerebellar homogenate proteins electrotransfered from 10% SDS-PAGE slab ls. Three categories of antibodies were identified that label single band at 49-50 kd which co-migrated with authentic AP. Group I MCA's stained all GFAP<sup>+</sup> cells in sections and in gels. GFAP. GFAP. Group I MCA's stained all GFAP<sup>+</sup> cells in sections and in astrocyte-enriched primary dissociated cell cultures. Rat liver Kupffer cells were also stained. Group II MCA's differ from Group I in that these MCA's appeared to stain fewer astrocytes in the granule layer of the cerebellum. The medial portion of Bergmann glial fibers was not stained. In astrocyte-enriched cultures, Group II MCA's stained approximately 75% of the GFAP<sup>+</sup> cells, but within a given cell, the pattern of staining was more restricted than that observed with a polyclonal rabbit antisera made against GFAP (glifts of Dr. R. Pruss and L. Eng). Kupffer cells were positive, but staining was anoraner only in small cells were positive, but staining was apparent only in small segments of Kupfer cell processes. The cellular distribution of Group III MCA specificities was similar to those of Group II, that the glial limitans and pial surface were not . In addition, the peroxidase reaction product was more excent not stained. stained. In addition, the peroxidase reaction product was more finely distributed along delicate astrocyte processes than was observed with rabbit anti-GFAP antisera or the MCA's of Groups I and II. In cultures, Group II and III MCA's showed similar staining of astrocytes except that the latter also stained a small population of GFAP<sup>-</sup> flat cells. When tested by indirect immunofluorescence, MCA's in Groups I, II and III and rabbit anti-GFAP did not stain the cytoskeleton of 3T6 fibroblasts, which are known to be vimentin-positive. This work was supported by USPHS grant NS 16518 and training grant GM 07069. 102.16 DORSAL-VENTRAL DIFFERENCES IN GLIA LIMITANS IN THE IRRADIATED DEVELOPING RAT SPINAL CORD. S. A. Gilmore and T. J. Sims. Dept. of Anatomy, Univ. of Arkansas Med. Sci., Little Rock, AR 72205 and Dept. of Neurology, Stanford Sch. of Med. and V. A. Med. Ctr., Palo Alto, CA 94304.

Schwann cells develop in spinal cords of immature rats following exposure to radiation. These intraspinal Schwann cells occur consistently in the dorsum of the spinal cord and develop only occasionally in the ventral region. The intraspinal conditions which facilitate the development of these Schwann cells are not totally clear, either from studies in this laboratory or from attempts of others to graft or transplant peripheral nervous elements into the central nervous system. Recent data from this laboratory showed that the glia limitans on the dorsum of the spinal cord was markedly damaged following irradiation. The present study examines possible differences in the dorsal and ventral aspects of the spinal cord (1) at the time of irradiation and (2) during the interval between irradiation and the development of intraspinal Schwann cells. A beam of soft x-rays (total dose, 4000R) was administered to

A beam of soft x-rays (total dose, 4000R) was administered to a 5mm length of lumbosacral spinal cord in 3-day-old Charles River rats. For light microscopy, the animals were perfused-fixed with 2% paraformaldehyde and the spinal cords were embedded in JB4. For ultrastructure, the rats were perfused with a modified Karnovsky's fixative and prepared in the usual fashion. Normal 3-day-old rats and rats killed at 5 and 10 days post-irradiation were examined.

At 3 days of age the glia limitans on the dorsal surface of the spinal cord consists of 1 or 2 layers of glial processes. The axons are mostly small-caliber, are interdigitated by glial processes and are rarely myelinated. Ventrally, subjal glial cclls appear more numerous, and the glia limitans is multilayered, often composed of 2 to 4 glial processes flattened against one another. More axons are myelinated ventrally than dorsally. By 10 days following irradiation a decrease in number of glia is evident light microscopically throughout the white matter. Ventrally the glia limitans shows some thinning in both irradiated and controls, but these two groups cannot be distinguished on this characteristic. In contrast, on the dorsal surface the glia limitans is markedly thinned and breaks are present. These data suggest that the glia at the ventral surface are either more mature than those dorsally or that the greater number ventrally is sufficient to maintain an intact glia limitans in the irradiated rat.

CYTOPLASMIC ORGANIZATION IN SYNAPTIC TERMINALS ON LIZARD MUSCLE. 102.17 J. P. Walrond and T. S. Reese. NINCOS, NIH, Bethesda, MD 20205. Axonal cytoplasm is known to contain interlocking domains defined by neurofilaments or microtubules, but little is known about how these domains end at the synapse, or how they inter face with the microfilament domains containing the synaptic vesícles. Furthermore, neither the exchange of organelles vesicles. Furthermore, helther the exchange of organizities between the axon and the synapse nor the fate of the filamentous systems constantly moving into the synapse is well understood. The low concentration of synapses in muscle and their complex and extensive cytoplasmic domains limits the productivity of conventional rapid freezing and deep etching for studying their extended attraction the synapse synthesize the synthesized attraction of the synapse synthesized attraction of the synthesynthesized attraction of cytoplasmic structure. Here we describe a new technique which provides better access to pertinent structural details in motor terminals from lizard intercostal muscles. Rapid-frozen Anolis intercostal muscles were freeze-substituted at -80°C, then warmed to 0°C and stained in 20% uranyl acetate in methanol, 0.5% hafnium tetrachloride in acetone, and 0.25% lead octoate in methanol, and finally embedded in Araldite for serial thin sectioning. The uniformity of staining and contrast were adequate to form detailed stereo images of the entire thickness of the section (~120 nm) without staining the individual. sections; series of 10-15 stereo pairs permitted small cubes of presynaptic cytoplasm to be reconstructed in fine detail. Synaptic vesicles reside in distinct cytoplasmic domains which are always contiguous to regions of the cell membrane contacted by basal lamina. This invariant juxtaposition of the synaptic vesicle domains to the basal lamina leads us to suggest that the basal lamina specifies the positions of synaptic vesicle domains, perhaps by transmembrane attachments. A ring of mitochondria and membrane sacs resides at the border between the vesicle-rich cytoplasm and a central core of axon-like cytoplasm. Serial longitudinal and transverse sections through the bouton-shaped terminals have revealed that neurofilaments end in specific regions of the core cytoplasm. Individual filaments in the bundle terminate simultaneously on or near disk-like structures (discontinuity plaques). A filament bundle (though not the same filaments) resumes a similar course on the distal side of the plaque. The presence of a discontinuity plaque in several consecutive longitudinal sections indicates that filaments do not leave the plane of section on either side of it; the neurofilaments are <u>discontinuous</u> at the plaques. It is therefore clear that the plaque transects the neurofilament bundle and that the neurofilaments terminate nearby. Discon-tinuity plaques would be obvious candidates for the sites of filament degradation in the synaptic terminal, but it is unknown yet whether they are found in the axon.

102.18 SPATIAL ANALYSIS OF THE DENDRITIC TREES OF TRICEPS SURAE <u>a-MOTONEURONS. S. Cullheim\*, R.E. Burke, J.W. Fleshman and I.</u> <u>Segev\*.</u> Lab. of Neural Control, NINCDS. NIH. Bethesda, MD 20205. Complete dendritic trees of six triceps surae (TS) <u>a-motoneurons(two each of types FF, FR and S) were reconstructed</u> from LM serial sections after intracellular staining with HRP. Soma dimensions and the lengths of all dendritic branches were measured from the original sections. Branches were then broken into segments, depending on total branch length, and the diameters of all segments were measured. The length, diameter and 3-space coordinates of the proximal and distal ends of each segment were input to computer files, along with code names specifying position in the dendritic tree. We then examined the three-dimensional distribution of dendritic branches and of membrane area within the space centered on the motoneuron sona and orthogonal to the axes of the spinal cord. Analysis of the dendritic tree of each cell in terms of vectors based on the coordinates of branch points and/or terminations showed little evidence for strong dendritic directivity in any cell. However, when the perisomatic space was divided into 24 equal radiating pyramids, the distribution of dendritic branch points, terminations and membrane areas in these pyramids was non-random for each cell studied (Z<sup>2</sup> analysis). This non-randomness was most prominent in the transverse (cross-section) plane and was less strong in the horizontal and sagittal planes. Each motoneuron studied showed a different pattern of dendritic predominance, particularly in the transverse plane, and pooling the results from the six TS cells studied disclosed no consistent departure from a basically radial organization and no apparent differences correlated with motor unit type. In all TS cells studied, the membrane area present in concentric shells centered on the soma increased with radial distance to reach a maximum (mean about 12 percent

- 102.19 MATCHING ELECTROPHYSIOLOGICAL WITH MORPHOLOGICAL MEASUREMENTS IN CAT  $\alpha$ -MOTONEURONS. J.W. Fleshman, I. Segev\*, S. Cullheim\* and R.E. Burke. Lab. of Neural Control, NINCOS, NIH, Bethesda, MO. In pentobarbital-anesthetized cats, the input resistance (R<sub>N</sub>) of triceps surae (TS)  $\alpha$ -motoneurons was measured (spike height and pulse methods), using HRP-filled micropipettes. Averaged records of voltage decay transients following short de-and hyperpolarizing current pulses were also obtained, permitting estimates (by "peeling" exponentials) of the effective electronic length of the cell (Lpeel) and of membrane time constant ( $(T_{o})$  (Rall, Biophys. J. 9:1483, 1969). Six HRP-filled motoneurons (2 each of types FF, FR and S) were completely reconstructed from serial LM sections, the lengths and diameters of dendritic branches were measured, and data representing the soma and dendritic tree of individual cells were stored in computer files (see Cullheim et al., this meeting; Fleshma et al., <u>Neurosci. Abstr.</u> 8:414, 1982). Using established cable theory (Rall, <u>Exp. Neurol</u>. 1:491, 1959), the R<sub>N</sub> implied by the morphology of each cell was calculated for cytoplasmic resistivity of 70 ohm-cm<sup>2</sup> and various values of specific membrane resistivity (R<sub>m</sub>). The electrotonic lengths (L<sub>1</sub>) of the paths from terminal dendritic tree (L<sub>6</sub>) was calculated from terminal dendritic conductance ratio, s. These results were compared with Lpeel obtained from the experimentally observed voltage transients. With the assumption that R<sub>m</sub> is uniform, values of R<sub>m</sub> that matched R<sub>N</sub> gave Lest values much longer than Lpeel. Furthermore, these uniform R<sub>0</sub> values an high as 5 6  $\omega$ /Crm<sup>2</sup> in order to match the physiologically determined  $T_0$ 's. It was possible, however, to reconcile observed and calculated values for R<sub>N</sub> and electrotonic length by assuming that R<sub>m</sub> was non-uniform and increasing R<sub>m</sub> also allowed us to match experimental and calculated values of  $T_0$  with  $C_m$  ere the conventional value of 1  $\omega$ /Cr<sup>2</sup>. The
- 102.20 THEORETICAL ANALYSIS OF NEURON MODELS WITH DENDRITES OF UNEQUAL ELECTRICAL LENGTHS. Idan Segev\* and Wilfrid Rall. Lab. Neural Control, NINCDS and Math. Res. Br., NIADOX, NIH, Bethesda, MO. A neuron's dendritic tree often includes paths from soma to dendrite terminals of different anatomical lengths. If the electrical lengths, of the paths are also different, the dendrit to trees of such cells cannot be strictly represented as a single equivalent cylinder. We have examined three cases analytically and with computer models: (1) two cylinders of equal diameters but different electrical lengths, L, coupled at a point of common origin (very small "soma"); (11) two cylinders of different diameters and L'S, coupled at a "soma": and (111) four cylinders with either equal or unequal diameters and different L's , coupled at a "soma". For all the cases, the passive decay of potential after a voltage perturbation anywhere in the system can be expressed as a sum of exponential decays: V(t) =  $\Sigma C_i \exp(-t/C_i)$ , where  $i=0, \dots, \infty$ . The values of the coefficients,  $C_i$ . If  $C_1 << C_2$ , we can recover  $C_0$  and  $C_2$ , but not  $C_1$ ; then the method (Rall, Biophys. J. 9:1483) of peeling the exponential decay to estimate L (L\_peel) from a time constant ratio requires re-evaluation. We addressed the question how the value of  $L_{peel}$  compares with the L values specified for each of the three cases above, for current injection and voltage decay at the "soma". In case (1) we find that when the L of each cylinder does not differ by more than 20 percent from the mean electrical length (i.e.,  $A = J(L_1-L_2)/(L_1+L_2)/C_2)$ ,  $L_{peel} = (L_1+L_2)/2$  (as is strictly true when  $L_1 = L_2$ . When  $A = L_2$ ,  $L_{peel} = L_3 = L_3$ , as expected. However when  $L_A < L_B$ ,  $L_{peel} = L_A = L_B$ , as expected. However when  $L_A < L_B$ ,  $L_{peel} = L_A = L_B$ , as expected. However when  $L_A < L_B$ ,  $L_{peel} = L_A = L_B$ , as expected. However when  $L_A < L_B$ ,  $L_B < L_B < L_A < L_B < L_B < L_$
- 102.21 IDENTIFICATION OF INTERNODES IN THE GOLDFISH MAUTHNER AXON WITH INTRA-SHEATH INJECTION OF LUCIFER YELLOW OR HRP. <u>Malcolm R.</u> <u>Wood, Paul G. Funch & Donald S. Faber</u>. Div. Neurobiology; Dept. Physiology; SUNYAB; Buffalo, NY 14214. The Mauthner (M-) axon of the goldfish apparently lacks the node of Ranvier characteristic of myelinated vertebrate axons.

The Mauthner (M-) axon of the goldfish apparently lacks the node of Ranvier characteristic of myelinated vertebrate axons. However, electrophysiological evidence has demonstrated active sites at 2.0-2.8 mm intervals along the axon in the medulla (Funch & Faber, J. Neurophysiol. 47:1214-1231, 1982). The experiments described here were desiged to determine the limits of single internodes.

The provide of single internodes. In 2 series of experiments, Lucifer Yellow (LY) (31 axons) or HRP (16 axons) were pressure injected into the myelin sheath of the M-axon in the medulla. Microelectrode recordings from the sheath display a maximal voltage  $\geq$  50 mV produced by the Maxon action potential;  $\geq$  20 mV was used as the criterion for sheath penetration. HRP injections labelled the cytoplasmic belts, incisures and Schmidt-Lantermann clefts forming a complex interlacing network. Nine oligodendrocyte somata have been identified with processes in continuity with the sheaths and are located either just dorsal to the sheath or close to the midline. The broad, flattened cytoplasmic process from the soma wraps around the M-axon forming a tight spiral of 5-7 loops and then spirals more loosely. A single glial cell may contribute more than 1 process to a single M-axon sheath. Cleared wholemounts of LY and reconstructions of 30 um vibratom sections of HRP preparations showed that dye diffusion stopped at specific loci (3.8 and 1.4 mm anterior to and 1.1 and 3.2 mm posterior to the posterior margin of the vagal lobes). The particular internodal segment stained was predictable on the basis of the rostral-caudal location of the site of dye injections within any particular internode. Although single HRP injections resulted in staining of segments as long as 2.45 mm, multiple injections along a single internode never resulted in staining over a distance greater than 2.75 mm (mean=1.94 mm; SD=0.53; n=16); thus HRP diffusion was restricted to single internodes. In contrast, in 31 single injections of LY, staining of less than 2.14 mm occurred only once; in 18 injections, dye coupling was observed between adjacent internodes. The resulting bimodal distribution (m\_1=2.5-3.0 mm; m\_2=4.0-4.5 mm) of LY-stained segments suggests a diffusion barrier exists between adjacent internodes. These data show that a) the Maxon sheath is divided into internodes and b) their termination point 102.PO TANYCYTES OF THE SPINAL CORD OF THE ADULT RAT: A COMBINED GOLGI-GOLD TONING STUDY. J.A. Rafols and H.G. Goshgarian Dept. Anat., Wayne State Univ., Sch. of Med., Detroit, MI 48201. In the course of a Golgi study of the cervical spinal cord of the adult rat, numerous tanycytes were observed radiating from the ependyma into the gray matter that surrounds the central canal. In 100 µm thick Golgi sections, ependymal (E) and sub-ependymal (S) types of tanycytes were distinguished by virtue of cell body of both types of tanycytes has an apical pole that reaches the surface of the central canal and a basal pole that gives rise to a tail process. The tail process extends into the adjacent gray matter. The tail ends as a foot-like process which surrounds blood vessels with cross sectional lumina measuring 6-15 µm.

After deimpregnation and gold-toning, the same tissue was embedded in plastic and sectioned for light or electron microscopy. At the ultrastructure level, gold-toned tanycytes contained fine clusters of gold particles underlining the plasma membrane of the cell body and coarse clusters of gold particles throughout the tail and foot processes. The apical surfaces of tanycytes is characterized by numerous microvilli and large, bleb-like protrusions containing mitochondria, microtubules, bundles of fibrils, ribosomes and vesicles. Cilia are found in association with the non-tanycytic ependyma. At the luminal surfaces, adjacent tanycytes are joined laterally by junctional complexes with punctate tight junctions and zonulae adherentes associated with microtubules and fibrils. Other types of junctions are found between apposing tail and foot processes of tanycytes. The foot process abutts the basement membrane of endothelial cells, pericytes, and/or smooth muscle cells of blood vessels. In addition thin astroglial sheets may interpose between the membrane of the foot process and the perivascular space. At their basal ends the lateral surfaces of adjacent foot processes form extensive infoldings which are filled with electron dense material. These basal membrane labyrinths are continuous with the basement membrane of the blood vessel and may provide an extensive surface relation for the exchange of substances between the cerebrospinal fluid and the neighboring vasculature of the spinal cord. Supported by U.S. Public Health Service grant NS-14705. 103.1 SYNTHESIS OF THE TRANSFERRIN RECEPTOR BY CULTURES OF EMBRYONIC CHICKEN SPINAL NEURONS. G.J. Markelonis, T.H. Oh, C.Y. Cha<sup>\*</sup>, J.W. Kim<sup>\*</sup> and P. Azari<sup>\*</sup>. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, Maryland, 21201.

We have purified a glycoprotein from chicken sciatic nerves, sciatin, which has pronounced trophic effects on avian skeletal muscle cells in culture. Recent studies have shown that sciatin is identical to the iron transport protein transferrin in terms of its physical properties and biological activity. In order to determine whether transferrin is synthesized and released by neuronal tissue, we incubated cultures of dissociated chicken spinal neurons in a medium free of L-leucine containing either 3H-L-amino acids or 14C-L-leucine and immunoprecipitated transferrin with highly specific antibodies. The radiolabeled protein precipitated by rabbit heteroclonal, goat heteroclonal or mouse monoclonal antitransferrin antibodies increased in specific activity in a linear manner for at least 30 min. Synthesis of this protein from cells was linear with a half-life (t<sub>4</sub>) of 8-10 h, although only about 10-12% was eventually released into the culture medium. When immunoprecipitates were separated by SDS gel electrophoresis, a prominent band corresponding to transferrin since this particular protein band was not generated by incubating with subled by incubating radiolabeled protein of Mr 56k was not simply a degradation product of transferrin since this particular protein band was not generated by incubating and spinal cord by immunoabsorption chromatography on mouse monoclonal antitransferrin IgG conjugated to Sepharose 48. As expected, the purified protein failed to crossreact with antitransferrin since that the receptor for transferrin is synthesized by this tissue and is precipitated by cultures of chicken spinal cord neurons but that the receptor for transferrin since that the spuntesized by cultures of the sugression antibodies. From these data, we conclude that transferrin is not synthesized by cultures of chicken spinal cord neurons but that the receptor for transferrin antibodies as an antigen-receptor complex. Furthermore, we suggest that the abundance of transferrin found in peripheral nerves in the chicken is

103.2 MONOCLONAL ANTIBODIES TO CHICK CILIARY GANGLION ISOLATE A NEURAL CREST SUBPOPULATION BY FLUORESCENCE ACTIVATED CELL SORTING. K.F. Barald. Neuroscience Program, Dept. Anatomy and Cell Biology, University of Michigan Med. School, Ann Arbor, Michigan 48109.

Two highly specific monoclonal antibody multiply much solutions in the provided state of the solution of the

These cells can then be placed in microwells of a 96-well tissue culture plate. Mini-assays for high affinity choline uptake, choline acetyltransferase (CAT) activity, and acetylcholinesterase (ACRE) activity have been developed to characterize both the sorted and the residual population.

The antibody-positive neural crest population (APNC) possesses a high affinity choline uptake mechanism that is inhibitable by hemicholinium-3, a specific inhibitor of high affinity choline uptake. The Michaelis constant (apparent) Km for the uptake is 0.5  $\mu$ M. The high affinity choline uptake Km for isolated ciliary ganglion neurones in tissue culture is 0.3  $\mu$ M. Neither the general (unsorted) mesencephalic crest population nor the antibody-negative neural crest (ANNC) expresses a high affinity choline uptake mechanism. Instead, both populations express only a low affinity apparent Km of 50-75  $\mu$ M. In addition, the APNC population possesses CAI activity, and autoradiography of the cultures using a technique for the identification of cells with high affinity choline uptake shows that all cells in the APNC but none in the ANNC cultures are labeled. This result indicates that the isolated population possesses some of the properties of cholinergic neurones without expressing a neuronal morphology. The presence of both cell surface

This result indicates that the isolated population possesses some of the properties of cholinergic neurones without expressing a neuronal morphology. The presence of both cell surface antigens and cholinergic properties supports the possibility that the FACS-isolated crest cells contribute to the ciliary ganglion. (Supported by USPHS NS-17262 and the Dysautonomia Foundation).

103.3 SELECTIVE STAINING OF PURKINJE CELLS, PYRAMIDAL CELLS, AND OTHER NEURONS WITH MONOCLONAL AD AGAINST A GLYCOPROTEIN OF PC12 CELLS. P. Sajovic, Ety Moraru\*, L. A. Greene\*, and M.L. Shelanski\*. Dept. of Pharmacology, N.Y.U. Medical Center, New York, NY 10016.

In order to study surface glycoproteins of the mature and developing nervous system, we have used the NGF-responsive PC12 pheochromocytoma cell line, a model neuronal system, as a source of material. Monoclonal antibodies were raised against high molecular weight glycoproteins of PC12 cells with an immunogen made by extracting the cells in  $1^{X}$  buffered deoxycholate, removing nucleic acids, running the extract over a wheat-germ agglutinin affinity column, and eluting with buffered N-acetylglucosamine in 0.002% deoxycholate. The eluate was then concentrated and fractionated on an HPLC sizing column. The first protein peak to come through contained three major glycoproteins at 230, 180, and 140 kd, as well as mior SDS-PAGE estimates). This mixture was used to immunize mice, and hybridomas that produce monoclonal antibodies were made in the usual way. Hybridoma supernatants were screened by their ability to stain PC12 cells via second-antibody immunofluorescence and to recognize immobilized immunogen in arradio-binding assay. We have developed three stable clones of interest thus far, as well as control clones.

One of the clones produces an IgG which specifically immunoprecipitates a single glycoprotein of 180 kd from PC12 cells labelled with radioactive fucose or methionine and extracted in Triton-SDS. When used for immunofluorescence microscopy on PC12 cells, the antibody stains a bright rim at the perimeter of the cell. Membranous sheets which form "spikes" and partial "skirts" around attached cells can be seen; the neurites of NGF-treated PC12 cells, including growth cones, are also stained. In fixed and frozen sections of adult mouse brain, this anti-180 antibody stains some but not all neurons. Within the cerebellum, only Purkinje cells are stained. Fluorescence is strong over cell bodies and the trunks of dendrites. In hippocampus, pyramidal cell bodies stain while cell bodies in adjacent layers do not. In neccortex, pyramidal cells are brightly stained on the soma and trunk portions of the apical dendrite. We have not seen any evidence of glial staining. Further studies of the distribution of the 180 kd protein in adult brain and other tiss biochemistry and possible functions.

its biochemistry and possible functions. Supported by NIH grant NS-16839 (to L.A.G. and M.L.S.), and by NIH Fellowship NS-07178 (to P.S.). 103.4 GANGLIOSIDE LOCALIZATION AT NODES OF RANVIER AND INTERNODAL SCHWANN CELL SURFACES BY CHOLERA AND TETANUS TOXIN BINNING. A. L. GABSER and D. A. Kirschner\*. Debt. of Neuroscience.

<u>A. L. Ganser and D. A. Kirschner</u><sup>\*</sup>. Dept. of Neuroscience, Children's Hospital and Harvard Medical School, Boston, MA 02115. Cholera and tetanus toxin receptors have been localized on the surfaces of myelinated, peripheral nerve fibers by indirect immunofluorescence. The toxins have high affinities for  $G_{\rm M1}$  and  $G_{\rm 1b}$  series gangliosides, respectively. To expose the most superficial, extracellular surfaces to the toxins, mouse sciatic nerves (unfixed) were teased into individual, intact fibers.

**Cholera toxin** binding sites were abundant at all nodes of Ranvier; they were scarce on the internodal Schwann cell surfaces. The nodal receptors were resistant to various degradative enzymes, including trypsin and proteinase K. The enzymes did not unmask receptors on the internodal surfaces. Exogenous  $G_{M1}$  successfully competed for the toxin binding sites on the fibers. From this evidence and the specificity of cholera toxin binding, we conclude that  $G_{M1}$  ganglioside is abundantly present on the membrane surfaces of peripheral nodes of Ranvier and is not present on the internodal Schwann cell surfaces in an appreciable amount. The pattern of fluorescence within the node suggests that both Schwann cell structures and axolemma are sites where  $G_{M1}$  is localized.

axolemma are sites where  $G_{M1}$  is localized. Cholera toxin binding to the internodal Schwann cell surface resulted from treatment of the teased fibers with <u>V. cholerae</u> neuraminidase which is known to reduce polysialogangliosides to the monosialoganglioside  $G_{M1}$ . The induced receptors, as well as their precursors, were resistant to trypsin and proteinase K. We conclude that the internodal Schwann cell surface is rich in an unidentified polysialoganglioside(s) that can be converted to  $G_{M1}$  by neuraminidase. Tetanus toxin also bound to the teased nerve fibers. Binding

Tetanus toxin also bound to the teased nerve fibers. Binding sites were localized exclusively to the nodes of Ranvier, i.e. no binding was apparent on the internodal Schwann cell surfaces. Proteinase K degradation of the fiber surface did not eliminate the toxin receptors at the node and did not unmask receptors on the internodal Schwann cell surface. Exogenous G<sub>Tlb</sub> was able to compete with the receptors at the nodes of Ranvier. These results and the pattern of nodal fluorescence with tetanus toxin suggest that the axolemma, and not Schwann cell structures, is the only site where the polysialogangliosides that bind tetanus toxin are localized.

103.5 A MONOCLONAL ANTIBODY (mAb) PRODUCED BY IN VITRO IMMUNIZATION AGAINST CLONAL PITUITARY CELLS RECOGNIZES A SURFACE PROTEIN ON SPECIFIC POPULATIONS OF NEURONS IN THE MOUSE CNS. <u>G. Kapatos\*</u>, M.T. Caserta and J.L. Barker, Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, Md. 20205 The GH3 clonal pituitary cell line expresses a wide variety of

The GHS clonal pituitary cell line expresses a wide variety of membrane receptors for hypothalamic hormones. These cells are also excitable, exhibiting several classes of ion channel mechanisms. The surface of GH3 cells may thus serve as a rich and ready source of the membrane components comprising receptor and ion channel mechanisms important in neurohormonal communication. These properties have led us to use GH3 cells as immunogens in the hope of generating a panel of immunoreagents that would bind with, and identify specific receptor and ion channel determinants.

Ion channel mechanisms important in neuronormonal communication. These properties have led us to use GH3 cells as immunogens in the hope of generating a panel of immunoreagents that would bind with, and identify specific receptor and ion channel determinants. A subclone of GH3 cells grown on polylysine-treated flasks were fixed in situ with 4% paraformaldehyde. To each flask was added freshly prepared Balb/c spleen cells and media conditioned by a 48 hour incubation of a mixed culture of Balb/c and C570L thymocytes. After 4-7 days in culture responsive spleen cells were harvested and fused 1:1 with SP2/0-Agl4 myeloma cells. Hybridoma culture supernatants were screened on fixed GH3/6 cells using an ELISA technique. From this in vitro immunization, hybridization and screening protocol a number of clones secreting mAbs were isolated. The first mAb studied, an IgM designated Gl, bound to living, as well as fixed GH3/6 cells. Vioratome sections taken from fixed ault mouse spinal cord showed that Gl stained an anomically distinct cluster of neurons. Analysis of mAb binding to fixed or living cells derived from embryonic day 13 mouse spinal cord demonstrated that Gl labelled a subpopulation of small cells using an succellate to synaptic boutons and that portion of the soma from which a process emanated. Flow cytometry of acutely dispersed embryonic SC elements demonstrated that the majority of the viable cells were labelled by Gl at fluorescent intensity equal to A285. Immunoblat analysis revealed that Gl binds to the same 41 Kdalton protein extracted from pituitary and SC cell membranes.

localized to synaptic boutons and that portion of the soma from which a process emanated. Flow cytometry of acutely dispersed embryonic SC elements demonstrated that the majority of the viable cells were labelled by A2B5. In contrast, only 5% of these cells were labelled by Gl at fluorescent intensity equal to A2B5. Immunoblot analysis revealed that Gl binds to the same 41 Kdalton protein extracted from pituitary and SC cell membranes. Further immunohistochemical and immunoblot analyses have shown that the 41 Kdalton protein bound by Gl is also present on certain neurons in primary cultures derived from rodent hypothalamus, hippocampus, and cortex, as well as neurons present in adult brainstem and diencephalon. The expression of this 41 Kdalton protein in vitro and in vivo may allow us not only to study what function, if any, this protein plays in excitability, but also the biological properties of the neurons that express it.

- 103.7 CHARACTERIZATION AND SUBCELLULAR DISTRIBUTION OF A CEREBELLAR GLYCOPROTEIN RELATED TO FODRIN. <u>Douglas E. Groswald and Paul T. Kelly</u>. Div. of Biol., Kansas State Univ., Manhattan, KS 66506. Subcellular fractions from rat cerebellum(CELM), forebrain(FB) and non-neural tissues were examined for the presence of a 240kd glycoprotein, designated GP-A. GP-A was enriched in CBLM synaptic junction(SJ) fractions when compared to synaptic plasma membrane(SPM) fractions and was not found in FB subcellular fractions. GP-A was not detected in myelin, mitochondria, purified nuclei, or cytosolic fractions from CBLM but was present in microsomal fractions. GP-A was absent from liver, kidney and lens plasma membranes. CP-A was sparingly soluble in Triton, however, it was completely solubilized when CBLM SPMs were extracted with the ionic detergent N-lauryl sarcosinate(NLS). The extent of solubilization of GP-A from CBLM membranes in Triton was dependent on calcium at concentrations in the uM range.
  - Comparisons between affinity purified fodrin (Levine and Willard, JCB, 90:631-643, 1981) and the 235kd/230kd doublet in CBLM and FB synaptic fractions by 2-D peptide mapping indicated that they were identical. Peptide mapping comparisons between Con A-agarose affinity purified GP-A and GP-A in SPM and SJ fractions indicated that GP-A was apparently homogeneous in synaptic fractions. Peptide mapping of GP-A and the 235kd fodrin polypeptide indicated that these two proteins are highly related (50% of their peptides were common). GP-A is the major Con A binding glycoprotein in CBLM SJ fractions and migrates on SDS-gels with a slower relative mobility than the 235kd/230kd fodrin doublet. Fodrin polypeptides did not bind dectectable amounts of Con A. To examine the possibility that GP-A may be a highly mannosylated form of fodrin, GP-A was digested with endoglycosidase H(endo-H). Endo-H treatment removed greater than 95% of GP-A's Con A binding activity. However, on the basis of apparent molecular weight, endo-H treatment di not convert GP-A to fodrin. Both the 235kd fodrin polypeptide in SJs and affinity purified fodrin reacted reacted on Western blots with anti-fodrin antisera. However, GP-A failed to react with anti-fodrin antibodies. These observations indicate that GP-A is a CBLM-specific, membrane glycoprotein that is enriched in SJs and related to fodrin. The role of calcium in synaptic transmission, together with GP-A's decreased solubility in Triton in the presence of micromolar concentrations of calcium, suggests that GP-A may play a role in stabilizing cerebellar synapses. (Supported by NIH grant NS-15554(to P.K.) and RCDA NS 00605).

103.6 GFA- AND NF-LIKE IMMUNOREACTIVITY IN RODENT IRIS AND ENTERIC NERVOUS SYSTEM. H. Bjorklund\*, D. Dahl<sup>1</sup>, L. Olson\* and A. <u>Seiger</u>.\* Department of Histology, Karolinska Institutet, Stockholm, Sweden, and <sup>1</sup>West Roxbury VA Medical Center and Harvard Medical School Boston MA USA

Harvard Medical School, Boston, MA, USA. We have studied the appearance and distribution of cells and fibers showing GFA- or neurofilament (NF)-like immunoreactivity in whole mounts of rodent iris and in the small intestine myenteric nervous system using immunofluorescence. In adult rodents we found dense plexuses of GFA- and NF-positive fibers organized in thicker bundles as well as in thinner fibers evenly distributed over the iris. GFA- but not NF-positive cells bodies were found. Grafting of irides to the anterior eye chamber caused a total disappearance of the NF-positive fibers but left the GFA-positive plexus intact. However, in grafted as well as in host irides strongly fluorescent spider-like cells with short branching processes not seen in normal irides were visualized with GFA antiserum. Sensory denervation of the eye caused a degeneration of most NF-positive fibers. Sympathetic and parasympathetic denervations, however, caused no observable degeneration of NF-positive fibers suggesting that most, if not all, such fibers emanate from cell bodies in the trigeminal ganglion. Prenatally, NF- and GFA-positive fibers were visualized at embryonic day 18 in the rat in a gradually increasing system of fibers. In whole mounts of rat and mouse myenteric plexus GFA- and NF-positive cell bodies and fibers were poserved in the ganglia of Auerbach's plexus as well as in the interconnecting strands, although most NF-positive peikarya were present within the ganglia. The NF-positive cells bodies were comparatively large with an excentric nucleus. Most of the cells seemed to be unipolar with a large axon-like fluorescent process. The GFA-positive cell bodies were more numerous, clearly smaller and had several short branching processes. Double labelling experiments showed that the GFA- and NF-positive fibers were studied in rat pups and embryos. We conclude that immunofluorescence with NF-antiserum can be used to study the distribution and appearance of neuronal populations in whole mounts of different per

03.8 EVOLUTIONARY PATTERNS OF MOLECULAR CONSERVATION AND VARIATION IN NEUROFILAMENT PROTEIN. L. L. Phillips, R. J. Lasek and L. Autilio-Gambetti. Dept. of Anat., and Inst. of Path., Case-Western Reserve Univ. Cleveland. OH 44106.

Autilio-Gambetti. Dept. of Anat., and Inst. of Path., Case-Western Reserve Univ., Cleveland, OH 44106. The high affinity of the Bodian silver stain for neurofilament (NF) polypeptides, originally described in rat brain (Gambetti, et al., <u>Sci</u>. 213: 1521), is now known to be a property of NFs in a wide variety of species (Phillips, et al., <u>Anat. Rec.</u> 202: 149A). Our initial comparative study showed that the NF binding of silver stain was conserved over a long span of evolution and demonstrated the potential for variability in both NF molecular weight and subunit number. In order to better determine the NF variability among vertebrates we expanded the comparative approach using Bodian silver and immunomethods as molecular markers. Nineteen additional species were chosen from both unexamined and previously selected vertebrate classes (mammalia, avia, reptilia, amphibia, ostaoichthyes, and chondrochthyes). Half of the sampled species represented the two classes of fish, whose

NFs showed the most variable pattern of molecular weights in our initial study. Samples of CNS tissue, concentrated in cytoskeleton, were separated by one-dimensional SDS-PAGE and stained with both the modified Bodian method and antibodies to NF polypeptides.

Bodian silver selectively stained a subset of polypeptides in all samples, each of which was confirmed as NF protein by immunochemistry. All of the species studied had at least one NF subunit with a molecular weight between 60-80 thousand and one or more subunits of molecular weight 130-200 thousand. Consistant with previous studies, all mammals had a NF triplet. However, non-mammalian vertebrates showed great variation in their NF subunit composition. In some of these species the NF subunit pattern consisted of only two major proteins. Other species had a triplet or even more complex patterns. This variation in NF subunit composition was observed in all of the major vertebrate classes. Selected examples of these differences are listed as follows: chicken (180,160,70), finch (180,145,68); <u>Anolis</u> (lizard) (160,68), turtle (140,68); <u>Xenopus</u> (frog) (200,145,68), newt (135,68); ogfish (147,130,68), hammerhead shark (180,68) and lamprey (170). These observations suggest that all vertebrate NFs contain a lower molecular weight subunit which may be relatively conserved in evolution and may be particularly important in forming the basic structure of the NF. Vertebrate NFs also contain higher molecular weight subunits that exhibit a great deal of evolutionary variation in their apparent molecular weight. These high molecular weight subunits may provide the potential for evolutionary changes in NF structure and function among species.

ISOLATION OF ACETYLCHOLINE RECEPTOR CLUSTERS FROM CULTURED RAT 103.9 MYOTUBES USING SAPONIN. <u>W.G. Resneck\* and R.J. Bloch</u> (Spon: L. Goldman) Department of Physiology, University of Maryland School of Medicine, Baltimore, Md. 21201.

> Clustering of acetylcholine receptors (AChRs) in muscle mem brane is an important step in neuromuscular junction formation. Because it occurs in muscle cells cultured without nerve, it can be easily studied, to learn more about events and structures in-volved in postsynaptic differentiation. Such studies would be facilitated if isolated preparations of muscle membrane enriched in AChR clusters could be achieved. We have developed such a preparation.

Cultured rat myotubes are washed in buffered saline containing EGTA, MgCl<sub>2</sub> and bovine serum albumin. They are then treated for 20 min in the same solution supplemented with 0.2% saponin, with gentle shaking. After a brief lag, most (95-97%) of the cellular material detaches, but large sheets of muscle membrane remain attached to the culture substrate. Scanning electron microscopy shows that such sheets of membrane are left associated with the substrate as the rest of the myotube retracts. If cultures are prelabeled with fluorescent  $\alpha$ -bungarotoxin (R- $\alpha$ BT) to visualize AChRs, the membrane sheets are found to contain essentially all (85%) of the large, substrate-apposed AChR clusters originally in the culture. Prelabeling with <sup>125</sup>I-BT reveals that ~15% of the total AChRs in the cultures are recovered in the cluster-rich

total ACRAS in the cultures are recovered in the culture-item fraction. As only 3-5% of the total protein is recovered, purifi-cation of ACRR clusters is >20 fold. By following individual ACRR clusters before and after isola-tion, we found that the isolated clusters are essentially identi-cal to the clusters in unextracted cells. The contact domains of isolated clusters are closely wighted more interformers acfine isolated clusters are clearly visible using interference reflec-tion microscopy, suggesting that they are still closely apposed to the culture substrate. However, vinculin, a cytoskeletal pro-tein closely associated with contact domains, is extracted from clusters within 5 min of addition of saponin. No other cytoskeletal proteins have been found at contact domains, suggesting that vinculin and associated structures detach from the cluster during the isolation procedure. However, actin and myosin appear to be associated with AChR domains in isolated clusters, and at least actin seems to be involved in maintaining AChR organization.

BIOSYNTHESIS AND EXTRACELLULAR TRANSPORT OF ACETYLCHOLINESTERASE 103.10 IN PRIMARY MUSCLE CULTURES. <u>M.W.Klymkovsky</u>\*, <u>R.I.J.appin\*</u> <u>L.L.Rubin</u>. (SPON: W.V.Bleisch)The Rockefeller University 1230 York Avenue, New York, New York 10021

The appearance of acetylcholinesterase (AChE) at newly formed chick nerve-muscle synapses in tissue culture is dependent upon synaptic transmission, specifically on muscle contraction. study the effects of muscle contraction on synaptic AChE, we have begun an examination of the synthesis of collagen-tailed (A12) begun an examination of the synthesis of collagen-tailed (AL2) AChE, the presumptive synaptic form, in primary cultures of chick, mouse, rat and <u>Xenopus</u> skeletal muscle. All of these types of cells synthesize the Al2 form, although in the case of chick muscle its appearance is inhibited by the presence of an acid-stable, high molecular weight factor(s) present in horse serum. When chick muscle cells were grown in a simple defined medium the monomeric (G1) and dimeric (G2) forms appeared rapidly, with in 5 to 10 minutes after inhibition of total cellular AChE. They were followed by tetrameric (G4) (1-2 hrs.) and A12 (6-8 hrs.) forms. Both G2 and G4 were secreted in soluble form into the culture media; their S-values were not significantly different culture media; their S-values were not significantly different from the corresponding cellular forms. Secretion of AChE was inhibited by lysosomotropic agents. Al2 was not secreted into the medium. By using the membrane-impremeable AChE inhibitor echothiophate, we found that both Al2 and G4 were located echothiophate, we found that both AL2 and G4 were located preferentially on the cell surface, although there was a substan-tial intracellular pool of both forms. The proportion of AL2 and surface AChE was increased by treatment with the sodium channel activator veratridine (VER), which concomitantly decreased the amount of surface acetylcholine receptor. The sodium channel blocker tetrodotoxin (TTX) decreased the percentage of A12 and surface AChE while it increased the amount of surface acetyl-choline receptor. VER and TTX had little effect on the level of choline receptor. VER and TTX had little effect on the level total cellular AChE in cultured chick muscle. In rat cultures, TTX decreased the total level of AChE and

decreased the percentage of Al2 form. In mouse, TTX decreased total levels of AChE and the percentage of Al2 form transported to the cell surface, although the level of Al2 as a percentage

of total cellular ACRE was not always decreased. Our results indicate that the secretion of soluble ACRE is activity-independent, while the accumulation of the A12, synaptic form on the surface of muscle cells is dependent on activity.

SYNTHESIS, ASSEMBLY, AND ACTIVATION OF ACETYLCHOLINESTERASE IN 103.11 STRINESIS, ASSEMBLY, AND ACTIVATION OF ACLIVICHOLINESIERASE IN CULTURED MUSCLE CELLS. <u>Richard L. Rotundo</u>. Carnegie Institution of Washington, Dept. of Embryology, Baltimore, MD. 21210 We have studied the synthesis and processing of acetylcholin-esterase (AChE) in muscle using monoclonal and polyclonal anti-

bodies to immunoprecipitate isotopically labeled enzyme molecules. We find that chicken muscle AChE consists of at least two distinct

bodies to immunoprecipitate isotopically labeled enzyme molecules. We find that chicken muscle AChE consists of at least two distinct polypeptide chains,  $\alpha$  and  $\beta$ , with apparent Mr of 105,000 and 100,000. Each polypeptide chain includes approximately 12,000 daltons of asparagine-linked oligosaccharides. Immunoblotting of AChE with monoclonal and polyclonal antibodies shows that the two polypeptides share antigenic determinants. The dimeric and tetra-meric forms of AChE, isolated by velocity sedimentation, appear to consist of equal numbers of  $\alpha$  and  $\beta$  subunits, however the struc-tural relationships are not yet understood. Pulse labeling studies using  $^{35}$ s-methionine indicate that the  $\alpha$ and  $\beta$  AChE subunits are synthesized concurrently and do not inter-convert. A portion of these subunits are rapidly assembled in the RER to dimeric and tetrameric forms. Comparisons of newly syn-thesized catalytically active AChE molecules with  $^{35}$ s-methionine labeled AChE molecules suggest that this enzyme is synthesized as a catalytically inactive precursor. The predominant enzymatically active forms of AChE in cultured muscle cells are dimers and tetramers, whereas the major  $^{35}$ s-methionine labeled species are monomers and dimers. The vast majority of newly synthesized AChE molecules do not become activated but rather are degraded intra-cellularly with a half-life of approximately one hour. On the other hand, once activated, the AChE molecules are stable. Using a variety of pulse-labeling procedures, irreversible AChE inhibitors immunoprecipitation. other hand, once activated, the AChE molecules are stable. Using a variety of pulse-labeling procedures, irreversible AChE inhibitors, immunoprecipitation, treatment with endoglycosidase-H, and lectin binding, we can show that all the catalytically active AChE molecules pass through the Golgi where further processing of the oligosaccharides occurs. However, only multimeric forms of AChE appear to follow this pathway and are exported by the cells whereas the monomers remain intracellular. In the presence of two services a drug which inhibits the addition of arcaraging whereas the monomers remain intracellular. In the presence of tunicanycin, a drug which inhibits the addition of asparagine-linked oligosaccharides, AChE is synthesized at least at half the control rate, yet none of these molecules are catalytically active nor are they exported by the cell. Thus glycosylation is neces-sary but not sufficient for activation and subsequent transport to occur. These studies suggest that post-translational controls of enzyme assembly and activation may play a role in the regulation of muscle AChE.

103.12 ADULT MAMMALIAN MUSCLE FIBERS CULTURED IN THE ABSENCE AND PRESENCE OF NEURONS. <u>D.S.Grega & J.J.Jay</u>. Dept. Anatomy & Biology, University of Michigan Medical School, Ann Cell Biology, Unive Michigan 48109. Ann Arbor.

In order to study the factors necessary for the formation and In order to study the factors necessary for the formation and maintenance of synapses, we have begun to examine the components of the basal lamina (BL) and the distribution of rhodamine-conjugated  $\alpha$ -bungarotoxin binding sites (R-BIX BS, putative acetylcholine(ACh) receptors as physiological confirmation is necessary), in cultures of single fibers of adult rat flexor digitorum brevis (FDB) muscle. Single muscle fibers were obtained by collagenase treatment and trituration. The effect of neurons was examined by the addition of pieces of embryonic ventral spinal cord. Fiber viability was assessed using trypan blue and/or acridine orange/ethidium bromide. In the BL,the distribution of laminin was determined using fluorescein-conjugated antilaminin and that of acetylcholinesterase (AChE) was assessed histochemically.

conjugated antifaminin and that of acetylcholinesterase (ACRE) was assessed histochemically. The continuity of the BL,as assessed by laminin distribution, is maintained after dissociation on most but not all fibers. The R-BIX BS at the endplate are clearly visible on FDB muscle ranging from freshly dissected muscle bundles to individual fibers in outture up to example due the state activity ranging from freshly dissected muscle bundles to individual fibers in culture up to several days. Thus, the endplate retains R-BIX BS (and presumed ACh receptor)integrity for several days after in vitro denervation (being placed in culture). In contrast, the AChE staining of fibers changes with time in culture. At the time of culturing, the AChE reaction product is observed only at the endplate, either as a discrete endplate alone or surrounded by diffuse stain. Generally within the first day in culture only a diffuse endplate area staining is seen. By 2 davs in culture,very few,if any,viable fibers demonstrate any stain; note that during this same time period R-BTX BS at any AChE the endplate can still be detected . By 7 to 11 days in culture a diffuse AChE stain is observed over entire fibers often with areas of concentrated reaction product which may include the old endplate region. Thus, the time course for changes in the distribution of AChE differs than that for R-BIX BS (putative ACh receptors) for muscle fibers denervated in vitro.

Preliminary experiments with nerve-muscle cocultures indicate Preliminary experiments with nerve-muscle cocultures indicate that there is not a directed growth of neurites to any particular region (e.g. old endplate) of the muscle fibers. Laminin distribution does not correlate significantly with areas of neurite-muscle contact. Further experiments will be done to assess ACh receptor and AChE distribution in these nerve-muscle cocultures. A Possible Molecular Mechanism For Modification of Dendritic 103.13 Spine Shape. <u>R. Siman, M. Baudry and G. Lynch</u>. Department Psychobiology, Univ. of Calif. Irvine, Ca. 92717. Although several kinds of experimental manipulations have Department of

(for example, Lee et al., J. Neurophys. <u>44</u>, 1980), the molecular mechanisms underlying these changes are not yet understood. Fodrin is a likely candidate to play a major role in regulating dendritic spine shape. This actin-binding protein lines the cortical cytoplasm of neurons (Levine and Willard, JCB <u>90</u>, 1981) and is present in postsynaptic densities (Carlin et al., JCB <u>92</u>, 1983). Furthermore, fodrin closely resembles erythrocyte spectrin, the principal component of the cytoskeleton that controls erythrocyte shape. We report here that a calcium-activated thiol-protease, calpain I, degrades neuronal fodrin and erythrocyte spectrin, and that proteolytic degradation of spectrin profoundly and irreversibly alters erythrocyte shape

The calcium-activated thiol-protease calpain I was purified from cytosolic fractions from rat erythrocytes or brain and was tested for its capacity to degrade fodrin and spectrin. In the presence of micromolar calcium concentrations purified calpain I degraded both purified fodrin and the fodrin present in hippo campal synaptic membranes. Both effects were blocked by the thiol-protease inhibitor leupeptin. Addition of calcium to hippocampal membranes also caused a leupeptin-sensitive decrease in fodrin content, suggesting that endogenous calpain I can degrade fodrin. Similarly, calpain I degraded both purified spectrin and the spectrin present in erythrocyte membranes. Using erythrocyte ghosts as a model system, we tested the possibility that calpain-mediated degradation of spectrin-like proteins could be involved in the regulation of cell shape. Resealed ghosts uniformly exhibited the concave disc shape characteristic of intact erythrocytes. In contrast, ghosts that were resealed to contain micromolar concentrations of calcium were spherical with no central concavity. The calcium-induced shape change was blocked by leupeptin in concentrations that prevented spectrin degradation, and was not reversed by lysis, removal of calcium, and subsequent resealing. We propose that in dendrites, as in erythrocytes, calpain-mediated degradation of spectrin-like proteins provides a mechanism by which brief increases in intracellular calcium levels irreversibly modify cell shape.

103.14 CHARACTERIZATION OF A 100,000 Mr PHOSPHOPROTEIN FROM THE NERVOUS SYSTEM OF <u>APLYSIA CALIFORNICA</u> WHICH IS RECOGNIZED BY AN ANTIBODY TO MUSCLE PARAMYOSIN Flora Katz<sup>\*</sup>, Tsunao Saitoh, ANTIBODY TO MUSCLE PARAMYOSIN Flora Katz<sup>\*</sup>, Tsunao Saitoh, Leland Ellis<sup>+</sup>, and James H. Schwartz. (SPON: D.J. Goldberg) Center for Neurobiology & Behavior; The New York State Psychiatric Insitute; and <sup>+</sup>Dept. of Anatomy & Cell Biology, Columbia College of Physicians & Surgeons, New York, N.Y. 10032.

Serotonin and cAMP are known to play a role in synaptic events in <u>Aplysia</u>. We are currently studying neuronal proteins phosphorylated in response to these modulators. In <u>in vitro</u> phosphorylation reactions, we detected a major cAMP-stimulated phosphoprotein with the molecular weight of paramyosin, a contractile protein which forms the core of the thick filament of invertebrate muscle. Because, additionally, phosphorylation of paramyosin is known to be modulated the certain molluscan muscles by serotonin and cAMP, we wanted to determine (1) if the 100K-phosphoprotein is paramyosin and (2) if the state of this molecule can be modified in response to the search of this molecule can be modified in response to these physiological modulators. Therefore, we have characterized paramyosin from <u>Aplysia</u> muscle. Using antiserum against this molecule, we identified a phosphoprotein in neurons which is recognized by this antiserum.

neurons which is recognized by this antiserum. Paramyosin, purified from <u>Aplysia</u> muscle by differential ethanol and salt extractions, migrated on two-dimensional gels with  $M_r$  100K and pI 6, and formed characteristic 72.5 nm paracrystals. Paracrystals were purified further by preparative gel electrophoresis. The paramyosin band was excised, electroeluted, and injected into rabbits. The antiserum raised precipitated a 100K Mr phosphoprotein from muscle.

Muscle. Neuronal cell bodies were isolated from desheathed ganglia. Contamination by muscle proteins was undetectable. On immunoblots of homogenates of these cells, the antiserum recognizes a protein that comigrates with muscle paramyosin and whose <u>in vitro</u> phosphorylation is stimulated by Moreover, this phosphorylation comigrates with CAMP. whose <u>in vitro</u> phosphorylation is stimulated by cAMP. Moreover, <u>this</u> phosphorylation comigrates with the phosphorylated muscle protein on two-dimensional gels. Together, these results suggest that paramyosin might be present in nerve cells of <u>Aplysia</u>. Structural studies of this neuronal molecule and its localization in nerve cells by immunofluorescence techniques are in progress. To investigate the functional role of this paramyosin-like molecule in the nervous system, we are now studying the actions of serotonin and cAMP on this protein's state of

phosphorylation and on its subcellular distribution in intact ganglia.

103.15

GANGLIOSIDES SUPPORT SPECIFIC ADHESION OF EMBRYONIC NEURAL RETINA CELLS. P. Swank-Hill\*, C.C. Blackburn\*, and R.L. Schnaar. Dept. of Pharmacology and Experimental Therapeutics, The Johns Hopkins University School of Medicine, Balto. MD 21205 Cell surface carbohydrates and carbohydrate-specific recognition proteins may mediate cell-cell recognition during neuronal development. We have recently reported an experimental system for testing the ability of gangliosides, an important class of cell surface glycoconjugates in neuronal tissue, to support specific cell recognition and adhesion in vitro (Blackburn, C.C. and Schnaar, R.L. (1983) J.BioT.Chem. 258, 1180-1188). In the present report, we have used this system to test the ability of cells dissociated from embryonic chick neural retina to adhere specifically to gangliosides purified from bovine brain or extracted from embryonic chick neural retina itself. Neural retinae were dissected from 10-day chick embryos, radiolabelled by incubation with trypsin. The cells were resuspended in HEPES-buffered medium and aliquots were placed in polyvinyl chloride microwells which had been adsorbed with the desired lipids. The cells were centrifuged onto the lipid-

desired lipids. The cells were centrifuged onto the lipid-adsorbed surface (60 x g, 1 min), then incubated at the desired temperature  $(0-37^{\circ}C)$  and time (15-60 min). After the incubation, wonderent cells were removed by immersing and sealing the wells in medium, inverting, and centrifuging at 500 x g. The well bottom (with adherent cells) was removed, and cell associated radiolabel was measured. The results indicate a rapid and specific adhesion of neural

radiolabel was measured. The results indicate a rapid and specific adhesion of neural retina cells to surfaces adsorbed with gangliosides. The most effective gangliosides were those extracted from the embryonic neural retina. Surfaces adsorbed with as little as 175 pmol/well of these gangliosides supported adhesion of 35-40% of the input cell population, compared to background adhesion of approx. 15%. Purified bovine gangliosides including GMI, GDIa, GDIb, and GTIb were typically less effective than neural retina gangliosides, while several lipids did not support adhesion above background levels including ceramide, the complex glycosphingolipid globoside, and the negatively charged phospholipids phosphatidyl glycerol and phosphatidic acid at concentrations up to 700 pmol/well. We conclude that neural retina cell adhesion is specific for the carbohydrate moiety of the adsorbed ganglioside and is not due to non-specific ionic or hydrophobic interactions. The ganglioside-specific adhesion was completely eliminated when adhesion was performed at 20°C or below, and was not dependent on the presence of calcium in the adhesion medium. The above results may indicate a key role for gangliosides in cell-cell recognition in the developing nervous system. Supported by NIH HD14010, GM07626 (CCB) and March of Dimes Grant 5-302.

103.16 A RETINOL-BINDING GLYCOPROTEIN SYNTHESIZED AND SECRETED BY MAM-A LEINOL-BINDING GLIOFROIEIN SINIHESIZED AND SECRETED BI ANA-MALIAN NEURAL RETINA. C.D.B. Bridges\*, S.-L. Fong\*, G.I. Liou\*, R.A. Landers\*, F. Gonzalez-Fernandez\*, P. Glazebrook\*, and D.M.K. Lam. (SPON: S.J. Fliesler). Dept. of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030 Exchange of nutrients and metabolites between the retina and Exchange of nutrients and metabolites between the retina and pigment epithelium (RPE) entails passage across the space between these tissues. This space is filled with interphoto-receptor matrix. We have demonstrated that the interphoto-receptor matrix of bovine eyes contains a glycoprotein that has all-<u>trans</u> and some ll-<u>cis</u> retinol as its endogenous ligands (Liou et al., Vision Res., 22:1457-1467, 1982). By gel-filtration, the M<sub>r</sub> = 260K. By SDS-PAGE the M<sub>r</sub> = 144K. We have referred to it as interstitial retinol-binding protein (IRBP). The protein has 2-3 binding sites for retinol (K<sub>D</sub> = 10<sup>-6</sup> M) and also binds  $\alpha$ -tocopherol, retinoic acid, cholesterol and retinal. All are displaced by retinol.

All are displaced by retinol. <sup>125</sup>I-lectins were used to achieve a tentative determination of the type of carbohydrate chain in IRBP (Irfnura and Nicolson, Carbohydrate Res., <u>115</u>:209-220, 1983). Wheat-germ agglutinin (WGA) bound to IRBP, but removal of sialic acid resulted in loss of binding. <u>Ricinus communis</u> agglutinin I (RCA<sub>I</sub>) bound to IRBP only after removal of sialic acid. These findings suggest the presence of terminal stalle acid residues (WGA) followed by galactose residues (RCA<sub>1</sub>). Lens <u>culinaris</u> hemagglutinin (LCH) bound to IRBP, suggesting a biantennary complex structure. Experiments described below suggest that fucose is present.

Similar retinol-binding glycoproteins are present in human  $(M_T = 135K)$ , rat, rabbit and frog. Since rabbit anti-bovine IRBP cross-reacts with human and rat IRBP, we have visualized IRBP in these eyes by immunocytochemistry. The results demonstrate that IRBP is confined to the space between the external limiting membrane and the apical surfaces of the RPE. It was not detected intracellularly.

Isolated rat, human and bovine retinas were incubated in Isolated rat, human and bovine retinas were incubated in media containing  $[{}^{3}H]$ -leucine, -fucose or -glucosamine. After 3 hrs, the medium contained labeled IRBP. Virtually no other labeled proteins were present. Medium from parallel incubations with RPE did not contain labeled IRBP. In retinas from rats of the RCS strain of retinal dystrophy, we could not detect IRBP synthesis or localization after the photoreceptors had degenerated. We conclude that IRBP is synthesized and secreted by cells of the neural retina, possibly the photoreceptors. The function of IRBP has not been determined. It may have a role in the transport of retinol and other hydrophobic compounds between the retina and RPE.

between the retina and RPE. Supported by the Retina Research Foundation of Houston and NIH/NEI. We thank T. Irimura for providing the <sup>125</sup>I-lectins.

THE INFLUENCE OF CLONED INTERFERON-Y ON THE EXPRESSION OF SURFACE 103.17 MAJOR HISTOCOMPATIBILITY ANTIGENS ON MURINE NEURAL CELLS. Perry F. Bartlett\* and Grace H.W. Wong\* (SPON: P. Jeffrey). Laboratories of Neuroimmunology and Immunoregulation, The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia 3054.

Mouse neural cells are unique in that they express very low levels of class I (H-2) and class II (Ia) major histocompatibility complex (MHC) antigens. Less than 5% of neural cells dissociated from 14 day old neonatal CBA mice have detectable levels of cell surface MHC antigens when examined using monoclonal anti-MHC antibodies on the fluorescent activated cell sorter (FACS) and adult brain tissue. The paucity of MHC antigen expression probably accounts for the immunologically privileged nature of brain tissue as these antigens are essential for the initiation and regulation of immune responses. It has recently been demonstrated that interferon-  $\gamma$  (IFN- $\gamma$ ) can increase the expression of class I and class II MHC antigens on a variety of cell types (Wong et al. Proc.Nat.Acad.Sci.USA 79:6989, 1982) and we have examined the effect on neural cells. Single cell suspensions from examined the effect on neural cells. Single cell suspensions from whole brain of 2 day old neonatal mice were prepared and cultured in the presence of IFN- $\gamma$  obtained from monkey cells (COS) trans-fected with the cloned murine IFN- $\gamma$  gene. (Provided by Dr. P.Gray of Genentech Inc.). It was found that within 24 hrs of exposure to IFN- $\gamma$  at the level of 1-2U/ml of antiviral activity high levels of H-2 antigens were expressed on more than 95% of viable cells. These included, astroglia, oligodendroglia and microglia as identified by double antibody labelling. In addition it was found that astroglia, identified by the presence of glial fibrillary acidic protein, would express surface Ia antigens when incubated with IFN- $\gamma$ . By contrast, sensory neurons obtained from the dorsal root ganglion were not able to express MHC antireens when exposed with IFN-Y. By contrast, sensory neurons obtained from the dorsal root ganglion were not able to express MHC antigens when exposed to Y-interferon. Thus it appears that cells within the brain are capable of expressing large amounts of MHC antigens when exposed to a T-lymphocyte product Y-IFN and that this may be essential if appropriate antigen presentation and subsequent immune responses are to be initiated in the brain. The lack of MHC expression in neurons may account, in part, for the ineffectiveness of immune mechanism to combat viral infection of neurons. Supported in part by a grant from the National Multiple Sclerosis Society Grant No. RG 1436-A-1.

NEURONS AND MYELIN ASSOCIATED GLYCOPROTEIN SHARE A DETERMINANT. R.C. McGarry\*, R.J. Riopelle and J.C. Departments of Microbiology and Immunology, and 103.18 COMMON Α Roder\* Medicine Queen's University, Kingston, Canada, (SPON: C. (Neurology) Romero-Sierra)

We have recently demonstrated that a well characterized monoclonal antibody HNK-1 (Leu 7), directed against a surface determinant of a subpopulation of human lymphocytes called natural killer (NK) cells recognizes an antigenic determinant of myelin associated glycoprotein (MAG). HNK-1 also recognizes a surface determinent compared are carted and approximate and surface determinant expressed on central and peripheral chick embryo neurons in vitro.

Dissociated cultures of 8 day embryo dorsal root ganglia (DRG), spinal cord, and optic lobe were enriched for tetanus positive process-bearing cells by differential defined medium and cytosine arabinoside. At various times, vitro cells were labelled with HNK-1 using immunofluorescence PAP techniques. HNK-1 labels beth area in the second adhesion At various times, in immunofluorescence or PAP techniques. HNK-1 labels both cell bodies and processes of neurons from all regions of the nervous system examined. Processes visualized at the light microscopy level by HNK-1 ramify extensively on the poly-D-lysine substrate of the culture dish.

Neurons will attach to, and extend processes on, MAG-coated culture plastic only if HNK-1 is present in the serum-free defined culture medium. Other monoclonal antibodies of the same class that do not recognize determinants on MAG or on neurons do not enhance neuron performance. These bridging data provide further evidence that the monoclonal antibody HNK-1 is recog-nizing a determinant shared between MAG and the neuronal cell surface.

Supported by the Multiple Sclerosis Society of Canada (RCM & JCR) and the Medical Research Council of Canada (RJR).

103.20 EXPRESSION AND DISTRIBUTION OF ENTACTIN IN EXTRACELLULAR MATRIX DAT THE ADULT RAT PERIPHERAL NERVE AND PERIPHERAL NERVE AND VERIPHERAL NERVE CELLS IN CULTURE. C. Cornbrooks, Dept. of Anatomy and Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

The synthesis and organization of extracellular matrix (ECM) occupies an important role in the development and regeneration of the PNS. Previous studies have demonstrated that the differen-tiating Schwann cell produces a number of ECM molecules and that the nature and distribution of these components varies with the development of the neuron-glial relationship. As a first step in understanding these relationships, I have begun to correlate appearance of individual ECM molecules with known events in the formation of the mature PNS. This study characterizes the loca-tion, temporal expression and cellular origin of a novel sulfated glycoprotein, entactin (JBC 256:5209, 1981) in the adult peripheral nerve and peripheral nerve cells in culture. Affinitypurified antibodies, directed against entactin were used as immunological reagents to visualize the expression of the antigen at light microscopic resolutions. Indirect immunohistochemical staining of unfixed, frozen 8  $\mu$ m cross sections of adult rat sciatic nerve revealed a pattern characterized by discrete rings around each Schwann cell-neuron unit in the endoneurium and conaround each Schwann cell-neuron unit in the endoneurium and con-centric lines in the perineurium. In order to correlate the expression of entactin with cell-cell interactions in the PNS, neurons, Schwann cells and fibroblasts (in various combinations) were established in culture. Pure populations of intact neurons (derived from either dorsal root or superior cervical ganglia), fibroblasts or Schwann cells were not stained regardless of the time in culture. However, Schwann cell cultures containing fibro-blasts demonstrated glial membrane fluorescence and a random, fibrillar staining pattern in areas where both cell types co-localized. Schwann cells in contact with neurons in defined localized. Schwann cells in contact with neurons in defined medium (which proliferate but do not differentiate to ensheath axons) were not stained unless permeabilized with 95% ethanol. Schwann cell-neuron cultures (maintained in serum/embryo extract supplemented medium) which differentiate and form an organized, mature ECM were intensely stained in a linear pattern identical to the distribution of basal lamina (BL). This linear pattern was maintained in similar cultures which were allowed to form a mature ECM, denervated and immunchistochemically examined one month later.

These results indicate that entactin is synthesized by Schwann cells regardless of neuronal contact and is organized onto intact tissue where fibroblasts are present and/or when mature BL are tissue where tibroolasts are present and/of and, matter an or organized around ensheathed or myelinated axons. Furthermore, entactin once added to the mature BL, remains as a stable component even though the integrity of the neuron-glial relationship is compromised.

103.19 IMMUNOCYTOCHEMICAL LOCALIZATION OF (Na<sup>+</sup>+K<sup>+</sup>) ATPase ALONG AXONS FROM SPINAL ROOTS OF NORMAL AND DYSTROPHIC MICE. R.G. FROM SPINAL ROOTS OF NORMAL AND DYSTROPHIC MILE. R.G. API-yasu, M.H. Ellisman, and J.A. Nichol\*. Laboratory for Neuros-cytology, Department of Neurosciences, School of Medicine, University of California at San Diego, La Jolla, CA 92093. Schwann cells in the PNS of dystrophic mice (Bar Harbor, 129 ReJ, Dy/Dy) apparently have a genetic defect in their ability to myelinate axons adequately in both ventral and dorsal spinal roots. The result is the presence of heminodes and "amyel-inted" avant in sections of humanyclipation. roots, the result is the presence of meminodes and amyer-inated" axons in regions of hypomyelination. Polyclonal anti-bodies raised against rat renal (Na<sup>+</sup>+K<sup>+</sup>) ATPase were used in immunocytochemical studies to examine the distribution of the enzyme along myelinated axons from peripheral nerves. These immmunoelectron microscopic studies revealed a concentration of Immunote rectron microscopic schemes revealed a concentration of the enzyme along the notal axolemma, with an absence of  $(Na^++K^+)$  ATPase along the paranodal region. Staining of the internodal axolemma has not been observed, however, the possibility of limited accessability of antibody into this region has not been fully discounted. These antibodies were also employed to determine the distribution of  $(Na^+K^-)$  ATPase along the paranodal regions of distrophic mice. the partially myelinated axons of dystrophic mice. Amyelinated axons were recognized by the absence of intervening Schwann cells and basal lamina and demonstrated punctate staining along the axolemma. Amyelinated axolemma in the region of heminodes revealed a similar distribution of the enzyme. In areas adja-cent to nearandal loops corresponding to the nodal axolemma of cent to paranodal loops, corresponding to the modal axolemma of normal nodes, the distribution of (Na +K') ATPase resembled the distribution in amyelinated axolemma. Occassionally larger patches of increased reaction product were observed in these patches of increased reaction product were observed in these regions. Enzyme distribution at complete nodes of Ranvier resembles the distribution at nodes in normal mice. The absence of (Na +K) ATPase along the paranodal axolemma of nor-mally myelinated axons, along with the data presented above suggests that the myelination process influences the distribu-tion of the enzyme along the axolemma of nerves. 104.3

104.1 CULTURED CHICK MYOTUBES INFECTED WITH A TEMPERATURE-SENSITIVE ROUS SARCOMA VIRUS: DEFECT IN ACETYLCHOLINE RECEPTOR CLUSTERING, Donna T. Anthony\* and Lee L. Rubin. The Rockefeller University, New York, NY 10021.

Motor innervation of embryonic skeletal muscle fibers causes acetylcholine receptors (AChRs) to accumulate at synaptic sites. The process of receptor aggregation on cultured embryonic myotubes has been studied extensively, but is still not well understood. Normal chick myotubes cultured at 37° or  $42^\circ$  show some AChR clusters, and the number of clusters can be increased severalfold by treatment with a high salt extract of <u>Torpedo californica</u> organ or with a soluble factor derived from chick brain. Transformation of myoblasts by temperature sensitive (ts)

Transformation of myoblasts by temperature sensitive (ts) mutants of Rous Sarcoma Virus (RSV) has been used in the past to study events occurring during cellular differentiation. Chick myoblasts transformed by tsNY66 fuse to form multinucleated myotubes at 42°, the nonpermissive temperature for transformation. At 42° both normal and transformed muscle cells produce similar levels of AChR and acetylcholinesterase. The AChR channels of transformed myotubes show kinetics characteristic of embryonic chick muscle AChR channels. However, tsNY68-infected myotubes do not cluster AChRs at 42°, even in the presence of active clustering agents. This phenomenon is not merely a result of viral infection, since myotubes infected with a transformationdeficient RSV - td-107A which lacks the src gene - behave like, the effects of tsNY68 on the clustering process must be mediated by the src gene product. It is known that viral transformation produces cytoskeletal alterations; our observation in tsNY68infected myotubes suggests that residual pp00<sup>STC</sup> kinase activity at 42° may phosphorylate cytoskeletal factors necessary for the formation or maintenance of AChR clusters. 104.2 MONOCLONAL ANTIBODIES TO THE α SUBUNIT OF <u>ELECTROPHORUS</u> ACETYLCHOLINE RECEPTOR CROSS REACT WITH A <u>COMPONENT IN THE</u> SYNAPTIC MEMBRANE OF CHICK CILIARY GANGLIA. <u>Michele H. Jacob</u>, Darwin K. Berg, and Jon M. Lindstrom. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093; and The Salk Institute, San Diego, CA 92138.

Chick ciliary ganglion neurons receive cholinergic transmission from preganglionic terminals. To identify markers for nicotinic acetylcholine (ACh) receptors on the neurons, we have tested monoclonal antibodies (mAbs) raised against purified ACh receptors from other sources for cross reactivity with membrane components on the neurons. We have found that mAbs which recognize the "main immunogenic region" (MIR) of the a subunit of skeletal muscle and electric organ ACh receptors (Tzartos et al., J. Biol. Chem. 256:8635 (1981)), and which cross react with components in the lateral spiriform nucleus of chick brain (Swanson et al., Proc. Natl. Acad. Sci.: in press), also recognize a component present at chemical synapses on chick ciliary ganglion neurons. Monoclonal antibody 35 (mAb 35), which was raised against

Monoclonal antibody 35 (mAb 35), which was raised against <u>Electrophorus</u> ACh receptor and recognizes the MIR, was conjugated with horseradish peroxidase (HRP-35) and used to label 16-d embryonic chick ciliary ganglia. Ultrastructural examination of labeled ganglia revealed HRP reaction product associated predominantly with synaptic membranes, often filling the synaptic cleft. Synapses were identified by relatively straight pre- and postsynaptic membranes, a wide synaptic cleft, the accumulation of synaptic vesicles along the presynaptic membrane, and a fibrous postsynaptic density. Reaction product was also present to varying extents along the surfaces of small processes which project out from the postsynaptic cell in the vicinity of the presynaptic terminals. Labeling of the processes was usually light and no reaction product was observed elsewhere on the neuron surface membrane. Synaptic and process labeling were specific in that omission of HRP-35 or co-incubation of the ganglion with HRP-35 and excess unlabeled mAb 35, mAb 203, or mAb 6 (mAbs specific for the same region of the MIR) resulted in no significant HRP reaction product. Competition with non-immune serum had no effect.

serum had no effect. The distribution of HRP-35 binding is different from HRP-labeled  $\alpha$ -bungarotoxin binding. HRP- $\alpha$ -bungarotoxin binding results in heavy labeling of the processes but no labeling of synaptic membranes on ciliary ganglion neurons (Jacob & Berg, J. Neurosci. 3:260 (1983)). Whether the antibody binding at synapses reflects the ACh receptor or some other synaptic component remains to be determined. (Supported by NIH grant NS12601, the Muscular Dystrophy Association, & the American Heart Association.)

104.4 THE PRESENCE OF INSULIN RECEPTORS IN PRIMARY CULTURED BRAIN CELLS J. A. Weyhenmeyer, I. Reynolds\* and A. Killian\*. College of Medicine, University of Illinois, Urbana, IL 61801. Recent evidence has indicated the presence of high affinity binding sites for insulin on cultured brain cells from the fetal

Recent evidence has indicated the presence of high affinity binding sites for insulin on cultured brain cells from the fetal rat that are associated with the incorporation of uridine and thymidine into macromolecules, suggesting that these receptors are involved in the biological responses of insulin in CNS tissues. In this study, we report the localization of insulin receptors in primary cultured brain cells with the use of a specific insulin receptor antibody. Dissociated cells from the fetal brain (E.D. 20) of the

Dissociated cells from the fetal brain (E.D. 20) of the Sprague Dawley rat were cultured as previously described (Neurosci. Lett. 16: 41). Aliquots of 2.8 x 10<sup>6</sup> cells in DMEM containing 10% fetal calf serum were inoculated onto 35 mm tissue culture dishes containing 25 mm glass coverslips. Medium was removed on the third day and replaced with either N1 or N2 medium. The medium was changed on days 5 and 7, and the cells were used for experiments on day 8. Cells were stained for the presence of insulin receptors according to the peroxidase antiperoxidase method. Insulin receptor antibodies (obtained from Dr. S. Jacobs, Wellcome Research Labs) were raised by the polyclonal method using purified (insulin-agarose affinity chromatography) insulin receptors from rat liver membranes.

raphy) insulin receptors from rat liver membranes. Insulin receptors were localized on approximately 5% of the neuronal population. In addition, the majority of the cells in the background monolayer, which are predominantly of glial origin, stained positively. When cultured brain cells were fixed prior to incubation with the antibody, the staining was relatively homogenous over the neuronal cell body and along its fiber profiles. When insulin receptor antibodies were incubated with the brain cells for 30 min prior to fixation, microaggregates or clusters of labeled insulin receptors were observed on the cell surface.

In this study, we report the immunocytochemical localization of insulin receptors on neuronal and non-neuronal cells in primary cultures from fetal rat brain. Insulin receptors were found to be either uniformly distributed or clustered on the cell surface in relation to the pre- or postfixation of the cells prior to incubation with specific insulin receptor antibody.

The KAT HIPPOCAMPUS: AN E.M. AUTOKADJUGKAPHIC ANALYSIS. M.B. Laskovski, B.L. Roth\*, A.J. Lechner\*, D.B. Bennett\* and C.J. Coscia. Department of Physiology and E.A. Doisy Department of Biochemistry, St. Louis Univ. Sch. Med., St. Louis, MO 63104. Binding studies on subcellular fractions from brain have revealed that receptor enrichment occurs in both synaptic plasma membranes (SPMs) and microsomes for several transmitters including acetylcholine, dopamine, norepinephrine, serotonin and enkephalins. To determine whether benzodiazepine receptors were also localized in these two fractions of adult rat hippocampi, binding assays were performed with the agonist, [<sup>3</sup>H]-flunitrazepam. SPMs and smooth microsomes were isolated by sucrose density centrilugation (Rot et al., J. Biol. Chem. 256, 10117, 1981). Benzodiazepine receptors were photoaffinity labeled by UV irradiation in the presence of 3 nM [<sup>3</sup>H]-flunitrazepam with or without 10  $\mu$ M unlabeled diazepam. Specific binding was determined by glass fiber filter, centrifugation and electrophoretic assays. Upon SDS gel electrophoresis of photoaffinity-labeled membranes, a single protein band was resolved that contained 2000 dpm (nonspecific binding = 100 dpm). By filter assay specific binding was 332 fmol/tube (0.5-11 mg protein) for SPMs and 175 fmol/tube (0.2-0.4 mg protein) for microsomes. Membranes photoaffinity labeled in this manner were also fixed and processed for EM autoradiography. Sections were placed on gold grids, coated with emulsion and incubated at 0°C for three months. Autoradiographs were processed with gold-latensification followed by fine grain development. The resultant grain density was 3.5 grains/1000 µm<sup>2</sup>. Each grain was photographed at 27,000x and an area 1.35 µm to the left (equivalent to 10 half-distances) was similarly photographed. Final prints were analyzed while remaining blind to the fraction and treatment identities. Over each grain a mask was placed consisting of the 50% probability circle (0.467 µm diameter)

SUBCELLULAR LOCALIZATION OF [ ${}^{3}$ H]-FLUNITRAZEPAM BINDING SITES IN THE RAT HIPPOCAMPUS: AN E.M. AUTORADIOGRAPHIC ANALYSIS. <u>M.B.</u>

EFFECTS OF DIVALENT CATIONS, CHELATORS AND NUCLEOTIDE TRIPHOSPHATES ON THE <u>IN VITRO</u> STABILITY OF GLUCOCORTICOID RECEPTORS IN BRAIN. <u>c.t. Densmore\*, W.G. Luttge and S.M. Emadian\*</u>. Dept. of Neurosci-ence, Univ. of Florida Coll. of Medicine, Gainesville, FL 32610. <u>In vitro</u> studies in a variety of tissues and cell types suggest 104.5 that glucocorticoid receptor binding capacity is not static and that binding sites are subject to up- and down-regulatory mechan-Studies reported here investigate effects of divalent cat-

that glucocorticoid receptor binding capacity is not static and that binding sites are subject to up- and down-regulatory mechan-isms. Studies reported here investigate effects of divalent cat-ions, heavy metal chelators and nucleotide triphosphates on these potential regulatory mechanisms in brain. All studies used CD-1 mice adrenalectomized and ovariectomized 5-8 days before perfusion with buffered saline, decapitation and removal of brain and liver. In our standard buffer (10 mM 4[2-hy-droxyethyl]-1-piperazineethanesulphonic acid [HEPES]. 1 mM dithio-threitol, 10% glycerol [w:v], pH 7.6), brain cytosol exhibited a temperature-dependent loss of [3H]dexamethsone binding capacity when incubated without steroid. Incubation at 12°C resulted in a 50% loss of binding capacity after 180 min (t/2). Addition of 5 mM MgCl2 resulted in a 15% decrease in the t/2 Whereas addition of 5 mM CaCl2 resulted in a 70% decrease in t/2. Dose-response stud-ies revealed that reducing the CaCl2 to even 0.25 mM still produced a significant 20% reduction in the t/2. Addition of 5 thm CaCl2 a significant 20% reduction in the t/2. Similar results were obtained in liver with EDTA. Simultaneous addition of 5 fmC CaCl2 and 5 mM EDTA resulted in a 90% increase in t/2. Similar results were obtained in liver with EDTA. Simultaneous addition of 5 mM CaCl2 and 5 mM EDTA resulted in a 90% increase in t/2 whereas simul-taneous addition of 5 mM MgCl2 and 5 mM EDTA resulted in a 9-fold increase in t/2 over control. When 16 mM EDTA was added to cyto-sol incubated previously for 2 hr at 12°C, stabilization again resulted but no recovery of lost binding was observed. Ethylene-glycol-bis-N,N'-tetraacetate (EGTA) and 0-phenanthroline provided some stabilization, but were less effective than EDTA. An adeno-sine triphosphate (ATP)-dependent (1 mM) increase (2 to 4-fold) in t/2 resulted from the incubation of crude homogenate or low speed (1000-17000 x g) supernatant salthough ATP hade no significant effect on high speed (109000 x g) cytosol. The

THROMBIN BINDING TO CELLS IN MURINE SPINAL CORD CULTURES. E.D. 104.7 Means, D.K. Anderson, M. Fitzgerald\*, C. Price\*, J.W. Fenton II\*, A J.L. Lessard\*. Spinal Cord Lab, VAMC and Depts. of Neuro. & Physiol., Univ. of Cinti. Col. of Med., Cinti., OH. 45220 and Cent. for Lab & Res., N.Y. State Dept. of Health, Albany, N.Y. 12208.

Alpha-thrombin a serine protease involved in hemostasis is known to bind to cell surface receptors of platelets and certain cell types. Snider and colleagues (Fed Proc, 42:883, 1983) redescribed thrombin binding to neuroblastoma cells and cently proposed that thrombin may be involved in certain pathological processes such as stroke or CNS trauma.

A polyclonal antibody was developed to alpha-thrombin in rab-bits and subsequently affinity purified. The antibody was tested for reactivity with the ELISA System. One nM alpha-thrombin was the reacted to cells in dissociated murine spinal cord cultures (12-14 day embryos). The cells were fixed in acetone and reacted with antibody (1/500) overnight after treatment with goat serum (1/100). This was followed by biotinylated goat antirabbit IgG (1/400) and finally, avidin-FITC (1/1000) or avidin-peroxidase (1/160). Cells identified as neurons and some glial stained heavily, while other cells, probably fibroblasts, stained weakly or not at all. Hirudin, a potent thrombin inhibitor, actually enhanced staining but produced significant clustering. Hirudin plus DIP-thrombin decreased staining. Negative controls including the absence of primary and linking antibodies eliminated most staining. The clustering produced by hirudin and alpha-thrombin was possibly attributed to an enzymic function of thrombin on the cell, leading to an irreversible event rendering thrombin inaccessible to hirudin.

Alpha-thrombin is known to produce alterations in the platelet membrane by activating phospholipase A2, which releases fatty memorane by activating phospholipase A2, which releases fatty acids (arachidonic) from membrane phospholipids. Arachidonate may be important in the pathogenesis of several CNS diseases. Thrombin is extravasated from the blood vessel into CNS parenchyma following trauma or other hemorrhagic injuries. We propose that thrombin, by altering the neuronal membrane, may play a role in cell death following hemorrhage into the CNS.

BINDING OF 125 I-TETANUS TOXIN TO NEURONAL CELL LINES IN 104.6 CULTURE, T.B. Rogers. Department of Biological Chemistry, University of Maryland, School of Medicine, Baltimore, MD 21201.

Many neuroblastorma cell lines do not display high affinity tetanus toxin receptors. However we have characterized tetanus toxin receptors in several cell lines including the pheochromocytoma cells, PC12, and a retinal ganglion hybrid, N18 RE105. When <sup>123</sup> I-tetanus toxin (0.1 - 0.3 nM) was incubated with these cells specific binding was observed. The binding was specific in that addition of mixed brain gangliosides (1 µM), tetanus antitoxin or unlabeled tetanus toxin (2  $\mu_{g/ml}$ ) nearly completely inhibited binding. Tetanus toxoid (5  $\mu_{g/ml}$ ) and tetanus toxin that had been incubated in boiling water for one hour (2  $\mu_{g/ml}$ ) did not compete for <sup>125</sup>I-tetanus binding. When <sup>125</sup>I-tetanus (2 µg/ml) did not compete for <sup>125</sup>I-tetanus binding. When <sup>125</sup>I-tetanus toxin (0.22 nM) was incubated with cells in suspension the binding reached a maximum in 1.5 hr at 0°. Under these conditions PC-12 cells bound 1.6 pmol of <sup>125</sup>I-toxin/mg of protein and the N18 RE105 cells bound about 5-fold more toxin relative to total cell protein. Preliminary data suggest that PC-12 cells grown in the presence of nerve growth factor bind about 30% more <sup>125</sup>I-toxin than the untreated cultures, relative to total cell protein. The affinity of the receptors was measured in competition binding assays using unlabeled tetanus toxin. The following  $IC_{50}$  values for tetanus toxin were measured: rat synaptic plasma membranes, 6 nM; PC12 cells, 65 nM; N18 RE105 cells, There was no indication of toxin degradation during the on. The properties of the N18 RE105 receptor-toxin 60 n.M. incubation. interactions were studied in more detail and were compared to those of rat cortical synaptic plasma membranes. Both systems showed similar dependencies on pH, cation concentration and temperature. The binding decreased with increasing pH; there was a 70% decrease in binding when the pH was increased from pH 6 to pH 9. NaCl (120 mM) inhibited binding by 80% and there was a 30% decrease in specific  $125_{1-1}$ tetanus toxin bound when the incubation temperature was increased from 4°C to 37°C. The reversability of <sup>125</sup>I-tetanus toxin bound to N18 RE105 cells was found to be temperature dependent. When the cells were incubated at 4°C for 1.5 hours nearly 80% of the bound toxin could be removed from the cells by the addition of 1  $\mu$ M mixed brain gangliosides. If the incubations were done at 37° less than 10% of the bound <sup>125</sup>I toxin could be removed by 1  $\mu$ M gangliosides. These data show that several cell lines contain receptors of tetanus toxin with similar properties as those that have been characterized in brain membranes. (Supported in part by USARMDC grant DAMD17-83-C-3114)

NGF RECEPTORS ON CENTRAL AND PERIPHERAL AXONS OF DORSAL ROOT 104.8

GANGLION NEURONS IN VIVO. R.J. Riopelle and P.M. Richardson Division of Neurology, Queen's Univ., Kingston, Canada and Division of Neurosurgery, McGill Univ., Montreal, Canada Previous studies of retrograde transport of NGF have indicated the presence of receptors at or near peripheral terminals of sensory axons. To investigate the distribution of NGF receptors Sensory axons. To investigate the distribution of wur receptors along the course of peripheral and central axons of primary sen-sory neurons,  $^{125}$ I-NGF was injected into the spinal cord or scia-tic nerve of adult rats. For most studies 0.1-40 ng  $^{125}$ I-NGF (30-60 microCi/microg) was injected in a volume of 1 microl intra-neurally or 2-4 microl intraspinally. Uptake and retrograde transport were monitored by gamma emission counting and radioautography of lumbar DRG. <sup>125</sup>I-NGF injected into the sciatic nerve was taken up

 $^{125}\mathrm{I-NGF}$  injected into the sciatic nerve was taken up by a saturable high affinity process with KM 0.2 pmoles and Vmax 1.0 fmoles. Receptor density was estimated to be at least 105 binding sites per cm segment of axon. The specificity of uptake of NGF was indicated by the observations that negligible activity the solution of  $^{125}\mathrm{I-MGF}$ accumulated in DRG after comparable solatic injection of <sup>125</sup>I-cytochrome C or <sup>125</sup>I-oxidized NGF. To study transport to DRG in central axons, <sup>125</sup>I-NGF was injected into the cervical, thoracic or lumbar regions of the spinal cord. <sup>125</sup>I-NGF injected into the conus medullaris was transported to lumbar DRG at a rate not more than 5mm/h. K<sub>M</sub> and Vmax were 0.5 pmoles and 0.5 fmoles respectively. In radioautographs, label was concentrated in large neurons. Following cervical or mid-thoracic injections of  $^{125}\mathrm{I-NGF}$ , significant gamma activity was detected in lumbar DRG compatible with retrograde axonal transport of 0.02-0.03 fmoles NGF/DRG. Activity in DRG was not above background following cervical or lumbar injection of  $^{125}$ I-cytochrome C. Labelled neurons were not found in the brainstem or lumbar grey matter after cervical injection of  $^{125}\mathrm{I-NGF}$ . Thus,  $^{125}\mathrm{I-NGF}$  was taken up specifically and selectively by spinal axons of DRG neurons.

NGF receptors on primary sensory neurons in the adult rat are not limited to peripheral axon terminals but are extensively distributed along both peripheral and central axons. Axonal receptors provide a mechanism whereby NGF of neuroglial origin could influence neuronal maintenance and axonal regeneration.

Supported by the Medical Research Council of Canada (RJR) and the Multiple Sclerosis Society of Canada (PMR).

ANALYSIS OF ASTROGLIAL BETA-ADRENERGIC RECEPTOR ( $\beta$ -AR) AND  $\beta$ AR-REGULATED GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) PHOSPHORYLATION FOLLOWING TREATMENT WITH BRAIN EXTRACT AND DIBUTYRYL CYCLIC AMP. <u>Teven A.</u> <u>Harmon\* and Ken D. McCarthy\*</u> (SPON: Michael J. Rosner). Dept. of Pharm., Univ. of N. Carolina, Chapel Hill, NC 27514. Primary cultures of purified astroglia contain at least two morphologically distinct cell populations. The predominant cell type (polygonal, GFAP positive) expresses  $\beta$ -AR and is mitotic. The second population (multipolar, GFAP positive) expresses very few  $\beta$ -AR and appears to be postmitotic. Studies in progress suggest that process-bearing astroglia are derived from polygonal astroglia. Treatment of polygonal astroglia with either brain extract (BE), dibutyryl cyclic AMP (dbcAMP) or the  $\beta$ -AR agonist isoproterenol has been shown to convert polygonal astroglia to process-bearing astroglia. 104.9

These changes often have been interpreted to reflect astroglial to Brocess-Dearling astroglial call maturation. However, it is not known whether treatment with BE or dbcAMP influences the expression of  $\beta$ -AR on cultured astroglial. To examine this question, <sup>12</sup>D<sub>1</sub>-cyanopindolol was used to label  $\beta$ -AR on astroglia treated with BE or dbcAMP. While treatment with these substances induced a morphological change in the polygonal astroglia, they had only a marginal effect on the number of  $\beta$ -AR expressed by the cells.

Our laboratory has shown that treatment of polygonal astroglia with isoproterenol results in the enhanced phosphorylation of GFAP. Experiments were carried out to determine if astroglia treated with BE or dbcAMP remained responsive with respect to the  $\beta$ -AR BE of dbcAMP remained responsive with respect to the p-and regulation of GFAP phosphorylation. Astroglia were treated for 1-3 days with 1 mM dbcAMP or 20% BE. After treatment, the medium was replaced with low-phosphate medium containing  ${}^{32}P_{ij}$ , and the cells incubated for 2 hours. Isoproterenol was added to the medium during the final 30 min. of labelling to stimulate GFAP phosphorylation. Under these conditions treatment with either BE or dbcAMP have little, if any, effect on the regulation of GFAP phosphorylation by  $\beta$ -AR agonists

The results of both the  $\beta$ -AR binding and phosphorylation experiments may reflect the presence of polygonal astroglia unchanged by BE or dbcAMP. To address this possibility,  $\beta$ -AR were analyzed via autoradiography on single, GFAP positive cells. The number of silver grains associated with untreated polygonal astroglia were compared to those from BE or dbcAMP-treated astroglia that had undergone morphological transformation. Treatment with BE or dbcAMP did not markedly alter the expression of  $\beta$ -AR on astroglia. These results suggest that astroglia treated with BE or dbcAMP

indergo morphological changes but continue to resemble polygonal astroglia with respect to their expression of  $\beta$ -AR and receptor regulation of GFAP phosphorylation. Supported by NS 16992.

104 PO PERINATAL MATURATION OF THE FC IGG RECEPTOR OF RABBIT CILIARY PROCESSES. N. S. Peress, V. Mederios-Roxburgh\* and M. C. Gelfand\* Lab. of Neuropathology, V. A. Medical Center, Northport, NY 11768. Using immunoglobulin-G (IgG) coated erythrocytes as a probe for FC-IGG binding sites, we studied the location, development and blocking characteristics of the rabbit ciliary body FC-IGG receptor in frozen sections of rabbit eyes obtained from 22 rabreceptor in frozen sections of rabbit eyes obtained from 22 rab-bits varying in age from 22 weeks of gestation to 4 weeks after birth. We compared the findings in the perinatal rabbits to those in adult eyes studied simultaneously. Adult eyes showed an intense, diffuse, selective adherence of the IgG coated erythro-cytes to the epithelial layer of the posterior portion of the ciliary processes. The iridal portion was free of adhering erythrocytes. There was no significant adherence in other eye tissues studied, viz, iris, cornea, sclera or retina. The degree of binding of the IgG coated erythrocytes to the ciliary processes depended upon age-related changes in the first 2 weeks of life being minimal before birth and within the first 24 hours (4% of the adult level), then rising to a mean of 18% of the adult level by days 3-5 and increasing sharply to full maturation by 2 weeks by days 3-5 and increasing snarply to full maturation by 2 weeks of age. When adherence was minimal the pattern was of scattered clusters of adhering cells. With increasing adherence a more diffuse pattern emerged. At all ages, binding was confined to the epithelial layer of the posterior, non-iridal group of processes, and it was blocked (95% or greater) by 5.0 mg/ml solutions of non-aggregated and aggregated IgG but not by albumin, IgM or F(ab')2. This selective pattern within the ciliary body is con-sistent with other morphological and biochemical data which suggest differences between the iridal and posterior processes. These studies have suggested that the iridal region is the main secretory area while our data suggest an immune function for the posterior portion of the ciliary processes.

AGE RELATED CHANGES IN THE EXPRESSION OF BETA ADRENERGIC RECEPTORS BY IMMUNOCYTOCHEMICALLY-DEFINED ASTROGLIA IN VITRO. Patricia A. Trimmer\* and Ken D. McCarthy\* (SPON: Ronald C. Bohn). Dept. of Pharmacology, Univ. of North Carolina, School of Medicine, Chapel Hill, NC 27514. The expression of beta adrenergic receptors ( $\beta$  AR) by astroglial cells has been firmly established using purified primary cultures prepared from newborn rat cerebral cortex. However, it has not been possible to determine if the expression of  $\beta$  AR by astroglia varies during development. This is primarily due to the difficulty in preparing purified astroglial cultures from fetal or older postatel cortical tissue purified astroglial cultures from fetal or older postnatal cortical tissue in the quantity necessary for standard radioligand receptor binding assays. Using a new method (McCarthy, 1983), however, the distribution of  $\beta$  AR on individual, immunocytochemically-defined astroglia can now be assessed via quantitative receptor astroglia can now be assessed via quantitative receptor autoradiography. Therefore, in order to examine the influence of <u>in</u> <u>vivo</u> maturation on the expression of  $\beta$  AR, primary cerebral cortical cultures were simultaneously prepared from fetuses 16 days <u>in utero</u> as well as rats 1,7,14,21 and 28 days postnatal and plated into 6 well culture dishes. At various times thereafter (4-30 days), cells from each age were harvested and replated at low density onto polylysine-coated glass chamber slides. Two days later the cells were fixed, permeabilized and double stained with antibody to glial fibrillary acidic protein (GFAP) and fibronectin. The ß AR were labelled with iodinated cyanopindolol. Following the binding procedure, the cells were dried and opposed to emulsion coated coverslips. Seven to fourteen days later the autoradiograms were developed. The distribution of silver grains over immunocytochemically-defined GFAP or fibronectin grains over immunocytochemically-defined GFAP or fibronectin positive cells was quantified using a microcomputer-based video digitizing system. Using this methodology we have detected the presence of  $\beta$ AR on polygonal astroglia from all ages examined. Preliminary results furthermore suggest that the levels of  $\beta$ AR did vary as a function of age in vivo. The maximum density of  $\beta$ AR was found on astroglia from newborn rats. Astroglia from fetal cerebral continued to be expressed lower levels of  $\beta$ AR. Furthermore,  $\beta$ AR continued to be expressed to astroglia prepared from older animale continued to be expressed lower levels of p AR. Furthermore, p AR continued to be expressed by astroglia prepared from older animals, although the levels were generally less than that expressed by astroglia derived from one-day-old animals. In contrast, process-bearing astroglia and fibronectin-positive fibroblasts consistently expressed low levels of  $\beta$  AR which did not appear to vary as a function of <u>in vivo</u> age. These observations infer that the expression of  $\beta$  AR on polygonal astroglia is subject to modification by maturation <u>in vivo</u>. Supported by NS 16992.

105.1 DOCOSAHEXAENOYL-COENZYME A SYNTHETASE AND ARACHIDONOYL-COENZYME A SYNTHETASE OF BRAIN MICROSOMES ARE INHIBITED BY CATIONIC AMPHI-PHILIC DRUGS. <u>T. Sanjeeva Reddy\*</u>, and Nicolas G. Bazan. LSU Eye Center, LSU Medical Center School of Medicine, New Orleans, LA 70112

The mechanism by which local anesthetics act on the neural membranes is not properly understood although some mechanisms have been proposed, e.g., interaction with the lipid bilayer causing increased membrane thickness and fluidity. Previous studies from our laboratory have shown an alteration in the biosynthesis of glycerolipids in retina incubated with propranolol in vitro (See reference in J. Neurochem. 40:260-266, 1983). In the present investigation, we tested a series of local anesthetics on rat brain microsomal arachidonoyl CoA synthetase in vitro. All the drugs were found to inhibit the activity of arachidonoyl CoA synthetase, but with differing potencies. The order of inhibitory potency was: propranolol > tetracaine > chloroquine > procaine > lidocaine. The ID50 values for propranolol, tetracaine, and chloroquine were 37, 68, and 125  $\mu$ m, respectively. The inhibition by lidocaine and procaine was very low (20-25%) and no additional effect was obtained by increasing the concentration of the drug from 100  $\mu$ m to 800  $\mu$ m. Since propranolol seemed to be a potent inhibit the results showed that cationic amphiphilic drugs inhibit the activation of the polyenoic fatty acids found in large quantities in phospholipids of excitable membranes.

of excitable membranes. (Supported in part by a grant from the Esther A. and Joseph Klingenstein Fund, Inc., New York City). 105.2 INTRAMEMBRANOUS PARTICLE DISTRIBUTION IN THE JUXTAPARANODAL AXO-LEMMA OF FROG OPTIC NERVES. J. H. Tao-Cheng and J. Rosenbluth. Depts. of Physiology and Rehab. Medicine, N.Y.U. Medical Center, New York, N.Y. 10016. In the freeze-fractured axolemma of myelinated fibers, high

In the freeze-fractured axolemma of myelinated fibers, high concentrations of large (~10mm) E face particles  $(1000-1500/\mu^2)$ have been shown at the node of Ranvier, and it has been proposed that these represent sodium channels. Accumulations of similar E face particles are sometimes seen, especially in the CNS, in the juxtaparanodal portion of the internode (JPI) immediately adjacent to the paranodal junctions. Each node is flanked by a proximal and a distal paranode and JPI with respect to the nerve cell body. The distribution of particles at the respective JPI's was examined in the present study.

cell body. The distribution of particles at the respective JPI's was examined in the present study. Optic nerves of adult frogs (<u>Rana pipiens</u>) were cut into 3-4 segments and prepared for freeze-fracturing with the proximal to distal orientation monitored throughout the process. E face particle accumulations are present in almost all examples of JPI's (90%), and they occur with equal frequency in proximal and distal JPI's. The concentration of these particles is usually highest (200-500/ $\mu^2$ ) immediately adjacent to the last strip of the paranodal junction and then decreases over  $\sim 1-5\mu$  to the background level ( $\sim 100/\mu^2$ ). It appears that the higher the concentrations in the JPI's and the number of myelin lamellae. However, all examples of JPI's with high concentrations over considerable lengths along the axons are from fibers with more than 10 myelin lamellae. No apparent difference was seen between optic nerve segments adjacent to or distant from the retina.

The last few rows of paranodal junctional strips near the internode are usually more loosely packed than the strips closer to the node. Accumulation of large E face particles can often be found in the wider and sometimes irregularly shaped axolemmal spaces ("lakes") between these junctional strips. The particle concentration in such "lakes" can be as high as  $\sim 600/\mu^2$  and appears to be in direct proportion to the particle accumulations are found with equal frequency in proximal and distal paranodal regions.

The number of E face particles in the paranodal "lakes" and JPI's flanking each node is considerable, compared with that at the node itself, and the total of all these particles is, therefore, much greater than the number at the node alone. Supported by grant NS 07495 from the NIH.

105.3 WEAK EXPRESSION OF HLA-A,B,C MOLECULES ON HUMAN NEURONS, NEUROBLASTOMA TUMOR, AND NEURONAL CELL LINES. James P. Whelan\*, William F. Hickey\*, Nicholas K. Gonatas and Lois A. Lampson. Univ. of PA, Depts. of Anatomy and Neuropathology, Phila., PA 19104

19104 HLA-A,B,C molecules have been demonstrated on many types of human tissue and play an important role in the immune response. In many cases, the recognition of tumor specific or other "iforeign" antigens by effector phase cytotoxic T cells is dependent on the co-recognition of HLA-A,B,C molecules on the target cell ("restriction phenomenon"). We have used a panel of monoclonal antibodies to different determinants on the HLA-A,B,C molecules (including polymorphic, non-polymorphic, conformational and sequential determinants) to assess the expression of HLA-A,B,C in human neural tissue. (1) Utilizing a variety of assays, we find that <u>cell lines</u> derived from <u>neuroblastoma</u>, a tumor of the sympathetic neuroblast, express less than 1% of the HLA-A,B,C activity seen in lymbhoid or glial cell lines (Lampson, L. A. et al., J. IMMUNOL., 130:2471, 1983). (2) In a microscopic PAP procedure,  $\langle 50\%$  of single cells from bone marrow infiltrated with metastatic <u>neuroblastoma</u> bone marrow. Additionally, cell aggregates in neuroblastoma bone marrow, identifiable morphologically as tumor, are HLA-A,B,C positive, as compared to  $\geq 96\%$  in normal bone marrow, identifiable morphologically as tumor, are HLA-A,B,C positive. (3) In normal brain, the strongest stain was seen in the blood vessel endothelium. No specific stain was seen in the cell bodies of neurons or glia, or in myelin.

105.4 IN VITRO MEMBRANE SUBSTRATES FOR PROTEIN CARBOXYMETHYLASE. <u>B.A. Johnson\* and D.W. Aswad\*</u> (SPON: J. Koerner). Dept. of Psychobiology, Univ. of California, Irvine, Irvine, CA 92717. Protein carboxymethylase (PCM) transfers methyl groups from S-adenosylmethionine to side chain carboxyl groups of its substrate proteins. The enzyme is abundant in brain and has been implicated in several neuron-specific processes, including the development of excitability in neuroblasts (Kloog et al., J. <u>Neurochem. 40</u>: 522, 1983), the regulation of neurotransmitter release in the striatum (Billingsley and Roth, <u>J.Pharmacol.Exp. Ther. 233</u>:681, 1982), and the regulation of acetylcholine receptor sensitivity (Kloog et al., <u>Biochem.Biophys.Res.Commun. 97</u>:1474, 1980). Another hypothesis is that PCM selectively methylates D-aspartyl residues of age-racemized proteins as a step in their repair (McFadden and Clarke, <u>Proc.Natl.Acad.Sci,USA 79</u>:2460,1982). It should be possible to discriminate between these hypotheses by identifying and characterizing the endogenous protein substrates for PCM.

We have studied the <u>in vitro</u> protein methylation patterns of various particulate fractions from brain and other tissues using an acidic disc-gel electrophoresis system which preserves the labile methyl esters while providing a good separation of protein bands. All of the methylation we have observed has required the addition of purified PCM.

Crude particulate fractions from rat brain, heart, skeletal muscle, lung, and liver all contain methyl accepting proteins. Of these tissues, brain has the greatest number of substrates and the greatest amount of total methyl incorporation. When particulate fractions from bovine brain are divided further, substrates are found in both the synaptic membrane and the myelin fractions, whereas none are found in the mitochondrial fraction.

The synaptic membrane substrates appear as lightly labeled bands, the most predominant of which migrate at apparent molecular weights of 50K and 94K. The reaction is specific, as there are bands with dark protein staining which fail to incorporate methyl groups.

Myelin contains one heavily methylated band of very low molecular weight. Judging from methyl incorporation relative to protein staining, this is the best substrate for PCM that we have found in brain, although even this band was apparently methylated with a low stoichiometry. It seems unlikely that this band is an in vivo substrate, because little PCM activity is found in myelin.

Our results suggest several candidates for endogenous synaptic membrane substrates for PCM. However, the presence of a good methyl acceptor in myelin and the low stoichiometry of the methylation of all substrates are more consistent with the aging-repair hypothesis. (Supported by NIH NS-17269.)

ENHANCEMENT OF Na<sup>+</sup>-K<sup>+</sup>-ATPase ACTIVITY & PREVENTION OF Fe<sup>++</sup> INITI-ATED FREE RADICAL INDUCED LIPID PEROXIDATION IN SPINAL CORD BY METHYLPREDNISOLONE. <u>D.K. Anderson, E.D. Means, E.S. Green\*, &</u> <u>T.R. Waters\*.</u> Spinal Cord Injury Lab, VAMC & Univ. of Cinti. Col. of Med., Cincinnati, Ohio 45220. Demopoulos, et al (Acta Physiol Scand Suppl, 492:91-119, 1980) have proposed that trauma initiated & Fe<sup>++</sup> & Cu<sup>++</sup> (from extrava-sated blood) catalyzed free radical induced lipid peroxidation of cellular membranes contributes to the autodestruction of spinal 105.5

have proposed that trauma initiated & Fe'r & Cu'r (from extrava-sated blood) catalyzed free radical induced lipid peroxidation of cellular membranes contributes to the autodestruction of spinal cord (SC) tissue subsequent to injury. We have demonstrated (J Neurosurg, 55:200-8, 1981) that the synthetic glucocriticoid, methylprednisolone sodium succinate (MPSS) in high doses is effec-tive in reducing the neurological deficit & preserving SC tissue following compression trauma to the feline SC. The purpose of this study was to assess the antioxidant capabilities of MPSS in an <u>in vivo</u> model known to damage cellular membranes by peroxida-tive mechanisms (i.e. microinjection of Fe<sup>++</sup> into the SC of cats). Lipid peroxidation & membrane integrity were evaluated by measur-ing the activity of Na<sup>+</sup>-K<sup>+</sup>-ATPase, a plasma membrane bound enzy-me & the levels of malonaldehyde (MDA), a product of lipid perox-idation. In pentobarbital anesthetized cats, a 29-gauge needle was stereotaxically placed in each anterior horn of the L4 SC segment. Five microliters of 100MM FeCl2 was infused into each anterior horn. Controls were infused with similar volumes of 0.9% NaCl. Normal values for SC ATPase activity & MDA levels were obtained from uninfused cats. 300g/kg of MPSS was injected I.V. 30min after either FeCl2 or NaCl infusion. The infused seg-ment of SC (in both untreated & MPSS treated cats) was frozen in situ with liquid nitrogen at 1 & 2hrs after SC infusion & removed. 1. V. Summater ertrevent let a water through the final set segment of SC (in both untreated & MSSS treated cats) was frozen in situ with liquid nitrogen at 1 & 2hrs after SC infusion & removed. Na<sup>+</sup>-K<sup>+</sup>-ATPase activity was unchanged at lhr post-FeCl2 infusion but fell to 30% of normal by 2hrs. MDA levels were elevated almost 2-fold in FeCl2 injected SC's at 2hrs. MDA levels & Na<sup>+</sup>-K<sup>+</sup>-ATPase activity were not different from normal in NaCl injected SC's. Treatment with MPSS resulted in a significant 1.8 & 1.6-fold increase in Na<sup>+</sup>-K<sup>+</sup>-ATPase activity at 1 & 2hrs post-NaCl injection, respectively, concurrent with halving of MDA levels at 2hrs. MDA levels at 2hrs. MDA levels at 2hrs. MDA levels at 2hrs. The extent of lipid peroxidation was inversely related to Na<sup>+</sup>-K<sup>+</sup>-ATPase activity suggesting a causal relationship between these 2 neurochemical events. This data shows that large I.V. doses of MPSS attenuates lipid peroxidation & enhances Na<sup>+</sup>-K<sup>+</sup>-ATPAse activity is agent. Since lipid peroxidation is a consequence of traumate the SC, Since lipid peroxidation is a consequence of trauma to the SC, MPSS likely exerts its protective effect, in part, by quenching these peroxidative reactions in cellular membranes. (Supported by the Veterans Administration.)

105.7 CELL CONTACT-MEDIATED REGULATION OF TYROSINE HYDROXY-LASE IN CULTURED BOVINE ADRENAL CHROMAFFIN CELLS. H. Thoenen and A. Acheson. Max-Planck-Institute for Psychiatry, Dept. of Neurochemistry, 8033 Martinsried, FRG.

Psychiatry, Dept. of Neurochemistry, 8033 Martinsried, FRG. A number of factors are known to influence adrenal tyrosine hydroxylase (TH) levels, such as splanchnic nerve activity and glucocorticoids. Cell contact may also play a regulatory role, since the specific activity of TH varies with cell density in primary cultures of bovine adrenal chromaffin cells (Naujoks et al. Dev. Biol. 92: 365, 1982). In order to further examine this effect, cells were cultured at a low density (.03 X 10° cells/cm³) for 24 hrs, during which time specific TH activity decreased to a value well below that found in vivo. This low level was main-tained if cells were kept at this low density. After this initial 24 hr period, cells were harvested using .01% trypsin and .5 mM EDTA in Ca -Mg -free PBS at 37°C. The enzymatic reaction was stopped by the addi-tion of trypsin inhibitor and 1% BSA. The yield of this procedure was 65-75% of originally plated cells. Cells harvested in this manner were then replated at the original low density showed no change in TH activity as compared to unreplated low density cells. However, there was a 6-fold rise in TH activity in cells replated at high density over 48 hrs. Conditioned medium from high density replated cells did not mimic the effect of direct cell contact. Immunotitration showed that the increased TH activity was due to an increased number of molecules, and cycloheximide increased number of molecules, and cycloheximide blocked the effect. These data suggest that increased TH synthesis, rather than decreased degradation, is responsible for the rise in TH. The effect was also blocked by both  $\alpha$ -amanitin and 9-B-arabinofuranosyl adenine inhibitors of mRNA synthesis and polyadenyl-ation respectively, consistent with a transcriptional level of regulation. Finally, the specific activity of acetylcholinesterase (which is induced together with TH by NGF in these cells, see Acheson and Thoenen, this volume), was not affected by cell density.

- 105.6
- CALCIUM PARADOX IN SKELETAL MUSCLE. <u>S. Carpenter\*, G. Karpati</u> and <u>M. Armani</u><sup>4</sup> (SPON: L.S. Wolfe). Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A-2B4. Calcium paradox was discovered in rat cardiac muscle by Zimmerman et al. 1967. Perfusion of the isolated heart for 3 minutes with a calcium-free, but otherwise physiological, solution destroys the cells' ability to control calcium fluxes through their generation. At this read they are permet by M. solution destroys the cells' ability to control calcium fluxes through their sarcolemma. At this point they are normal by EM except for separation of basal lamina from plasma membrane. Addition of physiological concentrations of calcium to the perfusate then results in rapid influx of calcium, egress of creatine kinase, and hypercontraction. We are describing calcium paradox for the first time in skeletal muscle in vivo and in vitro using EDTA solution to chelate interstitial calcium. Exposed purple of experimentation for 20 muscle of anesthetized rats was bathed in EDTA solution for 20 minutes. For <u>in vitro</u> experiments, the soleus muscle was suspended in oxygenated, glucose-enriched, calcium-free Tyrode solution with EDTA. The only immediate effects of EDTA were to separate basal lamina from plasma membrane and increase space between muscle fibers. These changes were visible after exposure to 5% EDTA on semithin sections. After 0.5% EDTA plasma membrane separation could only be seen by electron microscopy. Return of normal interstitial calcium resulted in necrosis in vivo and hypercontraction in vitro, presumably from excessive entry of calcium into muscle cells. EDTA saturated with calcium had no effect. An analogy may be drawn with Duchenne dystrophy, where one finds hypercontraction and necrosis, as well as separation of basal lamina from the plasma membrane of non-necrotic fibers. The analogy suggests that a fundamental abnormality in Duchenne dystrophy might involve calcium binding proteins in the plasma membrane.

106.1 A BASIC MECHANISM OF CENTRAL NERVOUS SYSTEM (CNS) FUNCTION. C. Torda. Res. Dpt. N. Y. Center PA Training, (Curr. Adr. P. O. B. 4866, Stanford University, Stanford, Calif., 94305). Several functions of mind and brain escape currently available in the function of mind and brain escape currently available

Adr. P. O. B. 4866, Stanford University, Stanford, Calif., 943051. Several functions of mind and brain escape currently available measuring techniques and cannot be explained by the concepts of classical physics (e.g. the automatically performed processing (including memory, recall, imagination), several time relationships of biological processes, etc.). Therefore, the possibility of involvement of submolecular processes in the function of the CNS has been here addressed. The nature of submolecular processes have been studied with quantum mechanical concepts based mainly on the theoretical rules and mathematics of David Bohm and Geoffrey F. Chew. Bohm's theory is based on conservation of energy. Everything in the universe is formed from the same energy. Each cm<sup>2</sup> contains 10<sup>9</sup> joules of energy that assumes implicit and explicit forms. The consequences are, in part, the human potential capacity for insight into every manifestation of the universe and for intellectual growth. Bohm's philosophical concept of quantum mechanics led to the holonomic principle: every part contains the whole. Theories based on the experimental data of the particle physics offer a more scientific explanation of the processes of the universe, mainly the "bootstrap" theory based on S-Matrix mathematics of Chew. Everything is formed by interactions of basic processes: The socalled elementary particles are formed from more basic processes related not only to conservation of energy, but also the several other conserved functions, e.g. momentum, electric charge, spin, parity, Baryon and Lepton numbers, etc. Due to intervention of soft photon energy, elementary particles and also classically observable objects are formed through interaction of these basic processes. This quantum mechanical theory implies limitless potential for change, regulated by soft photons. It can also accommodate far more processes than the functions of human mind and brain require. The immense number of possibilities is reduced by inherited species specifi

106.3 IMAGING OF CORTICAL SULCI IN MONKEYS WITH CONTRAST RADIOGRAPHY. P. E. Haenny\*, J. H. R. Maunsell and W. K. Abend\*. Of Psychology, M. I.T. Cambridge, MA 02139 and Department of Neurology, Harvard Medical School, Boston, MA 02115.

Individual variability in the position of cortical sulci limits the accuracy of stereotactic procedures for locating structures in the cortex. It is possible to determine the position of sulci from gyral bone impressions (Wolpaw 1979 Brain Res. 160: 505-508), but this technique requires a substantial trephination, which may be undesirable if chronically prepared animals are used, or when multiple determinations are necessary. We report a method of determining the location of sulci over large regions of individual hemispheres.

Sulcal images were obtained by taking skull X-rays after subarachnoid injections of a water-soluble contrast medium. Rhesus monkeys were anesthetized with ketamine and xylazine. Eight intrathecal injections of the contrast substance (metrizamide, 625mg in 2.5ml) were made in 5 rhesus monkeys by lumbar or suboccipital punctures. The animal was positioned so that the substance would distribute over the lateral surface of one hemisphere. At a series of times following the injection, skull X-rays were taken using a variety of X-ray beam angles. Images of sulci on the lateral convexity of the hemisphere

Images of sulci on the lateral convexity of the hemisphere were obtained. The best results were obtained 6 to 20 minutes after the injection, when the contrast substance was well distributed, but remained in the subarachnoid space. Projections which were roughly lateral gave the best results. With other views, bony structures obscured many of the sulci. The suboccipital approach provided greater ease of subarachnoid injection than did the lumbar procedure. When the head is properly aligned, X-rays can be used to establish sterotactic coordinates for the sagittal plane, providing an accurate approach to specific cortical loci.

Supported by the Swiss National Foundation and N.I.H. EY00676 and NS00747.

- 106.2 THE INTRAPARIETAL SULCUS OF THE RHESUS MONKEY: INTRINSIC CONNECTIONS AND ARCHITECTONICS. <u>Benjamin Seltzer and</u> <u>Deepak N. Pandya.</u> V.A. Hospital, Bedford, MA 01730 A previous study of the intrinsic connections of the
  - A previous study of the intrinsic connections of the parietal lobe in the rhesus monkey showed projections to the intraparietal sulcus (IPS) from both the superior and inferior parietal lobules (Pandya and Seltzer, '82). In addition, projections from visual-related cortex to a distinct architectonic sector (area POa) in the lower bank of the sulcus have also been demonstrated (Seltzer and Pandya, '80).

The present study combines a reappraisal of architectonics with a study of the intrinsic parietal connections of the IPS. Architectonically, the rostral part of the sulcus is a continuation of area 2. Caudally, its cortex merges with that of area 0A. Between these two extremes, the upper and lower lips of the IPS belong, respectively, to area PE of the superior parietal lobule and area PG of the inferior parietal lobule. Deeper within the sulcus, in the upper bank is area PEa and in the lower bank area POa. Finally, a distinct architectonic region is identified in depth of the IPS and designated "area IPA."

The afferent and efferent connections of these IPS regions were studied in 19 rhesus monkeys using autoradiographic techniques. Each architectonic zone has a specific set of connections. Rostrally, area 2-type cortex receives projections from the superior parietal lobule (area PE) and itself projects to area PEa. Area PEa also receives projections, in a topographical manner, from the ventral part of area PE in the upper lip of the IPS as well as the cortex at the apex of the superior parietal lobule (area PGm). Area POa, however, is the recipient of a projection from the rostral inferior parietal lobule (area PGm) and from area POa itself. Area IPd, by contrast, receives projections from both the medial parietal cortex (area PGm) and the caudal inferior parietal lobule (areas PG and Opt). The contribution from the latter is the more substantial. Thus, area IPd represents a zone of topographically-convergent somatic sensory input, from both the superior and inferior parietal lobules.

Supported by V.A. Hospital, Bedford, Mass. and N.I.H. grant NS 16841.

106.4 A COMPUTER SYSTEM FOR THREE-DIMENSIONAL ANALYSIS OF REGIONAL BRAIN ACTIVITY USING SERIAL 2-DEDXYGLUCOSE AUTORADIOGRAPHS. D.S. Schlusselberg, W.K. Smith, D.L. McEachron, D.J. Woodward, Dept. of Cell Biology, Univ. Texas Health Science Ctr., Dallas, Texas 75235.

This laboratory has been involved in the development of general purpose computer imaging for three-dimensional reconstruction of neuroanatomical information from serial sections. The system is designed for obtaining quantitative measurements, as well as delineating subtle differences in neuronal connectivity and regional neuronal distributions. In this report we describe an adaptation of this system for analysis of serial 2DG autoradiographs to provide similar three-dimensional information about relative metabolic activity in different brain regions.

Brains from rats injected with 2DG during an experiment are cut into serial sections which are then placed on radiographic film. The autoradiographic images for each section are digitized using a light box and video digitizer, and stored in an image memory buffer. Variations in lighting conditions are corrected by subtracting a pre-digitized background image. Pixel values in the image memory are then normalized to yield relative optical density values, using methods described by Gallistel et al (Neuroscience & Behavioral Rev, 6(4):409-420, 1982) to correct for differences caused by overall exposure of the radiographic image. Color coded windowing techniques can be used to enhance subtle variations in radiographic densities.

Perimeters which delineate neuroanatomical boundaries are generated by tracing histological images superimposed over the autoradiographs. A raster-scan conversion algorithm is used to read normalized pixel values within the regions bounded by the perimeters. The algorithm allows segments of pictures within specified regions to be stored in a three-dimensional anatomical database for further analysis. The system capabilities permit sequential section alignment and identification of neuroanatomical structures which appear in several sequential sections.

The perimeters and relative optical density data are used to create three-dimensional graphical images, showing regional brain activity per volume element in relation to reconstructed neuroanatomical structures. (Support from NIAAA 1F32-5198 to DSS, NIAAA 3901, and Biol. Humanics Foundation) 106.5 A DATABASE STRUCTURE FOR THREE-DIMENSIONAL RECONSTRUCTION OF M DEMONATOWICAL OBJECTS: W.K. Smith, D.S. Schlusselberg, B.G. Culter\* and D.J. Woodward, Dept. Cell Biology, Univ. Texas Health Science Ctr., Dallas, TX, 75235. Ongoing studies in this laboratory have explored the appli-

cation of computer graphics techniques for three-dimensional reconstruction of biological structures from serial sections. The design of a database for storage, manipulation and display of the serial section data has proven to be the dominant task. In comparison, software for graphical input-output has been relatively straightforward.

Data can be collected from a variety of sources: light microscopy, electron micrographs, enlarger, photographs and tracings. Points along the perimeters of biological structures and cell positions make up the largest part of the input data. A hierarpositions make up the largest part of the input data. A hierar-chical database has been designed to store this biological infor-mation. The 'C' programming language utilized for this task has proven useful for manipulating complex data structures. Data records are organized into nodes which contain information about the type of data stored and address pointers to lists of graph-ical data and other nodes. The hierarchical node relationships follow the Knuth transform of an n-ary tree.

Different levels in the hierarchy are represented by different types of nodes. The first node in a database file is the ROOT node, which contains global information about the file and pointers to a group of FAMILY nodes. Included among the FAMILY nodes are SECTIONS and OBJECTS. Data acquisition routines must nodes are SECTIONS and OBJECTs. Data acquisition routines must first create SECTION nodes for each section to be analyzed. Data is entered for each section as SEOMENT nodes, which are the chil-dren of SECTION nodes. Once section and segment data are entered, segments from each section which form part of biological objects must be identified. The biological object is identified by an OBJECT node which points to a hierarchy of BRANCH nodes. Each BRANCH node points to a family of STRIP nodes, which repre-sent the surface definition of that branch. Virtual memory emulation software eases the task of handling

Virtual memory emulation software eases the task of handling large amounts of information. A package of powerful data analsis and graphical display routines exists to access this data-base. This software provides such operations as file editing, interactive alignment, object building, surface triangulation and image generation on a variety of graphical output devices. Applications include: analysis of catecholamine cell distribution in the substantia nigra and locus coeruleus in normal and aging brain, examination of cortico-cortical connections in the rat and cortical-subcortical connectivity studies in the thalamus, the raphe nucleus and the inferior olivary nuclei. (Support from the Biological Humanics Foundation to DJW and the NIAAA 1F32AA05198-01 to DSS.)

COLLATERAL AXONAL BRANCHING OF VENTRAL TEGMENTAL AND RAPHE PROJEC-106.6 TIONS TO THE MEDIAL PREFRONTAL AND SULCAL CORTICES IN THE RAT: A RETROGRADE FLUORESCENCE DOUBLE LABELING STUDY. Erik C. Sobel\* and Dale Corbett\*. (SPON: J.R. Stellar). Dept. of Psych. & Soc. Rel., Harvard Univ., Cambridge, MA 02138. One striking characteristic of monoamine neurons is the dichot-

omy between extensive distribution of monoamine axons in the central nervous system and the relatively small number of monoamine neurons within each cell group (Fallon and Loughlin, 1982). This dichotomy has led investigators to suggest the possibility that monoamine neurons possess highly collateralized divergent axonal branches innervating their terminal fields. Within the A9-A10 regions there is anatomicallydemonstrated overlap of the origins of dopamine projections to functionally different parts of the forebrain (Fallon and Moore, 1978; Fallon, 1981). Fallon and Loughlin (1982) previously reported findings of the relative degree of collateralization to the forebrain from the three major monoamine cell groups. Their findings show that while the pars compacta (SNC) and VTA appear to contain less collateralized cells than the dorsal and median raphe nuclei (DR-MR) the cells of each nuclei sustain both highly branched and poorly branched axons The question remains as to the specific projections of collateral-ized and non-collateralized neurons within the monoamine nuclei.

The collateralization of SNC-VTA and raphe projections to two distinct areas of the frontal cortex was examined using a retro-grade fluorescent double labeling technique (Kuypers et al., 1980). 50 nl pressure injections of 3% propidium iodide (PI) and 10% bis-benzimide (Bb) were made into the medial prefrontal cortex (MFC) and sulcal cortex of 10 animals. Five animals received Bb in the MFC with PI in the sulcal cortex and five received each dye in the other cortical area in a balanced design. To compare the relative degree of labeling between the two dyes two additional animals re-ceived Bb in the MFC with PI in the homotopic MFC.

Double labeled cells were found in the VTA and medial portion of the SNC as well as in the MR and throughout the DR. Double labeled cells were found ipsilaterally located in the SNC-VTA and bilaterally in the DR-MR. Comparing the two dyes revealed that while they both label the same areas PI labels more cells than Bb.

The findings clearly indicate the collateralization of neurons in the VTA, SNC, MR and DR to the MFC and sulcal cortex. The apparent greater sensitivity of propidium iodide in labeling the cells of the SNC-VTA and the careful study of one specific collat-eral terminal field system made possible the visualization of the previously unreported collateralization from the VTA to the frontal cortex. Further study combining retrograde double label-ing fluorescence and catecholamine or immunohistochemical fluorescence is necessary to characterize the dopaminergic nature of these collateral projections to the prefrontal cortex.

106.7 THALAMIC CONNECTIVITY OF THE SOMATIC MOTOR CORTEX (SMI) IN THE

IHALAMIC CONNECTIVITY OF THE SOMATIC MOTOR CORTEX (SMT) IN THE RAT. L.D. Aldes\*. Department of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, Texas 77025. (SPON: J.F. DeFrance) The aim of this study was to investigate the organization of thalamocortical and corticothalamic projections of the somatic motor cortex (SMI) in the rodent, and thereby, further define the SMI on the basis of thalamic connectivity. This was accomplished by microintophoretically applying horseradish peroxidase (HRP) or tritiated amino acids into low threshold cortical foci within the leg, arm and head representations of SMI as defined by intracorti-cal microstimulation. cal microstimulation.

Injections at each cortical site produced consistent patterns

cal microstimulation. Injections at each cortical site produced consistent patterns of retrograde and anterograde labeling in several specific and non-specific thalamic nuclei. The former included the ventrolater-al (VL), ventromedial (VM), and posterior (PO) nuclei, and the lat-ter the centrolateral (CL), paracentral (PC), central medial (CeM) and parafascicular (PF) nuclei. The heaviest labeling oc-curred in the VL nucleus and, secondarily, in the PO nucleus, while labeling of specific nuclei was more extensive than in non-specific groups. The ventrobasal (VB) and lateral posterior (LP) nuclei were labeled after injection of the leg representation of SMI, and terminal fields, whose position varied with that of the injection site, were found in the reticular (Ret) nucleus. A topographic organization was indicated by the varied position of labeling following injections at different locations. Injection of the leg representation produced labeling in rostral, lateral and more dorsal regions of VL, in the dorsal, lateral and more rostral PO and ventrolateral VM. In contrast, labeling occurred in the caudal, medial and more ventral regions of VL, in the ven-tral, medial and more caudal PO and dorsolateral VM following in-jection of the head representation. Characteristic labeled pat-terns that occupied an intermediate position were found after in-jections into the arm representation of SMI. Finally, rostro-lateral injections of SMI labeled more rostral areas of these nuclei and CeM, whereas dorsomedial injections labeled more rostral areas

of these nuclei. The results from this study indicate that, in the rodent: 1)the U nucleus provides the principal source of input to the SMI; 2) there is convergence of multiple input from several specific and non-specific thalamic nuclei onto each functional area of the SMI; 3)the projections are reciprically organized and topographically arranged; and 4)the SMI may be further defined on the basis of

thalamic connectivity. Supported, in part, by NIH grant 05913-0 and a University of Texas Biomedical Research Support Grant.

CORTICO-THALAMIC FIBERS ARE DISTRIBUTED BILATERALLY IN RAT. M. Molinari\*, D. Minciacchi\*, M. Bentivoglio\*, G. Macchi\* (SPON: European Neuroscience Association). Inst. of Neurology, Catholic 106.8 University, Rome, Italy.

European Neuroscience Association). Inst. of Neurology, Catholic University, Rome, Italy. The anterograde transport of lectin-conjugated horseradish peroxidase (WGA-HRP) was employed in order to investigate the organization of corticothalamic fibers efferent from the sensori-motor cortex in rat. Cortical injections ranging from 0.1 µl to 0.4 µl of 5% WGA-HRP were made unilaterally in rats. The survival time was 48 hours, except for one case which survived 24 hours. The animals were perfused with 2.5% glutaraldehyde. The material was incubated with tetramethylbenzidine. Retrogradely labeled cells and anterogradely labeled terminals were seen in the ipsi-lateral thalamus. In addition, a consistent anterograde labeling was seen in the contralateral thalamus in the intralaminar nuclei and in the ventral nuclear complex. This finding could either indicate the existence of a crossed cortico-thalamic component or represent a false positive result . Control experiments were made in order to exclude this latter possibility. It was hypothesized that false positive results could have derived either from callo-sal cell bodies, labeled in the contralateral cortex, or from the ipsilateral labeled thalamo-cortical cells, due to two mechanisms: i) transport through axonal branches of the labeled cell populat-ions; ii) transport aronsfer. Three sets of control experiments were made: A) unilateral kainic acid injections in the sensorimotor cortex followed by WGA-HRP injections in the same clace. This percenture and contraions; ii) transneuronal transfer. Three sets of control experiments were made: A) unilateral kainic acid injections in the sensorimotor cortex followed by WGA-HRP injections in the same place. This procedure abolished both the ipsilateral and contra-lateral anterograde labeling in the thalamus, whereas labeled cells were still seen in the ipsilateral thalamus. These experiments indicated that the contralateral anterograde labeling, as well as the ipsilateral one, derived from cortical cell bodies. B) Kainic acid injections in the thalamus, followed by WGA-HRP injections in the ipsilateral cortex. This procedure abolished the ipsilateral thalamic retrograde labeling, whereas anterograde labeling was still seen in both thalami. These experiments indicated that the contralateral anterograde labeling could not derive from labeled thalamo-cortical cells. C) Split of the corpus callosum followed by WGA-HRP injections in the cortex. In these experiments anterograde labeling was still seen bilaterally in the thalami and this confirmed that the contralateral thalamic anterograde labeling could not derive from labeled callosal cell bodies. Altogether these experimental findings indicate that cortico-thalamic fibers are distributed bilaterally in the rat , as it was previously suggested in cat (Rinvik, E., <u>Exp. Brain Res. 5</u>: 129, 1968) and monkey (Goldman, P.S., <u>Brain Res. 165: 166, 1979</u>), and that the crossed cortico-thalamic fibers do not travel via the corpus callosum.

PROJECTIONS TO THALAMIC ASSOCIATION NUCLEI FROM WIDESPREAD PARTS OF THE LIMBIC CORTICES IN THE RHESUS MONKEY. E. H. Yeterian, Department of Psychology, Colby College, Waterville, ME 04901. Recent autoradiographic studies of corticothalamic connections in macaque monkeys have revealed more extensive and intricate in-106.9 in macaque monkeys have revealed more extensive and intricate in-terrelationships than had been observed using older anterograde methods. Within this area of research, thalamic projections of limbic cortices, in particular, projections from limbic cortices to thalamic association nuclei, have been less completely investi-gated than those of other cerebral cortical areas. The present study examined the distribution of projections from various lim-bic cortical areas to the dorsomedial (DM), lateral dorsal (LD), lateral posterior (LP), and medial pulvinar (PM) nuclei. In 15 monkeys, tritiated amino acids were injected into various archi-tectonic subdivisions of the limbic cortices as delineated by Brodmann, and Bonin and Bailey. Each case was examined for evimonkeys, tritated amino actos were injected into various archi-tectonic subdivisions of the limbic cortices as delineated by Brodmann, and Bonin and Bailey. Each case was examined for evi-dence of terminal label over thalamic association nuclei as de-marcated by Olszewski. Orbital frontal area 13 projects to medial regions of DM and PM. Area 32 on the medial surface of the fron-tal lobe sends projections primarily to dorsomedial DM, with a slight caudal extension into the rostralmost portion of PM. In contrast to the preceding cases, area 24 shows no evidence of projections to PM, but does project heavily to medial DM. Projec-tions to the medial pulvinar are again evident from rostral area 23, occupying a dorsomedial to central region of that nucleus. In addition, rostral area 23 sends projections to central DM, and also to dorsal LP. Caudal area 23 differs from rostral area 23 in projecting to LD but not to DM. Caudal area 23 also projects strongly to dorsal LP and to dorsal and central PM. Among the limbic cortices of the temporal lobe, area TF projects to dorsal PM and to ventromedial LD, while area TH projects to dorsal PM and to lateral and medial regions of LD. Area 35 projects only to dorsal PM, with evidence of terminal label extending to the caudal pole of the thalamus. Finally, area TG of the temporal pole projects heavily to medial PM and to dorsomedial DM. In summary, each of the areas investigated, with the exception of area 24, projects to PM--frontal areas medially and more cau-In summary, each of the areas investigated, with the exception of area 24, projects to PM--frontal areas medially and more cau-dal areas predominantly dorsally. Areas 13, 32, and 24, rostral area 23, and area TG project to DM, while caudal area 23, and areas TF, TH, and 35 do not show evidence of such connectivity. Projections to LD are from areas 23, TF, and TH, while those to LP are from area 23 only. Although each limbic cortical area has a distinctive overall pattern of projections to thalamic associa-tion nuclei, each area projects to at least one such nucleus. Thus, projections to thalamic association nuclei appear to be a general feature of limbic cortices in the rhesus monkey.

Thalamocortical mechanisms underlying non-barbiturate spindles in the cat association system. M. Avoli, R. McLachlan\*, D. Giaretta\* and P.Gloor. Montreal Neurological Institute and Dept. of Neurology and Neurosurgery, McGill University, Montréal, P.Q., H3A 2B4, Canada. Extracellular single unit recordings were performed simultaneously from pairs of neurons, one located in the cortex (middle suprasylvian gyrus, MSS), the other in the thalamus (n. lateralis posterior and pulyinar) of paiplety immediate other activities. gyrus, MSS), the other in the thalamus (n. lateralis posterior and pulvinar) of painlessly immobilized, awake cats. The unitary activity was studied during spontaneous non-barbiturate EEG spindles recorded with the intracortical and thalamic microelectrodes and with epicortical electrodes. Data were statistically analyzed by a computer which generated EEG averages and histograms of single unit activity (EA-HSU) which were triggered by: (a) peaks of EEG transients (i.e. spindle waves) or (b) action potentials (aps) occurring during selected sections of EEG (i.e. spindle bursts). As previously reported for barbiturate spindles those recorded in the

As previously reported for babiturate spindles those recorded in the present experiments displayed mixed features of type I (augmenting) and type II (recruiting spindles) (J.Neurophysiol. 24, 50-65, 1961). When EA-HSUs were triggered by cortical spindle waves, (a) 14 of 31 cortical neurons showed rhythmic oscillation between maximum and minimum neurons showed rhythmic oscillation between maximum and minimum firing probability at the same frequency as the cortical and thalamic EEG spindle bursts, while in the remaining neurons no relationship with spindle waves was observed; (b) 11 of 31 thalamic neurons displayed a rhythmic modulation of firing probability at the frequency of the thalamic and cortical spindles, while the others did not show any clear change of firing probability throughout spindle bursts. A similar pattern of neuronal behavior during non-barbiturate spindle was also observed when EA\_HSUs were triggered by thalamic spindle was also observed when EA-HSUs were triggered by thalamic spindle waves or by cortical or thalamic aps. In those cases in which both cortical and

cortical or thalamic aps. In those cases in which both cortical and thalamic cell firing was modulated during non-barbiturate spindles, the thalamic peak of firing probability preceded that of the cortex by 5-40ms in 7 cases and followed that in the cortex by 30-40ms in 2 cases. These data show that at least in nearly 30% of pairs of neurons studied in thalamus and cortex a mechanism similar to that described for barbiturate spindles (J.Physiol. 192: 282-307, 1967) is seen to operate in the absence of barbiturates. The lack of any relationship between EEG and unit firing probability at both the thalamic and cortical levels in a large number of neuronal pairs in the absence of barbiturates might in part be due to a lesser degree of effective synaptic coupling of neurons involved in spindle genesis. The action of barbiturates in enhancing neuronal synchronization may be due to an increased effectiveness of gating effect exerted by thalamic inhibitory interneurons.

CORTICAL-SUBCORTICAL MECHANISMS FOR "INTERICTAL AFTER-DISCHARGE" 106.11 Control = Down Fight Figh Biological Sciences, Cornell University, Ithaca, NY 14853.

Local application of sodium penicillin to the presigmoid gyrus (projection area of the ventral lateral nucleus of the gyrus (projection area of the ventral lateral nucleus of the thalamus) in urethane anestherized cats produced regular inter-ictal spikes, each followed by cortical after-discharge (AD) that required 10-30 min to develop. The AD occurred 170-200 mesc after the spike and consisted of 16-20/sec oscillations usually starting with positive polarity and lasting up to three cycles. Cooling selective subcortical sites revealed that AD could be readily and reversibly blocked without altering the spikes when the cooling thermode was placed in VL as compared to other sites. This observation plus current views of the thalamic pacemaker of cortical rhythms suggest two models in which the cortical spike triggers VL to fire synchronously. Then, after a delay of 170-200 msec caused by a thalamic ipsp, a rebound discharge activates either an independent oscillator in the cortex or a thalamic oscillator that in turn drives a phase-locked oscillator in the cortex. Extracellular recordings were made from over 60 VL units to test these two models. Consistent with the expected trigger action of the cortex on VL, sixty percent of the VL units fired during the penicillin spike. When AD was present all units recorded in VL, in conspike. When AD was present all units recorded in VL, in con-trast to other sites, showed a discharge pattern strongly related to AD. All units were inhibited for 170-250 msec follow-ing a spike indicating the presence of the expected long lasting ipsp. The units fired in bursts on either the positive or negative phases of AD but not immediately preceding or following it. Thus the units did not appear to initiate or show indepen-dence from the cortical AD. Although this is not conclusive evidence for differentiating between the two models, it does favor the independent cortical oscillator model. Additional support for this view is seen in increased delay of AD with cooling of VL without a change in AD frequency. (1) Fulbright Fellow from Phillipps University, Marburg, West Germany.

106.12 CORTICAL-STRIATAL DOPAMINE INVOLVEMENT IN AN ANIMAL MODEL FOR Augusta, Georgia 30912.

Chronic neuroleptic treatment can produce tardive dyskinesia in man. This is a result of chronic blockade of extrapyramidal dopamine receptors which results in a paradoxical increase in the numbers of these striatal receptors. The tardive dyskinesia model in animals produces not only the increase in the numbers of striatal dopamine receptors, but also a behavioral sensitization to dopamine agonst type drugs. Since involuntary movements also have a cortical involvement, we have studied the role of the have a cortical involvement, we have studied the role of the cortex in an animal model for tardive dyskinesia. Male Sprague-Dawley rats (200 - 250 g) were treated for 18 days with haloperidol (1 mg/kg, 1.p.). Half of these animals had stereotactically placed 6-hydroxydopamine lesions of the cortex above the striatum. After a five day washout from haloperidol, animals received either apomorphine (0.5 mg/kg) or d-amphetamine (3.75 mg/kg) and stereotyped behaviors were rated. Two days later brains were removed and the cortex above the striatum and the caudate-putamen nucleus were dissected out. These areas were analyzed for the affinity and number of dopamine receptors using <sup>3</sup>H-spiroperidol as the ligand. Compared to control animals, haloperidol treated rats ligand. Compared to control animals, haloperidol treated rats demonstrated an increase in stereotyped behavior to apomorphine and d-amphetamine and both cortical and striatal dopamine recep and dramphetamine and both other and stillar dopamine tecep tor numbers were increased over controls. In animals with corti-cal lesions, and haloperidol treatment for 18 days, there was no increase in the number of cortical or striatal dopamine recep-tors. Moreover, apomorphine produced a decrease in stereotypy whereas d-amphetamine increased stereotyped behavior in these animals. These results suggest that striatal dopamine hyperactivity is modulated by the cortical dopaminergic system

TECTAL METABOLIC DEFICITS IN MONKEYS WITH HEMISENSORY NEGLECT. 106.13 R.K. Deuel, Departments of Pediatrics and Neurology, Washington University, St. Louis, MO.

The syndrome of hemisensory neglect includes conditional but severe hemifield visual and somesthetic, and motor performance deficits. These are reliably produced by frontal or parietal polysensory association cortical lesions (FPC or PPC) in monkeys polysensory association contrast response (i.e.  $d_1 = -2$ ,  $d_2 = -2$ ,  $d_3 = -2$ ,  $d_4 = -2$ ). Complete recovery from symptoms occurs over 4 to 6 weeks after the locion (Deuel and Collins, 1979). We used quantitative  $1^{14}C^{-2-1}$ lesion (Deuel and Collins, 1979). We used quantitative  $^{14}C^{-2-}$  deoxyglucose autoradiography (DG) to study local cerebral glucose utilization (LCGU) in the brains of animals demonstrating neglect after FPC and PPC lesions and in recovered animals. Behavioral responses were the same in the acute lesion groups. In contrast, LCGU deficits in di- and tel-encephalic structures differed com-pletely between the two groups. With FPC lesions, basal ganglia and selected medial and ventral thalamic nuclei of the damaged hemisphere (DaH) were affected. With PPC lesions, DaH posterior and lateral thalamic, and cortical regions were affected. The only structure that exhibited LCGU deficits in both neglect groups was the superior colliculus (SC) of the tectum. The ratio of metabolic activity in the DaH, compared to the intact hemisphere (InH) differentiated the deeper layers of the colliculus in both FPC and PPC neglect brains from control brains. In brains of behaviorally

The neglect offants from control prains. In brains of benaviorally recovered FPC and PPC animals, SC LGU deficits had improved. The cardinal symptoms of hemisensory neglect, namely lack of orientation to and sustained attention for a spatial hemifield, may be related to decreased synaptic activity in the contralateral tectum in the monkey rather than dysfunction of di- or telen-orbalic attraction cephalic structures. Ratio of Damaged/Intact Hemisphere Metabolic Activity (group

medians)

	Acute		Recovered

PHYSIOLOGY OF CORTICALLY PROJECTING NEURONS IN RAT BASAL FOREBRAIN. <u>G. Aston-Jones, R. Shaver\*</u> and T. Dinan\*. Center for Neurobehavioral Sciences, SUNY, Binghamton, NY 106.15 13901.

Recent studies have confirmed a direct cholinergic Recent studies have confirmed a direct cholinergic projection from basal forebrain neurons to cerebral cortex in many species. These cells are of interest because they represent a diffusely projecting, non-thalamic cortical afferent system in addition to monoamine tracts, and because degeneration in this cholinergic system has been linked to Alzheimer's Disease. Unit recordings in waking monkeys have revealed that neurons in this area discharge in relation to feeding behavion. However, there have have monkevs have revealed that neurons in this area discharge in relation to feeding behavior. However, there have been no physiological studies of basal forebrain neurons that are known to innervate cortex. We examined the physiology of antidromically (AD) identified cortically projecting basal forebrain neurons in the rat. Extracellular recordings from single neurons were obtained in 46 chloral hydrate-anesthetized rats. Elec-trical stimulation of frontal cortex (FCx) revealed that 67 of 858 (7.8%) cells tested were AD activated, while 12 of 357 cells tested with parietal cortex (FCx) stimulation (3.4%) were AD driven. Antidromic activation was verified

b) of 357 cells tested with parietal cortex (PCx) stimulation (3,4%) were AD driven. Antidromic activation was verified by constant latency driving, activation at frequencies greater than 100 Hz, and occlusion of driven spikes by collision with spontaneous impulses. All AD driven cells were histologically localized to the globus pallidus area, corresponding to anatomical maps of acetylcholinesterase-positive cells. Latencies from FCx ranged from 1.0 to 13.0 msec (mean =  $4.8 \pm 0.4$  msec), reflecting conduction velocities of about 0.6 to 8.0 m/sec. Latencies for PCx activation ranged from 1.6 to 24.0 msec (mean =  $7.4 \pm 1.1$  msec), yielding conduction velocities had lowest thresholds in superficial cortex, while the faster fibers were most easily driven from deeper cortical placements. Single neurons often exhibited multiple antidromic latencies as a function of stimulation deeth or amplitude. These results indicate that efferent fibers from these basal forebrain neurons are highly branched in cortex, and These results indicate that efferent fibers from these basal forebrain neurons are highly branched in cortex, and that they may become non-myelinnated as they reach terminal fields in cortical gray matter. Spontaneous discharge rates and spike waveforms differed among AD driven neurons, indicating a physiologically heterogenous cell population. This work was supported by NINCDS Grant NS19360 and BRSG Grant S07RR7149-09 from NIH.

DIFFERENTIAL PROJECTIONS OF THE BASAL FOREBRAIN AND NUCLEI OF THE SUBTHALAMUS TO VISUAL CORTEX IN THE RAT. <u>Russell G. Carey</u> and <u>Richard W.</u> <u>Rieck</u> (SPON: A.S. Schwartz). Div. of Neurobiol., Barrow Neurol. Inst., Phoenix, AZ 85013, and Dept. of Anatomy, Tulane Univ., New Orleans, LA 70112. Previous reports (Mesulam & VanHoesen, '76; Rieck & Gould, '79; Wenk et al., '80; Jackson & Crossman, '81; Ribacak & Kramer, '82) have shown that large multipolar and fusiform AChE-positive neurons in the the basal telencephalon region of 106.14

ACRE-positive neurons in the the basal telencephalon region of the substantia innominata (SI) and the thalamic region of the subthalamic nucleus are retrogradely labeled following HRP injections in cortex. Destruction of portions of these AChE regions by either electrical or chemical lesions has resulted in a conspicuous depletion of both AChE and choline acetyl-transferase activity throughout the neocortex (Struble et al., '82; Johnston et al., '79). Thus, these subcortical regions are suggested to contribute substantially to the AChE plexus in cortex

We have recently reported (Rieck & Carey, '83) that, counter to previous beliefs, the terminal locus of the AChE projecting neurons is maximally in the infragranular cortical layers and only minimally in layer I of visual cortex. The present report extends this finding and further illustrates the existence of a rough topography of the projection of these AChE neurons onto visual cortex.

visual cortex. After injections of WGA-HRP into infragranular layers of cortex immediately medial to area 17 (area 18M), numerous labeled cells are localized in the rostral portion of nucleus basalis of SI and continue dorsomedially into the diagonal band of Broca. Caudally a few labeled cells are found within the medullary laminae of the globus pallidus. No labeled cells are localized in either the subthalamus or within the ansa lenticularis. In contrast, after injections into cortical regions lateral to area 17 (area 18L) numerous labeled cells are found in the subthalamus as well as within the the ansa lenticularis, and other regions of caudal SI. Further, in lenticularis and other regions of caudal SI. Further, in comparison with injections of 18M, fewer labeled cells are found in the rostral nucleus basalis. The pattern of labeled cells seen after injection in area 17 is intermediate between that seen with the more medial or lateral injections.

Thus, these data suggest that the proposed cholinergic afferent system arising from these nuclear regions not only terminate in the infragranular layers of visual cortex, but

also in a very preferential manner. Supported by NIH Grant EY03641(RGC), BRSG 53180(RWR), and funds from EPI-HAB Phoenix, Inc.

N-METHYLASPARTATE, A USEFUL EXCITOTOXIN FOR LESIONING SUB-STANTIA INNOMINATA NEURONS IN THE RAT. <u>Gregory Stewart\*</u>, <u>Madelon T. Price and John W. Olney</u>, Washington Univ, Dept Psychiatry, St. Louis, MO. A loosely clustered group of neurons in the substantia innominata (SI) region of the basal forebrain comprises the major source of extrinsic cholinergic inputs to the cerebral cortex. Evidence in recent years that these neurons are lost in Senile Dementia Alzheimer's Type (SDAT) has led to attempts to develop an animal model of SDAT by selectively lesioning SI neurons. Two excitotoxins, kainic acid (KA) and ibotenic acid (Ibo), have been used to delete SI neurons from rat and monkey brain respectively (Johnson et al., PNAS 76, 5392, 1979; Struble et al., Neurosci Abst 8, 211,1982). Efficacy of the lesioning approach, as reflected by loss of cholineacetyltransferase (CAT) from the cerebral cortex was reported as a 45-50% loss induced by KA (rat) or "significant" loss induced by Ibo (monkey). Since both of these agents have disadvantages as lesioning agents, KA being a potent convulsant that causes seizure-linked distant lesions and Ibo being exhorbitantly expensive, difficult to synthesize and unstable, we undertook the present experiments aistant lesions and lob being exnorbitantly expensive, difficult to synthesize and unstable, we undertook the present experiments to test the efficacy of N-methyl-DL-aspartate (NMA) a relatively potent excitotoxin that has none of these unfavorable properties. Adult female rats (~300g) were stereotaxically injected with NMA unilaterally at two dorsoventral levels (-6.0 and -7.0 from dura) through a single needle insertion (skull raised to 4.0, AP at bregna, L=2.6). Each injection consisted of 100 nmol NMA in It has been actively control of the sterior consistence of 100 mmon marking the sterile distilled HgO (pH adjusted to  $7.0\pm0.2$ ). Ultrastructural analysis of the SI lesion revealed sparing of most axons and acute degeneration of SI neuronal perikarya. If measurement in ipsilateral frontal and parietal cortices revealed a loss of 47% and 41% respectively (compared to CAT homotopic contralateral cortex) and was accompanied by a striking loss of cholinesterase staining. Electron microscopic evaluation of the ipsilateral cortex at appropriate postevaluation of the ipsilateral cortex at appropriate post-treatment intervals revealed numerous degenerating axon terminals, the majority of which were in synaptic contact with small caliber dendritic branchlets and were distributed diffusely through both superficial and deep cortical layers. The long-term fate of denervated cortical cholinergic receptors and ability of spared cholinergic neurons to reinnervate such receptors remain under investigation. We conclude that NMA is a useful agent for coloring a feature power of the second s useful agent for selectively lesioning SI cholinergic neurons and studying the synaptic organization and functional role(s) of their cortical projections. Supported in part by Research Career Scientist Award MH 38894 (JWO).

107.1 EFFECTS OF BRAINSTEM COOLING ON TREADMILL LOCOMOTION EVOKED FROM THE MESENCEPHALIC LOCOMOTOR REGION. L.M. Jordan, S.J. Shefchyk and R.M. Jell. Department of Physiology, University of Manitoba, Winnipeg, Canada R3E 0W3. Electrophysiological and anatomical studies of projections

from the mesencephalic locomotor region (MLR) have revealed pathways to pontobulbar reticulospinal nuclei (n. reticularis gigantocellularis and magnocellularis and n. raphe magnus) and to Jateral sites corresponding to the pontobulbar locomotor strip (PLS). We have examined the role of these sites in MLR-evoked locomotion was induced in high decerberate, decerbellate cats by stimulation of the MLR at stereotaxic coordinates P2-4, L2-4, H4.5-6.5. Locomotor activity was monitored by EMG recordings from the biceps brachii, triceps brachii, tibialis anterior, and lateral gastrocnemius muscles bilaterally. Selected brainstem sites were cooled using ice water circulating at a rate of 15 ml/min through a coaxial 18 gauge stainless steel probe. T temperatures reached in the closely surrounding tissue were within the range required for blocking synaptic but not axonal transmission. When locomotion was initiated by stimulation of the most lateral sites in the MLR (L3.5-4.0), cooling in the midline region 5mm rostral to the obex at a depth of 2-3mm below the surface of the medulla always reversibly abolished or severely impaired MLR evoked locomotion. Cooling within the ipsilateral PLS at a site 5mm rostral to the obex, 4mm lateral to the midline and at a depth of 2-3mm abolished or impaired locomotion induced from the lateral MLR in some animals and was without effect in others. Cooling within the contralateral PLS was always without effect when lateral MLR sites were stimulated. When the stimulating electrode was positioned in the medial MLR (L2.0-2.5), the evoked locomotion was unaffected by midline cooling; but cooling within the ipsilateral PLS (L4.0) reversibly abolished the locomotor response. These results suggest that relays within the medulla are required for the "locomotor command" from the MLR to reach the spinal cord. Furthermore, they suggest that lateral MLR sites form functional relays in both the midline reticulospinal areas and in the ipsilateral PLS, while the functional relays of medial MLR sites are in the ipsilateral PLS.

107.2 LOCOMOTOR STEPPING ELICITED BY ELECTRICAL STIMULATION OF THE LATERAL HYPOTHALAMUS IS MEDIATED BY AN IPSILATERAL DESCENDING PATHWAY, Sun Hi Lee,\* Harry M. Sinnamon and David G. Adams. Department of Psychology, Wesleyan University, Middletown, CT 06457.

The effects of unilateral midbrain lesions on stepping produced by ipsilateral MFB stimulation was determined in acute experiments. Rats were anesthetized with nembutal (50 mg/kg), mounted in a stereotaxic apparatus and suspended over a 30-cm diameter wheel. Stepping by the rat caused the wheel to rotate. Supplemental anesthesia was provided by nembutal (7.5 mg/kg). Stimulation consisted of 10-sec trains of 50 Hz cathodal pulses (0.5 msec) at currents up to 200 uA delivered through monopolar #00 insect pins. Lesions were made by radio-frequency current (6 or 8 mA) continued for 40 sec. The stimulation sites were in the MFB mainly at the level of the subthalamic nucleus. Prelesion baseline locomotor scores were determined and one side of the brain was randomly -selected to receive a midbrain lesion. Following the lesion, the MFB electrodes were tested priodically for approximately 1 hour. Certain midbrain lesions (N=6) abolished stepping elicited from ipsilateral MFB stimulation but

Certain midbrain lesions (N=6) abolished stepping elicited from ipsilateral MFB stimulation but produced no significant effect on contralaterally elicited stepping. These lesions destroyed a region which included the medial two-thirds of the medial lemniscus, the ventral red nucleus, the medial third of the substantia nigra compacta (SNC) and the ventral tegmental area (VTA). Partial reductions were produced by lesions that were generally more lateral. Lesions without effect spared the dorsomedial aspect of the VTA but damaged extensively either the SNC and SNR, ventrolateral VTA, red nucleus, medial lenniscus, central gray and superior colliculus. To determine if an ascending system was responsible, the effects of MFB lesions were determined on stepping elicited from VTA stimulation. In none of five cases was stepping reduced. We conclude that stepping elicited from MFB stimulation in this preparation requires a descending system projecting through the VTA.

107.3 CATALEPSY CAUSED BY INJECTION OF CHOLINERGIC AGENTS INTO THE MESENCEPHALIC RETICULAR FORMATION. S.L. Hartgraves\* and P.H. Kelly. Dept. of Physiology and Biophysics, USC School of Medicine, Ios Angeles, CA 90033. Catalepsy in rats is an experimentally-induced state which shares a common characteristic with Parkinson's disease, akinesia. Catalepsy can be caused by systemic injection of neuroleptics, cholinergics or narcotics, or by injection of neuroleptics, cholinergics or narcotics, or by injection of these agents into specific brain regions. Whereas neurolepticinduced catalepsy seems to depend upon an intact caudate nucleus, cholinergic-induced catalepsy is produced at another location(s) (Costall and Olley, Neuropharmacology, 10:297-307, 1971). There is a relationship between neuroleptic- and cholinergic-induced catalepsy, however, since systemic atropine can antagonize the catalepsy caused by systemic neuroleptic. This relationship may ultimately occur in the mesencephalic reticular formation (MRF), due not only to its connection with the substantia nigra (Beckstead, et al., <u>Brain Research, 175</u>:191-217, 1979), but also because of its involvement in extra-pyramidal movement (Imperato, et al., <u>Brain Research, 216</u>:437-443, 1981). To examine this hypothesis male Sprague-Dawley rats were stereotaxically implanted with cannulae into the ventral MRF at the level of the red nucleus. Bilateral injection of a mixture of 50 μg acetylcholine and 2.5 μg eserine in 0.5 μl saline caused pronounced catalepsy as measured by the bar test (front paws placed on a bar 10 cm above the table surface, average of two tests with the maximum score being sixty seconds). To examine the effects of atropine in the MRF on catalepsy elicited by haloperidol, rats were injected systemically with 1.5 mg/kg haloperidol, rats were injected systemically with 1.5 mg/kg haloperidol, rats were injected systemically with 1.5 mg/kg haloperidol, rats were since to bilateral MRF injection of atropine sulfate (5 µg in 0.5 µl saline) or

This study suggests that the MRF may be a site involved in the mediation of catalepsy by cholinergic agents, and in the reversal of neuroleptic-induced catalepsy by anticholinergic agents.

FORELIMB AND HINDLIMB STEPPING BY THE ANESTHETIZED RAT ELICITED BY ELECTRICAL STIMULATION IN THE DIENCEPHALON AND MESENCEPHALON, Harry M. Sinnamon, Laboratory of Neuropsychology, Wesleyan Univ., Middletown, CT 06457. Thirty rats anesthetized with a combination of chloralose, urethane and nembutal or nembutal alone were fixed in a stereotaxic apparatus and suspended over a moving treadmill belt. Electrical stimulation (100µA, 10-sec trains, 0.5-msec cathodal pulses, 50-Hz pulse frequency) was applied every 200-µm through 109 movable electrodes. The patterns of stepping elicited ranged from well-coordinated stepping of all four limbs to spastic stepping of only one limb. In the hypothalamus, stepping-positive sites were found in and dorsal to the medial forebrain bundle (FMP), the paraventricular, dorsomedial and posterior nuclei, and the supramammillary area. Dorsally, effective regions extended to the medial zona incerta and the fields of Forel. In the thalamus only the parafasicular nucleus and the anterior parts of the rhomboid and reuniens nuclei were positive. Positive sites were particularly dense in the ventral tegmental area but were infrequent in basal regions caudal to the interpeduncular nucleus. In the dorsal midbrain positive sites were most common at caudal levels dorsal and dorsolateral to the central gray. At sites in the area of the medial raphe, stepping was elicited only at the offset of the train. The distribution of positive sites resembled that found in unanesthetized rats and indicates that locomotor initiation pathways are separated into dorsal and ventral systems at the level of the midbrain.

BRAINSTEM AXONS MEDIATING CIRCLING: BEHAVIORAL MEASURE-107.5 MENT OF CONDUCTION VELOCITY DISTRIBUTIONS. J.S. Yeomans and L. Linney\*. Dept. of Psychology, Univ. of Toronto, Ontario, M5S 1A1. Electrical stimulation delivered near the crossed

<u>Toronto, Ontario, M55 1A1.</u> Electrical stimulation delivered near the crossed tectospinal tract elicits rapid ipsiversive circling at low currents. In this study the trajectory and conduction velocities of systems mediating this behavior were measured using the collision method of Shizgal et al. (J. Comp. Physiol. Psychol., 94, 227, 1980). C pulses were delivered through a midbrain electrode and T pulses through a pontine electrode, or vice versa. If axons passing near both sites mediate the circling, collision will occur between antidormic and orthodromic action potentials from the two elec-trodes at short C-T intervals, but not at long C-T intervals. Collision was measured by comparing T pulse effectiveness, i.e. the decline in frequency required to produce a constant amount of circling (Yeomans, Physiol. Behav., 15, 593, 1975; Miliaressis, Physiol. Behav., 26, 891, 1961.), at short and long C-T intervals. Clear evidence of collision was found for 3 electrode pairs, suggesting that a longitudinal bundle of axons mediates the circling behavior. In particular, 1) Double electrode (i.e. collision) measures of T pulse effectiveness. This suggests a range of conduction velocities in the axons. 2) No local potential summation was observed in double electrode curves at C-T intervals of 0.2 msec. 3) Collision and spatial summation increased systematical-ly as current increased. Conduction velocity was measured in two ways, one yielding a low estimate and the other yielding a high

ly as current increased. Conduction velocity was measured in two ways, one yielding a low estimate and the other yielding a high estimate. These estimates were 10-30 m/sec for the initial rise, 2.6-9 m/sec for the 50% level, and 1.1-3.7 m/sec for the final rise. For comparison, physio-logical estimates of the conduction velocity of tectal units driven contralaterally from the same brainstem sites that produced circling were determined. These units had conduction velocities that ranged from 1-20 m/sec. These crossed tectospinal axons, then are likely candidates for the substrate that produces circling. CONTROL OF LOCOMOTION USING LOCALIZED INJECTIONS OF GABA

AGONISTS AND ANTAGONISTS INTO THE MESENCEPHALIC LOCOMOTOR REGION (MLR). E. Garcia-Rill, R. D. Skinner and J. A. Fitzgerald\*. Dept. of Anatomy, Univ. of Arkansas, Little Rock, AR 72205. Following a precollicular-postmamillary brainstem transection

A ROLE OF NIGRAL DOPAMINE RELEASE IN DRUG-INDUCED CIRCLING 107.6 EFIAVIOR AND LOOMOTOR ACTIVITY. E.A. Jackson\* and P.H. Kelly (SPON: B.C. Abbott). Dept. of Physiology and Biophysics, USC School of Medicine, Los Angeles, CA 90033. Evidence has accumulated recently to indicate that dopamine

is released from dendrites in the substantia nigra (Cheramy et al., <u>Nature</u>, <u>289</u>:537-542, 1981). In the present studies behavioral effects of intra-nigral dopamine receptor stimulation and blockade were investigated. In rats pretreated with systemic pargyline, contralateral circling was elicited by substantia nigra pars reticulata (SNR). The latter of effect was of short duration, and could be reinstated 2 hours after intracranial infusion by systemic d-amphetamine. Unilateral intra-nigral infusion of the putative D-1 receptor agonist SKF38393 also caused short lasting contralateral circling, which could be reinstated by systemic d-amphetamine. In rats with uni-lateral 6-hydroxydopamine lesions of the nigrostriatal pathway, amphetamine-induced circling was markedly reduced by prior infusion of haloperidol into the SNR bilaterally. Infusion of a GABA-transminase inhibitor, y-acetylenic GABA (GAG) into one SNR caused pronounced contralateral turning when followed immediately by systemic d-amphetamine. Prior infusion of haloperidol into the SNR bilaterally reduced the circling caused by amphetamine after unilateral intranigral GAG. In pargyline-pretreated rats bilateral intra-nigral dopamine elicited pronounced stimulation of locomotor activity, whereas the locomotor activity elicited by systemic amphetamine was markedly reduced by bilateral intranigral haloperidol.

The results support a role for dopamine released from dendrites in the substantia nigra in both circling behavior and locomotor activity, and suggest the substantia nigra is a site involved in the behavioral effects of psychostimulants and neuroleptics.

107.8 ROLE OF SUBSTANTIA NIGRA IN LOCOMOTION. <u>E. Eidelberg</u>, <u>J. Yu and M.H. Droge</u>. U. of Texas Sch. of Med. and V.A. Hospital, San Antonio, TX, 78284

Thalamic cats walk on a treadmill when the subthalamic region (SLR) or the area of N. cuneiformis (MLR) are stimulated electrically. We tested the possibility that the cell bodies electrically. We tested the possibility that the cell bodies in the SLR and MLR are crucial to this by localized injection of glutamic and homocysteic acids. There was no locomotor response there, but electrical and chemical stimulation of the S. Nigra, pars reticulata, did evoke walking. Bilateral coagulation of this region, however, did not abolish walking in trained cats. Total cerebellar ablation did not prevent later eligitition of controlled leagention. These data indicate that elicitation of controlled locomotion. These data indicate that the crucial elements in the SLR and MLR are probably axons going to and/or from the substantia nigra. This seems to be important in view of the gait disorder in Parkinson's disease.

Supported in part by grant NS-14546, and by the Moody Foundation.

Supported by grants from NIH (NS16143) and NSF (ISP8011447).

Following a precollicular-postmamillary brainstem transection in the cat, controlled locomotion on a treadmill can be induced by <u>electrical</u> stimulation of the MLR. This study was undertaken to determine whether or not locomotion could be induced in the same preparation by localized, <u>chemical</u> activation of the MLR. An ensemble of stimulating wires about a 35 g cannula was lowered into the posterior midbrain until the tip was located in the MLR. Location was verified by the induction of controlled locomotion on a treadmill using current pulses of 50 uA or less locomotion on a treadmill using current pulses of 50  $\mu A$  or less. Several neurotransmitters, their agonists and antagonists (concentrations 0.001-1M), were infused (rates  $1-5 \mu J/min$ ) in standard volumes of  $1.5 \mu I$ . To date, only infusions of the GABA antagonist, picrotoxin (PIC), have resulted in locomotion on a treadmill in the precollicular-postmamillary cat. Amounts of 3-6  $\mu g$  of PIC (0.005M) resulted in a 10-30% decrease in the threshold for electrically-induced locomotion. Amounts of up induced greater than 50% decreases in threshold, leading Amounts of 6-9

within minutes to spontaneous and constant (over 1 hr) locomotion without need of electrical stimulation. PIC-induced locomotion could be blocked by infusion of the GABA agonist, muscimol (MUS) (0.005M) within seconds. Additional injections of PIC reinduced locomotion which could again be blocked by MUS. Injection spread was verified using similar volumes of Fast Green, Evans Blue or Bisbenzimide dyes. Only injections which included the cuneiform and pedunculopontine nuclei resulted in locomotion. Injections of more than 10  $\mu g$  of PIC which included the reticular formation were found to induce convulsions. Injection sites other than the MLR produced no locomotor movements. Sites in the inferior and superior colliculi had no effect.

Our findings demonstrate for the first time that localized chemical infusions into the MLR can induce and inhibit locomotion (Qualitatively, chemical-induced locomotion appears more "natural" than electrically induced locomotion). The fir The first indication of the presence of gabaergic receptors in the MLR is provided by the observed blockage by MUS of PIC-induced locomotion. The source of the gabaergic input is unknown, but the substantia nigra has been reported by others to provide ascending gabaergic projections. We have reported the presence of a descending substantia nigra projection to the MLR, the only afferent to the MLR located posterior to the precollicular-postmamillary transection.

ACTIVITY OF RETICULOSPINAL NEURONES DURING LOCOMOTION IN UNRE-STRAINED CHRONIC CATS. <u>T. Drew\*, G. Blanchette\* and S. Rossignol</u>. Centre de recherche en sciences neurologiques, Université de 107.9 Montréal, Montréal (Québec) CANADA.

Experiments in high decerebrate cats have suggested that dur-Experiments in high decerebrate cats have suggested that dur-ing locomotion reticulospinal (RS) cells in the medullary reticu-lar formation (MRF) are related principally to the electromyo-graphic (EMG) activity of flexor muscles (Orlovsky, G.N., 1970, Biophysics. 15: 761). Experiments in chronically implanted, un-restrained animals suggest, however, a more complex interaction. Under aseptic conditions a plate designed to hold a microdrive was storectartically most from the allow access to the MPF at

was stereotactically positioned to allow access to the MRF at coordinates in the range of AP-3 to AP-12 and L 0.5 to L 4.0. Teflon-insulated stainless steel wires were sewn into flexor and extensor muscles of all four limbs as well as into back and neck extensor muscles of all four limbs as well as into back and neck muscles; Tri-ML insulated  $50\mu$ m wires were implanted at L<sub>2</sub> into the spinal cord for antidromic identification of RS cells. Recordings were made using conventional glass-coated tungsten micro-electrodes ( $1-5M\Omega$  at IKH2). Temporal relations, on a step by step basis, were studied between the unit discharge and each recorded EMG.

76 reticulospinal neurons from 3 cats have been recorded 76 reticulospinal neurons from 3 cats have been recorded during locomotion. 27 of these neurones (36%) showed a clear frequency modulation during locomotion, displaying either one or two peaks of activity in each step cycle (20 and 7 neurones respectively). All 7 double burst neurones seemed best related to flexor muscle activity whereas the 20 neurones having only one burst in each step cycle were strictly related to the phase of onset, and/or the duration, of extensor (12 neurones) or flexor (8 neurones) muscle activity. Correlations were found with fore-limb and hindlimb muscle activity both insilateral and contralimb and hindlimb muscle activity both ipsilateral and contra-lateral to the recording site.

A further 26 neurones (34%) showed an intermittent but clear frequency modulation at the locomotor rhythm and could generally not be strictly correlated with any one of the recorded EMGs. It is noteworthy that the majority of these cells were excited by passive manipulation of both the neck and/or all four limbs so that they might be related to aspects of interlimb or head-limb coordination. The remaining 23 cells (30%), although projecting to the lumbar cord, either discharged in a completely unrelated manner to the rhythmical patterns of locomotion or were silent.

It is concluded that during walking RS neurones are related to the activity of flexor or extensor muscles, both ipsilateral and contralateral to the recording site. These results are consistent with those obtained by microstimulation of the MRF (Drew, Dubuc & Rossignol, Soc. Neurosci. Abstr., 8, p. 163, 1982). (Supported by a Group fund as well as a fellowship to T. Drew

granted by the Canadian MRC).

COORDINATION OF LOCOMOTION AND THE PAW SHAKE RESPONSE IN THE HINDLIMBS OF SPINALIZED CATS. <u>M.C.Carter and J.L.Smith</u>. Der Kinesiology, UCLA, Los Angeles, CA <u>30024</u> 107.11 Dept.

Kinesiology, UCLA, Los Angeles, CA 90024 In the normal cat, generation of the hindlimb paw shake response (PSR) during treadmill locomotion is confined to the swing phase of the step cycle (Neurosci. Abst. #47.6, 1982). To accommodate both actions, the PSR is usually limited to 1 to 4 cycles and the time devoted to the swing phase of the shaking limb is increased, as is the stance phase of the contralateral hindlimb. Although both imadeil locomotion and the DSR are be presented independently in

devoted to the swing phase of the shaking limb is increased, as is the stance phase of the contralateral hindlimb. Although both treadmill locomotion and the PSR can be generated independently in the hindlimbs of a spinalized cat, it is not known whether the lumbosacral cord alone can coordinate the simultaneous execution of the two behaviors. The purpose of this study was to examine the coordination of locomotion and the PSR in the spinalized cat. Young adult cats were spinalized at T12 and surgically implanted with bipolar fine wire electrodes in the right and left soleus (RSO, LSO), right lateral gastrocnemius (RLG) and tibialis anterior (RTA) muscles. EMG records obtained during unperturbed treadmill locomotion were compared with walking and concurrent shaking at speeds of 0.4 and 0.6 m/s. Paw shaking was induced by wrapping tape around the right paw. Cycle durations (BD) normalized to a percent of CD were obtained from the EMG records. Data analyses were limited to periods when the hindlimbs maintained stable weight support and rhythmical stepping. Average CD decreased from 1007 + 51 to 780 + 75 ms when the treadmill speed increased from 0.4 to 0.6 m/s. Similar to normal cats, when tape was applied to the hindpaw, the PSR occurred intermittantly and was initiated in the swing phase of the step cycle. However, the average number of PSR cycles generated by the spinal cat was greater than that observed for the normal cat, 12 + 2 and 4 + 2, respectively. To accommodate the complete PSR elicited in the right hindlimb, the left hindlimb of the spinalized cat simultan-eously produced multiple steps. At 0.4 m/s, two short steps were usually completed by the left leg with average CD of 677 + 45 and 850 + 83 ms. At 0.6 m/s, three steps were completed with the first two steps shorter than the third, 585 + 81, 559 + 121 and 884 + 108 ms, respectively. We conclude that the lumbosacral cord can coordinate the 884 + 108 ms, respectively. We conclude that the lumbosacral cord can coordinate the

We conclude that the lumbosacral cord can coordinate the simultaneous generation of the PSR during locomotion. Rather than being limited to a single swing phase, the PSR in the spinalized cat continues its full course, 9 to 12 cycles, and the contralateral limb compensates by taking multiple steps. This behavioral strategy was not observed in the normal cat and suggests that supraspinal input constrains the completion of the PSR in the normal cat, whereas generation of the PSR in the spinalized cat is unmodified.

MODULATION OF DENTATE NEURONS DURING THE PERTURBED AND UNPER-107.10

MODULATION OF DENTATE NEURONS DURING THE PERTURBED AND UNPER-TURBED STEP CYCLE IN DECEREBRATE CATS. <u>A. B. Schwartz, T.J.</u> <u>Ebner and J.R. Bloedel</u>. Depts. of Neurosurgery and Physiology, Univ. of Minnesota, Mpls., MN 55455. The purpose of these experiments was to examine the modula-tion of dentate neurons in spontaneously walking cats with and without two types of perturbation applied during specific phases of the step cycle. Employing an electrocoagulator, cats were decerebrated by transecting the brainstem at an angle of 23° to the horizontal from A3.7 dorsally to A7.2 ventrally. These cats walked spontaneously on a treadmill driven by a speed con-trolled motor. Approximate limb displacement was recorded with potentiometers attached to the front legs. The biceps and tri-ceps EMG activity was recorded bipolarly. Cells recorded with glass microelectrodes from the right dentate nucleus were anti-dromically identified using stimuli applied at the decussation of the brachium conjunctivum. Electrode tracks were verified dromically identified using stimuli applied at the decussation of the brachium conjunctivum. Electrode tracks were verified histologically. The discriminated spike activity, the integra-ted rectified EMG activity, and front leg displacement were averaged (100-200 step cycles) using a specific phase of the right front leg displacement to trigger each sweep used to con-struct the histogram. Two types of perturbation were used. All four legs were perturbed simultaneously by a dynamic brake which rapidly stopped the belt, halting the limbs in a given position for about 400 msec. On reacceleration of the belt, the cat resumed normal locomotion. The second type of perturbation placed an obstacle in the path of a single moving limb. A pneu-matic cylinder was triggered to thrust a rod, impeding the leg during a single step cycle only. Separate histograms were conmatic cylinder was triggered to thrust a rod, impeding the leg during a single step cycle only. Separate histograms were con-structed from step cycles with and without perturbations. Some dentate neurons were modulated in relation to the unperturbed step cycle. Use phase of this peak varied among the neurons with this characteristic. In cells that were well modulated in normal locomotion, perturbation of all four legs arrested the modula-tion during the perturbation. In some dentate cells that were poorly modulated, this type of perturbation elicited a response corresponding to the time course of the perturbation. Perturba-tion of a single leg did not produce a pronounced change in the corresponding to the time course of the perturbation. Perturba-tion of a single leg did not produce a pronounced change in the response of well modulated cells. However, in poorly modulated cells a short decrease in rate was evoked. These data show that dentate neurons can be modulated during the step cycle and that discharge of these neurons can be modified by at least two types of perturbation. This work was supported by NIH Grants ROI-NS 09447 and ROI-NS 18338.

107.12 ONSET AND PERTURBATION OF AIRSTEPPING IN THE CHRONIC SPINALIZED CAT. C. A. Giuliani and J. L. Smith. Neuromotor Control Lab., Dept. Kinesiology, UCLA, Los Angeles, CA 90024. Previous studies have identified the temporal characteristics of airstepping (ASTP), a commonly observed behavior in chronic spinalized animals, as similar to those of locomotion (Giuliani et al, <u>Neurosci</u>. Abst., #47.7, 1982). The purpose of the present study was to identify the onset of ASTP following cordotomy and to determine the effect of sensory perturbation on ASTP patterns. Five adult cats were cordotomized at T-12 and bipolar elec-trode wires were chronically implanted in the soleus (S0) and the

Five adult cats were cordotomized at T-12 and bipolar electrode wires were chronically implanted in the soleus (SO) and the tibialis anterior (TA) of both hindlimbs. The animals were tested 2-3 times welly for 3 mos following cordotomy. EMC parameters analyzed included: cycle duration (CD, defined as the interval between sequential SO burst onsets), burst duration, and integrated EMG (I-EMG). The effects of tonic sensory perturbation were studied druing immobilization of the ankle (110°) and knee (115°) in a plaster cast, with tape application to the hind paw, and after limb deafferentation. The earliest onset of ASTP occured at 13 days following cordotomy and required tail pinching to elicit the behavior, while the latest onset occurred at 29 days. Spontaneous ASTP, without additional exteroceptive stimuli, occurred between 21 and 39 days following cordotomy. Prior to the onset of ASTP, all cats extinbited paw shaking responses, myotatic, flexion, and crossed extension reflexes, all of which were present within 4 days of cordotomy. cordotomy

The effects of sensory perturbation were determined by com-paring the EMG parameters of perturbed ASTP to those of spontan-The effects of sensory perturbation were determined by com-paring the EMG parameters of perturbed ASTP to those of spontan-eous ASTP. Immobilization by casting had no effect on average CD (656 ms); however, burst durations of the ipsilateral SO and TA both increased 53%, while increases in I-EMG were 456% and 94% respectively. With tape application, ASTP was slower by 42% and exhibited a larger amplitude of movement in both limbs. Also, SO burst duration increased on average 60% and I-EMG increased 156%. In one cat, the left hindlimb was partially deafferented (L4-S2) to determine the effects of decreased segmental input. Pre-liminary results indicate that the spinal cord was still capable of generating a characteristic ASTP pattern, although tonic input (tail pinching) was required to elicit ASTP. The pattern of intralimb coordination was essentially unchanged while the normal interlimb coordination pattern occurred infrequently. Our results show that although some parameters of ASTP (CD and burst durations) may be modified substantially by sensory augmen-tation, others such as intra- and interlimb coordination remain invariant. Reduction of the segmental input by deafferentation alters interlimb coordination, but not intralimb control. Supported by NIH grant NS 16333.

EMG - FORCE RELATIONSHIPS IN CAT MG AND SOLEUS DURING TREADMILL LOCOMOTION. R.J. Gregor,\* R.G. Lovely,\* R.R. Roy and V.R. Edgerton, Brain Research Institute and Dept. of Kinesiology, 107.13 UCLA, Los Angeles, CA 90024. Neural control of locomotion has typically been described

Neural control of locomotion has typically been described through the phasic electromyogram. While individual muscle forces have been reported (<u>J. Neurophysiol</u>, 41:1203-1216, 1978) little attention has been given the temporal relationship be-tween EMG and subsequent force production of individual muscles in vivo. This study was designed to assess the phasic relation-ship between selected EMG and force parameters in vivo in the cat MG and SOL during unrestrained treadmill locomotion. A total of 180 step cycles in three cats walking/running at three different speeds (0.8 m/s, 1.6 m/s, and 2.2 m/s) were chosen for analysis. Each cat was surgically implanted with a force transducer (<u>J. Biomechanics</u>, 14:489, 1981) of both MG and SOL tendons and with a pair of electrodes (SO µm) implanted into the belly of each muscle (<u>Brain Res</u>. 117:529-533, 1976). Records were stored on FM tape and subsequently digitized off-line by a digital MINC 23 minicomputer. As treadmill speed increased, mean peak tension in the MG

As treadmill speed increased, mean peak tension in the MG increased (40%) while mean SOL peak tension declined (20%). While impulse duration (Ft) was similar for both MG and SOL, While impulse duration (Ft) was similar for both MG and SOL, at each speed EMG burst duration was always longer for the MG. The difference was 43 ms at 0.8 m/s and 23 ms at 2.2 m/s. Electrical activity in the MG began 12 ms before the SOL at the slow speed but 4 ms after the SOL at 2.2 m/s. The delay between onset of EMG and the onset of force was 10 ms longer (34 vs 44) for the MG than the SOL at 0.8 m/s but similar ( $\infty$ 55 ms) for both muscles at 2.2 m/s. Peak force in the SOL always occurred before the MG with differences of 14 ms at 0.8 m/s and 6 ms at 2.2 m/s. Additionally, the time between peak force and EMG cessation was always greater for the MG than the SOL. Although this time decreased as speed increased, a consistent difference of 15-20 ms remained.

These data suggest that in spite of the marked differences in contraction time, relaxation time and maximal velocity of shortening of the SOL and MG when tested in <u>situ</u>, the actual time to peak tension, time to complete relaxation and the duration of the force pulse are similar in the SOL and MG muscles when the cat walks at a slow speed or trots at a fast speed. (Supported by NIH grant NS 16333-03) 107.14

ARCHITECTURAL DESIGN OF ADULT CAT HIP MUSCULATURE. R.R. Roy, M.D. DiGiuro\* and V.R. Edgerton. Brain Research Institute and Dept. Kinesiology, UCLA, L.A., CA 90024. The hip musculature has been implicated as a "trigger" to initiate and maintain locomotory patterns in the normal and spinal cat (Grillner and Rossignol, <u>Brain Res.</u> 146:269, 1978). Although some of the sensory factors involved in this apparent hip joint control have been studied, details of the architecture of the musculature in which many of the sensory receptors are located have not been described. The design of the muscle appears to be important in determining the responsiveness of the muscle to length changes (Walmsley and Proske, <u>J. Neuro-physiol</u>. 46:250, 1981). Spindle density (#/g muscle) is often considered to be an important variable in this responsiveness. But receptor density can be misleading when comparing muscles

But receptor density can be misleading when comparing muscles differing in their architectural design. In addition, the force and velocity properties of a muscle are known to be dictated in large part by its architectural design (Bodine, et al., J. Neurophysiol. 48:192, 1982; Spector, et al., J. Neurophysiol. 44:951, 1980). Thus, the purpose of this study was to detail the archi-tectural features of the major extensor flexor, adductor and abductor muscles at the hip. Muscle wet weights (MW), muscle lengths (ML), fiber lengths (FL), approximate angles of pinnation ( $\theta$ ) and average sarcomere lengths (SL) were used to calculate the physiological cross-sectional area (CSA) of each muscle as described by Sacks and Rov (J. Morphol. 173:185 each muscle as described by Sacks and Roy (J. Morphol. 173:185, 1982)

Some data were provided by the latter study. MW's ranged from .2 (genellus inferior) to 29.6 (adductor femoris) g. Average FL normalized to a SL of 2.2  $\mu$ m ranged from 7.0 (obturator externus) to 105.5 (sartorius) mm. Generally, the was a tapering of FL from one surface of the muscle to the there was a tapering of FL from one surface of the Muscle to the other. Average FL to ML ratios were consistent for a given muscle. Theta was less than 6° in all muscles except for the quadratus femoris ( $\infty 10^\circ$ ). The CSA of the extensors was  $\infty 4$  times that of the flexors and the CSA of the abductors was  $\infty 3$  times that of the adductors. In general, the uniarticular extensors and flexors seem to be more appropriately designed for force production while the biarticular extensors and flexors appear to optimize velocity and displacement. These data suggest to optimize velocity and displacement. These data suggest that the appropriate control mechanisms of the hip could be accounted for by the marked variation in the basic architectural design of the involved musculature. (Supported by NIH Grant 16333)

107.15 DISCHARGE PATTERNS OF DYNAMIC AND STATIC GAMMA MOTONEURONES DURING LOCOMOTION IN THE PREMAMMILLARY CAT AND THEIR IMPLICATIONS FOR CONTROL OF LOCOMOTION. R.S. Stein, J. Taylor\* and P.R. Murphy. Dept. of Physiology, University of Alberta, Edmonton, Canada T6G 2H7

Although suggestions have been made for thirty years on the role of gamma motoneurones, few direct recordings are available in behaving animals to test these suggestions, and the function of gamma motoneurones remains unclear. To clarify their role, we recorded triceps surae gamma motoneurones from cut nerve filaments in a premammillary cat during locomotion. Even if one leg is largely denervated except for the muscles of interest and fixed in

Targety denervated except for the muscles of interest and fixed in place for recording, the other three legs walk spontaneously on a treadmill, and the fixed leg generates appropriate motor outputs. In this preparation, two distinct patterns of gamma activity were observed. One type of fibre ( $\gamma dm$ , 11 units) had a high resting discharge (41 i.p.s.), which changed little during walking (mean = 34 i.p.s.), but was dynamically modulated (mod. =  $\pm 82\%$ ) with each step. (mean = 34 1.p.s.), but was gynamically modulated (mod. -  $d_{x,y}$ ) with each step. Another type ( $\gamma_{SM}$ , 16 units) had a low resting discharge (11 i.p.s.), which increased at the onset of walking (static modulation) to a high mean level (58 i.p.s.) which varied less ( $\pm 24\%$ ) during each step. During each step, peak  $\gamma_{dM}$  activity generally occurred after peak EMC (10 out of 11 units) and some-times even after the time of peak tension (3 out of 11 units). In contrast, peak Ysm activity generally preceded peak EMG (13 out of 15 units).

In other experiments with premammillary cats, we found that the sensitivity of soleus muscle spindle primary afferent endings to small sinusoidal stretches (<1 mm, 4-10 Hz) is reduced near the time of peak Ysm activity and increased near the time of peak Ydm activity. In contrast, the sensitivity of secondary muscle spindle afferents to stretch is decreased throughout the stretch splite alterents to stretch is decreased throughout the stretch cycle. Finally, in anaesthetized cats, various stimulus patterns were applied to dynamic and static gamma motoneurones during stretch of muscle spindle afferents. For our parameters of stretch, we generally confirmed that dynamic gamma motoneurones increase and static gamma motoneurones decrease the sensitivity of primary afferents.

We conclude that  $\gamma_{\rm dm}$  and  $\gamma_{\rm sm}$  units correspond to dynamic and static gamma motoneurones respectively. The observed patterns of activity permit the velocity sensitivity of triceps surae spindles to be maximized when the active muscles are transiently stretched by the weight of the body during stance and minimized when the muscles are passively stretched by antagonists during the swing phase of locomotion.

Supported by Canadian Medical Research Council (RBS) and Alberta Heritage Foundation for Medical Research (JT and PRM). 107.16 THE KINEMATICS AND TASK GROUP ORGANIZATION OF BIFUNCTIONAL MUSCLES DURING LOCOMOTION. G.E. Loeb, W.B. Marks, A.J. Rindos, M. O'Malley\*, J.P. Chapelier\*, and W.S. Levine\*, Lab. of Neural Control, NINCDS, Betnesda, MD 20205, and Dept. of Electrical Engineering, U. of Maryland, College Park, MD 2077. The motor units of the cat anterior sartorius muscle (SA) are divided to the record with the the catting the particular to the strengthere.

The motor units of the cat anterior sartorius muscle (SA) are divided into task groups which each contribute to either stance or swing phase movements but not both (Hoffer et al., J. Physiol. 3U8:2DP, 1980). This division may be ascribed to one or more of the following characteristics peculiar to that muscle: 1) mixed polyarticular action - hip flexor and knee extensor 2) recruitment in both half cycles - stance and swing phases 3) kinematic dichotomy - active lengthening vs. shortening The biarticular hamstrings muscles (semitendinosus - ST and posterior biceps - BP) provide a test case of the importance of these factors. They are complete anatomical antagonists of SA, causing hip extension and knee flexion. and they also generate two

these factors. They are complete anatomical antagonists of SA, causing hip extension and knee flexion, and they also generate two bursts of EMG per step cycle (early flexion phase and early stance phase). However, there is evidence from thalamic locomotor prep-arations that single motoneurons projecting to ST are depolarized and can be activated during both EMG bursts (Perret and Cabelguen, Brain Res. 187:333-352, 1980), in contrast to SA motoneurons. The figure indicates the timing of EMG bursts (thick regions on meable batt converse more det by boreiasly).

muscle length curves) recorded by chronically implanted bipolar "patch" electrodes. The lengths were calculated from digitized video stick figures (60 fields/sec) and anatomical measurements of origin, insertion, lever arms, and pulleys as appropriate. The nearly-monarticular hip extensors semimembranosus (SM) and anterwhile the monarticular vastus knee extensors (V) undergo slight active lengthening. The biarticular ST and BP muscles undergo considerable length change during the step cycle, but the two bursts of EMG activity both occur as the muscles undergo virally identical velocity excursions, with a small lengthening followed

by active shortening. This is consistent with BA kinematics being the de-termining factor in the ST division of a muscle intoB task groups, presumably to cope with the different motor control prob-lems presented by active SA shortening vs. lengthen-ing, regarding both the fusimotor control of spindles and the use of stretch reflexes.

107.17 RECRUITMENT OF MOTONEURONS IN BIFUNCTIONAL MUSCLES BY CUTANEOUS NERVE (FRA) STIMULI DURING WALKING IN INTACT CATS. W.B. Marks, G.E. Loeb, and J.A. Hoffer, Lab. of Neural Control, NINCDS, NIH, Betnesda, MD 20205

We have previously reported on the activity patterns of single, identified hindlimb motoneurons during normal walking in the cat (Neurosci. Abst. 272.5-7, 1982). In the anterior sartorius muscle, there appear to be two independent groups of motor units which are similar in anatomical location and action but are independently recruited during the two bursts of activity of this muscle in each step cycle. We have tentatively identified these "task groups" as a flexor group, recruited during swing phase to perform a rapidly shortening contraction related to hip flexion, and an extensor group, recruited during stance, which undergoes active lengthening to assist in antigravity knee extension. Within each group, there is an orderly and strict recruitment based on conduction velocity, but the groups are never coactivated during normal walking. Chronically implanted nerve cuffs were used to stimulate sa-

Chronically implanted nerve cuffs were used to stimulate saphenous nerve with single shocks 4-10X threshold for the largest fibers. The stimuli were delivered at random phases of normal treadmill walking. The responses included an inhibition of pure extensor muscles (15-25 msec post-stimulus) and a double-peaked excitation of pure flexor muscles (10 msec and 25 msec latencies; Duysens and Loeb, J. Neurophysiol. 44:1024-1037, 1980). In this study, all single motoneurons projecting to the vasti muscles (pure knee extensors) demonstrated the same inhibition as their parent muscle EMGs, with occasional late excitation probably related to rebound and/or stretch reflex activation by yielding during the innibitory reflex. Six motoneurons projecting to the bifunctional sartorius and rectus femoris were studied; four were normally recruited with the extensor task group (during stance) and two with the flexor task group (during stance) the cutaneous nerve stimuli, all six participated in a typical double-peaked flexor reflex. Units were activated at both latencies, although rarely during a single trial. The flexor reflex recruitment task group thus appears to include motoneurons from both the flexor and extensor locomotor task groups of bifunctional muscles (probably all motoneurons in these pools). providing an efficient way to achieve maximal

The flexor reflex recruitment task group thus appears to include motoneurons from both the flexor and extensor locomotor task groups of bifunctional muscles (probably all motoneurons in tnese pools), providing an efficient way to achieve maximal mechanical synergy for ballistic movements which do not require orderly proprioceptive feedback. A similar analysis of cutaneous reflex EMG's from hamstrings and ankle muscles supports the notion that the FRA pathway generates two basic task groups: a double-peaked excitatory response in all muscles with significant flexion action, and an inhibition in all pure extensor muscles. Further refinements of these patherns are consistent with the effects of pre- and post-synaptic gating by the step cycle generator and proprioceptive sequelae of short latency responses.

107.19 MECHANICAL WORK IN CAT HINDLIMB MUSCLES DURING LOCOMOTION: IMPLICATIONS FOR MOTOR CONTROL. R. C. Lovely\*, R. J. Gregor\*, <u>R. R. Roy, and V. R. Edgerton</u> (SPON: J. J. Vidal). Department of Kinesiology and Brain Research Institute, UCLA, CA 90024. In vivo measurements of length, tension and electrical activity, although important in studying muscular function during locomotion, are limited indicators of a muscle's role in movement generation. This study employed in vivo length-tension and mechanical work measures to further assess the function of cat soleus (SOL) and medial gastrocnemius (MG) muscles in generating locomotion at different speeds. Three dult catt ware triand to locomote on a treadmill

Three adult cats were trained to locomote on a treadmill. Muscle lengths were determined using 3-D filming techniques (Med. Sci. Sports & Exercise 14:144-5, 1982), and forces were recorded using surgically implanted tendon buckle transducers (J. Biomech. 14:489, 1982). Length-tension curves were derived from digitized data, and mechanical work during the stance phase of a step cycle was calculated as the integral of tension with respect to length. Slow walking, fast walking and trotting corresponded to speeds of 0.8, 1.4, and 2.2 m/s. No significant differences were observed between the two colliderenceds in contributions of the stance base for the speeds of 0.8, 1.4, and 2.2 m/s.

No significant differences were observed between the two walking speeds in negative, positive or net mechanical work for either muscle. Each muscle did however, exhibit significant differences in work measurements between walking and trotting (Re.05). Values for negative, positive, and net mechanical work (averagetSE) in the SOL of an exemplar cat during fast walking were -13.93±1.45, 17.22±1.38, and 3.29±1.41 mJ, while during trotting these values were -7.38±1.32, 24.87±3.06, 17.50±4.04 mJ, respectively. Negative, positive and net work measurements in the MG during fast walking were -14.08±1.2, 5.78±0.76, and -8.30±1.34 mJ, while those during trotting were -9.38±1.62, 32.39±5.09, and 23.01±4.52 mJ, respectively. It is concluded that during walking, the SOL is active and producing tension to help control yielding, and to generate ankle extension for propulsion. In contrast, the MG at walking speeds, is captive and producing tension to fact the captivel of

It is concluded that during walking, the SOL is active and producing tension to help control yielding, and to generate ankle extension for propulsion. In contrast, the MG at walking speeds, is active and producing tension to assist in the control of yielding, but provides little energy for propulsion. During trotting, both muscles retain their roles in the control of yielding, but also become major sources of energy for ankle extension and propulsion. Supported by NIH grant NS 16333-03. 107.18 Locomotor Activity Patterns of Single Motor Units in Compartments of Cat Lateral Gastrocnemius Muscle. <u>A. W. English Department of Anatomy, Emory University, Atlanta,</u> GA 30322

GA 30322 Cat lateral gastrocnemius (LG) muscle is composed of four compartments, each of which contains a discrete population of motor units. To examine the extent to which they are used independently during locomotion, the behavior of motor units in the different compartments was determined using chronic unit recording techniques (eg. Hoffer <u>et</u> <u>al</u>, Science <u>214</u>:343-345, 1981). Single LG and soleus (SOL) motor units were recorded from "floating" "hatpin" microelectrodes which had been placed in the lateral gastrocnemius-soleus nerve under general anesthesia. Each motor unit was identified using the spike-triggered averaging technique (STA), in conjunction with chronically-implanted EMG electrodes and tripolar nerve cuffs. A unit was identified as a motor unit and its axonal conduction velocity determined by averaging onto a cuff placed on the sciatic nerve just distal to the branching of the hamstring nerve. Motor units were further characterized by averaging onto EMG recordings from each of the different LG compartments and SOL. From such records, the compartment into which the motor unit projected could be determined. Timing patterns of single motor units were then analyzed as the cats stepped on a motor-driven treadmill belt at a number of different speeds ranging from 0.3 to 1.0 m/sec. All single units examined displayed one of two temporal activation patterns. They were active either early or late in the EMG burst of their compartment, but not throughout. A few relatively fast-conducting LG units in different compartments displayed clear recruitment thresholds and firing patterns: they displayed no activity during quiet standing; they began activity only above certain treadmill speeds; and they displayed a fairly consistent spike train pattern. For most units, recruitment thresholds were less clear and firing patterns changed appreciably at different stepping speeds. A few were active during quiet standing but most were not. Most fired at all stepping speeds examined, and increased their firing rate w

EVIDENCE FOR THE PRESENCE OF A HIGH FREQUENCY OSCILLATOR 108.1 IN THE CPG FOR RHYTHMIC JAW MOVEMENTS IN THE GUINEA PIG. L.J. Goldberg and S.H. Chandler. Depts. of Oral Biology, Kinesiology, Anatomy and the Brain Research Institute, UCLA,

L.J. Goldberg and S.H. Chandler. Depts. of oral biology, Kinesiology, Anatomy and the Brain Research Institute, UCLA, L.A., CA 90024. We have previously demonstrated the occurrence of spontaneous rhythmical jaw movements (SRMs) in the ketamine anesthetized guinea pig. The frequency of the SRJMs are  $\approx 3-4$  Hz. The burst phase of each cycle ( $\approx 90$  ms) is composed of simultaneously occurring depolarizations in jaw opener motoneurons and hyperpolarizations in jaw closer motoneurons. The interburst phase of the cycle is  $\approx 200$  ms in duration. In the present experiments intracellular recordings were obtained from either digastric (jaw opener) or masseter (jaw closer) motoneurons along with EMG activity of the digastric muscle during SRJMs in the ketamine HCl (100 mg/kg i.v.) anesthetized guinea pig. In many cases the digastric EMG

anesthetized guinea pig. In many cases the digastric EMG response in the burst phase of the cycle was seen to be composed response in the burst phase of the cycle was seen to be composed of several distinct segments (sub-units) of EMG activity. The present experiments were designed to determine the frequency of these sub-unit bursts and their relationship to membrane potential fluctuations in jaw opener and closer motoneurons. Cross correlation analyses were performed between the rectified digastric EMG activity and opener and closer motoneuron membrane potential activity during SRJMs. Results of this analysis showed that the digastric EMG bursts were composed of sub-units ( $\simeq 25$  ms in duration) which occurred at a frequency of  $\simeq 30$  Hz. Synchronized with these EMG sub-units in the case of opener motoneurons and hyperpolarizing sub-units in the case of closer motoneurons. closer motoneurons.

closer motoneurons. These results demonstrate that within the digastric burst phase of the  $\simeq 3-4$  Hz SRJM cycle a separate high frequency oscillation ( $\simeq 30$  Hz) can be observed at the level of the membrane potentials of both opener and closer motoneurons. This is similar to what we have previously observed when RJMs are evoked by repetitive (20-60 Hz) stimulation of the masticatory area of the cortex in which the depolarizing and hyperpolarizing sub-units are time locked to each cortical stimulus. This suggests that the mechanism for SRJM generation is similar to that for cortically evoked RJMs. Furthermore, the sub-unit activity in both cases demonstrates that there is a centrally generated tightly coupled depolarization in opener motoneurons and reciprocal hyperpolarization in closer motoneurons. and reciprocal hyperpolarization in closer motoneurons. This research was supported by NIH grant DE4166.

THE EFFECT OF THE SEROTONIN AGONIST (QUIPAZINE) ON CORTICALLY 108.2 INDUCED RHYTHMIC JAW MOVEMENTS IN THE GUINEA PIG. S.H. Chandler, L.J. Goldberg, and B. Alba\*. Depts. of Kinesiology, Oral Biology, Anatomy and Brain Research Institute, UCLA, L.A., CA, 90024

Little information is available on neurotransmitters which

Little information is available on neurotransmitters which may be involved in the control of the central pattern generator (CPG) for mastication, although significant advances have been made in this area with respect to the CPG for locomotion. In a previous study we showed that the CPG responsible for rhythmic jaw movements (RJMs) evoked by cortical stimulation is not critically dependent on glycine. In the present study we investigated the role of serotonin on cortically induced RJMs. 5 albino guinea pigs (400-600g) were anesthetized with ketamine HC1 (100mg/kg). Prior to the administration of guipazine (3mg/kg i.v.), RJMs were produced by repetitive stimulation of cortex at 40Hz and an intensity sufficient to consistently evoke RJMs. Stimulating electrodes were also implanted in the tongue. Cycle time and EMG burst durations of the RJM's were measured. In addition, control amplitudes of the digastric EMG reflex response to single shock tongue stimulation were obtained.

were obtained. 8 to 12 minutes after the injection of quipazine the thres-hold intensity for evoking RJMs was markedly elevated. In some instances RJMs could not be evoked at any stimulus intensity. Accompanying the increase in threshold was a significant alteration in the RJM pattern. The pattern became arrhythmic with an increase in the variability of cycle times and burst durations. The occurrence of spontaneous RJMs was completely blocked by quipazine but the digastric EMG reflex response to tongue stimulation was not remarkably affected by the drug. Pretreatment with the serotonin antagonist methysergide (5mg/kg i.v.) blocked the above mentioned effects of quipazine. The finding that RJM cycle times and hurst durations became

i.v.) blocked the above mentioned effects of quipazine. The finding that RJM cycle times and burst durations became irregular while the short latency cortico-brainstem-trigeminal pathway remained intact suggests that serotonin has a direct effect on the CPG network responsible for RJM production. The inability of quipazine to modify the jaw opening reflex as evoked by tongue stimulation further indicates that the quipazine effect on RJMs is not the result of significant depreciae of directing. quipazine effect on RJMs is not the result of significant depression of digastric motoneurons. These results support the model we have previously presented indicating that the CPG for RJMs acts by modulating a cortico-brainstem-trigeminal short latency pathway and not by directly affecting trigeminal motoneurons. It further implicates the role of serotonin in the operation of the CPG for RJMs. This research was supported by NIH grant DE4166 and Academic Senate Euds at NCIA

Senate Funds at UCLA.

108.3 EFFECT OF SYNCHRONOUS ACTIVATION OF MEDULLARY INSPIRATORY PREMOTOR NEURONS ON PHRENIC NERVE DISCHARGE IN THE CAT. <u>D.F. SPECK, D.R. McCRIMMON\* and J.L. FELDMAN</u>. Departments of Physiology and Anesthesia, Northwestern University, Chicago, IL. 60611.

These experiments examined the effects on respiratory neural utflow elicited by synchronous activation of bulbospinal respiratory neurons. Experiments were conducted in chloralose-urethane anesthetized, paralyzed, vagotomized and artificially ventilated cats. Phrenic nerve activities were recorded bi-Ventilated cats. Frienc herve activities were recorded of-laterally. Descending respiratory axons were activated in the ventrolateral spinal cord at the C2 level using either monopolar or bipolar stimulation (25-100 uA, 100 us, 1-300 Hz). Stimula-tion at intensities of 100uA antidromically activated approxi-mately half of the inspiratory premotor neurons tested in the ventrolateral nucleus tractus solitarius (vINTS) or the nucleus ratroaphiqualis (NRA). Activation of descending inspiratory retroambigualis (NRA). Activation of descending inspiratory pathways was determined by recording both orthodromic phrenic excitation and antidromic invasion of single, inspiratory modulated units which was confirmed by the criteria of high modulated units which was confirmed by the criteria of high frequency following and collision tests. Stimulation pulses delivered to the spinal cord elicited a 2-6 msec orthodromic excitation of the ipsilateral phrenic nerve during inspiration. The onset latency of excitation was 2-4 msec and decreased as inspiration progressed. Following the initial excitation there was a 4-30 msec period of inhibition of phrenic nerve discharge. Continuous trains of stimuli or phrenic gated trains delivered during every fourth inspiratory or expiratory cycle had little effect on the duration of inspiration or expiration. Similarly, brief (400 msec) trains of <u>bilateral</u> spinal cord stimulation delivered at various delays from the onset of inspiration had only a transient effect on the amplitude and pattern of phrenic nerve discharge, with no noticeable effect 60 msec after the termination of stimulation. Since synchronous activation of a portion of a central pattern generator would be expected to phase shift or reset the rhythm, we conclude that the bulbo-spinal respiratory neurons do not themselves generate respiratory rhythmicity and have limited, or no, collateral projections to the neurons that do. (Supported in part by NIH grants NS-17489, HL-23820, HL-00554, and HL-06331 and the Parker B. Francis Foundation).

MORPHOLOGY OF EARLY VS. LATE RECRUITED PHRENIC MOTONEURONS AS REVEALED BY INTRACELLULAR INJECTION OF HRP. W.E. Cameron, D.B. Averill\* and A.J. Berger. Dept. Physiol. & Biophysics, Univ. of Washington, Seattle, WA 98195. Respiration represents a unique motor system for study because the descending central respiratory drive onto respiratory motoneurons persists during anesthesia. Rather than implying the order of a muscle fibers it incorrect the present study of horenic motoneuroneurons wuscle fibers it innervates, the present study of phrenic motoneurons (PMs) classified units based upon their recruitment relative to the onset of inspiratory activity in the phrenic nerve. The purpose of this study was to determine whether the morphology of PMs is related to their recruitment order.

PMs of the C5-C6 spinal cord were studied in anesthetized, paralyzed and ventilated cats. Antidromically identified PMs were

paralyzed and ventilated cats. Antidromically identified PMs were impaled with beveled glass microelectrodes and HRP was iontophoresed into the cell. The cervical cord was fixed, frozen, sectioned and reacted with DAB. Neuronal reconstructions were made. PMs were classified based on their extra- and intracellularly recorded discharge and the amplitude and trajectory of the central respiratory drive potential. Early recruited units initiated their discharge within the first quarter of the inspiratory cycle, while late recruited units fired within the second half of the cycle. A third group of cells was found that had no spontaneous discharge; these were classified as high threshold units. The mean ± SD of several measured variables are sum marized below. variables are sum marized below.

\*significantly different (p<.05) than preceding mean \*\*significantly different (p<.05) than both early & late means

The dendrites of two PMs (one early and one high threshold) were studied in detail. This analysis revealed no significant difference in either the number of end branches per stem dendrite, average or combined dendritic length or total dendritic surface area of these two cells. The two unit types did differ in the regional distribution of their dendrites. The high threshold cell had long dendrites coursing rostrocaudally within the motor column. In contrast, the early cell had many dendrites directed laterally and generated twice as many end branches that terminated outside the column. When compared to the early PM, the high threshold PM had a greater dendritic surface area within the corfinger of the obvoir column. Supported by USPHS within the confines of the phrenic motor column. Supported by USPHS grant NS 14857 and NRSAS HL 06 06474 & 06233.

108.5 EFFERENT CONNECTIONS OF THE VENTRAL RESPIRATORY GROUP IN THE MEDULLA OF CATS: AN AUTORADIOGRAPHIC STUDY. J.L. FELDMAN AND D.F. SPECK. Depts. of Physicology and Anesthesia, Northwestern University, Chicago, 111. 60611.

A large population of medullary respiratory premotor neurons is concentrated in the ventral respiratory group (VRG), which corresponds anatomically with the nucleus ambiguus-retroambigualis from the spino-medullary junction rostral to the retrofacial nucleus. Anterograde transport of tritiated amino acids was used to examine the spinal projections of VRG neurons. Cats were anesthetized with chloralose-urethane and placed in a rigid anesthetized with chloralose-urethane and placed in a right headholder. An occipital craniotomy was performed to expose the brainstem. At a given level relative to the obex, the VRG was mapped with a tungsten microelectrode. Subsequently, a glass micropipette containing trifiated leucine, lysine and proline (equal amounts totalling 90-120 uC/ul) in saline was inserted (totable VPC). The advancements were mounted in a holder which into the VRG. The micropipette was mounted in a holder which permitted simultaneous recording and pressure injection. Pressure injection of amino acids (20-50 nl) was controlled using visual examination of the miniscus level in the micropipette. After a two week survival period, cats were anesthetized and perfused. The entire neuraxis was removed and processed using standard autoradiographic procedures<sup>\*</sup>. Examination of the processed sections revealed a marked bilateral projection to the phrenic motor nucleus at the C4-C6 level and a primarily contralateral projection to upper thoracic motoneurons, presumably intercostal. The ipsilateral phrenic projection seems to include inputs both from axons descending in the ipsilateral spinal cord and from axons that descend contralaterally and recross at a cervical level. There seems to be some somatotopic distribution of projections since injection sites at different rostral-caudal sites labelled different regions of the phrenic nucleus. Propriobulbar projections from the VRG included a bilateral ascending projection to the nucleus parabrachialis medialis, the Kölliker-Fuse nuclei and the preolivary nuclei. There was also a projection to the contralateral nucleus retroambigualisambiguus. (Supported by NIH grants NS-17489, HL-23820, HL-00554 and HL-06331.) \*Tissue was processed by A.D. Loewy.

108.6 PROJECTIONS OF MEDULLARY INSPIRATORY NEURONS TO PHRENIC AND INTERCOSTAL MOTOR NERVES ASSESSED BY CROSS-CORRELATION ANALYSIS <u>D.R. McCRIMMON\*, D.F. SPECK AND J.L. FELDMAN</u>, (Spon:P.M. LALLEY) Departments of Physiology and Anesthesia, Northwestern University, Chicago, IL. 60611. Most of the bulbo-spinal neurons transmitting respiratory

Most of the bulko-spinal neurons transmitting respiratory neural discharges to phrenic and intercostal motoneurons have cell bodies located within the medulla in the ventrolateral nucleus of the tractus solitarius (vINTS) or nucleus retroambigualis (NRA). We attempted to determine whether axons of single neurons within these populations projected to populations of inspiratory motoneurons in one or a few neighboring cervical or thoracic segments. Experiments were conducted on chloralose-urethane anesthetized cats which were bilaterally vagotomized, paralyzed with gallamine triethiodide and artificially ventilated. End-tidal PCO2 was continuously monitored with an infrared CO2 analyzer and maintained constant at a level sufficient to maintain inspiratory neural discharges on phrenic and intercostal motor nerves. Discharges of single neurons within the vINTS or NRA were recorded with extra cellular tungstem microelectrodes. Simultaneous recordings were also made of the contralateral phrenic nerve, a rostral (T2-T4), an intermediate (T6-T7) and a caudal (T10-T12) external intercostal nerve. Nerve activities were digitized and the cross-correlations between medullary neurons and whole nerve recordings were computed for each nerve. Preliminary results indicate that single medullary inspiratory neurons may project differentially to these nerves. We observed neurons with short latency correlation peaks (4 to 8 msc.) with one or more of the intercostal nerves but no noticeable peak with the phrenic nerve. (Supported by NIH grants NS-17489, HL-23820, HL-00554, and HL-006331. DRM is recipient of a Parker B. Francis Fellowship in Pulmonary Research).

108.7 SYNAPTIC INPUT TO INSPIRATORY AND EXPIRATORY INTERCOSTAL MOTONEU-RONS IS HIGHLY COHERENT WITH THE INSPIRATORY ACTIVITY OF THE PHRENIC AND RECURRENT LARYNGEAL NERVES OF THE CAT. C.A. 108.8 MORPHOLOGY OF PHYSIOLOGICALLY DISTINCT INSPIRATORY NEURONS IN THE VENTROLATERAL NUCLEUS OF THE TRACTUS SOLITARIUS (vI-NTS) STUDIED BY UTILIZING INTRACELLULAR INJECTION OF HRP. A.J. Berger, W.E. Cameron and D.B. Averill\*. Department of Physiology & Biophysics, University of Washington, Seattle WA 98195.

In cats, two types of physiologically distinct inspiratory (I) cells have been described in the dorsal medulla associated with the vI-NTS. One type, Ia, exhibits reduced activity when the lungs are inflated simultaneously with central inspiratory activity compared with activity observed when the lungs are not inflated. A second type, IB, exhibits increased activity during lung inflation compared with activity observed when not inflating the lungs. Different functional roles have been postulated for these neurons. The purpose of the present study was to determine if these different cell types are morphologically distinct. HRP was injected into physiologically classified I-neurons of the vI-NTS in anesthetized, paralyzed and artificially ventilated cats. The brain stems were sectioned at 100  $\mu$ m in either the transverse (6 cases) or horizontal (4 cases) plane. These sections were preincubated in CoCl,, reacted with DAB and counterstained with cresyl violet. To date, 10 well-stained I-cells (4 Ia and 6 IB) have been reconstructed. All cells were located within the vI-NTS. We compared the somal, axonal and dendritic morphology of the Ia and IB cells at the light microscopic level. Mean somal diameters for the two cell types were similar in the two planes of section:  $32 \, \mu$ m (2 Ia) versus  $30 \, \mu$ m (4 IB) in transverse plane and  $38 \, \mu$ m (2 Ia) versus  $37 \, \mu$ m (2 IB) in horizontal plane. Axonal diameters for the two cell types were semilar both cell types coursed ventrally from the vI-NTS mean values were not statistically different (p>0.2). Both cell types produced a similar mean number of stem dendritic projection from these inspiratory cells was observed to travel parallel and ventrolateral to the tractus solitarius. The extent of these main dendritic arbors were similar between cell types. Dendrites of both types possessed spines and appendages. Based upon the ack of observable differences between Ia and Ig cells, we conclude that they are not morphologically distinct. Therefore, the different responses of

ULTRASTRUCTURAL EVIDENCE FOR PRIMARY AFFERENT SYNAPSES ON PREGANG-LIONIC SACRAL AUTONOMIC NEURONS. G.M. Mawe, J.C. Bresnahan, and M.S. Beattie. Dept. of Anatomy, Div. of Neurosurg., Neurosci. Res. Lab. The Ohio State University, Columbus, Ohio 43210 Primary afferent input to the cat sacral parasympathetic nuc-leus (SPN) has been examined by injury filling of sacral dorsal root axons with HRPin 24 cats. The relationship of primary affer-ent terminals to preganglionic neurons was studied by applying HRP to ventral root axons in 17 of those cats. Twenty hours after HRP application, the cats were perfused intracardially, and the next day appropriate spinal segments were sectioned processed with day appropriate spinal segments were sectioned, processed with DAB, and flat-embedded for sequential light and electron microscopic analysis.

scopic analysis. At the light microscopic level, the lateral collateral pathway described by Morgan et al. (1981) was clearly visible in our mat-erial. This fascicle of fibers passes ventrally along the lateral edge of the dorsal horn to the region of the SPN then sweeps med-ially across the intermediate zone. Swellings, which may represent synaptic boutons, are seen throughout the course of the axons, but are particularly abundant in the SPN. Injury filling of the vent-ral root axons resulted in Golgi-like labelling of preganglionic neurons and their dendritic arbors. Neurons located ventrally and laterally in the SPN were oriented dorsoventrally; those located more dorsally in the nucleus were primarily arranged mediolater-ally, but some were dorsoventrally oriented within the fascicle of primary afferents as they enter the nucleus. Primary afferent varicosities were often found in close apposition to labelled preganglionic neurons and their dendrites.

labelled preganglionic neurons and their dendrites. Upon ultrastructural examination of this tissue we found that labelled afferent terminals contained clear spherical vesicles; labelled afferent terminals contained clear spherical vesticles; some of these terminals also contained dense core vesicles. Of particular interest was the presence of labelled terminals syn-apsing on labelled preganglionic neurons. Careful documentation of tissue at the light microscopic level prior to thin sectioning indicates that at least some of these label-label contacts rep-resent monosynaptic input of sensory fibers onto preganglionic neurons. However other possibilities for the labelled presynaptic unified to the sensory fibers onto preganglionic neurons. which extend into the SPN. Any of these connections provide inter-esting and as yet unexplored possibilities for autonomic reflex integration. Supported by NIH Grant NS10165 to J.B. and M.B., and a Neuroscience Research Laboratory Fellowship to G.M.

AFFERENT PROJECTIONS TO THE FACIAL NUCLEUS IN THE RAT AS MAPPED BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. Masako 108.10 Isokawa and Barry R. Komisaruk. Institute of Animal Behavior -Rutgers Univ., Newark, NJ. 07102.

In order to study pathways involved in rhythmical vibrissae movements (Komisaruk, JCPP, 70:482, 1970; Semba et al., Br. Res., 195:281, 1980), we injected HRP iontophoretically into the lateral (L), dorsolateral (DL), medial (M), intermediate (I) and ventral (V) subdivisions of the facial nucleus (NVII), using positive DC current delivered in 0.5Hz square wave pulses of 1-2  $\mu A$ for total on-time of 5-15 min. Current was applied between a Ag-AgCl lead inserted into a micropipette containing a 4% HRP solution and a Ag-AgCl ground wire attached to exposed hind limb muscle tissue. After survival time of 44-48 hr the brains were processed for HRP-visualization using tetramethyl benzidine (Mesulam, J. <u>Histochem. Cytochem.</u>, 26:106, 1978). The results are summarized in the following table (I: ipsilateral, C: con-tralateral, -: no projection, blank: inconclusive).

STAPEDIAL COMPONENT OF THE FACIAL NUCLEAR COMPLEX. <u>G. C.</u> <u>Thompson, A.M. Cortez\* and M. Igarashi</u>. Dept. of Otorhinolaryn-gology & Communicative Sciences and Program in Neuroscience, Baylor College of Medicine, Houston, TX 77030. While studying the motor innervation of the stapedial muscle in surders in the studying the motor innervation of the stapedial muscle in 108.11

squirrel monkeys, we identified a previously-undescribed separate origin for those motoneurons. Based upon their cellular morphology and location, these motoneurons are not contained within the classical facial motor nucleus. But, because of their proximity to the facial nucleus and because of because of their proximity to the facial nucleus and because of their projection via a component of the facial nerve, they should be considered as yet another distinct nucleus comprising the facial nuclear complex. Since the origin of the stapedial motoneurons has been studied in cats without describing the discrete pool of motoneurons we saw in squirrel monkeys, we began comparative studies to determine if these motoneurons are unique to primates or characterize mammals in general. There-fore, we replicated the experiment in bush babies, a primitive primate. Horseradish percyldase was injected into the stapedial primate. Horseradish proxidase was injected into the stapedial muscle of four animals. After 24 hours, the animals were perfused with 1.25% gluteraldehyde and 1% paraformaldehyde. Frozen sections were cut at 40 micra and reacted with tetramethylbenzidine. Alternate sections were counterstained with neutral red. When HRP was wholly contained to the stapedial nuscle, a group of motoneurons was heavily labelled just outside the ventromedial edge of the facial motor nucleus (see photo). Since the location of the bush baby stapedial motoneuron pool is slightly different than that of the squirrel monkey, we have initiated efforts to identify this unique motor area in other mammals.

THE ORGANIZATION OF DIVERGENT AXONAL PROJECTIONS FROM THE MID-BRAIN RAPHE NUCLEI IN THE RAT. <u>D. A. Steindler\*, H. Imai\*, S. Afsharpour, and S. T. Kitai</u>, (SPON: R. A. Pax), Dept of Anatomy, Michigan State University, East Lansing, MI 4824 There is a paucity of information on the discrete intranuclear

organization of divergently projecting midbrain raphe neurons. We have examined the order of axonal projections arising from the midbrain raphe nuclei in the rat using a recently-developed double retrograde axonal tracing technique. Patterns of divergence in the axonal projections of the midbrain raphe were found after paired pressure or iontophoretic injections of the axonal tracers horseradish peroxidase (HRP) and wheat germ agglutinin (NGA),N-[acety1-3!1] were placed within known projection targets of the midbrain rabhe nuclei (caudate-putamen, amvgdala, hippocambus, substantia nigra, and locus coeruleus) in 67 Long-Evans hooded rats. The positions of single and double labeled raphe projection neurons in combined histochemical/autoradiographic sections were neurons in complete histochemical/autoralographic sections were reconstructed through the light microscope. Retrograde labeled projection neurons were found within the dorsal rabhe, caudal 86 group, and linearis and centralis superior divisions of the med-ian raphe complex after forebrain or brainstem injections of the tracers. Each structure receiving midbrain raphe projections has its own unique representation within a topographically distinct portion of one or more of the raphe subgroups, and an overall rostrocaudal topography in the intranuclear distribution of raphe projection neurons results in the formation of complex overlap zones where collateralized neurons reside. Raphe neurons projecting to the neostriatum occupy a rather rostral position within the dorsal rabhe as well as linearis nuclei of the median rabhe and neurons projecting to the substantia nigra also reside within rostral nortions of the dorsal raphe. Neurons projecting to the hippocampus and/or locus coeruleus are situated more caudally in the dorsal rank,  $B_6$  and centralis superior nuclei. Neurons with collateralized axonal projections were found within a distinct portion of the dorsal and median raphe after injections of the true tracers in the amvgdala and hippocampus, but no overlap zone and thus no double labeled raphe neurons were ever seen after paired injections in the neostriatum and hippocampus. Injections of the two tracers in the neostriatum and locus coeruleus, two structures not directly interconnected with each other, also resulted in no double retrograde neuronal labeling in the raphe. It is possibl that raphe axonal projections to the forebrain and brainstem are It is possible thus organized according to a plan of target structure interrelation i.e., raphe-innervated structures possessing inter-connections with each other are interrelated by a topographically distinct group of collateralized raphe projection neurons. (Supported by grants NS 15931 to D.A.S. and NS 14866 to S.T.K.from NIH/NINCDS).

108.13 ORGANIZATION OF THE DESCENDING NORADRENERGIC PATHWAYS TO THE RAT SPINAL CORD. R. Grzanna and E.W. Akeyson\* (SPON: J.C. Hedreen). Department of Cell Biology and Anatomy, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

To determine the organization of the noradrenergic (NA) spinal projections from the pontine cell groups subcoeruleus (SC), the A5 and A7 groups, we have combined the retrograde transport of fluorescent dyes (True Blue, TB and Diamidino Yellow, DY) with immunocytochemical (ICC) staining using antibodies to dopamine- $\beta$ hydroxylase (DBH). Injections of dye solution were made in a series of 5 penetrations of the spinal cord within a three segment area, delivering 0.1 µl per penetration for a total of 0.5 µl. Seven days after injections rats were perfused and the brains processed for DBH-ICC staining. DBH neurons and retrogradely labeled cells were identified in the same tissue section in the fluorescence microscope using different filter combinations and the percentage of DBH cells which were retrogradely labeled in each of the SC, A5 and A7 groups was determined. Retrogradely labeled DBH-cells were found within each of these groups. In addition, we observed numerous retrogradely labeled cells which were not DBH-positive, indicating the existence of non-NA projections from these regions to the injection sites.

non-NA projections from these regions to the injection sites. Injections of TB into a single level of the spinal cord, either cervical, thoracic or lumbo-sacral segments, revealed that A5 and A7 cells project primarily to plexus levels whereas subcoeruleus cells project uniformly throughout the spinal cord. Injections of TB into two levels of the spinal cord, either cervical/thoracic or cervical/lumbo-sacral segments, indicated that the majority of the cells of the A5 and A7 groups project to a single level whereas subcoeruleus cells project to multiple levels of the cord. These organizational features were confirmed with injections of TB into cervical levels followed by injections of DY into either thoracic or lumbo-sacral segments.

The data indicate the existence of two distinct NA projections to the rat spinal cord. The A5 and A7 cells form a focused projection which is organized such that the majority of these cells project primarily to restricted portions of the spinal cord and are thus in a position to selectively influence the activity of neurons in a fraction of the spinal cord segments. In contrast, the subcoeruleus cells form a highly collateralized projection which is organized such that cells in this group project to all levels of the spinal cord and are thus in a position to influence the activity of neurons throughout the entire spinal cord. (Supported by USPHS grants NS15199 and NS16654) 108.14 STATE-DEPENDENT ALTERATIONS OF MEMBRANE POTENTIAL AND EXCITABILITY OF MEDIAL PONTINE RETICULAR FORMATION NEURONS IN DESYNCHRONIZED SLEEP AND WAKING IN NATURALLY BEHAVING CATS. R.W. McCarley, K. Ito

OF MEDIAL POINTINE REFICUENCE FORATION NEDRONS IN DESIMARANTEES and <u>M. Rodrigo</u>. Harvard Medical School, Boston, Mass. 02115 Characteristics of medial pontine reticular formation (mPRF) neurons during behavioral state changes are of interest because of evidence for the presence of the neuronal generating machinery for PGO waves and rapid eye movements of desynchronized sleep (D) in this area, and we have hypothesized that a tonic depolarization of mPRF neurons during D might lead to the occurrence of these D events. However, extracellular recordings showing mPRF activity present during waking (W) as well as in D have raised questions about whether mPRF neurons have distinctive membrane polarization and excitability characteristics during D.

To help resolve this question we have performed chronic intracellular recordings in unanesthetized, undrugged cats during naturally occurring sleep-wake cycles. Cats were prepared with electrodes for recording behavioral state variables and for microstimulation (0.2 mS, <80 uÅ) in contralateral mPRF and ipsilateral mesencephalic and bulbar reticular formation. All recording and stimulation sites were histologically verified by marker lesions, and in some instances by intracellular injection of HRP; all neurons had membrane polarization levels more negative than -45 mV. We have thus far obtained continuous intracellular recordings of seven mPRF neurons during D and the succeeding portion of W.

During D, as we have previously reported, there was a tonic depolarization of membrane potential (mp) upon which was superimposed phasic runs of further depolarization associated with spontaneous discharge activity. With state change from D to W all neurons showed a tonic increase in mp (repolarization, p=.008, sign test) with the membrane potential becoming more negative by an average of 7.6 mV (SD=2.3 mV). In contrast to the slow time course of mp change we observed on transition from synchronized sleep to D the passage from D to W as electrographically more abrupt and mp repolarization became complete within 30 sec. During W the background level of the mp remained more polarized than in D, although in association with some eye and somatic movements in W some neurons showed EPSPs, sometimes with spikes. All seven neurons studied in W and D showed state-dependent excitability increases in D, as measured by the probability of antidromic and orthodromic responses to constant current microstimulation during D and W.

These data provide clear evidence for state-dependent alterations in mPRF mp and excitability in D and W and are compatible with a generating role for mPRF neurons in D sleep phenomena.

## EVOKED POTENTIALS

109.1 Developmental Analysis of Cortical Topography in Normal Children. Johnson, J., Buchsbaum, M.\*, Clark, C.\*, King, A.\*, Coppola, R. NIMH, Lab. of Psychology and Psychopathology, 9000 Rockville Pike, 10/4N317, Bethesda, MD 20205.

Despite the proliferation of studies examining electrophysiological development, it has generally been agreed that the normal development of this phenomena has not been clearly defined. Now, multilead studies of cortical topography, made possible with improved hardware and software development, cohesively present the complex data of event related potentials (ERPs) and make it possible to examine the relationships between age and topographical distributions of ERPs.

Utilizing a 16 lead montage, this study examined the ERPs of 85 normal subjects ranging in age from 5 to 18 years (40 females, 45 males). Sixteen electrodes were attached to the left hemisphere (12 according to the 10-20 system plus 4 additional interpolated leads: FTC, CP, TCP, PO). ERP stimuli consisted of a) 4 intensities of light flashes (2,30,80 and 240 ft La) presented in a random sequence and, b) alternating lights and tones consisting of 4 intensities of light flashes (as above) and 4 intensities of tones (40,50,60,70 db) each presented 64 times in a randomized sequence at 1-second intervals. Instructions to the alternating lights and tones were to attend to the brightest light, and ignore the tones. Only the N120 component (116-152 msec area data) will be reported.

For the lights only condition, a significant multivariate F was found for age (Hotellings TSQ=86.32; F=4.41; df=16, 67; p=.000). Univariate tests indicated that the following leads were significantly correlated with age: Fz, Cz, Pz, Oz, F3, P3, and P0. Significant main effects were found for intensities (F=23.33; df= 48, 697; p=.0000) with significant intensity x lead interactions for Fz, Cz, Pz, Oz, F3, C3, P3, 01, F7, T3, T5, and FTC. No significant sex differences were revealed. For the light attention condition, a significant multivariate F was also found for age (TSQ=74.72; F=3.79; df=16, 65; p=.0001). Univariate tests indicated that the following leads were significantly correlated with age: Fz, Cz, Pz, Oz, F3, C3, P3, T3, and P0. Significant main effects for intensities were also revealed (F=21.78; df=48, 679; p=.0000) while significant intensity x lead interactions were found at leads Fz, Cz, Pz, Oz, F3, C3, P3, O1, F7, T3, T5, FTC. Again, no significant differences for sex were found. Overall, younger children revealed larger amplitudes at each of the 16 leads than did the older children.

These results show that: a) differences in age are highlighted in midlime leads while 1 frontal and 2 posterior sites reflect similar changes, b) in addition to these sites, light attention is reflected by ERP activity in the temporal midlime area. 109.2 EFFECT OF α-CHLORALOSE ON REFRACTORY PERIOD OF ASSOCIATION CORTEX RESPONSE TO SENSORY STIMULATION. Norbert J. Pontzer\*, Douglas M. Wilkison\* and Michael J. Hosko (SPON:Zeljko Bosnjak). Dept. of Pharmacology and Toxicology, Med. College of Wisconsin, Milwaukee, WI 53226. α-Chloralose has long been a standard anesthetic for neuro-

 $\alpha$ -Chloralose has long been a standard anesthetic for neurophysiological and neuropharmacological experiments since it preserves autonomic, respiratory, reflex, and cortical association function. Small sub-anesthetic doses increase the amplitude and decrease the variability of the sensory-evoked long latency field potential measured at association cortex. This is in contrast to most other commonly used anesthetics such as barbituates which abolish association cortex response at sub-anesthetic dose anesthetic doses. Thus much of what is known about association cortex response has come from  $\alpha$ -chloralose anesthetized animals; 35-100 mg/kg commonly being used.

anesthetic doses. Thus much of what is known about association cortex response has come from  $\alpha$ -chloralose anesthetized animals; 35-100 mg/kg commonly being used. One frequently used paradigm for studying the refractory period after a response is entrainment of paired stimuli. The relative response amplitude to the second (test) stimulus of two stimuli is determined as a function of time after the first (conditioning) stimulus. It was noticed in our lab that the refractory period for association cortex response to sensory stimuli appeared to decrease with time in  $\alpha$ -chloralose and by giving an initial dose of 50 mg/kg i.v.  $\alpha$ -chloralose and measuring within 6 hours the refractory period of the test response to either the same or a different modality conditioning stimulus. Responses were measured at the four feline association areas: anterior sigmoid; anterior marginal; anterior suprasylvian; and posterior suprasylvian. Two additional doses of  $\alpha$ -chloralose quite slowly. We found that the refractory period dramatically increased after the first additional dose with only a small additional increase after the second. Because of the length of action of  $\alpha$ -chloralose, cumulative dosing can be assumed. These changes in refractory period occurred with minimal changes in the amplitude of the response. One explanation for this effect would be an  $\alpha$ -chloralose mediated increase of recurrent inhibition at a cortical or sub-cortical level. (Supported by USPHS Grant DA 01754).

EVENT RELATED POTENTIAL INDICES OF CROSSMODAL INFORMATION 109.3 PROCESSING. <u>R. Erwin\* and P. Tanguay</u>\* (SPON: D. Molfese). Electrophysiology Lab, Neuropsychiatric Institute, UCLA, Los Angeles, CA 90024.

Previous research (Thatcher, R., <u>Behav.</u> <u>Biol.</u>, 19:1, 1977) has indicated that a late positive component LPC of the event related potential (ERP) is enhanced for stimuli judged to be matches (i.e., related on some dimension) as compared to stimuli judged to be mismatches. The present study now reports similar findings using a crossmodal match-mismatch procedure in which subjects were trained to associate visually presented geometric figures with auditorily presented tones of different frequencies. Event related potentials were recorded over the temporal (T5, T6), parietal (P3, P4) and occipital (01, 02) regions of 12 adult volunteers. Stimuli were presented in two trial blocks. Each trial consisted of presentation of a stimulus in one modality (auditory or visual) followed by a stimulus in the alternate modality after a brief interstimulus interval (2 to 4 sec.) Subjects were required to press a button to match stimuli (as determined by previous training) on one trial block and to mismatch stimuli on the other block. Amplified ERPs for each condi-tion were averaged independently at 10 ms intervals over a 750 ms period following stimulus onset (for 75 points). The averages for each modality were then formed into a covariance matrix and which occurred in the latency range of the LPC was obtained for both the visual PCA and the auditory PCA. The peak latency of the auditory factor was 320 ms, while the peak latency of the visual factor was 350 ms. Factor scores were computed for each of these factors and submitted to independent analyses of of these factors and submitted to independent analyses of variance for Block (2) x Sites (6) x Stimulus (2) x Condition (2) to determine if either factor varied systematically as a function of experimental conditions. The visual factor indicated that the LPC to the match stimulus was enhanced in comparison to the LPC for the mismatch stimulus, F(1,11)=11.07, p=.01, over all recording sites and trial blocks. For the auditory factor, the match LPCs were enhanced only over right-hemisphere sites [T6, match LPCs were enhanced only over right-hemisphere sites (16, P4) during the trial block in which match responses were required, and over the left hemisphere (T5, P3) during the block in which mismatch responses were required. Overall these findings suggest that crossmodal processing can be assessed using a match-mismatch procedure with the ERP as a dependent measure. In addition, the findings indicate that endogenous components, such as the LPC, may be more sensitive to task demands when obtained in one modality as compared to other modalities. (Supported by grants HD04612 and HD05958).

CORTICAL EVOKED POTENTIALS AND WORD AND PICTURE RECOGNITION. R.J. Chabot<sup>\*</sup>, D.H. York, and W. A. Waugh<sup>\*</sup>. Departments of Physiology and Neurosurgery, U. of Missouri Sch. of Med., 109.4 Columbia, MO 65212.

Columbia, MU 65212. Whether or not separate substages of the word and picture recognition process can be identified in the cerebral activity following stimulus presentation was investigated using averaged evoked potentials. Eight right handed volunteers (x age = 29,6

following stimulus presentation was investigated using averaged evoked potentials. Eight right handed volunteers (x age = 29.6  $\pm$  4.7 yrs) served as subjects. Cerebral electrical activity was recorded from Cz, C3, C4, and Pz (standard international 10-20 system) with amplifier gain set at 10<sup>4</sup> and bandpass filters set at .1 to 300 Hz. Eighty trials were averaged for each experimental condition and the averaged waveforms were analyzed using the IBM Statistical Analysis System. Subjects made perceptual and cognitive decisions about either pairs of visually presented words or pictures. For the word pairs subjects made decisions associated with three substages of the word recognition process. These substages corresponded to feature detection and synthesis, lexical access and semantic memory access. Analogous decisions were made for pictures with decision levels corresponding to feature level decisions, basic category decisions, and superordinate category and semantic memory access. Analogous decisions were made for pictures with decision levels corresponding to feature level decisions, basic category decisions, and superordinate category decisions. Principal components factor analysis with varimax rotation described the evoked waveforms well with 7 factors which accounted for 93% of the total variance. Subsequent analyses of variance on the factor scores associated with each component showed that the type of cognitive decision made effected the maximum amplitude and the duration of a late positive component which extended from 418-754 msec after stimulus presentation. Variability associated with the latency and duration of this component was highly correlated with the response latencies of the various experimental conditions. It appears that this late positive component provides an internal index of the neural processes which accompany cognitive decisions. As such, this component serves as a source of converging evidence, along with response latency measures, that the pattern recognition processes for both words and pictures can be tapped at several different levels. The averaged waveforms were also examined for differences associated with accessing different superordinate categories in memory. The procedures outlined above should be applicable for studying disruptions to the pattern recognition process which accompany stroke, head trauma, and neurological deficits associated with learning disorders. These techniques should be particularly sensitive for defining neurological deficits which influence central processing mechanisms while leaving peripheral processing mechanisms relatively intact.

THE HABITUATION OF HUMAN EVENT-RELATED BRAIN POTENTIALS ELI-CITED BY SPEECH SOUNDS AND TONES D. L. Woods and R. Elmasian\*, Clinical Neurophysiology Laboratory, Dept. of Neurology, U.C. Davis, V.A. Medical Center, Martinez, CA 94553 and Dept. of Neurosciences, UCSD, La Jolla, CA 109.5

When auditory stimuli are repetitively presented to alert listeners, the event-related brain potentials (ERPs) which they elicit are reduced in amplitude. This habituation has been divided into two phases 1) <u>short-term habituation</u> which occurs when stimuli are repeated at interstimulus intervals (ISIs) of 20 sec or less; and 2) <u>long-term habituation</u> which occurs minute-by-minute over the course of an experiment. In this experiment we examined the short- and long-term habituation of exogenous (N100) and endogenous (P300) brain potentials eli-cited by speech sounds and various control stimuli. cited by speech sounds and various control stimuli.

METHODS. Pure tones, synthetic vowels, and digitized speech ands were presented monaurally to normal listeners (ages 18-yrs). ERPs were recorded from midline sites and from elecsounds 34 yrs). 54 yrs). Exits were recorded from midline sites and from elec-trodes overlying auditory cortical regions bilaterally. The stimuli were presented in trains, with ISIs fixed within a train (either 0.5 or 1.0 sec), but varying randomly between trains. Inter-train intervals were also randomized (2.0 or 6.0 sec). Half of the trains included either a single "target" stimulus which served to cue a motor response, or a "deviant" stimulus (a word or tone which was presented frequently in other conditions) which required no response.

RESULTS. 1). The ERPs elicited by "frequent" stimuli habi-tuated rapidly within trains, and the habituation was partially stimulus specific. 2). Habituation processes were similar for speech and non-speech stimuli. 3). The degree of short-term habituation of the N100 to the "deviant" stimulus was related to its acoustic similarity to the standard stimuli. The long-term habituation of the N100 component was partially specific for the stimulus which was repeated. 4). PSOOS elicited by "deviant" stimuli habituated rapidly at all scalp sites, while PSOOS elicited by target stimuli habituated gradually over frontal sites only. frontal sites only.

DISCUSSION. ERPs recorded from the human scalp show habituation patterns which reflect memonic persistence in several neural systems. A similar persistence is evident for linguis-tic and non-linguistic stimuli.

GENERATOR SUBSTRATES OF THE VERTEX SHORT LATENCY AUDITORY EVOKED 109.6

GENERATOR SUBSTRATES OF THE VERIER SHORT LATENCY AUDITOR EVOLED RESPONSE WAVE 6. C. Shipley\*, G. Strecker\*J. Buchwald Brain Res. Inst., Ment. Ret. Res. Ctr., Dept. Physiology, UCLA Med. Center, Los Angeles, CA 90024. In the cat, the "auditory brainstem response" recorded from the vertex consists of 5 potentials generated by auditory relays from the level of the eighth nerve to the inferior colliculus which the level of the eighth nerve to the inferior colliculus which occur within 6-7 msec of a click stimulus. Subsequently, a less well defined wave 6 is generally seen at a latency of 7-8 msec. This potential is of interest because it develops at a later age than waves 1-5 and may provide a sensitive index of maturation within the auditory pathway. In the present study, a combination of depth recording of local field potentials and surgical lesions was used to identify possible generators of wave 6. These experiments were carried out on a total of 10 cats with each procedure being performed on at least two animals.

Previous research has reported that local field potentials within pars principalis of the medial geniculate body occur in the latency range of wave 6 suggesting this structure as a likely generator substrate. This result was confirmed in the present study. However, precollicular decerebration which isolated the medial geniculate body from the brainstem changed the form of wave 6 slightly but did not result in its disappearance, suggest-that the medial geniculate body is not the major source of activ-ity reflected in vertex wave 6. Depth recording of auditory evok-ed activity in the superior colliculus revealed an evoked potential that was highly correlated with the surface wave 6 in form, latency, response to parametric manipulation of stimulus rate and response to monaural and binaural stimulation. Aspiration confined to the medial portion of the superior colliculus, i.e. which did not extend to the brachium of the inferior colliculus, reduced the amplitude of wave 6 substantially although the wave was not completely eliminated.

These results suggest that activity present in the superior colliculus is reflected in the vertex short latency auditory evoked response wave 6. Although a number of studies have shown that neurons within the superior colliculus are responsive to sound, this is the first report of involvement of superior col-liculus in the generation of vertex recorded short latency auditory evoked potentials. (This work was supported in part by HD 04612 and HD 05958).

109.7 A STUDY OF THE LONG LATENCY COMPONENTS OF THE AUDITORY EVOKED POTENTIALS IN THE CAT. <u>K. T. Tam\*, J. C. Hwang, and</u> <u>P. W. F. Poon</u>. Department of Physiology, Faculty of Medicine, University of Hong Kong, Sassoon Road, Hong Kong.

When tone bursts of short duration were presented at low rates (less than 0.1 Hz) to choralose anaesthetized (35 mg/kg) cats prominent and stereotyped potential changes could be recorded over the scalp of the animals. This response was not affected by the intravenous injection of galamine triethioddee (3 mg/kg). With vertex-to-nuchal differential recordings, the **averaged** response typically consisted of two large surface positive deflections. The deflections were identified as an early wave with a peak latency measured at  $45 \pm 3$  msec, and a late wave delayed at  $115 \pm 15$  msec to the stimulus. This response appeared to be reminisent to the auditory evoked potentials measured in unanaesthetized preparations (G. M. Gerken and W. D. Neff, <u>Electroenceph. Clin. Neurophysiol.</u>, 1963, 15: 947-957). Systematic mapping of this evoked potential over the 947-957). Systematic mapping of this evoked potential over the scalp of the animal showed that the early wave appeared with the greatest amplitude (140 uV) over the frontal region (peak latencies 42 to 48 msec), while the late wave was recorded with the largest amplitude (280 uV) at the vertex (peak latencies 100 to 130 msec). Intracranial recordings showed that strong positive deflections, with delays comparable to those of the early and late waves of the vertex potentials respectively could be differentially detected at the frontal cortex and at the corpus callosum. This suggested that the activities originated from both the frontal lobes and the corpus callosum might contribute to the early wave as well as the late wave of the auditory evoked responses measured over the scalp of the animal.

IS A PLACE MECHANISM RESPONSIBLE FOR WAVE V LATENCY DECREASE 109.8 WITH INCREASING CLICK INTENSITY? Robert Burkard\* and Kurt Hecox\* (SPON: G. Moushegian). Waisman Center, University of Wisconsin, Madison WI 53706.

The base-to-apex, frequency-to-place representation along the cochlear partition results in decreasing distance to the cochlear partition results in decreasing distance to traveling-wave maxima with increasing stimulus frequency. Electrophysiologically, this is manifested as decreased peak latencies of the whole-nerve action potential and brainstem auditory evoked response (BAER) with increasing stimulus frequency. Increasing stimulus intensity also causes a decrease in peak latencies. This has led to the hypothesis that increased stimulus intensity produces a basalward shift in the response-generating region of the cochlear partition, thereby reducing its time delay. This thesis may be tested by restricting the site of response-generating activity along the cochlear partition through the use of high-pass masking. If the site of response generation is displaced basally at higher stimulus intensities, then there should be a smaller stimulus intensities, then there should be a smaller intensity-dependent latency shift (shallower latency/intensity function) with decreasing masker cutoff, as the high-pass masker progressively restricts the response to more apical locations. Eggermont and Don (1980; J. Acoust. Soc. Am. Am. 68 1674-1675) used a similar technique, but varied both stimulus and masker intensity. However, if the region of response emanation is dependent on stimulus intensity, then the cochlear distribution of high-pass masking might also be level dependent.

The thesis that a place mechanism explains the intensity-dependence of wave V latency is reexamined by holding noise level constant while varying click intensity and high-pass level constant while varying click intensity and high-pass masker cutoff. Click intensities ranged from 15 to 65 dB nHL. Broadband noise was presented at an intensity adequate to perceptually mask 70 dB nHL clicks. Keeping spectrum level constant, the noise was high-passed at 20 (unmasked), 6, 5, 4, and 3 kHz. There was an increase in BAER threshold with decreasing high-pass masker cutoff, possibly a result of remote masking. With decreasing high-pass masker cutoff there was a steepening of the wave V latency/intensity function was a steepening of the wave V latency/intensity function. Thus, restricting the cochlear region responsible for Thus, restricting the eccelear region responsible for generating the response to progressively more apical regions did not result in a shallower latency/intensity function. This finding is difficult to reconcile with the theory that place shifts are responsible for intensity-dependent latency shifts of wave V of the BAER. (Supported by NIH grant #16436).

BRAINSTEM AUDITORY EVOKED POTENTIALS (BAEPs) IN MICE RECEIVING 109.9 CORONAVIRUS SD: <u>D.L. Asher</u><sup>\*</sup>, <u>L.M. Nelson<sup>\*</sup></u>, <u>S. Staller<sup>\*</sup></u>, <u>J.S.</u> <u>Burks<sup>\*</sup></u>, (SPON: <u>J. Nolte</u>). <u>Depts</u> of Otolaryngology and <u>Neurology</u>, Rocky Mountain Multiple Sclerosis Center, University of Colorado School of Medicine, Denver, CO 80262.

Coronavirus SD was previously isolated while working with fresh multiple sclerosis autopsy brain material (Burks et al (1980), <u>Science</u> 209:933). Following intracerebral inoculation of 3-4 month old mice with coronavirus SD, hyperexcitability and hind limb paresis were observed from days 4-9 followed by a and hind limb paresis were observed from days 4-9 followed by a lack of clinical signs until day 45. At that time, hind limb anesthesia and paresis was again observed (Mendelman et al  $\{1983\}$ , <u>Arch. Neurol.</u>, in press). Viral antigen was identified in brain and spinal cord sections with autoradiography (J. <u>Immun. Methods</u>  $\{1982\}$ , 54:191). Histopathology revealed demyelination in temporal cortex and spinal cord at times when infectious virus was not recoverable. This study reports preliminary BAEP findings observed in an additional group of coronavirus SD infected mice.

After normative BAEP data were collected from 4 and 6 week After normative BAEP data were collected from 4 and 6 week old C57 B16/J control mice, we measured the BAEPs of two groups of mice inoculated intracerebrally with either a sham inoculation (N=15) or with coronavirus SD (N=15). Baseline BAEP measurements were made for each mouse prior to inoculation and a minimum of two BAEP measurements were obtained weekly from each ear of each mouse for 6 consecutive weeks beginning with day 0 (6 wks. old). Click stimuli were presented at 60 dB SPL through TDH 39 earphones. Two hundred fifty clicks of 0.1 msec. duration were delivered unilaterally at 13.1 presentations per second. Recordings were obtained from needle electrodes placed subcutaneously at the vertex and referenced to ipsilateral ear lobe. lobe.

lobe. Five vertex-positive peaks were identified in the BAEPs of the normative control mice. Mean latencies for BAEP controls were Wave I = 1.03, Wave II = 1.76, Wave III = 2.73, Wave IV -3.45 and Wave V = 4.24 msec. Mean interpeak latencies were 1.70 for I-III, 1.52 for III-V and 3.22 for I-V. There were no significant morphology or latency changes in the sham inoculated mice over the eight-week test period. However, BAEP morphology and latency changes were observed in the coronavirus SD injected group. These changes included diminibled Waves II SD injected group. These changes included diminished Waves II and III and prolonged latency of the Wave IV-V complex;

abnormalities presented both unilaterally and bilaterally. These observations indicate that the BAEP may be useful as a non-invasive probe for assessing the effects of viral induced central demyelination in an animal model. (Supported by the Rocky Mountain Multiple Sclerosis Center)

109.10 EFFECTS OF WHOLE BODY HYPERTHERMIA ON AUDITORY BRAINSTEM, SOMATOSENSORY AND VISUAL EVOKED POTENTIALS. B.E. Lyons, R.H. Britt, T.P. Ryan\*, E.L. Saxer\*, W.G. Obana\*, and G.T. Rossi. Div. Neurosurgery, Stanford Univ. Sch. of Med., Stanford, CA 94305. A model of whole body hyperthermia has been developed in the cat using a cardiopulmonary bypass circuit with a heat exchanger (Britt, R.H. and Rossi, G.T., J. Neurosci. Meth. 6:231-244, 1982). The effect of systematically raising core and brain temperature from 36° to 45°C was studied in 18 pentobarbital anesthetized catus using multimodality evoked potentials (brainstem auditory, somature sensory and visual). Core temperature was monitored by esophageal and rectal probes. Brain temperature was monitored by esophageal and rectal probes. Brain temperature was monitored by copper/con-stantan thermocouple junctions housed in 26 awg stainless needles in the lower medulla and in the parietal cortex at depths of 0.5 and 1.0 cm. The effect of hyperthermia on the 5 component waves (I-V) of the brainstem auditory evoked response was studied in 6 cats. In general, both amplitude and latency of each peak decreas-ed as temperature was increased to a "critical" value at which the latencies increased and the amplitudes continued to diminis. In 3 experiments this "critical" temperature dependent effects of evoked potential waveforms (Rossi, G.T. and Britt, R.H., <u>Electro-enceph. clin. Neurophysiol.</u> In Press.). Arrhenius plots of I/latency or k (rate) versus temperature (1000/%) for the temper-ature range from 36°C to the "critical" temperature showed similar slopes for all five component wave reflecting the increase in latencies with further temperature evolution. This "critical" temperature was lower than the temperature at which there was a significant reduction in waveform amplitude. The Arrhenius analysis suggested that the abrupt change in slope at the "critical" temperature was lower than the temperature at which there wosserved with visual and somatosensory cor

109.11 CHANGES IN SOMATOSENSORY EVOKED POTENTIALS WITH HYPOTHERMIA IN HUMANS. <u>M.J. Taylor\*, J.G. Coles\*, D.S. Borrett\*, N.J. Lowry\*</u> <u>J.M. Pearce\*, G.A. Trusler\*, W.G. Williams\* (SPON: W.J. Logan)</u>. Departments of Neurology and Cardiovascular Surgery, The Hospital for Sick Children, University of Toronto, Toronto, Ont., Canada M5C 1X8

Somatosensory evoked potentials (SEPs) were recorded over the cervical spine and contralateral sensory cortex (C3' or C4') in 15 children during cardiopulmonary bypass surgery with hypothermia alone (n=11) or with profound hypothermia and complete circulatory arrest (n=4). SEPs in response to median nerve stimulation at the wrist were recorded throughout the surgical procedure in all patients. The lowest temperatures reached in the patients ranged from  $9 - 28^{\circ}C$  (oesophageal).

The latencies of the spinal and cortical SEPs increased systematically in all patients with hypothermia, showing marked slowing of conduction with decreasing oesophageal temperatures. The latency changes occurred as a nonlinear function of decreasing temperature.

The cervical SEP divided into a double response with hypothermia in all cases; this was in effect a widening of the notched N13 found in the patients and normal control children at normothermia. The slower of the two responses (N13s) was more sensitive to hypothermia - its latency increased more rapidly with cooling and it disappeared 2 - 6 degrees before the faster response (N13f).

In patients in whom SEPs were recorded at Erb's point, lower and upper cervical spine, the double response was seen at all three sites. Over the cervical spine the absolute latencies increased with the more rostral recording site as did the N13f-N13s interpeak latency. These latency differences were enhanced with hypothermia. These data suggest that the N13f and N13s represent travelling waves in two populations of primary afferent neruons, which have small but consistent differences in conduction speed. The existence of these two distinct populations of neurons contributing to the SEP is clearly shown by these studies with hypothermic patients. 109.12 SOMATOSENSORY EVOKED POTENTIALS (SEPs) AND SINGLE UNIT ACTIVITY EVOKED BY AIRPUFFS IN ALERT MONKEYS. H. Hamalainen\*, S. Warren\*, W. Young\*, J. Davis\* and E.P. Gardner (SPON: E.S. Flamm). Dept. of Physiology/Biophysics, NYU Sch. of Medicine, New York, NY 10016 In order to develop more physiological techniques for eliciting SEPs, we have applied airpuffs lasting 10 ms to the skin of the monkey's hand and arm. Unlike electrical shocks to whole nerves, airpuffs are highly selective for specific mechanorceptors, and permit stimulation of a restricted area of skin in a variety of spatial and temporal patterns. Short latency, 8-10 ms; duration, 25 ms) containing several peaks (P10, P16, P25, P30), a negative wave (N40) of 30 ms, and a late slow positivity (P70). Exact times of occurence and amplitude of the individual peaks varied somewhat from monkey to monkey, but each animal showed a consistent and reproducible SEP that fit the general pattern. The early positive complex appears restricted. Justimum in amplitude at regions of greatest early positivity. P70 is recorded over even wides regions of the pre- and postcentral cortices, and also displays less variability in amplitude. Short latency SEPs were seen only over the contralateral hemisphere, and could be shifted from right to left cortex depending upon which arm was stimulated. Bilateral stimulation due activity in bath SU cortices.

stimulation evoked activity in both SI cortices, although the N40 wave appeared somewhat attenuated. These results indicate that the SEPs we recorded are specific to the tactile stimulus. P16, P25, and N40 amplitudes depend upon both the position of the airpuffs on the forearm, and the number of points stimulated. SEPs were largest when the stimulus position coincided with the receptive field centers of the neurons recorded in the underlying cortex.

Single unit responses to airpuffs in monkey SI cortex typically consist of a short, high-frequency burst of impulses (12-15 ms latency, 25 ms duration). Thus the earliest positivity in the SEP occurs before cortical spike activity begins, and may be due to the thalamo-cortical volley. The remainder of the early positive complex coincides with airpuff initiated impulse activity in SI, while the onset of N40 is mirrored in the decay of unit responses. The latency, duration and spatial distribution of N40 correspond to those of in-field inhibition. No single unit activity in SI cortex could be attributed to P70, nor did we observe poststimulus facilitation in this time period. We suggest that P70 originates elsewhere in the cortex. Thus SEPs elicited by mechanical stimuli provide opportunities for assessing the spatial and temporal integrative capabilities of the somatosensory pathways, and for evaluating the neural mechanisms underlying pattern recognition. (Supported by NIH Grant NS11862).

OPERANT CONDITIONING OF SEP AMPLITUDE: SPECIFICITY OF THE CONDI-109 13 CHANGES IN AMPLITUDE AND ITS ASSOCIATED CHANGE IN FACIAL NOCI-CEPTIVE SENSITIVITY. R. Dowman and J.P. Rosenfeld. Dept. of Psychology, Northwestern Univ., Evanston II., 60201. Our present work focuses on extending our earlier finding that our present work focuses of extending our earlier finding in operantly conditioning somatosensory evoked potential (SEP) am-plitude is correlated with changes in facial nociceptive sensitivity (FNS). In the present study SEPs were recorded mono-polarly via a screw placed over the SI cortex contralateral to the evoking stimulus (non-aversive stimulation to the trigeminal tract). Animals (rats) were rewarded for increasing (uptrain) or decreasing (downtrain) the amplitude of a surface positive com-ponent of this SEP (latency= 30msec; P30). Ipsilateral SEPs and non-aversive reflex movements evoked by the stimulus were also recorded. FNS tests were taken immediately following each condi-tioning session. Four animals have successfully completed training. Uptraining the P30 component was correlated with decreased FNS and downtraining with increased FNS on the side of the face contralateral to the trained cortex (p<.05) but not on the ipsilateral side (p>.10). Changes in the conditioned SEP were restricted to components P30 and N14 (uptrain>downtrain, p<.05). There were trends seen in other components (uptrain>downtrain) but these were not significant (p>.05). Likewise, there were trends seen in the ipsilateral SEP components and the non-aversive reflex movements (uptrain>downtrain) but these were not significant (p>.10). These data demonstrate that the conditioned changes in SEP amplitude are relatively specific to the trained component and that this specificity is reflected in the correlated changes in FNS.

109.14 SOMATOSENSORY EVOKED POTENTIALS (SEPs) TO MUSCLE STRETCH STIMULATION PRODUCED BY TENDON TAPS IN HUMANS. L G Cohen\*and A Starr. Department of Neurology, Univ. of California, Irvine, Ca 92717. SEPs were recorded after gastrocnemius-soleus, anterior tibial, and quadriceps tendon displacement producing muscle stretch in normal humans. The techniques of recording involved the placement of surface electrodes at several levels of the somatosensory system and using a computer to define the small amplitude time-locked potentials to muscle stretch stimulation. We measured amplitude and latencies of the evoked potentials and defined the effects of age and stimulus variables on these parameters. Results were correlated with the SEPs to electrical stimulation of posterior tibial nerve at the ankle, anterior tibial nerve at the ankle and posterior tibial nerve at popliteal level. Control experiments defined the role of cutaneous afferent contributions to the evoked potentials. The latency of the initial scalp positivity to gastrocnemius-soleus tendon taps occurred earlier than that obtained after posterior tibial nerve at the ankle. The effects of anesthesia, muscle contraction and tendon vibration suggest that tendon tap stimulates predominantly muscle spindles and that the afferent volley travels along fast central pathways to the cerebrum.

EVALUATION OF SELECTED SITES FOR RECORDING TRIGEMINAL 109.15 EVORED POTENTIALS IN MAN. C.G. Widmer\* and W.D. McCall. Jr., Sch. Dentistry, S.J.N.Y. Buffalo NY 14214

McCall. Jr., Sch. Dentistry, S.U.N.Y. Buffalo NY 14214 Important features of trigeminal evoked potentials may depend on the location of the recording elec-trodes. Our purpose was to select sites for reference and active electrodes to record these potentials. We focused on the reliable waveform at 19 ms. Each of 13 subjects gave informed consent. An acrylic splint held a pair of stimulating electrodes over the left greater palatine nerve. Each of 6 trials at each of 2 sessions included 128 pulses, 0.2 ms width, 1.4/sec, and twice sensory threshold. Four sites were recorded simultaneously. Each channel was sampled at 2 kHz and averaged by a PDP 11/03 compu-ter. Analysis time was 64 ms prior to and 256 ms after the stimulus. the stimulus.

Our criterion for a reference electrode site was minimal electrical activity in the interval 15 to 25 minimal electrical activity in the interval 15 to 25 ms in trials where a 19 ms potential was observed with an amplitude of 3 uV or more in the C4-A2 trace. Electrical activity was quantified by dividing the variance of the averaged signal in the cited post-stimulus interval by the variance of a like interval prior to the stimulus. These variance ratios were obtained from signals recorded from FZ, A2, and mas-ted with reference to the back of the pook

Results from 6 subjects who had 19 ms potentials over 3 uV gave mean variance ratios of 1.6 for FZ, 3.9 for mastoid, and 10.0 for A2. All differed signifi-cantly (p<01). Thus FZ had the minimum electrical

The masteria, and the for A2. All differed signature cantly (p<.01). Thus FZ had the minimum electrical activity and was selected as the reference site. Our criterion for selecting the active electrode site was maximal electrical activity in the interval from 15 to 25 ms from those trials in which the A2-FZ recording contained a 19 ms potential over 3 uV. The activity was again quantified by a ratio of post-stimulus to pre-stimulus variances in the designated time intervals. The sites C4, C6, T4, and A2 were evaluated with reference to FZ. Variance ratios from 7 subjects with 19 ms poten-tials over 3 uV were 6.1 for C4, 6.7 for C6, 11.2 for T4, and 28.3 for A2. All active sites differed (p<.05) except C4-C6. Thus the signal was largest at A2 and increased in the superior to inferior direction when FZ was the reference site. Supported by USPHS Grants DE-07089 and DE-04889.

EVOKED POTENTIALS: VISUAL

110.1 ASSESSMENT OF RETINAL FUNCTION IN HUMAN AMBLYOPIA.

Robert F. Hess\* and Curtis I. Baker, Jr., Physiological Laboratory, Cambridge University, Cambridge, U.K. In an attempt to assess whether amblyopia in humans has a retinal basis, we compared the psychophysical and electro-retinographic responses between normal and severely amblyopic eyes using the same stimuli. Our stimuli were either sinusoidally modulated uniform fields

or sinusoidally contrast-reversing gratings. Electroretino graphic responses which were measured using gold-foil lid elec-trodes, were averaged and Fourier analysed.

We found no electrophysiological analogue of the psychophysical deficit in correctly refracted, but severely amblyopic eyes. We assessed responses for stimuli of various spatial frequencies and contrasts. In one amblyope reduced electroretinographic responses were recorded but only at low spatial frequencies and Similar results were obtained for uniform field stimulation. The linear and non linear response were of similar amplitude in normal and amblyopic eyes over a wide range of modulation depths except in the one amblyope who exhibit a pattern-evoked deficit. In this case, only the non-linear component was anomalous and only for stimuli of large modulation depths. We conclude that some severe amblyopes do not exhibit an electroretinographic anomaly that parallels their psychophysical deficit.

THE CONTRIBUTION OF THE ON CHANNEL TO THE ELECTRORETINOGRAM OF 110.2 R. Held). Dept. of Psychology, MIT, Cambridge, MA 02139.
 The electroretinogram. (ERG) is a complex signal reflecting

the light-evoked electrical activity of several different retinal elements. For this non-invasive measure to be of use in assessing retinal function, the cellular origins of the various ERG components must be understood. In this study, we used 2-amino-4-phosphonobutyric acid (APB) to selectively inactivate the retinal ON channel (Slaughter and Miller, <u>Science</u>, <u>211</u>:182, 1981) and examined the resulting changes in ERGs obtained from anesthetized monkeys (Macaca mulatta) and rabbits. The action of APB was monitored at the cellular level by obtaining microelectrode recordings from the lateral geniculate nucleus (LGN) in monkeys or the superior colliculus (SC) in rabbits. We have

in monkeys or the superior colliculus (SC) in rabbits. We have shown previously that ON responses in the central visual path-ways of both species accurately reflect the functional state of the retinal ON channel (Schiller, <u>Nature</u>, 297:580, 1982; Knapp and Mistler, <u>Neurosci</u>. <u>Abstr</u>, 8:262, 1982). ERGs evoked by a diffuse light stimulus (square-wave mod-ulated at 1 Hz) were recorded with corneal ring electrodes, amplified, filtered (0.1 Hz-1 KHz or 3.0 Hz-1 KHz), digitized, and averaged. The responses of LGN or SC units to spots of light flashed in their receptive fields were recorded with con-ventional techniques. 

µM diminished or abolished the ERG b-wave. The drug effects developed over 15-60 minutes and were maximal for several hours. The reduction in b-wave amplitude was accompanied by a diminu-tion of ON responses observed centrally. When the b-wave was entirely absent, no ON responses could be elicited from the LGN or SC, but OFF responses appeared unchanged in both amplitude and receptive-field properties.

The results indicate that the ERG b-wave can serve as a non-invasive measure of activity in the retinal ON channel. ERGs obtained under our experimental conditions arise primarily from photoreceptors, bipolar cells, and non-neural elements. Of these, APB affects only the depolarizing bipolar cells, suggesting that these are the main neural elements underlying the b-wave.

110.3 PATTERN ELECTRORETINOGRAMS IN THE HOODED RAT. <u>C. Harnois</u>, <u>A. Kahan\*, I. Bodis-Wollner, M. Marx\*</u>. Departments of Neurology and Ophthalmology, Mt. Sinai School of Medicine, New York, N.Y. 10029.

Recent studies in cats and humans suggest that pattern reversal electroretinograms (ERG) may be dominated by retinal ganglion cell activity, while the flash ERG has a preganglionic origin. We have simultaneously recorded ERGs and VEPs to pattern stimuli in slightly anesthetized hooded rats. ERGs were recorded with corneal silver chloride electrodes referenced to a subcutaneous electrode at the lower orbital margin. VEPs were recorded with chronically implanted screw electrodes placed over area 17 of each hemisphere referenced to the bregmatic suture. The stimulus was a vertical sinusoidal grating of 0.1 cpd and 50% contrast displayed on a CRT screen which subtended 46° of visual angle at the eye. This spatial frequency is optimal for the rat VEP as determined by our previous studies.

With square-wave counterphase modulation of the pattern at a rate of 1 Hz, the ERG of the rat shows three constant components: a small negative wave at 43 ms; a major positive at 66 ms; and a large negative at 111 ms. The ERG to on-off presentation differs in shape for the onset and offset of the pattern. The latency of the positive component at the onset is around 60 ms, which is 20 ms earlier than that for the offset of the pattern.

We studied the effect of the frequency of sinusoidal temporal modulation in the range of 2 to 30 Hz. The responses were analyzed by Fourier Transform, yielding both the amplitude and phase of the different harmonic components. The ERG to flicker stimulation is dominated by the first harmonic while the response to pattern stimulation is dominated by the second harmonic. The temporal transfer function is also different for the two types of stimuli suggesting differences in the origin for flicker and pattern ERG of the hooded rat.

110.4 VEPs AS PREDICTORS OF DEVELOPMENT IN HIGH RISK INFANTS. <u>I.P.</u> Weiss, <u>A.B. Barnet</u>, and <u>S.A. Reutter</u>. Evoked Response Lab, Children's Hosp. Natnl. Med. Ctr., Washington, D.C. 20010 Visual evoked potentials (VEPs) to flash and Bayley tests

Visual evoked potentials (VEPs) to flash and Bayley tests of infant development were periodically administered as part of a longitudinal study of sick premature infants who were high risk for developmental delays. We report here the predictive value of the VEPs obtained at 6 months of age (192 + 32 days) on development assessed at over 1 year of age (463 + 120 days). The Bayley Psychomotor Development Index (PDI) and Mental Development Index (MDI) were each classified as high if 100 or above. The VEPs were scored according to the presence or absence of 14 peaks named N<sub>1</sub> through P<sub>7</sub> (Barnet et al. <u>Electroenceph. Clin. Neurophysiol.</u> 49, 476-489, 1980). Since several VEPs were recorded for each child, a total of 109 VEPs were analyzed on 18 subjects, nine of whom proved to have high Bayley test scores and nine low.

Dayley test scores and nine 10%. Component  $N_6$ , the most prominent wave on most VEPs, was present in 90% of high PDIs but only 56% of lows (x<sup>2</sup> = 14.89, df = 1, p = .0001). Six VEP peaks were found to be present in at least half of the 109 VEPs, and all six were more frequent in the high PDIs than in the lows. The results were similar if the MDI was used as the index of development. Neither birth weight, gestational age, Apgar scores, number of days of neonatal hospitalization, nor incidence of respiratory distress was nearly as good a predictor of outcome in this population as was the 6 month VEP. The mean number of VEP components present at 6 months in children who were later shown to have high PDIs was 7.1 and 5.6 for children with low PDIs. VEPs to flash during infancy may be a useful tool to identify children most likely to experience developmental delay from a population already at considerable statistical risk.

110.6 CHLORDIMEFORM INSECTICIDE PRODUCES SPATIAL FREQUENCY-AND INTENSITY-DEPENDENT CHANGES IN VISUAL EVOKED POTENTIALS. W.K. Boyes<sup>1+</sup>, D.E. Jenkins<sup>\*</sup> and R.S. Dyer. Neurotoxicology Division, U.S.E.P.A., Research Triangle Park, NC 27711. (Spon. L. Reiter).

We previously reported that in hooded rats the formamidine insecticide chlordimeform (CDM) increased pattern reversal evoked potential (PREP) amplitude without changing flash evoked potential (FEP) amplitude, although the latency of both responses increased (Dyer and Boyes, The Toxicologist, 3:13, 1983). The present three studies further explore the effect of CDM on visual evoked potentials. First, PREPs were recorded from rats receiving either 0 (n=12), 5 (n=12) or 40 (n=13) mg/kg CDM to different spatial frequency patterns (horizontal square wave gratings generated on a TV screen, counterphase modulated at 0.25 Hz, 99% contrast, 30  $cd/m^2$ ). The 5 mg/kg group was not different from controls. Peak-to-peak amplitudes of the 40 mg/kg group were larger than those of the other two groups at spatial frequencies of 0.05, 0.10 and 0.44 cycles/degree (cpd), but were not different from the other groups at 0.8 cpd. To determine if the PREP changes were PREPs to 0.20 cpd gratings oriented at 0 (horizontal), 45, 90 and 135 degrees in rats exposed to 0 (n=13) or 40 (n=14) mg/kg CDM. CDM increased amplitudes and latencies equally at all stimulus orientations. The third study investigated whether the failure of CDM to change FEP amplitudes resulted from the high intensity (4.5 x  $10^{\star\star7}$  Lux) or the absence of pattern in the flash stimuli. Evoked potentials were recorded from two groups of rats, 0 (n=18) and 40 (n=18) mg/kg CDM, under three stimulus conditions, a lower intensity strobe flash (1.6 x 10\*\*5 Lux), a pattern reversi of 0.20 cpd horizontal bars, and when the TV went from all black to all white (2 to 33 cd/m<sup>2</sup>). Preliminary data analysis revealed CDM increased amplitudes and latencies of certain components in all three responses. These experiments indicate that the CDM effect on visual evoked potential amplitudes is both stimulus intensity- and spatial frequency- but not orientation-dependent. 110.5 DIFFERENTIAL EFFECTS OF HYPOTHERMIA AND ANESTHESIA ON FLASH-EVOKED POTENTIALS. Robert S. Dyer and William K. Boyes\*. Neurophysiology Branch, Neurotox. Div., U.S.E.P.A., Research Triangle Park, NC 27711.

Chloropent, a commonly used anesthetic for rat surgery, con-tains chloral hydrate and pentobarbital as active ingredients. At normal room temperatures (22C), a rat injected with an anesthetic dosage of Chloropent undergoes a decrease in rectal temperature from about 37.5C to about 33.5C within a two hour period. Anesthetics and body temperature alterations are both known to alter parameters of sensory-evoked responses. Howeve However few studies have quantitatively assessed the contributions of hypothermia to anesthetic-induced changes. Two experiments In the first, chronically implanted rats were were performed. injected on different days and in counterbalanced order, with either 0, 0.05, 0.10 or 0.20 ml Chloropent/100 gm b.w., while body temperature was maintained within the normothermic range (37C-38C). Flash-evoked potentials recorded 30 min later showed increased latencies but only minor (not statistically significant) changes in amplitude. The latency increases of peaks P1, N1 and P2 reached asymptote at the 0.10, 0.10 and 0.05 dosages, respectively, while latencies of later peaks increased progressively at all dosages. In the second experiment the same rats were anesthetized with 0.35 ml Chloropent/ 100 gm b.w. and rectal temperature was systematically varied between 31C and 37C. Latencies increased extensively (>30%) with this level of hypothermia. P1N1 amplitude doubled when temperature was lowered to 31C, but P2N2 and N2P3 amplitudes declined over the same temperature range. These studies show that hypothermia is a more potent modifier of flash evoked potentials than is Chloropent anesthesia. The findings also suggest that previously reported alterations in evoked potentials following anesthesia may have been confounded with hypothermia. (\* - Supported by NRC Research Associateship) This is an abstract of a proposed presentation and does not reflect EPA policy.

- 110.7 CHOLINERGIC EFFECTS ON THE VISUAL EVOKED RESPONSE OF THE CAT.
  - CHOLINERGIC EFFECTS ON THE VISUAL EVOKED RESPONSE OF THE CAT. A.W. Kirby, R.W. Wiley\* and T.H. Harding\*. U.S. Army Aeromedical Research Laboratory, Ft. Rucker, Alabama 3636. Anesthetized and paralyzed adult cats were held in stereo-taxic headholder and fitted with appropriate corneal and auxiliary lenses to focus one eye onto a cathode ray tube (CRT). The other eye was occluded. Square wave luminance gratings were generated on the face of the CRT and phase alternated at 2 Hz. Visual evoked responses (VERs) were recorded with stainless steel bone screws over the visual and parietal cortex. Stimulus presentation and collection of response histograms were controlled by computer. And collection of response histograms were controlled by computer. Arterial blood samples were used to measure blood gases as well as acetylcholinesterase (ACHE) and butyrylcholinesterase (BuCHE) levels. Following determination of the baseline response and initial enzyme levels, diisopropyl fluorophosphate (DFP) (0.5 to 5.0 mg/kg) was administered IV over one minute. VERs and enzyme

5.0 mg/kg) was administered IV over one minute. VERs and enzyme levels were then periodically measured. Following DFP administration, reduction in VER amplitudes ranged from essentially no change after 0.5 mg/kg to 100% at higher doses. The maximum reduction was generally seen about 2 hours after DFP. Administration of atropine sulfate provided at least partial recovery. Coincident with VER reduction, blood AChE and BuChE reduction ranged from 40% to 97%. The VER showed

AchE and BuChE reduction ranged from 40% to 97%. The VER showed slow recovery, returning to baseline about twenty hours after DFP, even though there was no recovery in enzyme activity. Three cats received increasing doses of DFP separated from each other by 2 hours. The VER reduction was greater and AChE activity lower as the DFP dose was increased. BuChE activity was reduced by the initial dose but remained unchanged with increasing doses. Since atropine sulfate provided partial recovery of the VER, an initial accumulation of acetylcholine (ACh) is likely involved in the initial visual loss. Recovery of the VER without recovery of AChE or BuChE activity suggests that mechanisms in addition to ACh accumulation are involved. Finally, a graded reduction in VER and AChE activity but not BuChE activity following multiple doses of DFP suggests that only activity related to AChE is involved in this effect although both enzymes are found in the visual system. system.

VISUALLY EVOKED POTENTIALS TO CONTRAST STIMULI RECORDED AT THE 110.8 SUBCORTICAL, EPICORTICAL AND SCALP LEVEL. <u>G. Dagnelie<sup>\*</sup></u>, <u>J.Maier<sup>\*</sup></u> and <u>H. Spekreijse<sup>\*</sup></u>(SPON: European Neuroscience Association). Dept. of Visual System Analysis, Neth.Ophthalmic Res.Inst, P.O.Box 6411,

1005 EK Amsterdam, The Netherlands. Visually Evoked Potentials (VEPs) find an increasing number of applications in clinical diagnosis and monitoring of CNS and sens-ory lesions. Models of the electrical transfer of VEPs from cortex to scalp still lack precision to allow accurate analysis of cortical functioning by means of surface recordings. In order to im-prove such models developed in our department and in order to gain a better insight in the physiology underlying the VEP we have corded VEPs in alert rhesus monkeys at the subcortical, epicorti-cal and scalp level. The monkeys were trained to fixate an attention grating in the center of a high frequency monitor connected to a digital display system, on which a variety of stimuli could be presented.

Six electrode bundles, each consisting of 7 stainless steel wires, insulated except for .8 mm recording sites at relative distances of 5 mm, were implanted in the cerebrospinal fluid over the visual cortex and in deep brain layers under the visual cortex. Scalp electrodes were standard EEG cup electrodes. Simultaneous recordings were made from these 3 levels. The data show that topology in the cortical VEP corresponds

closely to known visual projections in primary visual cortex. In combination with the electrical transfer model a reasonable agreement between these VEPs and surface recordings can be obtained. Manipulation of stimulus parameters such as contrast, edge sharp-ness and temporal modulation of stimulus elements allow a comparison to known electrophysiological properties of cells in visual cortical areas. The use of sophisticated stimulus equipment and real-time computer facilities has been of great advantage in this analysis.

SPATIAL FREQUENCY TUNING IN THE VISUAL EVOKED POTENTIAL ELICITED BY SINE-WAVE GRATINGS. J.G. May\*, J.L. Reed\*, (SPON: R.W. Beuerman). Dept. of Psychology, University of New Orleans; LSU Eye Center, LSU Medical Center School of Medicine, New Orleans, 110.9

Eye tenter, too mean and the source of the second state visual evoked potentials (VEPs) exhibit a spatio-temporal inter-action. Responses to low spatial frequencies are greatest at high temporal frequencies, while responses to high spatial fre-quencies are greatest at low temporal frequencies. It is not clear with such techniques which components of the transient VEP contribute to this effect. In the present study, transient VEPs were recorded monopolarly from the occiput of two subjects using ronstant-luminance, pattern-appearance techniques. These VEPs vere recorded monoporary from the occupit of two subjects using constant-luminance, pattern-appearance techniques. These VEPs were obtained with sine-wave gratings that ranged in spatial fre-quency from 0.5 to 8.0 c/d in octave steps. Across this spatial frequency range, each grating was adjusted so that it was pre-sented at equal apparent contrast. The amplitudes of two reli-ble components NIO0-PI00 and NIO0-P200 were found to be sented at equal apparent contrast. The amplitudes of two reliable components, N100-P140 and N180-P230, were found to be differentially tuned to spatial frequency. The early component was of greatest amplitude at high (> 4.0 c/d) spatial frequencies, while the later component was greatest in amplitude at low (< 4.0 c/d) spatial frequencies. These tuning functions were invariant over broad ranges of suprathreshold contrast (5-40%) and duration (25-200 msec). These results suggest that spatial training poserved with steady-state methods may involve the differential predominance of these two components at different rates of stimulation. The possible role of transient and sustained mechanisms is discussed. anisms is discussed.

PERIPHERAL AND CENTRAL CONTRIBUTIONS TO THE CAT VISUALLY EVOKED 110.11

PERIPHERAL AND CENTRAL CONTRIBUTIONS TO THE CAT VISUALLY EVOKED CORTICAL POTENTIAL: ANALYSIS IN A VISUAL MASKING PARADIGM. John S. Tootle\* and Mark A. Berkley, Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306 Human psychophysical studies have shown that two brief visual stimuli, presented close together in time, interact in ways which may make either stimulus less visible. This phenomenon, called masking, has been investigated in anesthetized cats in order to elucidate the neural mechanisms involved. Thus, the amplitude of a visually evoked cortical potential (VECP) to a test stimulus (S2) presented at various intervals after a prior stimulus (S1), was measured in anesthetized, paralyzed cats under stimulus conditions shown to produce masking in human psychophysical experiments. The stimuli were either pairs of sinusoidal gratings with a spatial frequency of .5 cycles/degree, a contrast of .5 and average lumi-nance of 2.0 ft-L, or 3 ft-L spatially homogeneous flashes. S1 and S2 always had a duration of 50 msecs and were presented by in-stantaneously exchanging them for a 2.0 ft-L, 10° diameter circular adapting field. The amplitude of the VECP was found to be reduced when the test stimulus (S2) was presented after S1 at intervals shown to produce masking in the psychophysical experiments (onset asynchronies of 55 to 150 msecs). Reduced VECP amplitude was observed with both monoptically and dichoptically presented gratings and flashes. Response reduction to S2 with dichoptic stimulation was assumed to be cortical in origin. However, the response to the test stimulus (S2) was re-duced significantly less for dichoptically as opposed to monopti-cally presented stimuli, suggesting that the effect observed monoptically has both peripheral and central components. To isolate these components, two procedures were used:

cally presented stimuli, suggesting that the effect observed monoptically has both peripheral and central components. To isolate these components, two procedures were used: 1) varying the orientation and phase between S1 and S2, and 2) simultaneous recording from optic tract and visual cortex. The response reduction produced by monoptically presented gra-tings was greatest when the contours of S1 and S2 had the same spatial phase and orientation, and recovered by half when the ori-entation of the contours differed 6° to 15°. When S1 had a high contrast or low spatial frequency, VECP amplitude to the test sti-mulus showed some reduction at all orientations, indicating an additional non-orientation-selective effect. The simultaneous re-cordings of evoked potentials in the optic tract and visual cortex showed the response reduction measured in the optic tract was in-dependent of test stimulus orientation.

dependent of test stimulus orientation. The findings demonstrate that peripheral and central factors contribute to the VECP and probably to the masking phenomenon as well.

110.12 FAR FIELD VISUAL EVOKED POTENTIALS? <u>T. J. Hoeppner and</u> <u>Fred Turner</u>.<sup>\*</sup> Dept. of Neurol. Sci., Rush Medical College, Chicago, Ill. 60618.

Theoretically, any electrical potential whose occurrence is synchronized to a stimulus should be detectable at a distance using signal averaging techniques. This has been applied usefully in recording brainstem auditory evoked potentials from the human scalp. The present study explores the application of this principle to the deep structures of the visual pathway of the cat.

In cats anesthetized with pentobarbital, an electrode array was constructed to determine the distribution of the electric field over the skull produced by visual stimulation (diffuse flash). We identified two relatively well separated electrical fields over the anterior and posterior skull, respectively. The prominent anterior field appears to be generated by the retina. The prominent posterior field is presumably generated by the visual cortex, possibly with a contribution from the lateral geniculate nucleus (LGN). To determine the extent and strength of the electric field generated by the LGN, electrodes were lowered through cortex and white matter to the LGN and the averaged visual evoked potential was measured at increments of 0.5 mm. At the dorsal surface of the LGN, there was a large (100 - 300 uV) positive potential occurring 20 - 40 msec after the stimulus onset. There was a phase reversal across the LGN with a negative potential ventral to the LGN. Dorsal to the LGN, the positive potential decremented monotonically with distance from the LGN until reaching the Clare-Bishop area where a local positive potential obscured the smaller potential from the LGN. If an oblique penetration to the LGN was utilized, thus avoiding the Clare-Bishop area, a monotonically decreasing potential was obtained from the LGN to the cortex. This suggests that appropriately placed electrodes on the skull or scalp may also detect the activation of the LGN. Studies combining ablation of visual cortex and radiations with recording of visual evoked potentials will be necessary to confirm this.

# 110.13 RAPID VISUAL EVOKED POTENTIAL INDEX OF CORTICAL ADAPTATION.

J.I. Nelson, W.H. Seiple, M.J. Kupersmith and R.E. Carr. Dept. Ophthalmology; NYU Sch. of Med; New York, NY 10016 Contrast thresholds and acuity limits were measured in four observers with the swept visual evoked response (VER) technique. In this technique, sine wave grating contrast or grating spatial frequency is electronically varied while the subject's evoked response is retrieved in real time using lock-in amplifiers (without averaging). For example, contrast is made to slowly decrease in time, causing VER amplitude to fall. The threshold value of the stimulus may be inferred from the point at which VER response has fallen to zero. This is termed a downward contrast sweep.

Large contrast threshold elevations occur when downward rather than upward contrast sweeps are used. From previous analysis of the instrumentation we knew these shifts could not have a technical origin (Nelson, Seiple, Kupersmith & Carr, submitted). We hypothesized that downward sweeps are adapted. Thresholds averaged 4.25 times higher for adapted sweeps (contrast swept from 20% to 0.1% over 20 seconds). Differences in spatial frequency sensitivity were considerably less between up and down sweeps.

Differences in spatial frequency sensitivity were considerably less between up and down sweeps. Rotating stimulus orientation during a sweep lessens adaptation, but typically not as much as using the unadapted sweep direction. 1 minute of prior exposure to a highcontrast stimulus elevates threshold, but typically not as much as using the adapted sweep direction. We conclude that up/down threshold differences are due to spatial frequencyand orientation-selective cortical adaptation. The swept VER technique can reliably measure adaptation to contrasts as low as 1.25% which fade within seconds to

The swept VER technique can reliably measure adaptation to contrasts as low as 1.25% which fade within seconds to threshold. Our findings are consistent with the view that cortical adaptation commences at threshold levels of excitation. The rapidity of adaptation's onset is consistent with the recent suggestion that adaptation provides a gain control for contrast sensitivity.

The novel ability to obtain a quantitative measure of cortical adaptability which is both psychophysically and neurophysiologically interpretable provides a useful tool for both basic and clinical research.

#### SPECIFICITY OF SYNAPTIC CONNECTIONS

111.1 THE SPECIFICITY OF NEW ELECTRICAL SYNAPSES IN THE ADULT <u>HELISOMA</u> NERVOUS SYSTEM DEPENDS UPON THE INTEGRITY OF EXISTING <u>SYNAPSES</u>. A.C.M. Bulloch. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada, T2N 4N1. Adult neurons of the mollusc <u>Helisoma</u> exhibit neuritic sprouting during organ culture which results in the development of new electrical synapses (Bulloch and Kater, J. Neurophysiol. <u>48</u>, 569-583). Most of these new connections are transient, however, and the present study is part of an ongoing investigation into the signals responsible for elimination of these new synapses. Specifically, this study tested the possibility that the dissolution of new, normally transient synapses requires the integrity of existing synaptic connections.

The integrity of existing synaptic connections. The symmetrical, paired buccal ganglia of <u>Helisoma</u> were cultured <u>in vitro</u> using a modified Liebowitz-15 medium. This study focused on the normally transient, new electrical synapse between the paired neurons 19 and neurons 5. The development of this connection was induced by proximal crush of the axons of both neurons 19 and neurons 5, a condition which ensures overlapping central growth and subsequent electrical coupling of these neurons. In Control preparations the extant 19-19 connection was intact, whereas in Experimental preparations this connection was broken by crush of the commissure between the pair of buccal ganglia. Preparations were assayed after short term (2 days) or long term culture (7-14 days) to determine the strength and stability of 5-19 electrical coupling.

Transient 5-19 coupling was observed in Control preparations as expected. In Experimental ganglia, i.e., those in which the extant 19-19 connection was disrupted before 5-19 coupling could develop, 5-19 coupling was stabilized. Thus, in the absence of an existing synapse between the two neurons 19, a normally transient 5-19 connection is stable. It is concluded that the signals to break normally transient

It is concluded that the signals to break normally transient connections between adult  $\underline{\mathrm{Helisoma}}$  neurons depend upon the integrity of existing connections. A previous study indicated that these signals require the presence of the soma rather than the axon of neurons with extant connections. Together these observations demonstrate that the persistence of the extant synapse itself in addition to the neuronal somata is needed to regulate new connections in this adult nervous system.

111.2 FORMATION OF ELECTRICAL COUPLING BETWEEN SPECIFIC REGENERATING NEURONS IN CELL CULTURE IS PREVENTED BY THE PRESENCE OF A RESIDUAL AXON. P. G. Haydon and S. B. Kater. Department of Zoology, University of Iowa, Iowa City, IA 52242. Identified <u>Helisoma</u> neurons with different neurotransmitters can be isolated from their normal ganglionic environment

Identified <u>Helisoma</u> neurons with different neurotransmitters can be isolated from their normal ganglionic environment and plated in cell culture where they grow neurites and form chemical and electrical synaptic connections. As has been previously demonstrated <u>in situ</u> (Murphy and Kater, Brain Res. 186:251, 1980) the presence of an axon in cell culture determines the locus of new neurite outgrowth and, furthermore, the presence of an axon affects the temporal competence of neurons to respond to a growth-promoting factor(s) (see Bodnar and Kater, these abstracts). Of primary importance to the present study is that the presence of an axon stump determines whether electrical synaptic connections can form between a pair of identified dopaminergic and serotonergic neurons. Electrical synaptic connections form where overlapping neuritic outgrowth occurs between cells initiating outgrowth as simple spheres. In contrast, in every case where either or both of the potential partners had even a small axon stump, overlapping neuritic outgrowth always failed to produce electrical synapses. Given the obvious importance of an axon stump in culture it is important to determine the conditions regulating whether or not axons are maintained or lost. We have found that we can reliably control whether these cultured neurons maintain their projecting axon or become essentially spherical. In cell culture axons remain only if they contact and adhere to the substrate, whereas neurons plated with their axon floating resorb their axon within hours.

These results on the effects of the axon stump on both the ensuing neurite regeneration and the potential for whether or not neurons interconnect indicates a significant stabilizing and regulatory influence for the normal morphologic features of these adult neurons.

Supported by PHS grant grant NS 18819.

111.3 SPECIFICATION OF THE STRENGTH OF ELECTRICAL CONNECTIONS BETWEEN ISOLATED IDENTIFIED NEURONS IN VITRO. C. S. Cohan and S. B. Kater. Dept. of Zoology, Univ. of Towa, Towa City, IA 52242.

Connectivity in the central nervous system can be highly precise in terms of <u>which</u> neurons interconnect. Although less directly studied, the <u>magnitude</u> of particular connections also appears to be specified. This report asks whether the strength of specific connections is an intrinsic property of particular neurons that is expressed in isolation from the normal CNS environment.

The identified neurons of the buccal ganglia of the snail, <u>Helisoma</u>, allow high resolution analysis of synaptic connections. Electrical connections are common among buccal neurons and their strength can be readily quantified. In the ganglion the magnitude of the coupling between bilaterally symmetric pairs of identified neurons occurs within a narrow, neuronspecific range. For example, the coupling coefficient measured in situ, for salivary effector neurons 4R and 4L is  $0.54\pm.11$ which is about 4 times that of protractor motoneurons 19R and 19L. Such specificity is apparent not only in normal ganglia but also in new connections that are induced to form during regeneration in adult animals (e.g.  $0.17\pm.03$  for 5R and 5L). Thus, the strength of electrical connections between pairs of identified neurons <u>in situ</u> appears closely constrained. The relative roles of intrinsic and extrinsic factors in determining the strength of electrical connections between

The relative roles of intrinsic and extrinsic factors in determining the strength of electrical connections between buccal neurons was explored by removing neurons from their normal environment and plating them in cell culture. Identified neurons 4, 5, and 19 readily grew when cultured in a brain-conditioned medium and coupled to one another. All 3 neuron types were able to interconnect with one another. When like-neurons were plated together the strength of electrical connections was neuron-specific. The coupling coefficients for pairs of neurons 4  $(0.27\pm.1)$ , neurons 5  $(0.50\pm.29)$ , and neurons 19  $(0.15\pm.09)$  were significantly different from one another. When different identified neurons were plated together, the strength of coupling appeared to be determined by the neuron with the lowest coupling in like-pairs (e.g. coupling coefficient between neurons 5 and 19 was  $0.13\pm.07$ ). These data suggest that the strength of electrical connections is determined, in part, by intrinsic neuronal properties. However, since the strength of coupling <u>in situ</u> differed from that of isolated neurons in cell culture, synaptic strength may be biased by extrinsic factors as well. Supported by a grant from the Muscular Dystrophy Assoc. and PHS grant NS 18819.

111.5 SURVIVAL AND MATURATION OF CEREBELLAR GRAFTS IN SITU IN HOST CEREBELLIM. P. Bickford, H. Bjorklurd<sup>++</sup>, L. Olson<sup>++</sup>, B. Hoffer<sup>+</sup>, and R. Freedman<sup>+</sup>. Dept. Fharmacology, Univ. Colorado Health Sci. Ctr., Denver CO 80302, and <sup>+</sup> Dept. Histology, Karolinska Inst., Stockholm Sweden.

Cerebellar grafts in situ in host cerebellum were analyzed for survival, maturation, and organization of the grafted tissue. The cerebellar grafts survived transplantation well. Histological examination revealed typical trilaminar organization with clearcut foliation.

Two strategies were used to determine electrophysiological maturation of the cerebellar grafts: spontaneous Purkinje (P) ceil discharge and responses to surface (local) stimulation. Adult P cells usually manifest a uniform and rapid discharge rate. P neurons recorded from intracranial cerebellar grafts also possess sustained regular activity. A total of 24 neurons from these grafts had a mean discharge rate of 19.3 ± 1.7 spikes per second. This compares with a discharge rate of 26.8 ± 1.0 for adult P cells in situ (N=30).

Patterns of activity can be readily analyzed using interspike interval histograms. P cells from adult animals usually have a small initial peak at 2-5 msec representing climbing fiber bursts and a much larger peak at 20-75 msec representing the most probable intervals for single spike discharge. Histograms from graft P cells show a prominent single spike modal peak. No initial climbing fiber peak is seen, nor are any complex spikes apparent on the oscilloscope tracings.

In the intact cerebeliar cortex, surface (local) stimulation can excite and/or inhibit P cells. Excitation is mediated by parallel fiber synapses onto P cell dendritic spines. Inhibition is modulated by local GABAergic interneurons, the basket and stellate cells. As evaluated with post stimulus time histograms (PSTM's) both local excitation and inhibition can be obtained from intracranial cerebellar grafts in a graded fashion.

Taken together these data show that cerebellar grafts in situ in host cerebellum demonstrate organotypic development.

This research was supported by USPHS grant DA 02429.

111.4 TRANSITORY EXPRESSION OF BOTH MOSSY AND CLIMBING FIBER PHENOTYPE ON SINCLE DEVELOPING CEREBELLAR AXONS. C. A. Mason and E. <u>Gregory\*</u>. Dept. of Pharm., N.Y.U. Med. Ctr., New York, NY 10016. Many afferent axons wait in target zones before the onset of synaptogenesis. In the cerebellum, climbing and mossy fibers interact with different targets, forming axons with characteristic morphologies. In cerebellar slices, we have examined the initial steps in the expression of axon phenotype and specific interactions with their targets. Bundles of axons were filled with HRP and studied in the light and electron microscope (Mason, 1982, Soc. Neurosci. Abstr. 8:301). At birth, before formation of cortical layers, axons labeled via the peduncular tracts extend well into the cerebellar anlage, and few growing tips are found within tracts. All axons have a similar structure: they branch infrequently and have either bud-like endings or small growth cones ( $\leq 5$  µm) with several filopodia. Immunocytochemical staining of cerebellum with antisera to neurofilament protein (Bovolenta <u>et al.</u>, this meeting) reveals that axons arrive in the cerebellar anlage and if the that axons arrive in the cere of the anlage until birth, indicating a long waiting period.

early as of uays prenatal and remain the the other of the anage until birth, indicating a long waiting period. By postnatal day 4-5, axon branches bear either large en passant or terminal expansions with many filopodia (mossy-fiberlike (MF)). These expansions establish glomerular contacts with granule cell dendrites. Others have finely branched endings with small foliate growing tips (climbing fiber-like (CF)), that contact Purkinje cell somatic spines. In the second postnatal week, each type is identifiable as CF- or MF-like, especially as CF extend over two or more adjacent Purkinje cells. However, during this period many individual axons display both morphologies and synaptic connections. That is, they bear some branches that extend into the granule cell layer and others that enter the Purkinje cell layer. The shape and synaptic connections of terminals on those branches are dictated by the respective layer, including the overbranching of CF-type branches in the Purkinje cell layer. Such fibers are rarely seen in late postnatal or mature cerebellum.

Thus, while afferent axons wait in the cerebellar anlage, they do not express their characteristic phenotype. Once target regions mature, some single axons then make supernumerary contacts not only with correct target cells, but also with incorrect cell populations. Whether these combination fibers evolve from expansion of axon terminals that have contacted both cell populations while in the waiting period or from secondary growth of filopodia must be determined. (Supported by NIH grant NS-16951. C.A.M. is recipient of a RCDA and an Irma T. Hirschl Career Scientist Award.)

111.6 CHOLINERGIC TRANSPLANTS EXHIBIT SPECIFICITY IN REINNERVATING THE ADULT RODENT HIPPOCAMPUS. Lawrence F. Kromer, Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, Vermont. The dorsal hippocampus (HPC) of adult mammals can be completely denervated of its normal cholinergic input (originating in the

The dorsal hippocampus (HPC) of adult mammals can be completely denervated of its normal cholinergic input (originating in the medial septum and diagonal band) by transecting the dorsal fornix and fimbria. Moreover, this cholinergic septal projection can be reinstituted by transplanting a piece of embryonic septum to the lesioned surface of the host HPC (Björklund & Stenevi, 1977, Cell Tiss. Res. 185:289). The pattern of this reinnervation appears to mimic the normal cholinergic septal input to the HPC (Björklund et al., 1979, Brain Res. 173:57), even when there is a long delay between the cholinergic denervation and the septal transplantation (Kromer, 1982, Brain Res. Bull. 9: 539). These observations raise the question whether this cholinergic reinnervation can arise only from septal cholinergic neurons or whether other embryonic CNS cholinergic cells also can innervate the denervated adult HPC.

In the present study embryonic cholinergic neurons from the region of the nucleus cuneiformis in the brainstem of fetal rats (ED 13-14) were transplanted to the lesioned surface of the anterior HPC in adult rats which received a fornix/fimbria transection immediately prior to the transplantation. The presence of cholinergic cells and axons within the transplant and host HPC was monitored by staining for acetylcholinesterase (AChE). At all survival periods studied (1-6 months), the brain-stem implants exhibited excellent survival and contained large numbers of AChE neurons and possessed a dense AChE plexus. However, in contrast to control specimens which received an embryonic septal transplant and exhibited extremely sparse ingrowth of AChE fibers into the host HPC even after an in situ survival of six months. Many brainstem specimens exhibited a dramatic and abrupt termination of AChE staining at the interface between the implant and the host HPC by they usually were restricted to the density or pattern of AChE fibers within the host HPC but they usually were restricted to the densite within the host HPC but they usually were restricted to the dentate hilus immediately bordering the transplant. In no brainstem specimen was the density or pattern of AChE fibers in the HPC symptone to the density or pattern of acether fibers in the HPC symptone to the density or pattern of a size specimen specimen with embryonic septal transplant.

the HPC similar to that observed in normal animals or in specimens with embryonic septal transplants. These results suggest that there is specificity in the cholinergic reinnervation of the HPC in an adult rodent when it is denervated of its cholinergic septal input. Thus, although embryonic neurons from different regions of the CNS may contain the same transmitter substance, only cholinergic cells from the appropriate presynaptic structure appear competent to replace this lesioned projection. (Supported by NIH Grant NS-18126). 111.7 SPECIFIC REINNERVATION OF DEVELOPING HINDLIMB FOLLOWING SPINAL MOTONEURON AXOTOMY. <u>P.B. Farel</u> and <u>S.E. Bemelmans<sup>8</sup></u>. Dept. of Physiology, Univ. N. Carolina Sch. Med., Chapel Hill, NC 27514. Regenerative specificity of an axotomized spinal motoneuron

Regenerative specificity of an axotomized spinal motoneuron requires that the injured motoneuron first elongate its axon to the hindlimb and then form functional contacts with, and only with, its appropriate target. We are interested in the possibility that the developmental mechanisms responsible for the initial formation of specific patterns of neuronuscular connectivity can act to produce greater specificity of regeneration in immature animals than is found in adults. Experiments were performed on bullfrog tadpoles (Rama <u>catesbeiana</u>) because their large size permits surgical procedures to be performed with facility even at early stages of development.

The hindlimbs in frog are innervated by motoneurons of the lumbar lateral motor column (LMC). Muscles derived from the ventral premuscle mass are innervated by motoneurons located dorsally in the LMC, and motoneurons innervating more proximal limb regions are located in the rostral half of the LMC. Specificity of hindlimb reinnervation following transection of the three lumbar ventral roots was assessed by placing HRP in circumscribed hindlimb regions and comparing the locations of retrogradely labeled hindlimb motoneurons with those found in normal, unoperated tadpoles.

Previously, we have shown that normal specificity of innervation is lost following ventral root transection after stage XIV (Soc. Neurosci. Abstr., §, 436, 1982). In the present study, specificity of reinnervation was assessed during limb bud and early foot paddle stages of development (stages IV-VII). At these stages, the major nerve trunks of the hindlimb are evident, and the muscle masses of the thigh are forming; however, individual muscle groups are not yet distinguishable. HRP was applied to the ventral thigh premuscle mass in normal tadpoles and in experimental tadpoles 6-8 weeks after lumbar ventral root transection. In normal tadpoles (n=8), 89% of the retrogradely labeled motoneurons are located in the dorsal half of the LMC. Sumilarly, in experimental tadpoles (n=6), 87% of the retrogradely labeled motoneurons were located in the dorsal half of the LMC. Further, a comparable tendency for clustering of labeled motoneurons in the rostral half of the LMC was seen in experimental and normal tadpoles.

Axotomy of immature motoneurons is thus followed by specific reinnervation of the hindlimb. The mechanisms underlying this specific reinnervation are presently under investigation. Supported by NIH grants NS14899 and NS16030.

111.9 EMBRYONIC NEURAL RETINA TRANSPLANTED TO SPINAL CORD. L. K. McLoon, M. A. Sharkey and R. D. Lund. Dept. of Anatomy, Medical Univ. of South Carolina, Charleston, SC 29425. Embryonic neural retina of rats, when transplanted over the tectum of

Embryonic neural retina of rats, when transplanted over the tectum of newborns, develops connections with only those nuclei which normally receive retinal projections (McLoon and Lund, '80, Exp. Brain Res.). The possibility existed that the retina might also form projections when confronted with a developing non-visual sensory system. To test this, E14 retinae were transplanted over the dorsal columns in the spinal cord at the level of Cl or C2. At this time, the sensory fibers are still growing through this region. Two experimental paradigms were used. In one, the cord was left intact with only the meninges disrupted. In the second, a lesion was placed in the cord at the time of transplantation, which interrupted the dorsal columns.

One month after transplantation, the cords of the host animals were exposed. If a transplant was visible, it was injected with HRP. If no transplant was evident, the dorsal columns were injected with HRP. Both sets of animals were perfused with 2% glutaraldehyde and sectioned frozen. Sections were processed for HRP histochemistry by reaction with DAB or TMB.

Transplants were found in 75% of the experimental animals. As in previous studies, the retina differentiated and the normal cell and plexiform layers were clearly discernable. Injections of HRP both into dorsal columns or into the transplants failed to back-fill any ganglion cells in the transplants, even in cases where the transplants were embedded in the host spinal cord. After injections of HRP into the transplants, no fibers were seen coursing between the transplant and the host spinal cord. Neurofibrillar stains failed to demonstrate an optic fiber layer in these transplants. Electron microscopic examination of the transplants also demonstrated the lack of large cells in the ganglion cell layer. This suggests the cells in the ganglion cell layer may be displaced amacrine cells. Although retina survives and differentiates when placed into spinal cord, it is unable to form connections with this non-visual sensory system. The possibility of initial non-specific outgrowth which is retracted during development is currently under investigation. (Supported by NIH Grants 5-R01-EY03326-04 and 1-R01-EY04627-01)

111.8 AFFERENTS AND EFFERENTS OF CORTICAL TRANSPLANTS IN HOST RAT CORTEX. <u>F.-L.F. Chang, J.G. Steedman\* and R.D. Lund</u>. Dept. of Anatomy, Med. <u>Univ. of S.C.</u>, Charleston, SC 29425. & Univ. of Pittsburgh, Pittsburgh, PA 15261.

Pittsburgh, PA 15261. An approximately 2 mm<sup>2</sup> superficial lesion of the left occipital cortex was made by suction on a series of newborn Long-Evans pigmented rats. In its place was laid a sheet of posterior cortex from E15 rat embryos. The objective of the experiment was to see whether the transplanted tissue would make connections with the host brain and whether these connections would reflect the origin and location of the transplants.

Would reflect the origin and location of the transplants. One to 3 days after transplantation, the host pups were injected intraperitoneally with tritiated thymidine (5  $\mu$ Ci/g body wt.) to help the later identification of the transplant. After 1-2 months, the transplants were located and labeled with a dry pellet of HRP. Brains were processed using TMB and DAB as chromogens. Seven animals with HRP clearly localized in the transplant were used for this study. Transplants were typically located on top of some remaining host cortical tissue. Labeled cells were seen in the host brain in the opposite cortex (6 animals), and ipsilateral thalamic nuclei (6 animals). Labeled cells in opposite cortices were frequently in areas more laterally located than the homotopic positions of the transplants. The thalamic nuclei labeled (following the terminology of Paxinos and Watson, '82) were lateral posterior (3 animals), centrolateral/paracentral (2 animals), ventrolateral (2 animals) and ventroposterior lateral (1 animal). The lateral geniculate nucleus ipsilateral to the transplant was largely degenerated as a result of the original lesion.

HRP filled fibers were also found in the dorso-medial part of the ipsilateral striatum after transplant labeling suggesting a transplant projection to the striatum. After HRP labeling the ipsilateral thalamus, filled cell bodies were found in transplants, suggesting that there is a reciprocal connection between transplant and thalamus. More detailed mapping of transplant efferents is now underway. These results showed that rat cortical transplants located in cortex do

These results showed that rat cortical transplants located in cortex do connect with host brains. However, they do not substitute for the missing cortex but rather seem to make connections with regions which would be expected to project to cortex around the edge of the original lesion. This raises the possibility that the connections which define individual cortical areas are determined by their context. Supported by EY 03326, MUSC Fellowship (to F.-L.F.C.).

111.10 ALTERATIONS OF WING MOTILITY AND MOTONEURON NUMBER FOLLOWING HETEROTOPIC NEURAL TUBE TRANSPLANTATION IN CHICK EMBRYOS.

P. Cauwenbergs\*, E. Cosmos and J. Butler\*. (Spon. J. Mazliah). Dept. of Neurosciences, McMaster Univ. Health Sciences Centre, Hamilton, Ontario. L8S 325. Thoracic neural tube segments transplanted to the brachial

Thoracic neural tube segments transplanted to the brachial region of chick embryos are viable, form a brachial plexus and make contact with the brachial musculature during the first 10 days <u>in ovo</u>. However, as development proceeds, the nerve-muscle contacts uncouple and the muscles deteriorate (Straznicky, K., <u>Acta.Biol.Hung.18</u>:437,1967;Butler,J. <u>et al.,Can.J.Neurol.Sci</u>. <u>9</u>:360,1982).

As a primary effort to understand the contributing roles of thoracic nerves and brachial muscles to the uncoupling phenomenon, we selected to examine both wing motility to monitor functional interaction and the status (number and structure) of motoneurons in the lateral motor column (LMC) of experimental versus control embryos.

wersus control embryos. To prepare experimental embryos, the brachial segment of the neural tube was extirpated at 48-52 hr and replaced by the thoracic segment of a donor embryo (50-53 hr). Controls were either unoperated or had received a brachial neural tube transplant. Daily observations of wing movements during 10 minute periods (M/10) were recorded from embryonic day-6 onward. Through day-8, the frequency of wing movements of experimental and control embryos was similar. By day-8, all embryos exhibited approximately 90 M/10. However, during subsequent development a dramatic change was noted. Whereas the frequency of wing movements of control embryos continued to increase and reached a peak value of 340 M/10 at day-14, experimental embryos demonstrated a reverse trend, <u>i.e.</u>, the frequency attained a peak value of 140 M/10 at day-10 and, then, rapidly decreased. By day-16 only slight move-

These motility observations provide evidence that initially foreign thoracic nerves do make functional contact with the brachial musculature. However, at a crucial period in development, marked by the onset of the formation of permanent nervemuscle junctions, the foreign nerves are deemed inappropriate for brachial muscles. The steady decline in wing motility of experimental embryos beyond day-10 monitors the progressive uncoupling of thoracic nerves and brachial muscles. Correlative analyses of the LMC revealed that, prior to the decline in wing motility, prolonged motoneuron survival occurred in experimental embryos. However, coincident with the loss of functional innervation, neurothanasia proceeded rapidly in the transplanted thoracic neural tube.

TARGETTING BY SURGICALLY MISROUTED OPTIC FIBERS IN GOLDFISH 111.11 WITH AND WITHOUT IMPULSE BLOCKADE Ronald L. Meyer, Developmental Biology Center, University of California, Irvine, California 92717

Optic fibers which innervate lateral posterior optic tectum were dissected from surrounding tectal tissue and redirected into the anterior medial edge of the opposite host tectum. The normal pathway at this entry site leads to medial posterior tectum. The eye innervating host tectum was removed at the same the end of the deflection or up to 18 months prior to deflection. The growth of deflected fibers was followed by autoradiography from 1 to 11 months after deflection. Roughly half of the deflected fibers immediately grew later-

koughly half of the deflected fibers immediately grew later-ally across the anterior end of tectum and then posteriorly within lateral tectum. The other half grew in a posterior-lat-erial direction from the insertion site. By 2 months most label was clearly in the lateral half of tectum and showed a weak tendency to be heavier posteriorly.

This contrasts to the medial labelling previously seen when medial posterior fibers were inserted into this same anterior medial position (BR 155:213). The laterality of the label did not noticeably change from 2 to 11 months after deflection and was not diminished in teeta which had been denervated for 18 months prior to deflection.

To test whether the capacity of deflected lateral posterior fibers to bypass denervated medial tectum required impulse act-ivity. Activity was chronically eliminated by periodic intra-ocular injections of tetrodotoxin (TTX) during regeneration. At 2 months after deflection in fish with simultaneous enucle-ation or enucleation 1 month prior to deflection, the innervation pattern was essentially the same as in fish without TTX. TTX also had no obvious effect on the innervation formed following deflection of medial posterior fibers. Thus TTX does not effect the "active" formation of gross topography. This suggests that the formation of refined topography which is inhibited by TTX (Dev. B. R. 6:293) represents a different patterning mechanism. (Supported by PHS Grant NS15381.)

# 111.12 EFFERENT FIBER PROJECTIONS FROM TRANSPLANTED EMBRYONIC SUPERIOR COLLICULUS IN RAT.

J.G. Steedman\*, A.R. Harvey\* and R.D. Lund (SPON: S.M. Bunt). Dept. Anatomy, Medical University of South Carolina, Charleston, SC 29425 and Dept. Anatomy, University of Pittsburgh, Pittsburgh, PA 15261. Presumptive superior colliculus of embryonic day 15 Long-Evans

Hooded rats was transplanted to the superior colliculus of newborns. It has been shown that such transplants connect with the host and receive has been shown that such transplants connect with the host and receive afferents from a wide variety of host brain centers (Harvey and Lund, J. comp. Neurol., <u>202</u>:505(1981)). The projections of transplant neurons to the host have been studied using horseradish peroxidase (HRP) and H-proline injected into the transplant 1-8 months after the operation. Alternate sections through host brainstem and transplant were stained for the presence of HBP, with diaminobenzidine or tetramethyl benzidine, and transported H-proline was demonstrated by autoradiography. Holmes' silver and Nissl stains were used to show general fiber and cell

architecture respectively. Whereas afferents to such transplants have been shown to come from remote parts of the brain (e.g. retina, cortex), the efferent projections were all to local structures at comparatively short range. Projections were never found to spinal cord or pontine nuclei. The principal output was to the host's superior colliculus and was largely confined to the deeper part of stratum griseum superficiale and below. The next most frequently found projections were to the central gray surrounding the cerebral aqueduct and to the midbrain tegmental nuclei lateral to this. Connections to these deeper parts of the brain stem were seen in those cases where the transplant was embedded in the host tissue; in those cases where the transplant was connected to the host used in the of fibers, projections tended to be localised to the adjacent superior colliculus. Other areas in which efferents were seen were the pretectum and inferior collicults. Terminations in the latter have only been observed when the final position of the transplant in the host brain resulted in a connection bridge straight from the transplant to inferior colliculus. Connections with inferior colliculus demonstrate that such transplants are capable of with inferior colliculus demonstrate that such transplants. Connections connections uncharacteristic of the superior colliculus of the normal animal when mechanical constraints dictate. However, the best devel-oped efferent projections from these transplants are clearly those to the host's own colliculus. The short-range nature of these projections contrasts with those observed for both cortical and retinal transplants performed by identical techniques (Jaeger and Lund, J. comp. Neurol., 194: 571(1980); McLoon and Lund, Exp. Brain Res., 40:273(1980)). Supported by NIH grants EY 03326 & EY 04064 and a MUSC fellowship (to JGS).

111.13

NORMAL AND ABNORMAL DEVELOPMENT OF CALLOSAL PROJECTIONS TO THE OCCIPITAL CORTEX OF RATS. R.D. Lund, P.W. Land and F.-L.F. Chang. Dept. of Anatomy, Med. Univ. of S.C., Charleston, SC 29425 and Univ. of Pittsburgh, Pittsburgh, PA 15261. In previous studies we (Cusick & Lund, J. Comp. Neurol., 212:385 '82) found that neonatal eye removal in rats substantially modified the extent to which callosal fibers invaded area 17 when examined as adults. In this to which callosal fibers invaded area 17 when examined as adults. In this study, we have investigated how the callosal projection develops and when in development the abnormality resulting from enucleation can be distinguished from the normal pattern. We were especially interested to know whether the inception of visual function or some other event correlated with the normal and abnormal development. The projection was studied by injecting HRP or nuclear yellow into one cortex of a series of normal, one eyed or bilaterally enucleated rats of varying ages from 1 day to 18 days postnatal. After 1 day survival the brains were processed and reacted for peroxidase using TMB and DAB as chromogens. Two series of animals were studied using degeneration techniques after lesions involving one cortex to show orthograde projection

techniques after lesions involving one cortex to show orthograde projection patterns

At birth, the callosal pathway arises from the whole occipital cortex, but the terminals do not appear to ramify substantially in the cortex at this By day 5, a substantial callosal projection becomes defined at the stage. By day 5, a substantial callosal projection becomes defined at the 17/18a border of area 17. This sequence of events progresses in normal animals to day 12 when the adult pattern is achieved. During this process of retraction, the callosally projecting cells are focussed in bands above and below layer V. In the intermediate stages, the extent of area 17 occupied by labelled cells is greater than that occupied by the focussed terminal field. After eye removal at birth or 4 days postnatal, the callosal projecting cells and 17 than normal in the cortex contralateral to the eye removal. This effect already can be seen by postnatal day 9; and while there is loss of callosally projecting cells in area 17 corresponds closely to the timing of segregation of crossed and uncrossed optic input into lateral geniculate nucleus (Maxwell and Land, <u>Anat. Rec.</u>, 199:165 A, 1981). Because of this coincident timing and because optic axon

199:165 A, 1981. Because of this coincident timing and because optic axon segregation does not occur after eye removal, it is suggested that the ordering of primary optic input is an important event in determining distribution of calloc.d axons. The establishment of an adult pattern of callosal distribution by day 12 and the fact that early eye removal already has an effect by day 9, indicate that normal visual function has no influence on the gross shaping of the rat's occipital callosal projection, since these events precede eye opening. Supported by NIH grants EY03414, EY03447, EY04064 and MUSC Fellowship to F.-L.F. Chang. 111.14 FIBER ORDER IN THE HAMSTER PYRAMIDAL TRACT. K. Kalil and J. Keifer\*. Dept. of Anatomy and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706. Recent studies have shown that the arrangement of fibers

within nerve tracts may contribute to an ordered pattern of connections. We undertook a study of fiber order within the hamster pyramidal tract to determine how axons are arranged within the tract and whether this reflects the pattern of connectivity in corticospinal terminations.

Injections of HRP were made into the sensorimotor cortex or into their spinal cord targets. Animals ranged in age from newborns to adults. The TMB method was used to trace axons labeled in the anterograde or retrograde direction. Localized injections of sensorimotor cortex resulted in a

series of contiguous labeled fascicles within the pyramidal tract. The fascicles maintained the same relative position with respect to one another along the corticospinal pathway. Axons adjacent to one another in the pyramidal decussation, for example, could be followed into the same fascicle within the dorsal column, and fascicles arising from a similar rostro-caudal region of the cortex tended to cluster together within the pyramidal tract. This highly fasciculated pattern was apparent at stages early in pyramidal tract outgrowth.

Although neurons contiguous in the cortex appeared to maintain contiguity of their axons, it is not clear what unit of cortical organization is represented by individual fascicles. Moreover, since axons retrogradely labeled by HRP injections into a single or several adjacent spinal segments were widely dispersed throughout the pyramidal tract, it is not likely that individual fascicles simply represent axons destined for neighboring spinal segments.

Supported by NIH Grant NS-14428.

111.15 MAINTAINED TARGETS OF OCCIPITAL CORTICAL NEURONS WHICH TRANSIENTLY EXTEND A PYRAMIDAL TRACT AXON DURING DEVELOPMENT. Brent B. Stanfield and Dennis D.M. O'Leary, The Salk Institute, P.O. Box 85800, San Diego, CA 92138. During the first postnatal week a large number of pyramidal tract neurons are present in the occipital cortex of the rat, but over the next

During the first postnatal week a large number of pyramidal tract neurons are present in the occipital cortex of the rat, but over the next two weeks pyramidal tract neurons become restricted to the more rostral cortical fields. We have previously shown that this developmental restriction in the distribution of pyramidal tract neurons is due to collateral elimination rather than to cell death, since neurons retrogradely labeled through their transient pyramidal tract axon can be identified in the adult occipital cortex. In order to determine the sites to which the transient pyramidal tract

In order to determine the sites to which the transient pyramidal tract neurons in the occipital cortex send a collateral which is maintained in the adult, injections of either True Blue or Fast Blue (0.3 µl of 2% TB or FB) were made into the pyramidal decussation during the first postnatal week, and three weeks later (12-24 hours before being killed) injections of Nuclear Yellow (0.05-0.3 µl of 2% NY) were made into one of five second sites: (1) In some animals the second injection (NY) was placed in the pyramidal decussation. NY- and FB-labeled cells within layer V were found throughout the rostral cortex; most of these neurons were doublylabeled. Although the population of FB neurons continued back into the occipital cortex, no NY cells were seen in the occipital cortex, confirming our previous findings. (2) In the brains of animals in which the second injection (NY) was into the occipital cortex on one side, most of the NY-labeled neurons seen in the contralateral occipital cortex seen outside of layer V; none of the NY-labeled cells within layer V, was doubly-labeled with TB. (3) Similarly, no doubly-labeled neurons were found in those cases in which the second injection labeled ipsilateral associationally-projecting neurons. (4) When the second injection (NY) was into the superior colliculus, NY-labeled cells in layer V were broadly distributed in the neocortex, and many of the NY-labeled neurons, both in the occipital cortex and in the more rostral cortical fields, were doubly-labeled. (5) In cases in which the second injection site (NY) was in the pons, NY-labeled neurons were also found in layer V of the occipital cortex and a great many of these were doubly-labeled with TB.

In an additional series of experiments the two dye injections were made and the rat pups were killed during the first postnatal week. None of the pyramidal tract neurons in the occipital cortex was doubly-labeled when the second injection was into the contralateral cortex, but even at this early age, many of these cells were doubly-labeled when the second injection was into the superior colliculus.

These findings suggest that none of the neurons in the occipital cortex that transiently send an axon into the pyramidal tract extends a callosal collateral, but that many of these neurons do send a collateral to the pors or to the superior colliculus, or to both regions and that these latter projections persist in the adult. Supported by NIH Grant NS-18506.

### DEVELOPMENT AND PLASTICITY: SENSORY SYSTEMS

112.1 FUNCTIONAL DEVELOPMENT OF THE VENTRAL CORTICAL VISUAL PATHWAY MEASURED BY THE 2-DEOXYGLUCOSE METHOD. K.A. Macko, J.Bachevalier\*, C.Kennedy, S.Suda\*, L.Sokoloff, and M.Mishkin Lab. Neuropsych. and Lab. Cer. Metabol., NIMH, Bethesda, Md. In primates, striate (area 0C), prestriate (areas 0B and 0A), and inferior temporal cortex (areas TEO and TE) as far forward as the temporal pole constitute the ventral cortical visual pathway, which is now known to be critical for object recognition. The functional development of this pathway was traced metabolically in infant monkeys that were prepared with a unilateral optictract section combined with forebrain commissurotomy at 1 day, 1 week, and 1, 2, 3, and 5 months of age. This procedure allowed comparisons between "blinded" and functional cortical pathways. The 2-deoxyglucose method for quantitative measurement of local cerebral glucose utilization (LCGU) was applied an average of two days postoperatively in the four older animals while each was awake and visually stimulated.

and visually stimulated. From the autoradiographs, representative sections were chosen at lmm intervals throughout the ventral cortical visual pathway. Weighted averages of LCCU for each visual area were calculated by means of a computerized image-processing system. The results revealed systematic age-related changes in 1) absolute LCCU within the normal hemisphere and 2) differences in LCGU between the normal and deprived hemispheres.

In all cortical visual areas of the intact hemisphere, LCGU was lowest in the youngest subjects, peaked at 4 months, and then declined in the 6-month-old subject to levels found in adults. As in adults, the intact hemisphere of infants shows a progressive decline in LCGU along the ventral cortical visual pathway from a high in area OC (ranging from 26.1 µmoles/100g/min at 9 days to 88.1 at 4 months) to a low in anterior TE (ranging from 17.6 at 2 days to 59.7 at 4 months). This gradient was present in all subjects, but was most shallow in the two youngest. The deprived hemisphere showed reduced LCGU relative to the normal hemisphere in all areas of the cortical visual pathway at all aces. Also at all aces hemienberic differences were great-

The deprived hemisphere showed reduced LCGU relative to the normal hemisphere in all areas of the cortical visual pathway at all ages. Also at all ages, hemispheric differences were greatest in area OC and smallest in anterior TE. These differences, however, varied systematically with the age of the animal. Thus, for each cortical area, the relative difference between the normal and deprived hemispheres was smallest in the youngest subjects and approached the differences seen in adults only at about four months of age, the time at which LCGU appeared to neak.

four months of age, the time at which LCGU appeared to peak. This finding that adult levels of metabolic activity are not reached until about 4 months of age is consistent with behavioral data indicating that the neural capacity for visual object recognition is probably not developed until about this time (Bachevalier and Mishkin, <u>Int. J. Psychophysiol.</u>, 1983). 112.2 A COMPARISON OF THREE TASKS EVALUATING VISUAL FUNCTION FOLLOWING TRANSPLANTATION OF EMBRYONIC NEOCORTICAL TISSUE INTO THE LCN IN THE HOODED RAT. R.B.Wallace, G.D.Das\*, P. Jasin\*, K. Kaufman\*, M. Lazar\*, R. Smeyne\*, and J. Thompson\*. Developmental Psychobiology Laboratories. University of Hartford, West Hartford, CT 06117.

Embryonic forebrain tissue obtained from 17 day embryos was transplanted into the caudal diencephalon at the coordinates of the lateral geniculate nuclei in 4 month old Long-Evans hooded Following growth and differentiation of the transplanted tissue, the animals were tested behaviorally on three tasks de-signed to assess visual function - a light avoidance task, an overhead orientation task, and a radial arm maze task. The lig avoidance task employed an apparatus and procedure similar to The light that used by Altman in an earlier investigation (Amer. J. of Physiol., 202:1208, 1962). The specifics of the overhead orien-tation task are in a thesis submitted to the Department of Psychology, MIT (G.E. Schneider, 1966). Finally, the details of apparatus and procedure for the radial arm maze task are outlined in a paper by Barnes, Smith and Latto (Q.J. Exp. Psychol., 22: 239, 1970). Results from these animals on the set of three tasks were compared with data from animals that received surgical lesions at the coordinates of the LGN, with data from animals that received surgical lesions at the coordinates of the LGN followed by transplantation of embryonic neocortical tissue and finally with data from normal control animals. Two enucleated animals were also tested as an additional control condition. Following behavioral testing, all animals were sacrificed, per-fused transcardially with 10% buffered formalin, the brains blocked in the coronal plane and stained with CV for microscopic evaluation. Histological results indicated that in the trans-plant and lesion/transplant animals, the neocortical tissue had replaced much of the ventral and lateral thalamic nuclear groups. Behavioral analysis for the light avoidance task revealed that all groups save for the enucleated condition spent significantly more time in the dark portion of the matrix; the enuncleated ani-mals distributed their time 50/50 between dark and lighted areas of the matrix. Results for the overhead orientation task (check-erboard pattern) indicated no overall significant differences across the treatment conditions although the enucleated animals had essentially random response frequencies and the control ani-mals had the highest response frequencies. Finally, data from the radial area maze task showed all conditions to be significantly different except for the control-transplant comparison. Additional behavioral testing involving more complex visual tasks remains to be done in order to determine if more marked deficits become apparent under these conditions.

REFRACTIVE ERROR, GROSS MORPHOMETRY AND LIGHT MICROSCOPY 07 EYES FROM CHICKENS FOLLOWING LID-SUTURE. <u>Gail S. Tucker</u> and <u>Uri</u> <u>Yinon\*</u><sup>4</sup>. Bascom Palmer Eye Inst., University of Miami School of Medicine, Miami, FL 33136<sup>4</sup> and Goldschleger Eye Institute, Sackler School of Medicine, Tel-Aviv Univ., Tel-Hashomer, Israel<sup>2</sup>. Keratometry, retinoscopy, A-scan ultrasonography and gross measurements of the intact globe were used to study eyes in normal chickens and in chickens lid-sutured early in life. These analyses of the globe and dioptric apparatus demonstrated a consistent myonia in the treated eyes of the lid-sutured chickens 112.3

Normal chickens and in chickens hubstured early in The. These analyses of the globe and dioptric apparatus demonstrated a consistent myopia in the treated eyes of the lid-sutured chickens. Survival times post-surgery ranged from 3-7 months. The observed changes favoring myopia were: development of a negative refractive error (9 normal eyes,  $\bar{X} = +.75$  D; 7 lid-sutured eyes,  $\bar{X} = -14.03$  D); increased axial length (normal/lid-sutured,  $\bar{X} = 14.72$  mm/17.5 mm); and increased equatorial diameter ( $\bar{X} = 18.78$  mm/21.16 mm); but these same eyes exhibited increased corneal radius ( $\bar{X} = 4.99$  mm/5.56 mm). The change in refractive error (1 and unrelated to the age at lid-suture (3-29 days) or to whether one or both eyes were lid-sutured. Corneal diameter and anterior chamber depth were equally variable in normal paired eyes and in eyes from monocularly or binocularly lid-sutured chickens. Light microscope analyses were done using glutaraldehyde fixed eyes embedded in paraffin, serially sectioned and stained with hematoxylin/eosin. Except for outer and inner segment length, all retinal layers were thinner in lid-sutured eyes, but the degree of retinal thinning also varied with retinal location.

the degree of retinal thinning also varied with retinal location. The planimetric density of cells in the nuclear layers was higher in retinas from lid-sutured eyes compared with normal retinas. in retinas from lid-sutured eyes compared with normal retinas. Stratification in the inner plexiform layer was well-defined in the normal retina but was poorly defined in the lid-sutured retinas. Examination of the ciliary body demonstrated an augmentation of the surface folds in lid-sutured eyes, suggesting that an enlarged ciliary body might be associated with myopia in the chicken. Regional differences in the complexity of the surface convolutions may also be a factor. The relationship of these changes to the dynamics of eye growth and the possible meaning of ciliary body augmentation following lid-suture in the chicken will be discussed. Supported in part by NIH grant 2 R01 EY00376 09 (GST) and an institutional grant from Research to Prevent Blindness (BPEI).

MITOSIS IN THE DIFFERENTIATED RETINA OF XENOPUS LAEVIS 112.4 AlTOSIS IN THE DIFFERENTIATED RETINA OF <u>XENOPUS</u> <u>LAEVIS</u> LARVAE: NISSL, GOLGI, AND COLCHICINE STUDIES. <u>George J</u>. <u>Kokoris</u> and <u>Leslie J</u>. <u>Fisher</u>. Neurosci. Prog., Univ. of Michigan, Ann Arbor, Mich. 48109, and Dept. Ophthal., Henry Ford Hospital, Detroit, Michigan 48202 The inner nuclear layer (INL) of the retina in <u>Xeno-pus laevis</u> larvae grows throughout larval life. In add-tion of the rolls of the reline the roll.

pus laevis larvae grows throughout larval lire. In ada-ition to the gradual addition of new cells at the reti-nal margins, we have demonstrated, with <sup>3</sup>H-thymidine, the appearance of DNA synthesis within the differentia-ted INL of the older, central retina at metamorphosis (Kokoris and Fisher, 1979). Subsequent ultrastructural vealed immature cells and variations in cellular strat-ification within the INL, consistent with our autoradification within the INL, consistent with our autorad-iographic evidence of mitotic activity in this region (Kokoris and Fisher, 1982). To complete our analysis of anatomical plasticity in the central retina, and to verify the presence of mitosis in the INL, we have pre-pared retinae from <u>Xenopus laevis</u> undergoing metamorph-osis for Nissl, Golgi, and colchicine analysis. In Nissl-stained material, we observed cells in the

central retina with dark, columnar nuclei, resembling germinal cells seen in the retinal periphery. These nuclei contain a varying distribution of aggregated henuclei Contain a varying distribution of aggregated he-terochromatin, characteristic of dividing cells in var-ious phases of the mitotic cycle. Moreover, we observed cells in the INL resembling immature, post-mitotic neu-rons, similar to those seen in newly-differentiated re-gions of the retina. These were scattered throughout the INL of the central retina. Analysis of Golgi material revealed, in additon to

These were identical to germinal cells seen at the re-tinal margins. Apical and basal processes extend from these cells to traverse the width of the INL to varying depths. These processes resemble cytoplasmic spindles of neuroepithelial cells dividing within the immature retina.

Retinae treated with colchicine, a mitotic inhibitor, contained many mitotic cells arrested in metaphase. Many of these cells were located at the retinal periphery; however, a number of metaphase figures were seen in the differentiated INL of the central retina. Taken together, these data confirm that the INL of

the central retina, although well-differentiated, dis-plays a capacity for cellular addition, and extensive anatomical re-organization throughout metamorphosis.

BILATERAL TRANSITORY PROJECTIONS FROM AUDITORY TO VISUAL AREAS IN KITTENS. S. CLARKE\*, G.M. INNOCENTI, Inst. of Anatomy, Univ. of Lausanne, rue du Bugnon 9, 1011 Lausanne, Switzerland. Neurons connecting homologous and heterologous visual areas through the corpus callosum are more numerous and more widely 112.6

through the corpus callosum are more numerous and more widely distributed in newborn kittens than in adult cats; many callosal axons are eliminated during the first two or three postnatal months. Callosal connections between somatosensory areas and between auditory areas undergo a similar reshaping. We now report transitory projections from auditory areas to the contra-lateral and ipsilateral visual areas 17 and 18. The study was done by injecting - separately or simultanously - the retrograde fluorescent tracers Fast Blue (FB; 0.05 -0.1  $\mu$ l at 1.5 % per injection) and Diamidino Yellow (DY; 0.1 -0.3  $\mu$ l at 2 % per injection) into areas 17, 18 and into ectosylvian auditory cortex of 12 kittens on postnatal days 0 - 10. After injections in areas 17 and 18, labeled neurons were found ipsilaterally and contralaterally in all visual areas and in addition in the ectosylvian auditory region (A). The latter was identified by its position and also by the fact that when injected it yielded retrograde labeling of the medial geniculate body. Axons from A reach most of the contralateral raes 17 and 18 since small injections into the gray and white matter at i) the

Axons from A reach most of the contralateral areas 17 and 18 since small injections into the gray and white matter at i) the medial bank of 17, ii) different positions along the 17/18 border, iii) lateral parts of area 18, all label a certain number of neurons in A. The projection seems to be roughly topographically organized: caudolateral parts of A project to caudal 17-18, rostro-medial parts of A to nostral 17-18. Simul-taneous injections of FB and of DY show that neurons in A which project to the contralateral homologue are in layer III, deeper than those projecting to contralateral 17 and 18; very few neurons, if any, project both to A and 17-18. The ipsilateral one. Its neurons of origin are in layers II, III and VI. Injections of the two tracers in 17-18 of the two hemispheres indicate that the ipsilateral and contralateral projections arise from different neurons (although less than 1% of the callosal neurons do also project pislaterally).

of the callosal neurons do also project ipsilaterally). Experiments with fluorescent tracers or horseradish peroxi-dase in adults indicate that the contralateral projection disap-pears completely during maturation and the ipsilateral one almost completely; the few remaining neurons are mostly in layer γI.

Thus, ipsilateral cortico-cortical projections, similarly to the callosal ones, develop through a phase of transitory exu-berancy in which ephemeral "connections" are formed between areas belonging to different sensory systems. (NSF 3.628-0.80)

IN PIGMENTED RATS. S. M. Lu,\*D. E. Schmechel\*and C.-S. Lin, Dept. of Anatomy, Duke University Medical Center, Durham, N. C. 27710 Previous studies have demonstrated that neonatal and embryonic brain tissue from the mammalian central nervous system may survive transplantation to an appropriate host. In our experiments, a piece of cortical tissue about 2 x 3 mm<sup>2</sup> wide and less than 0.5 mm deep was removed from the left somatosensory cortex and replaced with a similar size piece taken from the right visual cortex of the same animal. The purpose of these experiments was to deter-mine the patterns of connections of the cortical grafts. In parti-cular, we want to know whether the connections formed between the transplanted tissue and the host depend on the site of origin, or, on the new position of the transplant.

TRANSPLANTATIONS BETWEEN NEONATAL VISUAL AND SOMATOSENSORY CORTEX

The transplantations have been carried out in several age groups, postnatal day 1, 2, 3, 4, and 5. This series also allowed us to investigate the effect of age on the formation of connections. All animals survived to 50 or more days of age and then were subjected to experiments designed to assess the connections of the transplants. Our present findings are summarized as follows:

1) From Nissl-stained sections, most of the grafted cortical neurons which survive in the transplant exhibit abnormal morphology.

2) In the acetylcholinesterase (Ach E) stained sections, the pattern of Ach E activity within the transplant is more random and less dense compared to the patterns seen in normal cortical areas

3) In glutamic acid decarboxylase (GAD) antibody-stained sections, utilizing the immunoperoxidase technique, the density of the reactivity in the transplant is higher than in the surrounding normal cortical areas.

4) The physiological properties of neurons in the transplants also were studied. For example, visual cortical neurons transplanted to the somatosensory area are now responsive to somatic stimuli; however, the intensity of peripheral stimulation re-quired to drive these neurons is much higher than for normal neurons.

5) In one case, a small amount of horseradish peroxidase was injected into transplanted visual cortex which responded to peripheral somatic stimulation. The retrogradely-labelled neurons were found in the ventrobasal nucleus of the thalamus. Further experiments are in progress.

In conclusion, our preliminary results suggest that thalamic In conclusion, our preliminary results suggest that thalamic afferents do invade and form synapses in the transplanted tissue, and that the new position of the grafts is the main factor in de-termining the connections between the graft and the host. DEVELOPMENT OF SENSORY CELL ORIENTATION PATTERNS IN THE SACCULE OF THE TOADFISH, <u>OPSANUS TAU</u>. <u>Bernd Sokolowski\*</u> (SPON. C. McCormick), Department of Anatomy, Georgetown University Medical School, Washington, D.C. 20007. 112.7

Medical School, Washington, D.C. 2000/. Sensory hair cell orientation, defined by the relationship of the kinocilium to the stereocilia, is a phenomenon observed in the inner ear of many vertebrates. In particular, different species of fishes have different hair cell orientation groups on the sensory epithelium of the saccule. For example, the adult toadfish has a four-quadrant saccule with two rostral groups that are oriented horizontally and two caudal groups that are oriented vertically. Hair cells lying in an area between the rostral and caudal patterns have neither of the four orientations but appear to be in transition toward a horizontal or vertical orientation. The purpose of the present study was to determine the inner ear development in the particulation and the more study was to determine the inner ear development in the toadfish embryo, using SEM and TEM, in order to gain a better understanding of the factors involved in causing these orientation patterns.

the factors involved in causing these orientation patterns. The toadfish saccule is initially established at the caudal pole of the otcyst in the 14 somite embryo by the development of kinocilia with very short stub-like stereocilia. The initial cluster of approximately 20 hair cell bundles is grouped in a circular pattern, having neither an adult type horizontal nor vertical orientation. This cluster of cells is maintained in the 20-25 somite embryo at which time an otolith, without an otolithic membrane, begins to form on top of these cells. As the otcyst begins to divide inter the new unreleased even inferient the initial cluster of heirs membrane, begins to form on top of these cells. As the otocyst begins to divide into the <u>pars superior</u> and <u>pars inferior</u>, the initial cluster of hair cells begins to move and separate across the saccular macula, without the addition of any new hair cell bundles. The division of the <u>pars inferior</u> from the <u>pars superior</u> is completed by the invagination of epithelial cells at approximately 5 days prior to hatching. At this time the otolith and otolithic membrane have substantially increased in size. In addition, hair cell numbers have not significantly increased from the initial 20 cells, but bundles from din the scored and cauded partices of the developing scored cell numbers have not significantly increased from the initial 20 cells, but bundles found in the rostral and caudal portions of the developing saccule have respective horizontal or vertical patterns. This observation suggests that orientation is established when movement occurs into these areas from the original central region. Once the embryo hatches, saccular hair cells proliferate over the entire macula with cells developing in the respective orientation of a region. Thus, the hair cells developing rostrally are horizontal, those developing caudally are vertical and cells developing in the central region are in transition.     Univ. Wisconsin, Madison, WI 53706.
    The effects of mechanical lesions that destroy the organ of Waisman Ctr..

Corti on the functional and structural development of auditory cortex were studied by combining microelectrode mapping of neurons' best frequencies with horseradish peroxidase histochemistry for tracing neural connections. Cochlear destruction was aseptically performed during the first postnatal week and cats were older than six months at the time of the combined electrophysiology/anatomy experiment. Best-frequency maps of AI contralateral and ipsilateral to the intact ear were obtained under Nembutal anesthesia.

As expected, the best-frequency distribution formed an orderly and complete tonotopic map in the contralateral AI and the physiology of its neurons were, qualitatively, normal in all respects (except of course that neurons were no longer binaurally sensitive). In control experiments, a large part of AI in normal adult cats is devoted to cells which are excited by a sound delivered through either ear alone, although acoustic intensity thresholds for the ipsilateral ear are markedly higher than those thresholds for the ipsilateral ear are markedly higher than those for the contralateral ear. Surprisingly, AI ipsilateral to the intact ear of our experimental animals showed a normal tonotopic representation comprised of single neurons and neuron clusters securely driven by best-frequency tonal stimulation in virtually every electrode penetration examined. Furthermore, the acoustic thresholds where as low as those obtained in AI contralateral to the intact ear in experimental or normal cats. Closely spaced electrode penetrations in AI ipsilateral to the intact ear also revealed that along the isofrequency dimension loci containing neurons with the lowest acoustic thresholds alternated with loci

neurons with the lowest acoustic thresholds alternated with loc containing neurons with the highest acoustic thresholds. These findings are surprising because in normal adult cats approximately 30% of AI is devoted to cells that are <u>never</u> <u>excited</u> and <u>only inhibited</u> by sound delivered through the ipsilateral ear. Our observations suggest that some change may have taken place within field AI ipsilateral to the intact ear. Whether this involves changes in connections or some functional where a finite and interval out through the interval of the interval. unmasking of ipsilateral excitability is not yet known. (HD-03352, BNS 7912939)

TOPOGRAPHIC DISTRIBUTION OF PRIMARY AUDITORY CORTICAL FIELD (AI) CALLOSAL NEURONS IN CATS REARED WITH UNILATERAL OR BILATERAL 112.9 COCHLEAR DESTRUCTION. J. F. Brugge, J. Z. Feng, R. A. Reale, and J. <u>C. K. Chan</u> (SPON: R.E. Kettner). Dept. of Neurophysiology and Waisman Ctr., Univ. Wisconsin, Madison, WI 53706.

and Waisman Ctr., Univ. Wisconsin, Madison, WI 53706. The effects of unilateral and bilateral cochlear destruction, done within a few days of birth, on the development of auditory callosal connections were studied with horseradish peroxidase (HRP) histochemistry for tracing cortical connections related to the middle ectosylvian auditory cortex (AI). In some animals receiving a unilateral cochlear lesion, microelectrode mapping of neurons' best-frequencies served to guide the HRP injections and to assess the responsiveness of AI neurons both ipsilateral and contralateral to the intact ear. Cochlear lesions were aseptically performed under general anesthesia by exposing the tympanic bulla, opening it and inserting a blunt probe through the round window. Cats were older than six months at the time of the combined electrophysiology/anatomy experiment performed under Nembutal anesthesia. Large injections of HRP were made unilaterally in AI (contralateral to the intact ear in cats with unilateral lesion) one to two days prior to sacrifice. The distribution of callosal perikarya was revealed using TMB as the chromogen and the temporal bones were processed. In normal adult cats, AI neurons which give rise to callosal axons destined for the contralateral AI are not homogeneously interview the temporal both setter are out homogeneously

distributed throughout AI but, rather, are found aggregated into clusters separated from each other by regions containing relatively fewer callosal neurons. Furthermore the positions of these callosal aggregations are highly correlated with the these callosal aggregations are highly correlated with the binaural representation demonstrated in the high frequency representation of AI. Recently we showed in the kitten (Feng J.Z. & Brugge J.F., J.Comp.Neurol., 214:416-426, 1983) that AI neurons do not form these characteristic adult callosal clusters until the 6th or 7th week of postnatal life. Our present findings indicate that destruction of one or both ears at birth fails to prevent the aggregation of AI callosal neurons into their adult-like cluster distribution even though normal binaural stimulation is obviously absent stimulation is obviously absent. In combined microelectrode mapping experiments, AI ipsilateral

to the intact ear showed a normal tonotopic representation and, along the isofrequency dimension, loci containing neurons with the lowest acoustic thresholds alternated with loci containing neurons with the highest acoustic thresholds. Loci containing aggregates of HRP filled callosal neurons also alternated along aggregates of HKP filled callosal neurons also alternated along the isofrequency dimension and, in preliminary experiments, were found in registration with regions where acoustic thresholds of neurons were substantially below (approximately 20 dB or more) thresholds in surrounding areas. (HD-03352, ENS 7912939) 112.10 MIGRATORY STAGES OF THE DORSAL COCHLEAR NUCLEUS PRINCIPAL NEURONS. Willard, F.H., Thompson, D.M. and Martin, G.F., Department of Anatomy, The Ohio State University, Columbus, Ohio 43210.

The postmitotic migration of neurons is a fundamental event underlying the formation of the nervous system, yet little is known concerning the factors which influence these movements. To this end we are examining the migratory patterns of large neurons in the dorsal cochlear nucleus (DCN) of the North American opossum. in the dorsal cochlear nucleus (DCN) of the North American opossum. The opossum DCN consists of four cytologically distinct layers the most notable of which is layer II containing the vertically oriented cell bodies of the principal neurons. The apical den-drites of these neurons extend into layer I while their basal den-drites reach deep into layers III and IV. Two additional features characterize the principal neurons: each principal neuron has a prominent perinuclear cap of Nissl substance seen in no other DCN neuron (Willard et al., 1983); and all principal neurons trans-port horseradish peroxidase (HRP) from the contralateral inferior colliculus (IC. Willard and Martin. 1983). The only other DCN colliculus (IC, Willard and Martin, 1983). The only other DCN neurons sharing similar efferent connections are the few giant cells scattered throughout layers III and IV. Given the above criteria, it has been possible to identify principal neurons during early development in pouch-young opossums. These animals are born 12 days post-conception at about 15mm snout-rump length (SRL) and mature to approximately 120mm while residing in an external abdominal pouch.

Horizontally oriented, elongate neurons with perinuclear caps of Nissl substance can be recognized in the presumptive dorsal acoustic stria (DAS) of 18mm (SRL) opossums. In 27mm (SRL) opossums such neurons are present in the lateral extreme of the DAS and in the DCN; these neurons can transport HRP from the contralateral IC. When animals reach 35mm (SRL) most principal neurons are present in the DCN but no systematic orientation of their elongate somata is evident. By 40mm (SRL) the principal neurons are still scattered throughout the nucleus, however, their somata have assumed a vertical orientation. During the 50-60mm (SRL) growth period the vertically oriented principal cell somata form a distinct row in layer II.

Our results suggest a two stage migration of DCN principal neurons. During the 18-35mm (SRL) growth phase these elongate neurons apparently move laterally along the presumptive DAS, tangenital to the radial glial fibers observed in Golgi impregna-tions. As the animal grows from 35-60mm (SRL) the principal neurons, now contained within the DCN, shift from a horizontal to a vertical orientation and move dorsally, parallel to the radial glial fibers, until their cell bodies reach layer II. Supported by grants 1 F NS-6829-01 (FHW) and NS 07410 and ENS-8008675 (GFM).

ONTOGENY OF AUDITORY FUNCTION IN THE COCHLEA OF THE MONGOLIAN 112.11 GERBIL: CONTRIBUTION OF THE MIDDLE EAR. N. K. Woolf and A. F. GERBLI: CONTRIBUTION OF THE MIDDLE EAR. N. K. Woolf and A. F. Ryant Otolaryngology Research Laboratory, University of California at San Diego Medical School, San Diego, CA 92103. Cochlear microphonic (CM) potentials of mongolian gerblis (Meriones unguiculatis) were examined at 10, 12, 14, 16, 18, and 30 days after birth (DAB), and in the adult. This range of chronological ages included the onset of neonatal hearing through achievment of mature auditory system characteristics. The contribution of the middle ear to CM development was assessed by comparing at each chronological age acoustically driven CM with CM separated by direct mechanical stimulation of driven CM with CM generated by direct mechanical stimulation of the stapes.

Round window CM potential recordings in neonatal gerbils using the two stimulation paradigms revealed similar onto-genetic trends, but different temporal sequences. In both genetic trends, but different temporal sequences. In both cases, functional onset was followed by a period of rapid threshold improvement, which in turn was followed by a period of slow threshold improvement. The onset of acoustically generated CM occurred at 12 DAB, with thresholds at approx-imately 115 dB SPL. CM thresholds subsequently improved 65 dB between 12 and 16 DAB. This rapid phase of CM threshold maturation was followed by a slow phase of CM threshold development: CM thresholds improved only 15 dB between 16 and 18 DAB, at which time CM thresholds approximated adult levels.

18 DAB, at which time CM thresholds approximated adult levels. CM potential recordings generated by direct mechanical stimulation of the stapes revealed a similar trend for thresholds to that seen with accustic stimulation, but followed a different developmental sequence. The earliest stapes driven CM recordings were observed at 10 DAB, although at this age only a small percentage of the subjects were responsive. thresholds at 10 DAB were 85 dB, or more, above adult levels. Stapes driven CM responses were first consistently observed at 12 DAB, with thresholds elevated approximately 65 dB above adult thresholds. With increasing age, mechanically driven CM also exhibited rapid and slow maturational phases: CM thresholds improved 50 dB between 12 and 14 DAB and, thereafter, declined only 15 dB between 14 and 18 DAB. CM thresholds at 18 DAB equalled adult values. These results indicate that measures of CM development

reflect middle ear as well as inner ear maturational factors The effects of middle ear as well as inner ear maturational factors. The effects of middle ear immaturity are most pronounced during the rapid maturational phases and are responsible for increases in CM thresholds of approximately 40 dB. The small changes in CM thresholds observed during the slow maturational phases are, presumably, the result of terminal cochlear maturational changes. Supported by NIH/NINCDS grants NS14945 and NS00176.

<sup>3</sup>H-THYMIDINE-RADIOGRAPHIC STUDIES OF NEUROGENESIS IN THE RAT 112.13

<sup>3</sup>H-THYMIDINE-RADIOGRAPHIC STUDIES OF NEUROGENESIS IN THE RAT OLFACTORY BULB, S. A. Bayer. Dept. of Biol., Indiana-Purdue Univ., Indianapolis, IN 46223. Neurogenesis in the rat olfactory bulb was examined with <sup>3</sup>H-thymidine-radiography. For the animals in the prenatal groups, the initial <sup>3</sup>H-thymidine exposures were separated by 24 hrs.; they were the offspring of pregnant females given two injections on consecutive embryonic (E) days (E12-E13, E13-E14,..E21-E22). For the animals in the postnatal (P) groups, the initial <sup>3</sup>H-thymidine injections were separated by 48 hrs., each group receiving either four (PO-P3, P2-P4,..P6-P9) or two (P8-P9, P10-P11,..P20-P21) consecutive daily injections. On P60, the percentage of labeled cells and the proportion of cells added during either 24 hr. or 48 hr. periods were quantified at several anatomical levels for each neuronal population in the main olfactory bulb (mitral cells, tufted cells, granule cells, interneurons in the external plexiform layer, periglomerular granule cells) and accessory olfactory bulb (output neurons, granule cells), periglomerular granule cells). The total time span of neurogenesis extends from E12 to beyond P20. Output neurons are prenatally generated over 5-9 day periods (with most neurogenesis occurring over 2-4 days) in a strict sequential order beginning with the accessory bulb output neurons (E13-E14) and ending with the interstitial tufted cells lying between the glomeruli in the main bulb (E20-E22). These data indicate that the sequence of neurogenesis in the amygdal and its olfactory input. With the exception of the granule cells, incleased between E15-E22), the rest of the interneuronal populations are generated postnatally and nearly simultaneously. While most neurons (75-80%) originate during the first three weeks of life, all interneuronal populations, including accessory bulb granule cells, show some neurogenesis beyond P20. Injections of <sup>3</sup>H-thymidine in juvenile and adult rats indicates neurogenesis up to P60 in the accessory Foundation (BNS 79-21303).

112.12 ENHANCED NEURAL REPSONSE FOLLOWING POSTNATAL OLFACTORY EXPERIENCE IN NORWAY RATS. <u>R.M. Coopersmith\* and M.</u> Department of Psychobiology, University of California, Irvine CA 92717. and M. Leon.

Irvine CA 92717. Norway rat pups will preferentially approach the odor of their mother, a preference acquired by means of postnatal experience (Leon, Galef and Behse, 1977). The pups will also acquire an attraction to an arbitrarily selected odor such as peppermint if given daily eposure to it. In this study, we examined the possibility that this behavioral plasticity is accompanied by an enhanced neural response to pre-exposed odors by the olfactory system. Rat mothers were given a diet known to suppress their own odor to minimize early olfactory experience for the pups. The pups were pre-exposed for 10 min/day for the first 18 days of life to either the odor of peppermint or to clean air, using a flow-dilution olfactometer. Exposure was accompanied by perineal stimulation, a procedure found to

air, using a flow-dilution olfactometer. Exposure was accompanied by perineal stimulation, a procedure found to facilitate the acquisition olfactory preferences in neonates (Pederson and Blass, 1982). On day 19, rats previously exposed to either peppermint or air were given a test exposure to either peppermint or air for 45 min after administration of 14C-2-deoxyglucose (20uCi/100g). Autoradiographs of olfactory bulb sections along with reference standards were prepared using standard methods. The autoradiographs were then analyzed with a computer-based image processing and analysis system, which allowed quantitative comparisons between untake sites to be allowed quantitative comparisons between uptake sites to be made.

Rats receiving a peppermint test odor after peppermint pre-exposure showed an enhanced pattern of 2-DG uptake in the glomerular layer of the bulb, relative to rats tested

precexposition of the bulb, relative to rats tested with the identical odor but without previous experience with that odor. Both odor-naive and odor-experienced rats had activity in a dorsolateral complex of glomeruli, approximately 2mm from the rostral pole of the bulb. The intensity and extent of this activity, however, was significantly greater in the experienced rats. The experienced rats, though, may have sniffed the familiar odor more than the naive rats, and the enhanced neural response may have simply been a function of enhanced stimulus presence. Experienced and naive day 19 rats had their sniff rate to peppermint monitored by means of a sensitive pressure transduction device in a test chamber. No difference in sniff rate was found between the groups, suggesting that early odor exposure can cause functional changes in olfactory neural activity.

DEVELOPMENT OF PONTINE PARABRACHIAL NUCLEI TASTE RESPONSES IN 112.14

DEVELOPMENT OF PONTIME PARABRACHIAL NUCLEI TASTE RESPONSES IN RAT. <u>David L. Hill</u>. Ctr. Human Growth & Dev., and Dept. Oral Biol./Sch. Dent., Univ. of Michigan, Ann Arbor, MI 48109. Developmental changes occur in primary afferent chorda tympani nerve and second-order nucleus of the solitary tract taste responses in the rat. To determine whether there are functional changes in responses from third-order gustatory neurons during development in rats, recordings were made from chemosensitive neurons (DBM). development in rats, recordings were made from chemosensitive neurons in the pontine parabrachial nucleus (PBN). Thirty-one single neurons were studied in rats aged 14-25 days, 30 neurons in rats aged 25-35 days and 33 in adults (> 80 days). Chemical stimuli applied to the anterior tongue were 0.1M and 0.5M NH<sub>C</sub>l, NaCl, LiCl, and KCl, 0.1M citric acid, 0.01N HCl, 1.0M sucrose, 0.1M Na-saccharin and 0.01M guinine HCl. Neural activity was measured for the first 5 sec after stimulation of the tongue; a comparable period of prestimulus spontaneous activity was subtracted to yield response frequencies. Response frequencies of PBN neurons in rats aged 14-20 days

Response frequencies of PBN neurons in rats aged 14-20 days were significantly less than those in adults to all stimuli (pC0.05), except responses to HCl (pD0.20). Changes in PBN taste response frequencies were also apparent between rats aged 25-35 days and adult rats. Response frequencies to NaCl, LiCl, sucrose, and Na-saccharin increased 50% or more during postweaning development (pC0.05). In contrast, PBN responses to all other stimuli were similar between rats aged 25-35 days and dubte (pC0.02). adults (p>0.20). When neurons were categorized on the basis of responding maximally to 0.1M  $NH_4Cl$ , to 0.1M NaCl or LiCl, or equally to all 0.1M salts, most PBN neurons in rats aged 14-20 days, 25–35 days and adults responded equally to  $NH_ACl$ , NaCl and LiCl (58%, 77%, and 64%, respectively), and a relatively small proportion responded maximally to  $NH_4Cl$  (16%, 7%, and 3%,

respectively). Similar to the second-order gustatory neurons in the nucleus of the solitary tract (NST), striking developmental changes are found in responses to NaCl, LiCl, KCl, sucrose and saccharin. However, unlike NST responses, developmental changes also occur in PBN neurons to  $NH_4Cl$ , citric acid and hydrochloric acid. Further differences include a smaller proportion of PBN neurons maximally responsive to NH $_{4}$ Cl. Compared to peripheral chords tympani nerve taste neurons for each of the three age groups, NST and PBN neurons have greater average frequencies to all stimuli, a greater proportion respond equally to monochloride salts, and mature average frequencies occur in older rats to NaCl, LiCl, and KCl. Since responses from NST and PBN neurons alter during development, adult rats may also differ from younger rats in behavioral responses to some taste stimuli. (Supported by NIH Grant NS17404).

DORSAL ROOT GANGLIA DEVELOPMENT IN CHICKS FOLLOWING PARTIAL ABLATION OF THE NEURAL CREST. Virginia McM. Carr. Dept. Bio 112.15 chem., Molec. and Cell Biol., Northwestern U, Evanston II, 60201 Portions of the brachial neural crest of stage 13 and 14 (Hamburger and Hamilton, '51) chick embryos were partially ablated using an opthalmological cauterization unit. Ganglia developing from the remaining crest material were examined for ganglionic volume, degenerative activity, and neuronal nuclear diameter at stage 35 (9 days of inc.), when neuronal cell growth is becoming pronounced but while cellular degeneration is sti occurring (Carr and Simpson, '78a, b; Hamburger et al., '81). Results showed that the cauterization procedure caused the still reduction or absence of dorsal root ganglia (DRG) at the level of ganglia 15, 16, and/or 17 (G15, G16...). In contrast, hyper-trophies occurred in remaining ganglia. These hypertrophies trophies occurred in remaining ganglia. These hypertrophies were most pronounced, however, not in the ganglia adjacent to those lesioned but rather in nonadjacent ganglia. The mean vol-ume in brachial Gl4 was  $10.4 \pm 2.9 \ \mu\text{m}^3 \times 10^6$  ( $\mathbf{x} \pm 5.0.$ ) in experimental embryos versus  $9.9 \pm 2.6 \ \mu\text{m}^3 \times 10^6$  in controls. In contrast, in Gl3 these values were  $8.0 \pm 2.0$  versus  $4.7 \pm 1.6 \ \mu\text{m}^3 \times 10^6$ , respectively. Gl3 is a ganglion that contrib-utes to the brachial plexus but that does not normally innervate the wing (M. Hollyday, pers. commun.) nor show either degenera-tive or proliferative responses to early wing bud removal (Carr & Simpson, '78a, b). More anterior cervical ganglia also showed slight hypertrophies: 6.0 ± 1.4 versus 4.0 ± 1.6 µm<sup>3</sup> x 10<sup>6</sup> for G12 and 5.8 ± 0.9 versus 4.6 ± 0.7 µm<sup>3</sup> x 10<sup>6</sup> for G11.

Degenerative activity and the average neuronal nuclear diam-meter were measured in Gll, Gl3, and Gl5. Results showed that the mean number of degenerations/unit vol. Results showed that (611, 30% in G13, and 55% in G15 in experimental embryos. More-over, within individual embryos these reductions, up to a maxinum of 60-70%, were proportional to the degree of ganglionic hypertrophy. In lesioned GI5 all ganglia showed reduced degen-eration of 50-70%. Enlargements of 6%, 12%, and 16% were found in the average nuclear diameters of both lateroventral and medio-dorsal neurons in GI1, GI3, and GI5, respectively. Again, individual changes appeared proportional to the degree of DRG hypertrophy.

These changes indicate an enlargement of DRG neuronal periph-These changes indicate an enlargement of DRG neuronal periph-eral fields due to reduced peripheral competition. Such conclu-sions disagree with those of Eide <u>et al.</u> ('82) who found electro-physiological evidence for only limited plasticity of DRG inputs onto lumbosacral motoneurons when chicks subjected to neural crest lesions were examined at 19 to 21 days of incubation. Whether these differences are due to stage of development, axial level, or DRG projections examined remains to be determined.

- 112.16 CHRONIC VIBRISSA ACTIVATION PRODUCES DECREASED GLUCOSE UTILIZATION IN SI CORTEX BUT NOT IN SUBCORTICAL LEVELS OF RAT VIBRISSA-CORTI-
  - IN SI CORTEX BUT NOT IN SUBCORTICAL LEVELS OF RAT VIBRISSA-CORTI-CAL BARREL SYSTEM. C.L. Hand\* and P.J. Hand (SPON: J. Metzler). Dept. of Animal Biology, Sch. of Vet. Med., and Inst. of Neuro-logical Sciences, Univ. of Pennsylvania, Phila., PA 19104. Using the quantitative (<sup>14</sup>C)-2-deoxyglucose (2DG) method of Sokoloff (J.Neurochem., 1977), we reported that chronic repeated stimulation (5-15 min/day for 60-90 days) of a single vibrissa (#3 of row C; C3) in an intact vibrissa field produces a significant (p≤0.01) decrease in local cerebral metabolic rates of glucose (LCMRG) in the C3 vibrissa-barrel column in contralateral SI cor-tex of rat when compared to matched controls(<u>Neurosci. Abst</u>, 1982). In addition, bilateral C3-stimulated naive controls (n=4) show no significant right-left differences in SI C3 labeling (mean diff. of 1.2% in LCMRG in matched pairs; no preferred hemisphere). Based on the conservative criterion that 2DG labeling 20% above backon the conservative criterion that 2DG labeling 20% above back-ground is of significance, we now report that the functional re-presentation in SI of the chronically-stimulated C3 vibrissa not only has a lower LCMRG than the matched control, but also involves less cerebral tissue (mean areal decrease of 15% compared to controls). To determine if this phenomenon is specific to cortex, matched-pair quantitative analysis was extended to subcortical levels of the vibrissal pathway in the same experimental animals (n=13). Concurrently, to determine if receptor adaptation is a factor (and to serve as a check of results at other levels), C3labeling in both trigeminal ganglia was compared for each animal. Serial autoradiographs were analyzed both densitometrically and by computer-assisted pseudocolor-enhanced image processing routines. Labeled brain structures were identified using the actual Nissl stained sections. Analysis of C3-activated labeling in trigeminal ganglia indicates no significant differences in paired experiment-al and control LCMRG values. Evaluation of discrete C3 functional labeling in main sensory nucleus and subnuclei caudals and inter-polaris of the <u>trigeminal complex</u> reveals no significant differ-ences in metabolic activity between paired labeling (range=.1%-2% differences in LCMRG). Similarly, analysis of discrete C3 label-ing in <u>ventrobasal thalamus</u> of matched pairs indicates no signifi-cant change in labeling (1%-2% diff. in LCMRG). There is no con-sistent tendency for the decreased LCMRG to occur on the experi-

mental side, as it does in cortex. In conclusion, lack of LCMRG changes at lower levels of the vibrissal pathway, coupled with the observed decreases in cerebral metabolism in the chronically-activated C3 functional column in SI cortex suggests a cortical phenomenon. Additional studies are required to determine if this is the result of an intrinsic cortical mechanism, or whether alternate (as yet unanalyzed) subcorticalcortical mechanisms may be contributing. (Supported by NIMH Training Grant 15092 and NS-14935).

112.17 THE EFFECT OF PERTPHERAL SENSORY DEPRTVATION OF ENRICHMENT ON THE EXTENT OF FUNCTIONAL PLASTICITY IN RAT SI CORTEX PRODUCED BY CHRONIC SUBTOTAL VIBRISSAE DEAFFERENTATION. R.L. Craik, P.J. Hand C.L. Hand\* and B.A. Cozzens\*. Moss Rehab. Hosp. and Dept. of Ani-Hand, mal Bio., School of Vet Penna., Phila., PA. 19104 School of Vet. Med., Inst of Neurol. Sci., Univ. of

Penna, Phila., PA. 19104 The developing rat vibrissa-"barrel" system was selected to examine patterns of functional re-organization in SI in response to chronic subtotal vibrissae deafferentation(n=10). Previous ( $^{14}$ C)-deoxyglucose (2DG) studies revealed an enlarged and diffuse pattern of labeling of C3 representation in contralateral SI 90 days after neonatal follicle ablations sparing #3 vibrissa of row (C2)(Show and Ward Neurosci (htt 1922) C (C3)(Sheu and Hand, Neurosci. Abst., 1982). This study examined the effects of chronic activation or deprivation of the spared C3 vibrissa on the extent and pattern of its altered representation in SI. The intact contralateral C3 vibrissa served as an internal control. An <u>enriched</u> C3 vibrissa received 30 minutes of mechani-cal stroking daily from postnatal day 3 to 90 (PND 3-90). A <u>de-</u> <u>prived</u> C3 vibrissa was maintained clipped from PND 3-83; the vi-<u>prived</u> US Vibrissa was maintained clipped from PNU 3-63; the Vi-brissa was allowed to regrow PND 83-90 for stimulation. The 2DG method of Sokoloff(J. <u>Neurochem</u>.,1977) was used to quantitate functional changes in SI. In both enriched and deprived paradigms local cerebral metabolic rates of glucose (LCMKE) of spared C3 vibrissal representation showed a mean increase of 12% compared to the average C3 unbeined enterplate actions. Both enriched and to the normal C3 vibrissa representations demonstrated an increased areal extent of labeling in lamina IV (L.IV) compared to normal C3 in 5 of 7 matched pairs. SI areas immediately adjacent to the spared C3 representation have 12% higher LCMRG than control in 6 of 7 matched pairs. To further examine this phenomenon, 3 neonatal rats (PND2) underwent bilateral vibrissal ablations sparing C3. At PND 90 the LCMRG in the enriched spared C3 representation was 7% higher and the areal extent in LIV 2% larger than its matched spared C3 control. The <u>deprived</u>, spared C3 represen-tation demonstrated a 20% decrease in LCMRG and a 9% decrease in areal extent in LIV when compared to control spared C3. A bilateral control demonstrated a 4% left-right asymmetry in LCMRG (right higher) but had similar areal extents of labeling. In con-clusion, these preliminary results suggest that major features of functional plasticity produced by subtotal vibrissae deafferentation are independent of the level of activation of a spared re-However, finer aspects of such plasticity appear affected ceptor. by peripheral activation: stroking of spared C3 increased LCMRG in SI while LCMRG and SI representation was decreased in deprived spared C3. Ongoing studies involve completion of laminar analyses of the spared vibrissal representation in SI. (Supported in part by the Foundation for Physical Therapy, Inc., and NS-14935.)

112.18 ASCENDING NONVISUAL AFFERENTS TO THE SUPERIOR COLLICULUS IN NEO-ASCENDING NONVISUAL AFFRENTS TO THE SUPERIOR COLLICUES IN MED-NATAL KITTENS J.G. McHaffie\*, K. Ogasawara\* & B.E. Stein (SPON: H.P. Clamann), Department of Physiology & Biophysics, Medical Col-lege of Virginia, Richmond, VA 23298. Despite the strong interest in the development of superior col-Despite the strong interest in the development of superior col-liculus (SC) afferents, almost all work has been restricted to the visual system. Yet nonvisual cells are functional several days before visual cells. The present study was undertaken to determine which of the ascending nonvisual SC afferents are already present at birth or appear during early maturation. Injections of  $0.02 \ \mu$ l of 25% HRP were made in the SC of neonatal kittens (1-7 days of age). The animals were sacrificed 24 hrs. later and the tissue two inputted for the method of Mevulam (1078) was included for HRP after the method of Mesulam (1978). Since SC cells with perioral cutaneous receptive fields have been reported in pre- and early postnatal cats (Stein <u>et al</u>, J. Neurophysiol. 36:667-679, 1973) we were particularly interested in whether labelled neurons are present in the neonatal sensory trigeminal complex, and if so, how they are distributed. Labelled cells were found in this region in even the youngest animal studied; all were contralateral, and the majority were clustered in the rostral part of pars oralis. A few labelled cells were also present in the principal nucleus and pars caudalis, and fewer

still in pars interpolaris. Apparently, even in neonatal animals the distribution of trigeminotectal cells is similar to adult cats (e.g. Ogasawara & Kawamura, Okajimas Folia Anat. Jpn. 58:247-264, 1982).

A variety of other subcortical structures from caudal brainstem through diencephalon were found to project to the SC in animals 1-2 days of age. At the level of the medulla, labelling was observed in nucleus paragigantocellularis lateralis and the perihypoglossal nuclei. In the cerebellum sparse numbers of retro-gradely-filled cells were found in medialis, interpositus and lateralis nuclei. Auditory structures at pontine levels containing labelled neurons included the dorsomedial periolivary nucleus and the area medial to the medial nucleus of the trapezoid body. In the region of the midbrain, heavy labelling was noted in the sub-stantia nigra, parabigeminal nucleus and locus coeruleus, and in the dienencephalon the zona incerta was densely labelled. A scattering of cells was also seen in the contralateral SC. These observations indicate that the major ascending nonvisual

afferents to the SC are already well-developed at birth. Apparent-ly the major anatomical development of inputs to the SC is a prenatal event; comparatively few changes in the locations and num-bers of afferents take place postnatally. This contrasts with the protracted, functional maturation of many of the sensory proper-ties of SC cells. Supported by grants EY04119, BNS 8209857, and the Jeffress Foundation.

TUESDAY AM

WIDESPREAD LABELING OF AVIAN FOREBRAIN NEURONS AFTER SYSTEMIC 113.1 NIDECTIONS OF <sup>3</sup>H-THYMIDINE IN ADULTHOOD. F. Nottebohm and S. Kasparian\*, Rockefeller University, New York, N.Y. 10021. Kasparian\*, Rockefeller University, New York, N.Y. 10021. Adult male and female canaries were given 50uCi of <sup>3</sup>H-thymidine intramuscularly twice a day for 14 days and sacrificed 26 days after the last injection. Their brains were cut in 6um thick sections treated for autoradiography and stained with cresyl violet. The distribution of labeled cells was mapped in great detail in one male bird, using 8"x10" prints of photographs of the left half of the brain. Labeled cells were identified as falling in either of five categories, based on light-microscopic anatomical criteria, as described in Goldman and Nottebohm, PNAS 80, 1983: endothelial cells, glia, ventricular zone cells, neurons and cells of uncertain identity. A cell was accepted as labeled when the number of silver grains over its nucleus was at least five times that over surrounding neuropil. Labeled glia and endothelial cells were found throughout the brain. Labeled ventricular zone cells occurred profusely bordering the telencephalic ventricle, and were rare or absent elsewhere. Labeled neurons occurred throughout the forebrain, but were very rare or absent in hippocampus , septum, hypothalamus, cerebellum, thalamus, optic lobes or medulla. lobes or medulla. Extent of label over cells identified as neurons was comparable to that found over glia and endothelial cells. By analogy with the conclusion reached for labeled neurons in nucleus HVc of adult canaries (Goldman and Nottebohm, PNAS 80, 1983), we suggest that label was incorporated into the nucleus of cells during the S-phase of DNA synthesis which normally precedes The anatomical correlation between the distribution of mitosis. milesis. The anatomical contracton occurrence in the later of labeled cells in the telencephalic ventricular zone and the occurrence of labeled neurons in forebrain suggests that a process of neurogenesis may occur in the ventricular zone, followed by migration of neuroblasts through adult forebrain tissue. This migration of neuroblasts through adult forebrain fissue. In is interpretation, already advanced for nucleus HVc, awaits the ultra-structural confirmation of neuronal identity, and support from time course studies charting the distribution of labeled cells during the first 4 weeks after the last  ${}^{3}H$ -thymidine injection. Since adult brain weights in canaries occur as early as day 15 after hatching, the hypothesized neurogenesis cum migration would be accompanied by a turnover of the neuronal population. This may be the first suggestion of a constant rebuilding of adult forebrain networks in an adult higher vertebrate. The fact that it seems to occur in a part of the brain thought to be involved with learning may not be coincidental.

113.2 STEROID INDUCED NEURAL PLASTICITY IS MULTIFACETED. T. J. DeVoogd, B. Nixdorf\* and F. Nottebohm. Psychology Department, Uris Hall, Cornell University, Ithaca, N.Y. 14853 and Rockefeller University, 1230 York Ave., New York, N.Y. 10021. Robustus archistriatalis (RA) is a nucleus in the canary telen-

Robustus archistriatalis (RA) is a nucleus in the canary telencephalon involved in song production. This nucleus is smaller in females than in males. Giving testosterone to an adult female canary results in an increase of more than 50% in the volume of RA (Nottebohm, <u>Br. Res. 189</u>:429-436, 1980), and the development of male-like song. The dendritic fields of neurons within RA double in size and there is an increase of more than 60% in the number of synapses contained within the nucleus. We now report that the ultrastructural constituents of RA and the dimensions of synapses within it are also modified by adult exposure to testosterone.

Six adult female canaries were implanted with Silastic tubes of testosterone as reported last year (T.J. DeVoogd, B. Nixdorf and F. Nottebohm, <u>Soc. Neurosci. Abs.</u> 8:140, 1982). After one month, they and matched unimplanted female controls were sacrificed. RA samples were prepared for electron microscopy (sodium cacodylate buffer, 25% Karnovsky fixative). The distribution of tissue constituents was measured on micrographs taken about the center of RA and printed at 7000X. Testosterone treatment was associated with significant increases in the proportion of micrograph area occupied by neuronal somata (13.7 vs 4.8%) and by post-synaptic neurites (predominantly dendrites, 6.4 vs 3.7%). In contrast, no significant differences were seen in the proportion of micrograph area occupied by myelin or capilaries. Micrographs from nucleus which does not concentrate steroids. Testosterone-treated and control birds did not differ in rotundus area occupied by neuronal somata, dendrites or myelin.

Individual synapses were measured at 32,400X. Maximal cross section of the pre-synaptic area was measured parallel and perpendicular to the contact zone, yielding a mean "diameter" for the pre-synaptic area. Testosterone treatment was associated with an 11% increase in the mean "diameter" of the pre-synaptic area (p < .02) and a 10% increase in the number of vessicles seen within this area (p < .04). The length of the post-synaptic opaque zone also increased but the mean "diameter" of the post-synaptic area did not differ between the two groups. There were no differences between the groups in the frequency of gaps in the post-synaptic opaque zone. The shift in synaptic dimensions could be due to the properties of the new synapses or result from changes in the existing synapses.

We conclude that sytemic testosterone treatment can affect the anatomy of an androgen sensitive nucleus in several ways: increase in size of neuronal somata, increased dendritic length, a net gain in synapse numbers and a shift in some synaptic dimensions.

113.3 ADULT EFFECTS OF GONADAL STEROIDS ON SEXUALLY DIMORPHIC PREOPTIC/ANTERIOR HYPOTHALAMIC AREA NEURONS OF MALE AND FEMALE FERRETS. S.A. Tobet, D.J. Zahniser\* and M.J. Baum, Dept. of Nutrition and Food Science, M.I.T., Cambridge, MA 02139 and Image Analysis Laboratory, Tufts-New England Medical Center, Boston, MA 02111.

We recently reported the existence of a sexual dimorphism in the preoptic/anterior hypothalamic area (POA/AH) of adult ferrets (Tobet et al., Endocrinology 112(suppl.):240, 1983). In males 2 bilateral nuclear groups are discernable in the POA/AH (dorsal and ventral), whereas in females only l bilateral nuclear group is discernable (ventral). Furthermore, while dorsal cells are larger in both sexes, the cells within the dorsal nucleus in males are larger than cells in a comparable region in females. We now report that gonadal steroids can increase the somal size of neurons in this sexually dimorphic region of the adult ferret POA/AH. Adult male and female ferrets, castrated or castrated and steroid implanted (estradiol or testosterone in silastic capsules) for at least 2 weeks, were an esthetized and sacrificed via intracardiac perfusion with 0.9% saline followed by 10%neutral buffered formalin. Alternating 40 and 8  $\mu$ m paraffin sections were cut through the POA/AH and stained with thionin. Boundaries of individual perikarya were determined in 8 µm sections using a DeAnza Image Analysis System with a VAX-11/780 computer. Regions of 128  $\mu m^2$  were digitized according to optical density (3 regions from the ventral nucleus of each animal and 3 regions from the dorsal nucleus of each male and the comparable dorsal region of each female) and perikaryal dimensions within these regions were determined automatically (range: 10-28 cells/ region). In the dorsal nucleus of males and dorsal region of females, perikarya were significantly larger than in the male and female ventral nuclei. A sexual dimorphism of perikaryal size with larger cells in the dorsal nucleus of males compared to those in the camparable dorsal region in females were evident. to those in the camparable dorsal region in females were evident, as previously reported. Steroid treatment significantly increased the size of dorsal perikarya in males and females by 63% and 104% (somal volume), respectively. However, in the ventral nuclei only the soma of females increased in response to steroid treatment (123%, somal volume). The results indicate that sexually dimorphic neurons of the adult ferret POA/AH are steroid sensitive and respond to adult hormone treatment with an increase in perikaryal size.

Research was supported by NIH grant HD-13634 to MJB and a Whitaker Health Sciences Fund Fellowship to SAT. 113.5 TRANSPLANTATION OF FETAL MEDIAL BASAL HYPOTHALAMIC BRAIN TISSUE INTO THE THIRD VENTRICLE OF ADULT HOSTS: ULTRASTRUC-TURAL CHARACTERIZATION. P.W. Coates and H.K. Strahlendorf. Depts. of Anatomy and Med. Surg. Neurol./Physiology, Texas Tech Univ. HSC Sch. of Med., Lubbock, TX 79430. Fetal medial basal hypothalamic (MBH) grafts in the third

Fetal medial basal hypothalamic (MBH) grafts in the third ventricle (3V) of adult hosts were examined with scanning and correlative transmission electron microscopy (SEM and SEM/TEM). MBH tissue including the arcuate nucleus region was obtained from late gestation Sprague-Dawley rats and pooled for stereotaxic transplantation into the 3V of adult males. Hosts and controls (age-matched and sham-operated) were sacrificed after 7 weeks and prepared for SEM and SEM/TEM by procedures described previously. SEM revealed that some MBH transplants had lodged at sites distant from the original implantation on the 3V floor. Fractured surfaces of embedded grafts revealed blood vessels. Other graft tissue consisted of small spheres suspended above the 3V floor. These lacked blood vessels when sectioned. All grafts displayed attachment to host tissue via fiber networks and bundles, sometimes strikingly complex. Some thin varicose fibers terminated in small oval endings. Cells were present on the surface of transplants, and along fiber bundles. SEM/TEM revealed that neurons, glia, and nerve fibers were on graft surfaces. A band of mostly glial processes surrounded an inner core of neurons, glia and an intricate neuropil. Synaptic terminals containing small clear and dense core vesicles (DCV) were observed on neurons, within the neurofil, and in plexuess connecting grafts to hosts. Many graft neurons exhibited features suggesting ongoing maturation: indented cell and nuclear membranes, numerous Golgi complexes, some with associated DCV; rough endoplasmic reticulum; mitochondria; prominent nucleoli and synapses. Glial processes displayed filaments. These observations suggest that MBR grafts transplanted to the 3V: 1) may seed to sites other than the floor, possibly via cerebrospinal fluid currents; 2) display massive fiber bundles between grafts in recesses and adjacent median eminence, perhaps indicating a location more compatible to their original position; 3) show evidence of continuing development, suggesting an ult
DIFFERENTIAL DISTRIBUTION OF CERULOHIPPOCAMPAL PROJECTIONS: ANATOMICAL AND BIOCHEMICAL EVIDENCE.<u>J.H. Haring and J.N. Davis</u> V.A. Neurology Research Laboratory, Durham V.A. Medical Center 113.6 and Departments of Medicine and Pharmacolgy, Duke University Medical Center, Durham, N.C. 27705

We have been studying the possibility that the proliferation of locus ceruleus (LC) fibers in the hippocampus after septal lesions is mediated by branches of the injured axon rather than by collateralization of uninjured axons. Our "pruning" hypothesis requires that branches of a single LC neuron project hypothesis requires that branches of a single LC heuron project to the hippocampus by the ventral amygdaloid bundle (VAB) and either the fornix (Fx) or cingulum (Cb). We have recently reported that LC neurons projecting to the dorsal area dentata are localized in the dorsal half of the LC and that certain of these neurons project to both dorsal and ventral area dentata these neurons project to both dorsal and ventral area dentata (Exp. Neurol. 79: 785, 1983). We now suggest a differential distribution of the three cerulohippocampal pathways based upon observations obtained using the retrograde transport of HRP in combination with septal lesions and by measurement of norepinephrine (NE) levels after lesions of septum or Cb. Focal HRP injections of dorsal area dentate made immediately after septal lesion result in no observable LC labeling. Similar

injections 16 weeks after septal lesion produce labeling in the dorsal LC but fewer HRP-positive neurons are seen than in normal If large injections are made in dorsal area dentata such that the spread of enzyme includes the mid-septotemporal region, LC labeling is similar to that obtained from ventral injections even though the septum has been lesioned. Septal lesions presumably remove LC fibers destined for both Fx and Cb and produce an approximately 50% reduction in NE levels in both dorsal and ventral hippocampal formation. Lesion of Cb alone, results in negligable NE depletion dorsally however a significant decrement is seen in the ventral hippocampal formation. The present anatomical and biochemical observations suggest

that: 1) LC fibers in VAB project throughout the hippocampus with few terminals in the septal third, 2) Fx NE fibers mainly innervate the septal third, 2) fx NE fibers mainly innervate the septal third, 3) Cb provides a major NE input to temporal hippocampus. Moreover the observation of the return of LC labeling from dorsal area dentata 16 weeks after septal lesion implies the expansion of LC axons from VAB into the denervated region region.

SURVIVAL OF NONENZYMATICALLY DISSOCIATED RAT AND MONKEY ADRENAL 113.7

SURVIVAL OF NONENZYMATICALLY DISSOCIATED RAT AND MONKEY ADRENAL MEDULLARY CELLS IMPLANTED INTO ADULT RAT BRAIN. M.R. Wells and U. patel. Neurochemical Research Laboratory, Veterans Administration, Washington, D.C. 20422 and N.I.M.H., St. Elizabeth's Hospital, Washington, D.C. 20023. The implantation of adrenal medullary tissue into the ventricles of ipsilaterally substatia nigra lesioned rats results in survival of the implant and alterations in lesion induced rotational behavior (Freed et al. Nature 292;351, 1981). In order to optimize contact of the catecholamine producing implant with the deafferented caudate nucleus, we have developed a non-enzymatic dissociation technique for adrenal medullary cells of rats and monkeys which allows them to be injected directly into the caudate. Dissected adrenal medullary (Gibco 199) containing 20% fetal calf serum and gently teased through a 250  $\mu$  pore nylon mesh. This procedure alone was sufficient to produce viable dissociated cells either as single cells or small aggreviable dissociated cells either as single cells or small aggre-gates of two or three cells. After dissociation over 90% of gates of two or three cells. After dissociation over 90% of the cells could exclude trypan blue (0.1% in medium). Cells were injected into the caudate nucleus of ipsilaterally sub-stantia nigra lesioned adult host rats  $(2-4\mu \perp Approx.$ 160-300,000 cells). Both rat and monkey adrenal medullary cells survived for over 14 days in the host brain and showed rapid formation of cell processes. The mechanical dissociation of adrenal medullary cells is a rapid method for obtaining viable cells for implantation. Supported by the Veterans Administration and N.I.M.H.

## INVERTEBRATE MOTOR FUNCTION

IDENTIFICATION OF WIND SENSITIVE INTERGANGLIONIC INTERNEURONS IN THE COCKROACH. <u>R. E. Ritzmann and A. J. Pollack</u><sup>\*</sup>. Dept. of Biology, Case Western Reserve University, Cleveland, OH 44106. Interganglionic interneurons are now thought to play an impor-tant role in the pattern generation circuitry responsible for 114.1

flight in locust (Robertson and Pearson, J. Comp. Physiol., 146: 311-320, 1982) and intersegmental coordination in the walking system of the cockroach, <u>Periplaneta americana</u> (Person and Iles, J. <u>Exp</u>. <u>Biol.</u>, <u>58</u>:725-744, 1973). In the cockroach both walking and flying can be generated by similar wind stimuli directed at and trying can be generated by similar with stimuli directed at the cerci (Antenna-like sensory structures on the rear of the abdomen). Moreover, a set of identifiable interneurons, the dor-sal giant interneurons (dGI's) are capable of initiating either behavior (Ritzmann, et. al., J. <u>Comp. Physiol.</u>, 1<u>47</u>;131-322, 1982). The choice between walking and running is determined by the presence or absence of leg contact with a substrate. We are interested in determining whether components of these two systems other than the dGI's are also shared. For example, there may be interneurons that serve to coordinate activities between thoracic ganglia in both behaviors.

As an initial part of this study, we have identified over 40 wind-sensitive interganglionic interneurons. Our procedure involves recording intracellularly from axons in the meso-metathoracic connectives and subsequently dye-filling with Lucifer Yel-low CH. Identification is based upon three parameters: (1) wholemount morphology, (2) the tract (Gregory, Phil. Trans. R. Soc. Lond., (B), <u>267</u>:421-465, 1974) in which the main axon passes (identified in cross-sections of thoracic ganglia), and (3) the response to wind in a flying preparation. For the interneurons we have identified, the last parameter can be further divided into have identified, the last parameter can be in the divided into three categories:  $\underline{type}$  1-excited by wind and/or flight in an un-patterned manner,  $\underline{type}$  2-excited during flight in a burst pattern in phase with either wing elevator or depressor motor neurons, and  $\underline{type}$  3-spontaneously active but inhibited during flight. Most of the type 2 interneurons are located in the dorsal lateral breact tract; an area where interneurons associated with interganglionic coordination have previously been located.

We have also begun to determine connections that are made with these interneurons in the thoracic ganglia. At least one type 1 interneuron appears to be excited monosynaptically by a dGI (GI-7).

We plan to repeat these observations in preparations that make leg contact and are, therefore, capable of eliciting walking motor outputs. These studies will determine how the activity in these interneurons changes with leg contact.

Supported by NIH grant NS 17411-01 to R. E. R.

114.2 Spiking local interneurons are primary integrators of mechanosensory signals in the locust. M. Burrows and M.V.S. Siegler\*, Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, England.

> Two types of local interneurons in the thoracic ganglia of the locust can be distinguished on their gangila of the locust can be distinguished on their ability to spike. One, unable to spike (local non-spiking interneurons), controls sets of leg motor neurons in a graded fashion. The other, able to spike (local spiking interneurons), is involved in the control of local reflexes. Some synapse directly upon motor neurons. A major role for these spiking interneurons is to integrate the information provided by the huge number of receptors on a leg; about 10,000 afferents from a hind leg converge upon some 100 local spiking interneurons. The afferents from external mechanoreceptors synapse directly upon the local spiking interneurons but not upon the nonspiking ones, or upon motor neurons. A spike from a singly-innervated hair is followed at a constant latency (1-2ms) by a chemically-mediated EPSP in a local spiking interneuron. Each interneuron is excited by a specific and restricted array of sensory rectors, for example, some are excited by receptors on the anterior surface of a leg, others by receptors on the posterior surface. Each interneuron has two distinct areas of branches within a ganglion; a ventral area of fine and numerous branches that overlaps with the central projections of the mechanoreceptor afferents, and a dorsal area of sparse and varicose branches that overlaps with those of the leg motor neurons. We infer that the spiking interneurons are involved in two types of local pathways 1) sensory neuron, spiking local interneuron, motor neuron, and 2) sensory neuron, spiking local interneuron, non-spiking local interneuron, motor neuron. Supported by NIH grant NS16058 to MB and an MRC (UK) project grant to MVSS.

SYNAPTIC INTERACTIONS BETWEEN FLEXION-PRODUCING INTERNEURONS IN 114.4

CRAFFISH. J. Jellies and J.J. Larimer. Department of Zoology, University of Texas, Austin, TX, 78712. Abdominal posture is produced by segmentally arranged antagon-istic muscles in crayfish. Extracellular analysis revealed the presence of "command fibers" (CF's) in the abdominal nerve cord which produce coordinated postures, including a large number of which produce coordinated postures, including a large number of flexion-producing CF's (Evoy and Kennedy, J. <u>Exp. Zool.</u>, 165:223, 1967). By combining extracellular stimulation of CF's with intra-cellular recording, Miall and Larimer (J. <u>Comp. Physiol.</u>, 148:159, 1982) discovered that many flexion-producing interneurons received input from the CF's. However, extracellular stimulation of CF's in axonal bundles raises the possibility of a synaptic response contaminated by other neurons, thus making interpretation dif-figult. ficult.

We have succeeded in making simultaneous intracellular, neuro-We have succeeded in making simultaneous intraceilliar, neuro-pilar microelectrode penetrations in pairs of flexion-producing interneurons. We use high impedance, Lucifer Yellow filled micro-pipettes (100-400 MR) to impale interneurons in the third and fifth ganglia in an isolated abdominal nerve cord of <u>Procambarus</u> <u>clarkii</u>. An extended bridge balance in the preamplifiers allows us to interact pairs of interneurons and view their responses. Just over half of the pairs of flexion-producing interneurons

results over half of the pairs of flexion-producing interneurons encountered so far show no evidence of interaction. Of the remaining pairs there are examples where both apparent mono- and polysynaptic interactions are evident. In a smaller number, one flexion-producing interneuron recruited another to spiking and in many pairs synaptic interaction is not obvious but is indicated since one flexion-producing interneuron will influence the firing frequency of the other.

Two general features of all interactions are; when an inter-Two general features of all interactions are; when an inter-neuron is recruited it is activated at a low gain, and, inter-actions between every pair of interneurons we have studied in these two ganglia are "one-way" interactions. Thus, low gain recruitment and the absence of strong mutual interactions might allow the animal to activate several elements in this system of pre-motor interneurons to produce selected abdominal positions without sacrificing fine control to positive feedback. Supported by NIH grant NS 05423 to JLL and a University Fellow-ship to JJ, University of Texas at Austin.

FUNCTIONAL PROJECTIONS OF ABDOMINAL POSITIONING INTERNEURONS 114.5

FUNCTIONAL PROJECTIONS OF ABDOMINAL POSITIONING INTERNEURONS THROUGHOUT THE CNS OF THE CRAYFISH. <u>D. Moore<sup>\*</sup></u> and J.L. Larimer. Dept. of Zoology, Univ. of Texas, Austin, TX 78712. Recent evidence (Larimer, J.L. and Jellies, J., <u>J. Exp. Zool</u>., in press, 1983) suggested that many abdominal flexion-evoking interneurons in the crayfish <u>Procambarus clarkii</u> send their axonal projections anteriorly into the thoracic nerve cord. In an effort to determine the organizational relationships between flexion-evoking interneurons found in the abdominal ganglia and those which exist in the circumesophageal connectives (CECS), a semi-intact preparation was used. The ventral nerve cord was semi-intact preparation was used. The ventral nerve cord was dissected from the abdominal region, but left attached to the anterior CNS. Positioning interneurons were found with Lucifer-filled microelectrodes (50-300 MA) in the neuropile of abdominal ganglia 2 through 6. Motor outputs evoked by intracellular stimulation of these cells were determined with extracellular recording electrodes placed on flexor and extensor roots along the cord.

A 100 Hz, 100 msec pulse train was delivered separately to A 100 Hz, 100 msec pulse train was delivered separately to each CEC through wire hook stimulating electrodes. The responses of the impaled cells to CEC stimulation could be placed into 4 general categories: (1) Of the total of 82 flexion-evoking interneurons examined, 39% projected directly through the CECs as evidenced by phase-locked spikes occurring one-to-one with the stimulation paradigm. Abdominal flexion-evoking interneurons which course through the CECs may comprise the primary neural observed underlying relument of paratime. These the stimulation paraligm. Accounting internetions which course through the CECs may control of posture. These "through" fibers apparently do not decusate as they project through the ventral nerve cord to the brain. (2) Some flexion interneurons (13%) were remotely activated to spiking by CEC stimulation, failing to follow the 100 Hz pulse train one-to-one with constant spike latency. In these cases, higher order CEC or intermediary fibers presumably make synaptic connections onto the interneurons at sites distant from the ganglion in which the interneurons were impaled. (3) Approximately 34% of the flexion. Interneurons were neither directly nor remotely activated, but received strong EPSPs or IFSPs as a result of CEC stimulation. These locally activated interneurons may represent lower order elements for the control of abdominal movements. (4) Approx-imately 15% of the flexion interneurons were completely independent of CEC stimulation, perhaps reflecting a role largely limited to reflexive control of posture. The placement of flexion-evoking interneurons into separate categories based on the functional relationships with the

categories based on the functional relationships with the anterior nervous system suggests several different levels of neural control for the simple abdominal positioning behavior. (Supported by PHS grant NS 05423).

THE INFLUENCE OF MOTOR NEURON OUTPUT ON CONTRACTION AND WORK IN VENTILATORY MUSCLES OF THE SHORE CRAB. A. J. Mercier and J. L. Wilkens. Dept. of Biol., Univ. of Calgary, Calgary, Alberta, TZN IN4, Canada, and Marine Biol. Lab., Woods Hole, MA, 02543. Gill ventilation in the crab, <u>Carcinus maenas</u>, is achieved by the rhythmic, stereotyped movement of the gill bailer (second maxilla), which pumps water through the gill chambers. As the rate of ventilatory movement increases, the gill bailer works against an elevated gradient of hydrostatic pressure, resulting in an increased load on the ventilatory muscles (Mercier and Wil-kens, <u>Amer. Zool. 21</u>:Abst. 23, 1981). Since these muscles re-ceive polyneuronal innervation and possess highly facilitating synapses, it has been proposed that changes in motor neuron re-114.6 synapses, it has been proposed that changes in motor neuron re cruitment and intraburst impulse frequency compensate for such changes in load by increasing the force and work generated by the muscles (Moody-Corbett and Pasztor, J. Neurobiol. 11:21-30, 1980). Our analyses of electromyographic recordings as well as recordings from a small nerve branch innervating an individual muscle reveal that as the rate of bailer movement increases: (a) the intraburst impulse frequency increases significantly (40 to 120 Hz), and (b) the time interval between bursts decreases notably (2000 to 250 msec). The number of impulses per burst is variable (5 to 30) but does not correlate consistently with ventilation rate. changes in load by increasing the force and work generated by

In order to demonstrate that these changes in patterned output can compensate for increases in load, nerve-evoked contractions of single ventilatory muscles were recorded isotonically at of single ventilatory muscles were recorded isotonically at various loads. The motor neurons were given bursts of stimuli resembling the frequency and number of impulses of recorded pat-terns. Within the physiological range, (a) increasing the stim-ulus frequency or (b) decreasing the interburst interval in-creased both contraction and work and also increased the load which could be lifted by the muscle. In each case, muscle EJP's, recorded with floating, intracellular electrodes, were enhanced by the change in stimulus. The effect of increasing stimulus frequency was due mainly to summation of the EJP's, while that of decreasing the interburst interval appeared to result from in-creased facilitation from one burst to the next. Contraction and work were also enhanced by increasing either the number of stim-uli per burst or the number of axons recruited. These treatments also enhanced muscle EJP's. The results support the hypothesis that appropriate changes in motor neuron output compensate for the increased load on the gill bailer muscles at high ventilation the increased load on the gill bailer muscles at high ventilation rates.
